2. The discovery that E6 and E7 proteins are able to induce cellular transformation in vitro confirmed their oncogenic role. Immortalized rodent fibroblasts can be fully transformed by expression of HPV16 E6 or E7 protein. These rodent cells acquire the ability to grow in an anchorage-independent manner and to be tumorigenic when injected into nude mice. In addition, HPV16 E6 and E7 together are able to immortalize primary human keratinocytes, the natural cellular host of the virus. In agreement with the in vitro assays, transgenic mice coexpressing both viral genes exhibit epidermal hyperplasia and various tumors. Similar to the mucosal HPV types, E6 and E7 from certain cutaneous HPV types of the genus beta (e.g., HPV8 and 38) display transforming properties in in vitro and in vivo models. Independent studies have demonstrated that HPV16 E6 and E7 proteins do not induce cellular transformation via a "hit and run" mechanism, but continuous expression of both proteins is required for the maintenance of the malignant phenotype.
3. Finally, biochemical studies have clarified the mechanism of action of E6 and E7. The viral oncoproteins are able to form stable complexes with cellular proteins and alter, or completely neutralize, their normal functions. These events lead to the loss of control of cell cycle checkpoints, apoptosis, and cellular differentiation.

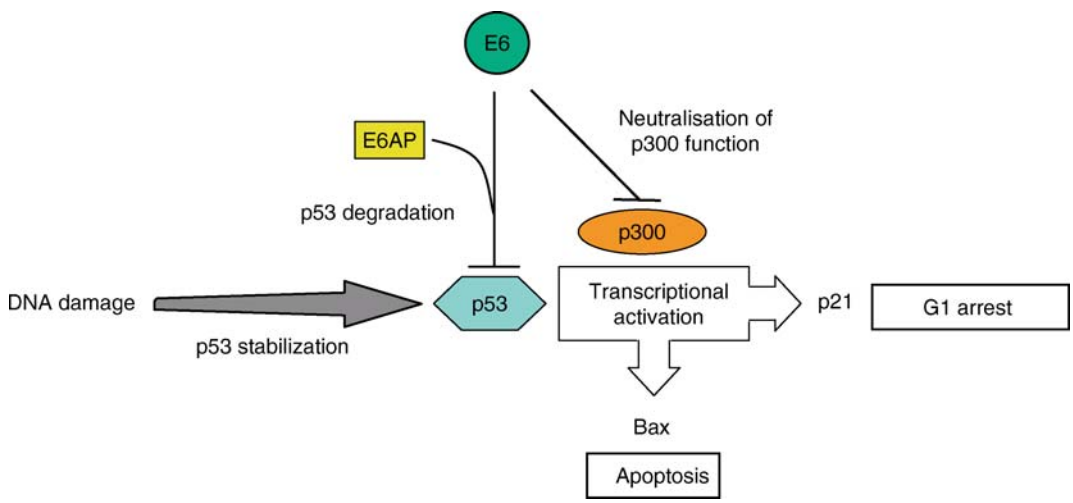
E6 protein. HPV16 E6 is a small basic protein of 151 amino acids. The major structural characteristic of E6 is the presence of two atypical zinc fingers. At the base of these zinc fingers are two motifs containing two cysteines (Cys-X-X-Cys), which are conserved in all E6 HPV types. The best characterized HPV16 E6 activity is its ability to induce degradation of the tumor suppressor protein p53 via the ubiquitin pathway. This cellular protein is a transcription factor that can trigger

cell cycle arrest or apoptosis in response to stress or DNA damage. E6 binds to a 100 kDa cellular protein, E6AP (E6-protein), which functions as a ubiquitin protein ligase (E3). The E6/E6AP complex then binds p53, which becomes very rapidly ubiquitinated and as a consequence is targeted to proteasomes for degradation. Since the major role of p53 is to safeguard the integrity of the genome by inducing cell cycle arrest or apoptosis, cells expressing HPV16 E6 show chromosomal instability, which greatly increases the probability that HPV-infected cells will evolve towards malignancy. Additional findings have demonstrated that HPV16 E6 also associates with the transcriptional regulators, CBP and p300, with resulting inhibition of p53-driven transcription. Thus, HPV16 E6 neutralizes p53 by two distinct mechanisms; the first is mediated by the p300/CBP association, while the second occurs via binding to E6AP to promote p53 degradation (Fig. 2).

Interestingly, the E6 protein from cutaneous HPV types is not able to induce degradation of p53. In fact, it has recently been shown that the beta HPV38 can inactivate p53 function by inducing accumulation of its antagonist, ΔNp73. HPV16 E6, as well as E6 from certain cutaneous HPV types, can also interfere with the apoptotic pathways via its association with Bak, a member of the Bcl-2 family. Analogously to its effect on p53, E6 induces Bak degradation via the ubiquitin-mediated pathway.

Several p53-independent cellular pathways, which are altered by the E6 molecule, have been identified. HPV16 E6 is able, through its association with E6AP, to promote the degradation of the transcriptional repressor NFX1-91, and consequently to activate the transcription of the *hTERT* (*human Telomerase Reverse Transcriptase*) gene encoding the catalytic subunit of the telomerase complex. This effect directly results in telomerase activity upregulation, a key event in the immortalization of primary keratinocytes. In addition, HPV16 E6 is able to interfere with cell mobility, through interaction with the human homologue of the Drosophila discs large protein (DLG). Also in this case, E6 binding leads to degradation of the cellular protein. However, different E6 domains are required to induce degradation of p53 and DLG. Deletion of the carboxy terminus of HPV16 E6 abolishes its binding to DLG without influencing its ability to promote p53 destabilization.

Another cellular target of HPV16 E6 is paxilin, a protein involved in transducing signals from the plasma membrane to focal adhesions and the actin cytoskeleton. The fact that E6 from the oncogenic HPV16, but not E6 from the low risk HPV types 6 and 11, is able to bind paxilin, suggests that this interaction has a role in the carcinogenesis of HPV infection. Several factors have been described to minimize or prevent exposure of HPV to the immune system. It has also been shown that HPV16 E6 interacts with interferon regulatory factor-3 (IRF-3), a positive transcriptional regulator of the INFβ promoter, which is activated in response to virus infection. E6 binding inhibits IRF-3 transactivation function. Thus, this E6-induced event may enable the virus to circumvent the antiviral response of the infected cell. The adhesion between keratinocytes and antigen presenting cells, i.e., Langerhans cells, in the epidermis



Early Genes of Human Papillomaviruses. Figure 2 p53 pathways targeted by HPV16 E6. When cells are exposed to DNA damaging agents, e.g., X-rays, the half-life of p53 can be greatly increased by posttranslational modifications (phosphorylation). In turn, p53 can either activate the transcription of the cyclin-dependent kinase (CDK) inhibitor, $p21^{WAF1/CIP1}$, leading to a G1 arrest and DNA repair before replication, or activate the transcription of the proapoptotic gene Bax with consequent induction of apoptosis. Cells expressing HPV16 E6 protein are resistant to the cell cycle arrest or apoptosis induced by DNA damaging agents.

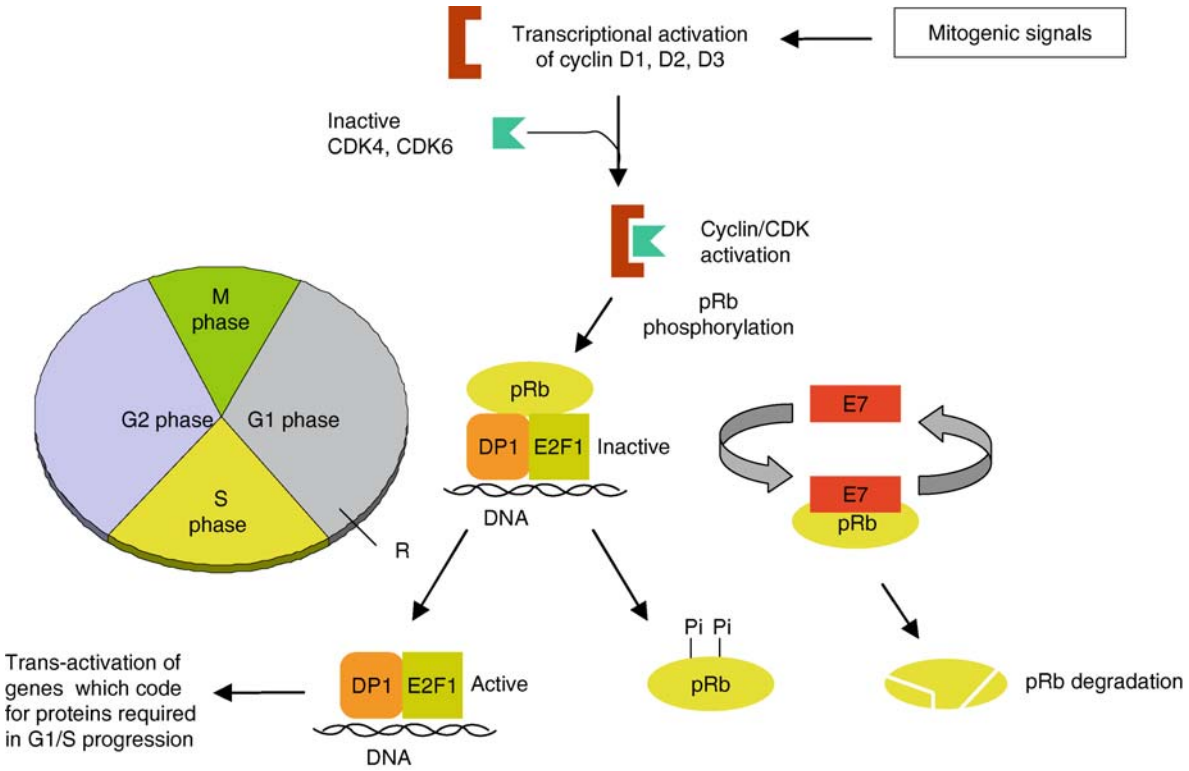
is mediated by E-cadherin. It has been shown that E6 can reduce the levels of cell surface E-cadherin on keratinocytes thereby limiting the presentation of viral antigens to the Langerhan cells and promoting viral survival. Furthermore, HPV16 E6 has been shown to suppress innate immune responses mediated by a family of toll-like receptors (TLRs) that are key sensors of evading pathogens. E6 is able to block the promoter of TLR9 which has been identified to recognize dsDNA sequences. Finally, E6 associates with ERC 55, a putative calcium binding protein located in the endoplasmic reticulum. However, the biological significance of this interaction is still unclear.

E7 protein. HPV16 E7 is an acidic phosphoprotein of 98 amino acids, which is structurally and functionally related to a gene product of another DNA tumor virus, the adenovirus E1A protein. On the basis of the similarity in primary structure between the two viral proteins, they can be divided into three domains: conserved region 1–3 (CR1–3). Mutational analysis of HPV16 E7 has demonstrated that all three regions are important for the in vitro transforming activity of the molecule. CR3 contains two CXXC motifs involved in zinc binding and essential for the stability of the protein. Independent studies have demonstrated that this viral protein is located in the nucleolus, nucleus, and cytoplasm. Indeed, it has been shown that the E7 molecule associates with cytoplasmic and nuclear proteins. The best understood interaction of E7 with a cellular protein is that involving the "pocket" proteins, pRb, p107, and p130. The pocket proteins are central regulators of cell cycle division. They negatively regulate, via direct association, the activity of several transcription factors, including members of the E2F family (E2F1–5), which are associated with their partners, DPs. Under normal cell cycle regulation, phosphorylation of pRb, which is mediated by cyclin-dependent kinase (CDK) activity, leads to the disruption of pRb/E2F complexes, with consequent activation of E2Fs. HPV16 E7 binds the pocket proteins and, analogously to the phosphorylation, results in the release of active E2Fs which in turn activate the transcription of a group of genes encoding proteins essential for cell cycle progression, such as cyclin E and cyclin A. As described for the interaction between E6 and p53, HPV16 E7 protein is able to promote the destabilization of pRb through the ubiquitin–proteasome pathway (Fig. 3). Similarly, the beta HPV38 E7 binds to pRB and promotes its degradation. This property is not shared by all E7s from the different HPV genotypes. Indeed, E7 from the benign HPV1 can efficiently associate with pRb without inducing its degradation. It is likely that the E7-induced pRb degradation represents a more effective way to neutralize the function of the cellular protein. The other two members of the pocket protein family, p107 and p130, are involved in controlling additional cell cycle checkpoints; p130 exerts its transcriptional regulatory function during the G0/G1 transition, while p107 is active in the G1/S transition and in the G2 phase. Analogously to pRb, HPV16 E7 protein associates with p107 and p130, inactivating key cell cycle checkpoints.

Besides targeting the pocket proteins, E7 can alter cell cycle control by additional mechanisms. The HPV16 E7 protein is able to associate with the CDK inhibitors $p21^{WAF1/CIP1}$ and $p27^{KIP1}$ causing neutralization of their inhibitory effects on the cell cycle. Cells coexpressing HPV16 E7 and $p21^{WAF1/CIP1}$ or $p27^{KIP1}$ are still able to enter S phase, while in the absence of E7 cells are arrested in G1 phase. HPV16 E7 can also directly and/or indirectly interact with cyclin A/CDK2 complex. The biological function of this interaction remains to be elucidated, but it is possible that E7 may act by redirecting the kinase complexes to a different set of substrates.

Other cellular proteins involved in transcriptional regulation have been identified as HPV16 E7 targets. HPV16 E7 binds the TATA box binding protein (TBP) and the TBP-associated factor TAF110, indicating that the viral protein is able to interfere with the basic transcriptional machinery of the host cell. Furthermore, E7 associates with AP1 complex, activating its transcriptional activity.

Similar to other stimulators of proliferation (e.g., c-myc or adenovirus E1A), the HPV16 E7 protein, besides the ability to deregulate the cell cycle, also promotes apoptosis. Expression of HPV16 E7 in normal human fibroblasts (NHF) or in human keratinocytes results in a cytocidal response, which displays the typical features of apoptosis and is much more evident in the absence of mitogenic signals. This E7-induced apoptosis requires pRb inactivation and is mediated by p53-dependent and -independent pathways. It is likely that the E7-induced apoptosis represents a cellular response elicited by the loss of cell cycle control. Interestingly, E6 protein is able to completely abrogate the E7 activity in promoting apoptosis. Thus, both viral proteins are required to induce transformation of the host cells. Although E7 is constitutively expressed in HPV16-associated lesions and therefore appears as candidate antigen for a specific immune response, the immune system fails to produce an efficient defense against tumor outgrowth in affected patients. As in the case of E6, E7 has also evolved to escape immune surveillance. E7 has the ability to bind and prevent the transcription factor IRF-1, from activating the INFα and β promoters. E7 is also capable of downregulating innate responses via suppressing TLR9 expression. Furthermore in HPV16 E6 and E7 transgenic mice, the transgene product E7 does not induce an immune response. However, upon vaccination with E7, anti-E7 antibodies were produced without causing signs of autoimmune disease. In contrast, E7-specific cytotoxic T lymphocytes (CTL) were not detected after immunization. Therefore the E7



Early Genes of Human Papillomaviruses. Figure 3 Deregulation of the restriction point (R) by HPV16 E7. E2F transcription factors form heterodimer complexes with members of the DP family and regulate the transcription of several genes during the cell cycle. In quiescent cells, pRb is present in a hypophosphorylated form and associates with E2F molecules, thereby inhibiting their transcriptional activity. When quiescent cells are exposed to mitogenic signals, genes encoding the G1-specific D-type cyclins (D1, D2, and D3) are activated. Subsequently, cyclins associate with a catalytic subunit, CDK4 or 6, and after transport into the nucleus, the kinase complexes phosphorylate pRb in mid-G1 phase causing release of active E2F/DP1 heterodimer complexes and progression through the restriction point (R). E7 binding to pRb mimics its phosphorylation. Thus, E7 expressing cells can enter S phase in the absence of a mitogenic signals.

transgene expression induces specific immunological tolerance at the CTL level.

E5 protein plays an early role in the HPV-induced transformation. Studies on ▶bovine papillomavirus (BPV) have provided evidence that E5 is a potent oncoprotein. Recently, it has also been shown that HPV16 E5 is able to induce cellular transformation, although with less efficiency than BPV E5. HPV16 E5 is a small hydrophobic protein, which is located in the endoplasmic reticulum (ER), nuclear membrane, and cytoplasmic vesicles. E5 is able to enhance growth factor-mediated signal transduction to the nucleus, resulting in stimulation of cellular proliferation. BVP1 and HPV16 E5 associate with the 16 kDa subunit c of the vacuolar H + -ATPase, which is responsible for acidification of membrane bound organelles, such as Golgi, endosomes, and lysosomes. It has been recently shown that BPV1 E5 induces alkalinization of Golgi, and that this activity is linked to its in vitro transforming activity. Mutations in E5 that abolish the interaction with 16 kDa subunit c abrogate Golgi alkalinization and cellular transformation. HPV16 E5-mediated immune evasion also involves suppressing the expression of the major histocompatibility complex class I (MHC I) and antigen processing via the TAP pathway, reflecting the lack of antigen presentation to CTL.

Since the integration of viral DNA, which occurs in tumor cells, results in a loss of *E5* gene expression, it is clear that E5 is involved in early events during the multistep process of cervical cancinogenesis, and that its function is no longer required after the establishment of the transformed phenotype.

E1 and E2 are involved in the regulation of viral DNA replication. The function of E1 is to control the replication of viral DNA. E1 contains the cyclin-binding RXL motif and is able to associate with cyclin E and A. Consistent with these findings, E1 is phosphorylated by cyclin E or A-associated kinase. Mutation of E1 phosphorylation sites results in a reduction of HPV

DNA replication, supporting the idea that the E1/cyclin association plays an important role in viral DNA replication. Moreover, it has been shown that E1 has an ATPase and helicase activity. E1 forms a stable complex with E2 and binds to the replication origin of HPV in order to recruit cellular factors essential for DNA replication. Furthermore, E1 has been found associated with components of the cellular DNA replication machinery, e.g., DNA polymerase α.

E2 regulates the transcription of the early genes. In addition to controlling viral DNA replication together with E1, E2 is able to negatively or positively regulate the transcription of the early genes. Like all transcription regulatory factors, E2 has an amino-terminal transacting domain and a carboxy-terminal DNA binding domain, which recognizes four *cis* elements (ACCN6GGT) in the long control region (LCR) of the HPV genome. These two domains are separated by a central region (hinge), which is important, together with the amino-terminal domain, for the nuclear localization of the molecule. Whether E2 binding results in repression or activation of the promoter of the early genes is dependent on the position of the E2-binding site in the LCR. E2 binding to the promoter-distal or -proximal elements leads to a positive or negative regulation of the promoter, respectively.

E4 is probably involved in virus maturation and/or replication. E4 is a late protein expressed from the early region of the genome. Most of the studies have been performed on E4 from the cutaneous HPV type 1. In these lesions E4 is present at very high levels and several E4-derived proteins have been detected. The primary product is a 17 kDa protein, which is expressed from E1^E4 transcript. E4 associates with and disrupts the cytoplasmic keratin network. The biological significance of this E4-induced event is not fully understood. It has been proposed that E4 plays a role in the productive phase of the infection establishing a favorable condition for viral maturation.

Clinical Relevance

HPV16 infection results in the induction of a benign proliferation, which after a long latent period, can progress to invasive cancer. Persistent HPV infection is necessary for the development of the malignant lesion. This requirement is explained by the fact that viral proteins, in order to induce full malignant transformation of the host cells, have to cooperate with an activated cellular oncogene. Accumulation of mutations in cellular genes, which possibly lead to activation of an oncogene, requires continuous proliferation. This is achieved by the abilities of E6 and E7 to respectively neutralize apoptotic pathways and to induce unscheduled proliferation. Therefore, a possible approach to induce regression of a HPV-positive lesion is to target the biological functions of E6 and E7. This possibility is supported by findings, which clearly demonstrate that continuous expression of the two viral genes is necessary for the maintenance of the host cell transformed phenotype. Thus, we can predict that a blocking of the activity of E7 can lead to a rapid exit from the cell cycle. Neutralization of E6 function should result in an even more efficient way to induce regression of the HPV-lesion. As described above, E7 has a dual activity, being able to induce proliferation and apoptosis. E6, acting upon p53-dependent and -independent pathways, completely abolishes the E7-induced apoptosis. Thus, we could imagine that in cells expressing *E6* and *E7* genes, the block of only E6 functions may push the balance between proliferation and apoptosis in favor of the latter causing regression of the HPV-lesion.

Alternative targets are E1 and E2, which are involved in viral transcription and replication. Several approaches to neutralize the early viral proteins are under investigation. These include strategies to block the transcription or translation of viral genes or to identify small molecules able to specifically associate with and inactivate the viral proteins.

In addition, HPV E6 and E7 are able to downregulate the innate and adaptive immunity. Identification of strategies to reactivate the immune response in HPV-infected cells may favor the clearance of the infection preventing the development of cervical diseases.

Synonyms

E-box; E motif

Definition

E-box is the collective term for DNA motifs with the consensus sequence CANNTG. E-boxes appear in a broad variety of promoters and enhancers and serve as protein binding sites. Proteins with affinity to this motif belong to the basic helix-loop-helix (bHLH) class of transcription factors, which can act as activators of transcription as well as repressors. More than 240 bHLH proteins are known to date in eukaryotes ranging from yeast to human, and the number continues to grow. Their binding specificity depends on both the nature of the "NN" nucleotides and sequences in the vicinity of the E-box. Genes containing E-boxes are activated during important developmental processes and some are described to be involved in cancer development and/or progression.

Characteristics

The DNA sequence "CAGGTGGC" was originally identified in 1985 within the sequence of the immunoglobulin enhancers, the first enhancers found to be activated in a tissue-specific manner. Later the name E-box, (with "E" for enhancer), was used as a common term for all motifs with the consensus sequence "CANNTG" and in 1989 the first two E-box binding proteins, E12 and E47, were identified. Both bind their recognition site as dimers, and dimerization is promoted by the helix-loop-helix (HLH) domain. HLH domains were subsequently found in other transcription factors such as MyoD and Myc proteins.

Genes Containing E-Boxes and the bHLH Proteins that Control them

To date an overwhelming number of E-box containing genes, regulated by bHLH proteins have been identified (Table 1), which include:

- Muscle (smooth and skeletal) specific genes that control myogenesis and are regulated by the ►bHLHs of muscle regulatory factors (Mrf).
- Genes involved in heart development that are regulated by the gene products of the ►Hand gene family, Hand1 and Hand2.
- Genes involved in neuronal development and differentiation are regulated by different bHLH proteins such as the Achaete-Scute family, Atonal family, E12/47 family, Hen family as well as by Nex, Hairy/E(Spl), and Id (►Id proteins).
- Insulin-inducible genes controlling pancreatic development are regulated by a member of the Atonal family, NeuroD. The latter is also a key player in neurogenesis.
- Genes involved in B- and T-cell development, regulated by bHLHs of the E12/E47 family.

E-Box. Table 1 Genes that contain E-boxes and that are involved in cell growth control or cancer development

Gene	Function/role in cancer development	E-box regulating protein
Bcl-6	Proto-oncogene coding for Krüppel-like zinc finger transcription factor, genetic rearrangements frequently found in lymphoma	?
Carbamoyl-phosphate synthase/aspartate carbamoyltransferase/dihydroorotase (CAD)	Enzyme involved in de novo pyrimidine biosynthesis, essential for cell growth	Myc
Cathepsin B	Protease, overexpression causes ability of cancer cells to metastasize	?
Cathepsin D	Estrogen induced protease, same mechanism as cathepsin B but mainly in breast cancer	USF1, USF2
Cdc2	Kinase, associates with Cyclin A and Cyclin B1, regulator of cell-cycle progression through G2 and M phase	USFs, myogenin
Cdc25A	Oncogene coding for cdk activating phosphatase, cell-cycle progression	Myc
c-Fos	Proto-oncogene coding for a transcription factor	E12, E47, myogenin
Cyclin B1	Activates cdc2 kinase, which regulates cell-cycle progression through G2 and M phase, increased expression often found in cancer cell lines	Myc
Cyclooxygenase-2 (COX-2)	Enzyme involved in prostaglandine synthesis in inflammatory processes, overexpression is correlated with tumor promotion	USFs
Fatty acid synthase (FAS)	Main enzyme in lipogenesis, overexpressed in wide variety of cancer types, mainly breast and prostate cancer, identical with prognostic molecule OA-519	USF
Heparin-binding epidermal growth factor like growth factor (HB-EGF)	Growth factor, member of the EGF family, postulated role in development of hepatocellular carcinoma, prostate cancer, breast cancer, esophageal, and gastric cancer	MyoD
3-hydroxy-3-methylglutyl coenzme A reductase (HMG-CoA reductase)	Rate-limiting enzyme in isoprenoid biosynthesis, inhibition blocks Ras activation and inhibits growth of ras-transformed cells	SREBP
Ornithine decarboxylase (ODC)	Rate-limiting enzyme in polyamine synthesis, essential for cell growth	Myc, MycN
Prothymosin alpha	Protein of unclear function, related to cell growth	Myc, MycN
Pulmonary surfactant protein A (Sp-a)	Lung-specific phospholipid-associated glycoprotein, mediates pathogen defense, frequently overexpressed in lung adenocarcinomas	USF1
Regulator of chromosome condensation-1 (Rcc1)	Guanine exchange factor, necessary for cell proliferation	Myc
Telomerase reverse transcriptase (Tert)	Catalytic subunit of telomerase which maintains chromosome ends and is an immortalizing enzyme	Myc

Genes and Gene Products that are Related to Growth Control and Cancer

- The proto-oncogenes ►BCL6 and ►FOS that encode transcription factors.
- CDC2 and CYCLIN B1 gene products, involved in cell-cyle regulation.
- Enzymes Cathepsin B and Cathepsin D, fatty acid synthase, and HMG-CoA reductase appear to be involved either in the process of tumor cells invading healthy tissue (Cathepsins) or seem to support the growth of cancer cells (fatty acid synthase and HMG-CoA reductase).

- Overexpression of the HB-EGF gene, encoding a growth factor, promotes cancer cell growth.
- COX-2 and SP-A gene products may be involved in tumor promotion. Underlying mechanisms are still unknown.

Many E-box-containing genes that are thought to be involved in cancer development provide binding for members of the Myc protein family, which play an important role in many cancer types. Being transcription factors they can activate transcription of the genes *CAD*, *CDC25A*, *CYCLIN B1*, *ORNITHINE DECARBOXYLASE*, *PROTHYMOSIN ALPHA*, *RCC1*, *ID2*, and *TERT*.

Members of the Usf (upstream transcription factor) protein family also contain the bHLH motif and bind to a variety of genes correlated with cancer. However, to date no oncogenic behavior has been described for these proteins and since Usfs are ubiquitously expressed, they may only play a less specific role in mechanisms of gene regulation (Table 2).

How do bHLH Proteins Bind to E-Boxes?

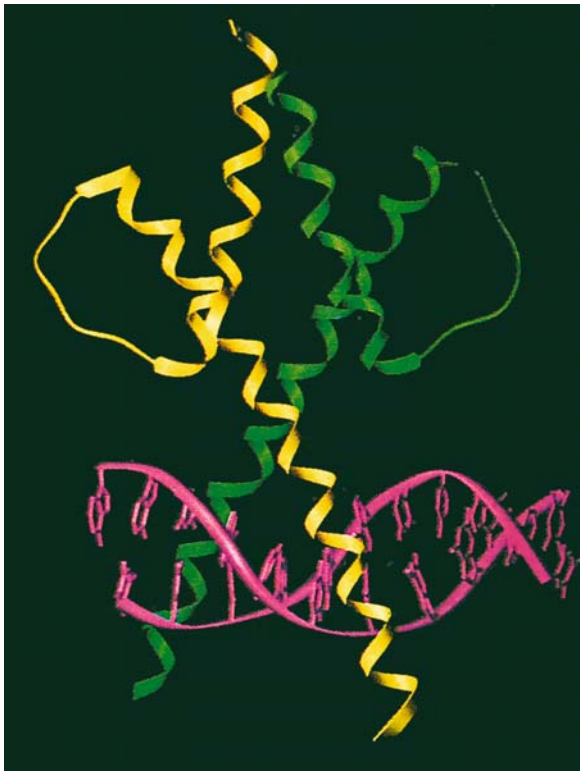
bHLH proteins bind to the E-box only as dimers, either as homodimers or heterodimers with other members of the bHLH protein family. The HLH motif within the protein allows dimerization: Two amphipathic α-helices are separated by a short stretch of amino acids, forming one or more β-turns, the "loop." Similar to the leucine-zipper motif, hydrophobic amino acid residues on one face of the helix interact with similar, also hydrophobic, residues of the helix from a second protein thus stabilizing the dimer. Some proteins possess a leucine-zipper as a second dimerization motif; these include members of the Mad, Srebp, Tfe, and Myc family (Fig. 1).

Dimerization is necessary but not sufficient for DNA binding. A sequence specific E-box recognition is mediated by a pattern of basic amino acids (Table 3). Since this basic region is localized N-terminal to the HLH region, it was this order which gave the name to a whole class of proteins, the "bHLH proteins."

E-Box. Table 2 List of bHLH protein families in animals and their E-box binding specificity

E-box sequence	bHLH family	Family members	Function
CAG (CTG)	Achaete/ Scute	Achaete, Scute, Mash-2, Hash-2, Fash-2	Neurogenesis
	Atonal	Atonal, Lin-32, Hath1, Math1, Math2, NeuroD, NeuroD2, NeuroD3, NeuroM	Neurogenesis; pancreatic development
	Delilah	Delilah	Differentiation of epidermal cells into muscle in Drosophila
	Hand	Hand1, Hand2	Cardiac morphogenesis; trophoblast cell development; neural crest development
	E12/E47	E12, E47, Pan1, Pan2	Ubiquitously expressed; myogenesis, neurogenesis; immunoglobulin gene expression
	Hen	Hen1, Hen2, Nhlh1, Nhlh2	Neurogenesis
	Lyl	Lyl-1, Nscl1, Nscl2, Scl/Tal-1, Tal-2	Hematopoietic proliferation and differentiation
	Mrf	MyoD, Myogenin, Myf5, Myf6, Mist1, Mrf4	Myogenesis
	Nex	Nex-1	Neurogenesis
	Twist	Twist, Paraxis, Scleraxis, Dermo-1, Tcf21	Specification of mesoderm lineages, myogenesis
CAC (GTG)	bHLH/ Pas	Arnt, Arnt2, trh, Hif-1α, Sim, ahr, BMAL1, clock, tim, per	Reaction to aromatic hydrocarbons; regulation of circadian rhythm; hypoxia response
	Hairy/E (Spl)	Hairy, E(Spl), Deadpan, Hes1, Hes5, Her1, Her4, Hesr-1, Sharp-1, Sharp-2	Neurogenesis; segmentation
	Mad	Mad, Mad3, Mad4, Mnt, Mxi1	Regulation of cell proliferation
	Myc	Myc, Mycn, Mycl, Max	Cell proliferation; differentiation
	Srebp/ Add	Srepb1, Srebp2, Add1, HLH106	Cholesterol homeostasis; sterol synthesis; adipocyte determination
	Tfe	Tfe3, Tfeb, Tfec, Mitf, Mi	Placenta vascularization; development of melanocytes, osteoclasts, masts cells
	USF	Usf1, Usf2, Spf1	Ubiquitous transcription factors
No binding	Id	Id1, Id2, Id3, Id4, TId1, TId2, XIdl, XIdx, XId2, emc	Negative regulators of myogenesis, neurogenesis

Extended, updated, and modified after Atchley and Fitch (1997).



E-Box. Figure 1 Shown is an E47 bHLH dimer bound to an E-box element (sequence: CACCTG). Each monomer consists of two α-helices that are separated by a loop; hydrophobic interactions between the α-helices stabilize dimerization. The basic region of each bHLH monomer makes contact with the major groove of the DNA molecule, each covering one half of the provided DNA binding site. [From Ellenberger et al. (1994) with permission].

E-Box. Table 3 Amino acid sequence comparison of bHLH proteins that bind the DNA sequences CAC GTG and CAG CTG

CAC GTG	bHLH	BB—N–ER-R—
	Myc	KRRTHNVLERQRRNE
	Max	KRAHHNALERKRRDH
	Usf	RRAQHNEVERRRRDK
	Tfe3	KKDNHNLIERRRRFN
CAG CTG	MyoD	RRKAATMRERRRLSK
	E12	RRVANNARERLRVRD
	E47	RRMANNARERVRVRD

B: basic residue.

bHLH proteins that rather bind to the "CAGCTG" DNA motif have different set of basic residues than those recognizing the DNA sequence "CACGTG." The change of only a single amino acid residue can alter binding specificity. The MyoD basic region usually recognizes the DNA sequence "CAGCTG." Replacement of the leucine at position 13 by an arginine within the basic MyoD region changed its binding preference to the "CACGTG" sequence.

Regulation of E-box-containing genes is also determined by the composition of the bHLH dimer bound to the DNA. Max, a member of the Myc family, can heterodimerize with Myc and activate target genes. If Myc is replaced by one of the Mad family members, the resulting heterodimer now represses the same target genes. Whereas Max is an ubiquitously expressed protein, the expression pattern of its potential partners are tissue-, developmental-, or cell cycle-dependent. Consequentely, transcriptional activation or repression of the target gene is determined by the ratio of Myc to Mad proteins, competing for Max dimerization.

Ecchymosis

Definition

The skin discoloration caused by the escape of blood into the tissues from ruptured blood vessels. Ecchymoses can similarly occur in mucous membranes as, for example, in the mouth.

►Rituximab

ECM

Definition

►Extracellular matrix
►Maspin
►Stromelysin-1

ECMRIII

►CD44

ECOG Performance Status

Definition

Eastern Cooperative Oncology Group performance status is a zero to five scale used by healthcare professionals to evaluate disease progression and determine appropriate treatment and prognosis

►Nutrition Status

Ecological Study

Definition

A study in which the unit of observation are populations rather than individuals.

►Cancer Epidemiology
►Epidemiology of Cancer

ECSA

►Erythropoietin

Ecteinascidin 743

►Trabectedin

Ectodermal

Definition
Derived from ectoderm, the embryonic germ cell layer that forms the skin and nervous system.

►Bone Tumors

Ectodermal Dysplasias

Definition
Refer to inherited human disorders characterized by abnormalities in two or more ►ectodermal organs, including hair, teeth, skin, craniofacial region, and limbs.

Ecto-Enzymes

Definition
Enzymes at the cell surface that face the external environment, which can either be embedded in the membrane or be bound to separate anchoring proteins.

►Adenosine and Tumor Microenvironment

Ectopic Expression

Definition
Referring to the expression of a gene in an abnormal place or at abnormal time of an organism or a cell. This can be caused by a disease, or it can be artificially produced by introducing a transgene with a modified promoter into the target organism or cell. The ectopic expression then will provide an idea of the function of the gene, depending on the new phenotype the organism or cell will develop.

Eczema

►Allergy

Edelfosine

Definition
►ET-18-OCH3.

Edible Salt

►Salt Intake

EDN

►Endothelins

EDTA

Definition
Abbreviation for the chemical ethylenediaminetetraacetic acid. EDTA is a chelating agent widely used to sequester di- and trivalent metal ions, like Mn(II), Cu(II), Fe(III), and Co(III).

►Chelators as Anticancer Drugs

EEN

Definition
Extra eleven-nineteen gene.

►Endocytosis

EF-Hand

Definition
A highly conserved helix-loop-helix motif, which binds a Ca^{2+} ion with high affinity. It is usually present in pairs in cytosolic Ca^{2+}-signaling proteins, as well as some extracellular proteins.

►Secreted Protein Acidic and Rich in Cysteine (SPARC)

EF-Hand Proteins

Definition
Consist of single or multiple pairs of the helix-loop-helix motif. It consists of two perpendicularly placed α-helices (e.g., helices E and F in parvalbumin) and an interhelical loop, which together form a single Ca^{2+}-binding site. In many proteins, EF hands exist as a pair, with a short antiparallel P-sheet interaction between the two Ca^{2+}-binding loops.

►Calcium-Binding Proteins

Effectors

Definition
Proteins that specifically interact with an activated GTPase and transmit signals to other molecules. Effectors can be enzymes themselves with the activation of an enzymatic cascade, such as in the case of the Raf kinase, or with the generation of second messengers, such as the PI3K, which generates polyphosphoinositides.

►GTPase
►B-Raf Signalling
►P13K Signalling

Efflux Pumps

Definition
Are active enzymatic transporters localized in the cytoplasmic membrane of cells.

►Xenobiotics

Efflux Ratios

Definition
Are the ratio of how fast a drug cross the gastrointestinal (GI) tract in the absorptive direction divided by how fast the drug is effluxed out of the GI tract back into the GI tract lumen (or its Caco-2 mimic). An efflux ratio greater than one indicates drug is being pumped out of the GI tract wall faster than it is coming in.

►ADMET Screen

Eg5

►KSP Mitotic Spindle Motor Protein

EGF

Definition
Epidermal growth factor is a potent mitogenic factor for a variety of cells, promotes epithelial cell proliferation and has a profound effect on the differentiation of

specific cells in vivo. EGF is also a strong inhibitor of gastric acid secretion.

►Urogastrone (URG)
►Securin
►EGFR
►Epidermal Growth Factor-like Ligands

EGF-CFC Protein Family

Definition
A family of structurally related proteins identified only in vertebrates that perform an essential role during embryogenesis ad tumorigenesis. Human Cripto-1 is the founding member of the EGF-CFC family.

►Cripto-1

EGF Family

►Epidermal Growth Factor-like Ligands

EGF-like Ligands

►Epidermal Growth Factor-like Ligands

EGFR

Definition
►Epidermal growth factor receptor. The protein found on the surface of some cells and to which epidermal growth factor (►EGF) binds, causing the cells to divide. It is found at abnormally high levels on the surface of many types of cancer cells, so these cells may divide excessively in the presence of epidermal growth factor. Also known as ErbB1 or HER1.

►Huntingtin Interacting Protein 1 (HIP1)

EGFR Transactivation

Definition
Activation of the EGFR by stimuli that do not directly interact with the EGFR ectodomain.

►Amphiregulin

EGP-2

►EpCAM

EGP34

►EpCAM

Egr-1 (Early Growth Response-1)

Definition
Is a transcription factor, commonly activated by growth factors, and that recognizes and binds to the DNA sequence 5′-CGCCCCCGC-3′, whereby it activates transcription of target genes whose products are often involved in mitogenesis and differentiation.

►MIC-1

EH

Definition
Epoxide hydrolase, also known as epoxide hydrotase, converts highly reactive eposides to trans-dihydrodiols which can be conjugated and excreted from the body.

►Phase 2 Enzymes

Eicosanoid Signaling

►Arachidonic Acid Pathway

Eicosanoids

Definition

Eicosa-, Greek for "twenty" are signaling molecules derived by oxygenation from omega-3 (ω-3) or omega-6 (ω-6) fatty acids. They exert complex control over many bodily systems, especially in inflammation, immunity, and as messengers in the central nervous system. The networks of controls that depend upon eicosanoids are among the most complex in the human body. There are four families of eicosanoids – the ►prostaglandins, the prostacyclins, the thromboxanes, and the leukotrienes. For each, there are two or three separate series, derived either from an ω-3 or ω-6 essential fatty acid.

►Arachidonic Acid Pathway
►Leukotrienes
►Lipid Mediators

Eicosapentaenoic Acid

Definition

EPA; is one of the principle omega-3 fatty acids from fish oil.

►Cachexia

eIF4A

Definition

Eukaryotic translation initiation factor 4A, a component of translation initiation factor, eIF4F, RNA helicase.

►Programmed Cell Death 4 (PDCD4/Pdcd4)

Eker Rat

Definition

Harbors a naturally occurring mutation (insertion of a 6.3 kb intracisternal A particle) in one allele of the ►tuberous sclerosis complex (*Tsc2*) gene and was first described as an autosomal dominant, hereditary model of predisposition to renal adenoma and carcinoma in 1954. Kidney lesions vary in morphology and include pure cysts, cysts with papillary projections and solid adenomas which can be seen as early as 4 months. A small minority of these tumors become malignant, with nuclear atypia and expand to include the entire kidney and metastasize to the lungs, pancreas and liver. Eker rats also develop pituitary adenomas, uterine leiomyomas and leiomyosarcomas, splenic hemangiomas and, at a low frequency, brain hamartomas resembling human ►tuberous sclerosis complex (TSC) subependymal nodules.

ELAM-1

►E-Selectin-Mediated Adhesion in Cancer

Electrical Coupling

Definition

Is the passing of electric charges between adjacent cells through gap junctions.

►Gap Junctions

Electrolytes

Definition

Are mineral nutrients for which a major physiological role is to provide electrical charge in biological fluids. The main biologically important electrolytes include sodium, potassium, and chloride and, along with bulk minerals, are sometimes referred to as macrominerals.

►Mineral Nutrients

Electromagnetic (EM) Heating

Definition

Energy deposited as heat in tissue by ohmic (i.e. resistive) loss. Ohmic loss is associated with the oscillating current generated by the electric field component of the Electromagnetic field.

►Hyperthermia

Electromagnetic Fields

Stefano Aterini, Marco Ruggiero
Department of Experimental Pathology and Oncology, University of Firenze, Firenze, Italy

Definition

Magnetic fields are generated by the movement of any electrical charge. A continuous electric current passing through a conductor creates a static magnetic field, while an electric current changing in time creates a variable magnetic field, which radiates electromagnetic waves spreading around the surrounding space at light speed. These electromagnetic fields enter living tissue but are known as non-ionizing radiation since they are weak and unable to break molecular bonds. Metals such as iron, zinc, manganese and cobalt are sensitive to electromagnetic fields that may exert their effects on proteins and cellular components containing these metallic elements.

Characteristics

Few environmental issues are as contentious as the question of whether exposure to electromagnetic fields affects biological systems. Considering the widespread use of electromagnetic radiation generating applications such as radio, television, wireless communications etc., the continuing change in the frequencies used, the health hazard implications of any connection between electromagnetic fields and cancer risk have raised a growing interest in the potential biological effects of electromagnetic fields on the mammalian cell growth, viability and response to genotoxic injury. This topic is still a subject of repeated argument, and caution in the interpretation of the effects of static and variable magnetic fields on cellular behavior needs to be claimed. A measurable magnetic field is created even by the residential electric current. It is noteworthy that we are pervaded by the Earth's static magnetic field that is hundreds of times greater than the low-frequency electromagnetic fields created by current within homes.

Epidemiological and Clinical Evidence

The first connection between human disease and electromagnetic fields was suggested by the observation of a higher incidence of cancer in children (►Childhood cancer) living near power distribution lines. Afterwards, major power lines have been held responsible for the occurrence of different cancer varieties. Results of different studies of a possible link between exposure to electromagnetic fields and childhood cancer, namely leukemia, have been rather inconsistent. One large study found no association between electromagnetic field exposure and an increased risk of childhood leukemia, in contrast to previous reports showing that the exposure to electromagnetic fields resulted in nearly a 20% increase in the risk of leukemia. This case–control investigation (►Case control association study) did not find a significant link between the risk of childhood leukemia and the actual measurement of magnetic fields in children's current and former homes, including homes their mothers lived in during pregnancy of the affected subjects. Electromagnetic field exposure has also been associated with the risk of breast cancer, mainly in men. Epidemiological studies have shown that in industrialized countries, where the electromagnetic field generating devices are in use on a large scale, breast cancer risk is higher. It has been suggested that electromagnetic field exposure might promote breast neoplasm through inhibition of ►melatonin release. Different occupational epidemiological studies have shown an increased incidence of breast neoplasm in women employed in occupations with high electromagnetic field exposure as well as in male electrical workers. However, other investigations, not producing any significant correlation, failed to confirm these suggestive data from occupational studies. In a large Swedish cohort study, an ~10% increase in the risk of cancer was documented in people in the medium and high exposure levels. Several types of cancer, including skin, digestive, respiratory, reproductive and urinary organs, were linked with occupational magnetic field exposure, suggesting an involvement of the endocrine and immune systems. Discrepancies in epidemiological studies dealing with this matter have involved different estimates of electromagnetic field exposure, measurement and characteristics; the statistical analysis performed with data obtained in such epidemiological reports is another Achilles heel and considerable biases can create misleading conclusions. Higher exposure has been associated with an increase in the cancer risk even though care needs to be taken in

drawing any conclusion, because no dose–response relation has been documented so far. New technologies have been introduced on a large scale only in more recent years and the possible short lag period between exposure and disease manifestation needs to be considered when examining the available data. Children are increasingly heavy users of communication sources (mobile phones) and they are likely to accumulate many years of exposure during their lives. They should be thoroughly monitored in study population to detect possible effects involving long induction periods or effects from long-term exposure.

Experimental Evidence

In case of high-frequency magnetic fields, biological effects and health risks are related to the thermal effect associated with sources emitting fields high enough to cause a significant temperature rise in living tissue. Carcinogenesis is a multistep process of accumulating mutations and promoting events. It has been proposed that electromagnetic field exposure might enhance the effects of other carcinogens, provided that both exposures are chronic. The potential for genotoxicity of electromagnetic fields has been investigated and several negative studies in several exposure categories have presented sound and independent, reproducible data. Using in vivo animal models of carcinogenesis the assessment of the potential carcinogenic activity of electromagnetic fields have yielded negative results in different studies, while using the rat mammary carcinoma model results seem to be conflicting. According to available data it is unlikely that long-term exposure to electromagnetic fields is carcinogenic per se in animal models. However, a promoting effect in the development of cancer under certain exposure conditions cannot be ruled out. Since exposure conditions vary widely in the different models thus far proposed, independent replication of experimental results is absolutely crucial. Exposure to electromagnetic field, alone or in combination with ionizing radiation, appears to induce an insult at the cellular level; to inhibit DNA synthesis and the growth of human tumor cell lines in vitro. However, controversies still exist about the possibility that electromagnetic fields may influence tumor promotion. Different in vitro studies have failed to demonstrate any detectable effect of electromagnetic fields on the rate of DNA synthesis and cultured cell growth. Moreover, exposure of cultured mammalian cells to electromagnetic fields has not resulted in the production of detectable DNA lesions and has not affected intracellular ►ATP levels, suggesting that electromagnetic fields are not genotoxic and cytotoxic. On the other hand, investigating the genotoxic potential of electromagnetic fields using in vitro experiments, statistically significant and suggestive positive results have been reported. Following electromagnetic field exposure, enzymatic activity induction, DNA mutation in human and non-human cells and DNA strand breaks in rat brain cells have been demonstrated. The static magnetic field has been shown to induce a remodelling and differentiation of human neuronal cells in the absence of any alteration of DNA, thus ruling out a direct effect of the magnetic field on DNA stability. Investigating the effects of a static magnetic field on the ability to proliferate of human breast cancer cells in vitro, it has been observed that magnetic field exposure only temporarily slows down cellular growth, which then eventually fully recovers. The reduced cell growth caused by the magnetic field could be explained by a temporary effect on some cellular metabolic events leading to the reduced DNA synthesis. Alternatively, it could be ascribed to a transient cellular differentiation, since induction of differentiated phenotype often correlates with decreased cell proliferation. These results are consistent with the observation that magnetic field induces time-dependent developmental effects on the process of differentiation of the chick cerebellar cortex. Human skin fibroblasts exposed to electromagnetic fields, generated by mobile phones, show alterations in cell morphology and increased expression of mitogenic signal transduction genes (►MAP kinase kinase 3 [MAP kinase], G2/mitotic-specific cyclin G1 [►Cyclin G-associated kinase]), cell growth inhibitors (transforming growth factor-beta [►Transforming growth factor]) and genes controlling apoptosis (bax) [►Apoptosis signaling]; a significant increase in DNA synthesis and intracellular mitogenic second messenger formation [►Signal transduction] matches the high expression of MAP kinase family genes.

Clinical Relevance

In conclusion, different studies have given no consistent or convincing evidence of a causal relation between electromagnetic fields and cancer. Available data from other reports suggest that the exposure to electromagnetic fields brings about a weak increase in the risk estimates of neoplasm. However, these studies generally lack statistical power and they have too many deficiencies to rule out an association. Considering that a weak association is not synonymous with a negligible or negative effect, additional more methodologically rigorous studies are warranted.

Electrophiles

Definition

Are molecules that are deficient in electrons. These molecules seek out an electron pair and react. In cancer electrophiles are responsible for carcinogenesis by binding to DNA or proteins causing changes that can lead to cancer. Cofactors like glutathione mediate this by providing electrons to interact with the electrophile.

►Glutathione Conjugate Transporter RLIP76

Electroporation

Definition

Introduction of biomolecules, such as DNA or proteins, into a cell or a tissue by applying an electric current.

Electrospray Ionization (ESI)

Definition

One of the "soft ionization" techniques used in mass spectrometry, whereby samples are analyzed to produce primarily molecular weight information. ESI is especially suitable for the mass measurement of most small organic molecules as well as high molecular mass biomolecules.

►Surface Plasmon Resonance

Electrostatic Interaction

Definition

An electrostatic interaction or bond results from the attraction of a charged group on one molecule with an oppositely charged group on another molecule.

►Lactoferricin Antiangiogeneis Inhibitor

Elimination

Definition

Of a drug comprises both metabolism and excretion.

►Irinotecan

ELISA

Definition

*E*nzyme-*l*inked *i*mmunosorbent *a*ssay is a biochemical analysis technique used to detect the presence of a protein in a fluid sample. The assay uses two antibodies, one that specifically detects the protein of interest, and a second antibody that reacts to the first antibody-protein complex. The second antibody is usually linked to an enzyme that produces a chromogenic or fluorogenic substrate, thus providing the read-out for the assay. ELISAs are often used to measure cancer biomarkers in the blood of cancer patients.

►Osteopontin

ELISPOT

Definition

Enzyme-linked immunospot (ELISPOT) assay is an antibody capture-based method for enumerating specific T or B cells that secrete a certain protein. Basically, cells are placed on a membrane coated with an antibody specific for a given protein. The protein is captured

directly around the cell (on the membrane) and is detected with a secondary antibody. Using colorimetry, protein-producing cells can be visualised as spots and counted.

Elk-1

Definition

The transcription factor which is a component of the ternary complex that binds the serum response element, phosphorylated by MAP kinase in response to growth factors.

►Major Vault Protein
►MAP Kinases

Elongin

Definition

Transcription factor that stimulates the rate of elongation by RNA polymerase II that is composed of subunits A, B, and C.

►Suppressors of Cytokine Signaling

Elongin BC Complex

Ronald C. Conaway, Joan W. Conaway
Stowers Institute for Medical Research, Kansas, MO, USA

Definition

The mammalian elongin BC complex is a heterodimer, composed of the 118 amino acid, ubiquitin-like elongin B protein and the 112 amino acid elongin C protein. The elongin BC complex interacts through a short, degenerate BC-box motif with multiple proteins, including the transcription factor elongin A, the von Hippel-Lindau (VHL) tumor suppressor protein and members of the SOCS-box protein family.

Characteristics

The elongin B and C proteins were initially identified as positive regulatory subunits of the three-subunit elongin complex, which is one of several transcription factors capable of controlling the activity of the RNA polymerase II elongation complex. The three-subunit elongin complex was originally purified from rat liver nuclei by its ability to activate the overall rate of elongation by RNA polymerase II, by suppressing transient polymerase pausing at many sites within transcribed sequences. The elongin complex is composed of a transcriptionally active A subunit of approximately 770 amino acids and the elongin BC subcomplex. The latter positively regulates the activity of the elongin complex by binding to a BC-box motif in the elongin A elongation activation domain and potently inducing elongin A transcriptional activity. The BC-box is an ~10 amino acid sequence motif with consensus Lxxx(C,A,S)xxx(A,I,L,V) Elongins B and C perform different functions in regulation of elongin A transcriptional activity. Elongin C functions as the inducing ligand and is capable of binding directly to the BC-box and maximally activating elongin A transcriptional activity in the absence of elongin B. Elongin B binds to elongin C and promotes stable binding of elongin C to elongin A.

Shortly after the discovery of the elongin complex, a large collection of BC-box motif-containing proteins were identified and found to function together with the elongin BC complex as integral components of members of two closely related classes of multiprotein E3 ubiquitin ligases (►Ubiquitination). In addition to a BC-box protein and the elongin BC complex, these E3 ubiquitin ligases include a heterodimeric submodule composed either of Cullin family member Cul2 and RING-H2 finger protein Rbx1 (also known as ROC1 or Hrt1) or the related Cul5 and Rbx2 proteins. In the context of these E3 ubiquitin ligases, the BC-box protein functions as the substrate recognition subunit. The elongin BC complex functions as an adaptor that links the BC-box protein to the Cullin/Rbx submodule, which in turn functions to recruit E2 ubiquitin conjugating enzymes of the Ubc5 family to the ubiquitin ligase complex and to activate ubiquitination of target proteins. Interaction of elongin BC with the BC-box is governed by interaction of a highly conserved leucine found at the N-terminus of the BC-box with a hydrophobic pocket created by residues in the C-terminal half of elongin C. A short N-terminal elongin C region binds to the N-terminal ubiquitin-like domain of elongin B. Additional sequences near the BC-box motif in BC-box proteins specify selection of the particular Cul2/Rbx1 or Cul5/Rbx2 submodule present in a given elongin BC-containing E3 ubiquitin ligase.

The VHL Tumor Suppressor Complex

The founding member of the family of elongin BC-containing E3 ubiquitin ligases is the VHL tumor suppressor (►Von Hippel-Lindau tumor suppressor

gene, ►Tumor suppression) complex, which is composed of the VHL BC-box protein, elongin BC, and a Cul2/Rbx1 submodule. The VHL gene on chromosome 3p25.5 is mutated in the majority of sporadic clear cell renal carcinomas, in familial erythrocytosis-2, and in the VHL disease, an autosomal dominant familial cancer syndrome that predisposes affected individuals to a variety of tumors including clear cell renal carcinomas, cerebellar hemangioblastomas and hemangiomas, retinal angiomas, and pheochromocytomas. A substantial fraction of VHL mutations found in sporadic clear cell renal carcinomas and in VHL kindreds results in mutation or deletion of the VHL BC-box and disruption of the VHL-elongin BC interaction and of the VHL ubiquitin ligase complex.

A major function of the VHL E3 ubiquitin ligase complex is to regulate transcription of genes such as vascular endothelial growth factor (VEGF), platelet derived growth factor β (PDGFβ), and E-cadherin by controlling the cellular levels of ►hypoxia-inducible transcription factors 1–3 by ubiquitin-dependent proteolysis. Under normoxic cell growth conditions, HIF transcription factors are rapidly ubiquitinated and destroyed by the proteasome. Under hypoxic conditions, ubiquitination of HIF transcription factors is inhibited and their concentrations rise to sufficient levels to activate hypoxia-inducible genes. Targeting of HIF transcription factors by the VHL ubiquitin ligase requires that HIFs are first post-translationally modified by hydroxylation of a critical proline in the HIF oxygen-dependent degradation domain (ODD) by a prolyl hydroxylase enzyme of the dioxygenase family. In light of evidence that the prolyl hydroxylase uses molecular oxygen as the oxygen donor, it has been proposed that the prolyl hydroxylase might serve as an oxygen sensor (or oxygen-dependent switch) for regulation of expression of HIF-dependent hypoxia-inducible genes.

Although it is well established that the VHL protein plays a crucial role in regulation of transcription of hypoxia-inducible genes through its control of cellular HIF levels, renal carcinoma cells expressing VHL mutants lacking a functional BC-box exhibit a collection of additional phenotypes, including

- defects in regulation of mRNA stability resulting in misregulation and constitutive expression of hypoxia-inducible genes;
- cell-cycle defects resulting at least in part from misregulation of the degradation of the Cdk inhibitor p27;
- defects in ubiquitin-dependent degradation of improperly processed or folded proteins;
- extracellular matrix defects resulting from failure of cells to secrete and/or properly assemble fibronectin.

At least some of these phenotypes result from defects in a VHL-dependent, HIF-independent pathway that remains to be defined. In addition, future studies are needed to determine whether these additional phenotypes are due to defects in the VHL E3 ubiquitin ligase complex or whether they result from other VHL defects not related to its function in the ubiquitin–proteasome pathway.

SOCS-box Proteins and the Elongin BC Complex

In addition to the VHL E3 ubiquitin ligase complex, which includes a Cul2/Rbx1 submodule, a growing collection of elongin BC-containing E3 ubiquitin ligases, which include Cul5/Rbx2 submodules, have been identified and found to play roles in human disease. Among the BC-box proteins that assemble with elongin BC and Cul5/Rbx2 are the so-called SOCS-box family of proteins and various virally-encoded proteins such as the Adenovirus E4orf6 and HIV-1 VIF proteins. In addition, elongin A assembles with elongin BC and Cul5/Rbx to form a potential E3 ubiquitin ligase that still possesses RNA polymerase II elongation factor activity.

SOCS-box proteins include the SH2 domain-containing suppressors of cytokine signaling (SOCS) proteins and more than 30 additional members of the ras, WD repeat, ankyrin repeat, and SPRY domain families. SOCS-box proteins are modular and are composed of an N-terminal SH2, ras, WD repeat, ankyrin repeat, or SPRY domain and a C-terminal SOCS-box. The SOCS-box is an ~50 amino acid motif composed of an N-terminal consensus BC-box and a short C-terminal L/P-rich region that helps specify interaction of SOCS-box proteins with Cul5/Rbx2. The founding members of the SOCS-box protein family were the SH2 domain-containing SOCS proteins, which assembly with elongin BC and Cul5/Rbx2 to form E3 ubiquitin ligases that function as negative regulators of cytokine-induced Jak/STAT signaling, at least in part by targeting Jak or receptor tyrosine kinases and inhibiting phosphorylation and activation of STATs.

The Adenovirus E4orf6 and HIV-1 VIF proteins, function together with cellular elongin BC and Cul5/Rbx2 as substrate recognition subunits of E3 ubiquitin ligases that promote virus growth. The E4orf6 ubiquitin ligase assembles shortly after Adenovirus infection of susceptible cells and targets the p53 tumor suppressor for ubiquitination and degradation by the proteasome, thus inhibiting apoptosis of infected cells and promoting viral infection. The VIF ubiquitin ligase targets the cellular APOBEC3G cytidine deaminase for ubiquitination and degradation by the proteasome. The APOBEC3G enzyme acts as a cellular antiretroviral factor by inducing hypermutations in newly synthesized HIV-1 minus-strand DNA.

Clinical Relevance

Although mutation of the elongin A or SOCS genes have not yet been identified in human disease, mutation of the VHL gene on chromosome 3p25.5 is responsible for the majority of sporadic clear cell renal carcinomas, for familial erythrocytosis-2, and for VHL disease, an autosomal dominant familial cancer syndrome that predisposes affected individuals to a variety of tumors including clear cell renal carcinomas, cerebellar hemangioblastomas and hemangiomas, retinal angiomas, and pheochromocytomas. Given their contributions to the adenoviral and retroviral life cycles, the E4orf6 and Vif ubiquitin ligases offer potential therapeutic targets for antiviral agents.

Emboli

Definition

Pieces of thrombus (commonly known as blood clots) or other material, which form at one site (in the cardiovascular system), breaks off and goes through the blood stream and lodges at another site, usually leading to significant problems, including sudden death. A common example is pulmonary thromboemboli.

►Cardiac Tumors

Embolization

Definition

Refers to the therapeutic introduction of various substances into the circulation to occlude vessels, by purposely introducing emboli. A treatment that clogs small blood vessels and blocks the flow of blood, such as to a tumor. Aim is to either to arrest or prevent hemorrhaging, to devitalize a structure, tumor, or organ by occluding its blood supply, or to reduce blood flow to an arteriovenous malformation.

Endocan

Philippe Lassalle, Maryse Delehedde
INSERM U774, Institut Pasteur de Lille, Lille, France

Synonyms
Endothelial cell specific molecule-1; Endocan; ESM-1

Definition
Endocan is a soluble ►proteoglycan of 50 kDa carrying a single dermatan sulfate chain. This dermatan sulfate proteoglycan, which is expressed by the vascular endothelium, has been found freely circulating in the blood of healthy subjects. Expression of endocan has been shown to be upregulated in inflammatory diseases and during progression of cancer.

Characteristics
Endocan, synonym endothelial cell specific molecule-1 (ESM-1), was originally cloned from a human endothelial cell cDNA library and described as being secreted by human umbilical vein endothelial cells (HUVEC). Endocan transcripts were detected from a variety of cultured endothelial cells of different origins,

i.e., in human coronary artery endothelial cells (HCAEC), human pulmonary artery endothelial cells (HPAEC), human dermal microvascular endothelial cells (HDMVEC) and human capillary endothelial cells (HUCE) purified from adipose tissues. Moreover, there have been rising evidences of endocan expression in cultured cell lines that are not of endothelial origin as in human adipocytes, in melanoma cells involved in ►vasculogenic mimicry process, in renal carcinoma cells and more recently in ►glioblastoma cells. Structurally, endocan is a soluble proteoglycan of 50 kDa, constituted of a mature polypeptide of 165 amino acids and a single dermatan sulfate chain covalently linked to the serine residue at position 137. Experimental evidence implicates endocan as a key player in the regulation of major processes such as cell ►adhesion or proliferation in ►inflammation disorders and tumor progression. Inflammatory cytokines such as ►TNF-alpha and growth factors involved in ►angiogenesis process such as ►vascular endothelial growth factor (VEGF) and ►fibroblast growth factor (FGF-2) strongly increased the expression, synthesis, or release of endocan by human endothelial and/or tumor cells. Endocan has then been shown to be clearly overexpressed in various human tumors, with elevated serum levels being observed in late-stage ►lung cancer patients, as measured by enzyme-linked immunoassay, and with its overexpression in tumors being evident by immunohistochemistry. Upregulation of endocan have also been recognized as a significant molecular signature of a bad prognosis in several types of cancers.

Malignant neoplasias originating in endocrine tissues or their target organs; Malignant tumors of the endocrine

glands; hormone-related cancers; Reproductive system cancers; cancers of hormone-responsive organs or tissues; Hormone-induced cancers; Endocrine-responsive cancers

Definition

The term endocrine-related cancers refers mainly to malignant tumors in either the endocrine glands or the endocrine target tissues. The endocrine system comprises the glands in the body that make and secrete hormones. All endocrine glands, such as the ovaries and testes, secrete hormones directly into the bloodstream, where they travel to a target organ or cell, such as the breast and prostate, to trigger a specific reaction. These glands are primarily involved in controlling a wide range of activities and functions in the body, such as metabolism, growth, and reproduction.

As is true for other types of malignant neoplasias, endocrine-related cancers are characterized by potentially out-of-control growth that either expands locally by invasion or spreads systemically by ►metastasis. In many cases, hormone production is abnormal when cancers are found in the endocrine glands, and hormone response can become disrupted when cancers occur in target tissues.

Other malignancies are also associated with the endocrine system. Carcinoids (►carcinoid tumors), a group of slow-growing but often malignant tumors, originate in the hormone-producing cells of the diffuse ►neuroendocrine. A large variety of other cancers that are not primary endocrine cancers also occur in endocrine tissues, including meningiomas, astrocytomas, and lymphomas. ►Metastases from other cancers can be found in such endocrine organs as the adrenal glands, pituitary, and thyroid gland. Malignancies such ►lung cancers can also produce hormones and cause patients to display clinically ectopic hormone syndromes.

Characteristics

The subject of endocrine-related cancers encompasses a vast area of clinical medicine and cancer biology. This essay mainly describes endocrine gland cancers. ►Breast cancers and ►prostate cancers, hormone target tissue cancers with a very high prevalence, will be described elsewhere.

Pathogenesis

The special natures of the origin and pathogenesis of endocrine tumors derive from a number of special properties of endocrine cells. As a result of environment risk and the stepwise accumulation of genetic defects, normal cells are transformed into malignant cells by a failure of normal growth regulation. The great majority of endocrine cells are stable, having a low growth rate and a long lifespan in contrast to the renewing tissues that are maintained by stem cells and have a short intermitotic life. In endocrine tissues, both function and growth are closely linked and are stimulated by one trophic hormone. In contrast to the renewing tissues, which undergo frequent cell divisions during which mutations commonly occur, endocrine tissues divide slowly and mutations are unlikely, but those that do occur are retained for a long time. In most types of endocrine cells, the mutation rate is low, but mutations accumulate; the chance of mutations is increased by any stimulus leading to mitotic growth in the endocrine tissues.

There are a number of possible explanations for the pathogenesis of endocrine cancers.

One possibility is the activation of ►oncogenes or inactivation of ►tumor suppressors. Defects in a variety of oncogenes and ►tumor-suppressor genes such as ►*ras*, ►p53, TGFβ, and ►IGF-I have been described in thyroid carcinomas.

Another possibility is that abnormal physiologic regulation disrupts the balance between stimulation and inhibition, and the resultant hyperfunction in the gland results in adenoma.

Abnormal stimulation may also induce gene disregulation, including oncogene activation or tumor-suppressor deactivation or damage, which has been described in the carcinogenesis of a number of human endocrine tumors.

Prevalence

Endocrine gland tumors are not common. There is a relative paucity of epidemiological investigations of endocrine cancers mainly because of the rarity of individual cases and the occult nature of the diseases (including asymptomatic, cases and their responses to therapy). In addition the reported incidence is also affected by variable levels of recognition or registration of the tumors in different clinical settings, including endocrinology, oncology, surgery, neurology, and even out-patient settings. In the United States, approximately 25,520 new cases of endocrine system cancer were diagnosed in 2004, and endocrine cancers have been estimated to account for approximately 4% of all new cancer cases each year. The most common malignancies of the endocrine system are gonadal tumors and thyroid tumors. In United States, ovarian cancer accounts for 44% of all endocrine system cancers, with an annual incidence of 8 per 100,000 women. Testicular cancer has an annual incidence of 2 per 100,000 men. In the United States, thyroid cancer has an annual incidence of approximately 6 per 100,000 persons (accounting for 36% of all endocrine cancers), whereas the annual incidence in the United Kingdom is around 0.6–1.5 per 100,000. The other endocrine tumors are less common. ►Adrenocortical cancer, carcinoids tumors, and other ►carcinoid tumors are all extremely rare, having incidences as low as 0.5 per 100,000 per year in the

United Kingdom. Parathyroid tumors are relatively more common, with an incidence of 28 per 100,000 per year in the United Kingdom, but the malignancy is still rare.

Clinical Presentation and Pathology

Most endocrine tumors are not malignant, although certain types when they do occur are likely to be cancerous. Endocrine tumors affect all age groups.

The clinical manifestations vary. Some patients are asymptomatic, with tumors incidentally discovered at autopsy or during sophisticated imaging techniques; others have multiple hormone-related symptoms or severe symptoms at late malignancy. Severity of symptoms depends on the site and the malignancy. Most endocrine tumors of childhood are benign or are low-grade malignancies. A small percentage of gonadal and ►germ cell tumors, thyroid cancers, and ►adrenocortical tumors are high grade.

Clinical manifestations of endocrine gland tumors are often associated with abnormalities of hormone secretion. For example, patients with insulin-producing islet cell tumors of the pancreas may have severe effects of low blood sugar due to the excessive insulin in the blood secreted by tumors. In addition to the hormone-producing tumors or functional tumors, there is another category of nonfunctional tumors that do not secrete hormones. Both types of tumors have the potential to be malignant.

Endocrine system tumors involve all anatomic areas from the head to the pelvic area and include tumors in single and multiple sites: pituitary cancer, thyroid cancer, parathyroid cancer, adrenal gland cancer, and endocrine ►pancreatic cancers, as well as ►multiple endocrine neoplasia (MEN), ectopic endocrine tumors, and neuroendocrine tumors, and metastases in the endocrine organs from other primary cancers.

Pituitary Tumors

Pituitary tumors are classified by the type of hormone they secrete. They are rarely malignant but, because of the production of a diverse spectrum of excess hormones varying with the cell type of origin, can cause a variety of health problems including ►Cushing syndrome, ►acromegaly, disturbance of milk secretion (prolactinoma), and local symptoms such as visual complication, headache, and injury to cranial nerves. In certain cases, tumors may cause pituitary hormone insufficiency due to pituitary tissue destruction.

Thyroid Tumors

Although only 5% of the tumors found on the thyroid are malignant, their biological behaviors may vary substantially, ranging from well-differentiated tumors to aggressive anaplastic cancers. A classification of thyroid tumors proposed by the World Health Organization (WHO) takes into account the histological features and clinical behavior of the tumor and classifies malignant thyroid tumors into four types. (►thyroid carcinogenesis).

Parathyroid Tumors

Around 5% of parathyroid tumors are malignant. Overproduction of parathyroid hormone, a condition known as hyperparathyroidism, is a common condition associated with both benign and malignant tumors. Untreated, hyperparathyroidism can result in osteoporosis (causing bones to become brittle and fracture easily), kidney stones, peptic ulcers, and nervous system problems.

Endocrine Pancreatic Tumors

Pancreatic islet-cell tumors are rare, with malignant tumors even more rare. The most common types of tumors are gastrinomas, which are associated with ►Zollinger–Ellison syndrome. Pancreatic islet-cell tumors include functioning and nonfunctioning varieties. Islet cells are multipotential in respect to peptide production, so functioning tumors can be classified into entopic-hormone tumors (e.g., insulinoma, glucagonoma, and somatostatinoma) and ectopic-hormone tumors (gastrinoma, VIPoma). Benign tumors are often treatable with surgery combined with medicine. For treatment of malignant tumors, in addition to surgery and radiation, cytotoxic ►chemotherapy has also been used.

Adrenal Tumors

There are two adrenal glands, one above each kidney in the back of the upper abdomen. The adrenal gland consists of two layers: an outside layer (the adrenal cortex) and an inner layer (the adrenal medulla).

Cancer of the adrenal cortex is also called ►adrenocortical cancer. The cells in the adrenal cortex make hormones that help the body work properly. When cells in the adrenal cortex become cancerous, they may make too much of one or more hormones, which can cause symptoms such as high blood pressure, weakening of the bones, and diabetes. If male or female hormones are affected, the person may undergo changes such as a deepening of the voice, growth of facial hair, swelling of the genitals, or swelling of the breasts.

Tumors that start in the adrenal medulla are called pheochromocytomas. About 10% of pheochromocytomas are malignant.

Most adrenal tumors are disorders of hormonal excess, but rarely malignant disease can cause adrenal insufficiency.

Ovarian Tumors

►Ovarian cancer can develop in the egg cells inside the ovary (germ cell tumors), but most occur in the cells

lining the outside of the ovary, and most of these tumors are benign.

Testicular Tumors

►Testis cancer can occur in one or both of the testes. Most testicular tumors are malignant and account for approximately 1% of all cancers in men. Over 90% develop in the germ cells and are generally malignant. Only 4% involve the endocrine cells of the testes, and these tumors are rarely malignant.

Multiple Endocrine Gland Tumors

Some disorders result in the simultaneous occurrence of tumors on several endocrine glands. Many of these are inherited disorders, including ►multiple endocrine neoplasia syndromes, ►Von Hippel–Lindau syndrome, and ►Von Recklinghausen disease (►neurofibromatosis types).

Carcinoids

►Carcinoid tumors a group of slow-growing but often malignant tumors, originate in hormone-producing cells of the diffuse neuroendocrine system and have been found in almost every organ of the human body. Approximate 10% of carcinoids secrete excess amounts of hormones, most notably the peptide serotonin (5-HT). Presenting symptoms including flushing, diarrhea, wheezing, abdominal cramping, and peripheral edema. The only curative therapy for carcinoid tumor is surgery.

Secondary Endocrine Malignancies

In addition to primary endocrine cancers, a large variety of other cancers—including ►meningiomas, ►astrocytomas, and ►lymphomas—occur in endocrine tissues. Metastases from other cancers can be found in such endocrine organs as the adrenal glands, pituitary, and thyroid gland.

Ectopic Hormone Syndromes

Nonendocrine tumors can also produce hormones, causing patients to display clinically ectopic hormone syndromes. For example, lung cancers produce parathyroid hormone-related protein and ►ACTH. Ectopic hormone syndromes are important because of several clinical reasons. Such syndromes may appear as the first signal of a malignancy. Ectopic hormone production may serve as a tumor marker even before the tumor mass is apparent and may serve as follow-up evidence for a response to therapy.

Treatment

Many endocrine cancers can be treated and some can be cured. However, given the complex nature of endocrine tumors, therapy for such cancers is unlike treatment for many other types of cancer. Targeting of these cancers as well as normalizing hormone levels requires the cooperation of medical endocrinologists and endocrine surgeons to apply both surgical and biochemical therapies. Surgery is generally the treatment of choice for most endocrine cancers. Chemotherapy is frequently used and is most effective in germ cell tumors of the ovary and testis. Although some tumors are resistant to radiation, radiation therapy may nonetheless decrease the chance of recurrence and halt the spread of cancer cells. ►Hormone replacement therapy is frequently used.

Prognosis

Many benign and malignant endocrine tumors are treatable with a combination of surgery and medication, and the survival rate for many patients with endocrine cancers is good. The best outcome is for patients with ovarian or testicular germ cell tumors, with most achieving disease-free long-term survival. Prognosis for patients with pituitary and thyroid tumors and adrenal adenoma and MEN is generally good. The survival rate for patients with adrenal carcinoma is poor, with an average survival of approximately 1.5 years.

In the United States, 25,520 new cases of endocrine system cancer were diagnosed in 2004, with an estimated 2,440 deaths, for a ratio of deaths to incidence of 0.096 for endocrine system cancers.

Cancers of Endocrine Target Tissues

Hormones have wide effects on a variety of cellular processes, including cell growth and differentiation, metabolic activity, and the metabolism of substances. In fact, the endocrine system directly or indirectly influences all mammalian organs and tissues. Unbalance of endocrine hormones is an endogenous factor that may sensitize the cells to the carcinogenic insult, thereby promoting cancer development. It has been well established that sex hormone-induced cell proliferation plays a critical role in corresponding hormone-initiated carcinogenesis, as is reflected in the fact that the many types of human cancers, including breast cancer, prostate cancer, and ►endometrial cancer, occur in sex-hormone target tissues.

More than 25% of human tumors originate in the endocrine organs or their target tissues. However, with aspect to prevalence, the major entity in the spectrum of endocrine-related cancers is endocrine target organs such as the breast and prostate. In the Western world, breast cancer is the most common tumor in women, and prostate cancer is the most prevalent malignancy in men and the second most common cause of male cancer deaths. They have attracted great attention in endocrinology because of not only their extremely high incidence but also their endocrinological nature. Specifically, breast cancer and prostate cancer as instance start as estrogen and androgen dependent-noninvasive disease, respectively, and are sensitive to

endocrine agents and treatable at an early stage with hormone therapy and surgery. However, if left undetected or untreated, these cancers eventually develops into a more aggressive, hormone-independent, highly invasive disease and the patients die of their diseases after tumor cells metastasize to distant sites in the bodies. These high-incident cancers of endocrine target tissues are described elsewhere.

Endocytosis

Pier Paolo Di Fiore, Simona Polo
IFOM, the FIRC Institute of Molecular Oncology, Milan, Italy; University of Milan, Medical School, Milan, Italy

Synonyms

Internalization; Receptor-mediated endocytosis; Clathrin-mediated endocytosis; Pinocytosis; Fluid phase endocytosis

Definition

A process in eukaryotic cells consisting of a progressive invagination of a small region of the plasma membrane which is subsequently pinched off to form a cytoplasmic vesicle.

Characteristics

Eukaryotic cells use endocytosis to internalize plasma membrane, surface receptors and their bound ligands, nutrients, bacterial toxins, immunoglobulins viruses, and various extracellular soluble molecules. The molecular machinery of endocytosis is also largely overlapping that of ►synaptic vesicle recycling. Once an intracellular vesicle is formed, following the endocytic process, its content is trafficked through the ►endosomal compartment and normally destined to either degradation in the lysosomal compartment, or to ►recycling to the cell surface. The definition of endocytosis should be limited to the process leading to the formation of vesicles of 100–200 nm, which is also known with the general name of pinocytosis.

On the contrary, phagocytosis is the intake of large particles, such as bacteria or parts of broken cells. It is used by many protozoans to ingest food particles and by blood cells (macrophages) to take in and destroy pathogens and dead-cell debris. After the binding of the target particle to the cell surface, the plasma membrane expands along the surface of the particle and eventually engulfs it. Vesicles formed by this process are much larger than those formed by endocytosis (1–2 μm).

Four different types of endocytic processes are described below:

1. Fluid phase endocytosis or macropinocytosis is the simpler and nonspecific form of endocytosis in which any fluid extracellular material is taken up at a rate that is simply proportional to its concentration in the extracellular fluid. Fluid phase endocytosis does not require a specific interaction of extracellular material with surface-bound receptor structures. Macropinocytosis shares similarities with phagocytosis as both require activation of GTPases that, in turn, stimulates actin polymerization and depolymerization events necessary for membrane protruding. After the collapse of the ruffles onto the plasma membrane, macropinosomes are formed with a mechanism that is independent of the fission-inducing protein ►dynamin.
2. ►Clathrin-mediated endocytosis occurs through the formation of clathrin-coated pits at the plasma membrane, followed by the generation of clathrin-coated vesicles of 100–150 nm in diameter. The process requires, in addition to clathrin, the presence of the adaptor protein complex ►AP2, or of other adaptors. The general function of the adaptors is that of establishing a physical link between plasma

membrane receptors and clathrin. The formation of clathrin-coated pits at the plasma membrane shares structural and molecular similarities with the budding of clathrin-coated vesicles from the Golgi apparatus, which also requires clathrin and a different adaptor complex, AP1. Clathrin-mediated endocytosis requires interaction of an extracellular ligand with a surface receptor, and takes the name of receptor-mediated endocytosis (or internalization). Two types of receptor-mediated endocytosis are known: (a) constitutive and (b) ligand-induced.

(a) In constitutive endocytosis, membrane receptors are continuously internalized and after sorting in the endosomal compartment, they are recycled back to the cell surface. When a ligand binds to the receptor, the ligand is also internalized and can undergo different metabolic destinies. Two paradigmatic examples are provided by the constitutive endocytosis of the low-density lipoprotein (LDL) receptor and of the transferrin receptor. In the former case, LDL complexed to cholesterol is internalized with its receptor. In the endosomes, the LDL receptor dissociates from the LDL–cholesterol complex and it is redirected to the cell surface for more cycles of internalization. The LDL–cholesterol complex is routed to the lysosomes, where LDL is degraded and free cholesterol is made available to the cell. The cycle of the transferrin receptor is more complex. Transferrin, bound to iron, is also internalized together with its receptor. In the endosomal compartment, the acidic pH causes the dissociation of iron. Iron-free transferrin (apotransferrin) remains, however, bound to the receptor, and it is recycled to the plasma membrane. The process of constitutive internalization is thus used by the cell mostly for the uptake of nutrients.

(b) In the ligand-regulated process, internalization is triggered by the interaction of a ligand with its surface receptor. Both ligand and receptors are normally routed to the lysosomal compartment with ensuing degradation. However, a fraction of the internalized receptor can be redelivered to the plasma membrane, in a recycling process not dissimilar to that of constitutive endocytosis. The process of induced internalization therefore serves, in the majority of cases, as a down-regulation mechanism to extinguish signals originating on the plasma membrane from signaling receptors, for instance receptor tyrosine kinases (►Tyrosine kinase receptors). It has, however, become increasingly clear that endocytosis is also required to propagate signals originated from surface receptors, thus not merely constituting an attenuation mechanism (see below).

3. Caveolae-mediated endocytosis occurs through flask-shaped, nonclathrin-coated surface structures called caveolae. The vesicles formed in this process are of 50–85 nm in diameter and ►caveolin-1 is an essential component, as caveolin-1-null mice lack caveolar structures. By this process, cells are able to internalize certain glycosylphosphatidylinositol-linked proteins, albumin, bacterial toxins as well as membrane-associated receptors like MHC class I, TGFβR, or E-cadherin. Caveolae remain for long periods at the plasma membrane, but their internalization can be stimulated by various agents. These include the SV40 virus which uses caveolae for entry into cells and stimulates caveolar budding, as well as sterols and glycosphingolipids. Although the molecular circuitries underlying caveolar internalization are not completely understood, critical requirements for dynamin, Src kinases, protein kinase C (PKC), and actin recruitment have been demonstrated. It is important to point out that caveolae represent one type of cholesterol-rich microdomain on the plasma membrane and that in the absence of caveolin, lipid-raft-dependent trafficking occurs (see below).
4. Clathrin- and caveolin-independent endocytosis probably encompasses more than one pathway. Given the poor molecular definition, the mechanisms that govern caveolin- and clathrin-independent endocytosis remain in large part unknown, as illustrated by the fact that these pathways are described only in negative terms. These internalization routes have been shown to mediate the internalization of interleukin-2 receptor-β (IL2Rβ), some GPI-anchored proteins, and receptor tyrosine kinases.

It is likely that these different pathways have evolved so that pinocytosis can be coordinated with more complex aspects of cell physiology, such as signal transduction, development and modulation of the cell responses to, and interaction with, its environment.

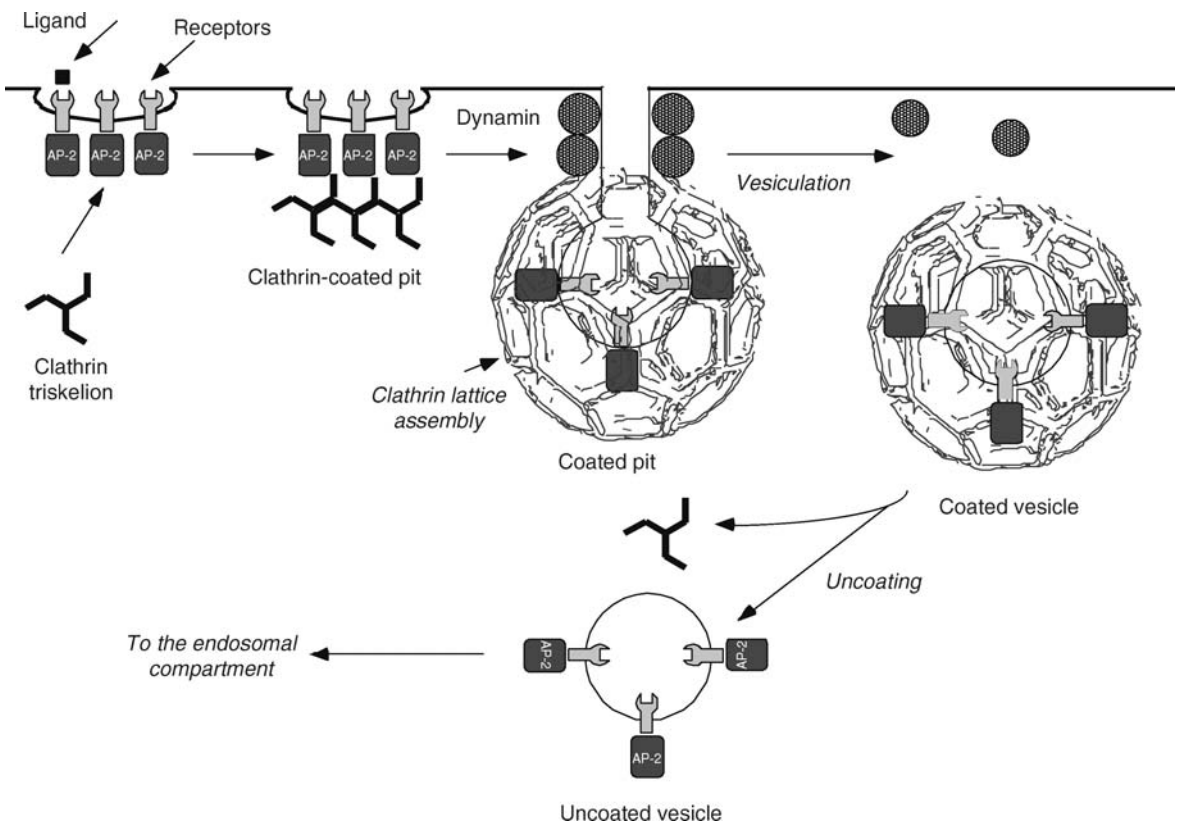
Endocytosis and Signaling

One aspect of endocytosis that has attracted much attention in recent years is the relationship between internalization of surface receptors and their ability to transduce signals within the cell. Many surface receptors (including, but not limited to, receptor tyrosine kinases) act as molecular transducers, by binding to extracellular ligands and delivering their signal to the cell, with various mechanisms. By-and-large these receptors are removed from the cell surface through endocytosis and destined to lysosomal degradation. Thus, for many years, endocytosis has been considered the major form of receptor attenuation leading to signal extinction. It has, however, become clear that signaling receptors continue to signal while en

route through the endosomal compartment, and that in many cases they gain access, in this compartment, to interactors and/or substrates, not available at the plasma membrane. In addition, the recycling of a fraction of the receptor to the cell surface might have a profound effect on signaling. It is becoming apparent that recycled signaling receptors are not simply redelivered to the plasma membrane, but might, in many cases, be delivered to specific regions of the membrane where local signaling is necessary. Therefore, endocytosis provides spatial and temporal dimension to signaling, ensuring prolonged signaling in the endosomes and local redistribution of signaling molecules. In this framework, endocytosis should not be considered merely as an attenuator of ►signal transduction, but rather as an integrator of signaling and attenuation. This complex interplay is at the basis of numerous cellular functions, including motility, proliferation, and determination of cellular fate/differentiation.

Molecular Mechanisms

The structural and regulatory mechanisms of the clathrin-mediated endocytosis are being elucidated. Four major structural components are required in the formation of an endocytic vesicle (see Fig. 1): clathrin, AP2, receptor tails, and dynamin. Polymerization of clathrin into a hexagonal/pentagonal array forms a cagelike lattice around the internalizing pit and provides the organizing framework of the pit. The AP2 complex drives the polymerization of clathrin and serves as a recruiter of receptors to the forming pit, due to its ability to simultaneously interact with the receptor intracytoplasmic tails and with clathrin. Receptor tails contain endocytic codes, i.e., amino acid sequences capable by themselves of sustaining internalization. Endocytic codes are thought to be cryptic in receptor tyrosine kinases and to be unmasked by conformational changes that follow receptor activation and autophosphorylation. In other types of receptors, such as the transferrin receptor, endocytic codes are probably continuously exposed, thus determining constitutive internalization. In many cases, endocytic codes contain a critical tyrosine residue, thus being known as "tyrosine-based" signals. There is ample evidence that tyrosine-based signals bind directly to the clathrin adaptor protein complex AP2, thus allowing receptor recruitment into the pit. Once a clathrin-coated pit is formed, dynamin is responsible for its release into the cytosol as a vesicle



Endocytosis. Figure 1 Schematic of clathrin-mediated endocytosis. From left to right, the various temporal phases of endocytosis are depicted: recruitment of receptors into pits, clathrin assembly, vesiculation, uncoating, and trafficking to the endosomal compartment.

(vesiculation). Vesiculation is caused by conformational changes of dynamim, which require its intrinsic GTPase activity, and which lead to pinch off of the vesicle from the plasma membrane. Once a vesicle is formed, it appears as a coated vesicle, still being surrounded by a clathrin lattice. Subsequent shedding of clathrin and AP2 leads to the formation of an uncoated vesicle. Uncoated vesicles fuse with other vesicles in the endosomal compartment, where decisions are made whether to recycle the content of the vesicles (or part of it) to the plasma membrane or to further process it in the lysosome. Several other proteins (AP180/CALM, epsins, Eps15 and Eps15R, amphiphysins, synaptojanins etc.), globally referred to as accessory or regulatory proteins, participates to the various phases of the endocytic process, frequently entering in contact with a forming pit through AP2, in a precise hierarchical fashion. Finally posttranslational modifications, such as phosphorylation, dephosphorylation, and ►ubiquitination, are known to play a role in the various cycles of assembly and disassembly of structural and regulatory endocytic proteins.

Clinical Relevance

Pathogenesis of a number of membrane receptor-linked diseases can be directly traced to primary defects in endocytosis. In Familial Hypercholesterolemia, genetic defects in the LDL receptor result in the absence of cholesterol internalization into the cell. Both receptor absent and receptor-defective mutants occur. Among the latter, internalization-defective mutants can be caused by nonsense or frameshift mutations or by single amino acid substitutions. In insulin-resistant diabetes mellitus, mutations of the insulin receptor gene occur that fall into various categories, among which those involving accelerated receptor degradation and impaired transport of receptors to the cell surface. Another genetic disease that might be linked to the processes of endocytosis and of vesicle transport is Huntington disease. The disease is associated with increased length of a glutamine stretch, located in the NH2-terminal region of the protein huntingtin. Abnormal protein interactions have been proposed as a pathogenetic mechanism. ►Huntingtin localizes to vesicles of the secretory and endocytic pathway and interacts with proteins involved in vesicle trafficking. Recent data suggest that huntingtin is a regulator of these pathways, through association with clathrin-coated vesicles.

A remarkable overlap of molecular events between endocytosis and vesicle recycling in synapses is emerging with increasing relevance for those conditions, of neurological interest, in which alterations affecting components of the synaptic vesicles were shown. Among those are the Lambert-Eaton myasthenic syndrome, in which synaptotagmin might be a target of autoimmunity; the Stiff-Man syndrome, in which amphiphysin and the glutamic acid decarboxylase (GAD) (both of which are associated with the cytoplasmic surface of synaptic vesicles) are targets of autoimmunity; and possibly even Alzheimer's disease, in which the progressive cognitive loss is associated with synaptic loss in the cortex and decrease in the levels of synaptobrevin and synaptophysin.

Alterations of the processes of endocytosis and intracellular vesicular sorting might play a role in ►cancer. For instance, several receptor tyrosine kinases, including Met, EGFR, and ErbB-2, display alteration of their endocytosis in human cancers. In addition, translocations are described in leukemia, which involve accessory endocytic proteins. The *Eps15* and ►*EEN* genes (►*extra eleven-nineteen genes*) are translocated with the ►*MLL* gene (myeloid/lymphoid, or mixed lineage, leukemia), resulting in the production of fusion proteins. The *CALM* gene is rearranged with the *AF-10 gene* (ALL1 fused gene from chromosome 10), which in turn is a partner in *MLL*-involving translocations. Tumor suppressor and/or cancer predisposition genes are also linked to endocytic/sorting pathways, including *ATM*, the cancer predisposition gene mutated in ataxia-teleangiectasia, and the two genes *TSC1* and *TSC2*, encoding hamartin and tuberin respectively, identified in tuberous sclerosis.

Another emerging field in cancer research concerns plasma membrane receptors that signal to the cell in a negative fashion, by transducing antiproliferative signals. In such cases, endocytosis could represent a mechanism to attenuate these signals, leading to increased proliferation. This is exemplified by studies of E-cadherin, a transmembrane adhesion molecule that, by establishing homophilic interactions at sites of cell-to-cell contacts, downregulates the β-catenin pathway and participates in the tight control of epithelial tissue homeostasis. There is strong evidence that loss of the tumor-suppressor function of E-cadherin represents a common event in human cancers and causes cell invasiveness in vitro and tumor progression in vivo.

Finally, recent data demonstrated that endocytic proteins are involved in cell-fate determination. This is particular relevant considering the emerging concept of cancer ►stem cell compartments. Signaling by the Notch receptor affects cell-fate specification, proliferation, apoptosis, and migration, and it is frequently deregulated in human malignancies. Both the Notch receptor and its ligands undergo ubiquitin-regulated internalization and degradation, and functional subversion of the endocytic/trafficking events is predicted to have profound impact in the regulation of this receptor. Another endocytic protein, involved in tumors, is Numb, which is also linked to the Notch pathway. Numb is a negative regulator of Notch, and loss of Numb expression is a frequent event in human breast tumors. This, in turn, results, in increased

Notch signaling, an event that contributes to cellular transformation.

Endometrial Cancer

Alexey Davydov, V. Craig Jordan
Fox Chase Cancer Center, Philadelphia, PA, USA

Definition

Endometrial carcinoma is the most common malignancy of the female genital tract, and it is estimated to account for approximately 40,880 new cases and more than 7,310 deaths in 2005 in the United States and a similar figure in Europe. It is more frequent than ovarian cancer, but can be treated successfully more often by surgery and radiation therapy.

Characteristics

Risk Factors

Several risk factors for the development of endometrial carcinoma are related to an extended exposure to unopposed estrogen action, such as in nulliparity, late menopause, obesity, diabetes mellitus, estrogen replacement therapy, and tamoxifen treatment (►Estrogenic hormones and cancer; ►hormones and cancer; ►obesity and cancer risk; ►progestin and cancer; ►tamoxifen). Tamoxifen has proven to be highly effective in the treatment of all stages of ►estrogen receptor (ER) positive breast cancer, however, it has a partial estrogen agonist effect in the human uterus. In the uterus of postmenopausal women, the estrogen-agonistic activity of tamoxifen results in an increased risk for the development of endometrial hyperplasia and endometrial cancer. The National Surgical Adjuvant Breast and Bowel Project-P1 study showed that tamoxifen increases the risk of endometrial cancer in postmenopausal women by four- to fivefold. It is important to stress, however, that the stage and grade of endometrial cancers observed in postmenopausal women were the same as in the general population. There is also evidence that the increase risk of endometrial cancer continues for years after tamoxifen therapy is discontinued.

Classification

Endometrial carcinomas are classified into two types on the basis of biological and histopathological variables:

1. Type I tumors, are usually well-differentiated and endometrioid in histology, and are associated with a history of unopposed estrogen exposure or other hyperestrogenic risk factors such as obesity.
2. Type II tumors, which often poorly differentiated, non-endometrioid and are not associated with hyperestrogenic factors. These tumors are more likely to be metastatic and can recur even after clinical intervention.

Pathogenesis Mechanisms

The pathogenic mechanisms of endometrial cancer are poorly understood. However, as in other malignancies, accumulation of genetic abnormalities and epigenetic alterations is thought to cause the transformation of normal endometrium to cancerous tissue. These changes disrupt cellular signaling networks that govern processes such as cell proliferation, apoptosis and angiogenesis. So far, no specific gene or genes have been linked to the majority of cases of endometrial cancer. However, molecular analyses have implicated several well-characterized oncogenes and tumor-suppressor genes in endometrial carcinogenesis. Current data indicate that type I tumors are more commonly associated with abnormalities in the DNA-mismatch repair genes KRAS, PTEN (phosphatase and tensin homologue) and β-catenin, whereas type II tumors seem to be linked to abnormalities in TP53 and ERBB2 (also known as HER2/neu). These can be mutations, deletions and amplification/overexpression of genes or/and epigenetic deregulation.

Approximately 10% of EC cases are associated with hereditary nonpolyposis colorectal cancer (HNPCC), a dominantly inherited syndrome with germ-line abnormalities in one of five DNA-mismatch repair genes with resultant micro-satellite instability. Females with HNPCC have a ten-fold increased lifetime risk of EC compared with that of the general population and the lifetime risk of EC (42%) is higher than that for colorectal carcinoma.

Treatment

Treatment for uterine cancer depends on the stage of the disease and the overall health of the patient. Removal of the tumor (surgical resection) is the primary treatment. Radiation therapy, hormone therapy, and/or chemotherapy may be used as adjuvant treatment (i.e., in addition to surgery) in patients with metastatic or recurrent disease.

Surgery

Treatment for uterine cancer usually involves removal of the uterus, including the cervix (called total hysterectomy), and removal of the fallopian tubes and ovaries (called bilateral salpingo-oophorectomy). Surgery may be performed through an incision in the abdomen or through the vagina (called transvaginal hysterectomy).

Surgical treatment is required to determine the degree of myometrial invasion. The following surgical staging has been adopted by the International Federation of Gynecology and Obstetrics (FIGO) and by the American Joint Committee on Cancer (AJCC):

1. Stage I endometrial cancer is carcinoma confined to the corpus uteri:
   (a) Stage IA: tumor limited to endometrium
   (b) Stage IB: invasion to less than one half of the myometrium
   (c) Stage IC: invasion to greater than one half of the myometrium
2. Stage II endometrial cancer involves the corpus and the cervix, but has not extended outside the uterus:
   (a) Stage IIA: endocervical glandular involvement only
   (b) Stage IIB: cervical stromal invasion
3. Stage III endometrial cancer extends outside of the uterus but is confined to the true pelvis:
   (a) Stage IIIA: tumor invades serosa and/or adnexa and/or positive peritoneal cytology
   (b) Stage IIIB: vaginal metastases
   (c) Stage IIIC: metastases to pelvic and/or para-aortic lymph nodes
4. Stage IV endometrial cancer involves the bladder or bowel mucosa or has metastasized to distant sites:
   (a) Stage IVA: tumor invasion of bladder and/or bowel mucosa
   (b) Stage IVB: distant metastases, including intra-abdominal and/or inguinal lymph nodes

Radiation Therapy

Radiation uses high-energy x-rays to destroy cancer cells and shrink tumors. This treatment may be used prior to surgery (called neoadjuvant therapy) or after surgery to destroy remaining cancer cells. Radiation also may be used in patients who are unable to undergo surgery.

Hormonal Therapy

Endometrioid endometrial cancer has long been associated with states of estrogen excess. As a result, a variety of antiestrogens have been used for systemic treatment.

Progestogens

Following the theory of estrogen excess as a carcinogenic promoter, progestogens have been used in the treatment of endometrial cancer for their antiproliferative effects on the endometrium.

Aromatase Inhibitors

Another approach to reducing the estrogen stimulation of the tumor is to use aromatase inhibitors. Aromatase inhibitors are known to reduce levels of circulating estrogen by reducing estrogen production.

Endometrioma-benign endometriotic ovarian cysts; DIE; deeply infiltrating endometriosis

Definition

Endometriosis is a disease characterized by the presence of ►endometrium-like epithelial and stromal tissue outside their normal location in the uterus, commonly on the ovaries and peritoneum. It is benign but has been linked to the development of ►ovarian cancer and may be a ►preneoplastic lesion.

Characteristics

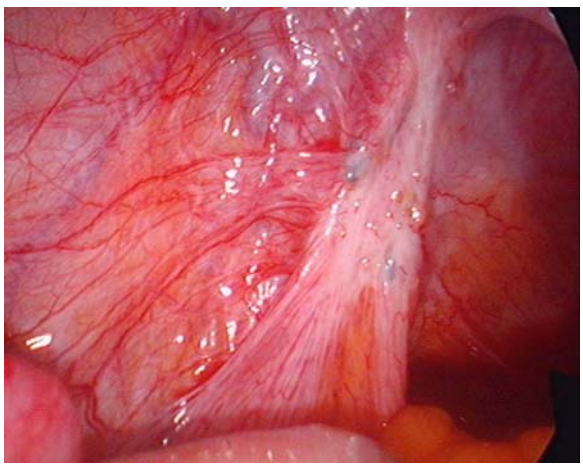
Endometriosis affects ~10% of women of reproductive age. Its symptoms include pelvic pain, ►dysmenorrhea and subfertility, although it may also be asymptomatic. The main pathological processes associated with endometriosis are peritoneal inflammation and fibrosis, and formation of adhesions and ►endometriomas. It is hormone-dependent, and is more common in women of low ►parity. Most endometriosis occurs sporadically, although it can be inherited as a complex genetic trait.

Surgery is required to make a formal diagnosis of endometriosis, e.g. at ►laparoscopy (Fig. 1), when laser or diathermy ablation of lesions can be carried out. Medical treatments act by inhibiting hormonal stimulation of the lesions, and include the oral contraceptive pill (OCP), ►progestogens and ►gonadotrophin-releasing hormone analogues.

The pathogenesis of endometriosis is unclear; one theory is retrograde menstruation, whereby endometrial tissue spills out of the Fallopian tubes during menstruation and implants on the ovaries and peritoneum. However, endometriotic lesions can be found in sites outside the peritoneum; hence, alternative theories include epithelial metaplasia of tissues into endometrium, and lymphovascular spread.

Interestingly, endometriosis shows many characteristics of tumorigenesis (Fig. 2). Endometriosis may invade tissue, traversing the basement membrane, and ►metastasise to other locations. Accordingly, ►matrix metalloproteinases are up-regulated and there is a deregulation of cell adherence signaling molecules such as β-catenin, ►E-cadherin and integrins.

Tumors may show self-sufficiency of growth and insensitivity to anti-proliferative signals. Similarly, endometriosis increases local ►estrogen production and its own responsiveness to estrogen, and the disease is associated with progesterone resistance related to an overall reduction in the levels of ►progesterone receptors (PRs) and the lack of a specific PR isoform – progesterone receptor B (PR-B). These aberrant mechanisms set up a positive feedback cycle of growth.



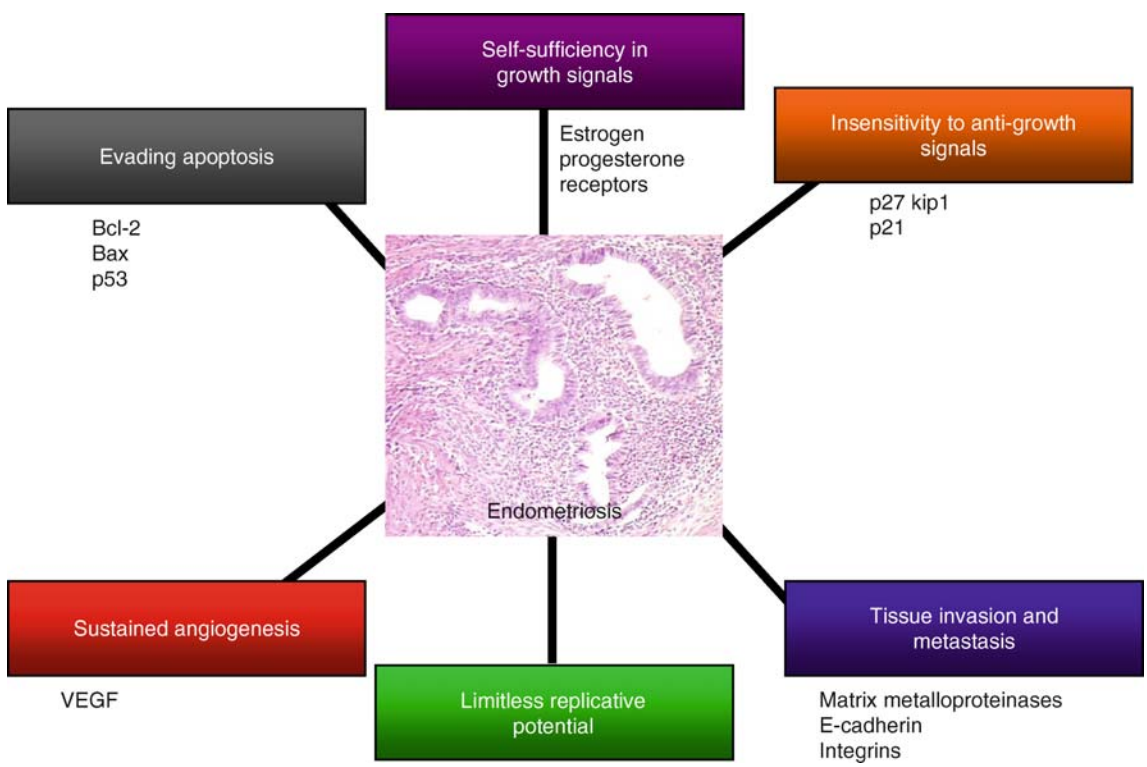
Endometriosis. Figure 1 Tumor phenotype.

Furthermore, endometriosis may differ from normal endometrium in its expression of ►transforming growth factor-β, ►insulin-like growth factors and ►cyclin dependent kinase inhibitors. It has increased ►Bcl-2 and decreased Bax expression, suggesting a degree of resistance to ►apoptosis.

►Angiogenesis is thought to be one of the mechanisms in tumor development, and indeed it seems to be important for the survival of endometriosis. In mouse models using transplanted endometrium, administration of ►endostatin and ►VEGF antibodies is effective at treating the "endometriotic" lesions.

Tumors are formed by the somatic acquisition of multiple genetic alterations producing a clone with a selective advantage. We would expect endometriosis to show some of these alterations if it is a neoplasm, albeit a benign one. Most importantly, it appears that endometriosis can be monoclonal in nature, a key feature of cancer.

It has been reported that endometriosis increases the risk of various cancers, namely ►breast cancer, ►ovarian cancer, ►non-Hodgkin lymphoma and ►melanoma, although the nature of this link has not been completely elucidated. In fact the risk of breast cancer may be decreased when endometriosis is diagnosed at an early age, possibly due to exposure to drugs with antiestrogenic effects. This suggests that a complex interplay of hormonal factors



Endometriosis. Figure 2 Tumor-biological qualities.

may influence the development of the two pathologies concomitantly.

Research has mainly focused on the relationship between endometriosis and ovarian malignancies. Endometriosis has been associated with the development of two histological subtypes of ovarian cancer: endometrioid and clear cell. The possibility that endometriosis may act as a precursor to these types of ovarian cancer, by malignant transformation of endometriosis, has attracted the most interest. Endometriosis may therefore be an early step in a neoplastic process which culminates in ovarian cancer.

Evidence supporting the link between endometriosis and ovarian cancer comprises:

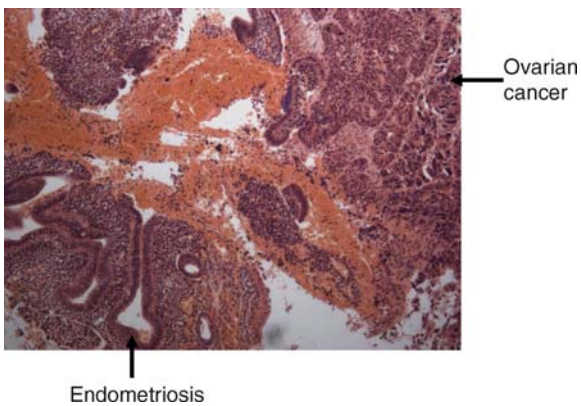
Pathological Studies

It has been observed for some time that ovarian tumors may be found on a background of endometriosis, leading to the description ►EAOC (Endometriosis-associated ovarian cancer) (Fig. 3). Sixty per cent of these cancers are found arising from within the endometriotic lesion itself; in the remaining 40% the endometriosis is at a distant site. This physical proximity suggests that there might be a causal relationship between endometriosis and ovarian cancer, rather than endometriosis existing merely as an epiphenomenon.

In 60–80% of these EAOCs the endometriosis found is histologically atypical, in that its cytological or architectural appearance is abnormal. This is in contrast to a 12–35% prevalence of atypia in endometriosis without co-existing malignancy.

The histology of EAOCs differs considerably from that of ovarian tumors in general, in that more than 90% are clear-cell or endometrioid carcinomas (which respectively make up 6 and 14% of all ovarian tumors). Conversely, endometriosis is found in a much higher proportion of operations for endometrioid and clear-cell tumors than for ovarian cancer in general. Location of endometrioid carcinoma and endometriomas follows the left-sided preponderance of endometriosis, whereas ovarian cancer in general does not.

Large pathology series have found ovarian cancer in 5–10% of endometriomas Other studies have found endometriosis in 21–54% of clear cell and endometrioid ovarian cancers. The presence of malignant tumors appearing on a background endometriosis is likely to be underestimated. Most women with endometriosis are asymptomatic and so unaware that they have the disease; by the time they develop ovarian cancer in the post-menopausal years, the endometriosis has atrophied and no longer visible. In younger women, the tumor may have obliterated the area of original endometriosis by the time it is removed.



Endometriosis. Figure 3 Histopathology.

Epidemiological Studies

The risk of developing ovarian cancer is increased by a factor of 1.7 in women with endometriosis, when confounding factors such as parity, infertility and use of the oral contraceptive pill (►OCP) are taken into account. Patients hospitalized for endometriosis are almost twice as likely to go on to develop ovarian cancer. A long standing history of ovarian endometriosis increases the risk of ovarian cancer by a factor of more than four, supporting the concept of a continuum from benign endometriosis to carcinoma.

Women with endometriosis who develop EAOCs are younger at diagnosis; they present with less advanced disease and they have longer disease-free survival than women with epithelial ovarian cancers. Conceivably, this occurs because women with endometriosis have frequent hospital appointments, ultrasound scans and possibly even increased awareness of ovarian cancer.

It is difficult to be able to draw firm conclusions from these epidemiological data. Endometriosis and ovarian cancer are hormonally-influenced diseases in which it is hard to separate causation from epiphenomena. For example, treatments for endometriosis such as ►danazol may increase the risk of ovarian cancer, and in the most part have not been confounded for. Alternatively, women who have a tendency to retrograde menstruation may be at risk of both endometriosis and ovarian cancer, due to increased exposure to environmental carcinogens transported into the peritoneal cavity. Thus, endometriosis and ovarian cancer, rather than being at different ends of a neoplastic spectrum, could be different endpoints brought about by similar risk factors or a common genetic predisposition, which therefore often co-exist.

A further explanation for the link is that endometriosis is itself a risk factor for ovarian cancer because of its hormonal and inflammatory effects, acting locally and systemically. Inflammation can promote cancer development by increased cell division in tissue repair,

which increases the potential for mutations to occur. Indeed, protective factors for ovarian cancer such as OCP use and parity are thought to act by suppressing ►ovulation, which involves inflammation and repair, and in ovarian cancer cell lines, anti-inflammatory drug administration is protective.

Molecular Genetic Studies

In contrast to the pathological and epidemiological studies discussed above, which cannot exclude an indirect link involving common environmental, immunological, hormonal or genetic factors, molecular genetic studies can go some way towards proving causation.

Research has focused on endometriosis as a precursor of ovarian cancer, in which endometriosis could be an early stage of a ►multi-step development process. By cumulative acquisition of aberrant genetic changes, endometriosis might progress through atypical stages to endometrioid and clear cell ovarian cancer (Fig. 4). This is analogous to the adenoma-carcinoma sequence in ►colon cancer, or the neoplastic progression of Barrett's esophagus to esophageal adenocarcinoma. Indeed, in these examples molecular genetic studies have been used to demonstrate clonal progression from precursor lesion to cancer.

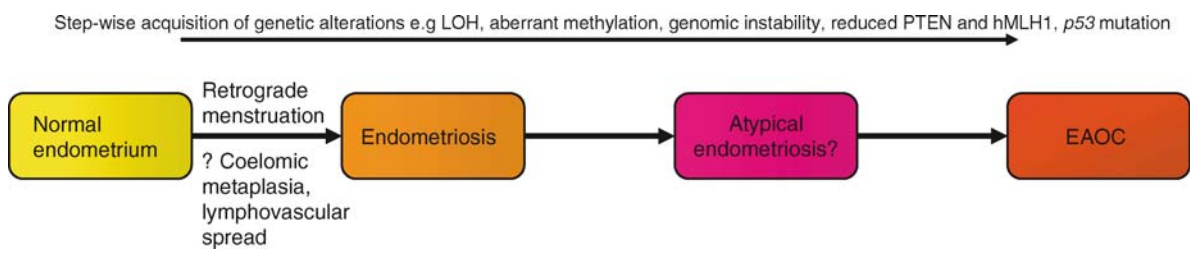
To prove that endometriosis is a precursor of EAOCs, one would expect them to have common genetic (and epigenetic) alterations. EAOCs are very often found in association with endometriosis which is metaplastic or atypical. Studies have compared the molecular genetics of endometriosis and EAOCs in an attempt to prove that malignant transformation of endometriosis occurs.

Advancing tumor stages are associated with accumulation of genetic alterations leading to gain of ►oncogene, and loss of ►tumor suppressor gene (TSG), function. ►Loss of heterozygosity (LOH) (which can indicate loss of TSG function) has been compared in various genomic regions in endometriosis co- existing with EAOCs, and these studies have consistently found common LOH events in the EAOCs and benign endometriotic tissue. For example, in a study using ►microsatellite markers across the genome, a third of LOH events detected in EAOCs were also detected in endometriosis samples from the same patient; the same allele was lost in each case indicating a common pathway, as it is very unlikely that the same allele was affected due to independent events. No LOH events were found only in the endometriotic tissue. These data strongly suggest that ovarian endometriosis can be a clonal precursor to EAOCs.

As would be expected from the "multi-hit" model of tumorigenesis, LOH was detected more frequently in EAOCs than endometriosis. Fluorescence in situ hybridization (►FISH) analysis has also been used to compare chromosomal aberrations in ovarian endometriosis compared to EAOCs. Abnormalities, specifically trisomies 1 and 7 and monosomies 9 and 17, were detected in a larger percentage of cells in EAOCs than in ovarian endometriosis, which in turn had a larger percentage of these chromosomal aberrations than normal endometrium. This suggests that there may be an expansion of the aberrant cell clones in carcinogenesis, which supports the theory of malignant transformation of endometriosis. Interestingly, many fewer chromosomal aberrations were found in extragonadal endometriosis compared to ovarian endometriosis; this suggests that it might be ovarian endometriosis alone which can progress to ovarian cancer, perhaps due to the ovarian environment inducing genetic changes, and/or a different aetiology for the two types of endometriosis.

The analysis of specific oncogenes and tumor suppressor genes has also provided weight to the malignant transformation theory. ►TP53 mutations are found with increasing frequency through the spectrum of normal endometrium, endometriosis, endometriosis co-existent with cancer, and ovarian cancer. In terms of ►epigenetic alterations, hyper-►methylation of the promoter region of hMLH1, which has a role in DNA ►mismatch repair, has been found in endometriosis. Notably, there is decreased hMLH1 expression in a greater proportion of cases of aggressive endometriosis associated with cancer than in lower stage endometriosis.

Further supporting a "multi-hit" theory, a mouse model of ovarian endometriosis has shown that both K-►RAS and ►PTEN mutations are necessary for the development of endometrioid ovarian cancer. Alone, each mutation in the ►ovarian surface epithelium cells



Endometriosis. Figure 4 Tumor evolution.

caused the development of endometriosis-like lesions, but it was only when the mutations were in combination that carcinoma resulted. Clearly the development of ovarian cancer as a result of two mutations is oversimplified, but the study adds strong weight to the malignant transformation theory.

Interestingly, there is some evidence for a role of PTEN in the progression of ovarian endometriosis to EAOCs in humans; LOH of the same allele has been detected in co-existing endometriomas and EAOCs, and LOH, reduced expression and mutation of PTEN have been detected in solitary endometriomas. In addition, PTEN lies near a chromosomal region of significant linkage for familial endometriosis, identified using 1,176 affected sister pairs (although unfortunately there are no data regarding how many have had ovarian cancer). However, in a recently published large case-control study, there was no evidence that genetic variants in the PTEN gene are contributing to genetic susceptibility for endometriosis.

Pathology, epidemiology and molecular studies have added weight to the theory of malignant transformation of endometriosis to EAOCs. Endometriosis can be clonal; in addition, the disease is associated with genetic and epigenetic alterations in genes previously implicated in tumorigenesis. Therefore, endometriosis may be a useful model for understanding early events in tumorigenesis, particularly ovarian cancer. However, it is still not known what proportion of endometrioid and clear cell ovarian cancers are EAOCs, and what proportion have arisen *de novo* or from other precursor lesions. There is extensive work to be done to elucidate the molecular alterations involved in endometriosis, EAOCs and endometrioid and clear cell ovarian cancers in general. Only then can we ascertain the relevance of endometriosis in ovarian cancers, and the potential for screening and targeted therapies geared towards early detection and treatment of ovarian cancer.

Endoplasmic Reticulum (ER)

Definition

An ►organelle in ►eukaryotic cells that is an interconnected network of ►tubules, ►vesicles and ►cisternae and that is responsible for several specialized cellular functions including ►protein translation, folding, and transport of proteins to be used in the ►cell membrane or to be secreted from the cell. The ER is an intracellular tubular or cistern-like membrane system partly arranged in tight contact with the nuclear membrane and with tubular structures reaching the cell's periphery. Depending on the presence of ribosomes/polysomes on the ER surface, it is classified as either rough or smooth ER; the former is responsible for synthesis of about a third of the cellular proteins while the latter is the metabolic compartment of lipids and ►xenobiotics.

Endoplasmic Reticulum Stress

Patrizia Agostinis
Catholic University of Leuven, Leuven, Belgium

Synonyms

Endoplasmic reticulum stress response; ER stress

Definition

The endoplasmic reticulum (ER) is an organelle with several essential functions in eukaryotic cells. The ER is both a major intracellular calcium store and the place where proteins entering the secretory pathway are synthesized, folded, modified and delivered to their final cell surface or extracellular destination. Moreover, in

mammalian cells the ER is the site of sterols and lipids synthesis. Disturbance in any of these functions, which results in the disruption of the proper folding and secretory capacity of the ER and increased load of unfolded proteins in its lumen, defines a condition known as "ER stress." ER stress activates a complex and multifaceted intracellular signal transduction pathway that is essentially designed to re-establish ER homeostasis. Inability to restore ER functions induces cell death, which is usually in the form of ►apoptosis. ER stress contributes to the etiology of several human pathologies, including diabetes, neurodegeneration and cancer.

Characteristics

Proteins that are expressed at the cell surface or secreted extracellularly, as well as resident proteins of the organelles along the secretory pathway, are first co-translationally translocated into the lumen of the ER as unfolded polypeptide chains. The unique highly oxidizing ER environment, which is equivalent to the extracellular space, is required to sustain a variety of post-translational and co-translational modifications to which proteins are subjected after entering the ER. These modifications include the formation of intra- and intermolecular disulphide bonds and N-linked glycosylation. In the Ca^{2+}-rich ER lumen several resident chaperones and Ca^{2+} binding proteins, including the glucose-regulated proteins (GRPs) and the ►lectins, ►calreticulin and ►calnexin critically assist and monitor proper folding, maturation and stabilization of the nascent protein. These ATP-requiring processes are part of the stringent ►ER quality-control mechanisms that allow only proteins adopting a correctly folded or ►native conformation (Protein), or a proper oligomeric assembly in case of multi-subunit proteins, to be exported to the Golgi complex and move on through the secretory pathway. Terminal failure in protein folding or in oligomer assembly results in ►ER-associated protein degradation (ERAD), in which non-native conformers are retrotranslocated to the cytosol and degraded by the ►26S proteasome. ER stress is set off by various intracellular and extracellular perturbations, which alter the protein folding capacity of the ER. These include glucose deprivation, which interferes with N-linked glycosylation and affects ATP levels, redox unbalance and depletion of the ER Ca^{2+} store. Perturbation in ER homeostasis activates an evolutionarily conserved stress response, collectively called the Unfolded Protein Response or UPR. The UPR is primarily a pro-survival response initiated to restore normal ER homeostasis.

Molecular Mechanisms

The UPR consists of three major mechanisms: (i) translational attenuation to limit the biosynthetic load of the ER; (ii) transcriptional activation of cytoprotective genes encoding ER resident chaperones to increase the ER folding capacity; and (iii) increase clearance of unfolded proteins through the upregulation of ERAD. When these mechanisms fail to restore normal ER homeostasis, ER stress promotes the cell death program, which is likely activated to protect the host from the accumulation of dysfunctional cells.

At the molecular level the UPR is characterized by the activation of three ER transmembrane receptors: the pancreatic ER kinase (PKR)-like ER kinase (PERK), the inositol-requiring enzyme 1 (IRE1), and the activating transcription factor 6 (ATF6). These transmembrane proteins contain a lumenal domain, which functions as a sensor of the ER folding capacity, and a cytosolic effector domain that provides a signaling bridge connecting the ER to other cellular compartments. In unstressed cells the luminal domain of the transmembrane receptors is bound to a 78-kDa ER resident chaperone referred to as the glucose-regulated protein (GRP)78 or immunoglobulin binding protein, BiP. BiP belongs to the heat-shock protein (►HSP) 70 class of ►molecular chaperones and can form complexes with heterologous proteins that are processed through the ER. Similar to other HSP70 members, BiP binds both ADP and ATP, which serve to regulate its binding and release from nascent polypeptide chains. BiP cycles between an oligomeric and monomeric state, the latter of which is thought to bind preferentially to unfolded proteins. Association of the ER transmembrane receptors with BiP lock them into an inactive, monomeric conformation that prevents their oligomerization or trafficking to other compartments. On accumulation of unfolded proteins, which promotes a dramatic increase in the luminal pool of monomeric BiP, BiP is competitively titrated away from the luminal domains of the three receptors. BiP dissociation triggers the activation of these proximal ER stress sensors and initiates the first molecular event of the complex transcriptional and translational program defining the UPR.

Signal Transduction by the Three Arms of the UPR

Adaptation to ER stress involves the sequential activation of three major arms of the UPR: the PERK-eIF2α-ATF4, ATF-6 and IRE1 pathways.

- PERK is a ►type I transmembrane Ser/Thr protein kinase. Dissociation of BiP from PERK drives PERK homo-oligomerization and self-activation by *trans*-autophosphorylation. PERK mediates the specific phosphorylation of the ►eukaryotic initiation factor-2α (eIF2α) at Ser51. Phosphorylation of eIF2α interrupts the translation of most mRNAs, thereby reducing the load of newly synthesized proteins in the ER. However, while global translation is transiently repressed, the PERK-eIF2α pathway results in the preferential translation of a subset of mRNAs containing regulatory sequences in their 5′

untranslated regions, that allow them to bypass the eIF2α translational block. One of these mRNAs encodes ATF4, a member of the bZIP family of transcription factors. ATF4 promotes cell survival through the induction of several genes involved in restoring ER homeostasis. Under conditions of sustained ER stress, ATF4 prompts the expression of the transcription factor C/EBP homologous protein (CHOP) and of one of its target genes, the growth arrest and DNA damage-inducible gene 34 (GADD34). GADD34 is a protein phosphatase 1 (PP1) regulatory subunit that promotes eIF2α dephosphorylation, which ends the translational block and restores protein synthesis in the ER.

- ATF6 is a ►type II transmembrane protein that contains a transcription factor in its cytoplasmic domain. Under ER stress conditions the dissociation of BiP frees ATF6 to translocate to the Golgi apparatus, where it is cleaved by Golgi-resident proteases. The limited proteolysis of ATF6 releases the transcription factor domain into the cytosol and allows its migration into the nucleus, where it binds DNA and activates gene expression. AT6-responsive genes are activated rapidly after the induction of ER stress, and include the ER molecular chaperones BiP and GRP94, as well as ►protein disulphide isomerase (PDI). ATF-6 also leads to the transcriptional upregulation of the X-box binding protein (XBP1) mRNA, which is converted into a stable transcription factor by the endonuclease activity of IRE1.
- IRE1 contains a Ser/Thr kinase domain and an endonuclease domain facing the cytosol. Like PERK, IRE1 is a type I transmembrane receptor that is activated by oligomerization-induced *trans*-autophoshorylation in the ER membrane upon BiP dissociation. IRE1 autophosporylation stimulates its endonuclease activity and does not result in the propagation of a phosphorylation cascade. Active IRE1 catalyses the removal of a 26-nucleotide intron from the XBP1 mRNA, generating the $XBP1^s$ frameshift splice variant which encodes a stable and active transcription factor. $XBP1^s$ translocates to the nucleus and transactivates several cytoprotective genes involved in ER quality-control. $XBP1^s$ can also induce a negative feedback loop which, by relieving the PERK-mediated translational block, returns the ER function to normal once the UPR has been successful. The IRE1 pathway is thought to be the final branch of the UPR to be activated, subsequent to the rapid induction of PERK and ATF6 signaling which have a major cytoprotective role. The IRE1 signal plays a dual role in the UPR and if the ER stress persists, $XBP1^s$ initiates pro-apoptotic protein synthesis, thereby facilitating the induction of apoptosis.

Cell death after ER stress. The adaptive responses initiated by the UPR restrain cell death to the extent that ER homeostasis and protein folding capacity can be re-established. If, in spite of this, protein aggregation persists, the UPR shifts into a proapoptotic response, whose molecular effectors are still poorly defined.

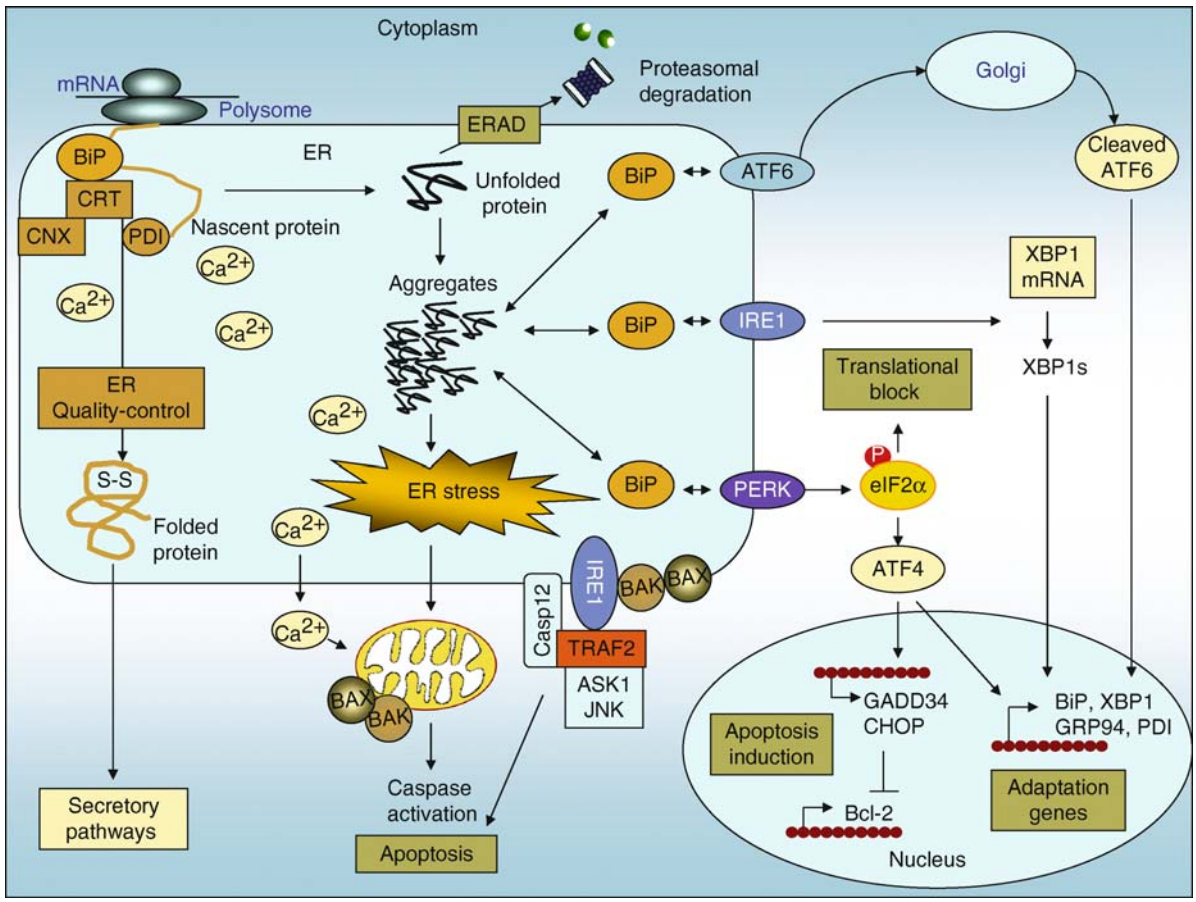
- *CHOP and IRE1.* Sustained CHOP induction, resulting from the late phase of ATF-6 activation and the PERK-eIF2α-ATF4 axis, tips the balance towards apoptosis under conditions of persistent ER stress. Several CHOP target genes contribute to the proapoptotic effect of CHOP induction. One mechanism entails CHOP-mediated suppression of *bcl-2* transcription, which increases the sensitivity of the cell to apoptotic cell death. Also, restoration of protein synthesis by the CHOP-mediated induction of GADD34 can promote the expression of proapoptotic effectors when the ER folding capacity cannot be restored. The IRE1 pathway leads to activation of the ►MAPK family member c-Jun N-terminal kinase (JNK) through the adaptor molecule TNF receptor-associated factor 2 (TRAF2) and apoptosis signal-regulating kinase-1 (ASK1). JNK can favor apoptosis induction following ER stress by increasing the proapoptotic activity of some ►BCL2 proteins, such as BIM.
- *Ca^{2+} signaling and BCL2 proteins.* The physiological ER Ca^{2+} content is maintained by the balance between the active Ca^{2+} uptake, controlled by ►SERCA (sarco-endoplasmic reticulum Ca^{2+}-ATPase) pumps, and its release, through opening of IP_3R (inositol 1,4,5-triphosphate receptor) or RyR (ryanodine receptor) ►Ca^{2+}-release channels. Various stimuli that cause depletion of ER Ca^{2+} store and result in cytosolic Ca^{2+} overload also stimulate the UPR, since the vast majority of ER resident chaperones involved in ER quality-control are Ca^{2+} binding proteins, and can induce cell death. Excessive Ca^{2+} uptake by mitochondria induces changes in the permeability of the inner mitochondrial membrane, which can result in the breakdown of the mitochondria membranes triggering apoptosis. Increased Ca^{2+} leak from the ER activates Ca^{2+}-dependent enzymes in the cytosol, including the Ca^{2+}/calmodulin-dependent phosphatase calcineurin and ►calpains, which can regulate apoptosis induction by modulating the activity of BCL-2 proteins. In addition to having a crucial role as regulators of mitochondria function during apoptosis, proapoptotic BAX, BAK and antiapoptotic BCL2 proteins regulate ER Ca^{2+} homeostasis and the UPR machinery. For instance, interaction of BAX and BAK with IRE1 during ER stress is required for IRE1-mediated JNK activation and apoptosis induction.
- ►*Caspases.* The execution phase of apoptosis following ER stress involves the activation of caspases. Both murine caspase 12 and human caspase 4 associate with the ER and are proteolytically processed after ER stress. The general relevance of this

E

event for the initiation of apoptosis following ER stress is however still dubious as catalytically active caspase 12, which is found only in rodents, and caspase 4 belong to the subclass of inflammatory caspases with primary role in inflammation and innate immunity rather than in ER stress (Fig. 1).

Clinical Relevance

Activation of the UPR is observed in several ►conformational diseases, including Alzheimer's and Creutzfeldt–Jakob diseases, and involves the accumulation of protein aggregates in the ER. In general, it is becoming increasingly clear that a range of pathological conditions are associated with ER stress, including diabetes, ischemia, lysosomal storage disease, cardiovascular diseases, atherosclerosis, neurodegeneration, viral infection as well as cancer. With respect to cancer, tumors often exhibit activated molecular effectors of the UPR. Also, conditions found in the tumor microenvironment – which, due to insufficient vascularization, often include glucose starvation, hypoxia and acidosis – can promote ER stress in tumors. Although the UPR is generally considered a protective response, prolonged ER stress can activate apoptosis and therefore its role in the disease process can be dualistic. The activated UPR could either



Endoplasmic Reticulum Stress. Figure 1 ER stress signaling pathways. After import in the ER lumen a nascent unfolded protein undergoes different post-translational modifications monitored by molecular chaperones and folding enzymes (CRT; calreticulin, CNX; calnexin, BiP, PDI), prior to its export from the ER through the secretory pathways. Incorrectly folded proteins are retrotranslocated to the cytosol and degraded by the proteasome through the ERAD. Perturbations in the ER environment resulting in the accumulation of unfolded proteins in the ER lumen, promotes the dissociation of BiP from three proximal ER-stress sensors. This triggers PERK and IRE1 oligomerization/activation and ATF6 release from the ER membranes. The PERK-eiF2α-ATF4 signal is responsible for the initial translational block, whereas the ATF-6 and the IRE1 axis mediate the rapid transcriptional activation of cytoprotective genes, including several ER resident chaperones. If ER stress persists, apoptosis is activated through several mechanisms involving Ca^{2+} signaling and the transcriptional upregulation of CHOP, which represses *bcl-2* expression. BAX and BAK proteins regulate the IRE1-TRAF2-ASK1 pathway which leads to JNK activation and processing of murine caspase-12.

limit tumor growth (by the induction of apoptosis in conditions of chronic stress), or instead facilitate it (by increasing the survival of cancer cells). Also, further research will be necessary to determine the extent to which UPR induction in tumors plays a role in chemotherapy resistance, which is currently a major obstacle for the treatment of human cancer.

Endoplasmic Reticulum Stress Response

Definition

Synonymous: unfolded protein response (UPR); A series of ►endoplasmic reticulum (ER) alterations such as calcium depletion, protein misfolding and impairment of protein trafficking to the Golgi triggers this response, which involves attenuation of protein synthesis and selective transcription and translation of a series of genes, mainly involved in favoring correct protein folding. When these ER alterations cannot be repaired by the ER stress response, the damaged cells undergo ►apoptosis. Several stimuli, including ischemia, viral infection and drugs such as ►tunicamycin or ►cisplatin induce apoptosis through this pathway.

►Endoplasmic Reticulum Stress

Endoproteolysis

Definition

Is the directed digestion of the internal regions of ►proteins as opposed to exoproteolysis that is the cleavage of the terminal regions of proteins.

Endoscopic-Ultrasound Guided Fine Needle Aspiration (EUS-FNAB)

Definition

The use of endoscopic-ultrasound (EUS) for real-time guidance of an FNA biopsy needle into a lesion within or adjacent to the gastrointestinal tract (GI tract). EUS-FNAB is valuable for diagnosing and staging GI and mediastinal malignancies.

Endosomal Compartments

Vincent Dammai
Hollings Cancer Center and Department of Pathology and Laboratory Medicine, Medical University of South Carolina, Charleston, SC, USA

Synonyms

Receptor-mediated endocytosis; Endosomal protein sorting; Endolysosomal pathway

Definition

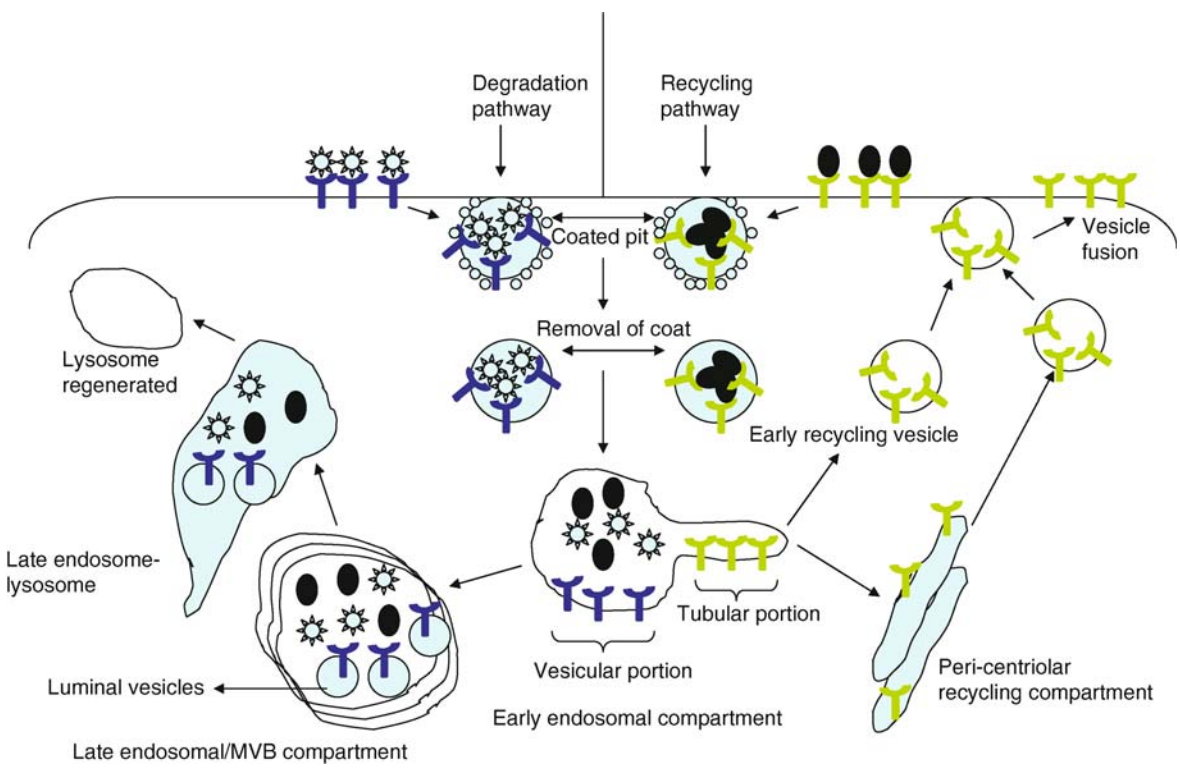
In eukaryotic cells, receptor-mediated ►endocytosis releases cargo-loaded vesicles at the plasma membrane. The vesicle content pass through a series of discontinuous closed membrane systems called ►endosomal compartments. In strict sense, ►endosomal compartments are temporal sorting stations where the fate of endocytosed cargo is determined.

Characteristics

Eukaryotic cells internalize a variety of extracellular material (cargo) either nonspecifically by phagocytosis and pinocytosis, or selectively through receptor-mediated endocytosis. In phagocytosis, specialized cells (e.g., ►macrophages and neutrophils) engulf large particles such as cell debris, bacteria, and viruses. Pinocytosis, exhibited by all cell types, involve uptake of extracellular fluid continually as tiny droplets (micropinocytosis) or sometimes as large droplets (macropinocytosis). By contrast, receptor-mediated endocytosis involves selective uptake of cargo by cognate cell surface receptors. Pinocytosis and receptor-mediated endocytosis are closely related, while phagocytosis is mechanistically distinct and therefore is not considered as endocytosis. In phagocytosis, plasma membrane

evaginates to wrap around the particle. Additionally, exocytosis adds membrane material to phagocytic vacuoles and compensates for loss of plasma membrane. In phagocytosis and pinocytosis, hydrolytic enzymes packed in Golgi-derived vesicles are directly delivered to the vesicle/vacuole and subsequent fusion with lysosomes result in degradation of contents. On the other hand, in receptor-mediated endocytosis, not all cargo is degraded. To illustrate with familiar examples, transferrin (Tf, carry iron) and low-density lipoprotein (LDL, carry cholesterol) are endocytosed along with their respective receptors, TfR and LDL-R. After internalization, iron is released inside the cell and both Tf and TfR are recycled to the plasma membrane for additional iron uptake. However, LDL is degraded to release cholesterol but LDL-R is recycled to the plasma membrane for further LDL uptake. Ubiquitinated growth factor receptors, on the other hand, are degraded to abolish receptor signaling. To achieve this, the incoming cargo is delivered to endosomal compartments where they are sorted either away from (to be recycled) or towards lysosomes (to be degraded). Besides their roles in differentiated cells, endosomal compartments are important during development, for example, in interpretation of morphogen gradients. In light of the details provided later, the illustration in Fig. 1 is self-explanatory and offers a basic view of the endosomal compartments.

The endosomal compartments are (i) early endosome (EE), (ii) recycling endosome (RE), (iii) late endosome (LE)/multivesicular bodies (MVBs), and (iv) lysosomes. Endosomal compartments are distinguished by (i) morphology in electron and fluorescence microscopy, (ii) differential density in Ficoll gradients, (iii) pH differences, and (iv) molecular signature provided by marker proteins. Morphologically, EEs are recognizable as tubulovesicular. LEs are tubular, multilamellar, and multivesicular (with internal vesicles). MVB contain internal vesicles (up to 200) because of protein sorting into the lumen by invagination of outer endosome membrane. Electron tomography studies suggest that the internal vesicles are free-floating and discontinuous with outer endosomal membrane. Distinct endosomal subpopulations can be enriched by density centrifugation and has allowed study of membrane fusion events between endosomal compartments. Also, molecular probes sensitive to pH changes can identify individual endosomal compartment as the luminal pH decreases along the degradative but increase along the recycling pathway (cytosolic pH is ~7.2). EEs are mildly acidic (pH ~ 6.0), recycling compartment is towards neutral (pH 6.4–6.5), LE/MVB is at pH ~ 5.0–5.5



Endosomal Compartments. Figure 1

and lysosomes at pH < 5.0. Finally, proteins recruited to specific endosomal compartments, such as Rab GTPases, serve as markers for identification of the compartment in fixed or live cell imaging experiments. The maturation theory suggests that EE progress towards lysosome by sequential addition of some material and removal of other material. The vesicular transfer theory proposes permanent existence of discrete compartments through which passage of cargo occurs by vesicle-mediated transfer.

Our current knowledge of endosomal compartments is mostly from studies of clathrin-dependent endocytosis (100–200 nm). Other mechanisms, classified as clathrin independent, exist and involve smaller vesicles (40–80 nm). These are mediated by ►caveolins (caveolae) and lipid rafts. Upon cargo binding, receptor adaptor proteins mediate polymerization of clathrin or caveolin on the cytosolic side causing plasma membrane invaginations (pits). The receptors and their cargo concentrate in these pits. Receptors and the initially assembled proteins provide binding sites for several proteins, such as Eps15, epsin, amphiphysin, intersectin, endophilin, SNX9, dynamin, and Rab5. Mostly, dynamin activity constricts and snip such invaginations to release receptor/cargo-loaded primary endocytic vesicles. The released vesicles are coated with clathrin or caveolin. Studies of cholera toxin-B (CTB) and Simian Virus-40 (►SV40) endocytosis revealed clathrin- and caveolin-independent pathways. Interestingly, dynamin and Arf6 are not required in this pathway.

After vesicle release, chaperone-mediated removal of the bulky clathrin or caveolin coat enables vesicles to deliver cargo to EEs. The EE compartment (also called sorting endosome) is the first compartment to receive all incoming cargo and is characterized by marker proteins such as Rab5 and EEA1 and the absence of coat. GTP-bound Rab5 interacts with at least 20 different proteins and along with EEA1, Rabex-5, and SNAREs mediates homotypic fusion and fusion of primary vesicles with early endosomal compartment. Until recently, it was thought that all endocytic cargos fuse with a homogenous early endosomal compartment, where individual cargo is separated via recognition of specific determinants (protein domains, a ubiquitin moiety, or other modifications) and shunted accordingly. Recently, however, EEs have been subdivided into dynamic and static EEs (DEE and SEE). This so-called preendosomal sorting mechanism suggests that the type of protein coat and adaptor proteins assembled around the primary vesicle (at the plasma membrane) predetermines whether the cargo is delivered to DEE or SEE. The cargo to be degraded is delivered to DEE and the cargo to be recycled effectively concentrates in the more abundant SEE.

Within the early endosomal compartment, most receptors disengage from their ligands and the receptors to be recycled move into tubular portions, while proteins to be degraded are retained in the vesicular portion. Although specific sorting mechanisms remain unknown for many receptors, ►ubiquitinated growth factor receptors are retained in the vesicular portion by sequential assembly of ubiquitin-binding Hrs, Escrt-1, -II, and -III complexes and later sorted into intraluminal vesicles (ILV) for degradation by lysosomes. Additional proteins such as STAM, AMSH, and UBPY may positively and negatively regulate the ILV sorting steps. From the tubular portions, Rab4 and Rab11 generate recycling vesicles that fuse with plasma membrane, returning receptors (mostly nonubiquitinated) directly back to cell surface. Such recycling vesicles are called early (fast) REs. A tubular compartment (Rab11-positive but Rab4-negative) exists, which is known as pericentriolar recycling endosomal compartment. It performs similar functions, i.e., returning endocytosed proteins to cell surface. However, its significance is apparent where recycling is important for membrane domain maintenance and membrane protein mobilization. For instance, in migrating fibroblasts, recycling TfRs are routed through the pericentriolar area and reach the plasma membrane of the leading lamella. In neurons, with distinct axonal and somatodendritic plasma membrane domains, polarized sorting of TfR is mediated in pericentriolar recycling compartment. In polarized epithelia, apical–basal polarity is reinforced by endocytosis-mediated recovery of missorted proteins or transcytosis and localized to correct membrane domain by traversing through the pericentriolar recycling compartment.

Beginning from EE, a process of endosome maturation ensues. This involves increasing acidification of the compartments and changes that permit fusion with next endosomal compartment, thereby progressively moving nonrecycled cargo towards lysosomes. LEs acquire Rab7 and lose Rab5, a process called Rab5–Rab7 conversion. Rab7 defines the functional identity of LE and makes the compartment competent for fusion with lysosome (degradation competent). Live-cell imaging shows that Rab5 is either replaced by Rab7 in early endosomal microdomains or Rab7 initially assembles on Rab5-positive EE and bud-off, taking cargo with it to become late endosomal compartment. Thus, the early compartment gradually convert/mature to LEs. An important feature is that LE membranes are highly tubular or multilamellar and contain an unusual lipid, called lysobisphosphatidic acid (LBPA). LEs become MPR-positive, allowing vesicles from the *trans*-Golgi network to deliver degradative enzymes to the compartment. Resident lysosomal proteins are also delivered by this mechanism through LEs. Some protein and lipid cargo are degraded in LEs as the pH-sensitive degradative enzymes are not fully activated. MPR is eventually carried away by vesicles back to *trans*-Golgi (to be used again later) following which fusion with

lysosome occur. LEs are identified by presence of both Lamp-1 and MPR.

Sorting of ubiquitinated cargo into ILVs results in the characteristic appearance of MVBs. A clear distinction between MVB and LE is difficult and thus mentioned as LE/MVB. In specialized cell types or under specific conditions a few typical characteristics of MVB assume prominence. In MVB that have a nondegradative function, the LBPA-containing ILVs undergo retrofusion with outer endosomal membrane, releasing their contents into cytosol (such as vascular somatitis virus and anthrax lethal factor). Also, MVBs serve as precursors for antigen-processing compartments (nonendosomal compartment), exosome release, T-cell secretory granules and melanosomes. Interestingly, ubiquitinated proteins are sorted to MVBs that are distinct from MPR- or LBPA-positive MVB. Since MPR is recycled and LBPA-containing internal vesicles can undergo retrofusion, this mechanism may represent separation of distinct classes of receptors and explain why not all proteins and lipids are degraded in LE/MVB. Finally, the cargo in LE/MVB is delivered to lysosomes. Lysosomes are the endpoint of endocytosis and contain all enzymes necessary for degradation of proteins and lipids. Syntaxin 7 and Rab7 appear to be critical for LE/MVB to deliver lipid and protein material to lysosomes. The cargo is transferred by both complete fusion and transient membrane interactions (kiss and run). In case of complete fusion, a hybrid LE–lysosome is observed. The resultant products are utilized by cells and in mammals, lysosomes reform after endosome–lysosome fusion and degradation of cargo.

Clinical Aspects

Defects in protein trafficking influence many aspects of tumor growth and ►metastasis. Tumorigenic mutations in receptor domains (EGFR, FGFR, PDGFR), adaptor proteins (AP-2), or E3 ubiquitin ligases (oncogenic forms of Cbl) that prevent receptor endocytosis may not represent direct defects in the endosomal compartment, but nevertheless influence normal trafficking of activated membrane receptors through the endolysosomal pathway. By contrast, activation of ►oncogenes such as V-Src and K-Ras promote increased growth factor uptake by stimulating macropinocytosis, contributing to tumor growth and metastasis. Hip1, an endocytosis regulator is directly implicated in tumor formation but its precise role remains unknown. Defects in the endosomal compartments are known to promote tumor progression by multiple mechanisms. Genetic defects leading to fusion of ALL/HRX, AF-10, and PDGFR with protein components of the endocytic pathway (Eps15, CALM, and Hip1, respectively) create abnormal oncogenic protein fusion forms and is detected in certain forms of leukemia. Recently, increased recycling of metastasis-promoting integrins (integrin β1, integrin α6β4, and integrin αvβ3) was directly attributed to Rab11 overexpression. As Rab11 expression is regulated by HIF, a transcription factor found elevated in many human cancers, this phenomenon may have significant implications. Not surprisingly, Rab11 and one of its family member, Rab11c, is linked to skin carcinogenesis, Barrett's dysplasia and aggressiveness of breast and ovarian cancers. Additionally, mutants of Rab5 prevent receptor endocytosis, while mutations in ubiquitin sorting machinery (Hrs, Tsg101, GGA, Escrt complexes) inhibit sorting of ubiquitinated receptors and prolong ►receptor tyrosine kinase activity of EGFR, PVR, and Torso by preventing degradation. Cadherins are Ca^{2+}-dependent homophilic cell–cell adhesion molecules (forming ►adherens junctions, AJ) and are critical determinants of tissue architecture. ►Epithelial to mesenchymal transition (EMT), hallmark of malignant tumors, is promoted by AJ disruption, prominently seen in breast, colon and gastric carcinomas. Cadherin internalization-recycling cycle has recently emerged as a major route for maintenance of AJ adhesion strength. MDM2, a E3 ubiquitin ligase found overexpressed in brain, breast, lung, and prostate cancers, interferes with this cycle by promoting sorting of E-cadherin towards lysosome for degradation thus inhibiting cadherin recycling and compromising AJ integrity. Finally, Rab GTPases control both endocytic and exocytic pathways. Abnormal activities of Rabs or their regulatory proteins and effectors lead to several human diseases, including many types of cancers.

Endosomal Protein Sorting

►Endosomal Compartments

Endostatin

S. Ramakrishnan
Department of Pharmacology, University of Minnesota, Minneapolis, MN, USA

Definition

Endostatin is a proteolytic fragment derived from the carboxyterminal, non-collagenous domain 1 (NC1) of ►collagen Type XVIII. Endostatin inhibits ►angiogenesis by blocking ►endothelial cell proliferation and ►migration.

Characteristics

Discovery

Endostatin was originally identified in the culture medium of a murine endothelioma cell line by Michael S. O'Reilly et al., from the laboratory of Dr. Judah Folkman. The same group of investigators has also discovered another angiogenesis inhibitor, ►angiostatin. The search for angiogenesis inhibitors began with the premise that the primary tumor secretes an inhibitor which suppresses the growth of metastatic cells at secondary sites. Biochemical characterization of endostatin showed a molecular mass of 20 KDa containing 184 amino acid residues. Endostatin selectively inhibits ►endothelial cells and does not affect the growth of non-endothelial cells, including tumor cells. Recombinant mouse endostatin was initially produced in E. coli in insoluble form. Treatment of mice with recombinant endostatin inhibited >99% of tumor growth. Soluble forms of both mouse and human endostatins are currently produced in yeast, insect and mammalian cells.

Structure and Function

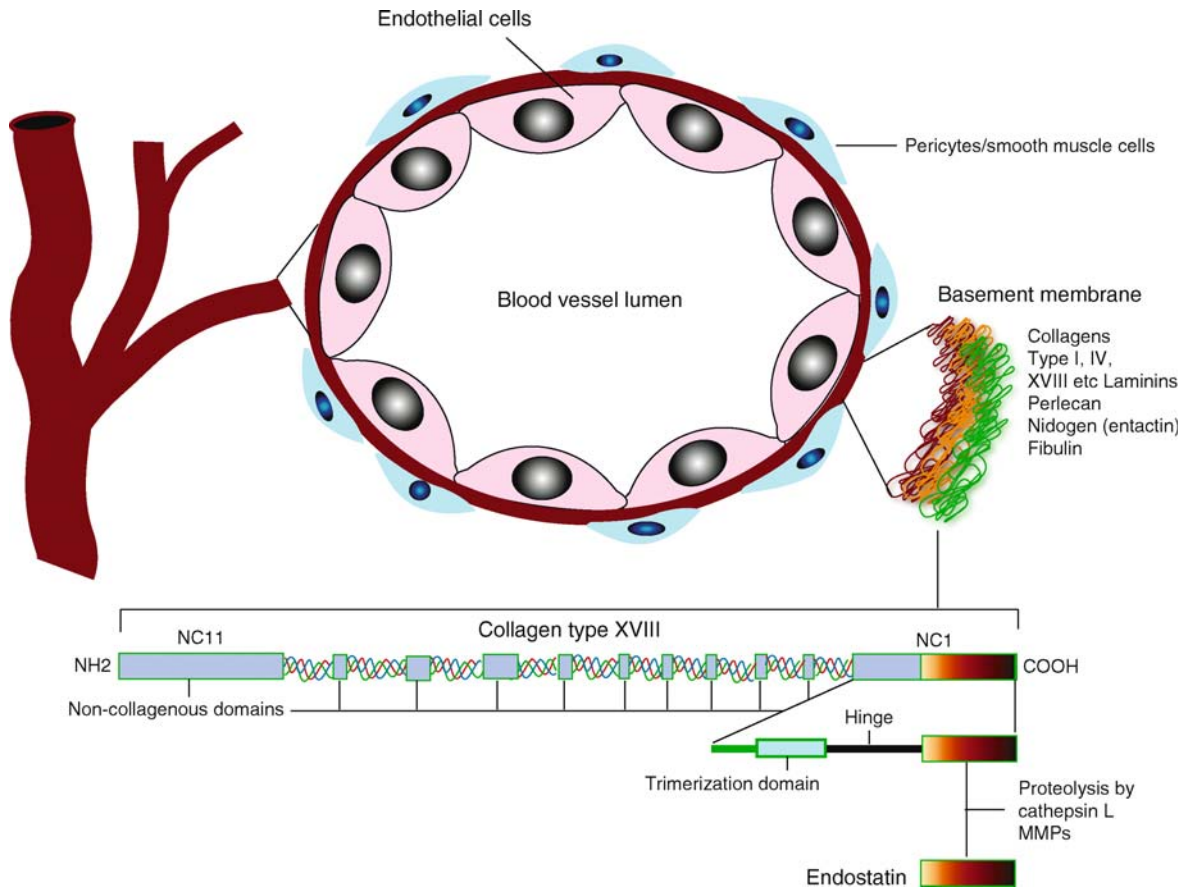
The precursor for endostatin is collagen Type XVIII, a special kind of collagen found at the basement membrane of endothelium and epithelium. Collagen XVIII along with collagen XV belong to a subfamily called multiplexin. Collagens normally have a contiguous, long stretch of triple helical region (collagenous domain) which ends at the carboxyterminus with a globular, non-collagenous domain (NC 1). Collagenous domains are characterized by repeated sequence of Glycine–Hydroxylysine–Hydroxyproline amino acid residues. The multiplexin subfamily of collagens has multiple interruptions in the collagenous domain. Collagen type XVIII, for example, has eleven non-collagenous (NC1–NC11) domains flanking ten collagenous domains (Fig. 1). Endostatin is generated from the NC1 domain, which contains a trimerization domain at the amino terminus followed by a protease-sensitive hinge region which culminates at the carboxyterminus as endostatin. Cathepsin L and, to some extent, matrix metaloproteinases cleave at the hinge region of NC1 domain to release endostatin. X-ray crystallographic studies have shown that endostatin is a compact globular molecule.

Schematic diagram shows the complex architecture of vascular basement membrane/extracelluar matrix. In addition to providing the scaffold for vascular assembly, the matrix contains a number of sequestered growth factors which can be locally released to modulate angiogenic response. The domain organization of collagen type XVIII is shown. Endostatin is generated by the proteolysis of the carboxyterminal NC1 domain.

A number of positively charged arginine residues are located at the major alpha helix aligning towards the surface of endostatin. Substitution of arg residues affects heparin binding but does not alter the biological activity. A single point mutation at proline 125 to alanine has been found to increase the biological activity of human endostatin. Comparison of amino acid sequences between various organisms reveals substitutions of proline to a different amino acid residue at this site. Endostatin sequence from chicken and *Xenopus* show proline to alanine substitution. Japanese puffer fish and Drosophila (fruit fly) have glycine at this position. *C. elegans* has an aspartic acid at this location. However, no polymorphism has been found in human collagen XVIII/endostatin at this position. Some of the recent studies suggest even shorter fragments of endostatin are biologically active and inhibit angiogenesis.

Mechanism of Action

Endostatin binds to α5β1 ►integrin and induces clustering within the lipid rafts. In addition, ►glypican 1, a heparin sulphate glycosaminoglycan, serves as a low affinity binding site for endostatin. Two phenylalanine residues (F31 and F34) are found to be critical for glypican binding. Mutation of these two residues affects endostatin binding to glypican 1. The Integrin binding site of endostatin has not yet been identified. Clustering of integrin-bound endostatin activates ►*Src* kinase and inhibits RhoA activity leading to the disruption of ►focal adhesion. Associated changes in the actin stress fibers ultimately affect endothelial cell migration. Endostatin is also known to affect a second signaling pathway, the ►Wnt signaling pathway, leading to the proteosomal degradation of ►β-catenin. Reduced levels of cytoplasmic β-catenin blocks T cell factor (TCF) mediated transcription of ►cyclin D1 and ►c-myc. Repression of cyclin D1, one of the critical mediators of cell cycle progression, arrests endothelial cells at the G1 phase of the cell cycle. Other reports have identified cell surface-bound tropomyosin, ►vascular endothelial growth factor (VEGF) receptor 2 and ►matrix metalloproteinase-2 (MMP-2) as potential targets for endostatin.



Endostatin. Figure 1 Generation of endostatin from the vascular basement membrane.

Genetic Variations

Mutations in collagen XVIII/endostatin gene has been identified in humans. Absence of collagen XVIII/endostatin is associated with ►Knobloch syndrome. In mice, collagen XVIII/endostatin gene knock out did not affect developmental angiogenesis but however showed progressive loss of vision. Other mutation, such as D104N substitution in endostatin, has been observed in Knobloch syndrome patients (heterozygous, with one allele truncated and the other with a mutation leading to D104N substitution) as well as in many cancer patients. D104N endostatin does not affect the biological activity of endostatin but showed reduced affinity to ►laminin. Cancer patients having D104N mutation in endostatin did not show any correlation with the disease progression and survival. These studies suggest that loss of collagen XVIII/endostatin does not paralyze the entire vascular system but leads to some selective changes associated with the eye. In contrast, increased expression of collagen XVIII/endostatin has been postulated to reduce the risk of cancer development. Normal serum levels of endostatin in human is between 25 and 30 ng/ml. Higher levels (about 70%) of endostatin has been observed in Down's syndrome patients who have an extra copy of chromosome 21 (trisomy). Collagen XVIII gene is located in chromosome 21. In comparison to age matched, control healthy population, a decreased risk for cancer development has been noticed in the Down syndrome patients. Folkman and Kalluri have hypothesized a physiological tumor suppressive role for endostatin based on these observations.

Preclinical Studies

Endostatin inhibits tumor growth in several model systems. More than fifteen different types of human tumor cell lines (e.g. ►ovarian cancer, breast cancer, glioblastoma cancer and renal cancer) transplanted into immunodefficient mice were inhibited, to varying degrees by endostatin treatment. Endostatin treatment was successful when initiated at an early stage of tumor growth. In a few studies, endostatin treatment induced the regression of established tumors. Furthermore, twice daily injections of endostatin were found to be more effective than daily bolus injections. Serum half-life (►Pharmacokinetics) and bioavailability are

responsible for the schedule dependent differences seen in the efficacy of endostatin treatment. This notion was further supported by the observation that tumor growth was better inhibited when endostatin was delivered by mini-osmotic pumps and in slow release formulations. Endostatin is well tolerated in mice and does not show any toxicity.

Clinical Trials

In 1999 human trials were initiated at three institutions, Dana-Farber Cancer Institute, Boston, University of Wisconsin, Madison and MD Anderson Cancer Center at Houston. Recombinant endostatin expressed in yeast was used in these Phase I trials. A total of 61 patients with advanced disease of different tumor types were enrolled into these studies. Recombinant endostatin was administered either as a 20 min or 1 h intravenous infusion. Dosages ranged from 15 to 600 mg/m^2/day. There was no dose limiting toxicity observed in all the three trials. Serum half-life of endostatin was found to be between 10 and 11 h. In two of the 25 patients treated at the MD Anderson Cancer Center, there was evidence of minor anti-tumor effect. Out of the total of 15 patients enrolled in Dana-Farber Cancer Institute there was a minor response in a patient with a pancreatic neuroendocrine tumor while two of the other patients showed stabilization of the disease. In the University of Wisconsin trial, there was no objective clinical response in any of the 25 patients treated with endostatin. Dynamic CT scans of the patients treated with endostatin showed some evidence of changes in the microvessel density. Other imaging methods to study functional changes in tumor vasculature indicated changes in blood flow and metabolism following endostatin treatment. A definitive ►antiangiogenic effect in treated patients could not be documented due to the lack of suitable biomarkers to validate changes in tumor angiogenesis. Another Phase I study was undertaken at the Vrije Universiteit Medical Center in the Netherlands. Thirty-two patients received recombinant endostatin as a continuous infusion for 4 weeks. Treatment was continued after 1 week of rest by twice daily subcutaneous injections. This trial also noted no adverse side effects in the treated patients and again there was no objective clinical response. However, two patients had a long-lasting stable disease.

Since one of the patients with pancreatic neuroendocrine tumor showed partial response in Phase I trial, a Phase II trial was initiated at multiple centers. Forty patients with advanced neuroendocrine tumors were treated with recombinant endostatin by daily subcutaneous injections. Even though a steady state level of potentially effective serum concentration of endostatin was achieved in these patients, no partial or clinical response was observed. While it is disappointing to note that the anti-tumor effects seen in experimental animals could not be replicated in these early clinical trials, a lot has been learnt on the pharmacological properties of endostatin. Future studies will focus on combining endostatin treatment with other modalities to improve the anti-tumor effects. In deed, the inhibition of tumor growth by ►radiotherapy and ►chemotherapy are potentiated by endostatin treatment. Furthermore, ►gene therapy approaches using viral vectors have shown promising effects in experimental animals. In fact, Adeno associated virus (AAV)-mediated expression of endostatin is in the early phases of clinical development. Surgical removal of tumors followed by chemotherapy in combination with endostatin treatment is a promising strategy for cancer treatment.

Endothelial Derived Gene-1

Mai N. Brooks
Surgical Oncology, School of Medicine, University of California, Los Angeles, CA, USA

Synonyms

Magicin; Med28

Definition

Endothelial-derived gene EG-1 was discovered in 2002. Although first cloned from a human endothelial cell cDNA library (►Angiogenesis), EG-1's transcript has been shown to be present in other cell types as well, particularly in epithelial cells (►Epithelial tumors). The calculated mass of EG-1 is 19,520.2 Da based on amino acid sequence alone, whereas the native complete protein is ~22 kDa. The homology between the human EG-1 peptide to its mouse counterpart is 94.9%, 95.5% to its rat counterpart, and 31% to the Drosophila one.

Characteristics

EG-1 is strongly associated with cellular proliferation. Over-expression of EG-1 achieved by transfection results in increased proliferation of multiple human cell lines in culture. When these cells are injected subcutaneously into immunodeficient mice, EG-1 over-expressed cells develop into larger xenograft tumors [1].

Mechanisms

Over-expression of EG-1 results in activation of the MAPK (mitogen-activated protein kinase) pathway (►MAP kinase-01015), which has been shown to be crucial in promoting cellular proliferation. This manifests as increased levels of phosphorylated p44/42 MAP kinase, phosphorylated JNK (Jun-terminal kinase) (►JNK subfamily and cancer), and phosphorylated p38 kinase.

EG-1 overexpression also results in c-Src activation. c-Src is a member of the Src family of cytoplasmic tyrosine kinases that regulate cell growth, differentiation, cell shape, migration and survival (►SRC). c-Src has been reported to be over-expressed and to play a role in human carcinomas of the breast, colon, and others. Src family tyrosine kinases are often activated by receptor tyrosine kinases (►Receptor tyrosine kinase), such as EGF-R (epidermal growth factor receptor) (►EGR ligands) or PDGF-R (platelet derived growth factor receptor) (►PDGF). Via its proline-rich region, EG-1 binds to the Src family of protein tyrosine kinases c-Src and Yes, and possibly FYN and Hck (Hemopoietic cell kinase). As a result of EG-1 binding, c-Src then becomes catalytically active. However, EG-1 is not a direct substrate of c-Src, nor does it increase c-Src expression [2].

Two proteins with identical sequences to EG-1 have been identified: Magicin for Merlin and Grb2 interacting cytoskeletal protein in 2004 [3], and Med28 in 2004 [4]. Magicin is described to associate with the actin cytoskeleton, and is proposed to have a role in receptor-mediator signaling at the cell surface. Magicin binds directly to Grb2 (growth factor receptor bound 2 protein). Med28 is a member of the Mediator, a multiprotein transcriptional coactivator that is expressed ubiquitously in eukaryotes for induction of RNA polymerase II transcription by DNA binding transcription factors. As Med28, this protein is one subunit of the "adaptor" that bridges RNA polymerase II with its DNA binding regulatory proteins and transduces both positive and negative signals.

In summary, EG-1 is an important protein that has multiple interactions with crucial cellular pathways involved in cellular proliferation, cytoskeletal function, and transcriptional regulation.

EG-1 in Human Cancer

Immunohistochemistry of human samples demonstrates that EG-1 is present in the nucleus as well as in the cytoplasm, and possibly in the cell membrane. There are significantly higher levels of EG-1 peptides in cancer specimens of the breast, colon (►Colon cancer) and prostate (►Prostate cancer, basic characteristics and experimental models; clinical oncology), in comparison with their benign counterparts [5] (►Cancer). EG-1 has been detected at elevated levels in sera from breast cancer patients (►Serum biomarkers). In human urine, EG-1 appears primarily at a larger molecular weight, suggesting that these peptides may co-aggregate or associate with other moieties in urine (►Biomarkers). Thus, EG-1 may be secreted or it may be shed with cell death/turnover.

Translational Aspects

More recent studies have shown that endogenous EG-1 can be targeted to inhibit breast tumor growth [6]. This inhibition, whether delivered via siRNA lentivirus (►siRNA) or polyclonal antibody, results in decreased cellular proliferation in culture and smaller xenograft tumors in mice (►Mouse models). The effects are shown in both ER (estrogen receptor)-positive human breast cancer MCF-7 cells (►Estrogen receptor), as well as in ER-negative MDA-MB-231 cells. As breast cancer is the most common malignancy diagnosed in women and as one-third of these patients will die of their disease, a novel target for breast cancer therapeutic development such as EG-1 would be very

useful (►Breast cancer). Because EG-1 is unique, its use may not be redundant to other gene products/potential targets involved in other molecular pathways (►Molecular therapy; ►small molecule drugs). Further pre-clinical studies are warranted to explore the usefulness of targeting EG-1 for future cancer therapy.

Endothelial Leukocyte Adhesion Molecule-1

►E-Selectin-Mediated Adhesion in Cancer

Endothelial Progenitor Cells (EPCs)

Definition

EPCs constitute a unique population of peripheral blood mononuclear cells derived from bone marrow that are involved in postnatal ►angiogenesis, wound healing, limb ischaemia, post-myocardial infarction, atherosclerosis and tumor vascularization. EPCs are derived from a precursor called a hemangioblast, and in the bone marrow these cells share many antigenic determinants with hematopoietic stem cells, including CD34, CD133, Sca-1, c-Kit, Tie-2 and Flk-1. However, once in the circulation, these cells express markers of endothelial commitment including ►von Willebrand factor (vWF) and VE-cadherin. The primitive EPC is probably best defined as $CD133^+$ $CD34^+$ $Flk\text{-}1^+$.

►Stem Cell Plasticity

Endothelial Transglutaminase

►Transglutaminase-2

Endothelin (ET)

Definition

A family of three similar 21 amino acid peptides which are amongst the strongest vasoconstrictors known and hence modulate blood pressure and flow.

►Endothelins

Endothelin-2

►Endothelins

Endothelin Converting Enzyme (ECE)

Definition

Two enzymes (ECE-1 and ECE-2), which catalyze the processing of the preproendothelins to the mature peptide.

►Endothelins

Endothelins

Synonyms

Endothelin; ET; EDN; Endothelin-2; ET-2; vasoactive intestinal contractor or VIC

Definition

►Endothelins (ETs) are a family of three similar, small peptides that are among the strongest ►vasoconstrictors known and play a key part in vascular homeostasis. Endothelins have numerous roles in tumors including modulating ►angiogenesis and blood flow, inducing mitogenesis and ►invasion of tumor cells, immune activation, and protecting cells from ►apoptosis.

Characteristics

Endothelins (ETs) are a family of small, structurally related, vasoactive peptides that have a variety of physiological roles in many tissues, notably vascular homeostasis. The "ET axis" consists of three peptides, two receptors and two activating enzymes Table 1. Some examples of the roles of ETs in both normal physiology and pathological conditions are shown below:

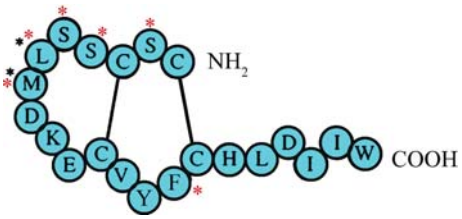
1. *Blood vessels:* Maintain basal level of vasoconstriction ("contraction of blood vessels" which controls blood pressure). Involved in the development of hypertension and atherosclerosis.
2. *Heart:* Affect the force and rate of contraction of the heart. Mediate hypertrophy and remodeling in congestive heart failure.
3. *Lungs:* Regulate the tone of airways and blood vessels. Involved in pulmonary hypertension.
4. *Kidney:* Controls water and sodium excretion, and acid-base balance. Participate in renal failure.
5. *Brain:* Modulates cardio-respiratory centers and hormone release.
6. *Cancer:* Numerous tumors – including carcinomas of the breast, lung, prostate and ovary – produce one or more of the ETs and their receptors, and there are many potential roles of the "ET axis" in cancer.

Mitogenesis: Endothelins have a mitogenic ("growth promoting") effect on both tumor and ►stromal (i.e. the non-cancer cell component of a tumor including blood vessels, immune cells and fibroblasts) ►(stroma) cells and enhance tumor growth. *Tumor angiogenesis*: Angiogenesis is the growth of new blood vessels and is critical for the growth of a solid tumor. ETs stimulate angiogenesis within solid tumors by acting directly on endothelial cells to modulate proliferation, migration, invasion and morphogenesis. ETs also modulate angiogenesis indirectly through induction of the angiogenic cytokine ►vascular endothelial growth factor (►VEGF) expression. ETs also affect blood flow through the established tumor vasculature due to their vasoactive nature. However, the effect of ETs on blood flow appears to be tissue- and tumor-specific. *Tumor invasion and metastasis*: Invasion is the process by which cancer cells spread beyond the border of the tumor enabling the tumor to grow and spread. ETs stimulate invasion of several types of tumor cells including ►ovarian carcinoma cells, Ewing's sarcoma and neuroblastoma cells and ►breast cancer cells. Stimulation of, for instance, breast tumor cell lines with ETs leads to an invasive phenotype via several autocrine and paracrine mechanisms including induction of ►matrix metalloproteinases (MMPs) and ►chemokine receptors, and the activation of macrophages. *Protection from apoptosis*: ETs can protect several cell types – including tumor cells, macrophages and endothelial cells – from apoptosis ("programmed cell death") induced by cellular stresses including ►hypoxia, serum-starvation and chemotherapeutic agents. *Immune modulation*: Trafficking, differentiation and activation of tumor-infiltrating immune cells are all modulated by ETs.

The Endothelin Axis. The ET axis consists of three 21 amino acid (aa) peptides (ET-1, ET-2 and ET-3) (Fig. 1),

Endothelins. Table 1 Genes and peptide sequences of ET axis members. Amino acids that differ in ET-2 and/or ET-3 from ET-1 are marked in Bold/Red

Gene	Mapping position	Peptide or protein	ET isoform peptide sequence
EDN1	6p24	ET-1	CSCSSLMDKECVYFCHLDIIW
EDN2	1p34	ET-2	CSCSS**WL**DKECVVFCHLDIIW
EDN3	20q13	ET-3	C**TC**F**TYK**DKECVY**Y**CHLDIIW
EDNRA	4q31	ET-RA	–
EDNRB	13q22	ET-RA	–
ECE1	1p36	ECE-1	–
ECE2	3q28-29	ECE-2	–



Endothelins. Figure 1 *Structure of ET-1.* ET-1 is a 21 amino acid peptide with a hydrophobic C-terminus and two disulphide bonds at the N-terminus. ET-2 and ET-3 are structurally similar to ET-1, differing by two and six amino acids respectively. The amino acids which differ in the ET-2 sequence are indicated by " *," while those which differ in ET-3 marked by " *."

two G-protein-coupled receptors (►ET-RA and ►ET-RB), and two membrane-bound ►endothelin-converting enzymes (ECE-1 and ECE-2). ET-1 was initially found in the conditioned medium of cultured endothelial cells and its activity as a potent vasoconstrictive peptide was described. ET-2 and ET-3 were rapidly described following ET-1's discovery, and further roles in a variety of tissues have been described.

The three ET isoforms – which are highly conserved in human, rat and mouse – derive from three separately regulated genes yet have a similar structure. Human ET-1 derives from a 212 aa precursor, preproendothelin-1. Removal of the signal sequence generates the 195aa proendothelin-1, which is further processed to release the intermediate 38aa "Big ET-1." ECEs hydrolyze Big ET-1 to yield the active 21aa ET-1. The gene for each ET has a distinct pattern of tissue expression: ET-1 is expressed by endothelial cells of many organs, ET-2 in the ovary and intestine, and ET-3 is found in the brain. There is a relatively low basal level of synthesis of ETs but these genes are readily inducible by inflammatory stimuli.

Endothelin Receptors. Two receptors for ETs have been characterized: ET-RA (also known as EDNRA or ET_AR) and ET-RB (EDNRB, ET_BR). Both receptors are expressed in a wide variety of tissue types. ETs bind these receptors with varying affinity: ET-RA binds ET-1 $\geq$ ET-2 > ET-3, but ET-RB shows no selective affinity for any ET subtype. Binding of the ligands to these ►G protein-coupled receptors (GPCR) modulates several overlapping signaling pathways resulting in the activation of phospholipase C and MAPK pathways, an increase in intracellular calcium and the induction of immediate early genes.

Induction of Endothelin Expression by the Tumor Microenvironment. One region of tumor, compared to another, may differ in the levels of hypoxia, cytokine concentration, immune infiltrate, vascularization, necrosis *etc.* The ►"tumor microenvironment" – particularly hypoxia and soluble factors such as cytokines – modulates expression of numerous "pro-tumor" genes, including those of the ET axis. Transcriptional regulation of numerous hypoxia-responsive genes is via the hypoxia-induced transcription factor, HIF-1, which initiates transcription of genes whose promoter contains a hypoxia response element (HRE). Hypoxia induces ET axis transcription in several cell types including endothelial and tumor cells. There is a functioning HRE in the anti-sense strand of the promoter of ET-1 and induction of ET expression by hypoxia is via HIF-1.

Endothelin Receptor Antagonists. The role of ETs in vasoconstriction has led to the development of several antagonists of the ET receptors that are currently under investigation for the treatment of hypertension, heart failure and renal disease. Several are now in phase II and III trials for the treatment of various neoplasms, particularly ►prostate cancer. ET receptor antagonists hold the attractive possibility that they will "hit" several different cell types and mechanisms of cancer progression.

Of the antagonists available, it is the modified peptide-based antagonists BQ123 (ET-RA antagonist) and BQ788 (ET-RB antagonist) that have been used extensively both *in vitro* and *in vivo*. Small molecule antagonists such as ►atrasentan, a highly selective ET-RA antagonist, have been used clinically. These antagonists can be administered orally, are well tolerated and have few toxic side effects. ET receptor antagonists inhibit proliferation of Kaposi's sarcoma cells, Ewing's sarcoma and neuroblastoma cells, melanoma cells and ovarian carcinoma cells.

As well as the commercially produced antagonists, it is of interest that ET activity may be modified by dietary factors. An extract of red wine polyphenols causes inhibition of ET-1 synthesis in endothelial cells; this is associated with modifications in phosphotyrosine staining, indicating that the active components of red wine cause specific modifications of tyrosine kinase signaling. Green tea polyphenol epigallocatechin-3-gallate inhibits the ET axis and downstream signaling pathways in ovarian carcinoma.

Endothelin Expression in Cancer

Numerous types of tumors produce one or more of the ETs and their receptors. However, the expression and actions of ETs in cancer are incompletely described and are tumor-type specific. ET axis expression is increased in many types of tumor, yet in several types of tumor, expression of the ET axis – particularly the receptors – is *decreased* in neoplastic tissue. For instance, in carcinomas of the breast both ET-RA and -RB are increased, yet in prostate cancer ET-RB is decreased while in lung cancer ET-RA is down-regulated. The function of the ET-RB receptor in tumors is particularly enigmatic; in some cases, such as breast

cancer, ligand-binding to ET-RB initiates several pro-tumor actions, such as promoting invasion, yet in prostate cancer the loss of ET-RB expression is postulated to increase ET-1 peptide in the tumor due to the loss of ET-RB's ET-clearance function.

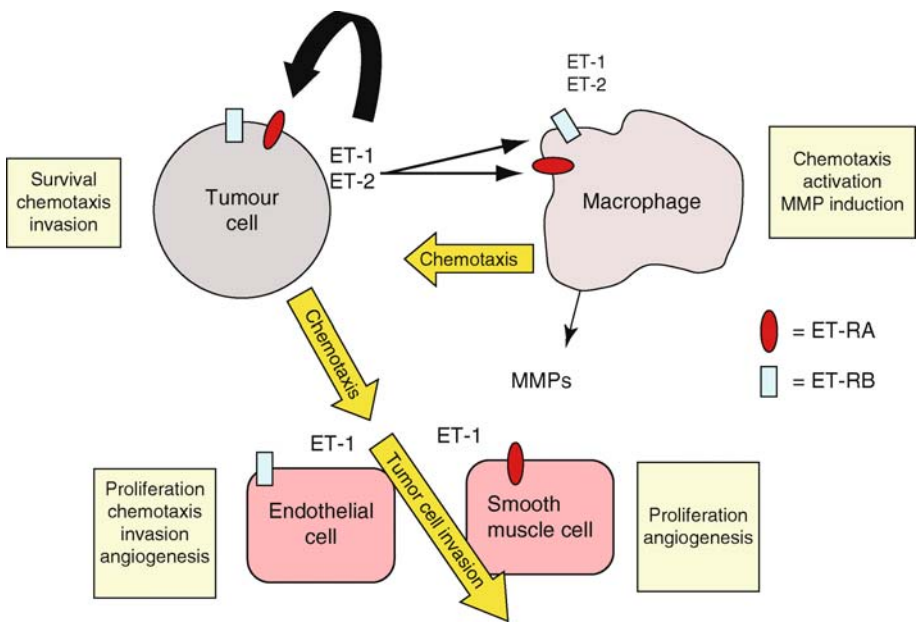
Ovarian Carcinoma. ETs have several roles in ovarian tumors including promoting growth and invasion, and ETs stimulate both tumor and stromal cells. Ovarian carcinoma cells secrete ET-1, which acts as an autocrine growth factor via ET-RA and also has a paracrine growth effect on the fibroblastic cells via both receptors. ETs acting through ET-RA promote invasion of the tumor cells by up-regulating secretion and activation of MMPs.

ET-RA is found in both tumor cells and intratumoral vessels, whereas ET-RB is expressed mainly in endothelial cells and ETs induce angiogenesis via hypoxia inducible factor (HIF)-1α and VEGF. Atrasentan decreases growth of ovarian xenografts in mice and this is associated with decreased angiogenesis and MMP expression, and increased apoptotic tumor cells.

Prostate Cancer. The role of ETs has been studied in both the normal and transformed prostate. ETs are produced in the normal prostate gland by epithelial cells and are found in high concentrations in seminal fluid (up to 5 μg/l). ET-RA and ET-RB are found in normal prostate tissue, but in the malignant prostate there is a loss of ET-RB and increased levels of ET-1. Roles for ETs in prostate cancer include growth promotion, apoptosis inhibition, and bone formation. Atrasentan delays time to progression in prostate cancer in phase III clinical trials. ETs modulate nociception ("sense of pain") and ET-RA antagonism attenuates prostate carcinoma-induced pain.

Breast Cancer. There are numerous potential consequences of ET expression in breast tumors that may lead to a more aggressive tumor cell phenotype (Fig. 2). These include the induction of invasion and angiogenesis via stimulation of tumor cells and tumor-associated macrophages (►TAMs). There is increased expression of the ET axis in ►invasive ductal carcinoma (IDC) of the breast compared to the normal breast; ►lymph node metastases (►Metastases) have a higher degree of ET staining still. Cells expressing ETs and their receptors in IDC include the tumor cells, the $CD68^{+}$ macrophage infiltrate and the endothelial cells.

ETs have a role in recruiting TAMs – macrophages express both ET receptors and chemotax towards ETs via ET-RB and a MAPK-mediated signaling pathway. Exposure of macrophages to ETs leads to an "activated" phenotype and cytokine secretion. Macrophages not only react to ETs but also produce ETs themselves and the TAMs contribute to the ETs in the breast tumor microenvironment.



Endothelins. Figure 2 *Putative roles of ETs in breast tumors.* TAMs express inflammatory cytokines that may induce ET expression by both tumor cells and macrophages, which release ETs and express both receptors. Microenvironmental factors, including hypoxia and the ETs themselves, further stimulate the ET axis. Stimulation of tumor cells and macrophages with ETs leads to chemotaxis of these cells, induction of MMP activity and cytokine expression, and invasion of the tumor cells. ET-2 also protects tumor cells from apoptosis and activates macrophages. Endothelial cells and VSMCs express ET-RB and ET-RA respectively. Stimulation of endothelial cells and VSMCs with ETs may stimulate angiogenesis.

ETs induce expression of chemokine receptors including CCR7 and potentiate the response of breast tumor cells to chemokines including CXCL12 and CCL21, which modulate the organ-specificity of breast cancer metastasis. A further potential function of ETs in breast cancer is the modulation of angiogenesis. ►Bosentan (a mixed ET-RA/B antagonist) inhibits tumor vascularization and bone metastasis in a murine model of breast carcinoma cell metastasis. Expression of ET-RA predicts unfavorable response to neoadjuvant chemotherapy in locally advanced breast cancer.

►*Melanoma*. The ET axis may be a promising therapeutic target for the treatment of melanomas. Activation of ET-RB promotes melanocyte precursor cell proliferation while inhibiting differentiation, two hallmarks of malignant transformation. In melanoma cell lines, ETs prevent apoptosis and ET-RB antagonists cause an increase in cell death. ETs are also involved in angiogenesis in mouse models of melanoma. *In vivo,* BQ788 slows growth of human melanoma tumors in nude mice. A Phase II study of Bosentan as monotherapy in patients with stage IV metastatic melanoma showed disease stabilization in 6 of 32 patients.

►*Lung Cancer*. ET-1 has been proposed as a prognostic marker in non-small cell lung carcinoma (NSCLC). There is higher expression of ET-1, ET-RA and ECE-1 in lung tumors compared to the normal tissue, whilst ET-RB is decreased. Interestingly, ET-1 is increased in the breath condensate of NSCLC patients and this could potentially be used as a non-invasive test for early detection of NSCLC.

►*Bladder Cancer*. The ET axis, particularly ET-RB, is over expressed in bladder cancer. Patients with ET-RB expression tend to have organ-confined tumors and no vascular invasion, and as such ET-RB is associated with *favorable* disease-free survival. When metastatic bladder carcinoma cells were injected into mice treated with Atrasentan, there was a dramatic reduction of metastases to the lungs.

►*Nasopharyngeal Carcinoma*. Elevated plasma big ET-1 is associated with distant failure in patients with advanced-stage nasopharyngeal carcinoma.

►*Cervical Cancer*. In human papillomavirus-positive cervical cancer cells, ET-RA mediates an ET-induced mitogenic effect. Atrasentan inhibits growth and angiogenesis in cervical cancer xenografts.

Endothelium

Definition

Is the layer of epithelial cells that lines the cavity of the heart, and the lumina of the blood and lymph vessels. ►Endothelial cells are at the center of the angiogenic process.

►E-selectin-Mediated Adhesion in Cancer

Endotoxins

Definition

Are part of the outer membrane of the cell wall of Gram-negative bacteria such as *E. coli, Salmonella, Shigella, Pseudomonas, Neisseria*, and other pathogens. Another name for endotoxin is lipopolysaccharide (LPS). The lipid component (Lipid A) of endotoxin gives it its toxicity and other biological effects. The polysaccharide component acts as an immunogen. Endotoxins produce a variety of responses in animals including the production of ►cytokines and other inflammatory molecules.

►Kupffer Cells

Enediynes

Definition

A very potent and naturally occurring antibiotic from bacteria that acts by cleaving DNA. The adverse effects of enediynes on cells include mutagenicity, halting ►mitois by arresting the ►cell cycle, and inducing ►apoptosis. Enediynes were first isolated in the 1960s by the fermentation of microbes.. Enediynes are characterized by a nine- and ten-membered ring containing two triple bonds separated by a double bond. The enediyne group is often called a warhead because it is ready to cyclize, forming benzene via a highly reactive 1,4 benzeniod diradical intermediate. This diradical intermediate is responsible for the oxidative DNA cleavage. This cyclization process is named the Bergman cycloaromatization reaction. The enediyne group readily cyclizes via a diradical

intermediate that cleaves the DNA, giving rise to enediynes' powerful antitumor activity.

Energy of Photon

Definition

Is proportional to the frequency of the electromagnetic wave associated with the photon. For particles with non-zero mass and non-zero charge (such as the proton), the particle energy is associated with motion energy (the kinetic energy). Unit of energy that is often used in radiation biology or therapy is electron volt (eV). 1 eV = 1.602×10^{-19} Joule. Other energy units frequently encountered in radiological sciences are the ►MeV = 10^6 eV and the ►keV = 10^3 eV.

►Radiation Oncology

Engineered Antibody

►Diabody

Enhancer

Definition

A specific DNA sequence that binds transcriptional regulatory proteins that increase the expression of a gene. The enhancer can be positioned to either side of or within the gene.

►Retroviral Insertional Mutagenesis
►Prostate-Specific Membrane Antigen (PSMA)

eNOS

Definition

Endothelial nitric oxide synthase.

►Nitric Oxide

Enterohepatic Recirculation

Definition

Is the process whereby a chemical is reabsorbed in the gastrointestinal tract following biliary excretion.

►Irinotecan

ENU

Definition

N-ethyl-N-nitrosurea. A highly potent mutagen in mice.

Enucleate

Definition

Removal of the nucleus from the cell.

►Microcell-Mediated Chromosome Transfer

Enucleation

Definition

Removal of the eye from the orbit leaving the orbital tissues, extraocular muscles, conjunctiva and eyelids. Performed for certain intraocular malignancies, blind painful eyes, and in certain cases of severe trauma.

►Uveal Melanoma

Environmental Tobacco Smoke

Definition

►ETS (Environmental Tobacco Smoke).

Enzyme

Definition
Is any of several complex proteins that are produced by cells and act as catalysts in specific biochemical reactions.

Enzymic Mouth to Mouth Feeding

►Substrate Channeling

EOC

Definition
Epithelial Ovarian Cancer.

Eosinophil

Definition
A white blood cell that contains granules filled with chemicals damaging to parasites, and enzymes that damp down ►inflammation reactions.

Eosinophilic Granuloma

Definition
Is a benign form of Langerhans cell histiocytosis characterized by single or multiple bone lesions.

►Langerhans Cell Histiocytosis

►Erythropoietin

EPA

Definition
US Environmental Protection Agency.

►Benzene and Leukemia

EpCAM

M. Asif Chaudry
University Department of Surgery, Royal Free and University College London Medical School, London, UK

Synonyms
Epithelial cell adhesion molecule; Ep-CAM; 17-1A; GA733-2; EGP-2; EGP34; HEA125; MK-1; KSA; TROP-1; ESA

Definition
Epithelial specific cell adhesion molecule. A membrane protein found on all simple epithelia to varying degrees; is a type I membrane protein. It is a pan-epithelial differentiation antigen expressed on the basolateral surface of all ►carcinomas, varying in density and glycosylation.

As a homotypic cell adhesion molecule it is intimately integrated within the ►cadherin-►catenin and ►WNT signaling pathways. It modulates the expression of protooncogenes such as ►Myc oncogene. Its status as a pan-carcinoma antigen has rendered it an attractive target for cancer ►immunotherapy.

Characteristics
Structure and Function
Structure
This 37 kDa protein is formed from 314 amino acids (aa) of which only 26 aa face the cytoplasm.

The extracellular component contains three domains: the first is novel and is the site to which most of the

antibodies developed are targeted (323~A3, 17-1A and others). The second is similar to EGF-binding proteins 1 and 6 and ►thyroglobulin. The third has a novel structure that also has similarities with ►EGF. The intracellular portion of the antigen has a tyrosine phosphorylation site, the significance of which is uncertain.

Tissue Morphogenesis

EpCAM is essential for stable adhesion formation and tissue morphogenesis similar to adhesion molecules: carcino-embryonic antigen ►(CEA) and ►ICAM-1. The mechanism by which cytoskeletal and intracellular elements mediate this function are being characterised. EpCAM inhibits intercellular adhesion mediated by ►E-cadherins, in turn interacts with α-, β- and γ-►catenins forming the cadherin-catenin complex.

Catenins link cadherins with the actin cytoskeleton and form complexes with other proteins. Cadherins are crucial for the establishment and maintenance of epithelial cell polarity, morphogenesis of epithelial tissues, and regulation of cell proliferation and apoptosis. Their association with β-catenin is particularly interesting as this is a component in the ►Wnt Signalling pathway that regulates the expression of proto-oncogenes such as c-myc: fundamentally associated with tumor development. Wnt glycoproteins are signaling molecules that regulate cell-to-cell interaction during embryogenesis. Wnt proteins bind to receptors of the Frizzled family. Through several cytoplasmic relay components, the signal is transduced to β-catenin, which is stabilized, accumulates in the cytoplasm, and enters the nucleus, where it binds a lymphoid enhancer factor/T-cell factor transcription factor. Together, β-catenin and lymphoid enhancer factor/T-cell factor activate expression of many target genes, such as Myc Oncogene, ►VEGF, ►*cyclooxygenase-2* all associated with neoplasia.

EpCAM directly impacts the cell-cycle by up-regulating c-myc and cyclin A/E. Human epithelial cells expressing EpCAM reduce growth factors dependency, increase metabolism and colony formation. Inhibition of EpCAM expression with ►antisense nucleic acid reduces proliferation and metabolism in human carcinoma cells. The intracellular domain is essential for these effects.

EpCAM adhesive properties promote calcium independent homotypic cell sorting. Cells transfected to express EpCAM are sorted from cells of the same line that do not normally express EpCAM. It also inhibits invasive growth in cell colonies. Both activities are inhibited by anti- EpCAM antibodies.

The function of EpCAM thyroglobulin domain is being actively investigated. These domains commonly inhibit cathepsins: cysteine proteases frequently produced by tumor cells and known to be involved in metastasis.

Pattern of Tissue Expression

Normal Tissue

EpCAM is present on all normal epithelia excluding stratified squamous epithelia. Within the gastrointestinal (GI) tract colonic expression is greatest and gastric lowest. Glandular GI epithelium displays a marked expression gradient from crypts to the apex of villae.

Abnormal Tissue

Carcinomas and actively proliferating tissues show increased and differential expression of EpCAM.

Expression correlates with differentiation in gastric lesions. Immunochemical and mRNA studies show well-differentiated tumors are more expressive than those less differentiated. Normal background mucosa shows weak expression but interestingly areas of ►Barrett oesophagus or metaplasia are highly expressive.

Ninety percent of Colorectal carcinoma cells express EpCAM but in a differential form. Modifications include variable glycosylation analogous to tumor specific antigens such as colonic tumor antigen ►MUC1. EpCAM exists in the cell membrane of colon carcinoma cells as a high affinity noncovalent *cis*-dimer. Dimers on opposing membranes can associate *via* a head-to-head interaction to form tetramers with moderate affinity consistent with reversible intercellular associations. It is not known how exactly ►antibody binding correlates with variable glycosylation or oligomerization in a functional or structural sense, further investigation is required.

Tissue microarray assessment of EpCAM expression in 3,900 tissues of tumor of stratified stages and grades of 134 different histological subtypes sourced from head and neck, lung, gastrointestinal, breast, urogenital and mesenchymal tumors showed 75% tumor categories expressed EpCAM. At least weak EpCAM expression in >10% of tumors was observed in 87 of 131 different tumor categories. ►Colon cancer (81%), ►gastric cancer, ►pancreas cancer (78%) and ►lung cancer revealed a high proportion of strongly positive tumors suggesting EpCAM is an attractive target for pan-carcinoma ►immunotherapy.

Paradox of Expression with Advance in Carcinomas

A simple linear pattern of an increase in EpCAM expression with the progression of all tumors is not seen. The exact nature of EpCAM temporal expression vis a vis the grade of different tumor types remains to be stratified.

The functionally paradoxical up-regulation of EpCAM with disease progression in colorectal, breast, prostate and upper-GI carcinomas remains unexplained. This is intriguing in metastatic carcinoma in which degradation of intercellular adhesions is a primary feature. Perhaps, EpCAM is up-regulated in response to

other intra and extracellular processes that promote destruction of tissue adhesion and morphology, maintaining its constitutional stabilising function. Conversely in some tumors, e.g., colorectal cancer a loss of EpCAM expression is associated with increased local recurrence risk and a diffusely infiltrative morphology but not distant recurrence. In prostatic cancer reduced EpCAM expression correlates with a higher Gleason score but expression is higher on hormone-refractory tumor tissue than at earlier stages. In cholangiocarcinomas, squamous cell carcinoma of the head and neck and oesophagus increased expression correlates with reduced survival.

The relative loss of EpCAM expression in patients with gastric cancer is associated with a significant reduction in survival indicating that loss of Ep-CAM-expression identifies aggressive tumors especially in patients with stage I and II disease. Data from a Dutch study compared ►p53, ►CD44, E-cadherin, Ep-CAM and c-erB2/neu in tumors of 300 patients, investigating the extent of lymph node clearance. Patients without loss of EpCAM -expression of tumor cells (19%) had a significantly better 10-year survival compared to patients with any loss: 42% versus 22%. The prognostic value was stronger in stages I and II, and independent of the TNM stage. Similarly, in breast cancer, a relative reduction in EpCAM expressing disseminated tumor cells in the bone marrow of patients is associated with a relatively poorer prognosis whereas an increase in EpCAM positive tumor cells in lymph nodes and peripheral blood is associated with reduced survival.

In ►prostate cancer patients staged as M0 (no metastasis), BR (biochemical ►PSA relapse), and M1 (established metastasis), the presence of bone marrow EpCAM expressing tumor cells significantly increased with progression from M0 to BR, and M1 stages from 9 to 16–33%. These cells had double the ►chromosomal aberrations compared to cytokeratin positive tumor cells. There was only a small overlap between $EpCAM^+$ and CK^+ DTC populations of 9.5%. EpCAM marked a cohort of DTC in ca prostate patients that unlike CK^+ DTC expanded during biochemical relapse and had a phenotype different from that of CK^+ tumor cells. This differential expression of EpCAM as compared to cytokeratin indicates a specific functional role for EpCAM in the development of metastatic precursors over and above the simple role of an adhesion molecule once thought. The possible interaction of EpCAM with immune escape remains to be elucidated.

Once neoplastic transformation has taken place, a reduced EpCAM expression is an indicator of a more aggressive tumor phenotype with increased ►invasion, ►metastasis and mortality. This seemingly contradicts a recent study that suggested EpCAM silencing leads to reduced invasive potential of tumor cells. Breast cancer cell-lines were grown in ►Matrigel invasion/migration chambers. Cells in which EpCAM expression was silenced with ►SiRNAs showed a reduction of 35–80% in proliferation, 92% in cell-migration and 96% in cell-invasion without increase in cell-death or apoptosis. There was however an increase in E-cadherin, α-catenin, and β-catenin, This may be due to silencing of the inhibition that EpCAM exerts on E-Cadherin. Alternatively, EpCAM gene silencing may lead to decreased cytoplasmic β-catenin through an increase in its association with the E-cadherin adhesion complex. Hence, reducing EpCAM may decrease β-catenin availability for the wnt pathway and activation of its target genes downstream.

A process whereby EpCAM expression increases up to a point after which destabilising factors predominate and its expression is no longer stimulated is plausible. Once this point is reached, which may be variable according to the particular tumor type, tumors are less stable and display greater invasive and metastatic potential. A comprehensive study of the temporal expression of EpCAM during tumor progression is currently lacking. This would be useful as a predictor of the efficacy of immunotherapy in individual patients according to their tumor stage.

A 10-fold reduction in expression of EpCAM is seen in ►circulating tumor cells compared to primary tumors from whence they emerged and established metastases. Absence of homotypic adhesions stimulating EpCAM expression in the vascular microenvironment may be the causal link. EpCAM targeted immunotherapy may be more effective in established tumors or metastases as opposed to fluid borne disease. This does not preclude ascites due to peritoneal metastases for which treatment with ►trifunctional antibodies is effective. However the efficacy of destroying blood borne circulating tumor cells in a hope of eradicating minimal residual disease may be limited.

EpCAM Targeted Immunotherapy

Immunotherapy manipulates competent host immune system inducing tumor growth inhibition, regression or cytolysis. Approaches include the use of monoclonal antibodies and their derivatives, hybrid bispecific (trifunctional) antibodies, tumor cell vaccines, anti-idiotypic antibodies and dendritic cell vaccines. Pure immunomodulatory cytokines have been used to enhance the effect of MAbs.

Mechanism of Tumor Inhibition

The mechanisms by which anti–EpCAM antibodies exert tumor inhibition in-vivo remain controversial. Cytotoxic mechanisms include antibody dependent cell cytotoxicity (►ADCC) mediated by natural killer cells and T-lymphocytes, Complement mediated cytolysis

(CMC) and opsonization promoting ►phagocytosis mediated by PMNs.

The question of whether anti- EpCAM antibodies directly inhibit tumor cell proliferation remains unanswered. It could be postulated that EpCAM antibodies directly interfere with the activation of the Wnt pathway causing downregulation of c-myc: this remains untested. The majority of anti- EpCAM antibodies produced are specific for epitopes within the first of two EGF-like domains in the extracellular segment of EpCAM (Fig. 1) none have been shown to mimic the dimerization/tetramerization that EpCAM undergoes on ligation or to interfere with downstream gene activation or cell proliferation in-vivo. EpCAM antibodies do obliterate EpCAM mediated homotypic cell-sorting activity in-vitro; this effect may be a competitive event preventing dimerization alone. Although it is unlikely that a similar competitive effect takes place in established tumors, an investigation to see any effect on the establishment of metastases would be interesting.

A comparison between any difference in the cytotoxicity of antibodies according to the functional EpCAM domain targeted is awaited. It is possible that the majority of these antibodies work to opsonize cells alone – inducing the cytolytic mechanisms mentioned above – particularly as no physiological ligands for the extracellular domain of EpCAM other than EpCAM itself have been identified.

EpCAM forms a complex with the tight junction protein Claudin-7 within its intra-membranous segment the physiological significance of this is not yet known although an effect on apoptosis resistance in tumors is intriguing.

A flurry of interest followed the assertion that ►LAIR-1, a member of the inhibitory group of the immunoglobulin-like receptors, was a novel receptor for EpCAM. Speculation that neoplastic cells escape immunological surveillance and clearance by interacting with LAIR-1 via EpCAM gaining selective advantage for their growth, spread and dissemination was nullified when the original paper by Meyaard et al. was retracted because the observed binding of the LAIR-1 to EpCAM transfected cells was an artefact, attributed to the contamination of the LAIR-1 fusion protein preparation with an anti-human EpCAM monoclonal antibody.

Clinical Trials (Table 1)

Monospecific Murine Antibody

The murine Ig2a anti-human 17-1A monoclonal antibody Ederecolomab was the first immunotherapeutic agent licensed for use in large scale human anti-tumor immunotherapy trials. Initial trials in patients with advanced colorectal cancer showed little improvement in morbidity or mortality. Augmentation with ►interferm and ►GM-CSF increased ►ADCC with associated tumor lymphocyte infiltration and complement deposition. Patients with greater ADCC survived longer.

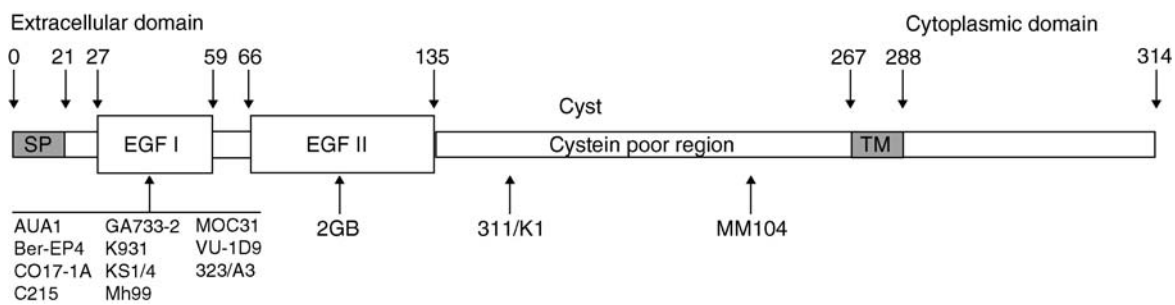
In 1994, 189 patients with ►Dukes C CRC were randomly assigned to adjuvant therapy with Ederocolomab or resection alone. Survival at 3 years was 72% for the Ederocolomab cohort and 62% for surgery alone. Further follow up at 7 years showed significantly reduced mortality (32%), disease recurrence (23%) and metastases leading to further phase II and III trials.

In 2002, Punt published results of a trial of 2,761 patients randomized to MAb 17-1A monotherapy, 5-FU and Folinic acid or 5-FU + Ederocolomab. No additional benefit was seen by adding immunotherapy to the standard chemotherapy regimen at 26 months. Immunotherapy alone was associated with significantly shorter disease free survival. Ederecolomab was removed from circulation.

The discrepancy between pre-clinical and clinical findings has lead to much debate. What are the reasons for this discrepancy?

EpCAM expression density varies at different stages of tumor growth suggesting patient antigen positivity should be assessed prior to clinical use. EpCAM density is a proven predictor of survival in breast cancer patients.

As a murine antibody, Ederecolomab induces a neutralising humoral response in humans resulting in a



EpCAM. Figure 1 Protein domain structure.

EpCAM. Table 1 Trials to assess efficacy of ►EpCAM targeted Immunotherapy for intra-abdominal carcinomas

Author	Patients	Treatment	Results	Conclusions
Weiner et al. (1986)	27 Metastatic adeno carcinoma colon or pancreas	Passive MAb17-1A preceded by 4 days γIFN	No objective clinical markers. Serum tumor markers reduced in 36%. 11 developed Ab3 response	MAb 17-1A safe for clinical use. Evidence of anti-idiotypic response
Herlyn et al. (1994)	Nine CRC	Active anti-idiotypic CO17-1A aluminium hydroxide precipitated	Three patients developed Ab3 response to Ab2 determinants	Marginal success
Herlyn et al. (1994)	54 CRC	Active polyclonal goat and monoclonal rat anti-idiotypic CO17-1A	Majority developed Ab3 response 30% developed delayed type hypersensitivity	Anti-idiotypic CO17-1A effective in stimulating log-term immunity in cohort
Fagerberg et al. (1995)	6 CRC	Active anti-idiotypic CO17-1A	Six patients developed T-cell immunity 5 mounted Ab3 response	Small study evidence of anti-idiotypic response
Ragnhammar et al. (1995)	86 Adv CRC	Passive murine MAb17-1A (76) or chimeric MAb17-1A (10)	All patients developed anti-idiotypic Abs increased by GM-CSF; c-MAb less response and more allergic side effects than Mab	Patients with Ab2 response – median survival 9/12
Riethmuller et al. (1998)	189 Dukes C	Passive observation or MAb17-1A adjuvant	7-year evaluation, mortality decreased by 32% and recurrence by 23%	Therapeutic effect maintained after 7 years, mortality/recurrence reduced
Shetye et al. (1998)	20 Adv CRC	Passive single infusion MAb17-1A +GM-CSF	Increased tumoral and PMN, monocytes and T lymphocytes	Increased TILs representing ADCC and CTLs
Hjelm et al. (1999)	20 Adv CRC	Passive MAb17-1A + IL-2 +GM-CSF	One patient partial remission 2 patients stable disease for 7 and 4 months	No augmentation of effect of MAb 17-1A
Punt et al. (2002)	2761st III CRC	Passive multicenter; (1) 17-1A MAb/5FU/LV or (2) 5 FU/LV or (3) 17-1A MAb	3-year surv DFS (1) 74.7% 63.8% (2) 76.1% 65.5% (3) 70.1% 53.0%	Addition of ederocolomab to standard therapy does not improve the disease outcome Panorex withdrawn
TRION Pharma, Fresenius 2003	23 symptomatic ascites Ca ovary	Passive trifunctional multicentre open label intraperitoneal Removab	Well-tolerated 22 of 23 patients ascites free at day 37	Effective treatment of malignant ascites phase III for all-cause malignant ascites underway
Heiss 2005	Eight peritoneal carcinomatosis	Passive trifunctional 4–6 applications intraperitoneal	Seven of eight patients no further paracentesis needed. Eradication of tumor cells in ascites	

ADCC = antibody-dependant cell cytotoxicity.
CRC = colorectal cancer.
CTL = cytotoxic T cells.
DFS = disease-free survival.
GM-CSF = granulocyte-macrophage-colony stimulating factor.
IFN = interferon.
MAB = monoclonal antibody.
PMN = polymorphonuclear cells.
TIL = tumor infiltrating lymphocytes.

short serum half-life. Foreign MAbs are rapidly cleared as immune complexes depositing in the liver, greatly reducing bioavailability. Reduced compatibility with human effector cells may also be significant.

EpCAM-targeted immunotherapy to date has targeted advanced disease: its value weighed against classic adjuvant treatments. The effect of such immunotherapy on earlier, less established disease or cancer models is unknown.

What are the Solutions?

►*Humanized Antibody*

A human IgG antibody, MT-201 (Adecatumumab) combines binding affinity similar to Ederecolomab with considerably enhanced ADCC potency with human gastric carcinoma cell lines. Addition of human serum containing IgG or human peripheral blood monocytes halves MT201 ADCC but abolishes that of Ederecolomab: indicating the importance of human anti mouse antibodies (HAMA) and compatibility of syngeneic effector cells.

MT201 reduces tumor growth in xenotransplanted HT-29 CRC cells in nude mice but only to a level similar to Ederecolomab. It is hoped human effector cells with greater type specificity of FCγ receptors will facilitate amplified tumor inhibition clinically. Three clinical trials are currently underway: two phase II studies with metastatic breast cancer and early-stage prostate cancer patients, respectively, and a phase I study testing the safety of a combination with taxotere.

►*Bispecific Antibodies*

Structure and Rationale for Development (Fig. 2)

Normal IgG molecules compose of Fc and FAb segments. The monospecific FAb segment binds to specific epitopes on antigens whereas the Fc portion recruits cells expressing Fc receptors (e.g. FcγR) such as macrophages. These are described as being bifunctional and monospecific. In trifunctional antibodies, the two halves of the FAb segment have different specificity: they are bispecific and trifunctional.

Both Ederecolomab and MT201 are bifunctional antibodies: IgG1 and IgG2A respectively with active components being the anti light chains and Fc portions. Zeidler (1999) successfully constructed a bispecific/trifunctional targeting both and CD3 (BiUII or Removab). The rationale being that ADCC is complemented by the presence of CD3 + T-lymphocytes in addition to Macrophage/Monocytes, NK and dendritic cells: known to express FcγR binding to the Fc portion of the antibody. This antibody consists of a Murine IgG2a associated with an anti light chain and Rat IgG2b associated with anti CD3.

In-vitro Cytotoxicity

in-vitro experiments of ADCC with cell-lines, effector-cells and BiUII demonstrated increased production of ►interleukins IL-1β, IL-2, IL-6, IL-12 and DC-CK1. simultaneous stimulation of accessory cells and T lymphocytes leads to antigen presentation to T-lymphocytes inducing immunomodulation and cytotoxicity. BiUII

induces production of IL-2 in the presence of + cells activating accessory and T-cells without the requirement of exogenous IL-2. An immunologically self-supporting tri-cell complex is formed which is efficient for immune cell activation.

Cytolysis occurs within 1–3 days. The mode of cell-death is characteristically necrotic and not apoptotic. Lymphocytes with pore forming perforin proteins surround the tumor cells causing cytolysis.

Prolonged Anti-Tumor Immunity in-vivo

Another bispecific antibody: BiLu induces long-lasting antitumor immunity consisting of both humoral and cell mediated responses when administered intra-peritonealy in a murine syngeneic model It targets *murine* CD3 and human EpCAM. The Fc portion is identical to.

The human CD3 counterpart of BiLu: Catumaxo-mab/Removab has shown promising results.

Clinical Trials (Table 2)

A Phase I/II study for the treatment of ovarian cancer patients with symptomatic ascites has now been completed (23 patients) showing that Removab was safe and effectively reduced ascitic flow and tumor-cell content. A substantial Phase II/III trial assessing efficacy in patients with all causes of malignant ascites including primary gastrointestinal tumors commenced in September 2004 (250 patients) and a Phase IIa study of platinum refractory ovarian cancer patients is also underway. Finally, a Phase I/II study of patients with peritoneal carcinomatosis due to GI tumors but without symptomatic ascites is underway. Preliminary results are promising indicating the utility of Removab in the treatment of minimal fluid borne disease and micro-metastases.

Eph Receptors

Diego Arango
Molecular Biology and Biochemistry Research Center (CIBBIM), Valle Hebron Hospital Research Institute, Barcelona, Spain

Definition

Eph receptors are tyrosine kinases (RTK) bound to the extracellular membrane that function as "switches" that upon activation by Ephrin (EFN) ligands initiate signaling cascades that regulate numerous developmental processes, particularly in the vasculature and nervous system.

Characteristics

The name of the Eph receptors is derived from the name of the cell line used to characterize them initially (erythropoietin-producing hepatocellular carcinoma cell line). These receptors and their Ephrin (EFN) ligands constitute the largest family of ►receptor tyrosine kinase (RTK) known to date. Eph receptors are integral membrane proteins with a conserved N-terminal domain responsible for ligand binding, followed by a cysteine

rich region and two fibronectin type III repeats which are essential for dimerization and interactions with other proteins. The intracellular region of these receptors contains a juxtamembrane domain, a conserved kinase domain, a sterile alpha motif (SAM), and a PDZ-binding motif. There are at least 15 Eph receptors in the human genome. Based on sequence homology and the preferred type of Ephrin ligands that they bind, the Eph receptors can be divided in two subclasses, EPHA and EPHB. The ligands of the Eph receptors (Ephrins) are also bound to the extracellular membrane. Ephrins of the A subclass are bound to the membrane through a GPI anchor (*Glycosyl Phosphatidyl Inositol*), whereas members of the B subclass have a transmembrane domain. At least five Ephrins of the A subclass and three of the B subclass have been described.

The signaling cascade is initiated by the binding of a membrane-bound Ephrin and an Eph receptor in neighboring cells. This leads to the autophosphorylation of the Eph receptor on several tyrosine residues and the activation of the tyrosine kinase activity. In addition to the "forward" signaling elicited by the Eph receptors, the Ephrin ligands are also able to transduce a signal upon interaction with their cognate Eph receptor. This is often referred to as "reverse" signaling. The signaling cascade initiated upon ligand binding regulates many developmental processes and has an important role in tumor initiation and progression in different tissues.

Normal EPH Signaling

The role of Eph signaling in the nervous and vascular systems during normal development has been characterized in detail. During normal embryogenesis, Eph signaling has an important role in the development of the nervous system. Eph signaling regulates the migration of neural crest cells, the formation of the corticospinal tract, the boundary formation between hindbrain segments (rhombomeres), the establishment of neural topographic maps, and the formation and functional properties of neuronal synapses. Eph signaling also plays an important role in the angiogenic process by restricting arterial and venous endothelial mixing. In addition, interactions between Eph receptors and Ephrin ligands mediate cytoskeleton organization, cell migration, and substrate attachment. The EPH family also has an important physiologic role in the normal intestinal epithelium. EPHB2 and EPHB3, together with their ligand Ephrin-B1, regulate proliferation and cell positioning within the intestinal crypts.

EPH Signaling in Cancer

Deregulation of the levels of expression and normal Eph signaling are commonly observed in tumors of various origins. This is not surprising since aberrant Eph signaling can interfere with processes that are crucial during malignant transformation such as cell attachment, ►migration, proliferation, cytoskeleton organization, and ►angiogenesis. Eph/Ephrin activation has been implicated in several ►signal transduction pathways contributing to the tumorigenic process. For instance, Akt/PI3K (phosphatidylinositol 3-kinase) has been shown to be implicated in the increase in proliferation and migration of endothelial cells after activation of EphB4 with its ligand Ephrin-B2. In addition, Eph signaling can regulate cell ►motility by modulating the activity of other signal transduction proteins such as ►focal adhesion kinase (FAK) and ►Rho. The important role of Eph signaling in the modulation of the cellular attachment to the extracellular matrix seems to be regulated through the modulation of integrin-mediated adhesion.

Most of the studies in the literature report increased levels of expression of Eph receptors and/or Ephrin ligands in most of the tumor types studied, compared with the respective normal tissue. For instance, EphA2 is overexpressed in melanomas, EphA1 shows elevated levels in breast, liver and lung tumors, and EphB4 has been reported to be overexpressed and significantly contribute to tumor progression in prostate, bladder, breast, and head and neck tumors. Although the general view emerging is that Eph receptors and Ephrins may function as ►oncogenes in the sense that elevated levels or kinase activity, promote tumor formation and/or progression, Eph receptors may be important ►tumor suppressor genes in some tissues. This is the case of EphB2 and EphB4 in the intestine. The expression of these two EphB receptors is reduced in colorectal tumors compared to the normal intestinal cells and the premalignant lesions. The levels of expression of EphB2 and EphB4 negatively correlate with tumor progression and mechanisms of inactivation of these receptors include somatic mutations and hypermethylation of ►CpG islands situated within the promoter regions regulating their expression. Moreover, animal studies clearly support the tumor suppressor role of EPHB2 in colorectal tumors and germline mutations in this gene seem to predispose to prostate and possibly to colorectal cancer.

Epidemiology of Cancer

Elizabeth B. Claus
Department of Epidemiology and Public Health, Yale University School of Medicine, New Haven, CT, USA

Synonyms

Cancer epidemiology

Definition

Is the study of the incidence, distribution, and ultimately, the prevention and control of cancer within the general population.

Characteristics

The discipline of cancer epidemiology is a relatively young one, with much of the methodology developed over the past 50 years. Prior to the advent of formal methods of collection and analysis of cancer incidence and risk factor data, associations were generally the result of reports or observations of astute clinicians or scientists. The literature is full of fascinating stories of early attempts at epidemiologic cancer studies such as that of the nineteenth-century physician, Alfred Haviland, who created elaborate maps of cancer deaths in England and Wales using national mortality statistics. One of the first and probably most well-known reports of a relationship between a risk factor and the occurrence of cancer occurred in 1950, with the publication of several case-control studies detailing the association between cigarette smoking and the development of lung cancer.

Study Design

There are a number of basic study designs in cancer epidemiology. Descriptive cancer epidemiology examines how cancer incidence and mortality rates vary according to demographic characteristics of the study population such as geographic location, race and sex. One may further analyze such information by categories of age as well as by birth cohort and time period. Ecological studies generally examine aggregate measures of risk and cancer outcome such as median income and cancer incidence across counties of a given state in an effort to identify an association between the two. Alternatively, many epidemiologic studies are based on the use of individuals as the study unit rather than larger groups, or populations of study subjects. Within this category of analysis there are essentially three study designs (with several variations) including the cross-sectional, case/control and cohort study design. Cross-sectional study designs allow for the consideration of a reference population at a given point in time. In a case-control study, the frequency of a particular risk factor among individuals with a cancer of interest (cases) is compared with that among individuals without cancer (controls). Case/control studies have been instrumental in the identification of numerous important cancer risk factors including the association between family history and breast cancer as well as between tobacco and lung cancer. In a prospective or cohort study, researchers assemble a cohort of healthy individuals who provide information on risk factors of interest at a baseline point in time. The study subjects are then followed prospectively until they develop cancer or the study is completed. An advantage of this type of study design is that risk factor data is collected before any cancer is diagnosed, thus reducing the amount of recall bias associated with disease status in the reporting of risk factor data such as family history information. There are many well-known examples of cancer cohort studies including the Atomic Bomb Casualty Commission established in 1947 to study the effects of exposure to radiation with outcomes such as leukemia, the British physicians cohort from the 1950s that examined the association between smoking and lung cancer and the Nurse's Health Studies I and II, started in 1976 and 1991, respectively, which have examined a wide range or hormonal and dietary risk factors (among others) in the development of breast and other cancers.

Risk Factors

Categories of cancer risk factors are many and include infectious agents, diet and lifestyle factors, endogenous and exogenous hormonal components and genetic factors, to name a few. It is currently popular to divide cancer risk factors into two broad categories defined as genetic and environmental. This has come about because of the many laboratory-based advances in the identification of genetically transmitted or regulated diseases such as cancer, leading to the emergence of a new field of

investigation, that is, the genetic epidemiology of cancer. For cancers, a small subset of cases exist that are attributable to rare inherited cancer susceptibility genes. The majority of cases appear to be due to sporadic mutations that may be a result of genetic or environmental events or the result of an interaction between genetic and environmental factors. Much of traditional epidemiologic methodology has been adopted for use in genetic epidemiology. In addition, new methods specific to genetic epidemiology have been developed including the twin, adoption, and pedigree study designs as well as segregation and linkage analyses.

The many advances in genetic testing, as well as in some instances, prevention or treatment options associated with particular cancer diagnoses, has led to a surge of interest in the availability of personalized risk estimates in the clinical setting and hence the development of cancer risk assessment models used to generate these estimates. Cancer risks may be presented in both relative and absolute terms and may define risk for a discrete period of time or over a lifetime. A wide variety of statistical methods exist to estimate cancer risk, with the most fully developed existing in the area of breast and ovarian cancer. Although the concept of risk assessment is not new to the fields of medicine or genetics, the use of detailed genetic information on a large population-based scale is, with all the associated difficulties of presentation and interpretability.

The field of cancer epidemiology is an exciting scientific discipline, which is able to adapt well to new information and technology. New developments in the field include the integration of biomarkers into exposure data, the inclusion of both molecular genetics and environmental risk factor data into study designs in an effort to explore the complex interaction between genotype and the environment, the creation of international data-bases via the Internet, and the merging of large data-bases that combine risk factor information with cancer incidence and mortality data. All of these advances should continue to assist scientists and health care-professionals in the identification of individuals at increased risk of developing cancer so that screening and prevention regimes as well as treatment plans may be developed.

Epidermal Growth Factor Inhibitors

Michael Pishvaian, Dongmei Wang, Ruth He, John L. Marshall
Georgetown University, Lombardi Comprehensive Cancer Center, Washington, DC, USA

E

Definition

The epidermal growth factor receptor (EGFR) is a member of the HER family of receptor tyrosine kinases that includes the EGFR itself (ErbB1/HER1), ErbB2 (HER2/*neu*), ErbB3 (HER3), and ErbB4 (HER4). These proteins are classic membrane-bound tyrosine kinase receptors whose activation is typically ligand dependent. The principal ligands for the EGFR are EGF and TGF-α. Other ligands include amphiregulin, heparin-binding EGF, the poxvirus mitogens, epiregulin, and β-cellulin.

Characteristics

EGFR Activation and Downstream Signaling

Receptor activation results in homo or heterodimerization and autophosphorylation of c-terminal tyrosine residues. Receptor activation enables the docking of cytoplasmic proteins that bind to specific phosphotyrosine residues, and initiate several cell signaling pathways. These pathways include the Ras-Raf-MAPK pathway, the PI3K-AKT pathway, the protein kinase C pathway, the STAT pathway, and the src kinase pathway all of which play important roles in tumor cell proliferation, invasion, migration, and inhibition of apoptosis. Recent reports have also demonstrated that the EGFR can be found in the nucleus where it can act as transcription factor. EGFR activation does not initiate linear downstream pathway signaling, but rather can activate multiple pathways that cross-connect intracellularly. The pattern of activation is often cell/tissue specific and likely contributes to the rich variety of biological responses to EGFR activation. Ligand activation of the EGFR also results in receptor down-regulation, mediated through endocytosis and ultimately Cbl-mediated EGFR ubiquitination and degradation [1]. However, the EGFR can be activated in a ligand-independent manner. This aberrant EGFR activation can result from receptor overexpression, gene amplification, activating mutations or loss of regulatory mechanisms.

Molecular Mechanisms of Targeted Therapies

Anti-EGFR therapies include monoclonal antibodies (mAbs) that recognize the EGFR and small molecule inhibitors of EGFR tyrosine kinase activity (TKIs). The mAb Cetuximab prevents receptor dimerization through steric inhibition of the extracellular domain.

Cetuximab also promotes receptor internalization and degradation without receptor activation, resulting in receptor down-regulation and reduced cell surface expression levels of the EGFR. Cetuximab also blocks the transport of EGFR into the nucleus, thus inhibiting any direct affects on DNA transcription and/or repair. Finally, Cetuximab has the potential to kill target cells by mediating antibody-dependent, cell-mediated cytotoxicity (ADCC) and complement fixation.

The TKIs are competitive inhibitors of adenosine triphosphate (ATP). They block the enzymatic activity of the intracellular domain of the EGFR. Because of their mechanism of action, these TKIs can block EGFR mutants that lack an extracellular domain, and can block ligand independent receptor activation.

EGFR Mutations

A number of genetic mutations of the EGFR have been found in cancer cells. These mutations generally result in constitutive activation of receptor signaling and can, by themselves be oncogenic, but also often confer responsiveness to targeted therapy.

The somatic gene mutations associated with an increased response to the TKIs are clustered within the receptor kinase domain, in exons 18–21 near the ATP binding region. These mutations result in structural changes that confer exquisite sensitivity to the TKIs, wherein the presence of EGFR mutations in patient's tumors results in increased responsiveness and thus progression free survival compared with patients with no EGFR mutations. Conversely, mutations in exon 20, including the T790M point mutation confer resistance to the TKIs. Furthermore, TKI resistance may also result from coexistent mutations in ras, raf, PI3K or loss of the tumor suppressor PTEN.

EGFRvIII (also referred to as del2-7 EGFR or ΔEGFR) is a constitutively active EGFR mutant variant that is the most common mutation found in glioblastoma (GBM). The mutation arises from an in-frame deletion resulting in a loss of the majority of the extracellular ligand binding domain leading to a constitutively active, ligand-independent tyrosine kinase. The variant constitutively activates the phosphatidylinositol 3′ kinase (PI3K) signaling pathway. Interestingly, while only about 10–20% of patients with GBM respond to EGFR inhibitors (despite the fact that most GBMs overexpress the EGFR) ~43% (13/30) of the patients with tumors that expressed EGFRvIII responded the TKIs. This percentage was increased to 78% (11/14) if the tumors coexpressed EGFRvIII and PTEN. PTEN is a tumor suppressor whose expression is frequently lost in GBM and acts as an inhibitor of the PI3K/AKT pathway. Loss of PTEN confers resistance to EGFR inhibitors, presumably because of the persistent activation of the PI3K pathway *downstream* of the EGFR. Nevertheless, only about 25% of the patients (14/59) actually exhibited this co-expression of EGFRvIII and PTEN. In fact, mutations are often cancer-type specific. For example, while ~50% of GBMs and head and neck cancers exhibit expression of EGFRvIII, only ~1.5% of NSCLC and 0% of metastatic colorectal cancers express EGFRvIII). By contrast, 10–25% of patients with NSCLC, very few head and neck cancers, and no GBMs contain EGFR TK gene mutations. (There has surprisingly been no assessment of EGFR TK mutations in CRC).

EGFR Inhibitors in GI Tumors

The Epidermal Growth Factor Receptor is implicated in the pathogenesis of several cancers including colorectal, pancreatic, NSCLC, Head and Neck, Breast, Brain cancer, and overexpression of EGFR has been associated in metastasis, chemotherapy resistance and poor outcome. The receptor has emerged as a rational target for anticancer treatment in these tumors. Monoclonal antibodies to EGFR and tyrosine kinase inhibitors to EGFR kinase have been developed to inhibit EGFR signaling.

Cetuximab and Panitumumab are the two monoclonal antibodies to EGFR approved by the US Food and Drug Administration (FDA) in the treatment of colorectal cancer. Cetuximab was FDA approved in Feb 2004 in combination with irinotecan in irinotecan refractory disease, or as a single agent in patients intolerant to irinotecan. Cetuximab has demonstrated efficacy in Phase II clinical trials in patients with refractory, metastatic colorectal cancer, either alone or in combination with irinotecan (Table 1). About 20% of patients with irinotecan refractory patients responded to the combination of cetuximab and irinotecan treatment, however only 10% responded to cetuximab treatment alone. The safety and efficacy of cetuximab plus irinotecan were compared with Cetuximab as a single agent (Table 1). The response rate for the combination arm was 22.9% (95% confidence interval (95% CI), 17.5–29.1%), and the medium time to progression was 4.1 months. The response rate for single-agent cetuximab as monotherapy was 10.8% (95% CI, 5.7–18.1%), and the median time to progression was 1.5 months. Cetuximab in combination with irinotecan reversed the irintecan resistance in over 20% of patients who progressed on prior irinotecan therapy.

Although the response rate from cetuximab is only around 10%, from recent press release in November of 2006 on the Phase III study (NCIC-CO.17) cetuximab demonstrated survival benefit over best supportive care as a single agent in the third-line treatment of colorectal cancer. These are the first data of an EGFR targeted antibody to demonstrate overall survival in the third-line treatment setting.

In September of 2006, FDA approved panitumumab, a recombinant human monoclonal antibody that binds

the human EGFR, for the treatment of patients with EGFR-expressing metastatic adenocarcinoma of the colon or rectum (MCRC) after disease progression on or following fluoropyrimidine-, oxaliplatin-, and irinotecan-containing chemotherapy regimens. The efficacy of panitumumab was demonstrated in a phase III randomized, open-label, controlled trial comparing panitumumab plus best supportive care (BSC) versus BSC alone in a total 463 patients with 5-FU, irinotecan and oxaliplatin refractory disease. Nineteen of 231 (8%) subjects in the panitumumab arm had a partial response, and there was significant prolongation of progression free survival in the panitumumab arm.

Clinical benefits of monoclonal antibodies to EGFR (Cetuximab and Panitumumab) combined with irinotecan and oxaliplatin have been tested for first-line treatment of MCRC in phase II clinical trials. In the phase II studies, the response rate of the combination therapy of EGFR inhibitor and cytotoxic chemotherapy reaches as high as 77%, disease control rate as high as 96%, rate of metastatses resection is over 20%. The high response rate of the combination therapy not only enable rapid improvement of MCRC associated symptoms but also improve the long term survival to the subgroup of patients whose tumor becomes resectable after combination therapy. The data from the phase II studies requires confirmation by randomized Phase III clinical trials. Large ongoing randomized phase III studies will establish the clinical the benefit of Cetuximab and Panitumumab as first-line in colorectal cancer. The role of cetuximab in adjuvant treatment of CRC is being evaluated with two randomized Phase III clinical trials, NCCTG/INT N0147 and PETACC-8.

Survival advantage of cetuximab to radiation therapy was demonstrated in a randomized phase III study comparing concurrent cetuximab radiation with radiation alone in locoregionally advanced head and neck squamous cell carcinoma. The role of cetuximab in concurrent chemoradiation has been tested in esophageal/gastric cancer, rectal cancer and pancreas cancer in phase II clinical trials. Patients with localized esophageal/gastric cancer received radiation and concurrent chemotherapy of cetuximab, carboplatin and paclitaxel. 67% of the patients had clinical complete response, 43% of the patients were found to have pathologic complete response at surgery. A confirmatory phase III study is being planned. Neoadjuvant chemotherapy and chemoradiation in rectal cancer treatment decreases local relapse rate of rectal cancer with higher sphincter preservation rate compared to post-operative chemoradiation. Cetuximab has been evaluated in combination with capecitabine, or oxaliplatin based CapOx regimen in concurrent neoadjuvant radiotherapy for the patients with rectal cancer in two phase II studies. The combination therapy was found be feasible and resulted in pathologic complete response (CR) in some patients. Currently the role of Cetuximab in the neoadjuvant chemoradiation is tested in the phase III EXPERT-C clinical trial.

Management of borderline resectable pancreas cancer is challenging and neoadjuvant chemotherapy or chemoradiation is controversial in those patients. The role of cetuximab in combination with gemcitabine in concurrent neoadjuvant chemoradiation was examined in a phase II clinical trial. Two of ten patients exhibited partial response. Six patients went on to margin (−) resection, including one patient each with borderline resectable and unresectable disease prior to therapy. The role of cetuximab with neoadjuvant chemoradiaiton in downstaging pancreas cancer for resection needs to be confirmed by phase III randomized study.

More than 80% patients treated with cetuximab experiences acneiform rash. Her1/EGFR is expressed in epidermis, sebaceous glands and hair-follicle epithelium. Her1/EGFR plays a role in the normal differentiation and development of skin follicles and keratinocytes. From the study of mice with Her1/EGFR gene knock out or with dominant negative mutation, it is predicted that EGFR inhibition in human is feasible,

but may be associated with cutaneous toxicity. Indeed skin rash become the class toxicity of EGFR inhibitors including monoclonal antibody to EGF receptor and small molecule inhibitor to EGF receptor kinase. Can the presence and intensity of skin rash predict the response to EGFR inhibitors? Sub-group analysis has been carried out to correlate the skin reaction and efficacy for the BOND study. The RR, mTTP and mOS increase with higher grade of skin toxicity to cetuximab. The same phenomena are observed with pantitumumab treatment. To take a step further, should the dose escalation of anti-EGFR antibody continue until skin rash is detectable? In patients who have had no or mild skin reactions in response to standard cetuximab dose, dose escalation (up to 500 mg/m^2) improved tumor response rate in a phase II study.

Is there any molecular marker that predicts Cetuximab efficacy in GI malignancy? Both the trials of Cunningham and Saltz have failed to show a significant correlation between EGFR expression based on immunohistochemistry (IHC) and response to treatment with either cetuximab and CPT-11, or cetuximab alone. Different from the positive association between Her-2 gene amplification and response to Herceptin (monocloncal antibody to Her-2) in breast cancer, Epidermal growth factor gene amplification is not frequent and cannot account for antitumor activity of cetuximab plus chemotherapy in advanced colorectal cancer patients. Unlike the co-relation between EGFR mutation and positive response to erlotinib in NSCLC, 50 primary untreated CRC tumors were sequenced. No mutation was identified. Multiple molecular markers including EGF A61G polymorphism and Cyclin D1 A870G polymorphism, have been proposed as molecular markers that predict response of CRC to cetuximab. However evaluation of these markers in larger data set is required to determine their usefulness in patient care.

Small Molecule inhibitors to EGFR tyrosine kinase (TKI) and Monoclonal Antibodies to EGFR are developed to target EGFR and its signaling transduction pathway. However due to different chemistry and mechanism of action, their clinical activities differ among different disease. Despite the clinical activities and safety data of anti-EGFR antibodies (cetuximab, panitumumab) in colorectal cancer, TKI as single agent showed minimal activity in MCRC. While patients with MCRC were treated with combination of TKI and fluoropyrimidine-, oxaliplatin-, and irintecan-based regimen, the clinical response rate was observed from 24 to 74% in phase II studies. However, TKI was found to increase grade 3, four toxicities and some of the trials had to be closed prematurely due to adverse effects. To confirm the clinical benefit of TKI to chemotherapy, a Phase III study of an Optimized chemotherapy plus bevacizumab with or without Erlotinib in MCRC is ongoing with a target accrual of 640 patients.

Erlotinib in combination with gemcitabine has demonstrated benefit in patients with pancreatic cancer in a Phase III study. Results from that trial are the first to our knowledge that demonstrated a clinical benefit from EGFR TKI used in combination with chemotherapy. Cetuximab, the anti-EGFR antibody was found to have encouraging activities while combining with gemcitabine and concurrent radiation in localized pancreas cancer, in addition cetuximab showed clinical efficacy in combination with gemcitabine/oxaliplatin (GEMOXCET) in the treatment previously untreated metastatic pancreatic cancer. Further evaluation in a phase III trial is warranted.

Treatment for Hepatocellular Carcinoma (HCC) is limited due to low response rate and transient response from most cytotoxic chemotherapy. Although cetuximab showed very modest activity in HCC, Erlotinib demonstrated clinical efficacy in patients with HCC. Thirty-two percentage of the 38 patients with HCC treated with erlotinib at 150 mg daily were found progression-free at 6 months. Disease control was seen in 59% of the patients. Median overall survival time was 13 months. Role of EGFR TKI needs to be confirmed with phase III study.

EGFR Inhibitor in Lung Cancer

Lung cancer could be divided into small cell lung cancer and non-mall-cell lung cancer (NSCLC). The development of epithelial growth factor receptor (EGFR) inhibitor as a therapeutic option is mainly in NSCLC. Both tyrosine kinase inhibitors (TKIs) and monoclonal antibodies of EGFR have demonstrated activity in NSCLC. Gefitinib (Iressa, AstraZeneca), a small molecule inhibitor of the EGFR, was the first selective EGFR inhibitors received accelerated approval from U.S. Food and Drug Administration after phase II clinical studies showed promising clinical response in NSCLC patients. However, subsequent large phase III trials failed to show survival benefit with gefitinib, which led to FDA restricting gefitinib use to only those patients who has been on this medication with good response. Erlotinib (Tarceva, Genentech) is a very similar molecule to gefitinib, has the same mechanism of action by competing with ATP for the ATP-binding site of EGF receptor. Its efficacy has been shown in phase III trial with prolonging overall survival by 2 months in advanced NSCLC. As a result of this, FDA approved erlotinib for second-line therapy of NSCLC. The different destinies of these two similar drugs elicited a lot discussion among investigators. Some hypothesized that the different results due to erlotinib was given to maximally tolerated dose while gefitinib was not, and patient population/genetic may be

different in those clinical trials. Both Gefitinib and erlotinib are oral medication, usually well tolerated. The main toxicities of these TKIs are acneiform rash, diarrhea and occasional interstitial lung disease. In addition to TKIs, anti-EGFR monoclonal antibody (MoAb), such as cetuximab (Erbitux) has also been tested in NSCLC with cytotoxic chemotherapy. The role of anti-EGFR MoAb in lung cancer is not very clear as these studies are still ongoing.

NSCLC patients respond differently to EGFR inhibitors, especially to TKIs as suggested by several clinical trials. Women, Asian, never smoked, and adenocarcinoma histology were found correlated with higher response rates to TKIs. Molecular analysis has given us mixing results on defining molecular predictors to TKIs. Several phase II studies demonstrated that mutations in Exon 18–21 of the EGFR correlated with responsiveness of NSCLC to gifitinib and erlotinib. While in a large randomized, placebo- controlled, phase III NSCLC study reported by NCI Canada, clinical response to erlotinib was associated with amplification of EGFR gene, not mutations of EGFR. K-ras is a downstream molecule in EGFR signally pathway. K-ras mutation has been consistently shown related to resistance to TKIs. Other molecules such as Her2 gene amplification, Akt phosphorylation have been reported to correlate with clinical response to TKIs (Cappuzzo, Eberhard). Like other target therapy in oncology, the molecular target for EGFR inhibitor need to be further defined in NSCLC, so we could individualize this therapy to achieve the best outcomes.

Epidermal Growth Factor Receptor

Definition

Synonym ERBB, EGFR, ERBB1 and HER-1, is a protein of 1210 aa and 134 kD that mediates the biological signal of ►epidermal growth factor (EGF), also of transforming growth factor [transforming growth factor β] (TGF). The binding of EGF to EGFR leads to the internalization of the EGF-EGFR complex, induction of the tyrosine kinase activity associated with EGFR, stimulation of DNA synthesis and cell proliferation. The gene maps to 7p12, and is amplified or rearranged in glioblastoma multiforme and prostate carcinoma.

Epidermal Growth Factor-like Ligands

Aleksandra Glogowska, Thomas Klonisch
Department of Human Anatomy and Cell Science, University of Manitoba, Winnipeg, MB, Canada

Synonyms

EGF-like ligands; EGF family; Growth factors; EGF

Definition

►Epidermal Growth Factor (EGF)-like family members bind to and activate EGF receptor tyrosine kinases ErbB-1, -2, -3 and -4, also named HER1–4. This triggers the activation of intracellular signal transduction pathways resulting in cellular proliferation and differentiation. All members of the EGF-like family are produced as membrane-anchored precursors and are processed and released through the action of specific membrane-bound proteolytic enzymes of the sheddase family.

The Epidermal Growth Factor (EGF)-like family consists of at least 12 members: Epidermal Growth Factor (EGF), Transforming Growth Factor alpha (TGFα), Heparin binding-EGF like growth factor (HB-EGF), Amphiregulin (AR), Betacellulin (BTC), Epiregulin (EPR), Epigen, Cripto, and Neuregulins 1–4 (NRG1–4). These EGF-like members are defined by three characteristics: (i) they display high affinity binding to membrane-bound epidermal growth factor tyrosine kinases receptors ErbB1–4, (ii) they are eliciting a mitogenic response in EGF-sensitive cells and (iii) they possess at least one primary EGF structural motif of 50–60 amino acid

residues with the general sequence $X_nCX_7CX_{2-3}$-$GXCX_{10-13}CXCX_3YXGXRCX_4LX_n$ embedded in the transmembrane precursor molecule. Usually present as multiple structural units in the extracellular domain of EGF-like ligands, this conserved cysteine-rich EGF-like motif is crucial for the binding to ErbB receptors. The EGF-like ligands are proteolytically cleaved and liberated from the extracellular region of the transmembrane precursor. Ligands, either membrane-bound or soluble, can bind to homo- and heterodimer combinations of the four currently known membrane-anchored tyrosin kinase receptors ErbB1 (EGFR, HER-1), ErbB2 (Neu antigen, HER-2), ErbB 3 (HER-3), and ErbB4 (HER-4). Of all possible combinations, ErbB2 homodimers appear not to be stable. EGF, AR and TGFα bind preferentially to EGFR, while BTC, HB-EGF and EPR bind to both EGFR and ErbB4. NRG1 and NRG2 preferentially bind to ERbB3 and ERbB4, whereas NRG3 and NRG4 bind to ErbB4. Growth factor binding induces homo- or heterodimerization of the receptors and stimulates intracellular protein-tyrosine kinase activity resulting in ►auto- and cross-phosphorylation of key ►tyrosine residues in the C-terminal ►domain in the ErbB homo- or heterodimer. This autophosphorylation sites are docking stations for several proteins that associate with the phosphorylated tyrosine residues through ►SH2 domains (Src homology 2). This initiates downstream ►signal transduction cascades, among them being the ►MAPK, ►AKT and ►JNK pathway, which leads to ►DNA synthesis, cell proliferation, alterations in ►apoptotic pathways and ►cell migration and ►adhesion.

►Epidermal Growth Factor (EGF) was originally isolated from the mouse submaxillary gland as a stimulatory of eyelid opening and tooth eruption in newborn rodents. Other sources of (pro)EGF are the kidney*, epidermis* (*mainly membrane-bound proEGF), pancreas, small intestine, and brain. Human EGF precursor (preproEGF) is a large protein consisting of 1,207 amino acids (aa) containing nine EGF motifs in the extracellular proEGF region. The EGF motif closest to the transmembrane domain corresponds to soluble EGF. The enzyme responsible for cleavage of the extracellular proEGF domain is ADAM 10 (A Disintegrin and Metalloprotease domain 10). EGF null mice do not show a significant phenotype. Transgenic overexpression of mouse EGF targeted to villous enterocytes of the jejunum and ileum causes increased villous height and crypt depth in these intestinal parts. Transgenic mice over-expressing human proEGF-driven by the β-actin promoter have revealed that (pro)EGF is the active ligand for the EGFR in germ cells and proper EGF expression is important for the completion of spermatogenesis.

►Transforming Growth Factor alpha (TGFα) derives from a 160 aa precursor (preproTGFα). This protein was originally characterized by its capacity to induce ►oncogenic transformation in rat kidney fibroblasts. TGFα is targeted preferentially to the basolateral compartment of polarized epithelial cells where it is cleaved by TNF Alpha Converting Enzyme (TACE)/ADAM17. TGFα mRNA and protein have been detected in various adult tissues, including pituitary gland, brain, skin keratinocytes and macrophages. Transgenic animals with overexpression of TGFα display hypertrophy of skin and hyperkerotosis with alopecia. These animals also have stunted hair growth and psoriasis-like lesions. TGF α null mice show a very mild phenotype which includes wavy fur and whiskers.

►Heparin binding-EGF like growth factor (HB-EGF) derives from a 204 aa molecule. HB-EGF was identified in conditioned media of human monocytes/macrophages and was purified from phorbol ester-treated human U-937 macrophages as a 22-kDa factor with strong affinity for heparin. HB-EGF is expressed in a wide variety of hematopoietic cells, endothelial cells, vascular smooth muscle and epithelial cells. Cleavage of proHB-EGF may involve ADAM9, 10, 12, and 17. Over-expression of human HB-EGF decreases the weight and growth rate in these transgenic mice and this may involve alternation of insulin-like growth factor binding protein (IGFBP) pathways. Moreover, histological analysis showed over-expression of HB-EGF exclusively in kidney, liver, lung and stomach. Employing several mutant mice lacking HB-EGF expression revealed a critical role for HB-EGF in cardiac valve formation and normal heart function. HB-EGF null mice develop heart failure as a result of grossly enlarged ventricular chambers.

►Amphiregulin (AR) is synthesized as a 252 aa transmembrane precursor. AR was originally isolated from the phorbolester-treated human breast adenocarcinoma cell line MCF7. ProAR is expressed in many human tissue including ovary, placenta, pancreas, testes, lung, cardiac muscle, breast, kidney, spleen and colon. In polarized epithelial cells, cleavage of basolateral proAG is facilitated by TACE/ADAM17 to release a 78–84 aa growth factor. Posttranslational modification results in several different cell surface and soluble isoforms. Keratin-14 promoter-driven overexpression of AR in the basal epidermal cell layer in transgenic mice induces severe, early-onset skin pathology, resembling psoriasis. Histological examination of the skin in these AR over-expressing mice revealed hyperkeratosis, focal parakeratosis and acanthosis, mixed leukocyte infiltration, including CD3-positive T cells and neutrophils in the epidermis and dermis. These mice also display tortuous dermal vasculature. AR null mice similar to EGF null mice, do not display any gross or histological abnormalities.

►Betacellulin (BTC) has been isolated from conditioned media from a pancreatic β cell tumor cell line. BTC is also expressed in a variety of mesynchymal and epithelial cell lines and in many tissues including

pancreas, liver, kidney and small intestine. Membrane-bound proBTC is processed by ADAM10 to release soluble BTC. Transgenic chicken actin promoter-driven BTC over-expression in mice causes bony deformations of the skull, pulmonary hemorrhage syndrome, and complex eye pathology. Trangenic animals showed decrease in the weight of pancreas and increase weight of the eye, lung and spleen.

►Epiregulin (EPR) was initially purified from conditioned medium of the mouse fibroblast-derived tumor cell line NIH-3T3 clone T7. EPR is expressed in adult pancreas, liver, kidney and small intestine. Human epiregulin encodes a 46 aa growth factor which exhibits 24–50% identity with the sequences of other EGF-like ligands. Epiregulin exhibits a bifunctional regulatory property in that it inhibits the growth of several epithelial cell lines, like NIH-3T3, and stimulates the growth of fibroblasts, primary rat hepatocytes, human smooth muscle cells and various other cell types, including COS-7 (monkey) and Swiss 3T3 (mouse). Epiregulin can bind to and activate EGFR and ErbB4. EPR can also transactivate ErBB2 and ErbB3. Although EPR displays lower affinity toward EGFR, EPR-mediated receptor activation is more sustained when compared with EGF or BTC. The lower affinity of EPR to EGFR results in enhanced dissociation of EPR from the ligand-receptor complex during receptor endocytosis and renewed EGFR activation by recycled EPR. EPR-deficient mice develop chronic dermatitis.

Neu differentiation factors (NDF, heregulins, Neuregulins, Glia Growth Factors-GGFs, Acetylocholine Receptor Inducing Activity-ARIA) were isolated from mesenchymal cells based on their ability to elevate phosphorylation of ErbB proteins At least four different genes of neuregulins are known. NRGs are widely expressed in neurons of the central and peripheral nervous system. They are known to play important functions during neuronal development and migration. Furthermore, NRG-1 is also involved in heart development. Mice defective in genes encoding either NRG-1 or the receptors ErbB-2 or ErbB-4 display identical failure of trabecular formation in the embryonic heart, consistent with the notion that trabeculation requires NRG-1-mediated activation of ErbB-2/ErbB-4 heterodimers.

►Epigen encodes a protein of 152 amino acids that contains EGF-like features. Epigen has 24–37% identity with EGF, TGFα, and Epiregulin. In epithelial cells, Epigen stimulates the phosphorylation of ErbB1 and causes activation of MAP kinase signaling pathways. Epigen also activates genes under the control of the SRE (Serum Response Element). Epigen is a mitogen for the human keratinocyte cell line HaCaT and this activity can be significantly reduced by a blocking antibody to the receptor ErbB-1.

►Cripto-1 (Cr-1) is a glycoprotein member of 188 aa. Cr-l has been implicated in development. Expression of Cr-l was reported in trophoblast and embryoblast of 4-day old mouse blastocysts, and the myocardium of developing heart tubes in 8.5 old mice embryos. Transgenic murine embryos lacking Cr-l are devoid of cardiac specific gene expression (α and β- myosin heavy chain, myosin light chains 2A and 2V). Antisense RNA silencing studies showed that inhibition of Cr-1 expression inhibits the growth of human colon carcinoma cell lines expressing this factor.

E

EGF-Like Ligands and Cancer

Members of the EGF-like ligand receptor system are often amplified in various cancers. Over-expression of EGFR in brain tumors (oligodendrogliomas, glioblastomas) and in carcinoma of the stomach, thyroid, lung and breast (for the latter two also Neu/ErbB2 amplification) identifies these tumors as targets for the actions of EGF-like ligands and anti-cancer drugs directed at inhibiting ligand-mediated ErbB1/2 activation. EGF-like ligands affect tumor cell growth, differentiation and metastasis. Amplification and ligand-induced activation of EGFR correlates with increased *in-vitro* tumor cell migration, matrix degradation and enhanced *in-vivo* tissue invasiveness. EGFR transactivation as a result of the prior activation of ►G protein coupled receptors (GPCRs) involves the proteolytic cleavage of membrane-anchored EGF-like ligands by GPCR-mediated activation of members of the metalloproteinase superfamily. GPCR-mediated EGFR transactivation in COS-7, HEK-293, and breast cancer cells involves cleavage of proHB-EGF, while in colon epithelial cells and head and neck squamous cell carcinomas proTGFα has been implicated.

Brain Cancer

Malignant human gliomas are the most common form of primary tumors of the central nervous system and display an invasive growth pattern. Among the genetic alternations found in these tumors, p53 inactivation and PDGF/PDGFR activation represent early events, whereas the loss of chromosome 10, gene amplification, and rearrangement of genomic EGFR are late events in glioma carcinogenesis. The coamplification of TGFα and EGFR in human glioma cell lines and primary glioma tissues coincides with sustained glioma proliferation and suggests an autocrine growth loop promoted by this EGF-like ligand-receptor pair, especially in high grade glioma. Antisense-mediated down-regulation of TGFα expression was shown to inhibit glioma growth.

Breast Cancer

TGFα stimulates growth and differentiation of mammary epithelial cells and is implicated in the pathogenesis of human breast cancer. High expression of AR has been detected in several human breast cancer cell lines and primary human breast carcinomas. AR acts as an

autocrine/juxtacrine growth factor in human mammary epithelial cells transformed with an activated c-Ha-*ras* proto-oncogene or overexpressing Neu/ErbB2. EGF and AR may modulate invasion of metastatic breast cancer cells by increasing the expression of matrix-metalloproteinases. EGFR transactivation by membrane-anchored G protein coupled estrogen receptor GPR30 in breast cancer cells involves the MMP-2- and MMP-9-mediated release of HB-EGF.

Carcinoma of the Lung

EGF-like growth factors play an important role in the pathogenesis and progression of non-small cell lung cancers (NSCLC) comprising large cell cancer, squamous cancer and adenocarcinoma, and small cell lung cancer (SCLC). The amplification of TGFα combined with the presence of cytoplasmic, but not its membrane-anchored, EGFR and/or enhanced expression of EGFR in its cytoplasmic or membrane-bound form significantly associate with poor patient survival rates.

Colorectal Cancer

Most human colon cancer cell lines express TGFα, AR, and Cr-1. AR and Cr-1 appear to be suitable markers for human colorectal cancer tissues since transcripts for both EGF-like ligands are detected in 60–70% of primary or metastatic human colorectal cancers but are present in only 2–7% of normal human colonic mucosa. Immunoreactive AR was reported in primary and metastatic colorectal tumors but not in normal colon. Agonists to the GPCR prostaglandin E_2 receptor and the M3 muscarinic receptor lead to a metalloproteinase-/TACE-dependent processing of TGFα resulting in EGFR transactivation and proliferation of colon cancer (Caco-2, LoVo and HT-29) cell lines.

Head and Neck Squamous Cell Carcinoma (HNSCC)

GPCR-mediated EGFR transactivation via GPCRs for gastrin releasing peptide, lysophosphatidic acid (LPA) and carbachol was shown *in vitro* to result in a matrix-metalloproteinase-dependent enhancement in growth and invasiveness of HNSCC cells. This coincides with the release of TGFα and AR, but not EGF or HB-EGF, into the supernatant of HNSCC. Enzymatic processing of proAR and proTGFα upon treatment with lysophosphatidic acid (LPA) or carbachol involves the activation of TNF-converting enzyme (TACE/ADAM17) and the downstream activation of EGFR-induced MAPK signaling pathways in HNSSC.

Epigallocatechin

Ann M. Bode, Zigang Dong
The Hormel Institute, University of Minnesota, Austin, MN, USA

Synonyms

Green tea polyphenol; Catechin

Definition

Epigallocatechin is one of several biologically active ingredients that make up the bulk of the potent antioxidant polyphenols known as catechins, which are found in green tea.

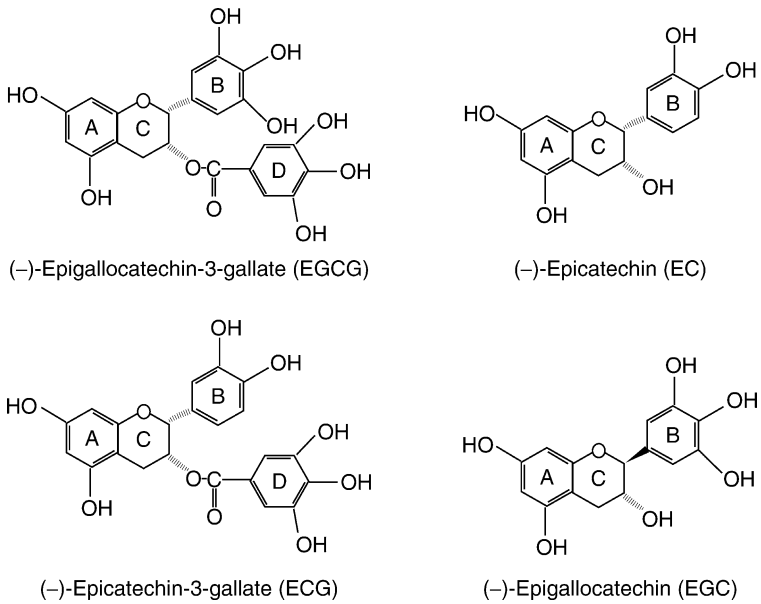
Characteristics

Next to water, tea is the second most widely consumed beverage in the world. Green tea, like oolong and black teas, is derived from the *Camellia sinensi* plant, but is processed immediately from fresh leaves and is protected from oxidation. The biologically active ingredients in green tea are a family of polyphenols (catechins) and flavonols, which are very strong antioxidants. The catechins comprise about 90% of the bulk of green tea and include epicatechin (EC), epigallocatechin (EGC), epicatechin gallate (ECG) and epigallocatechin gallate (EGCG) (Fig. 1). The catechins are characterized by the presence of a di- or tri-hydroxyl group substitution on the "B"- ring and the meta-5.7-di-hydroxyl substitution at the "A"-ring (Fig. 1). EGCG appears to account for 50–80% of the total catechins found in green tea and is considered to be the most biologically active. A cup of green tea (2.5 g of dried green tea leaves brewed in 200 mL of water) usually contains about 90 mg of EGCG. In addition, green tea contains a similar or slightly smaller amount (65 mg) of EGC, about 20 mg each of ECG and EC, and about 50 mg of caffeine. However, physiologically achievable tissue levels of EGCG appear to be in the low micromolar range (i.e. 1–7 μM).

Epidemiologic and laboratory studies suggest that consumption of green tea might be associated with a decreased risk of developing skin, lung, bladder, esophageal, stomach, liver, duodenum and small intestine, pancreatic, colorectal, prostate, or breast ►cancer. Many chronic diseases, including cancer, are associated with ►oxidative DNA damage produced by free radicals. Much of the effectiveness of green tea has been attributed to its potent antioxidant activity, which is suggested to be greater than that of vitamin C or E or equivalent servings of most vegetables and fruits. Research data also suggest that some of the effects of green tea might be due to its ability to generate ►reactive oxygen species as a pro-oxidant molecule. However, direct unequivocal evidence for either mechanism of action *in vivo* is lacking. On the other hand, an accumulating number of research studies suggest that EGCG may specifically target and modulate distinct cancer genes or proteins, with little or no effect on normal molecules, in order to exert its anticancer effects.

Cellular and Molecular Targets of EGCG

Cells respond to their environment through a process known as signal transduction in which information from a stimulus outside a cell is transmitted from the cell membrane into the cell and along an intracellular chain of signaling molecules to perpetuate a response. The development of cancer is a complex, several-step process (i.e. initiation, promotion, progression) that affects innumerable genes and proteins, including signaling molecules that are critical in the regulation of many cellular functions but especially proliferation or growth. The initiation step is an irreversible period involving a



Epigallocatechin. Figure 1 Chemical structures of the major green tea catechins.

process in which a normal cell becomes changed so that it has the capacity to form a tumor (i.e. preneoplastic). The change results from DNA damage that can be induced by a number of "initiators," including radiation, ultraviolet irradiation, chemical carcinogens, or retroviruses. Under normal conditions, the DNA damage is either repaired or if the damage is too extreme, the cell is eliminated by a tightly controlled process of cell death called "►apoptosis." If the damaged DNA is allowed to duplicate, the cell may be predisposed to cancer. The promotion step is a potentially reversible process by which actively proliferating preneoplastic cells accumulate and begin to develop characteristics, including growth factor independence, lack of contact inhibition, and resistance to apoptosis, all of which enhance the cells' ability to proliferate by escaping normal control mechanisms. This step generally occurs over a period of many years and environmental tumor promoters or host factors may play roles in cancer promotion and latency. The final step of cell transformation is progression in which preneoplastic cells acquire increased metastatic potential and the ability to spread to other tissue sites of the afflicted organism.

Research findings have shown that the dysfunction or deregulation of various cellular signaling molecules is a major factor in cancer development and prevention. The prevailing idea today is that cancer may be prevented or treated by targeting and modulating the activity of specific cancer genes or signaling proteins. Each step of cancer development could be a potential target for anticancer agents, but especially the promotion step because of its length and reversible nature. In addition, an increased interest in discovering and developing natural, non-toxic compounds as chemopreventive agents now exists. The molecular mechanisms explaining how normal cells undergo transformation induced by tumor promoters are rapidly being clarified and the mechanisms by which natural compounds such as the green tea polyphenol EGCG, can act as chemopreventive agents are also being elucidated.

General Anticancer Effects of Green Tea Polyphenols

Green tea polyphenols have been reported to suppress cancer cell proliferation, enhance apoptosis, decrease ►angiogenesis and suppress oncoprotein activation. In particular, the mitogen-activated protein or ►MAP kinase signaling pathways are activated differentially by various tumor promoters. The MAP kinases generally transmit signals initiated by tumor promoters such as 12-*O*-tetradecanoylphorbol-13-acetate (TPA), epidermal growth factor (EGF) and platelet-derived growth factor (PDGF) and are also strongly stimulated by stresses such as ultraviolet (UV) irradiation or arsenic. The activation of these signaling cascades can result in a multitude of cellular responses including apoptosis, proliferation, inflammation, differentiation and development. MAP kinases activate a variety of target proteins that are important in tumor development, including activator protein-1 (►AP-1) and nuclear factor-kappaB (NF-κB), which in turn may promote transcription of a variety of cancer-related genes such as *cyclooxygenase-2* (*cox-2*).

A substantial body of evidence suggests that EGCG or other green tea polyphenols inhibit the phosphorylation and activation of the MAP kinases and various components of another critical cancer-associated pathway, the phosphatidylinositol-3 kinase (►PI3K)/►Akt pathway. Green tea polyphenols have also been reported to suppress tumor promoter- or growth factor-induced cell transformation and AP-1, NF-κB or COX-2 activation. EGCG has also been shown to inhibit the phosphorylation of the upstream epidermal growth factor family of proteins. Furthermore, consumption of green tea polyphenols has been associated with suppression of numerous markers of angiogenesis and ►metastasis, including expression of ►matrix metalloproteinases 2 and 9 and ►vascular endothelial growth factor. Other studies indicate that EGCG also inhibits ►telomerase activity to induce cell ►senescence and suppress DNA methyltransferase resulting in the re-activation of the ►tumor suppressor gene $p16^{INK4a}$.

Direct Molecular Targets of EGCG

Identifying EGCG receptors or high affinity proteins that bind to EGCG is a key step in understanding the molecular and biochemical mechanism of this polyphenol's anticancer effects. The structure of EGCG (Fig. 1) facilitates its ability to bind with varying affinity to a number of proteins. Proteins that have thus far been reported to directly bind with EGCG include ►fibronectin, laminin and the 67-kDa laminin receptor, ►insulin growth factor-1 receptor (IGF-1R), ►Bcl-2 and Bcl-x_L, vimentin, the glucose-regulated protein 78 (GRP78) chaperone protein, apoptosis-associated Fas, and fatty acid synthase. However, not all of these proteins (i.e. Fas, 400 μM; fatty acid synthase, 52 μM) show a high binding affinity and the consequences or details of the binding with EGCG are not fully understood.

EGCG was first reported to inhibit cancer cell ►adhesion to fibronectin by directly binding with this protein. However, the inhibition of cancer cell adhesion was not caused by EGCG binding to the cell-binding domain because EGCG interacted with the adjoining domain. EGCG was also reported to bind to another extracellular matrix protein, laminin, and resulted in an inhibition of ►melanoma cell adhesion. EGCG was later found to inhibit cell growth by binding with the invasion- and metastasis-associated 67-kDa laminin receptor (67LR), which is expressed on various cancer cell types. Importantly, the K_d value for binding was

39.9 nM suggesting possible *in vivo* relevance. The intermediate filament protein, vimentin, which has an important functional involvement in cell division and proliferation, was also identified as an EGCG-binding protein. Vimentin displayed an even higher affinity (K_i = 3.3 nM) for binding with EGCG and the association also appeared to have a regulatory role in controlling cell proliferation. Other work has suggested that EGCG (20 μg/mL) blocks anchorage-independent growth and human breast and cervical cancer cell phenotype expression through inhibition of IGF-1R downstream signaling. Thus EGCG appears to interact with surface proteins to suppress cancer cell proliferation.

EGCG may also interact with key proteins to modulate apoptosis. The pro-survival Bcl-2 proteins are over-expressed in many cancer types and thus contribute to resistance of cancer cells to apoptosis. EGCG was reported to directly bind to the BH3 pocket of Bcl-x_L (K_i = 490 nM) or Bcl-2 (K_i = 335 nM), resulting in the suppression of the anti-apoptotic activity of these proteins. EGCG was also shown to directly interact with GRP78, which is associated with the multidrug resistance phenotype of many types of cancer cells. EGCG suppressed GRP78's function and caused an increased etoposide-induced apoptosis in cancer cells. These results strongly suggest that EGCG can enhance apoptosis of cancer cells. Data suggest that EGCG has multiple targets and identification of novel EGCG-binding proteins could facilitate the design of new strategies to prevent cancer and hopefully help translate the effectiveness of EGCG observed in cell and animal models to humans.

Clinical Relevance

Tea polyphenols have attracted a great deal of interest because of their perceived ability to act as highly effective chemopreventive agents. EGCG has been reported to cause growth inhibition, G1-phase arrest, and apoptosis in a variety of human cancer cells. Notably, EGCG's effects appear to target only cancer cells with little or no effect on normal cells. This apparent specificity suggests that EGCG can be used in combination with traditional chemotherapeutic agents to enhance cancer cell death without harming normal cells. For example, treatment of lung cancer cells with EGCG plus ►celecoxib, a COX-2 inhibitor, has been shown to synergistically induce apoptosis. EGCG has also been shown to increase the toxicity of the chemotherapeutic drug, ►cisplatin, by several-fold in ovarian cancer cells and showed IC_{50} values for EGCG in the μM range even for ovarian cancers that are known to be resistant to cisplatin. Furthermore, the combination of EGCG with radiotherapy has been suggested to improve the efficacy of ionizing radiation in treating glioblastoma cells.

Although animal and cell culture data suggest a potent anticancer effect for EGCG, reports of anticancer activity of tea polyphenols in humans are less dramatic. Phase I and II clinical trials have been performed to test the anticancer effects of oral administration of green tea but results are still inconclusive. Laboratory data clearly indicate that EGCG and other green tea polyphenols are very unlikely to have only a single target or receptor to account for all its observed activities and effects. Furthermore, based on limited bioavailability, experimental concentrations of EGCG greater than 20 μM may not be relevant to the *in vivo* situation. Understanding the molecular mechanisms of tea in anti-tumor promotion may reveal additional high affinity molecular targets for the development of more effective agents with fewer side effects for the chemoprevention of cancer. A continuing emphasis on obtaining rigorous research data and critical analysis of those data regarding tea polyphenols and other food factors is vital to determine the molecular basis and long-term effectiveness and safety of these compounds as chemopreventive agents. Large-scale and comprehensive studies using combined approaches of biochemical, molecular, animal and clinical studies are needed to address the bioavailability, toxicity, molecular target, signal transduction pathways, and side effects of tea polyphenols for translation to humans.

►Hepatic Epithelioid Hemangioendothelioma

Epigen

Definition

Encodes a protein of 152 amino acids that contains EGF-like features. Epigen has 24–37% identity with EGF, TGF , and ►Epiregulin. In epithelial cells, Epigen stimulates the phosphorylation of ErbB1 and causes activation of MAP kinase signaling pathways. Epigen also activates genes under the control of the SRE (Serum Response Element). Epigen is a mitogen for the human keratinocyte cell line HaCaT and this activity can be significantly reduced by a blocking antiBody to the receptor ErbB-1.

►Epidermal Growth Factor (EGF)-Like Ligands

Epigenetic

Definition

Heritable changes in genome function that occur without a change in DNA sequence. DNA-►methylation at ►CpG-islands and posttranslational histone modifications are the molecular basis for epigenetic information. Epigenetic changes of DNA influence the phenotype without altering the genotype. They consist of changes in the properties of a cell that can be transmitted through cells cycle divisions but do not represent a change in genetic information. The main epigenetic changes that target gene regulatory regions and modulate gene expression are methylation and acethylation.

Medical Sciences, Indiana University School of Medicine Bloomington, IN, USA
Indiana University Simon Cancer Center, Indianapolis, IN, USA

Definition

Epigenetic: A heritable change in gene expression that is not accompanied by changes in DNA sequence. The two most studied ►epigenetic phenomena are ►DNA methylation and modifications of histone tails.

Characteristics

The term epigenetics was originally coined to describe the development of phenotype from genotype. The field of epigenetics now encompasses DNA methylation, covalent modifications of histones, nucleosome–DNA interactions, and most recently, small inhibitory RNA molecules. While it is well documented that genetic changes, such as mutations and deletions, play a functional role in silencing tumor suppressor genes in

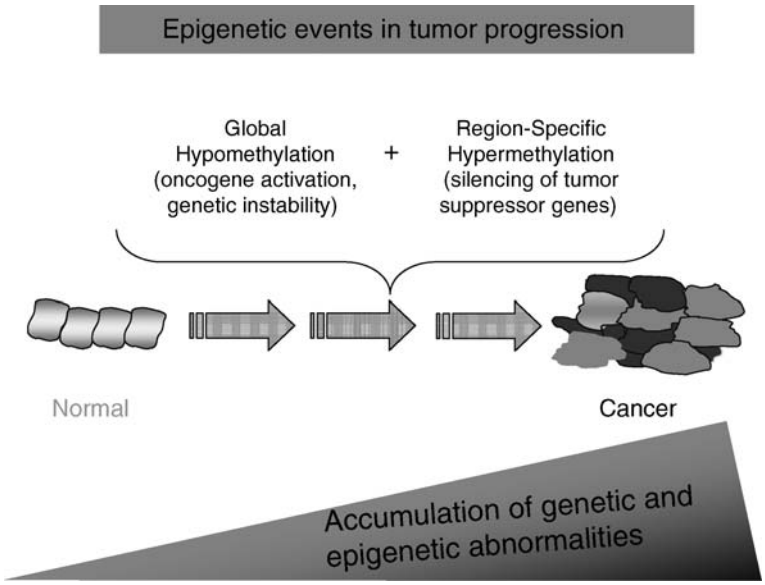
cancer cells, the functional importance of covalent epigenetic modifications, such as DNA methylation and histone post-translational modifications, is becoming increasingly recognized as an important early event during carcinogenesis and tumor development.

Epigenetics and Cancer

Epigenetic alterations are widely observed in cancer, and it has been shown that epigenetic mechanisms can be important to all phases of the cancer process, including tumor initiation, tumor progression and maintenance of the malignant state of cancer cells (Fig. 1). Tumors exhibit two characteristic changes in DNA methylation patterns. One is genome-wide hypomethylation, primarily in repeat elements and pericentromeric regions, which is responsible for genomic instability. The other is promoter hypermethylation of normally protected ►CpG islands near the transcription start site of genes, which is responsible for transcriptional inactivation. Another characteristic of tumors includes hypoacetylation of histones, and ►HATs have been reported as up- or down-regulated in a number of tumors. In this essay, both DNA methylation and histone modifications are discussed in the context of cancer.

DNA Methylation

The transfer of a methyl group to the carbon 5 position of a cytosine residue within the context of a CpG dinucleotide is the only known epigenetic modification of DNA itself. The 5-methylcytosine is the best-studied epigenetic modification and often referred to as the "fifth base" present in DNA. Although 5-methylcytosine comprises approximately 1% of the human genome, it is underrepresented in the bulk of the genome due to spontaneous deamination to thymine, which is not recognized by DNA mismatch repair systems. The CpG dinucleotides that are present are almost always methylated in normal cells, as 5-methylcytosine is widely believed to act to "silence" expression and/or retrotransposition of parasitic repeat sequences, such as Alu repeats and long-interspersed elements (LINEs) found throughout the genome. Aberrations in DNA methylation patterns are firmly associated with cancer, as evidenced by vast alterations in methylation patterns that occur during tumorigenesis, including global loss of methylation at CpG dinucleotides and region specific hypermethylation of distinct regions of 5-methylcytosine, located within specific CG-rich sequences known as CpG islands, often found within the promoter and associated with active genes. About 60% of human genes are associated with unique CpG islands, and recently it has been estimated that the human genome contains about 29,000 CpG islands. These normally unmethylated CpG islands may become methylated in cancer cells, and the event is associated with loss of expression of flanking genes. It has also been estimated that aberrant methylation can accumulate in as many as 10% of the CpG islands during tumor development. Thus, abnormal *de novo* methylation of CpG islands in human cancer cells represents one of the most prevalent molecular markers yet identified, and the list of methylated genes identified in various tumor types continues to grow. DNA is methylated by ►DNMTs, a family of proteins. ►DNMT1



Epigenetic Gene Silencing. Figure 1 Schematic representation of cancer progression. Characteristic epigenetic features of cancer are listed. During tumor progression, accumulation of both genetic and epigenetic abnormalities contributes to carcinogenesis.

is responsible for the maintenance of DNA methylation after each round of replication. De novo methylation of DNA is the responsibility of DNMT3a and DNMT3b.

Histone Modifications and Chromatin Remodeling

While DNA methylation is currently the best-studied epigenetic modification, other well-known chromatin alterations play critical roles in normal and aberrant physiological processes, including cancer. Histones are the major components of chromatin, the complex of DNA and protein found within the nucleus of eukaryotic cells. Early structural studies of chromatin revealed that 146 base pairs of DNA are "wrapped" around a core nucleosome, the fundamental unit of chromatin. A nucleosome consists of an octamer of histones, with 50 base pairs of "linker" DNA between repeating octamers. The N-terminal "tail" regions of histones extend from the nucleosome core octamer and are subject to various posttranslational modifications. Histone tails can be acetylated and deacetylated by HATs and ►HDACs, respectively. These enzymes are gene activators and repressors, and histone acetylation/deacetylation is important in transcriptional regulation. Additional histone modifications include methylation, by HMTs, phosphorylation, sumoylation, and ubiquitination. Overall, these and other modifications of histone tails play a critical role in chromatin compaction (e.g., tightly vs. loosely compacted chromatin), which can determine the access of various factors involved in transcription and gene expression and whether a gene is switched on (activated) or off (repressed). Furthermore, establishing transcriptional silencing of a gene involves a close interplay between histone modifications and DNA methylation, and loss and gain of DNA methylation, histone acetylation and methylation are observed in cancer cells. The sum total of these covalent alterations in the ►epigenome has been referred to as the "histone code", which can be "written" by the various modifying enzymes and "read" by various binding proteins that act to further modify chromatin and/or alter gene expression. According to the histone code hypothesis, the combination of DNA and histone modifications allows genes to go from the activate or inactive state interchangeably. The relatively new discipline of ►epigenomics promises to reveal novel insights into the histone code and a better understanding of normal development and human disease, including cancer.

Clinical Relevance

Unlike genetic changes, the epigenetic changes in cancer are potentially reversible. The ability to reactivate ►epigentically-silenced tumor suppressor genes and key control pathways and reverse the cancer cell phenotype is a promising strategy. Epigenetic drugs include both DNMT inhibitors ("demethylating" agents) and HDAC inhibitors (agents that cause "hyperacetylation" of histones). These agents can be used singly or in combination with currently available cancer chemotherapies. Epigenetic therapies themselves are now approved for various hematological malignancies and currently being studied in clinical trials for solid tumors. Furthermore, the combination of DNMT inhibitors with HDAC inhibitors has shown synergistic re-expression of epigenetically silenced genes and inhibition of tumor growth. Moreover, many investigators have shown that DNMT inhibitors with HDAC inhibitors can act to re-sensitize drug-resistant cancer cells to standard chemotherapeutic and hormonal agents. The ability to measure biochemical responses to epigenetic drugs, such as demethylation of previously hypermethylated genes and correlate this with clinical responses has also been shown, and epigenetic therapies for chemoprevention in individuals with aberrant epigenetic alterations but have not yet developed cancer is an exciting possibility.

Distinct CpG island methylation profiles for various cancers continue to emerge; consequently, aberrant DNA methylation and histone modification patterns are now being investigated as potential biomarkers and pathway-specific therapeutic targets. Thus, epigenetic profiling of tumors could provide new therapeutic targets and epigenetic biomarkers for prognosis, such as predicting therapy outcome in patients with cancer or, ideally, early cancer detection. Clearly, attractive and promising clinical possibilities exist for epigenetic-based therapies

In summary, perhaps all human cancers are at least partially associated with epigenetic dysregulation of gene expression, forming a rational basis for future treatment strategies designed to alter this fundamental processes in cancer. Comprehensive elucidation of epigenetic modifications, in both normal and diseased tissues, will allow for an extensive understanding of gene regulatory networks that control both normal and cancer phenotypes. The realization of the Human ►Epigenome Project (HEP), proposed as an exhaustive annotation of all histone and deoxcytosine modifications throughout the human genome, should have a major impact on cancer.

Definition

Epigenetic therapy refers to therapy using inhibitors of DNA ►methylation and histone deacetylation, which reverse these epigenetic modifications. These compounds inhibit tumor growth in vitro and in vivo, which is thought to be due to reactivation of epigenetically silenced ►tumor suppressor genes by inhibition of promoter DNA methylation and histone deacetylation of these genes.

Characteristics

DNA Methylation and Histone Deacetylation

►Epigenetic modifications regulate heritable changes in gene expression without changing the primary DNA sequence. The best-studied epigenetic mechanisms are DNA methylation and posttranslational histone modifications. DNA methylation is the covalent addition of a methyl group to the DNA, predominantly to the base cytosine 5′ to guanine, also called a CpG dinucleotide. CpG dinucleotides are clustered in small stretches of DNA called ►CpG islands, often located in or near the promoter region of approximately half of all human genes. Methylation of CpG dinucleotides, which occurs nonrandomly, is an important ►epigenetic gene silencing mechanism. Most methylation in the human genome occurs in the noncoding DNA, preventing the transcription of repeat elements, inserted viral sequences, and transposons. In contrast, CpG islands are largely unmethylated in both expressing and nonexpressing tissues under normal conditions. Exceptions to this unmethylated state of CpG islands involve the silenced gene alleles for imprinted genes and genes located on the inactive X chromosome of females. DNA methylation is catalyzed by DNA methyltransferases (DNMTs). DNA methylation can induce gene silencing through several mechanisms. By sterically hindering the binding of activating transcription factors to gene promoters, DNA methylation can directly repress gene transcription. Another mechanism is through recruitment of several methyl-binding domain proteins (MBDs) that recognize methylated DNA, including MeCP2, MBD1–4, and Kaiso. These proteins themselves can repress gene transcription, or bind proteins which cause gene silencing. The DNA helix is wrapped around a core of ►histone proteins. The basic amino-terminal tails of histones are subject to various posttranslational modifications, including acetylation, methylation, phosphorylation, ubiquitination, sumoylation, ADP-ribosylation, glycosylation, biotinylation, and carbonylation. The best-characterized histone modification is histone acetylation, which is controlled by histone acetyltransferases (HATs) and histone deacetylases (HDACs). Histone acetylation generally correlates to active gene transcription, whereas ►histone deacetylation is associated with transcriptional repression, by blocking accessibility of transcription factors to their binding sites.

DNA methylation and histone deacetylation are interconnected in gene silencing. Methyl-binding domain proteins are components of HDAC complexes or recruit these complexes to methylated DNA,

resulting in transcriptional silencing. Furthermore, a much more direct connection between DNA methylation and histone deacetylation exists by direct interactions between DNMTs and HDACs. DNA methylation and histone deacetylation are pivotal in X chromosome inactivation, ►imprinting, and establishment of tissue-specific gene expression. However, aberrant epigenetic regulation of gene expression also plays a major role in the development of human cancer.

Epigenetic Abnormalities in Cancer

Aberrant epigenetic silencing of tumor suppressor genes by promoter DNA hypermethylation and histone deacetylation plays an important role in the pathogenesis of cancer. According to ►Knudson's two-hit model, complete loss of function of a tumor suppressor gene requires loss of function of both gene copies. Epigenetic silencing of the wild-type allele of a tumor suppressor gene by aberrant promoter hypermethylation and histone deacetylation can be considered as the second hit in this model, resulting in complete loss of function of the gene. It has become apparent that many genes, located across all chromosome locations, are epigenetically silenced in cancer cells. Examples are genes involved in cell cycle regulation and apoptosis (*p14ARF*, *p15INK4b*, *p16INK4a*, *APC*, *RASSF1A*, *HIC1*), DNA repair genes (*hMLH1*, *GSTP1*, *MGMT*, *BRCA1*), and genes related to ►metastasis and invasion (*CDH1*, *TIMP-3*, *DAPK*, *p73*, *maspin*, *TSP1*, *VHL*).

DNA Methyltransferase and Histone Deacetylase Inhibitors

In contrast to genetic alterations, which are almost impossible to reverse, ►chromatin remodeling in cancers is potentially reversible. This resulted in the development of pharmacologic inhibitors of DNA methylation and histone deacetylation. By inducing DNA demethylation and histone acetylation, DNMT- and HDAC inhibitors can reverse epigenetic silencing of tumor suppressor genes, resulting in reactivation of these genes in tumor cells and restoring of crucial cellular pathways. The most extensively studied DNMT inhibitors are 5-azacytidine and ►5-aza- 2′-deoxycytidine [5-aza-2′deoxycytidine and Cancer], which were initially developed as chemotherapeutic agents. These ►nucleoside analogs are incorporated into DNA in place of the natural base cytosine during DNA replication, and are therefore only active during S phase. Once incorporated into the DNA, a complex is formed with active sites of DNMTs, thereby covalently trapping these enzymes. This results in the depletion of active enzymes and the demethylation of DNA after several cell divisions. 5-Aza- 2′-deoxycytidine is the most commonly used DNMT inhibitor in assays with cultured cells. This compound reactivates dormant tumor suppressor genes by demethylation of their hypermethylated promoter, thereby restoring their normal function. This seems to be a widespread effect of 5-aza- 2′-deoxycytidine, because all cancer cell lines studied so far are sensitive to the DNA demethylating effects of this agent. Reactivation of silenced tumor suppressor genes might be the mechanism by which this compound suppresses growth and induces differentiation of human tumor cell lines. Examples of other DNMT inhibitors are the cytidine analogs 5,6-dihydro-5-azacytidine, 5-fluoro-2′-deoxycytidine and zebularine, the small molecule RG108, which blocks the DNMT active site, and MG98, an antisense oligonucleotide that specifically inhibits DNMT1 mRNA.

By inhibiting histone deacetylation, HDAC inhibitors cause accumulation of acetylated histones, leading to increased transcription of previously silenced tumor suppressor genes in malignant cells. Both naturally existing and synthetic HDAC inhibitors have been characterized. The effects of HDAC inhibitors on gene expression in transformed cells are selective; only about 2–10% of all known genes are affected by these agents. One gene most consistently induced by HDAC inhibition is *CDKN1A*, which encodes the cell cycle inhibitor ►p21. HDAC inhibitors can also relieve inappropriate transcriptional repression mediated by ►chimeric oncoproteins, such as ►PML-RARα, thereby inducing differentiation in cells harboring these translocations. HDAC inhibitors have many antitumor effects including induction of cell cycle arrest, differentiation, and/or apoptosis in virtually all cultured transformed cell types and in cells from different tumors.

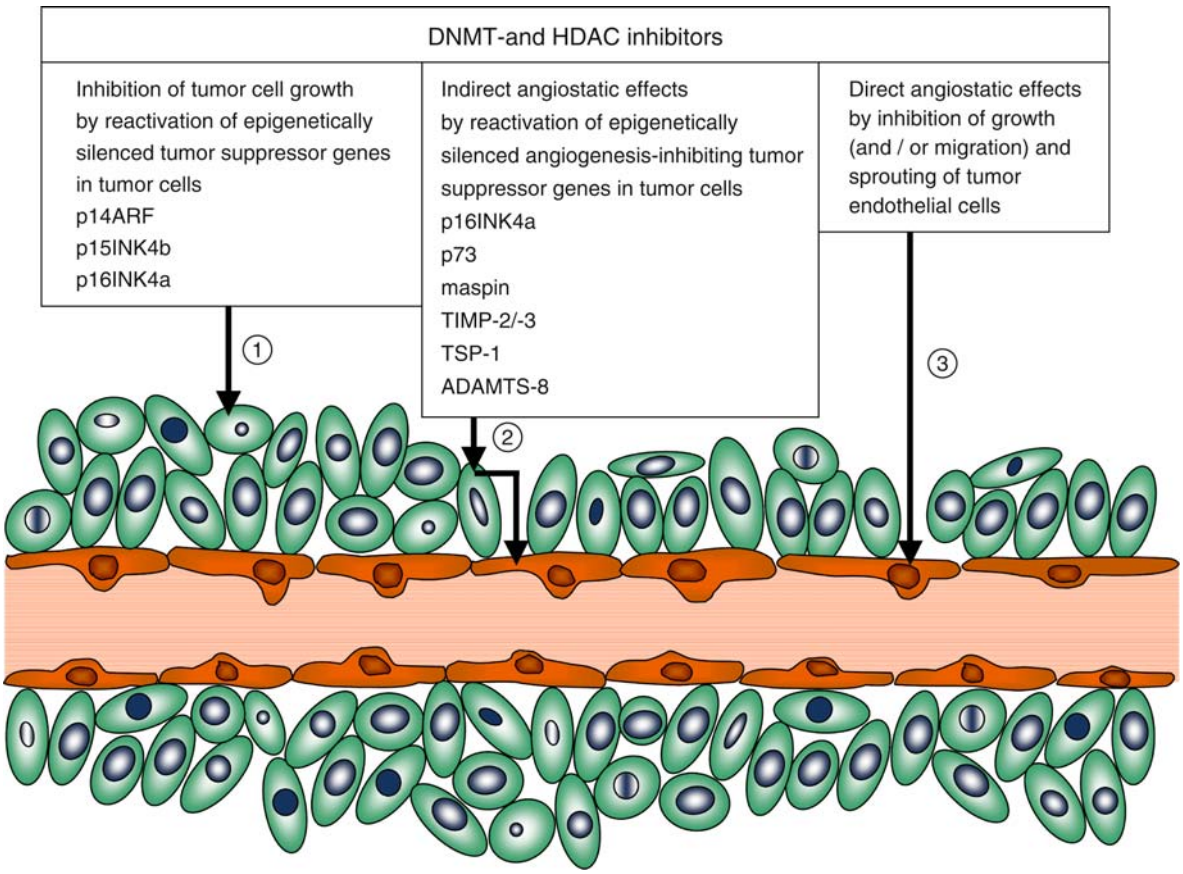
Epigenetic Therapy in Cancer

It is clear from in vitro and preclinical studies that the clinical application of reversing epigenetic aberrations in tumor cells, called epigenetic therapy, is an exciting strategy for cancer treatment. Many agents have been discovered that inhibit DNA methylation or histone deacetylation, and the value of these compounds will be established by ongoing ►clinical trials.

5-Azacytidine (Vidaza) and 5-aza- 2′-deoxycytidine (Decitabine) represent the two most prominent DNMT inhibitors that are being used in clinical practice, and these drugs have been approved by the ►FDA for the treatment of myelodysplastic syndrome (MDS). The use of DNMT inhibitors in the treatment of MDS results from the knowledge that epigenetic gene silencing of, in particular, *p15INK4b* is present in poor-risk MDS subtypes and often predicts transformation to acute myeloid leukemia (AML). Multiple HDAC inhibitors are currently being tested in patients through intravenous or oral administration. Suberoylanilide hydroxamic acid (SAHA) is one of the HDAC inhibitors most advanced in development. Encouraging results were obtained in Phase I, II, and III clinical trials for patients

with both hematologic and solid tumors. Other examples of HDAC inhibitors undergoing clinical testing in a range of solid and hematological malignancies are ►valproic acid, PXD101, NVP-LAQ824, LBH589, depsipeptide, MS-275, and CI-994. Complete targeting of epigenetic gene regulation might require a combination of ►chromatin modifying agents. The synergy between demethylating drugs and HDAC inhibitors in reactivation of epigenetically silenced tumor suppressor genes in vitro makes combined treatment with DNMT and HDAC inhibitors a promising epigenetic therapy. Reduction of individual doses should minimize toxic effects and optimize the therapeutic response of such combination. Encouraging anticancer activity of epigenetic therapy has been shown particularly in the treatment of hematologic disorders, but their effectiveness in solid tumors largely remains to be determined.

In addition to the inhibitory effects of DNMT and HDAC inhibitors on tumor cells, by reactivation of epigenetically silenced tumor suppressor genes, these compounds have also been described to inhibit ►tumor endothelial cell growth and ►tumor angiogenesis. ►Angiogenesis is required for tumor growth to a size of approximately 2 mm^3, but is also instrumental for tumor cells to metastasize to other locations in the body. Angiogenesis is considered to be a promising target of anticancer treatment. By influencing the gene expression profile of tumor cells, DNMT and HDAC inhibitors target genes, which are regulating angiogenesis. Among the epigenetically silenced tumor suppressor genes in tumor cells are genes with angiogenesis inhibiting properties. By re-expression of these genes in tumor cells, DNMT and HDAC inhibitors might indirectly – via the tumor cells – exhibit angiostatic effects in vivo. An example of these genes is *p16INK4a*, which can regulate angiogenesis by modulating ►vascular endothelial growth factor (VEGF) expression by the tumor. Another epigenetically silenced tumor



Epigenetic Therapy. Figure 1 Anti-tumor effects of DNA methyltransferase and histone deacetylase inhibitors in vivo. 1. DNMT- and HDAC inhibitors decrease tumor cell growth by reactivation of epigenetically silenced tumor suppressor genes in tumor cells. 2. Release of transcriptional repression of angiogenesis inhibiting tumor suppressor genes in tumor cells might result in indirect angiostatic effects of DNMT- and HDAC inhibitors. 3. DNMT- and HDAC inhibitors directly decrease endothelial cell growth and angiogenesis, thereby exhibiting direct angiostatic effects.

suppressor gene that inhibits angiogenesis by down-regulation of VEGF is *p73*. The tumor suppressor ►maspin, which is often silenced in tumors by epigenetic promoter modifications, is also an effective inhibitor of angiogenesis. Methylation-associated inactivation of the angiogenesis inhibiting factors tissue inhibitor of metalloproteinase-2- and -3 (*TIMP-2/3*) is frequent in many human tumors. Thrombospondin-1 (*TSP-1*) has been described to be repressed by epigenetic promoter modifications in several adult cancers, and can be reactivated by 5-aza- 2′-deoxycytidine. The secreted protease ADAMTS-8 (METH-2) has anti-angiogenic properties, which can specifically suppress endothelial cell proliferation, and significant down-regulation of *ADAMTS-8* by promoter hypermethylation, which has been described in different tumor types. Besides the indirect effects of DNMT and HDAC inhibitors on tumor angiogenesis, these compounds also directly inhibit endothelial cell growth and angiogenesis in vitro and in vivo. Potent anti-angiogenic activity has been described for several HDAC inhibitors, such as trichostatin A (TSA), SAHA, depsipeptide, valproic acid, butyrate, apicidin, LBH589, and NVP-LAQ824, as well as for the DNMT inhibitors 5-aza- 2′-deoxycytidine and zebularine. These drugs suppress spontaneous or VEGF-induced angiogenesis in different in vitro, ex vivo, and in vivo angiogenesis assays.

Clearly, the dual targeting of epigenetic therapy in cancer treatment, inhibiting both tumor cells as well as tumor angiogenesis, makes them suitable combinatorial anticancer therapeutics (Fig. 1). By targeting multiple genes and pathways in tumor cells, as well as endothelial cell biology and angiogenesis, DNMT and HDAC inhibitors decrease the development of resistance that is associated with many of the current chemotherapeutic- and ►anti-angiogenic drugs. Despite the promising data from clinical trials, there are several pitfalls regarding the clinical application of epigenetic therapy. An important side effect that should be taken into account in the use of these drugs is induction of global hypomethylation, which might induce tumorigenesis by aberrant activation of repetitive DNA sequences, transposons and ►oncogenes, induction of chromosomal instability and mutagenesis. Furthermore, the existence of many different DNMTs and HDACs makes the development of selective inhibitors that target individual enzymes imperative.

►ABC-Transporters

Epiregulin

Definition

EPR, was initially purified from conditioned medium of a mouse fibroblast-derived tumor cell line. EPR is expressed in adult pancreas, liver, kidney and small intestine. Human epiregulin encodes a 46 aa growth factor which exhibits 24–50% identity with the sequences of other EGF-like ligands. Epiregulin exhibits a bifunctional regulatory property in that it inhibits the growth of several epithelial cell lines and stimulates the growth of fibroblasts, primary rat hepatocytes, human smooth muscle cells and various other cell types, including COS-7 (monkey) and Swiss 3T3 (mouse). Epiregulin can bind to and activate ►EGFR and ErbB4. EPR can also transactivate ErBB2 and ErbB3. Although EPR displays lower affinity towards EGFR, EPR-mediated receptor activation is more sustained when compared with EGF or BTC. The lower affinity of EPR to EGFR results in enhanced dissociation of EPR from the ligand-receptor complex during receptor endocytosis and renewed EGFR activation by recycled EPR. EPR-deficient mice develop chronic dermatitis.

►EpCAM

Epithelial Growth Factors

Definition

Growth factors are proteins that bind to cell membrane receptors, including tyrosine kinase receptors, and activate cellular proliferation and/or differentiation. Growth factors can act in an ►autocrine, paracrine, or endocrine manner. Many growth factors can stimulate cellular division in numerous cell types, while others are specific to a particular cell type. Examples of growth factors include: fibroblast growth factor (FGF), epidermal growth factor (EGF), insulin-like growth factor I and II (IGF-I, IGF-II), and ►platelet-derived growth factor (PDGF). Growth factor expression and subsequently expression of the corresponding cell receptors are altered during ►progression of cancers.

►Aging and Cancer
►Fibroblast Growth Factors
►Insulin-like Growth Factors

Epithelial Tumorigenesis

Definition

Epithelial tumorigenesis relates to the process of developing and/or progressing of a tumor, originating from ►epithelial cells. Malignant tumors of this origin are known as ►carcinoma, whereas malignant tumors derived from cells of the connective tissue are known as ►sarcoma.

►Stromagenesis

Epithelial-to-Mesenchymal Transition

Ayyappan K. Rajasekaran,
Sigrid A. Rajasekaran
Nemours Center for Childhood Cancer Research, Alfred I. Dupont Hospital for Children, Wilmington, DE 19803, USA

Definition

Phenotypic alterations in which ►epithelial cells adopt characteristics of mesenchymal cells. Epithelial-to-mesenchymal transition (►EMT) is a physiological process during normal development and a pathological process during cancer progression and fibrosis.

Characteristics

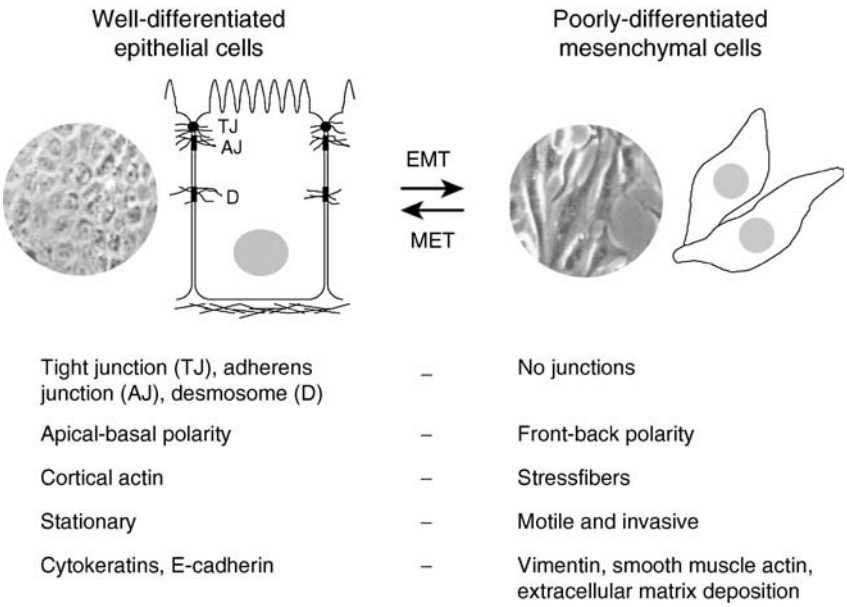
Epithelial cells line the external surfaces and internal cavities of the body. A distinguishing characteristic of epithelial cells is the presence of junctional complexes, such as ►tight junctions, ►adherens junctions, and desmosomes and segregation of the plasma membrane into apical and basolateral domains. These features promote adhesion, restrict motility, facilitate intercellular communication, and permit individual cells to function as a cohesive unit. The phenotype of epithelial cells cultured in vitro or in tissues is often described as well-differentiated (Fig. 1, left panel).

Mesenchymal cells are spindle-shaped with fibroblast-like morphology, lack adhesiveness, and are highly motile. They do not have junctional complexes and specialization of the plasma membrane into apical and basolateral domains. When cells of epithelial origin show a mesenchymal phenotype under in vitro culture conditions or in tissues they are often described as poorly differentiated (Fig. 1, right panel).

The plasticity of epithelial cells enables them to convert between the epithelial and mesenchymal phenotypes. These phenotypic transformations are highly regulated by specific signaling events and molecules. Conversion of the epithelial cell to a mesenchymal phenotype is known as EMT and vice versa as mesenchymal-to-epithelial transition (►MET). EMT and MET occur during normal development as well as in cancer progression.

EMT provides a mechanism for epithelial cells to overcome the physical constraints imposed upon them by intercellular junctions and to adopt a motile phenotype. The process was originally identified during specific stages of embryogenesis in which epithelial cells migrate and colonize various embryonic territories to form different organs. EMT is critical for the formation of ectoderm, mesoderm, and endoderm during gastrulation as well as for the differentiation of neural crest cells into neurons and glia of the peripheral nervous system. During embryogenesis EMT is spatially and temporally regulated in a subtle manner that is essential for normal organ development.

EMT during cancer progression occurs in an aggressive and uncontrolled fashion and might facilitate the invasive and metastatic potentials of cancer cells. The phenotypic conversion of epithelial cells to mesenchymal cells involves a series of events that includes dissolution of tight junctions, adherens junctions, and desmosomes, the suppression of molecules involved in restricting invasiveness and motility, and induction of factors that promote invasiveness and motility. A characteristic feature of cells undergoing EMT in culture is the change in the organization of the ►actin



Epithelial-to-Mesenchymal Transition. Figure 1 Transitions between well-differentiated epithelial cells and poorly differentiated mesenchymal cells during EMT. *Left panel*, phase contrast microscopy and schematic diagram of well-differentiated polarized epithelial cells with characteristic apical-basolateral polarity and junctional complexes. *Right panel*, cells that have undergone EMT display mesenchymal morphology with no junctions and are highly motile and invasive. The process of reversion of mesenchymal cells to an epithelial phenotype is called mesenchymal to epithelial transition (MET).

cytoskeleton. In most cases stress fibers are induced with a concomitant loss of the cortical actin ring. Although it is established that such morphological changes accompany EMT, the chronology of these events is still not deciphered. It is also not known whether all these changes are essential for induction of EMT and the metastatic potential of cancer cells.

Mechanisms

EMT is in part achieved by downregulation of epithelial specific molecules and induction of proteins expressed in mesenchymal cells. One of the epithelial cell molecules extensively studied that change during EMT is the cell–cell adhesion molecule ►E-cadherin. During epithelial morphogenesis, E-cadherin regulates the establishment of adherens junctions, which form a continuous adhesive belt below the apical surface. The extracellular domain of E-cadherin mediates calcium-dependent homotypic interactions with E-cadherin molecules on adjacent cells and the intracellular domain binds cytosolic catenins and links the E-cadherin complex to the actin cytoskeleton. A stable E-cadherin complex at the plasma membrane is essential for the cell–cell adhesion function of this protein.

Several studies have shown that expression of E-cadherin is reduced during EMT, associated with the loss of junctional complexes and the induction of a mesenchymal phenotype of carcinoma cells. It is believed that the decrease in adhesive force following reduced expression of E-cadherin facilitates invasion and dispersion of carcinoma cells from the primary tumor mass. Methods to abolish E-cadherin function promote epithelial cell invasion into a variety of substrates, as determined by a number of in vitro and in vivo experimental systems. Loss or reduced expression of E-cadherin is also accompanied by expression of mesenchymal markers such as vimentin, smooth muscle actin (►SMA), γ-actin, β-filamin, and talin and extracellular matrix (►ECM) components such as fibronectin and collagen precursors. Upregulation of these proteins facilitates cytoskeletal remodeling and promotes cell motility (Table 1).

The diverse molecular mechanisms mediated by growth factors and ECM proteins contribute to EMT. Growth factors such as epidermal growth factor (EGF), hepatocyte growth factor (HGF), or insulin-like growth factor II (IGF-II) promote signaling cascades through their cognate receptor tyrosine kinases, which in turn signal through various downstream effector molecules such as Ras, Src, phosphatidylinositol-3-kinase (PI3K) and MAPK leading to EMT. In addition, signaling pathways essential for stem cell function during development such as the ►Wnt, ►Notch, and ►Hedgehog signaling pathways are activated during EMT. The role of Wnt signaling has been well established during normal development as well as in EMT. Binding of the soluble ligand Wnt to its receptor frizzled inhibits β-catenin degradation and facilitates its nuclear

translocation together with the TCF/LEF transcription factors to activate transcription of target genes such as cyclin D1 and Myc. The transcriptional activity of β-catenin is increased in a wide variety of cancers as well as in growth factor-induced EMT of cultured cells.

A key molecule involved in the induction of EMT and extensively studied is the ►transforming growth factor-β ►(TGF-β). The ►TGF-β growth factor superfamily comprises TGF-βs, bone morphogenetic proteins (BMPs), activins, and other related proteins. TGF-β induces EMT in epithelia either through transcriptional or transcription-independent mechanisms. Cooperation between TGF-β and Ras/Raf/MEK/MAPK signaling is involved in the induction and maintenance of EMT. TGF-β has been shown to stimulate ERK1/2 activity in cell culture models of EMT that is required for the disassembly of junctional complexes and the induction of motility. TGF-β also activates PI3K in a RhoA-dependent manner, which has been implicated in the disassembly of tight junctions. In keratinocytes and several epithelial cell types, TGF-β treatment activates the Notch pathway by inducing the Notch ligand *jagged1* and the Notch target genes TLE3, HEY1, HEY2, HES1 at the onset of EMT. TGF-β, in cooperation with oncogenic Ras, induces EMT by the activation of the transcription factor ►nuclear factor κB (NF-κB). Constitutive activation of NF-κB induces EMT and metastasis, whereas inhibition of NF-κB by inhibitory IκBa suppresses EMT and metastasis in a breast tumor model. Although in different cell types TGF-β induces various signaling pathways, these signals subsequently target E-cadherin expression and the disassembly of epithelial junctional complexes to induce EMT. For example, the TGF-β type I receptor is localized to tight junctions through the tight junction protein occludin allowing for efficient ►TGF-β-dependent dissolution of tight junctions during EMT. The epithelial polarity protein Par-6 interacts with the TGF-β type I receptor and TGF-β binding initiates Par-6 phosphorylation and activation of the E3-ubiquitin ligase, Smurf-1. Activated Smurf-1 promotes degradation of local RhoA resulting in tight junction dissociation, inhibition of cell adhesion and transition to a mesenchymal phenotype.

The signaling cascades described earlier induce two major types of transcriptional regulators that mediate EMT, zinc finger (►Snail, Slug, ZEB-1, ZEB-2), and basic helix-loop-helix (Twist, E12/E47) proteins. The transcription suppressors SNAI1 (Snail) and SNAI2 (Slug) play a central role in the induction of EMT. These zinc finger proteins recognize E-box elements in the cognate target promoters and SNAI1 represses the transcription of the E-cadherin gene during EMT as well as embryonic development. Factors that regulate SNAI1 by phosphorylation, subcellular localization, and transcription have been well-described in development and EMT. While phosophorylation of SNAI1 in the two GSK3β phosphorylation consensus motifs targets it for export from the nucleus (motif 2) and ubiquitinylation and degradation (motif 1), phosphorylation of SNAI1 at Ser^{246} by p21-activated kinase (PAK1) results in its accumulation in the nucleus and induction of EMT.

LIV-1, an estrogen-regulated member of the LZT subfamily of zinc transporters is activated by STAT3, which is essential for nuclear localization of SNAI1 and suppression of E-cadherin expression during gastrulation in zebrafish embryos. Further, SNAI1 expression is transcriptionally suppressed by metastasis-associated gene 3 (MTA3), a subunit of the Mi-2/NuRD transcriptional corepressor, thereby establishing a mechanistic link between estrogen receptor status and invasive growth of breast cancers. While there is great deal of knowledge about SNAI1 regulation, much less is known about SNAI2. It has been shown that SNAI2 suppresses E-cadherin expression when ectopically expressed in well-differentiated epithelial cells. HGF and FGF induce SNAI2 to suppress desmoplakin and desmoglein thereby destabilizing desmosomes. The SMAD-interacting repressors SIP-1/ZEB2 and δEF1/ZEB1 that can be induced by TGF-β bind to the E-cadherin promoter to suppress its transcription. The basic helix-loop-helix transcription factors involved in the induction of EMT are E12/E47 (E2A gene product) and Twist, both of which have been shown to repress E-cadherin expression and induce EMT. The mechanisms by which these factors suppress E-cadherin expression are not well-established.

Clinical Relevance

Although EMT represents a fundamentally important process for tumor dissemination and is widely believed to be an essential event involved in cancer metastasis, there are several lines of evidence to suggest that many invasive and metastatic carcinomas have not undergone a complete transition to a mesenchymal phenotype. Many advanced carcinomas of prostate, breast, squamous cell carcinomas derived from a variety of origins, including the esophagus, oral epithelium, lung, cervix, and salivary neoplasms possess molecular and morphological characteristics of well-differentiated epithelial cells, with the presence of epithelial junctions and apical-basolateral plasma membrane asymmetry. High E-cadherin expression was also observed in a wide variety of carcinomas and E-cadherin levels did not correlate with invasiveness and metastasis. These results are consistent with the idea that complete EMT might not be necessary for cancer cell metastasis or that cancer cells redifferentiate to an epithelial phenotype following metastasis.

While EMT is well established in cultured cells there is no evidence for EMT in vivo and if EMT occurs it is not known at what stage of tumor progression. There are several possibilities by which cancer cells could spread without undergoing complete EMT: (i) Incomplete EMT by which epithelial cells partially convert to a mesenchymal phenotype acquiring invasive and metastatic potential. (ii) Cohort migration in which well-differentiated epithelial cells migrate as a cluster and cause metastasis. (iii) Reversion of poorly differentiated cells to a well-differentiated phenotype by MET at the site of metastasis. These diverse mechanisms might be regulated by the tumor microenvironment and/or signaling pathways distinct from the molecular machinery of EMT. Thus, there are several mechanisms by which cancer cells could metastasize and EMT may represent one of the global changes associated with malignant transformation of epithelial cells.

Recognizing EMT as a fundamentally important process for tumor dissemination together with the increasing knowledge about the molecular pathways leading to EMT may offer new targets for therapeutic intervention. Inhibitors of the TGF-β, ERK1/2 and PI3K/Akt pathways have shown encouraging results in the suppression of tumor progression. Further understanding of the molecular requirements of EMT will allow for more effective approaches for future therapeutic intervention.

Epothilone B Analogue

Robert P. Whitehead
Department on Medicine, Division of Hematology/Oncology, University of Texas Medical Branch, Galveston, TX, USA

Synonyms

Aza-epothilone B; BMS-247550; Ixabepilone; NSC 710428

Definition

The epothilone B analogue, ixabepilone, is the term used to denote one specific agent of a new class of anticancer drugs, the epothilones. The epothilones A and B are derived from fermentation of the myxobacteria *Sorangium cellulosum*. They have been found to have potent cytotoxic activity, which, like that of the taxanes, has been linked to stabilization of cellular microtubules resulting in the blocking of cell division at the ►G2/M transition portion of the cell cycle. The epothilone B analogue ixabepilone is a semi-synthetic analog of the natural product epothilone B, made by replacing the lactone oxygen of epothilone B with a lactam (azo-epothilone B) designed to overcome the metabolic instability of the natural product.

Chemical Name: [1S-[1R*,3R*(E),7R*,10S*,11R*,16S*]]-7,11-Dihydroxy-8,8,10,12,16-pentamethyl-3-[1-methyl-2-(2-methyl-4-thiazolyl)ethenyl]-17-oxa-4-azabicyclo[14.1.0] heptadecane-5,9-dione.

Molecular Formula: $C_{27}H_{42}N_2O_5S$ M.W.: 506.7 g/mole

Characteristics

Introduction

The epothilones A and B, are a new class of anticancer agents isolated in the mid 1990's. They are in the macrolide class of drugs but have a mechanism of action similar to the taxanes. ►Paclitaxel, the first taxane to be widely used, was found in 1971 in a screening assay for antitumor agents. It is a complex diterpene compound. Its cytotoxic activity derives from its binding to cellular microtubules stabilizing them and preventing the dynamic growth and shrinkage that

occurs during normal cellular processes. In dividing cells, this leads to mitotic arrest and cell death by causing a block at the transition between G_2 and M phase of the cell cycle. Paclitaxel has been found to have important clinical activity against breast, ovarian, lung, and head and neck cancers. However some tumors such as colorectal cancer have innate resistance to this agent. Other tumors develop resistance to paclitaxel through the multidrug resistance mechanism in which ►P-glycoprotein removes cytotoxic agents from the tumor cell, or by genetic mutations leading to altered tubulin protein. Side effects such as ►neutropenia and ►peripheral neuropathy can limit its activity and usefulness in the clinic. Its low solubility requires that paclitaxel be administered in a Cremophor vehicle which itself can induce hypersensitivity reactions. Modifications to paclitaxel to improve its solubility or reduce side effects are difficult because of its complex ring structure. Therefore when the epothilones A and B were found to have a mechanism of action similar to the taxanes, it was hoped that they might lead to more effective anticancer agents. It was found that the epothilones did show important cytotoxic activity against tumor cells when tested in *in vitro* cell assays, but when tested in *in vivo* models of cancer, only modest antitumor activity was present. This was found to be due to poor metabolic stability, and other unfavorable characteristics. To overcome these problems, multiple semisynthetic analogues of the epothilones were made and tested. One of these analogues, BMS-247550, epothilone B analogue, or ixabepilone, was found to be the most effective epothilone in a variety of laboratory assays and was also active in paclitaxel resistant tumor models. It has now been tested in the clinic and has been found to have activity in a variety of clinical cancers.

Preclinical Testing

Ixabepilone has shown potent cytotoxic activity when tested against a broad panel of tumor cell lines *in vitro*, including human ►ovarian carcinoma, ►colon carcinoma, breast, prostate, lung, ►squamous cell carcinoma, human leukemia, and mouse ►lung carcinoma. The concentration of drug at which 50% of the tested cells were killed (IC_{50}) ranged from 1.4–34.5 nM. Included in this panel were cell lines resistant to paclitaxel by either Multi-Drug Resistance (MDR) due to P-glycoprotein overexpression, or due to mutations of β-tubulin, the two most common mechanisms of resistance to paclitaxel. Ixabepilone is more potent than paclitaxel in causing tubulin polymerization and has similar activity to that of the parental compounds, epothilones A and B. Ixabepilone maintained its activity in whole animal systems. Using paclitaxel sensitive human ovarian or colon tumor cell lines in the nude mouse models, ixabepilone produces comparable ►log cell kill and tumor growth delay as paclitaxel while in nude mouse or rat tumor models using paclitaxel resistant human ovarian, breast, colon, or ►pancreatic cancer cell lines, ixabepilone produced much greater tumor log cell kill and tumor growth delay than did paclitaxel. In contrast to paclitaxel which is usually ineffective when given orally, ixabepilone was also active in paclitaxel resistant human ovarian cancer and paclitaxel sensitive human colon cancer nude mouse models when given by the oral route.

E

Phase I Studies in Cancer Patients

In animal studies, the main toxicities of ixabepilone were related to the gastrointestinal tract, peripheral neuropathy, and bone marrow toxicity. Similar to the taxanes, when tested in cancer patients, ixabepilone required the same solvent for i.v. use, a Cremophor-based formulation (ethanol plus polyoxyethylated castor oil) which can lead to hypersensitivity reactions. After this type of reaction occurred in a patient, subsequent patients were prophylactically treated with histamine-1 (H1) and histamine-2 (H2) blockers. Schedules tested included an every 21 day cycle, weekly administration, a daily times 5 every 21 day cycle, and a daily times 3 every 21 day cycle. In each of these schedules, the drug was administered by the intravenous route. All of the phase I trials showed antitumor responses. These occurred in patients with breast, non-small cell lung, and ovarian cancer, and ►melanoma. Some of these patients had previous treatment with paclitaxel or ►docetaxel.

The 21 day cycle trials consisted of a 60 min i.v. infusion on day 1 repeated every 21 days. The dose limiting toxicities for this schedule were neutropenia and sensory neuropathy. One study recommended a phase II dose of 50 mg/m^2 and another trial of the same schedule suggested 40 mg/m^2 as the phase 2 dose. Most subsequent trials have used the lower dose. Other toxicities commonly seen with this schedule included fatigue, arthralgias, myalgias, and vomiting.

With treatments using weekly infusions or daily times five or daily times three infusions, maximum tolerated doses were lower. Neutropenia, sensory neuropathy, fatigue, and hypersensitivity reactions were seen with the weekly schedules. With the daily times five or three schedules, dose limiting toxicity was neutropenia with fewer hypersensitivity reactions and less severe neurotoxicity.

In patients given a 1-h infusion of ixabepilone, there was found to be bundling of microtubules in the peripheral blood mononuclear cells and this correlated with the plasma area under the curve, the concentration of drug measured in the blood multiplied by the time it is present. Similar microtubule bundle formation was seen in ►breast tumor cells obtained from a chest wall mass in a patient who showed a partial response after receiving drug on the 1 h infusion schedule. This

patient was taxane refractory and the tumor expressed multi-drug resistance protein. Cell death occurred in these tumor cells 23 h after the peak formation of microtubule bundles.

Phase II Studies in Cancer Patients

There is data from some phase II trials of ixabepilone in cancer patients. With ixabepilone given by a 1 or 3 h infusion on an every 21 day schedule, responses have been seen in a modest number of ►gastric or ►breast cancer patients previously treated with a taxane or ►non-small cell lung cancer patients who had previously received a platinum-based regimen. In breast cancer patients who were previously treated but had not received a taxane, a higher response rate of 34% was seen. A trial in colorectal cancer patients who had previously received an ►irinotecan-based regimen did not show any responses.

Multicenter phase II trials in the Southwest Oncology Group of ixabepilone in previously untreated patients with advanced pancreatic cancer or chemotherapy-naïve patients with hormone-refractory ►prostate cancer have shown encouraging results that suggest that further testing is warranted.

Summary and Future Outlook

The epothilone B analog ixabepilone is a cancer therapeutic agent with a mechanism of action similar to the taxanes, stabilization of cellular microtubules leading to mitotic arrest and cell death. However it demonstrates anti-tumor effects against both taxane-sensitive and taxane-resistant tumors and is clinically active against a broad spectrum of tumor types. Further testing as a single agent or in combinations in previously untreated patients is needed. Phase III trials in which it is compared to standard regimens will further define its role in cancer treatment. Ixabepilone is felt to be an important new anti-cancer agent that may surpass the taxanes in usefulness.

Epothilones

Definition

Are a group of microtubule-targeting agents, like ►taxanes, and ►vinca alkaloids. Epothilones were originally identified as metabolites produced by the common soil myxobacterium *Sorangium cellulosum*. They were found initially to have a narrow antifungal spectrum, but they also were found too toxic for use as an antifungal. Subsequently, their anticancer properties were detected. They are important and powerful options in the management of breast cancer and prostate cancer. The epothilones are a new class of cytotoxic molecules, including epothilone A, epothilone B, and epothilone D, identified as potential chemotherapy drugs. Early studies in cancer cell lines and in human cancer patients indicate superior efficacy to the taxanes. Their mechanism of action is similar to that of the taxanes, but their chemical structure is simpler and they are more soluble in water. Although taxane-based therapy has been used successfully, its effectiveness is often compromised by the emergence of ►drug resistance. Efforts to overcome drug resistance have led to the discovery of several novel anti-►microtubule agents, including the epothilones. Epothilones exhibit broad antitumor activity similar to that of the taxanes, but they are less sensitive to known resistance mechanisms. The ongoing development of microtubule-targeting agents provides new strategies for overcoming taxane resistance and may improve clinical efficacy and patient outcomes.

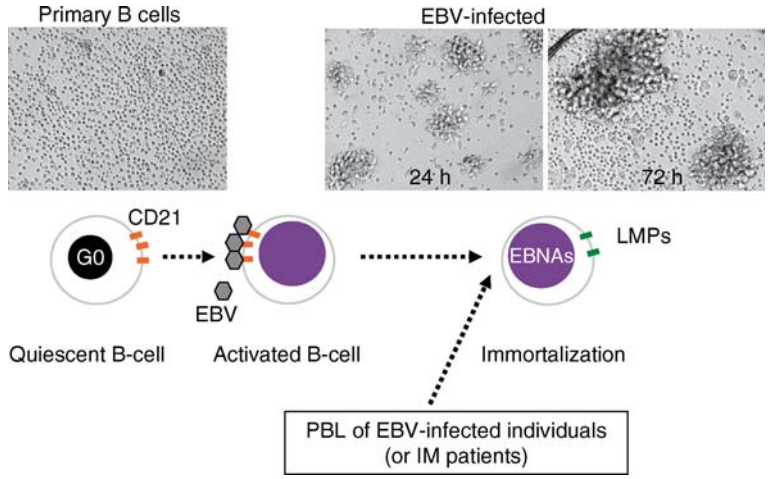
Epstein-Barr Virus

Evelyne Manet
INSERM U758, Ecole Normale Supérieure de Lyon, Lyon, France

Synonyms
Human Herpes virus 4; HHV4

Definition
Epstein-Barr Virus (EBV) was the first virus isolated from a human tumor, the Burkitt's lymphoma (BL). EBV is a lymphotropic γ-herpesvirus widely spread in the human population: 90–95% of adults have antibodies against the virus. In the majority of cases, the primary infection occurs within the first 3 years of life and is asymptomatic. When EBV infection occurs later in life, usually during adolescence, it results in the symptomatic illness known as Infectious Mononucleosis (IM). Infected individuals carry the virus all their life, in a very low number of lymphoid B cells (probably resting B cells) in their peripheral blood and lymphatic organs. Intermittent viral shedding occurs into the saliva, due to viral replication in the oropharyngeal lymphoid or epithelial tissues: saliva is the main transmission route of the virus. Since its first discovery in 1964 in a Burkitt's lymphoma tumor, EBV has been found to be associated with several other human malignancies including the undifferentiated ►nasopharyngeal carcinoma (NPC), ►Hodgkin's disease, rare T-cell and Natural killer (NK)-cell lymphomas, gastric carcinomas and B and T cell lymphomas in immuno-compromised individuals. A characteristic unique to EBV is its capacity to induce the indefinite proliferation or immortalization of quiescent B lymphocytes, upon their infection *in vitro*.

Characteristics
In vitro Immortalization of Primary B Cells by EBV: The Growth Transcription Program
In vitro, infection of B cells by EBV is not productive but results in the outgrowth of latently infected ►lymphoblastoid cell lines (LCL) (Fig. 1). Such cell lines can also be obtained by culture of peripheral blood



Epstein-Barr Virus. Figure 1 Immortalization of B cells by EBV. EBV infection of resting primary human B-cells *in vitro* causes cell cycle entry of the infected cells, establishment of latent viral infection and conversion of the cell culture into permanently growing lymphoblastoid cell lines (LCLs), which progress to a fully immortalized state. Such LCLs can also be obtained by culture of PBL from individuals infected by EBV (mostly IM patients). The first step of infection is the interaction of the EBV gp350 glycoprotein with its receptor, the CD21. This induces a decondensation of the chromatin, a prerequisite for expression of a subset of the viral genes that cooperate to induce B cell proliferation and the expression of several cellular activation markers and adhesion molecules. These latency genes code for three nuclear proteins, the Epstein-Barr virus nuclear antigens (EBNA1, -2, -3A, -3B, -3C, -LP), three integral membrane proteins (LMP1, LMP2A, LMP2B) plus two non-polyadenylated small nuclear RNAs (EBERs). The EBV genome is maintained in these proliferating cells as multiple extrachromosomal episomes and is replicated by cellular proteins, concomitantly with the cellular genome, via a DNA replication origin called ►*oriP*.

Epstein-Barr Virus. Table 1 EBV gene latency transcription programs

Transcription program	Type of latency	EBV genes expressed	Occurrence
Growth	III	EBNA1, 2, 3a, 3b, 3c, LP, LMP1, LMP2a and LMP2b	PTLD, Immunoblastic lymphoma (HIV)
Default	II	EBNA1, LMP1 and LMP2a	HD, NPC, Gastric carcinoma
EBNA 1 only	I	EBNA1	BL, PEL
Latency	0	None	Memory B cells in peripheral blood

PTLD: Post transplant lymphoma disease; HD: Hodgkin's disease; NPC: Nasopharyngeal carcinoma; BL: Burkitt's lymphoma; PEL: Primary effusion lymphomas.

lymphocytes (PBL) from naturally infected individuals. The phenotype of LCLs (i.e. morphology and cell surface markers) is very similar to that of antigen activated B cells, and a limited set of viral gene products is expressed: six nuclear proteins, the Epstein-Barr Nuclear Antigens (EBNA-1, -2, -3A (or -3), -3B (or -4), -3C (or -6) and -LP (or -5), three integral membrane proteins (LMP-1, -2A (or TP-1) and -2B (or TP-2) and two small non-polyadenylated nuclear RNAs (EBER-1 and EBER-2). This expression profile is referred to as the growth transcription program or ►latency III (Table 1). In such immortalized cell lines, the viral DNA (a 172 kpb double-stranded DNA molecule) is maintained in the nucleus as multiple extrachromosomal copies of the viral episome. Among the nine proteins expressed in latency III, EBNA-1, -2, -3A, -3C, -LP and LMP-1 are essential for efficient transformation/immortalization of B-lymphocytes *in vitro*. These proteins are thought to cooperate for the initiation and maintenance of B cell proliferation *in vitro*.

EBNA-1 is a sequence-specific DNA-binding protein which binds to the EBV origin of replication (►*OriP*). This interaction is required for viral DNA replication and for equilibrated distribution of the EBV episomes to the daughter cells during cell division. EBNA-1 may have other roles in EBV-induced oncogenesis as EBNA-1 transgenic mice display an increased incidence of B-cell lymphoma.

EBNA-2 is a transcriptional activator which regulates the expression of all EBV genes expressed in

►latency III as well as certain cellular genes including CD21, CD23 and cfgr. EBNA-2 does not bind DNA directly but is recruited to EBNA2-responsive elements by the cellular sequence-specific DNA-binding factor RBP-Jκ (also called CBF-1). As RBP-Jκ is part of the Notch signalling pathway, EBNA-2 may mimic part of notch signal transduction (►NOTCH/JAGGED Signaling in Neoplasia). Although the exact function of EBNA-LP is still unknown, this nuclear factor has been found to cooperate with EBNA-2 for the transcriptional activation of the LMP-1 gene. Furthermore, co-expression of EBNA-2 and EBNA-LP in primary resting B cells previously activated through binding of the EBV glycoprotein gp350 to the EBV receptor CD21, induces Cyclin D2 expression and drives resting B lymphocytes into the G1 phase of the cell cycle.

EBNA-3A, -3B and -3C are related proteins but only -3A and -3C are essential for B-cell immortalization by EBV *in vitro*. However, these proteins have at least one common function: repression of EBNA2-activated transcription by directly contacting RBP-Jκ and inhibiting its binding to DNA. Furthermore, EBNA-3C is able to cooperate with activated (Ha)-Ras (►RAS), to induce the proliferation of primary rat fibroblasts.

LMP-1 (►Epstein-Barr Virus Latent Membrane Protein 1) is an integral membrane protein with a very short 24 aa N-terminal cytoplasmic domain, six membrane spanning hydrophobic segments and a 200 aa cytoplasmic C-terminal domain. LMP-1 transforms rodent fibroblast cell lines and Rat-1 cells expressing LMP-1 are tumorigenic in nude mice. LMP-1 acts as a constitutively activated member of the tumor necrosis factor receptor (TNRF) superfamily. It activates NF-κB transcription factor activity through a pathway that involves the recruitment of TNF-RI receptor-associated factors (TRAFs). It also induces ►AP-1 transcription factor activity via triggering of the c-jun N-terminal kinase (JNK). The STAT-1 transcription factor has also been shown to be a target of LMP1 which induces STAT-1 phosphorylation and thus its subsequent transfer to the nucleus.

LMP-2A is an integral membrane protein with a 119 aa hydrophilic N-terminal cytoplasmic tail which contains Immunoreceptor Tyrosine-based Activation Motifs (ITAMs) followed by 12 transmembrane domains and a 27 aa hydrophilic C-terminus. LMP-2B differs from LMP-2A by the lack of the N-terminal cytoplasmic domain. Although dispensable for in vitro immortalization of B-lymphocytes LMP-2A has an important role in the biology of EBV *in vivo* (see below) in mimicking the presence of a B-cell receptor (BCR) and providing important survival signals for B-cells.

EBV Biological Cycle in Vivo

Although understanding of EBV infection biology *in vivo* is still rudimentary, it is believed to mimic the normal B cell response to environmental antigen. EBV transits the epithelium and infects naïve B cells in the underlying tissue. Expression of the latency genes (transcription growth program: Table 1) causes the cell to become activated, proliferate and migrate to the follicle. After this initial clonal expansion, some EBV-infected cells undergo germinal center reactions. EBV transcription is then limited to EBNA-1, LMP-1 and LMP-2 expression (the default transcription program: Table 1). These germinal center B cells will then differentiate into memory B cells in which EBV expression is turned off (latency program: Table 1). These cells constitute the long-term reservoir of EBV. The lytic viral cycle can be reactivated in these cells by signals that cause B cells to differentiate into antibody-secreting plasma cells (through antigen stimulation) and migrate to the mucosal epithelium allowing the release of viral particles in the saliva, the main route for transmission of the virus between individuals.

Although EBV is considered to be a B-lymphotropic virus, it can also infects epithelial cells *in vitro* and is found in several EBV-associated carcinomas *in vivo*. A role of the epithelial cells of the oropharynx in the amplification of virus production *in vivo* has long been suspected but not yet demonstrated.

Viral Productive Cycle

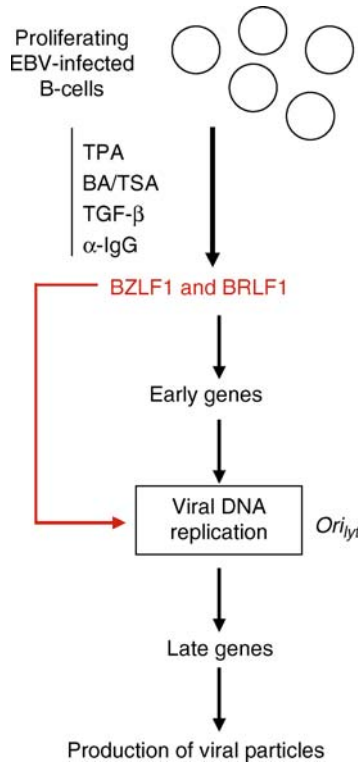
In vitro, the lytic productive cycle can be induced in EBV-infected cell lines (either LCL or cell lines established from Burkitt's lymphoma) by treatments of the cells with various agents such as the phorbol ester TPA, butyric acid (BA) or cross-linking of surface immunoglobulin etc. A key mediator of the entry into the productive cycle is the viral-encoded transcription factor BZLF1 (also called EB1, Zta and Zebra) which activates both transcription of all the EBV early genes and DNA-replication from the replication origins (►Ori_{lyt}) active during the lytic cycle (Fig. 2).

Clinical Relevance

EBV is associated with several human malignancies both in immuno-compromized and immuno-competent individuals.

In immuno-depressed individuals – post-transplant patients or AIDS (Acquired Immunodeficiency Syndrome) patients – EBV is probably directly involved in the appearance of immunoblastic B-lymphomas (in AIDS patients) or posttransplantation lymphoproliferative diseases (PTLDs) (in patients undergoing organ transplantation) due to the loss of normal cytotoxic T cell surveillance. These lymphomas are monoclonals or polyclonals and the cells usually express the full set of EBV genes found in LCLs proliferating in culture (latency III, Table 1).

In immuno-competent individuals EBV is associated with several cancers. Endemic Burkitt's lymphoma (BL) is found in certain parts of Africa and South



Epstein-Barr Virus. Figure 2 The EBV replicative cycle. The EBV lytic replication program can be induced *in vitro* by treatment of proliferating EBV-infected B cells with various chemicals, crosslinking of the surface immunoglobulins or by expression of the EBV transcriptional activator EB1 (also called Zta or ZEBRA), product of the BZLF1 gene. In cooperation with another viral transcriptional factor (also called R or Rta), product of the BRLF1 gene, EB1 activates the expression of all the EBV early genes. EB1 also directly stimulates viral DNA replication which is dependent on viral proteins (a DNA-polymerase, a polymerase processivity factor, a single-stranded DNA binding protein, a primase and a helicase/primase associated protein). This viral DNA replication is initiated at replication origins, called ori_{lyt}, which are different from the one used during latency. This lytic replication program leads to amplification of the viral genome, synthesis of structural viral proteins and the assembly of infectious virus particles.

America where malaria – which appears to act as a cofactor – is also endemic, and affects mainly children from 7 to 9 years old. In these regions, BL is associated with EBV in more than 90% of cases. In lower incidence regions the association is only found in 20–30% of cases. BL is a monoclonal tumor characterized by a translocation of the c-myc gene (►Myc Oncogene) to one of the immunoglobulin loci which results in an altered regulation of c-myc. The expression of EBV in the tumor cells is limited to EBNA-1, the EBER RNAs, plus several transcripts from the BamHI A region of EBV, also called Complementary Strand Transcripts (CST). This profile of expression is defined as ►latency I (Table 1). ►Burkitt's lymphoma cell lines can be readily established from tumor biopsies. On the contrary to LCLs, these cells are tumorigenic in nude mice. However, after several passages of these cells in culture, the expression profile of the EBV genes has been shown to derive towards a latency III profile.

In ►Hodgkin's disease, EBV is present in the Reed-Sternberg cells (►Hodgkin and Reed-Sternberg cells), in about 40% of cases, mostly of the mixed cellularity type. Expression of EBV in Hodgkin's disease is characteristic of latency II (Table 1).

EBV is also found associated with rare but specific types of nasal T-cell lymphomas more common in Southeast Asian populations and also natural-killer (NK) cell (►Natural killer cells) lymphomas. These types of lymphomas seem to arise either after acute primary infection or in some cases of chronic active EBV infection. The EBV expression profiles in these tumors are characteristic of latency I/II (Table 1).

EBV is also associated with a variety of carcinoma and in particularly the undifferentiated nasopharyngeal carcinoma (►Nasopharyngeal carcinoma) (NPC). NPC is associated with EBV in almost 100% of cases worldwide and is particularly common in areas of China and South-east Asia. Genetic disposition as well as environmental cofactors such as dietary components are thought to be important in the aetiology of NPC. EBV gene expression in NPC epithelial cells consists of EBNA-1, the EBER RNAs and LMP-1, LMP-2A/-2B (in 65% of cases) plus the CSTs (Complemetary Strand transcripts). This profile of expression is similar to latency II (Table 1). Several factors suggest that a reactivation of EBV (i.e. entry into the lytic cycle) precedes or accompanies the development of NPC. EBV is also found in about 10% of gastric adenocarcinomas (►Gastric cancer) with a pattern of expression of EBV genes similar to that observed in NPC.

The exact role of EBV in the development of these different tumors is not yet understood and both environmental and genetic cofactors also contribute. However, the fact that the EBV genome is present in the great majority of the cells in EBV-associated malignancies and the demonstration that the virus is present in the tumor cells at a very early stage, argue for a causative role for EBV in these cancers.

Epstein–Barr Virus Latent Membrane Protein 1

Martina Vockerodt
Department of Pediatrics I, Children's Hospital, Georg-August University of Goettingen, Goettingen, Germany

Definition

The latent membrane protein 1 (LMP1) of the ►Epstein–Barr virus (EBV) is an ►oncogene that is expressed during latent EBV infection. LMP1 sufficient for the transformation of rodent fibroblast cells and is essential for efficient B ►cell transformation. LMP1 mimics a constitutively active tumor necrosis factor (TNF) receptor and interacts with and deregulates the ►signal transduction network of the host cell leading to altered cell survival, differentiation, and phenotypic changes.

Characteristics

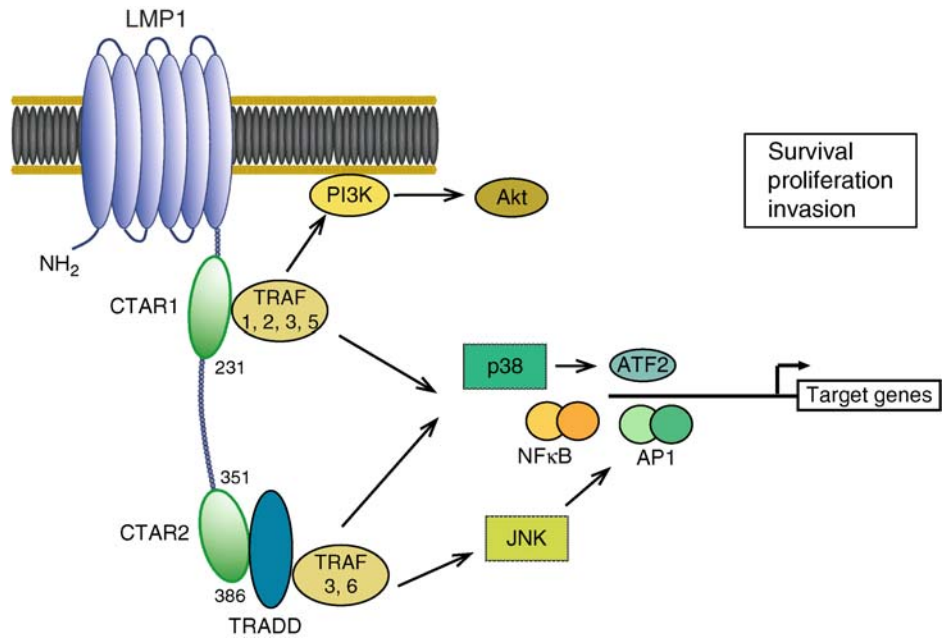
EBV belongs to the family of gamma herpes viruses; it infects humans and establishes a latent infection for the lifetime of the individual. Infection in childhood is usually asymptomatic, but in young adults can lead to infectious mononucleosis. Due to its association with ►B cell tumors as Burkitt lymphoma (BL), ►Hodgkin disease/lymphoma (HL), posttransplant lymphoproliferative disorder, and epithelial tumors as nasopharyngeal carcinoma (NPC) and gastric carcinoma, EBV was the first human tumor virus to be discovered and is now classified as a Group 1 carcinogen by the WHO. In vivo, EBV does usually not replicate in B lymphocytes, but instead establishes a latent infection with defined expression of the virus latent genes. In vitro, EBV infection leads to continuously proliferating lymphoblastoid cell lines (LCLs) and a different expression pattern of virus latent genes. The virus genes influence both viral and cellular transcription in the host cell. Among them LMP1 is essential for B cell transformation in vitro and behaves as a classical oncogene in rodent fibroblast transformation assays. When expressed in the B cell compartment of transgenic mice, LMP1 induces the development of B cell lymphoma whereas its expression in the murine epidermis results in hyperplasia. It is interesting to note that expression of LMP1 is variable among EBV-associated tumors, being always present in EBV-associated Hodgkin lymphoma, almost always absent in virus-positive Burkitt lymphoma and variably present in NPC.

Structurally, LMP1 is a 66kDa integral membrane protein consisting of 386 amino acids. It can be divided into three domains: A short cytoplasmic amino-terminus of 24 amino acids; a transmembrane domain consisting of six transmembrane helices which oligomerize to form membrane patches; and a carboxy terminal cytoplasmic domain of 200 amino acids. The cytoplasmic domain contains two carboxy terminal activating regions (CTARs), also known as transformation effector sites (TES). The CTARs are critical for EBV transforming activity; while CTAR1/TES1 is essential for initial B cell transformation, CTAR2/TES2 mediates growth factor-like signals which are required for long-term outgrowth of EBV infected cells. The region between CTAR1 and CTAR2, sometimes referred to as CTAR3, is not required for B cell ►immortalization.

Mechanisms

Cell transformation requires activation of the host cell signaling machinery. LMP1 mediates this activation by recruiting molecules of the TNF receptor and ►toll-like receptor family (Fig. 1). CTAR1 interacts with the TNF receptor-associated factors (TRAF) 1, 2, 3, and 5 through the PxQxT binding motif of LMP1. Recruitment of TRAF molecules to CTAR2 may be mediated indirectly through binding of the TNF receptor-associated death domain protein (TRADD), although much of CTAR2-mediated ►nuclear factor kappa B (NF-κB) activity has been shown to be TRADD-independent (Fig. 1).

These adaptor proteins subsequently recruit multiprotein complexes containing the NF-κB-inducing kinase (NIK) and the I-κB kinases (IKKs). This results in the activation of the canonical I-κB-dependent NF-κB pathway (involving p50-p65 heterodimers) and the noncanonical pathway, leading to the processing of p100 to generate p52-p65 heterodimers. While activation through the CTAR1 domain of LMP1 is mediated by the noncanonical NF-κB pathway, CTAR2 appears to activate the canonical pathway by utilizing TRAF6 and TAK1. CTAR2 is also important in activating the c-Jun N-terminal kinase (►JNK) leading to activation of the transcription factor ►AP-1. The phosphatidylinositol 3-kinase (►PI3K) pathway is triggered through CTAR1 leading in epithelial cells to actin polymerization and cell ►motility.



Epstein–Barr Virus Latent Membrane Protein 1. Figure 1 Structure of LMP1 and its functional domains. The signaling domains recruit TRAFs and TRADD which results in the activation of host cell signal transduction pathways and the regulation of host cell target genes.

Other signaling pathways activated by LMP1 are the p38 ►MAP kinase pathway and the ►signal transducers and activators of transcription (STAT) pathway.

The NF-κB pathway plays a key role in the activation of many genes and is essential for the transformation of B cells by EBV. NF-κB mediates induction of antiapoptotic genes (►*bcl-2*, *bfl-1*, *A20*, *c-IAPs*, ►*c-FLIP*) and downregulates proapoptotic genes as *Bax* (*Bcl-2*-associated protein x). LMP1 expression in B cells also results in the upregulation of activation markers and ►adhesion molecules.

LMP1 also modulates the communication between EBV-infected cells and its cellular environment by upregulating the expression of a large number of cytokines (►interleukin-6, -10, TNF-α) and ►chemokines (RANTES, IP-10, interleukin-8). It is also involved in migration and invasion processes as it activates proangiogenic factors as ►vascular endothelial growth factor, ►matrix metalloproteinases, and modulators of the cytoskeleton.

Although LMP1 shows no homology with any cellular protein it functionally mimics an activated CD40 receptor, which is a costimulatory receptor required for B cell proliferation. Although LMP1 and CD40 both recruit TRAF molecules and regulate an overlapping pattern of signaling pathways and target genes, they have divergent roles in B cell development. For example, in CD40-deficient LMP1 transgenic mice, LMP1, like CD40 can induce extrafollicular B cell differentiation, but in contrast to CD40, LMP1 leads to a defective germinal center reaction, characterized by splenomegaly and lymphadenopathy.

Erionite

Definition

Is a zeolite silicate that in its native form, contains aluminum, calcium, and magnesium but no iron. The crystals resemble and feel like wool. They are sieve-like and, following inhalation, accumulate large amounts of iron. Over time, ►mesothelioma arises at sites of erionite deposition.

►Asbestos

ERK

Definition

Extracellular signal-regulated kinase. ERK1 and ERK2 are members of the ►MAP kinase family. MAP kinases act as an integration point for multiple biochemical signals, and are involved in a wide variety of cellular processes. Upon activation, this kinase translocates to the nucleus and peripheral adhesion sites, where it phosphorylates target substrates.

►Calpain
►Trefoil Factors

ERK/MAP Kinase (ERK/MAPK)

Definition

Mammalian MAP Kinase can be divided into four groups based on their structure and function: ►ERKs (Extracellular signal-Regulated Kinases), p38MAPKs, JNKs (c-Jun NH2-terminal Kinases) and ERK5 (Extracellular signal-Regulated Kinase-5) or BMK. The MAPK/ERK signaling cascade is activated by a wide variety of receptors involved in growth and differentiation including GPCRs (G-Protein Coupled Receptors), RTKs (►Receptor Tyrosine Kinases), integrins, and ion channels. The specific components of the cascade vary greatly among different stimuli, but the architecture of the pathway usually includes a set of adaptors like SHC, GRB2 (Growth Factor Receptor Bound protein-2), Crk, etc. linking the receptor to a GEF (Guanine nucleotide Exchange Factor) like SOS (Son of Sevenless), C3G, etc. transducing the signal to small GTP binding proteins (Ras, Rap1), which in turn activate the core unit of the cascade composed of a MAPKKK (Raf), a MAPKK (MEK1/2 (MAPK/ERK Kinase-1/2)) and MAPK (ERK). An activated ERK dimer can regulate targets in the cytosol and also translocate to the nucleus where it phosphorylates a variety of transcription factors regulating gene expression.

Erlotinib

Bassel F. El-Rayes, Shirish Gadgeel, Shadan Ali, Philip A. Philip, Fazlul H. Sarkar
Karmanos Cancer Institute, Wayne State University, Detroit, MI, USA

Synonyms

Tarceva

Definition

Erlotinib is a potent and selective ►epidermal growth factor receptor (EGFR) tyrosine kinase inhibitor. Erlotinib is commercially available in tablets of 25, 100, and 150 mg formulations. Erlotinib is currently approved for use in previously treated nonsmall cell ►lung cancer and in frontline management of ►pancreatic cancer in combination with gemcitabine chemotherapy.

Characteristics

Rationale for Targeting the EGFR. The EGFR is frequently dysregulated in epithelial cancers. Overexpression of EGFR can result in malignant transformation of cells. Patients whose tumors have overexpressed or dysregulated EGFR and/or ligand expression may have a worse prognosis. Activation of the EGFR initiates dimerization of the receptors leading to activation of the tyrosine kinase domain. The kinase in turn phosphorylates (►Phosphorylation) and activates proteins in the signal transduction cascade promoting cell proliferation, angiogenesis, invasion, and survival. In preclinical models, erlotinib selectively inhibited EGFR tyrosine kinase activity in human cancer cell lines and resulted in inhibition of various tumor growths and induction of apoptosis. Erlotinib potentiated the activity of cytotoxic agents and radiation in cancer cell line as well as in animal models.

Phase I Trials. The maximal tolerated dose of erlotinib was 150 mg once daily in Phase I trial. The most commonly observed toxicities were an ►acneiform rash and diarrhea.

Experience in Nonsmall Cell Lung Cancer (*NSCLC*). Three randomized trials evaluated the efficacy of erlotinib in advanced NSCLC. In the first trial, patients with previously treated advanced NSCLC were randomized to erlotinib or best supportive care. The results revealed a significant improvement in median survival (6.7 vs. 4.7 months, $p = 0.001$) and survival at 1 year (31.2% vs. 21.5%) in favor of erlotinib. The median time to progression and response rates in the erlotinib and best supportive care arms were 9.7 versus 8.0 weeks ($p < 0.001$) and 8.9 versus 1.0%, respectively. The incidence of grade 3 and 4 rash and diarrhea in the erlotinib arm was 9 and 6%, respectively. A very important finding, in a multivariate analysis, was that nonsmokers and those with adenocarcinoma histology benefited most from erlotinib. Based on this trial, erlotinib was approved in patients with previously treated NSCLC.

Two trials compared conventional chemotherapy to the same chemotherapy and erlotinib in patients with newly diagnosed advanced NSCLC. The chemotherapy regimens evaluated were ►gemcitabine/carboplatin (TALENT) and ►paclitaxel/cisplatin (TRIBUTE). No significant difference was observed between patients receiving chemotherapy or erlotinib and chemotherapy with respect to objective response rate, survival, or time to progression. Therefore, erlotinib is not used in combination with chemotherapy to treat patients with NSCLC.

Experience in Pancreatic Cancer. A randomized trial compared gemcitabine to gemcitabine and erlotinib in patients with advanced pancreatic cancer. The trial resulted in a significant improvement in median survival (6.37 vs. 5.91 months, $p = 0.01$) and 1 year survival (24 vs. 17%) in favor of erlotinib. Significant predictors for favorable outcome were performance status 0–1, locally advanced disease, and normal albumin. Treatment with erlotinib resulted in an improvement of progression free survival (3.75 vs. 3.55 months, $p = 0.009$). The incidence of grade 3 and 4 toxicities were higher in the erlotinib arm with respect to rash (6 vs. 1%), and diarrhea (7 vs. 2%). The Food and Drug Administration (FDA) approved erlotinib in combination with gemcitabine for previously untreated advanced pancreatic cancer. More recently a similar approval was granted in Europe for this particular indication.

Trials in Other Tumor Types. Erlotinib has been evaluated in ►bile duct, gastric, ►esophageal, ►hepatocellular, and ►colorectal (CRC) and ►head and neck cancers. In bile duct cancer, a multiinstitutional phase II trial evaluated single agent erlotinib in 42 patients with advanced disease. The trial met its primary endpoint with a progression free survival at 6 month of 17%. Three patients had a partial response. The Southwest Oncology Group (SWOG) performed a phase II trial of erlotinib in advanced gastric and gastroesophageal (GEJ) tumors. The response rate was 9%. All responses were observed in the GEJ patients. Interestingly, no responses were seen in the patients with gastric cancer. Philip et al. reported the results of 38 patients with advanced hepatocellular cancer treated with erlotinib. Forty seven percent of the patients had received prior chemotherapy. The study met its primary endpoint with a 6 month progression free survival of 32%. Three patients had partial response. Erlotinib has been evaluated in CRC as a single agent and in combination with ►FOLFIRI, ►capecitabine, capecitabine/oxaliplatin, and ►FOLFOX. As a single agent, erlotinib was evaluated in patients with previously treated CRC.

Erlotinib. Table 1 Ongoing trials of erlotinib in combination with targeted agents

Agent	Target	Phase (disease)
Isoflavone	Akt/NF-kB	II (Pancreatic)
Sorafanib	VEGFR, PDGFR, Raf	I
Dasatinib	Src	I
Cetuximab	EGFR	I
Celecoxib	Cyclooxygenase 2	II (NSCLC)
RAD001	mTOR	Phase I

Thirty nine percent of patients had stable disease no responses were observed. The combination of FOLFIRI and erlotinib resulted in excessive toxicity and the trial was discontinued. Erlotinib and capecitabine were well tolerated, and in the phase I trial, 2 of the 9 patients with CRC had a partial response. The phase II trial is still ongoing. Two trials evaluated erlotinib and capecitabine/oxaliplatin in patients with previously treated CRC. The partial response rates and stable disease were 20–22%, and 61–64%, respectively. There is still uncertainty whether erlotinib plays any role in CRC. Currently research in CRC is focused on the use of monoclonal antibodies that target the EGFR. Erlotinib in combination with FOLFOX is currently in a phase II trial. Modest activity was observed with erlotinib in head and neck cancer patients with a response rate of 4% and disease stabilization rate of 38%. In conclusion, erlotinib has demonstrated promising activity in cholangiocarcinoma, hepatocellular, and GEJ tumors. The role of erlotinib in these diseases requires further randomized trials.

Future Directions. Erlotinib has demonstrated a significant but modest activity in a number of carcinomas. The future challenge is how to improve the activity of erlotinib. Two approaches are being evaluated in clinical trials. The first is to select patients with a higher likelihood of benefit from erlotinib. For example, patients with NSCLC and either activating mutations of the EGFR or no smoking history have demonstrated an increased benefit from erlotinib therapy. Additional trials are evaluating the efficacy of erlotinib in previously untreated patients whose tumors have EGFR mutations. On the other hand, a trial is evaluating the combination of erlotinib with chemotherapy in previously untreated patients with NSCLC and no smoking history. The results of these trials will determine whether erlotinib should be used in the frontline management of NSCLC in selected patient populations.

The second approach is based on combining erlotinib with other targeted agents because of the redundancy of the signaling pathways and existence of independently activated survival pathways. Since the inhibition of the EGFR results in inhibition of angiogenesis, the combination of erlotinib and ▶bevacizumab is being evaluated in a number of malignancies including: hepatocellular, cholangiocarcinoma, NSCLC, and pancreatic cancer. The combinations of erlotinib with other agents targeting the signaling cascade are currently at different stages of development (Table 1).

ERM Proteins

Ling Ren, Chand Khanna
National Cancer Institute, Center for Cancer Research, Pediatric Oncology Branch, Bethesda, MD, USA

Synonyms

Villin 2; Cytovilin

Definition

The ERM family consists of three closely-related proteins, ezrin, radixin, and moesin. ERM proteins are cell membrane and cytoskeleton linker proteins.

Characteristics

History, Structure, and Sequence

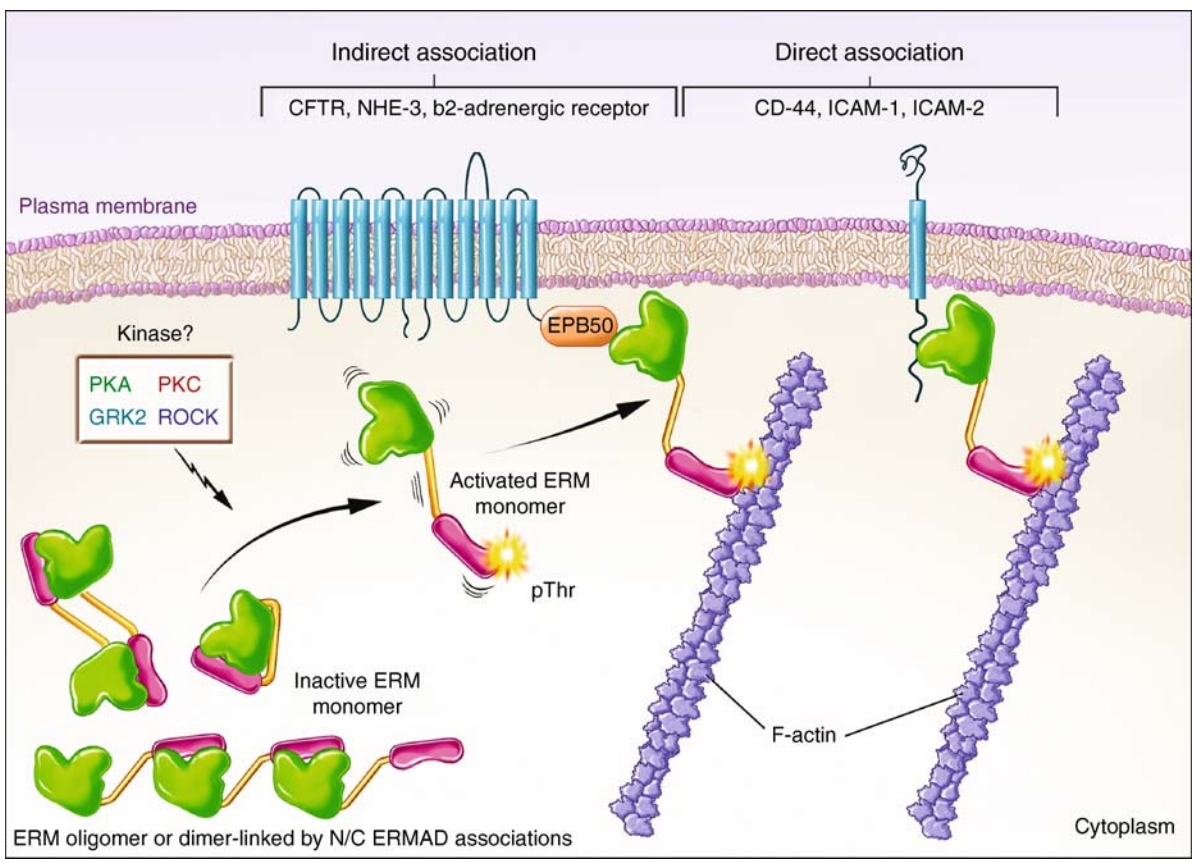
Ezrin, the prototype ERM protein is a 585-amino acid polypeptide, first identified as a constituent of

microvilli and shown to be present in actin-containing surface structure on a wide variety of cells. ERM proteins share homology in sequence structure and function. They are composed of three domains: an N-terminal globular domain; an extended α-helical domain; and a charged C-terminal domain. The N-terminal domain of ERM proteins is highly conserved and is also found in ►merlin, band 4.1 proteins, and members of the band 4.1 superfamily. This domain called FERM (four.one protein, ezrin, radixin, moesin) domain. The crystal structure of moesin revealed the FERM domain is composed of three structural modules that, together, form a compact clover-shaped structure. The C-terminal domain can extend across the FERM domain surface, potentially masking recognition sites of other proteins. Ezrin and radixin also contain a polyproline region between the helical and C-terminal domains. The cDNA sequence of radixin encodes a protein of 583 amino acids with 77% identity to ezrin. Moesin, isolated as a heparin binding protein, consists of 577 amino acids with 74% identity to ezrin.

Regulation

ERM proteins are conformationally regulated. ERM proteins exist in proposed dormant forms in which the C-terminal tail binds to and mask the N-terminal FERM domain (Fig. 1). The activation of ERM protein is mediated by both C-terminal threonine phosphorylation (T567 in ezrin, T564 in radixin, T558 in moesin) and exposure to PIP2. It is likely that phosphorylation at other residues in ERM proteins are needed to maintain an open activated conformation for ezrin and to direct ezrin-specific effects in cells. It is also unclear what functions are ascribed to the so-called "inactive" closed conformation of ERM proteins. Several protein kinases have been found to phosphorylate the C-terminal threonine residue of the ERM proteins. Examples include PKCα (►protein kinase C family), PKCθ (protein kinase C family), Rho kinases/ROCK, G protein-coupled receptor kinase 2 (GRK2), and Myotonic dystrophy kinase-related Cdc42-binding kinase (MRCK).

Dephosphorylation of C-terminal Thr of moesin has been suggested to be a crucial step for lymphocyte adhesion and transendothelial migration. The disassembly of microvilli on lymphocyte cell surfaces caused by dephosphorylation of moesin facilitates the cell—cell (lymphocyte–endothelium) contact. Protein phosphatase 2C is involved in the dephosphrylation of moesin through the activation of Rac1 small ►GTPase.



ERM Proteins. Figure 1

Function, Distribution, Localization

ERM proteins either directly associate with the cytoplamic domains of adhesive type I membrane proteins, such as ►CD44, CD43, ICAM-1, -2, and -3, or indirectly associate with membrane proteins via PDZ-containing adaptors EBP50 and E3KAP. Regulated attachment of membrane proteins to F-actin is essential for many fundamental cellular processes, including the determination of cell shape, polarity, and surface structure, cell ►adhesion, ►motility, cytokinesis, phagocytosis, and integration of membrane transport with signaling pathways. There is functional redundancy between ERM proteins. This is best exemplified by the phenotype of the ezrin knock-out mouse. This mouse is viable at birth, suggesting the ability of radixin and moesin to fill the role of ezrin during development. Interestingly, the fatal phenotype of this mouse is characterized by intestinal villous malformations seen at day 13 postpartum. The normal intestinal epithelial cells nearly exclusively express ezrin. Although ezrin, radixin, and moesin are coexpressed in most cultured cells, they exhibit a tissue-specific expression patterns. Ezrin is highly concentrated in intestine, stomach, lung, and kidney although moesin is prominent in lung and spleen, radixin in liver and intestine. Ezrin is expressed in epithelial and mesothelial cells while moesin is expressed in endothelial cells. As indicted, the brush border of intestinal epithelial cells express only ezrin, and hepatocytes express only radixin.

The Expression and Functions of ERM Proteins in Cancer

Ezrin has been recently shown to be expressed in most human cancers and linked to progression in several cancers, including carcinomas of endometrium, breast, colon, ovary, in uveal and cutaenous ►melanoma, ►brain tumors, and most recently soft tissue sarcomas. cDNA array (►Microarray (cDNA) Technology) analysis of highly and poorly metastatic ►rhabdomyosarcoma and ►osteosarcoma, ezrin was indicated as a key metastatic regulator. In several murine and human cancer models, suppression of ezrin protein and disruption of ezrin function significantly reduced the metastatic phenotype despite the expression of other ERM proteins. This suggests that the redundancy provided by the other ERM proteins for ezrin does not extend to ►metastasis and that ezrin contributes a unique and necessary function to cells undergoing metastasis. Comparing lung adenocarcinoma with normal lung tissue, the expression of ezrin, radixin, and moesin were decreased on mRNA level as well as the protein level. Interestingly, the high expression of ezrin was observed in the invading tumor cells in lung adenocarcinoma.

ERp57

Definition

Is a member of the protein disulfide isomerase (PDI) family and catalyzes the disulfide oxidation, isomerization, and reduction of proteins in the ER. It is distinct from other PDI family members in that it associates noncovalently with ►calreticulin or ►calnexin.

►Calreticulin

ERp60

►Calreticulin

Erythema

Definition

Refers to redness of the skin caused by capillary congestion. It can be caused by infection, massage, electrical treatments, allergies, exercise or ►solar ultraviolet light (sunburn). Erythema is a common side effect of ►radiation therapy due to patient exposure to ►ionizing radiation.

Erythema Multiforme Major

Definition
Synonym Stevens-Johnson syndrome; is an unusual, life-threatening reaction characterized by fever and flu-like symptoms followed by a severe, blistering rash on the skin and/or mucous membranes, that may occur after a respiratory infection (e.g., herpes simplex and mycoplasma infections) or as an allergic reaction to drugs (e.g., sulfonamides, penicillins, barbiturates, and phenytoin).

►Rituximab

Erythematous Pruritic Macropapular Rash

Definition
A red, itchy, and raised rash.

►Taxotere

Erythrocytosis

Definition
An excess of erythrocytes, or red blood cells (RBCs).

►Erythropoietin
►Polycythemia

Erythroid Colony Stimulating Activity

►Erythropoietin

Erythroleukemia

Definition
A form of acute myeloid leukemia where the myeloproliferation is of abnormal, immature red blood cells

►Erythropoietin

Erythroplakia

Definition
A red patch on the mucosa that is not attributable to any obvious cause. Generally, these lesions have a well-defined border and a soft, velvet-like appearance. Their atrophic nature contributes to the red coloration, as underlying vasculature is more prominent. Around 90% show signs of severe dysplasia or carcinoma-in-situ and may progress to invasive squamous cell carcinoma.

►Squamous Cell Carcinoma

Erythropoiesis

Definition
The development of mature red blood cells (erythrocytes).

►Erythropoietin

Erythropoiesis Stimulating Factor

►Erythropoietin

Erythropoietin

Epo; Ep; epoetin; ESF; Erythropoiesis stimulating factor; ECSA; erythroid colony stimulating activity

Definition

Erythropoietin (Epo) (from Greek erythro for red, and poietin to make) is a small glycoprotein hormone that is essential for the production of red blood cells. Epo promotes the survival, proliferation and differentiation of erythroid progenitor cells (►BFU-E, CFU-E) to mature erythrocytes and initiates hemoglobin synthesis.

Characteristics

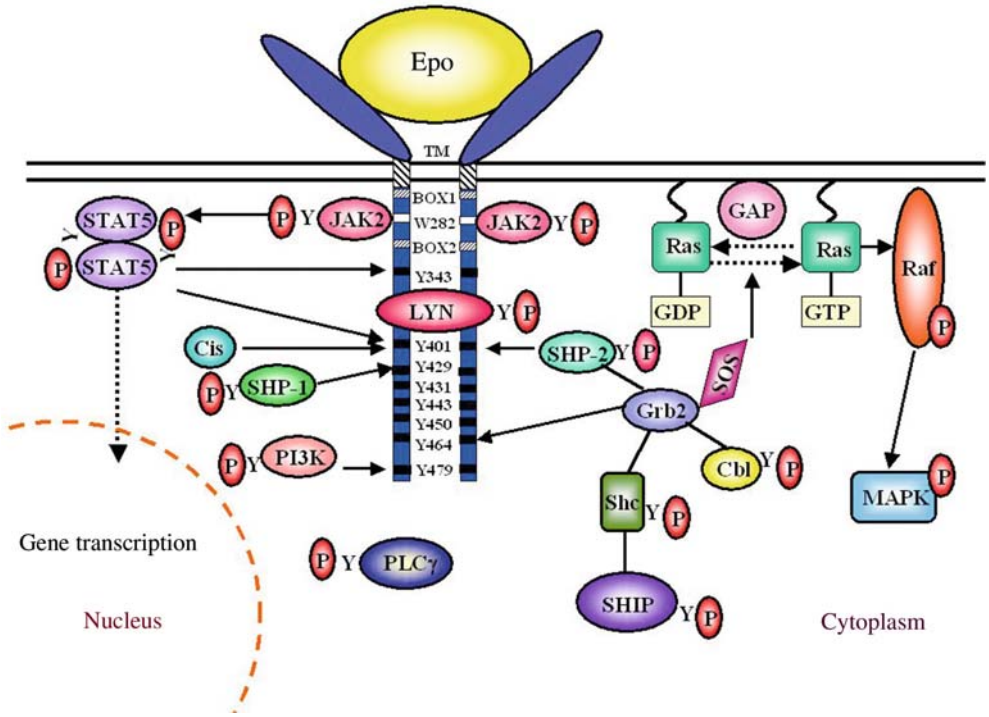
The Epo gene contains at least five exons and resides on chromosome 7q21-q22 in humans and chromosome 5 in mice. DNA sequences from monkey and mouse display 90 and 80% homology to human Epo, respectively. Epo is produced primarily in the kidney, and to a lesser extent in the liver. It is an acidic glycoprotein hormone with a molecular weight of 34–37 kD, and circulates in the blood plasma at a very low concentration (about 5 pmol/l). It is composed of a single chain polypeptide and is resistant to denaturation by heat, alkali or reducing agents. Epo is synthesized as a 193 amino acid precursor that is cleaved to yield an active protein of 165 amino acids. It is N-glycosylated at asparagine residues 24, 36 and 83 and O-glycosylated at serine 126. Epo is also sialylated and contains two disulfide bonds at positions 7/161 and 29/33. The alpha form of the hormone consists of 31% carbohydrates while the beta form consists of 24%. These two forms of Epo have similar biological and antigenic properties. The carbohydrate moiety of Epo plays an important role in the mediation of its full biological effect and the pharmacokinetic behavior of the protein in vivo; non-glycosylated Epo has a very short biological half-life. Epo is fully synthesized in its active form prior to secretion into circulation. Epo, already known as the stimulating hormone for ►erythropoiesis, has displayed different and interesting pleiotropic actions. It not only affect erythroid cells, but also myeloid cells, lymphocytes and megakaryocytes. This hormone can enhance phagocytic function of polymorphonuclear cells and reduce the activation of macrophages, thus modulating the inflammatory process. Epo also exerts diverse biological effects in many nonhematopoietic tissues and is involved in the wound-healing cascade, functions as a proangiogenic cytokine during physiological angiogenesis in the embryo and uterus, and exerts tissue-protective effects as part of the innate response to stressors.

Cellular and Molecular Regulation

The synthesis of Epo in the kidney is under the control of an oxygen-sensing mechanism. Transcriptional response of the Epo gene to hypoxia is mediated partly by promoter sequences but mainly by a 24 bp hypoxia-response element located at the 3′ flanking region of the Epo gene bound to the hypoxia inducible factor-1 (►HIF-1). Epo production is also modulated by several other factors such as hypoglycemia, increased intracellular calcium, insulin release, estrogen, androgenic steroids, and various cytokines.

The biological activity of Epo is mediated by its specific receptors present at 300–3,000 copies per cell, that undergo phosphorylation in response to Epo. The Epo receptor (EpoR) belongs to the class I cytokine receptor superfamily. The mouse EpoR consists of 507 amino acids with an extracellular domain, a single hydrophobic transmembrane domain and a cytoplasmic domain. The human EpoR is a 66 kD protein comprised of 508 amino acids. It consists of eight exons spanning some 6 kb on human chromosome 19p13.3.

The interaction of Epo with its receptor results in the formation of a homodimer and its subsequent internalization (Fig. 1). Dimerization of the receptor results in the autophosphorylation of Janus kinase 2 (JAK2), a protein kinase that is tightly associated with the EpoR. Once activated, JAK2 phosphorylates eight tyrosine residues located in the cytoplasmic domain of the EpoR. Phosphorylation of the EpoR leads to the recruitment and phosphorylation of a number of signal transduction proteins. One such protein is ►STAT5, a transcription factor that plays an important role in the regulation of in vivo erythropoiesis. Once phosphorylated by binding to tyrosine 343 and 401 of the EpoR, STAT5 translocates to the nucleus to activate the expression of several downstream target genes. Other signaling cascades triggered by Epo binding to its receptor include phosphatidylinositol 3-kinase (PI3K) that binds to tyrosine 479 and is involved in erythroblast survival, and Grb2 that binds to tyrosine 464 and is involved in the activation of the Ras pathway. Ras pathway may be required for the synergistic expansion of erythroid progenitors and precursor cells in response to Epo and stem cell factor (SCF). EpoR mediated activation of phospholipase A2 and C also leads to the release of membrane phospholipids, the synthesis of diacylglycerol and increase in intracellular calcium



Erythropoietin. Figure 1 Schematic diagram of the EpoR depicting the positions of tyrosine (Y) residues (black bars; Y) in the cytoplasmic domain and attachment sites of signal transduction proteins such as STAT5, SHP-1 and SHP-2. Binding of Epo to its receptor results in the autophosphorylation and activation of JAK2, which in turn phosphorylates eight tyrosine residues in the cytoplasmic domain of the EpoR.

levels and pH. Since phosphorylation of the EpoR by Epo is diminished after 30 min of stimulation, a number of tyrosine phosphatases have been identified that are involved in attenuating the signal. The tyrosine phosphatase ►SHP-2 binds to tyrosine 401 of the Epo-receptor and stimulates erythroid proliferation, while ►SHP-1 binds to tyrosine 429 and inhibits proliferation.

Expression of the EpoR is not restricted to hematopoietic cells and exhibits a multi-tissue distribution that includes vascular endothelial cells, muscle cells, and neurons, therefore, Epo is believed to play a physiological role in angiogenesis, cardiac and brain development. Abnormal regulation of Epo-EpoR signaling in hematopoietic cells has been associated with proliferative disorders of the bone marrow, such as ►polycythemia vera, a disorder characterized by ►erythrocytosis, as a consequence of an active mutation in the EpoR. Additionally, prolonged activation of STAT5 has been observed in cells transfected with mutant (tyrosine 429) EpoR, suggesting that STAT5 DNA binding activity may play a role in the pathogenesis of erythrocytosis. A point mutation at position 129 of the mouse EpoR gene results in constitutive activation of the receptor without stimulation with Epo. Mice infected with a retrovirus expressing this aberrant receptor develop ►erythroleukemia and splenomegaly. Taken together, these provide evidences that the precise control of Epo-EpoR signaling are critical for the normal proliferation and differentiation of erythroid progenitor cells.

Clinical Relevance

The synthesis of Epo is subject to a complex circuit that links the bone marrow and kidney in a feedback loop. Its reference interval in the blood plasma ranges between 3.3 and 16.6mIU/ml Patients suffering from most ►anemias display higher than normal concentrations of serum Epo; whereas, those suffering from anemia associated with chronic renal disease have values either low or within the normal range. Epo levels are disproportionately low in anemic patients with chronic disorders as well, such as rheumatoid arthritis, AIDS, and cancer, in which inhibition of Epo production and erythroid progenitor proliferation by inflammatory cytokines, such as IL-1 and TNF, are thought to play major causative roles. Abnormally high concentrations may also be induced by renal neoplasms, benign tumors, polycystic kidney disease, renal cysts, and hydronephrosis. The pathophysiological excess of Epo leads to erythrocytosis that is accompanied by an increase in blood viscosity and may cause heart failure and pulmonary hypertension.

Chronic kidney disease causes the destruction of Epo-producing cells resulting in hyporegenerative normochrome normocytic anemias. Epo is therefore clinically used for the treatment of patients with severe kidney insufficiency. In uremic patients, treatment with recombinant human Epo (rhEpo) effectively reactivates the bone marrow to produce erythrocytes, and also improves platelet adhesion and aggregation. Hypertension is an important complication in the treatment of renal anemia with rhEpo. rhEpo is also used to treat non-renal forms of anemia caused by chronic infections, inflammation, radiation therapy and chemotherapy. Beyond ameliorating anemia, rhEpo has been shown to restore radiosensitivity and increase cytotoxity of chemotherapy in the treatment of cancer-related anemia. However, clinical trials have shown increase in the relative risk of thrombo-embolic complications and lower survival, which raises concerns about the potential adverse effects of rhEpo in cancer patients. Additional studies show that Epo and EpoR expression also occurs in tumor cells, suggesting the potential for the generation of an autocrine or paracrine growth-stimulator Epo-EpoR loop in cancer cells. Further studies will be required to investigate the effects, if any, of rhEpo therapy on disease progression and survival. For its role in stimulating the production of erythrocytes, an important application of Epo is the pre-surgical activation of erythropoiesis allowing for the collection of autologous donor blood. rhEpo has emerged as a novel anti-inflammatory and cytoprotective agent, as evidenced by its physiological response to various forms of tissue injury. Accordingly, the therapeutic potential of Epo has been shown in acute renal failure, diabetic neuropathy, myocardial infarction and cerebral ischemia. The recent characterization of Epo variants, such as asialo-Epo and carbamylated-Epo, that retain nonhematopoietic, tissue-protective properties of Epo without stimulating erythropoiesis has uncovered new areas of research into the mechanisms of Epo-mediated signaling in nonhematopoietic tissues as well as novel clinical applications for rhEpo and its derivatives in disorders other than anemia.

Esophageal Cancer

Ruggero Montesano
Former Staff Member, International Agency for Research on Cancer,
Lyon, France

Definition

Esophageal cancer comprises two main types of malignant epithelial neoplasms: squamous cell carcinoma, originating from the lining squamous epithelium of the esophagus and adenocarcinoma (also called Barrett adenocarcinoma), originating from metaplastic columnar epithelium in the lower part of the esophagus.

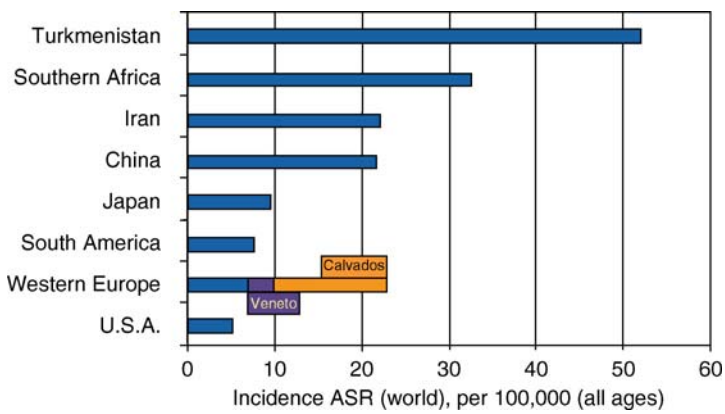
Characteristics

Esophageal cancer is the sixth most frequent cancer worldwide. In 2001, the estimated number of deaths due to esophageal cancer amounted to about 338,000 out of a total of 6.2 million cancer deaths. Of those, more than 80% occurred in developing countries, the majority being squamous cell carcinomas. The occurrence of this cancer varies greatly in different part of the world, with areas of high mortality rate per year in regions of South Africa, North east of Iran and China (30 or more per 100,000 in males and 10 per 100,000 in females). In Europe or USA, the age standardized annual mortality of squamous cell carcinoma is no more than 5 in males and 1 in females per 100,000. There are however, areas in Europe, namely in Normandy and Brittany in France and North east of Italy, where the mortality rates, at least in males, are as high as those observed in China.

Adenocarcinoma of the esophagus is less frequent and occurs mainly in industrial countries. However, recent epidemiological data show increasing numbers of adenocarcinoma cases and this type of cancer accounts for more than 50% of all oesophageal cancer in USA.

The 5-year survival rate for patients with squamous cell carcinoma and adenocarcinoma of the esophagus is similarly poor (~10%), with no difference between industrial and developing countries. This is mainly due to their late detection and the poor therapy efficacy. No reliable prognostic markers are available.

Epidemiological studies have clearly shown that tobacco smoke (►Tobacco carcinogenesis) and alcohol, together with a low intake of fresh fruits, vegetables, and meat, is causally associated with squamous cell carcinoma. It is estimated that in industrial countries approximately 90% of this cancer is attributable to tobacco and alcohol consumption. Other risk factors are chewing of betel, consumption of pickled vegetables, and hot mate drink in South East Asia, China, and South America, respectively.



Esophageal Cancer. Figure 1 Incidence of esophageal cancer in males by selected world regions. [From Parkin et al. (1999)].

Adenocarcinoma of the esophagus arises from Barrett's esophagus, a condition in which the normal squamous epithelium is replaced by metaplastic columnar epithelium. This condition is frequently present in patients with chronic gastroesophageal reflux and these patients have a more than 100-fold higher risk than the general population to develop adenocarcinoma.

Squamous cell carcinoma and adenocarcinoma of the esophagus show multiple genetic alterations (point mutations, allelic loss, and gene amplification) of several oncogenes and tumor suppressor genes. The most interesting observation in both cancer types is the high prevalence of mutations (up to 80%) of the tumor suppressor gene *p53*. In addition a distinct pattern of p53 mutations, namely a high prevalence of G>A transitions at CpG sites in adenocarcinoma and a higher prevalence of G>T tranversions and mutations at A:T base pairs in squamous cell carcinoma. There is good evidence that the mutations in squamous cancer types are attributable to carcinogens present in tobacco smoke. In both types of cancers, p53 mutations occur very early and are followed by the accumulation of other genetic alterations during the process of esophageal carcinogenesis. It is evident that these genetic alterations are relevant not only in the understanding of the multifocal monoclonal origin of this cancer but also to the elucidation of his multifactorial etiology.

ESR2

►Estrogen Receptor

Estradiol

Jose Russo, Irma H. Russo
Breast Cancer Research Laboratory, Fox Chase Cancer Center, Philadelphia, PA, USA

Definition

Estradiol or Estradiol-17β is biologically the most active estrogen and circulating estrogens are mainly originated from ovarian ►steroidogenesis in premenopausal women and peripheral aromatization of ovarian and adrenal androgens in postmenopausal women.

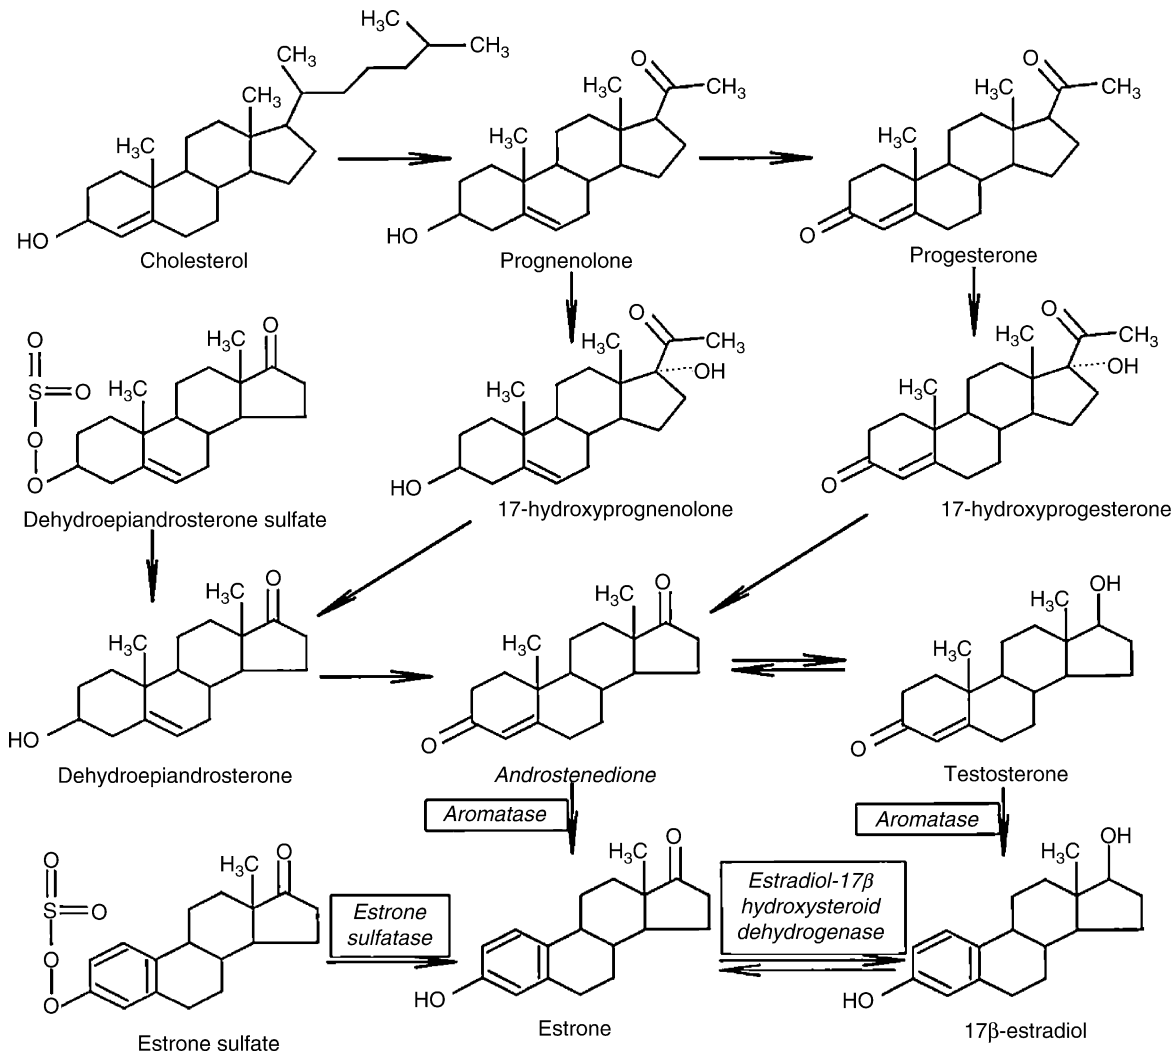
Characteristics

Mechanism of Action

It is generally accepted that the biological activities of estrogens are mediated by nuclear ►estrogen receptors (ER) which, upon activation by cognate ligands, form homodimers with another ER–ligand complex and activate transcription of specific genes containing the estrogen response elements (ERE). According to this classical model, the biological responses to estrogens are mediated by the ER universally identified until recently, which has been termed as ERα after the discovery of a second type of ER (ERβ). The presence of ERα in target tissues or cells is essential to their responsiveness to estrogen action. In fact, the expression levels of ERα in a particular tissue have been used as an index of the degree of estrogen responsiveness. For example, human breast carcinomas are initially positive for ERα, and their growth can be stimulated by estrogens and inhibited by ►antiestrogens. The ERβ has been cloned from the rat, mouse, and human. ERβ and ERα share high sequence homology, especially in the regions or domains responsible for specific binding to DNA and the ligands. ERβ can be activated by estrogen stimulation, and blocked with antiestrogens. Upon activation, ERβ can form homodimers as well as heterodimers with ERα. The existence of two ER subtypes and their ability to form DNA-binding heterodimers suggests three potential pathways of estrogen signaling: via the ERα or ERβ subtype in tissues exclusively expressing each subtype and via the formation of heterodimers in tissues expressing both ERα and ERβ. In addition, estrogens and antiestrogens can induce differential activation of ERα and ERβ to control transcription of genes that are under the control of an AP1 element.

Sources of Estrogens

Circulating estrogens are mainly originated from ovarian steroidogenesis in premenopausal women and peripheral aromatization of ovarian and adrenal androgens in postmenopausal women. Three main



Estradiol. Figure 1 Steroidogenic pathways leading to the biosynthesis of estrogens. [Reprinted from: Russo, Russo IH (2004) Biological and molecular basis of breast cance. Springer–Verlag, Heidelberg].

enzyme complexes that are involved in the synthesis of biologically active estrogen (i.e., estradiol-17β) (Fig. 1): (i) aromatase that converts androstenedione to estrone, (ii) estrone sulfatase that hydrolyses the estrogen sulfate to estrone, and (iii) estradiol-17β hydroxysteroid dehydrogenase that preferentially reduces estrone to estradiol-17β in tumor tissues.

Role of Estrogens in Human Breast Carcinogenesis

There are three mechanisms that have been considered to be responsible for the carcinogenicity of estrogens: receptor-mediated hormonal activity, which has generally been related to stimulation of cellular proliferation, resulting in more opportunities for accumulation of genetic damages leading to carcinogenesis, a cytochrome P450 (CYP)-mediated metabolic activation, which elicits direct genotoxic effects by increasing mutation rates, and the induction of aneuploidy by estrogen. There is also evidence that estrogen compromises the DNA repair system and allows accumulation of lesions in the genome essential to estrogen-induced tumorigenesis.

Receptor-Mediated Pathway

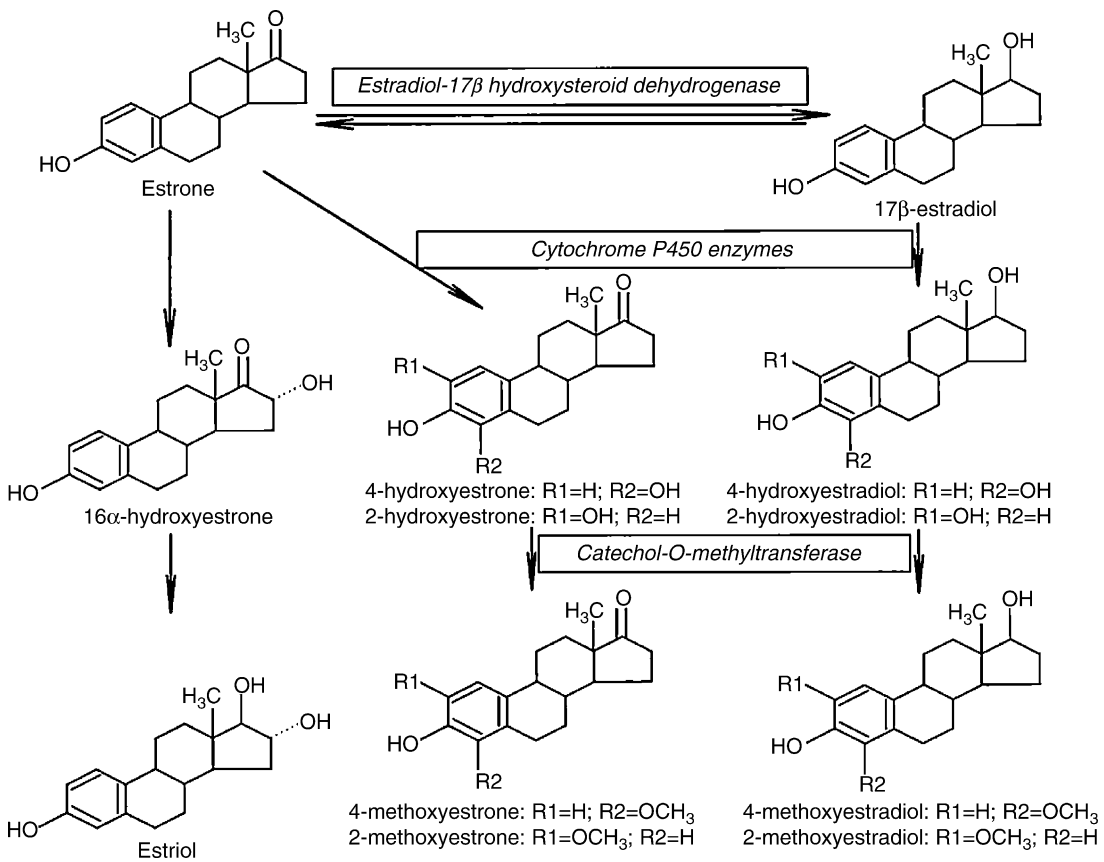
The receptor-mediated activity of estrogen is generally related to induction of expression of the genes involved in the control of cell cycle progression and growth of human breast epithelium. The biological response to estrogen depends upon the local concentrations of the active hormone and its receptors. The proliferative activity and the percentage of ERα-positive cells are highest in ►Lob 1 in comparison with the various lobular structures composing the normal breast. These findings provide a mechanistic explanation for the

higher susceptibility of these structures to be transformed by chemical carcinogens in vitro, supporting as well the observations that Lob 1 are the site of origin of ▶ductal carcinomas. The presence of ERα-positive and ERα-negative cells with different proliferative activity in the normal human breast may help to elucidate the genesis of ERα-positive and ERα-negative breast cancers. Even though it is now generally believed that alterations in the ER-mediated signal transduction pathways contribute to breast cancer progression toward hormonal independence and more aggressive phenotypes, there is also mounting evidence that a membrane receptor coupled to alternative second messenger signaling mechanisms are operational, and may stimulate the cascade of events leading to cell proliferation. This knowledge suggests that ERα-negative cells found in the human breast may respond to estrogens through this or other pathways. The biological responses elicited by estrogens are mediated, at least in part, by the production of autocrine and paracrine growth factors from the epithelium and the stroma in the breast. In addition, evidence has accumulated over the last decade supporting the existence of ER variants, mainly a truncated ER and an exon-deleted ER. It has been suggested that expression of ER variants may contribute to breast cancer progression toward hormone independence. Although more studies need to be done in this direction, it is clear that the findings that in the normal breast the proliferating and steroid hormone receptor positive cells are different open new possibilities for clarifying the mechanisms through which estrogens might act on the proliferating cells to initiate the cascade of events leading to cancer.

E

Oxidative Metabolism of Estrogen

There is evidence that the oxidative catabolism of estrogens, which is mediated by various CYP complexes, constitutes a pathway of their metabolic activation to reactive free radicals and intermediate metabolites that can cause oxidative stress. Estradiol-17β and estrone, which are continuously interconverted by estradiol-17β hydroxysteroid dehydrogenase (or 17β-oxidoreductase), are the two major endogenous estrogens (Fig. 2). They are generally metabolized via two major pathways: hydroxylation at C-16α position



Estradiol. Figure 2 Biosynthesis and steady-state control of catechol estrogens in human breast tissues. [Reprinted from: Russo J, Russo IH (2004) Biological and molecular basis of breast cancer, Springer–Verlag, Heidelberg].

and at the C-2 or C-4 positions (Fig. 2). The carbon position of the estrogen molecules to be hydroxylated differs among various tissues and each reaction is probably catalyzed by various CYP isoforms. For example, in MCF-7 human breast cancer cells, which produce ►catechol estrogens in culture, CYP 1A1 catalyzes hydroxylation of estradiol-17β at C-2, C-15α, and C-16α, CYP 1A2 predominantly at C-2, and a member of the CYP 1B subfamily is responsible for the C-4 hydroxylation of estradiol-17β. CYP3A4 and CYP3A5 have also been shown to play a role in the 16α-hydroxylation of estrogens in human.

The hydroxylated estrogens are catechol estrogens that will easily be autooxidated to semiquinones and subsequently quinones, both of which are electrophiles capable of covalently binding to nucleophilic groups on DNA via a Michael addition and, thus, serve as the ultimate carcinogenic reactive intermediates in the peroxidatic activation of catechol estrogens. In addition, a redox cycle consisting of the reversible formation of the semiquinones and quinones of catechol estrogens catalyzed by microsomal P450 and CYP-reductase can locally generate superoxide and hydroxyl radicals to produce additional DNA damage. Furthermore, catechol estrogens have been shown to interact synergistically with nitric oxide present in human breast generating a potent oxidant that induces DNA strand breakage.

Steady-state concentrations of catechol estrogens are determined by the CYP-mediated hydroxylations of estrogens and monomethylation of catechols catalyzed by blood-borne catechol *o*-methyltransferase (Fig. 2). Increased formation of catechol estrogens as a result of elevated hydroxylations of estradiol-17β at C-4 and C-16α positions occur in human breast cancer patients and in women at a higher risk of developing this disease. There is also evidence that lactoperoxidase, present in milk, saliva, tears, and mammary glands, catalyzes the metabolism of estradiol-17β to its phenoxyl radical intermediates, with subsequent formation of superoxide and hydrogen peroxide that might be involved in estrogen-mediated oxidative stress. A substantial increase in base lesions observed in the DNA of invasive ductal carcinoma of the breast (34) has been postulated to result from the oxidative stress associated with metabolism of estradiol-17β.

The breast is an endocrine organ and can synthesize E_2 in situ from precursor androgens via the enzyme aromatase. Breast tissue contains aromatase and produces amounts of E_2 that exert biologic effects on proliferation. The effects of local production exceed those exerted in a classical endocrine fashion by uptake of E_2 from plasma. One critical factor is excessive synthesis of E_2 by overexpression of CYP19 in target tissues and/or the presence of excess sulfatase that converts stored E_1 sulfate to E_1. The observation that breast tissue can synthesize E_2 in situ suggests that much more E_2 is present in some locations of target tissues than would be predicted from plasma concentration. A second critical factor might be high levels of 4-CE due to overexpression of CYP1B1, which converts E_2 predominantly to 4-OHE_2. This could result in relatively large amounts of 4-CE and, subsequently, more extensive oxidation to their CE-3, 4-Q. A third factor could be a lack or low level of COMT activity. If this enzyme is insufficient, either through a low level of expression or its low activity allele, 4-CE will not be effectively methylated, but will be oxidized to the ultimate carcinogenic metabolite, CE-3, 4-Q. Fourth, a low level of GSH and/or low levels of quinone reductase and/or CYP reductase can leave available a higher level of CE-Q that may react with DNA.

The effects of some of these factors have already been observed in analyses of breast tissue samples from women with and without breast cancer. The levels of E_1 (E_2) in women with carcinoma were higher. In women without breast cancer, a larger amount of 2-CE than 4-CE was observed. In women with breast carcinoma, the 4-CE were 3.5 times more abundant than the 2-CE and were 4 times higher than in the women without breast cancer. Furthermore, a statistically lower level of methylation was observed for 2-CE and 4-CE in cancer cases versus controls. Finally, the level of CE-Q conjugates in women with cancer was three times that in the controls, suggesting a larger probability for the CE-Q to react with DNA in the breast tissue of women with carcinoma. The levels of $E_1(E_2)$ ($p < 0.02$) and quinone conjugates ($p < 0.01$) are highly significant predictors of breast cancer, and the levels of methylated CE ($p < 0.02$) are significant predictors of protection against breast cancer. Altogether, these data are supporting the concept that estrogen and its metabolites can be found at high concentration in the breast tissue indicating a direct carcinogenic effect in the breast epithelial cells.

Estrogens as Inducers of Aneuploidy

Breast cancer is considered the result of sequential changes that accumulate over time. DNA content changes, i.e., loss of heterozygosity (LOH) and aneuploidy, can be detected at early stages of morphological atypia, supporting the hypothesis that aneuploidy is a critical event driving ►neoplastic development and progression. Aneuploidy is defined as the gain or loss of chromosomes; it is a dynamic, progressive, and accumulative event that is almost universal in solid tumors. The extensive array of altered gene expression observed in tumors and the numerous altered chromosomes detected by comparative genomic hybridization provide striking evidence, that aneuploidy can totally disrupt cell homeostatic control. The main question is whether aneuploidy is a consequence of neoplastic development or a cause of

neoplastic development. One of the several mechanisms proposed for the development of aneuploidy is the failure to appropriately segregate chromosomes. For example, interference with mitotic spindle dynamics, abnormal centrosome duplication, altered chromosome condensation and cohesion, defective centromeres, and loss of mitotic checkpoints. Functional consequences of centrosome defects may play a role during neoplastic transformation and tumor progression, increasing the incidence of multipolar mitoses that lead to chromosomal segregation abnormalities and aneuploidy. In considering estrogen as a carcinogenic agent, there is evidence that it affects microtubules and a recent report indicates that progesterone may facilitate aneuploidy. The importance of these findings is magnified with the recent publications that demonstrate women on ►hormone replacement treatments that include progesterone have increased mammographic breast density and increased breast cancer risk than women taking only estrogen.

In the center stage of the research endeavor on aneuploidy are the centrosomes that are organelles that nucleate microtubule growth and organize the mitotic spindle for segregating chromosomes into daughter cells, establishing cell shape and cell polarity, processes essential for epithelial gland organization. Centrosomes also coordinate numerous intracellular activities, in part by providing a site enriched for regulatory molecules, including those that control cell cycle progression, centrosome and spindle function, and cell cycle checkpoints. Although the underlying mechanisms for the formation of abnormal centrosomes are not clear, several possibilities have been proposed and implicated in the development of cancer such as alterations of checkpoint controls initiating multiple rounds of centrosome replication within a single cell cycle and failure of cytokinesis, cell fusion, and cell cycle arrest in S-phase uncoupling DNA replication from centrosome duplication.

17β-Estradiol

Definition

The major sex hormone present in females.

►Estrogenic Hormones

Estramustine

Definition

A ►nitrogen mustard linked to ►estradiol; used to treat ►prostate cancer. Estramustine and its major metabolite estramustine bind to microtubule-associated proteins (MAPs) and ►tubulin, thereby inhibiting ►microtubule dynamics and leading to ►anaphase arrest in a dose-dependent fashion. Also has radiation-protective properties.

Estrogen Receptor

Gwendal Lazennec
INSERM, Montpellier, France

Synonyms

ER; Estrogen receptor alpha ESR1; Estrogen receptor beta; ESR2

Definition

Estrogen receptors are represented by two main members (estrogen receptor alpha, ERα and estrogen receptor beta, ERβ), which bind ►estrogens. These receptors are mainly nuclear, even though membrane receptors are also suspected to exist. Nuclear estrogen receptors belong to a large family of ►nuclear receptors, which are ligand-activated ►transcription factors able to modulate the expression of different genes.

Characteristics

History

The mediators of estrogens, namely estrogen receptors, remained elusive until the synthesis of radiolabeled ►estradiol by Jensen and Jacobsen in 1960, which allowed the identification of such receptors. But it

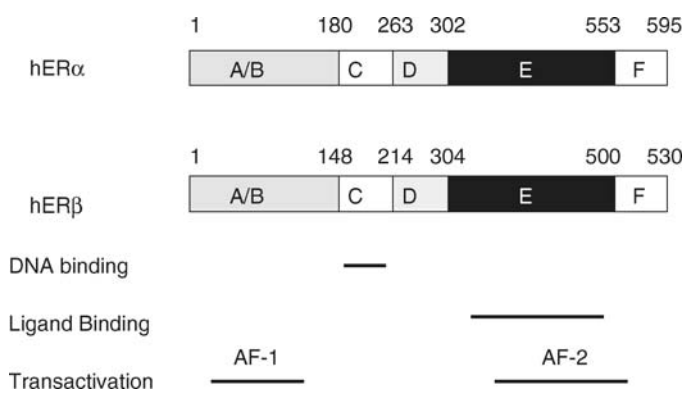
took more than 20 years, with the development at a high rate of molecular biology techniques to have the first cDNA encoding estrogen receptor (α) cloned by the group of Chambon in Strasbourg. In 1996, when most of nuclear receptors had already been cloned, a great surprise arose with the fortuitous isolation of a second estrogen receptor (β) cloned from a prostate library.

Molecular Mechanisms of Action

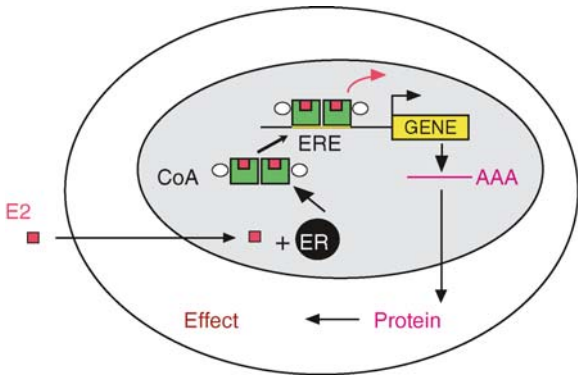
The genes coding for estrogen receptors ERα and ERβ are located on two distinct chromosomes (ERα on chromosome 6q25.1, and ERβ on chromosome 14q22–24). ERα and ERβ proteins have a respective size of 595 and 530 amino acids (Fig. 1). As indicated by their membership to nuclear receptors, estrogen receptors are mainly present in the nucleus of cells, even in the absence of estrogens. In addition, a small pool of ERs localize to the plasma membrane and signal mainly through coupling to G-proteins, but we will not discuss this issue here. Upon binding to estrogens, nuclear estrogen receptors dimerize, bind ►coactivators and interact with DNA or DNA-bound proteins to modulate the transcription of estrogen target genes (Fig. 2). Estrogen receptors share the common structure of nuclear receptors composed of 5 domains (A, B, C, D, E, and F) (Fig. 1). The C domain (DBD) is responsible for DNA binding. Two distinct synergistic transcriptional activation functions (AFs) have been identified: the ligand-independent AF-1 located in the N-terminal A/B region, and the ligand-dependent AF-2 encompassing region E (the LBD). Both ER AF-1 and AF-2 were found to act in promoter context and cell-specific fashions. Coactivators are mainly interacting with the E domain, but an increasing number of coactivators are also able to interact with the AB domain and the DBD. Estrogen receptors modulate the transcription either by binding to classical estrogen receptor element (ERE) or by interacting with ►AP-1, SP-1, or NF-kB-bound transcription factors. Many EREs consist of two inverted, palindromic half sites and are frequently present in the upstream regulation region of estrogen target genes. On the majority of ERE promoters, ERβ is less potent activator than ERα. Interestingly, ERα and ERβ form preferentially heterodimers rather than homodimers when they are both expressed in the same cell, which enables ERβ to decrease ERα transcriptional potential. Both estrogen-bound receptors mediate gene transcription similarly through the ERE pathway but have opposite effects when signaling through the AP-1 pathway. Indeed, ERα activates AP-1 gene transcription, whereas ERβ inhibits this pathway. Moreover, Tamoxifen-liganded ERα is inactive on AP-1 elements, but ERβ is able to activate the transcription response.

What have We Learned from ER Knock-Out Mice?

Disruption of the ERα gene (αERKO animals) is not lethal, but rather the animals develop normally and exhibit a life span comparable to their wild-type litter mates. αERKO mice exhibit several abnormalities and deficiencies, most notable of which are the phenotypic syndromes that result in infertility in both sexes. The mammary phenotype of αERKO female mice demonstrates that embryonic mammary gland development is independent of ERα but ERα is required for ductal elongation during puberty and complete mammary gland development in the mature mouse. The female reproductive tract of αERKO undergoes normal pre- and neonatal development but is insensitive to estrogens during adulthood. Ovaries undergo normal pre- and neonatal development, but are anovulatory during adulthood, exhibit multiple hemorrhagic cysts, and no corpora lutea. There is also a 30–40% incidence of ►ovarian tumors by 18 months of age. Male reproductive tract of αERKO displays dilation of Rete testis, atrophy of the seminiferous epithelium, and decreased sperm counts, leading to infertility.



Estrogen Receptor. Figure 1 Schematic representation of ERα and ERβ proteins.



Estrogen Receptor. Figure 2 Mechanism of action of estrogen receptors. CoA: coactivator; E2: ►estradiol; ERE: estrogen responsive element.

Mice lacking ERβ (βERKO) display a much less pronounced phenotype than αERKO. They develop normally and are indistinguishable grossly and histologically from their littermates. Sexually mature βERKO females are fertile and exhibit normal sexual behavior, but they produced substantially fewer litters as well as significantly less number of pups per litter when compared with their wild-type littermates. This reduction in fertility is the result of reduced ovarian efficiency. The mutant females have normal breast development and lactate normally. However, lactating glands display alveoli which are larger and there is less secretory epithelium in ERβ than in wild-type mice. Ovaries undergo normal pre- and neonatal development, but do not exhibit normal frequency of spontaneous ovulations during adulthood, exhibit a severely attenuated response to superovulation treatment with reduced number of oocytes and multiple trapped preovulatory follicles. In addition, male βERKO mice develop prostate hyperplasia.

ER disruption has also distinct effects on sexual behavior of the animals. αERKO male mice, although they rarely ejaculate and are infertile, show almost normal levels of mounts and just reduced levels of intromissions. In contrast, all three components of sexual behaviors are present and robust in βERKO males. Aggressive behavior is greatly reduced in αERKO male mice. In particular, male-typical offensive attacks are almost completely abolished, whereas lunge and bite attacks are still present. On the other hand, the aggressive behavior of βERKO is not reduced but rather elevated depending on age and social experiences.

Involvement of Estrogen Receptors in Physiology and Cancer

Estrogens play a critical role in many physiologic processes, including reproduction, cardiovascular health, bone integrity, immune system, cognition, and behavior. But estrogens are also involved in many pathologies including for instance osteoporosis, endometriosis, or neurodegenerative diseases, but also cancer (breast, ►ovarian, ►endometrial, ►prostate, ►colorectal).

ERα and ERβ display disparity in their tissue distribution. Studies on rat have shown that ERα mRNA is predominant in the uterus, mammary gland, testis, pituitary, liver, kidney, heart, and skeletal muscle, whereas ERβ transcripts are significantly expressed in the ovary and prostate. In human, ERα and ERβ are both present in the brain, breast, cardiovascular system, and bone. In addition, ERα is much more abundant than ERβ in uterus and liver, whereas the opposite is true for ERβ in ovary, prostate and gastrointestinal tract. This differential distribution suggests that the two receptors could play distinct roles.

The most characterized cancer location involving estrogen receptors is definitely the breast. The cumulative exposure of the breast epithelium to estrogens is one of the first risk factor for ►breast cancer incidence. Estrogens are not only believed to be involved in the development and growth of breast tumors but also the late course of the disease, in their ►metastasis. The potential carcinogenic properties of estrogens are also suspected for endometrial and ►ovarian cancers. Two current hypothesis could account for estrogen carcinogenic action. First, estrogen metabolism could lead to the production of genotoxic products which directly alter DNA integrity. Second, by stimulating cell proliferation, estrogens could increase the number of cell divisions and thus the risk of replication errors, leading possibly to selective advantages for the mutated cells, which would exhibit defects in terms of apoptosis, proliferation, and DNA repair. It is interesting to note that this second hypothesis can be further divided into two subhypothesis. Indeed, ERα is generally expressed at low levels in normal breast epithelium cells (approximately 10–20% depending on the phase of menstrual cycle). Moreover, in the normal breast, it seems that there is a discordance between the cells which express ERα and the one that proliferate. For this reason, some people believe that estrogens act directly on epithelial cells to stimulate the proliferation and others suggest that estrogens act on stromal cells, which in turn secrete soluble growth factors stimulating epithelial cell growth.

In contrast to the situation observed in normal breast, breast cancer cells express frequently ERα and the same cells are actively proliferating. Breast cancers are first divided into two subtypes based on whether or not the tumor cells express ERα. ERα-positive cancers represent about two thirds of all breast cancers. The reason for analyzing ERα status is based on the facts that estrogens constitute one of the major mitotic signals for ERα-positive breast cancers. Moreover, antiestrogen drugs such as tamoxifen are commonly used as first line therapy against ERα-positive breast cancers. Unfortunately though, the use of tamoxifen is rarely associated with long-term remissions in metastatic diseases.

In contrast to the situation described for ERα, it has been reported by several groups that ERβ expression was lower in cancerous tissues compared with normal tissues. This is true for breast, ►ovarian, ►prostate, lung, and colon cancers, suggesting that this could be a general trend. Moreover, the exogenous delivery of ERβ to breast and prostate cancer leads to an inhibition of proliferation of tumor cells both in vitro and in vivo. In addition, ERβ is able to reduce the ►invasion potential of tumor cells. Moreover, ERβ knock-out animals display prostate hyperplasia suggesting the possible proliferation gatekeeper role of ERβ. Unlike ERβ, ERα levels are frequently correlated to tumor grade. Patients whose tumors express ERα have a longer interval to recurrence and an improved survival. Concerning ERβ, the prognostic value of this receptor is more controversial, even though several studies have shown that ERβ was associated with a longer disease-free survival.

At the present time, it is not completely understood why tumor cells in some instances lose the expression of ERα or ERβ. Several studies suggest that promoter hypermethylation of both genes could silence the activity of ERα and ERβ promoters. On the other hand, the hyperexpression of ERα in the vast majority of breast cancers is not at all clarified. In addition, the role of the numerous splice variants identified for ERα and ERβ transcripts is not well established. The alternative splicing of ERα mRNA occurs frequently in breast tumors, but the expression of these transcripts is also usually conserved not only in primary tumors but also in distant metastases. In the same line, several single nucleotide polymorphisms (SNPs) in ERα gene have been and associated either with an increased or a decreased risk of breast cancer, whereas the situation is much less clear for SNPs found in ERβ gene.

Estrogenic Hormones

Elwood V. Jensen
National Institute of Health, Bethesda, MD, USA

Definition

Estrogens are steroid sex hormones produced chiefly in the ovary and responsible for development and function of the female reproductive tissues such as uterus and mammary gland. Smaller amounts are also are produced by the testis in the male and the adrenal gland in both sexes, and contribute to maintenance of bone density and function of cardiovascular and neurological tissues. Estrogenic hormones play a role in both the genesis and treatment of several types of cancer. In general, estrogen-related tumors are those involving tissues of the female reproductive tract, although estrogens produce liver cancers in the hamster and are probably a factor in their occurrence in humans.

Characteristics

Etiology

Carcinogenesis is known to be a multistep process (►multistep development), involving both initiation (alteration of DNA) and promotion (proliferation of the altered cells). It is generally agreed that the principal effect of estrogenic hormones is on the promotion stage, especially in tissues where growth and function are normally regulated by estrogen. It has been controversial whether estrogens, especially in physiological amounts, also cause genetic changes in a manner similar to the action of chemical carcinogens such as dimethylbenzanthracene or nitrosourea.

Breast Cancer

The human malignancy most studied in relation to estrogen is carcinoma of the breast, both because

of its high incidence and because its involvement with estrogens is especially striking. Much evidence indicates that estrogenic hormones play an important role in the appearance of mammary cancer, both in experimental animals and in the human. It has long been known that early menarche and/or late menopause increases the risk of ►breast cancer and that artificial menopause induced by ovariectomy or radiation reduces the risk, suggesting a cumulative effect of the number of ovulatory cycles on the incidence of the disease. It is also known that full-term pregnancy before the age of 20 years confers a significant protective effect, whereas nulliparous women have an increased susceptibility to breast cancer, but the basis of this phenomenon is not clear. The effect of ►hormone replacement therapy has been the subject of much investigation and some controversy, but from the most recent studies it appears that for breast cancer the risk from unopposed estrogen is small, and the addition of progestin to the regimen makes little difference.

The putative involvement of estrogens in the genesis of breast cancer has afforded an approach to its prevention that is currently under investigation. The ►antiestrogen tamoxifen was shown to prevent both the induction of mammary tumors by dimethylbenzanthracene in the rat and the appearance of cancer in the contralateral breast after ►mastectomy in the human. Following this, a large clinical trial has demonstrated that this agent, and related antiestrogens, can lower the incidence of breast cancer in women who are at high risk for developing this disease.

Uterine, Cervical and Ovarian Cancer

Exposure to estrogen, unopposed by progestin, is a major factor in the occurrence of cancer of the uterine ►endometrium. Unopposed estrogen-replacement therapy for more than 5 years results in an elevated risk of endometrial cancer, which persists for several years after the medication has been discontinued. The addition of progestin to the estrogen-replacement regimen substantially reduces this risk. In comparison with cancers of the breast and uterus, involvement of estrogens in the etiology of cervical neoplasia is less clear. Most studies have been of the effect of oral contraceptives and generally have shown some correlation between the prolonged use of these agents and the incidence of cervical cancer. As in the case of breast cancer, late menopause, which gives rise to a longer period of ovulatory activity, results in an increased risk of ovarian cancer. Similarly, pregnancy and the use of oral contraceptives, which decrease the number of ovulatory cycles, are protective.

Vaginal Adenocarcinoma

During the period 1945–1955, large doses of estrogenic hormones were often administered to pregnant women with a history of miscarriage in the belief that this would protect against spontaneous abortion. Because orally-active steroidal hormones were not available at that time, a synthetic estrogen called diethylstilbestrol (DES) was used. In the early 1970s, a previously rare cancer, clear cell ►adenocarcinoma of the vagina, began to appear in the daughters born to the DES-treated mothers, leading to the impression that estrogens in general, and DES in particular, are carcinogens and should not be used for human medication. However, the amounts administered (0.5–1.0 g) were 5,000–10,000 times the hormonally active dose, and the cancers produced were not in those persons receiving the estrogen but in their offspring, indicating that this is an in utero phenomenon and the action of the hormone is better described as ►teratogenic than carcinogenic. Longer follow-up has demonstrated a slightly increased incidence of breast cancer among the DES-treated mothers, but not what might be expected from such high doses of a true carcinogen. Genital abnormalities were produced in the male offspring, in keeping with a teratogenic phenomenon.

Hepatoma

In certain animal species such as the hamster, liver cancer can be induced by the simple administration of estrogens. In the western world, primary liver cancer in humans is a relatively rare phenomenon, except for individuals with cirrhosis. However, it is a major cause of death in Asia and South Africa. The introduction of oral contraceptives has led to an increased incidence of liver tumors after long-term use of preparations containing substantial amounts of estrogen. It has been reported that hepatomas can arise from the use of prolonged ►diethylstilbestrol (DES) therapy for prostatic cancer.

Therapy

When cancer occurs in tissues where growth and function depends on estrogenic hormones, in some instances the malignant cells retain their hormone dependency while others lose the need for continued stimulation. It is not clearly established what is the exact basis for hormone dependency, and whether escape from this regulation takes place on neoplastic transformation or during subsequent tumor progression. For cancers that retain hormone dependency, depriving them of estrogen provides an effective palliative treatment, less traumatic than ►cytotoxic chemotherapy, which is the only recourse for the majority of non-hormone-dependent ►metastatic cancers.

Breast Cancer

Hormone-dependent mammary tumors can be deprived of supporting estrogen either by removing the organs in which the hormone is produced, administration

of substances that inhibit estrogen ►biosynthesis, or by giving a so-called antiestrogen that prevents the hormone from exerting its growth-stimulating effect in the cancer cells. More than a century ago, before it was known what estrogens are or that they are produced in the ovary, it was found that removal of the ovaries from young women with advanced breast cancer caused remission of the disease in some patients. But the majority of breast cancers occur in postmenopausal women, where the ovaries are no longer functional, and it was long suspected that in the older patient the adrenal glands are the source of supporting estrogen. When cortisone became available, first for the treatment of inflammatory diseases, it became possible to remove the adrenal glands or the pituitary gland which controls them and maintain the patient on ►glucocorticoid replacement therapy. Subsequent clinical experience showed that about one-third of all the patients have mammary tumors that undergo remission when deprived of supporting hormone by any of these procedures, and ►endocrine ablation became first-line therapy for advanced breast cancer, especially after methods were developed to predict which patients will or will not respond to endocrine manipulation.

When it was demonstrated that estrogens, like steroid hormones in general, exert their physiological actions in combination with specific receptor proteins, it was established that patients whose tumors contain low or negligible amounts of ►estrogen receptor (ER) rarely respond to any kind of endocrine therapy, whereas most, but not all, patients with ER-rich cancers benefit from such treatment. Determination of estrogen receptor on excised breast cancer specimens, either by immunological or hormone-binding procedures, is now standard clinical practice.

As an alternative to endocrine ablation, hormone deprivation can be effected by inhibiting the enzymes involved in estrogen biosynthesis. This approach has the advantage that it eliminates not only estrogen arising from the ovary or adrenal gland, but also that which, in some cases, appears to be produced by the tumor itself. The first successful agent for this purpose was aminoglutethimide, which inhibits the key enzyme, ►aromatase, but its clinical utility has been limited by undesirable side effects. Several improved compounds have been developed recently including fadrozole, letrozole, vorozole and arimidex, which show promise of increased activity with reduced toxicity.

With the advent of ►tamoxifen, the first antiestrogen to be tolerated on prolonged administration, this reversible treatment has largely replaced the irreversible endocrine ablation as first-line therapy for ►endoplasmic reticulum (ER)-rich breast cancers. Although there are side effects from prolonged treatment, as well as a slightly increased risk of endometrial cancer, the benefits greatly outweigh the drawbacks. Tamoxifen and related non-steroidal compounds such as torimifene, raloxifene and droloxifene, show curious pharmacology in that depending on species, tissue and dose they can act either as stimulators or inhibitors. A limitation of tamoxifen therapy is the development in many patients of an "acquired tamoxifen resistance" in which the medication no longer inhibits but actually stimulates the growth of the cancer. More recently, steroidal antiestrogens such as faslodex (ICI 182,780) and RU 58668 have been developed, which show only inhibitory (antagonist) but not stimulatory (agonist) action.

Uterine and Cervical Cancers

Because growth and development of the uterus are stimulated by estrogen, attempts have been made to treat ►endometrial cancer with ►tamoxifen in a manner analogous to mammary cancer, but the response rate is low and variable. The most widely used hormonal therapy for this malignancy is treatment with ►progestin. Cervical cancer is especially sensitive to radiation and does not metastasize agressively and so surgery and/or radiotherapy are the usual therapeutic procedures, and endocrine therapy has found little application.

Ether à-go-go Potassium Channels

Javier Camacho
Pharmacology Division, Centro de Investigación y de Estudios Avanzados del I.P.N., Mexico City, Mexico

Synonyms
Eag; Kv10.1; KCNH1

Definition
Ether à-go-go potassium channels are transmembrane proteins opening in response to changes in ►membrane potential and allowing the movement of potassium ions.

Characteristics
Ion transport is crucial for maintaining proper cellular function; this important task is performed by several ►membrane transporters including ►ion channels.

Among other functions, ion channels play key roles in neurotransmission, muscle contraction, metabolism, sensory transduction, ►apoptosis and cell cycle progression. Because of their pivotal role in cellular function, altered expression and/or activity of ion channels leads to several diseases including cardiac arrhythmias, diabetes and epilepsy, turning these proteins into major drug targets. Participation of ion channels in cell proliferation and cell death makes them not only fundamental elements for the understanding of ►cancer but also potential clinical tools both for diagnosis and therapy of cancer.

Ether à-go-go (Eag) comprises a family of voltage-gated potassium channels opening in response to changes in membrane potential. Some members of the Eag family, namely, *human Eag1* (h-Eag1) and *human-eag-related gene* (h-Erg) are linked to major diseases. H-Erg channels have an essential role in the cardiac action potential; h-Erg mutations produce the long Q-T syndrome type 2 leading to cardiac arrhythmias and eventually – in many cases- death of the patient. A huge number of very different drugs inhibit h-Erg channels producing cardiac arrhythmias as a non-desirable side-effect, thus h-Erg has become an intensively studied ion channel when designing new drugs. In addition, both Eag1 and Erg have been found to be over-expressed in a variety of tumors. H-Erg channels have been found in leukemic cells and biopsies from ►colorectal cancer and ►endometrial cancer; hence, h-Erg expression has been suggested as a molecular marker for human neoplastic hematopoietic cells and a potential prognostic factor for colorectal cancer. H-Eag1 is the other member of the EAG family involved in cancer. In addition to be over-expressed in many human tumors, h-Eag1 possess oncogenic properties, has a more restricted distribution in normal healthy tissues in comparison to h-Erg channels and specific inhibition of h-Eag1 gene expression reduces tumor cell proliferation. In the following, only oncogenic Eag1 channels will be discussed.

Oncogenic Potential of h-Eag1 Channels

Eag1 channels display oncogenic properties. Some characteristics of tumor cells are that they are able to grow in very low serum concentration, lose ►contact inhibition and induce tumor formation when injected into immune-deficient mice. ►Cell lines that normally do not display these characteristics, acquire properties of tumor cells when forced to express h-Eag1 channels. The oncogenic potential given to the cells by Eag1 channels is specific because the expression of another type of voltage gated potassium channel in the same cell type does not induce tumor properties like those induced by Eag1. In addition, cell lines forced to express Eag1 have a higher metabolic activity and DNA synthesis than cells lacking Eag1 or expressing a different potassium channel. Findings of these oncogenic properties of Eag1 raised immediately research on the distribution of Eag1 in normal human tissues and tumor samples and its potential use as a cancer ►biomarker.

Eag1 as a Diagnostic Marker

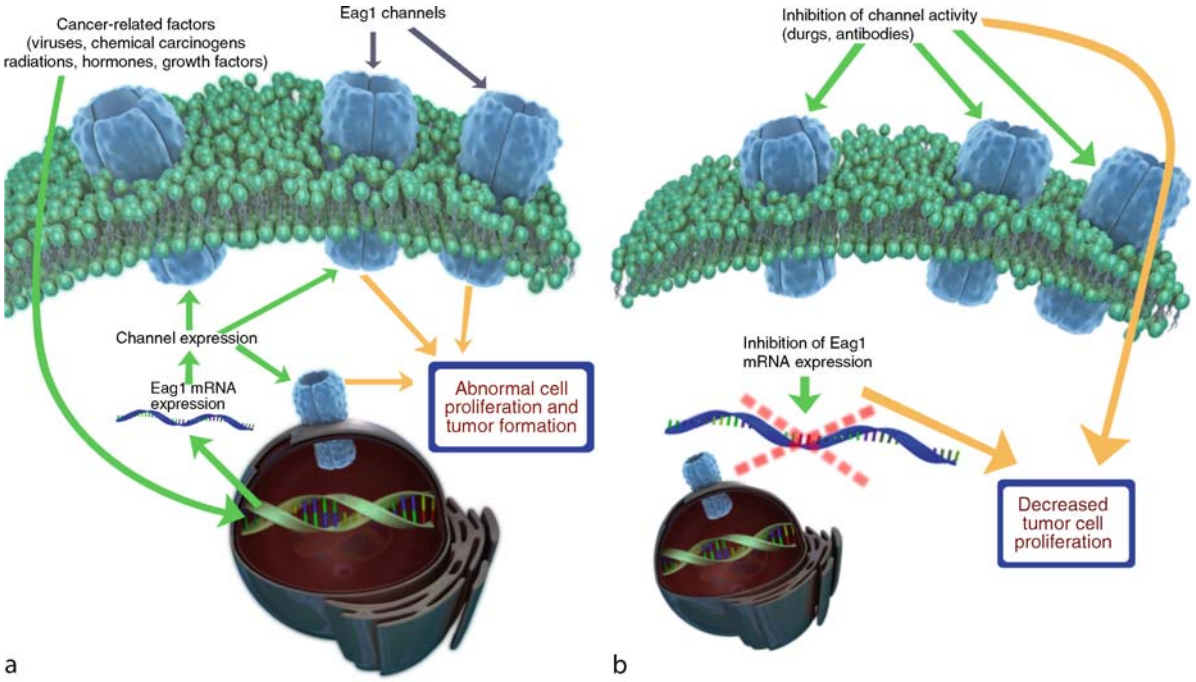
Eag1 mRNA is distributed in a very restricted manner in healthy tissues. It is mainly expressed in brain, although few amounts are found in testis, adrenal gland, placenta and is also transiently expressed in myoblasts. Actually, Eag1 expression before myoblasts fusion is the only known role of Eag1 in normal non-tumor cells; the precise participation of Eag1 in brain function remains elusive. In sharp contrast, Eag1 mRNA, protein expression (detected by specific antibodies) and/or protein activity (studied with the ►patch-clamp technique) have been found in several tumor cell lines and in a wide variety of biopsies from human tumors including lung, mammary gland, prostate, colon and uterine-cervix.

Eag1 mRNA expression has been also suggested as a potential early indicator of tumor formation. ►Cervical cancer studies revealed Eag1 mRNA expression in all of the samples from carcinomas but also in some control samples from patients with normal cervix (diagnosed by pap smears studies); these patients presented either ►human papilloma virus (HPV) infection or alteration in nearby regions (for example an ovarian cystadenoma or endometrial hyperplasia) suggesting Eag1 as a potential sign of early cellular alterations. Cancer etiological factors like viruses -including HPV-, chemical carcinogens, radiations (including ►UV radiation), ►estrogens, etc. are potential inducers of Eag1 expression with the subsequent altered cellular proliferation and tumor formation (see Fig. 1). Besides, Eag1 mRNA is present not only in mammary gland tumors but also in some free-tumor tissues from the vicinity of the tumors, while Eag1 is not found in commercially available RNA from normal mammary epithelium.

Diagnostic methods based on Eag1 expression are promising because in some cases (for example cervical cancer) cells can be obtained from the patients and tested for Eag1 protein expression with specific antibodies. On the other hand, it has been shown that fluorescent labeled antibodies against Eag1, show the presence of the protein in lymph nodes that had not been clinically evident; this approach represents a non-invasive optical technique to detect Eag1. The restricted distribution of Eag1 in normal tissues, the abundant and ubiquitous expression in tumors and the potential regulation by cancer-associated factors convert Eag1 expression in an attractive cancer biomarker.

Eag1 as a Therapeutic Target

Several approaches have demonstrated that Eag1 expression in tumor cells has an important role in cell



Ether à-go-go Potassium Channels. Figure 1 Clinical relevance of Eag1 channels. (a) Eag1 channels are overexpressed in tumor cells favoring cell proliferation, some cancer related factors are potential inducers of Eag1 channels which are expressed at the plasma membrane but also probably in the nucleus. (b) Inhibition of either channel activity or RNA expression decreases tumor cell proliferation. Therefore, Eag1 channels represent powerful tools both for cancer diagnosis and therapy.

proliferation. Eag1 channels are inhibited by several non-specific potassium channel blockers, however, at the moment there are no drugs inhibiting specifically Eag1 channel activity. Imipramine, a common antidepressant drug inhibiting several ion channels including Eag1, decreases tumor cell proliferation of different cell lines expressing Eag1, strongly suggesting that Eag1 channel activity is necessary in proliferation of human tumor cells.

More recent molecular biology strategies like ►RNA silencing have been proved to be very useful for inhibiting specific gene expression. This approach has been used to study the role of Eag1 in proliferation of tumor cells. Specific inhibition of Eag1 gene expression by small interfering RNA (►siRNA) caused a marked decrease in proliferation of several tumor cell lines. In some cases, specific Eag1 RNA silencing inhibited tumor cell proliferation in more than 80%.

Targeting Eag1 for cancer therapy (see Fig. 1) offers at least two important advantages:

1. Because of Eag1 restricted distribution in normal tissues, targeted cells would be mainly cancer cells and the side-effects in normal cells should be almost insignificant. In healthy tissues Eag1 is mainly expressed in the brain which is already protected by the ►blood brain barrier.
2. The well-known drug-resistance showed by some cancer cells via membrane transporters would be bypassed when using specific blockers of channel activity targeting the plasma membrane Eag1 channels.

Mechanisms of Oncogenicity

Molecular mechanisms explaining the oncogenic potential of Eag1 channels remain unknown, however, there are several current hypothesis which can be divided into two groups, general and particular. General hypothesis include the following:

1. Eag1 channels establish a negative membrane potential required for cell cycle progression from the G1 to the S phase. Potassium channel inhibition arrest the cells in the G1 phase of the cell cycle.
2. The negative membrane potential increases the electromotive force for calcium entry which in turn might trigger several transduction pathways.
3. Potassium movement regulates cell volume and volume changes are associated to cell proliferation for instance by altering nutrient concentration.

Particular current hypothesis are based on more structural features. Like other voltage gated potassium channels, Eag1 protein is composed by four subunits (see Fig. 1) having six transmembrane spanning

segments numbered S1–S6; the S4 segment forms the voltage sensor due to its positively charged amino-acids residues, and the loop between the segments S5–S6 forms the pore of the channel. Nevertheless, Eag1 has special sequences not shared as a whole with other potassium channels that provide potential clues on its oncogenic mechanisms and include the following:

1. Eag1 has a nuclear targeting signal presumably to direct the channel to the nucleus. It has been demonstrated for a calcium channel that a segment of the channel encodes a transcription factor regulating the expression of several genes. Something similar should be expected to happen with Eag1 if the channel or at least part of the protein was expressed in the nucleus (see Fig. 1).
2. Epsin is a protein participating in the ►endocytosis of growth factor receptors. Epsin binds to Eag1, probably this binding changes the free-epsin levels deregulating endocytosis of growth factor receptors and allowing growing signals to proceed.
3. Calmodulin binding sites (integrating calcium signals), a nucleotide binding domain and a Pern-Arnt-Sim domain (PAS domain involved in responses to ►hypoxia) as well as putative phosphorylation sites by ►protein kinase C and mitogen activated kinase (►MAP kinase) described for Eag1 might also act in concert to regulate channel activity or interaction with other proteins and favor cell proliferation.

Outline

Expression of Eag1 potassium channels confers oncogenic properties to mammalian cells. Because of their very restricted distribution in normal human tissues but more general distribution in tumor samples, Eag1 mRNA and/or protein expression offer potential tools for the diagnosis of a wide variety of neoplasms. Moreover, the potential regulation of Eag1 by cancer etiological factors like human papilloma virus, suggest Eag1 as a possible indicator of early cellular transformation. Specific inhibition of Eag1 produces a drastic decrease in tumor cell proliferation, making Eag1 a promising target for cancer therapy. Despite the molecular mechanisms of Eag1 oncogenicity are unknown, Eag1 represents a hopeful tool for cancer diagnosis and therapy.

Etiology

►Cancer Causes and Control

Etk

Definition

Synonym Bmx, a Btk family tyrosine kinase, mediates cellular transformation by linking Src to STAT3 activation, binding to the FERM domain of FAK

►Focal Adhesion Kinase (FAK)

Etoposide

Definition

Synonym VP-16, with common trade names etopophos (etoposide phosphate) and vepesid. Etoposide is a cytotoxic chemotherapeutic. Most commonly it is used to treat ►Ewing sarcoma, testicular cancer, ►lung cancer, lymphoma, non-lymphocytic leukemia and ►glioblastoma multiforme. Etopososide inhibits DNA synthesis, through inhibition of ►DNA topoisomerase II.

Ets

Definition

Family of transcription factor genes with similar DNA-binding domain named after the first member, the avian erythroblastosis virus oncogene E26 (E twenty-six).

►Ets Transcription Factors

ETS (Environmental Tobacco Smoke)

Definition

Is the complex mixture of chemicals formed from the smoldering of a tobacco product; smoke exhaled by the smoker, smoke that escapes while the smoker inhales, and some vapor-phase components that diffuse into the environment. To date, over 50 compounds in ETS have been identified as carcinogens. Exposure to ETS is also known as passive smoking or involuntary tobacco smoke.

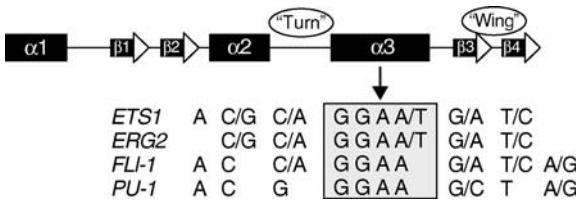
Ets Transcription Factors

Jürgen Dittmer
Klinik für Gynäkologie, Universität Halle-Wittenberg, Halle (Saale), Germany

Definition

Ets transcription factors are defined by a unique DNA binding domain, the ETS domain, which specifically interacts with an ~10 bp long DNA sequence containing a 5′-GGAA/T-3′ core motify (Fig. 1) Ets stands for E26 transformation specific or E26, as the Ets sequence (v-ets) was first identified in the genome of the avian retrovirus E26. c-Ets1, closely related to v-Ets, was the first cellular Ets protein that was discovered. More than 30 different Ets proteins have been identified, found throughout the metazoan world including mammals, sea urchins, worms and insects. Currently, 27 human Ets proteins are known. The Ets family is subdivided into subfamilies based on the similarity in the ETS domain (Fig. 2).



Ets Transcription Factors. Figure 1 The ETS domain. This winged helix-turn-helix domain binds DNA by a loop-helix-loop scaffold, composed of the helix (α2)-turn-helix(α3) motif and the loops between α2 and α3 (turn) and between the β strands β3 and β4 (wing). All direct contacts with specific bases of the DNA are made by residues in the α3 recognition helix while residues of the two loops contact the phosphate backbone. The resulting neutralization of the phosphate charges is likely to induce DNA bending, as observed in Ets protein-DNA complexes. In contrast to the helices, the loops are not strictly conserved among members of the Ets family. They may, therefore, be responsible for the preference of an individual Ets protein for the sequences flanking the conserved GGAA/T binding motif.

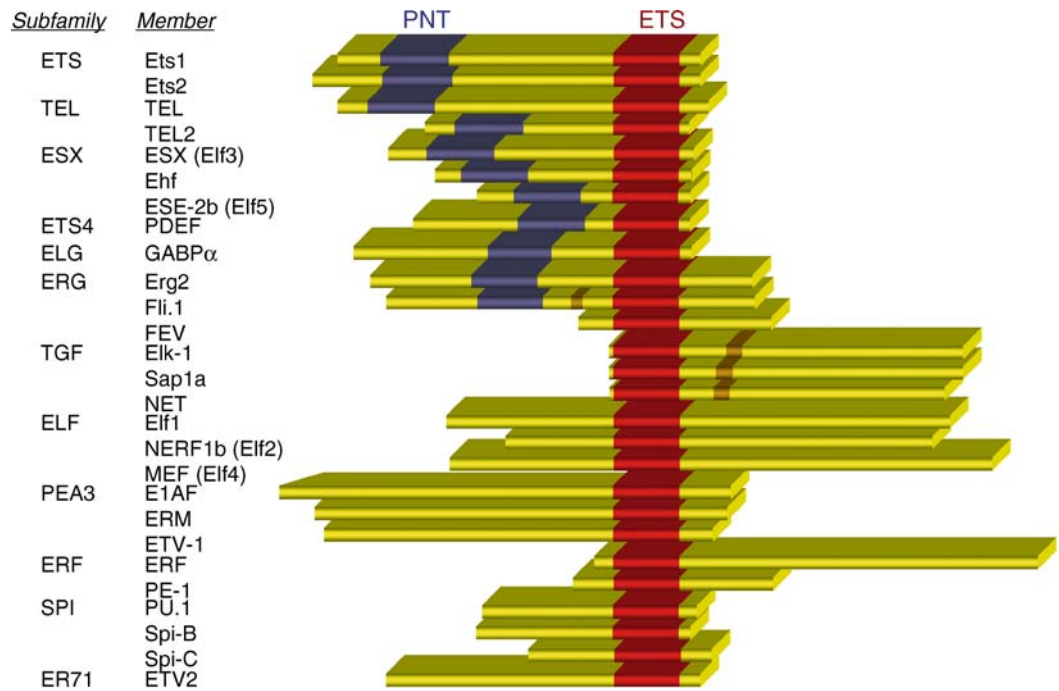
Characteristics

In contrast to many other transcription factors, Ets proteins bind to DNA as monomers. Most eukaryotic cells express a variety of Ets proteins at the same time. To achieve functional specificity, Ets proteins display differences in preference for certain nucleotides flanking the core motif in the Ets responsive DNA element and, more important, for certain cooperating partners. A strong interaction with a cooperating partner may even force Ets proteins to bind to an unfavorable DNA binding site, such as GGAG (Pax5/Ets1 partnership). In many cases, interactions with other proteins depend upon particular protein domains. E.g., for the cooperation with ►SRF, the so-called B-domain is required, which is found in the proteins of the TCF subfamily and the Fli-1 protein. The Pointed domain, named after the Drosophila Ets Protein Pointed and shared by many Ets proteins of different subfamilies, shows similarities to the sterile alpha motif (SAM) domain and is an interface for homotypic and heterotypic protein-protein interactions. In Ets1 and Ets2 proteins, the Pointed domain is the docking site for ERK1/2 allowing these kinases to phosphorylate Ets1 and Ets2 at an N-terminal threonine. In contrast, the Pointed domain of the TEL protein mediates homo-oligomerization. Most Ets proteins are transcriptional activators, others (ERF, NET, Tel, Drosophila YAN, Caenorhabditis lin-1) act as repressors. Some, such as Elk-1 and Net, can undergo activator-repressor switching (Fig. 2).

Ets proteins play an important role in transcriptional regulation. Many eukaryotic genes contain Ets DNA binding sites and are responsive to Ets proteins. Ets-responsive genes are found among critical genes that regulate fundamental cellular processes such as proliferation, differentiation, ►invasion and ►adhesion.

Ets Factors and Development

Some Ets factors, including Ets2, Esx, Ese-2, Fli-1, Pu.1, GABPα and Tel, are essential for embryonic development. Disruption of the ets2, ese-2, fli-1, pu.1, gabpα or tel gene in mice results in early death of the embryo. Lack of Ets2 or Ese-2 leads to defects in trophoblast development and to the absence of extraembryonic ectoderm markers. Ese-2 is also involved in mammary



Ets Transcription Factors. Figure 2 Members of the Ets transcription factor family in humans. The DNA binding domain (ETS), the Pointed (PNT) domain and the SRF-interacting B-domain are marked. Note that most Ets proteins have several different names. The Esx and Elf proteins are grouped into two separate subfamilies. Splicing variants of the different Ets proteins are not listed. Tel – translocation, Ets, Leukemia, Esx – epithelial-restricted with serine box, Ehf – Ets homologous factor, ESE – epithelium-specific Ets, PDEF – prostate derived Ets factor, ELG – ets like gene, GABP – GA-binding protein, Erg – ets-related gene, Fli – Friend leukemia integration, FEV – Fifth Ewing variant, TCF – ternary complex factor, Elk – ets like gene, Sap – SRF accessory protein, NET – new ets transcription factor, Elf – E74-like factor, NERF – new ets related factor, MEF – myeloid elf-1 like factor, PEA3 – polyoma enhancer A3, E1AF – adenovirus E1A factor, ERM – Ets related molecule, ETV – Ets translocation variant, ER81 – Ets related clone 81, ERF – Ets2 repressor factor, PE – PU-Ets-related, Spi – SFFV provirus integration site, PU – recognizes purine-rich sequences.

alveolar morphogenesis. Tel null mutant embryos fail to develop a vascular network in the yolk sac. Pu.1 is necessary for B- and T-cell development, erythropoiesis, terminal myeloid cell differentiation and maintenance of hematopoietic stem cells. Fli-1 null embryos die of aberrant hematopoiesis and hemorrhaging. Deficiency of GABPα which is expressed in embryonal stem cells leads to embryonic death prior to implantation. GABPα is also required for the function of neuromuscular junctions. Mice lacking Esx die early after birth. Their intestinal epithelial cells fail to differentiate and polarize as result of reduced levels of the TGFβII receptor (►transforming growth factor β). Ets1 deficiency leads to defects in B- and T-cell development. In ER81 null mice, two types of mechanoreceptors, muscle spindles and the Pacinian corpuscles, are either absent or degenerated. MEF is involved in osteogenic differentiation.

Regulation of Ets Protein Activities

The activities of Ets proteins are controlled transcriptionally and post-translationally. The expression of many Ets genes are restricted to certain cell types and/or can be induced by specific extracellular stimuli. E.g., the transcription from the Ets1 gene can be activated by a variety of factors including phorbol ester, ►AP-1, ►TP53, ►retinoic acid, ERK1/2 (►MAP kinase) and HIF-1 (►hypoxia Inducible Factor-1). Many Ets proteins undergo post-translational modifications, which have an impact on their activities. The most common post-translational modification of Ets proteins is phosphorylation by MAP kinases, such as ERK1/2. Phosphorylation by MAPK leads to activation of activating Ets proteins, such as Ets1, Ets2, Er81, Erm, Sap1, Elk1, Pea3 or GABPα, and loss of activity of repressing Ets proteins, such as Tel or Erf. When phosphorylated by ERK1/2, Net even switches from a repressor to an activator phenotype. It seems that MAPK-dependent phosphorylation (►phosphorylation of proteins) ►shifts the balance between Ets-dependent activation and repression toward activation. In the case of Ets1, MAPK-dependent phosphorylation enhances the transcriptional activity by recruitment of the coactivator CBP/p300 (►p300/CBP Co-Activators). Some Ets proteins are also targets of ►PKA, PKC (►protein kinase C Family), CaMKII (►Calcium binding proteins and Cancer), ►CKII and cyclin A-dependent

cdk2 (►cyclin-dependent kinase). CKII increases the activity of Pu.1 and Spi-B and PKCα activates Ets1. In contrast, PKA inhibits the DNA binding activities of Er81 and Erm, whereas CaMKII and cdk2 act inhibitory on Ets1 and GABPα, respectively. CaMKII phosphorylates Ets1 on serines of a serine-rich region flanking an autoinhibitory module that regulates Ets1 DNA binding activity. The inhibitory effect of CaMKII on the Ets1 protein increases with each serine that is phosphorylated within the serine-rich region allowing fine-tuning of Ets1-dependent transcription.

A few Ets proteins, Ets1, Elk-1 and Tel, have been shown to undergo ►sumoylation. This post-translational modification inhibits transcriptional activity of Ets1 and Elk-1 and abrogates the repressing activity of Tel. When sumoylated, the activating Elk-1 protein even transforms to a repressor. ►Acetylation is another means nature uses to modify the activities of Ets proteins, such as Ets1 and Er81. Er81 becomes acetylated and phosphorylated in response to Her2/neu-stimulated signaling. Acetylation takes place on two lysines within the transactivation domain of Er81 increasing its DNA binding affinity and protein stability. Elf-1 is an example of an Ets protein that becomes glycosylated. ►Glycosylation affects the subcellular localization and DNA binding activity of Elf-1.

Ets Proteins and Cancer

The Ets proteins Ets1, Ets2, Fli-1 and Erg are able to transform murine cells. These and other Ets proteins are also involved in human carcinogenesis and/or tumor progression. This is in line with the fact that many of these Ets proteins are targets of the ►Ras/Raf/MEK/ERK signaling pathway which is often deregulated in human tumors. The Ras-responsive Ets1 protein is found in different types of solid tumors, including ►carcinomas and ►sarcomas. Its overexpression often correlates with increased invasion, higher tumor microvessel density, higher grading and unfavorable prognosis. Ets1 has been linked to the regulation of key proteases, such as ►matrix metalloproteases, involved in the degradation of the ►extracellular matrix. In tumors, Ets1 is expressed by tumor cells as well as by stromal cells. By its ability to convert endothelial cells to an angiogenic phenotype, Ets1 is involved in tumor-dependent ►angiogenesis. A number of other Ets proteins, such as ERG, PEA3 and E1AF, are capable of upregulating proteases and supposed to be involved in tumor progression. PEA3 has particularly been linked to mammary gland development and oncogenesis. Fli-1 and Ets1 has been shown to regulate tenascin C (►tenascin and cancer), an extracellular matrix protein, associated with tumor progression. In some tumors, Ets genes are subject to mutations and recombinations. The inhibitory Ets protein Tel2 has been shown to induce myeloproliferative diseases in mice by cooperating with the ►Myc oncogene and stimulating proliferation. Elf-1 has been implicated in tumor-associated angiogenesis. A target of Elf-1 is Tie2 (►receptor tyrosine kinases), a receptor tyrosine kinase involved in the activation of endothelial cells. Chromosomal translocations leading to fusion proteins containing Ets proteins are observed in Ewing tumors and certain types of leukemias. EWS-Ets fusion proteins (►EWS-FLI (ets) Fusion Transcripts), most often containing Fli-1 or Erg, rarely ETV-1, E1AF or FEV, are critically involved in the development of Ewing tumors. The fusion protein presumably acts as a transcription factor that binds through the Ets domain to Ets-responsive genes. In addition, EWS-Ets proteins have been suggested to interfere with RNA splicing. Ets fusion proteins, as found in leukemias, harbor either Tel or Erg2. Erg2 is fused to TLS, a protein structurally related to EWS. Hence, TLS-Erg2 chimeric proteins are supposed to have similar functions as EWS-Ets proteins. Tel is frequently fused to tyrosine kinases, such as PDGFRβ (►platelet-derived growth factor), Abl (►BCR-ABL1) or Jak2 (►Signal Transducer and Activators of Transcription in Oncogenesis). The Pointed domain of Tel mediates homo-dimerization resulting in constitutively active kinases. In another fusion protein, Tel is linked to the DNA binding factor AML-1 (►runx) which together with CBFβ forms the transcription factor CBF. CBF activity is often inhibited in leukemic cells. As a result of Tel-dependent dimerization, CBF function is also blocked when AML-1 is fused to Tel.

ETV6

Stefan K. Bohlander
Medizinische Klinik und Poliklinik III, Klinikum Großhadern, Universität München, München, Germany

Synonyms

ETS variant gene 6

Definition

A gene encoding an ►*ets* domain transcription factor located on human chromosome 12 band p13. It is a frequent target of ►chromosomal translocations.

Characteristics

Discovery

The short arm of chromosome 12 is a hot spot for chromosomal rearrangements in diverse types of hematological malignancies. These rearrangements include balanced translocations with a great number of different chromosome partner bands as well as unbalanced translocations and deletions. The latter two rearrangement leads to the loss of genetic material from 12p. Molecular cytogenetic studies showed that more than half of the observed balanced translocations of 12p have breakpoints that involve the *ETV6* gene. There are currently more than 40 different 12p translocations described that involve the *ETV6* gene.

ETV6 was originally identified as the fusion partner of the ►platelet derived growth factor receptor beta gene (*PDGFRB*) in a balanced t(5;12)(q31:p13) translocation from a case with chronic myelomonocytic leukemia (CMMoL). Initially, *ETV6* was called ►*TEL* (translocation *ets* leukemia gene), but was later renamed as *ETV6* (*ets* variant gene 6) to avoid confusion with the abbreviation for telomere.

Protein Domains

ETV6 is a member of the *ets* (E-26 transforming specific) family of ►transcription factors. All *ets* family proteins share a very conserved protein domain of about 88 amino acids in length, the so called *ets* domain (Fig. 1). The *ets* domain is a sequence specific DNA binding domain but also mediates protein-protein interaction. It is evolutionarily highly conserved and found in invertebrates such as *Drosophila* and *C. elegans*. The *ets* domain of *ETV6* is more closely related to the *ets* domain of the Drosophila protein *yan* than to *ets* domain of the human ►*ETS1* or *SPI1* (PU.1) genes.

The other evolutionarily conserved domain in ETV6 is the N terminally located *pointed* or SAM (sterile alpha motif) domain. This domain is even more highly conserved in evolution than the *ets* domain, and is found in many *ets* family members as well as in many other transcription factors and signal transduction proteins. The *pointed* domain serves as a homo- and heterodimerization module.

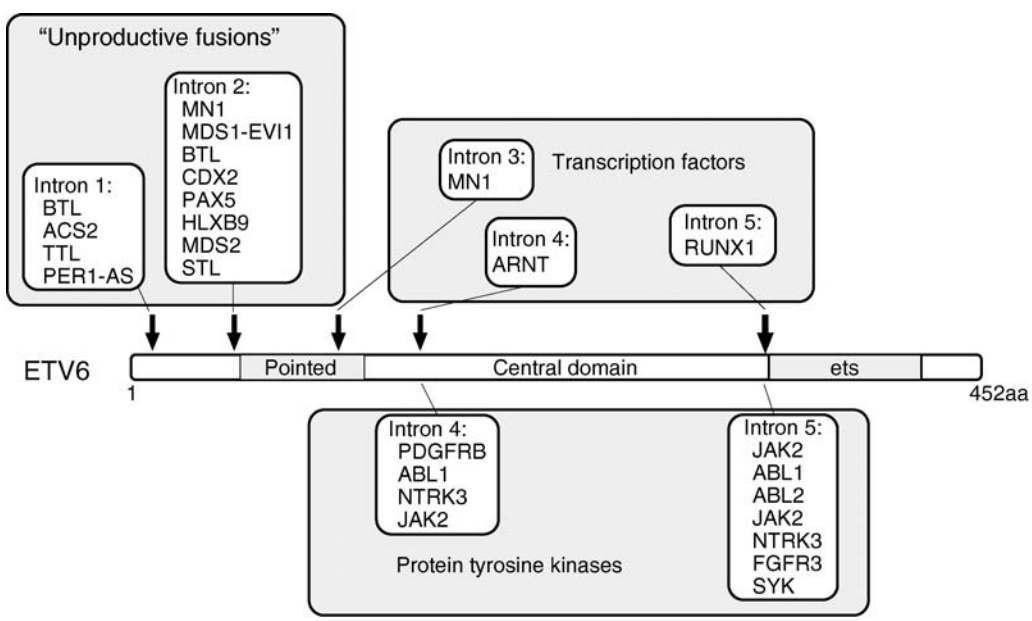
ETV6 Fusion Partners in Cancer

After the initial cloning of *ETV6*, several other fusion partners of *ETV6* were identified in quick succession. There are now well over 20 fusion partners of *ETV6* described, and the list is still growing.

The various *ETV6* fusions can be assigned to three groups: (i) protein ►tyrosine kinases (PTK); (ii) transcription factors and others; (iii) "unproductive" fusions, i.e. fusion that do not result in an obvious fusion protein.

Protein Tyrosine Kinase Fusion Partners of ETV6

The first identified fusion partner of *ETV6* was the protein ►tyrosine kinase (PTK) platelet-derived growth



ETV6. Figure 1 Diagrammatic representation of the ETV6 protein with the position of the breakpoints of the various fusion partner genes.

factor receptor beta gene. The ETV6/PDGFRB fusion protein is a constitutively active PTK and is the critical product of this translocation. In the ETV6/PDGFRB fusion protein, the N terminal portion of ETV6, which includes the *pointed* domain, is fused to the C terminal two thirds of the PDGFRB protein, which includes the tyrosine kinase domain of PDGFRB. This general structure, i.e. the *pointed* domain of ETV6 in the N terminal half and the tyrosine kinase domain of the fusion partner in the C terminal half of the fusion protein, is characteristic of all ETV6/PTK fusions. Many studies have shown that the *pointed* domain of ETV6 serves as a dimerization module for the fusion protein. Dimerization of the fusion protein leads to the constitutive activation of the PTK domain, which results in autophosphorylation of the fusion protein as well as phosphorylation of cellular proteins like rasGAP, Shc, SH-PTP2, SH-PTP1, CRK-L, CBL, paxillin, and STATs. Expression of ETV6/PTK fusions in the interleukin 3 dependent hematopoietic cell line Ba/F3 leads to factor independent growth. Several ETV6/PTK fusion proteins have also been assayed in murine bone marrow transplantation or transgenic mouse models where they lead to various hematological diseases like myelo- or lympho-proliferative syndromes. The different protein tyrosine kinase genes that have been found to be fused to ETV6 are listed in Table 1. It should be noted that most of these fusions are rather rare. For several partners just one or a handful of cases have been described in the literature.

ETV/PTK fusions are not only found in various types of leukemia but the ETV6/NTRK3 fusion has also been found in solid tumors such as congenital fibrosarcoma, mesoblastic nephroma and secretory breast carcinoma.

Transcription Factors and Other Fusion Partners of ETV6

There are only two fusions of *ETV6* with non PTKs for which the transforming potential of the fusion protein could be established. This is the very common ETV6/►RUNX1 and the much rarer MN1/ETV6 fusion.

The ETV6/►*RUNX1* Fusion

The ETV6/RUNX1 (TEL/►AML1) fusion was the second fusion of ETV6 that was identified. It was soon recognized that the ETV6/RUNX1 fusion is the most common fusion gene found in childhood ►acute lymphoblastic leukemia, which is present in up to 25% of all childhood B-ALL cases.

The ETV6/RUNX1 fusion protein, which is the critical fusion in this translocation, comprises the *pointed* domain of ETV6 as well as the DNA binding and transactivation domain of RUNX1.

Many ETV6/RUNX1 positive ALLs have interstitial deletions (detectable by Fluorescence in situ hybridization, ►FISH) of the short arm of the non-rearranged chromosome 12, which encompass the ETV6 locus. Even in cases in which no interstitial deletion of the non-rearranged ETV6 allele can be detected by FISH, there is no expression of the wild-type ETV6 allele suggesting a very important role for ETV6 loss of function in the pathogenesis of ►ALL.

Little is known about mechanisms by which the ETV6/RUNX1 fusion protein causes leukemia. Several attempts to establish ETV6/RUNX1 transgenic or bone marrow transplant leukemia models have failed or yielded leukemia only after a very long latency. There is some evidence that leukemogenesis by ETV6/RUNX1 is accelerated if cell cycle regulation is compromised by other mutations.

Some hints as to the function of ETV6/RUNX1 have been gleaned from reporter gene assays. In these experiments, the ETV6/RUNX1 fusion protein behaves as a strong transcriptional repressor on AML1 target genes. The *pointed* domain and the central domain of ETV6 have been shown to recruit transcriptional corepressors like SMRT, N-CoR and mSin3A.

The MN1/ETV6 Fusion

The MN1/ETV6 fusion is found in some patients with ►acute myeloid leukemia (AML) or ►myelodysplastic syndrome with a t(12;22)(p13;q11) translocation. *MN1* was originally found as a gene disrupted by a translocation in ►meningeoma. The critical MN1/ETV6 fusion protein, which is able to transform murine NIH3T3 fibroblasts in vitro (►NIH3T3 transformation assay) contains transcriptional activation domains derived from MN1 and the *ets* DNA binding domain of ETV6. This is the only known example in which the *ets* domain of ETV6 seems to be critical for transformation.

The ETV6/ARNT Fusion

Another rare ETV6/transcription factor fusion is the ETV6/ARNT fusion gene reported in one patient with AML and a t(1;12)(q21;p13), which links the N-terminal portion of ETV6 including the *pointed* domain to almost the complete ►aryl hydrocarbon receptor nuclear translocator (ARNT).

"Unproductive" ETV6 Fusions

A large number of chromosomal translocations involving *ETV6* have been cloned, in which the breakpoints lie in intron 1 or 2 of *ETV6*. These translocations result in *ETV6* fusions that contain only the 54 amino terminal amino acids of ETV6 and lack any of the important protein domains of ETV6 like the *pointed* or *ets* domain (Table 1). Almost all of these translocations have been identified in only one or at the most a handful of leukemia cases.

It is very likely that most, if not all, of these translocations do not result in the formation of a

ETV6. Table 1 Translocation partners of ETV6

transforming ETV6/other fusion protein, but rather that they lead to the transcriptional up-regulation of genes adjacent to the translocation breakpoints. This has been elegantly shown for the t(12;13)(p13;q12) which results not only in the formation of a fusion between *ETV6* and the caudal-related homeobox gene *CDX2,* but also in the upregulation of a transcript that codes for the full length CDX2 protein. In a bone marrow transplant model, the upregulation of the wild type CDX2 protein and not the expression of the ETV6/CDX2 fusion protein is critical for the development of leukemia in a murine bone marrow transplantation model.

Putative Tumor Suppressor Gene and Physiological Function

There are several lines of evidence that suggest that *ETV6* might function as a ►tumor suppressor gene. In up to 70% of childhood ALL cases with ETV6/RUNX1 fusions, there is concomitant deletion of the non-rearranged *ETV6* allele. Deletions of the short arm of chromosome 12 are frequently found in a broad spectrum of hematological malignancies, and the common region of deletion was mapped to a small genomic region including *ETV6* and *CDKN1B*. In addition, several studies showed that even if no deletion of the *ETV6* locus can be detected there was no expression of *ETV6* at the mRNA level or absence of the ETV6 protein.

In vivo and in vitro studies provide additional evidence that *ETV6* might function as a tumor suppressor gene. *ETV6* expression inhibits growth in soft agar of *RAS* transformed NIH3T3 fibroblasts cells and leads to the differentiation of erythroleukemia cells into erythrocytes. Additionally, the expression of *ETV6* in serum-starved NIH3T3 cells induces apoptosis. Reporter gene assays have demonstrated that ETV6 is a strong transcriptional repressor, which requires corepressors like N-Cor, mSin3 and SMRT.

Targeted deletion of the murine *Etv6* gene demonstrated that *Etv6* is essential for yolk sac angiogenesis and the establishment of definitive hematopoiesis in the bone marrow, while hematopoiesis in the yolk sac and fetal liver was not affected. $Etv6^{-/-}$ mice die between day 10.5 and 11.5 of embryonic development due to a defect in yolk sac ►angiogenesis and widespread apoptosis of mesenchymal and neural cells.

Furthermore, *Etv6* could be shown to be an essential regulator for the maintenance of hematopoietic stem cells in adult murine bone marrow.

Ewing Sarcoma

Heinrich Kovar
Children's Cancer Research Institute, St. Anna Kinderkrebsforschung, Vienna, Austria

Synonyms

Ewing tumor; Ewing sarcoma family tumors; Peripheral primitive neuroectodermal tumor; Neuroepithelioma

Definition

Aggressive small-round-cell tumor affecting bone and soft tissue in children and young adults. Ewing's sarcoma (►ES) and peripheral primitive neuroectodermal tumor (►pPNET), also called ►neuroepithelioma are currently defined as biologically closely related tumors along a gradient of limited neuroglial differentiation. ►Askin tumor is the historical designation of Ewing's sarcoma of the chest wall. Today, all these neoplasms are summarized as Ewing tumors (►ET), or Ewing sarcoma family tumors (►ESFT). Although first described in 1866 and 1890 by Lücke and Hildebrand, respectively, the disease carries the name of the American pathologist James Ewing who, in 1921, was the first to recognize the tumor as a separate entity, which he defined as diffuse endothelioma of the bone.

On the genetic level, Ewing sarcoma family tumors are defined by the consistent presence of a reciprocal ►chromosomal translocation between the long arms of chromosome 22 and either chromosome 11 (85%) or 21 (10%). In rare cases, alternative rearrangements of chromosome 22 with either chromosome 7, 17 or 2 have been reported. These aberrations result in a gene fusion that serves as a diagnostic criterion allowing to discriminate Ewing sarcoma family tumors from osteomyelitis and childhood malignancies with a similar small-round-cell phenotype, including ►neuroblastoma, ►rhabdomyosarcoma, non-Hodgkin lymphoma and small cell osteosarcoma. Immunohistochemically, Ewing sarcoma family tumor cells are defined by the abundant presence of the cell surface marker ►CD99. The exact histogenesis of the disease is not known. An origin from a very primitive, ectodermally derived, migrating cell from the neuroepithelium has been suggested based on ultrastructural and histological signs of limited neural differentiation. More recent experimental evidence indicates that at least part of the neural resemblance is a functional consequence of the characteristic gene fusion in Ewing sarcoma family tumors. Based on these molecular biological findings, a mesenchymal origin is currently discussed for the disease.

Characteristics

Ewing sarcoma family tumors comprise about 10–15% of malignant bone tumors with a yearly incidence of 0.6 per million in the caucasian population. The disease is rarely observed among black Africans, African Americans and Chinese people. It typically occurs in adolescence, in the second decade of life (average age at diagnosis is 13.5 years) with a slight male prevalence. Nevertheless, infants less than 5 years of age as well as adults up to 60 years of age are occasionally diagnosed with Ewing sarcoma family tumors. The tumor usually presents as a painful swelling, rapidly increasing in size. The duration of symptoms prior to the definitive diagnosis can be weeks to months, or rarely even years, with a median of three to nine months. In patients with metastatic disease, nonspecific symptoms such as malaise and fever may resemble symptoms of septicemia. The most frequent tumor localizations are pelvis, the long bones of the extremities, the ribs, the scapula and the vertebrae. Less frequently, Ewing sarcoma family tumors arise from extraosseous locations. Unlike ►osteosarcomas, Ewing sarcomas tend to arise from the diaphyseal rather than the metaphyseal portion of the bones and is frequently accompanied by tumor-related osteolysis, detachment of the periosteum from the bone, and spiculae of calcification in soft tissue tumor masses.

About 20–25% of Ewing sarcoma patients present at diagnosis with gross, clinically detectable metastases in the lung and/or in bone and/or bone marrow. Metastases to lymph nodes or other sites like liver or central nervous system (CNS) are rare. In contrast to patients with localized disease, cure of this group of patients is very difficult to achieve.

Classic Ewing sarcoma is composed of a monotonous population of small round cells with high nuclear to cytoplasmic ratios arrayed in sheets. The cells have scant, faintly eosinophilic to amphophilic cytoplasm, indistinct cytoplasmic borders, and round nuclei with evenly distributed, finely granular chromatin and inconspicuous nucleoli. Mitotic activity is usually low. By means of immunohistochemistry, the tumor cells occasionally stain positive for neuroglial markers, such as neuron specific enolase, S100 protein, chromogranin A and B or the gene product PGP9.5. This is in addition to CD99, which is highly expressed in Ewing sarcoma family tumors with consistency. The inclusion of glycogen can frequently be observed in the tumor cells. Infrequently, Ewing sarcoma is focally immunoreactive for cytokeratins.

Cytogenetics and Gene Alterations

The most consistent marker of Ewing sarcoma family tumors is the rearrangement of the Ewing sarcoma gene ►EWS on chromosome 22 (band q12) with a gene encoding for an ►Ets transcription factor. These proteins are characterized by a unique structure of their DNA binding domain determining target gene specificity. In the majority (85%) of Ewing

sarcoma family tumors EWS is rearranged with ►Fli-1, which is located on chromosome 11 (band q24). The second most frequent translocation partner of EWS in this disease is the ►Ets family member ►ERG on chromosome 21 (band q22) (10%). In rare cases of Ewing sarcoma family tumors, complex or interstitial chromosomal rearrangements fuse EWS to related Ets transcription factor genes located on chromosomes 7 (band p22), 17 (band q12), and 2 (band q36). These gene rearrangements are currently monitored for diagnostic purposes, either on the chromosomal level using fluorescent in situ hybridization (►FISH) or on the RNA level using reverse transcriptase polymerase chain reaction (►PCR) (►RT-PCR). The latter method also allows for high sensitivity detection of minimally disseminated disease in blood, bone marrow and peripheral blood progenitor cell (►PBPC) collections. The prognostic impact of RT-PCR detectable tumor cells in these samples is currently under prospective evaluation in several clinical studies.

As a result of the gene fusion a potent novel transcription factor with altered structural and functional features is expressed in the tumor cells. EWS-Fli-1 and EWS-ERG fusion proteins have been shown to render mouse fibroblast cell lines and bone marrow-derived mesenchymal progenitor cells tumorigenic in animal models. Using antagonistic agents, generated by means of gene technology, involvement of these aberrant gene products in Ewing sarcoma tumor cell proliferation has experimentally been demonstrated. It is commonly assumed that the EWS-Ets chimeric transcription factors mediate their transforming properties by inappropriately activating or repressing other genes. In-vitro gene transfer experiments into a number of different cell types indicated that the spectrum of genes responsive to EWS-Ets fusion proteins is context-dependent. EWS-Fli-1 is toxic to most primary human cell types with only very few exceptions. Among tissues tolerant of the expression of the Ewing sarcoma oncogene are bone-marrow derived mesenchymal progenitor cells. Here, EWS-Fli-1 interferes with the differentiation potential of these cells. With the advent of new technologies to modulate EWS-Ets expression in Ewing sarcoma cells such as ►RNA interference (RNAi), we are just starting to understand the mechanisms underlying malignant transformation by this oncogene. Large scale gene expression profiling studies have identified a specific signature of EWS-Fli1 within the Ewing sarcoma ►transcriptome. Current functional studies attempt to separate malfunctions essential for tumorigenesis from collateral damage.

Due to variable chromosomal breakpoint locations in the individual tumors the EWS-Ets translocation products vary in size. A prognostic impact of certain EWS-Fli-1 gene fusion types for localized disease has been suggested and is currently under prospective evaluation.

Otherwise, no reliable genetic indicators of prognosis have been identified for Ewing sarcoma family tumors, so far. Cytogenetically, trisomy 8 and 12 accompany the characteristic rearrangement of chromosome 22 in about 44 and 12% of tumors, respectively. Additional structural changes affect chromosomes 1 and 16 in about 20% of tumors, most frequently leading to a gain of 1q and a loss of 16q and the formation of a derivative chromosome. A possible prognostic impact of these cytogenetic alterations has been discussed controversially. Genetic aberrations associated with unfavorable disease in many human malignancies such as mutations of the tumor suppressor gene p53 and of the Ras oncogene are infrequent in Ewing sarcoma family tumors. Besides the EWS-Ets gene rearrangement the only molecularly defined recurrent genomic alteration occurring in 20–30% of primary Ewing sarcoma family tumors is the homzygous loss of the ►INK4A gene located on chromosome 9 (band p21). This aberration most frequently occurs as a small interstitial deletion undetectable with classical cytogenetic means. Preliminary retrospective data suggest an adverse prognostic impact of this aberration and of rare p53 mutations. However, in the absence of any prospectively confirmed molecular prognostic marker, the extent of disease monitored by clinical imaging techniques at the time of diagnosis (computed tomography of the chest to document or exclude intrathoracic metastases and 99m-Technetium whole body radionuclide bone scans to search for skeletal metastases), microscopically detectable bone marrow micrometastases, and the histopathologically determined tumor response to initial chemotherapy, still serve as the only accepted criteria for treatment stratification.

Aetiology

The aetiology of Ewing sarcoma family tumors is not known. Neither is there evidence for genetic predisposition nor for a role of environmental exposure. Except for an interethnic polymorphism within a EWS gene region frequently affected by the Ewing sarcoma specific chromosome translocation, the molecular basis for differences in Ewing sarcoma incidence between Caucasians, Asians and Africans have only poorly been investigated. Due to its tight association with the disease, the EWS-Ets gene rearrangement is considered the primary event during Ewing sarcoma pathogenesis. No specific recombinogenic activity has been identified as responsible for this aberration and although involvement of a viral agent in generating the chromosomal translocation has been suggested, it has not been confirmed.

Therapy

In the pre-chemotherapy era, less than 10% of Ewing sarcoma patients survived the disease despite the

well known radiosensitivity of the tumor and despite its radical resection, calling for systemic treatment to eradicate disseminated tumor cells. Today, patients with Ewing sarcoma family tumors are treated by multimodal therapeutic regimens including radiotherapy and chemotherapy (combinations of vincristine, actinomycin D, cyclophosphamide, doxorubicin, ifosfamide, etoposide) as well as surgical resection whenever possible. By using this treatment strategy together with optimized schedules and dose intensities, the results for patients with localized disease was improved to an overall survival rate of 60–70% in recent years. The treatment of Ewing sarcoma patients worldwide is organized in cooperative trials, aiming to further improve treatment outcome. In contrast, the management of primary metastatic disease and early relapse remains a clinical challenge that is currently assessed by myeloablative approaches, combining high-dose chemotherapy and total-body irradiation with stem cell reinfusion. The efficacy of this therapeutic approach for high-risk Ewing sarcoma patients remains to be established. Novel therapeutic approaches that are currently under investigation in pilot clinical studies target the tumor vasculature. To avoid the toxic side effects of chemotherapy, future biologically tailored therapy may target the EWS-Ets fusion protein or genes downstream of this tumor specific aberration.

Ewing Sarcoma Family Tumors

►Ewing Sarcoma

Ewing Tumor

►Ewing Sarcoma

EWS

Definition

Ewing sarcoma gene; also termed EWSR1 (Ewing sarcoma breakpoint region 1); identified as a gene on chromosome 22 consistently disrupted by chromosomal translocation in Ewing sarcoma family tumors, and frequently in myxoid liposarcoma, clear cell sarcoma, myxoid chondrosarcoma, and some acute leukemias.

►Ewing Sarcoma

EWS-FLI (ets) Fusion Transcripts

Enrique de Alava[1], Santiago Ramón y Cajal[2]
[1]Centro de Investigación del Cáncer-IBMCC, Salamanca, Spain
[2]Hospital Universitario Vall d'Hebron, Barcelona, Spain

Definition

The *EWS-FLI1* fusion ►transcript is the result of a ►balanced reciprocal chromosomal ►*translocation* between chromosomes 11 and 22, which fuses the *EWS* gene in chromosome 22 to the *FLI1* gene in chromosome 11. This fusion transcript is detected in approximately 85% of cases of the ►Ewing sarcoma family of tumors, and is considered a tumor-specific molecular rearrangement, therefore useful for diagnosis, prognosis, and presumably for specific therapeutics. Approximately 10% of Ewing tumors have fusions involving *EWS* and *ERG* genes. An additional 5% bear fusions between EWS and other less frequent genes.

Characteristics

Structure

Chromosomal translocations result in the genesis of chimeric genes, encoding hybrid transcripts and novel fusion proteins. Many fusion proteins contain juxtaposed functional domains usually found in separate proteins.

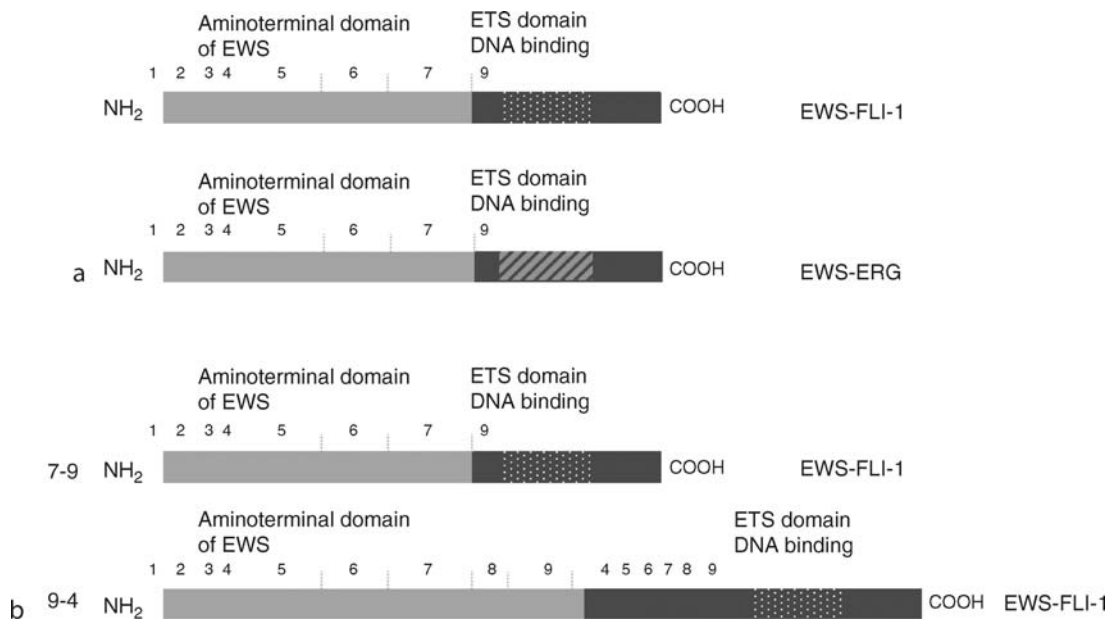
The EWS-FLI1 fusion protein contains the aminoterminal domain of EWS and the carboxyterminal region of FLI1. *EWS* gene is an RNA-binding protein, which is believed to mediate mRNA transcription probably through its interaction with RNA polymerase II complex. Several forms (at least 12 types) of EWS-FLI1 exist because of variations in the location of the EWS and FLI1 genomic breakpoints. They contain different combinations of exons from EWS and FLI1, the most frequent being the fusion of EWS exons 1–7 to FLI1 exon 6–9 (type 1) and fusion of EWS exons 1–7 to FLI1 exon 5–9 (type 2).

Properties of the *EWS-FLI1* Fusion Transcript and Protein

EWS is widely expressed in most tissues, and because the genomic structure of the fusion, the EWS promoter drives the expression of EWS-FLI1. The aminoterminal domain of EWS, included in the fusion, has strong transactivating properties. The *FLI1* gene encodes a member of the ETS family of ►transcription factors and its expression is highly restricted to hematopoietic, endothelial, and mesodermal cells as well as to neural crest cells. The ETS DNA-binding domain of FLI1 is included in the fusion. The resulting EWS-FLI1 protein is therefore an aberrant transcription factor. The chimeric product EWS-FLI1 can transform some cell lines in culture and can inhibit or activate diverse cellular pathways. For example, EWS-FLI1 protein can suppress transcription of transforming growth factor beta type 2 receptor gene leading to TGF-beta resistance; can activate MFNG, a member of fringe family, related to somatic development, and other genes. The action of EWS-FLI1 as a transcription factor is probably related to the cell context in which this fusion is detected. This cellular context is probably influenced by the cell type, stage of differentiation, and microenvironment, and could include expression of several growth factors, for example, IGF1 and its receptor. On the other hand it is likely that *FLI1* gene is developmentally regulated, being expressed at certain times and places, and this can confer some site and tissue specificity to the transcriptional activity generated by the EWS-FLI1 fusion protein.

EWS and Other Specific Human Translocations

EWS can fuse after chromosomal translocation to other genes, including several members of the ETS transcription factor family. In an analogous way to FLI1, EWS can be detected fused to *ERG* gene through a t(21;22), to *ETV* gene through a t(7;22), to *E1A-F* gene through a t(17;22) or to *FEV* gene through a t(2;22) ►chromosomal translocation. All of these *EWS-ETS* gene fusion transcripts can confer a common tumorigenic phenotype of small round cells and can be found in the Ewing family of tumors. But, interestingly, EWS can fuse to other genes and be detected in other tumor types. For example, in desmoplastic small round cell tumor, EWS is fused to the tumor suppressor gene *WT1* through a t(11;22), in clear cell sarcoma of soft tissue is fused to the ATF1 through a t(12;22), in myxoid and round cell liposarcoma can also be found fused to the CHOP



EWS-FLI (ets) Fusion Transcripts. Figure 1

gene, and to CHN gene, located in chromosome 9, in extraskeletal myxoid chondrosarcoma.

Genesis of the Translocation

The mechanism by which the translocation is generated is another field worth to be studied. In other words why do the breakpoints always occur in the same introns? Is that a random event or are there certain areas of these particular genes particularly prone to recombine? There is some evidence that several chromosomal translocations may not be random events, but may be specifically promoted by the presence of certain DNA sequence motifs at or around certain target genes. A number of recombinogenic sequences have been described, like topoisomerase-binding sequences in leukemias or lymphomas, and translin sequences in alveolar rhabdomyosarcoma and in myxoid liposarcoma. Furthermore it has been suggested that mobile elements or endogenous retroviruses may take part in gene rearrangements. In Ewing tumors, in which ►illegitimate recombination has been reported to occur, recombinogenic sequences have not been described in a large study of genomic breakpoints.

The EWS-FLI1 Fusion and the Pathogenesis of ►Ewing Sarcoma

A problem to study sarcoma pathogenesis, in general, and Ewing tumor genesis, in particular, is the absence of preneoplastic lesions, as well as the lack of animal transgenic models. Therefore, to study the mechanism by which EWS-FLI1 induces ►Ewing sarcoma there are two complementary approaches:

1. Induced expression of the fusion in different cellular models. For example, induced expression in NIH3T3 fibroblastic cells accelerates tumor growth in immunodeficient mouse models, while expression in alveolar rhabdomyosarcoma or neuroblastoma cell lines induces a shift in differentiation, which becomes closer to that of Ewing tumor. The same experiment performed in other cell lines induces, however, cell death, showing that the cellular context matters in the pathogenesis of Ewing tumor.
2. By small interference RNA studies blocking EWS-FLI1 mRNA, cell cycle arrest and a decrease in tumor growth in animal models, is observed.

Both types of experiments confirm that EWS-FLI1 functions as an aberrant transcription factor, although the target genes are still relatively unknown. The availability of expression microarrays in the last years, coupled to the experiments described earlier, has been useful to suggest possible target genes. EWS-FLI1 participates in Ewing tumor pathogenesis controlling cell proliferation and survival by promoting expression of IGF1, MYC, CCND-1, PDGFC, DAX1-NR0B1, and NKX2-2, and by repressing genes such as $p21^{WAF1}$, $p57^{kip}$, *TGFbRII*, and *IGFBP3*. The genes related to the induction of the undifferentiated phenotype of Ewing tumor are largely unknown.

In addition, EWS-FLI1 exerts its function with the help of other proteins such as RNA helicase A, which binds to the promoters targeted also by EWS-FLI1, enhancing its function.

Clinical Relevance

EWS-FLI1 (ets) in Diagnosis

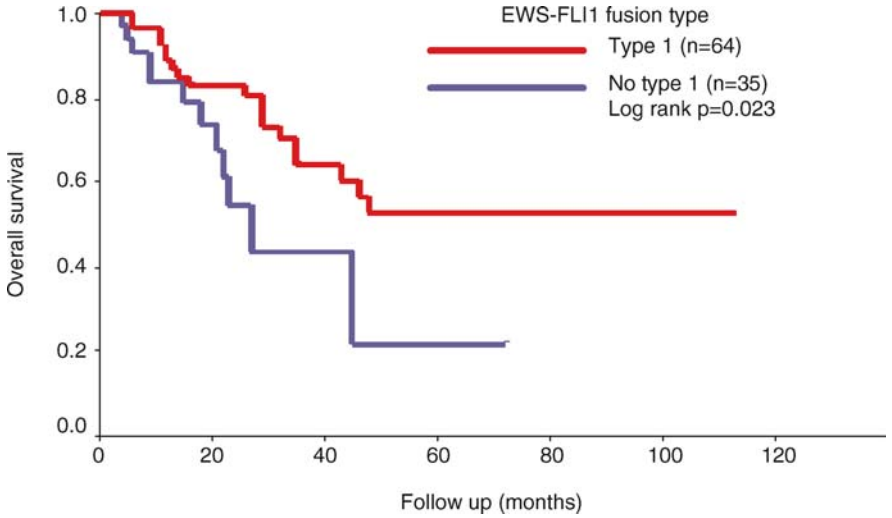
The detection of the chimeric product *EWS-FLI1*, in the adequate morphologic and immunophenotypic context, is diagnostic of a ►Ewing family tumor. The fused product can be studied by fluorescence in situ hybridization (FISH) or by ►RT-PCR in very small samples of tissue or cytological specimens. Frozen tissue is the preferred source of RNA, which can also be extracted from ►formalin-fixed paraffin-embedded tissue with variable success. *EWS-FLI1* detection is particularly useful in cases in which a Ewing family tumor arises in unusual locations (kidney, skin, lung, ovary, pancreas), or in patients over 40 years, or shows atypical features (epithelial differentiation, no ►CD99/MIC2 expression).

EWS-FLI1 (ets) Fusion Type and Prognosis

Ewing tumors display a moderate level of molecular heterogeneity. The variability in the chimeric transcript structure may help to define clinically distinct risk groups of Ewing tumors. In fact, two independent groups have found that the type 1 *EWS-FLI1* fusion transcript is associated with less aggressive clinical behavior than the patients carrying tumors with other *EWS-FLI1* fusion types (Fig. 2), regardless stage at diagnosis, tumor location, or tumor volume. A recent study has shown that this particular gene fusion (type 1) encodes for a chimeric protein that functions as a weaker transcription factor than chimeric proteins encoded by other fusion types. In fact tumors with *EWS-FLI1* type 1 fusions have a lower proliferative rate than their counterparts with other fusion types. So far, no clinical differences have seen between patients with tumors bearing *EWS-FLI1* fusions, and those having *EWS-ERG* transcripts. These results are still pending of confirmation; a European prospective study is being conducted to assess for clinical differences among tumors having the most prevalent fusion types.

EWS-FLI1 (ets) and Detection of Minimal Residual Disease

EWS-ETS fusion transcripts can be detected by RT-PCR in peripheral blood and bone marrow. That



EWS-FLI (ets) Fusion Transcripts. Figure 2

demonstration may contribute to patient management and staging, although clinical relevance is still unclear. A French study has shown in 2003 that presence of circulating Ewing tumor cells and/or Ewing tumor cells in the bone marrow at the time of diagnosis is a significant predictor of tumor relapse.

EWS-FLI1 (ets) and Therapeutics

Current efforts are focused on directly inhibit chimeric proteins (or their downstream targets) and on immunotherapy directed at tumor cell-specific epitopes derived from chimeric products. A potentially useful approach is the delivery of siRNA in the appropriate vectors. The results of an animal model of metastatic Ewing tumor in which EWS-FLI1 siRNA has been injected intravenously is encouraging, and could potentially be used in the future treatment of patients with this neoplasm.

Excretion

Definition
Is the process by which a chemical is removed from the body.

►ADMET Screen

Excretory Urography

Definition
A test to evaluate the kidneys, urinary tract and bladder. Medicine is given through an intravenous line (IV). This medicine moves through the body and is ultimately concentrated in the kidneys. A series of X-rays are taken, and are viewed by the radiologist to evaluate the kidneys, urinary tract and bladder. ►Bladder cancer; ►Transitional Cell Carcinoma.

Exfoliation of Cells

Alexandre Loktionov
Colonix Medical Limited, Babraham Research Campus, Cambridge, UK

Synonyms
Shedding of cells; Sloughing of cells

Definition
Cell exfoliation (Latin – *exfoliare* – to strip of leaves) is a process of spontaneous or induced complete

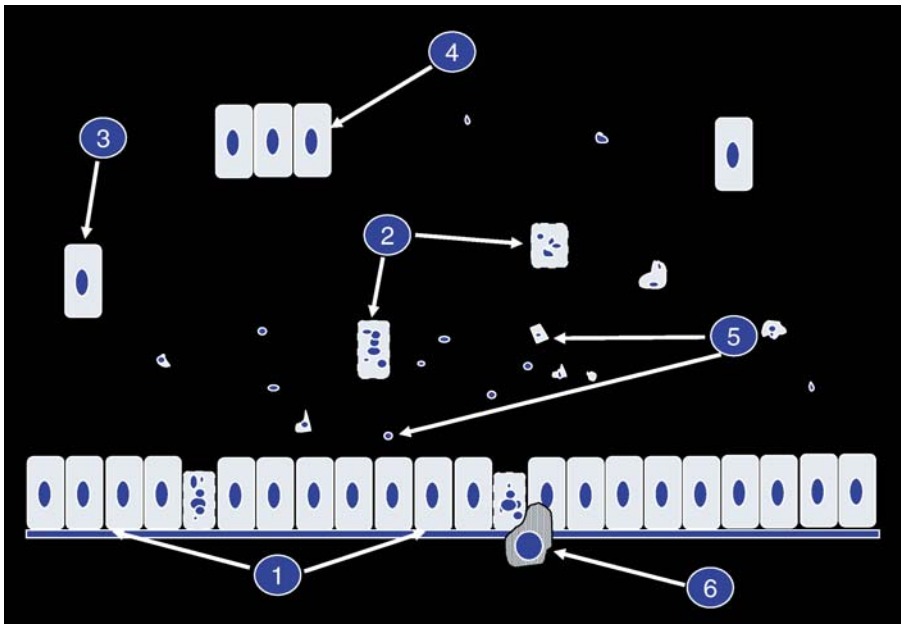
detachment of single epithelial cells or groups of cells from an epithelial layer.

Characteristics

Exfoliation of cells is one of the main mechanisms of cell loss participating in the homeostatic control of cell population size. Cell exfoliation is a characteristic feature of epithelial tissues forming epithelial layers covering both external body surface (skin epidermis and skin appendages) and surfaces of internal cavities and passages (gastrointestinal tract, respiratory system, and genitourinary system) as well as major exocrine glands and glandular ducts (mammary gland, exocrine pancreas, biliary system, etc). Cell exfoliation process in normal physiological conditions is closely associated with terminal differentiation and orderly loss of dying cells compensated by permanent cell population renewal. This relationship is exemplified by the structure of stratified squamous (epidermal type) epithelia where layers of maturing cells are being moved towards the surface due to continuous arrival of younger counterparts produced by proliferation in the basal layers of the epithelium. Eventual death, keratinisation (in the epidermis) and inevitable exfoliation of cell remnants is the normal destiny of these terminally differentiated cells. Less is known about cell exfoliation in the epithelia of internal organs; however, studies of well-structured columnar colonic epithelium can be chosen as the most reliable source of information. Obvious links between cell differentiation and eventual shedding exist in this dynamic cell population with extremely high rates of cell proliferation and loss. The progeny of stem cells located at the base of the colonic crypt constantly migrate in the direction of the lumen. During this migration colonocytes gradually lose their proliferative capacity and undergo differentiation, thus terminally differentiated cells reaching surface (luminal) epithelium should be promptly eliminated to be replaced by future generations of their counterparts. Two ways of cell loss coexist in the colonic epithelium under normal conditions (Fig. 1).

1. Exfoliation of single colonocytes or colonocyte groups into the lumen of the gut. Strictly speaking, the shed cells enter the ►mucocellular layer covering colonic mucosa rather than the gut contents.
2. Apoptosis *in situ* followed by the engulfment of apoptotic cells by adjacent colonocytes or subepithelial macrophages.

Physiological changes or development of pathological processes can significantly shift proportions of cells eliminated by each of these mechanisms. There are two principal variants of post-exfoliation cell fate (Fig. 1). Some colonocytes undergo immediate apoptosis (detachment-induced apoptosis or ►anoikis) following exfoliation, whereas other exfoliated cells and especially groups of cells maintain their structural integrity and possibly viability for minutes or even



Exfoliation of Cells. Figure 1 Schematic representation of cell exfoliation in normal physiological conditions. Colon model, surface epithelium, crypts are not shown. 1. Normal epithelium (two apoptotic cells shown). 2. Anoikis immediately following exfoliation. 3. Exfoliated normal epithelial cell preserving its structure. 4. Group of exfoliated normal epithelial cells preserving their structure. 5. Cellular and nuclear debris. 6. Subepithelial macrophage.

hours following exfoliation. In the human colon, exfoliated cells enter the mucocellular layer overlaying colonic mucosa and can be transferred distally, protected by the mucus, without being incorporated into the faeces. The movement of the cell-containing mucocellular layer is mostly driven by its close contact with moving faecal flow as well as by constant peristaltic movements of the gut. There is no doubt that some proportion of exfoliated colonocytes can reach the gut contents, but these cells should be rapidly destroyed in the anaerobic bacteria-dominated faecal milieu rich in bile acids and other cytolytic agents. Observations of the presence of well-preserved epithelial cells in human faecal samples mostly concern colonocytes excreted together with the mucocellular layer fragments or exfoliated squamous cells of the anal epithelium sometimes misidentified as colonocytes.

Similar exfoliation models with tissue-specific corrections can be applied to the epithelial populations of other internal organs. Preservation of cellular structure after exfoliation is described for cells of bronchial epithelium in sputum samples, bladder, urethral and prostate epithelium in urine samples, gastric epithelium in gastric lavage liquid, cervical, vaginal, and endometrial epithelium in cervical smears, mammary gland epithelium in nipple aspirates and pancreatic duct epithelium obtained endoscopically. Exfoliated cell migration or passive transport occurs in all internal passages or ducts, being facilitated by contents flow, peristaltic movements or cell-driven mucus transport (►*cilia* of the bronchial epithelium). Shed cells can be commonly found in human body excretions (cells of bladder, urethra and occasionally prostate epithelium in urine, colonocytes and squamous anal epithelium in faeces, bronchial, nasopharyngeal and oral cavity epithelium in sputum, etc.). Exfoliated epithelial cells should be distinguished from non-epithelial free cells (leukocytes, macrophages, lymphocytes, etc) that are also often present in the excreted materials, but are unrelated to the process of cell exfoliation.

Mechanisms

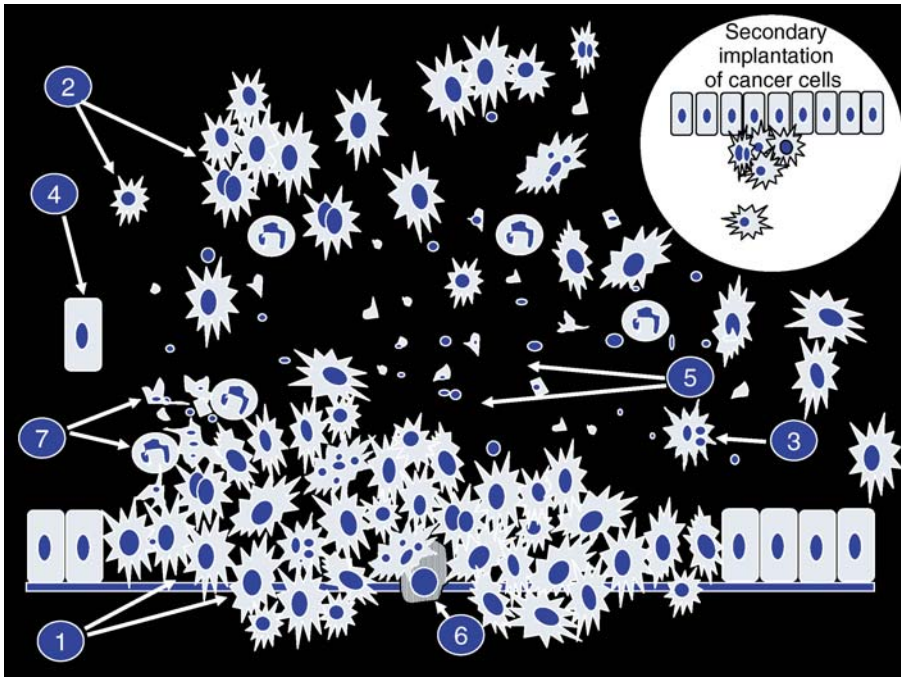
Molecular mechanisms underlying cell exfoliation in normal conditions are poorly investigated and remain largely unknown. Extrapolation of the information obtained *in vitro* might be misleading; therefore, only tentative suggestions can be made. At the cellular level, pathways leading to cell exfoliation should involve considerable structural and functional changes of the cytoskeleton, cell membrane and membrane-bound subcellular structures responsible for the preservation of contacts between neighboring cells (►adherens junctions, ►tight junctions, ►gap junctions) as well as between cells and basal membranes (►focal adhesions). A number of proteins associated with these structures (adherens junction–associated cadherins and catenins, tight junction-associated claudins and occludin, gap junction-associated connexins and focal adhesion-associated integrins and focal adhesion kinase) are likely to participate in exfoliation induction. In particular, the ►integrin system appears to be intimately involved in the homeostatic regulation of cell differentiation, providing communication between epithelial cells and the underlying stromal extracellular matrix. The loss of contact with the extracellular matrix can trigger anoikis through integrin-mediated signaling, but it is evident that many exfoliated cells are able to evade this fate. Mechanisms of this phenomenon remain obscure and need profound investigation as well as other aspects of cell exfoliation *in vivo*.

Cell Exfoliation in Neoplasia

Cancer development is usually associated with a dramatic increase in cell exfoliation from tumor surface (Fig. 2). The increased exfoliation may reflect a compensatory response to the impairment of the apoptotic mechanism of cell elimination *in situ* commonly observed in malignant tumors. Anoikis induction appears to be the ultimate homeostatic goal of the enhanced exfoliation. Although this mechanism of cell elimination may be partially functional in early tumors, resistance to anoikis is now regarded as a hallmark of metastatic cancer cells, which tend to survive exfoliation. Loss of cell adhesion (often associated with E-cadherin function impairment) and disruption of normal interactions with underlying stroma associated with malignant progression, also strongly contribute to the enhancement of exfoliation from tumors. Cancer cells are better adapted to survival in the conditions of oxygen deficiency; therefore their prolonged post-exfoliation persistence on the surfaces of internal cavities, passages and glandular ducts can be expected. These cells shed by tumors are often immature and retain proliferative capacity. Therefore their metastatic potential and ability for secondary implantation can be manifested. Reports describing the occurrence of secondary cancers or peritoneal carcinomatosis following surgical interventions on tumors of several sites (colorectum, ovary, gallbladder) attribute these secondary metastatic cancers to the direct re-implantation of malignant cells exfoliated from the primary tumors. There is a strong probability that cell exfoliation without immediate anoikis in physiological conditions presents a normal "prototype" of metastatic behavior.

Clinical Aspects

The possibility of using exfoliated epithelial cells for various clinical and research purposes is highly attractive because analysis of this material often allows avoiding highly invasive sampling (►biopsy) of



Exfoliation of Cells. Figure 2 Schematic representation of cell exfoliation from tumor surface. Colon model, surface epithelium, crypts are not shown. Inset demonstrates secondary implantation of malignant cells distally from the primary tumor. 1. Tumour (malignant cells). 2. Exfoliated tumor cells and cell groups preserving their structure. 3. Occasional anoikis of a tumor cell immediately following exfoliation. 4. Exfoliated normal epithelial cell preserving its structure. 5. Cellular and nuclear debris. 6. Subepithelial macrophage. 7. Neutrophilic leukocytes and necrotic tumor fragments (focal necrosis and inflammatory reaction).

normally inaccessible tissues. Exfoliated cells can be collected either non-invasively (from sputum, urine, faeces etc) or by simple and minimally invasive procedures (cervical smears, buccal swabs, direct cell collection from the surface of rectal mucosa during proctoscopy, etc.). Although exfoliated cells became widely employed for some specific medical, forensic and research purposes (e.g. buccal mucosal cells are routinely used for DNA isolation for genotyping), clinical oncology remains the main area where their use is already common and looks even more promising with the introduction of modern molecular methodologies.

Cytological diagnostic approaches based on the examination of exfoliated cells were developed first. Exfoliative cytology analysis of smears prepared from cervical epithelium (examination of ►PAP smears) has become a standard screening procedure for cervical cancer. Diagnostic cytology is used for endometrial carcinoma, bronchogenic lung cancer, tumors of the bladder and prostate, and gastric cancer.

The recent introduction of molecular assays targeting cancer biomarkers created another major direction, aiming to employ exfoliated cells as the material of choice for the molecular diagnosis and screening of oncological conditions. Approaches to colorectal cancer screening occupy a leading position among problems addressed in this direction. Significant efforts were concentrated on the analysis of exfoliated colonocytes (or DNA derived from these cells) present in human stool samples. Although cancer-specific molecular changes are often detected by such analysis, especially when ►multi-marker panels of PCR-based assays were applied, the sensitivity of the method has not reached desirable levels. The main reason for this problem is likely to be the relatively low presence of exfoliated colonocytes in the faecal samples. Human DNA found in this material can also derive from exfoliated anal epithelium or free cells (leukocytes, lymphocytes, macrophages, etc), which certainly do not contain tumor markers. Moreover, strong faecal presence normally decreases PCR efficiency. Direct collection of exfoliated cells from the surface of rectal mucosa appears to provide much more abundant and contamination-free material that can be used for different analytical procedures. Even simple detection of unusually high DNA yield in samples of exfoliated material directly collected at standardized conditions can be interpreted as a warning signal indicating a high probability of colorectal tumor presence.

Multiple other applications of exfoliated cells for cancer diagnosis by molecular biomarker detection are being developed, but these studies remain research

projects rather than proven clinical approaches. The present absence of a single biomarker allowing 100% positive identification of cancer presence is the most important obstacle interfering with the development of molecular diagnostic procedures based upon the use of exfoliated cells.

Extracellular Matrix

Definition

Is a meshwork of glycoproteins, proteoglycans and glycosaminoglycans that serves as support for adhesion and growth of cells in coherent tissues. It is the connective tissue that fills up the space between cells, consisting of a network of protein fibers in a polysaccharide matrix. The compounds making up the extracellular matrix are mainly secreted by fibroblasts. The ECM serves as a structural element of tissues to which cells attach through cell-substrate adhesion molecules. Interaction of cells with the extracellular matrix is important for a variety of processes such as adherence, cell migration, differentiation and the regulation of inflammation.

Extracellular Matrix Remodeling

Malgorzata Matusiewicz
Department of Medical Biochemistry, Wroclaw Medical University, Wroclaw, Poland

Definition

Extracellular matrix (ECM) remodeling is a series of quantitative and qualitative changes in ECM during neoplastic transformation facilitating tumor growth and ►metastasis.

Characteristics

ECM is produced and assembled by the cells it is surrounding. The main components of ECM include glycosaminoglycans (with predominant hyaluronic acid) and proteoaminoglycans (e.g., perlecan, aggrecan), noncolagenous glycoproteins (such as ►fibronectin, laminins, tenascin), collagens and many other biologically important molecules involved in cell–cell and cell–matrix interactions as well as in matrix remodeling. ECM provides not only the mechanical support for the attachment and organization of cellular structures but is also actively involved in the exchange of information with cells, and therefore in the regulation of many important processes such as cell proliferation, migration, differentiation, and survival. Cell–cell and cell–matrix interactions are mediated via adhesive proteins such as cadherins and integrins – adhesive membrane receptors localized on cell surface.

Matrix anchors cells however, it is also physically confining them. This restriction becomes a problem as organs are growing. To some extent, it can be endured due to the inherent plasticity of a matrix, but after a certain point, structural changes are necessary for a proper functioning of the organ and organism. The cells of a given organ must therefore posses an ability to change/remodel its surroundings. Hence, during physiological processes, such as embryonic development,

tissue morphogenesis, ►angiogenesis, cartilage, and bone remodeling, a degradation of old elements of matrix and a synthesis of new ones are taking place. The process is governed by signals from regulatory proteins of ECM that are ensuring the divisions and differentiation of cells according to the needs of organism. The mechanisms that are designated for physiological processes are adapted for the needs of tumor cells. Tumors can be viewed as functional tissues with cells surrounded by ►microenvironment of ECM. Tumor cells must remodel the matrix to establish the communication between tumor cells and ECM and break barriers of the controlling mechanisms of the host cells. Local host stroma plays an important role in the transition from normal to malignant tissue. It has been established that stroma and tumor cells can interchange growth factors, cytokines, angiogenesis factors, and proteases to activate surrounding ECM and facilitate the expansion of tumor cells. Stromal cells by the release of specific molecules can change cell phenotype and induce neoplastic transformation in the neighboring cells. It has been demonstrated that tumor associated fibroblasts have altered properties in comparison to fibroblasts from normal epithelial cells. Tumor cells are changing the composition of ECM either by forcing the production of ECM components in an altered form or by stimulation or inhibition of the expression of some other compounds. Hyaluronic acid, which is promoting cell ►migration via its surface receptor, is very often overexpressed in malignant tissues. Laminin, which is essential for the integrity of tissue, is produced in an altered form and in lower quantities. A desmoplastic reaction, which accompanies many solid tumors, is characterized by altered expression of many proteins (such as α-smooth muscle actin, smooth muscle myosin, and desmin) in desmoplastic fibroblasts as well as altered production of some ECM components (such as collagen types III and IV, tenascin, ►matrix metalloproteinases (MMPs), tissue inhibitors of metalloproteinases (TIMPs), other proteases involved in ECM degradation, and growth factors).

One of the ways tumors are facilitating their migration is by suppressing cell–cell adhesion. A key molecule in maintaining cell–cell adhesion is ►E-cadherin. In human epithelial cancers, a downregulation of E-cadherins and upregulation of another form called N-cadherin has been observed. Downregulation of E-cadherin promotes the invasive and metastatic phenotype of transformed epithelial cells.

Other adhesive receptors – integrins – are engaged in specific binding of the cells and components of ECM. They are heterodimeric proteins composed of α and β subunits. There are several types of both α and β subunits, and therefore a certain number of combinations. Overexpression of many of them has been observed in a number of cancers. Integrins are engaged in signal transmission from the ECM into the cells and regulation of genes expression, for example, of enzymes participating in ECM degradation. They also mediate cell migration. Some integrin receptors are recognizing a RGD sequence (arginine–glycine–asparagine) – a conserved element, which is present in many ECM components. Peptides containing this sequence are implicated in inhibition of metastasis. The manner in which it is conducted is still unclear. It is speculated that they can selectively inhibit either adhesion of tumor cells to structural proteins, the production of proteases or the migration of tumor cells.

Degradation of ECM is a key event in ECM remodeling. It is conducted by a number of hydrolytic enzymes such as metalloproteinases, cysteine proteases (cathepsins B and L), aspartic proteases (►cathepsin D), serine proteases (elastase), sulfatases, and glycosidases. These enzymes function both under physiological and pathological conditions and most of them is produced in a form of inactive zymogens activated by proteolytic processes. Some of the proteases (e.g., cathepsins) are considered lysosomal enzymes but in case of cancer cells a change in cellular distribution with significantly elevated expression in cytosolic fraction has been observed. Cathepsins are working at acidic pH and are involved in intracellular proteolysis, while serine proteases and MMPs act at neutral pH and are mostly responsible for extracellular proteolysis. The proteases can either directly degrade ECM components or indirectly by activation of other proteases, which in turn will also degrade ECM. It seems that the enzymes act in a determined order resulting in a cascade of proteolytic processes. Cathepsin D is produced in inactive form as procathepsin D. The zymogene undergoes autocatalytic activation in an acidic environment. Compared to normal tissue, the extracellular pH in tumors is usually more acidic. The second cathepsin, cathepsin B, also produced in a form of zymogene, can be activated either by cathepsin D or other proteases (elastase, cathepsin G, uPA, tPA). Active cathepsin B can in turn activate prourokinase-type plasminogen activator (pro-uPA). uPA activates plasminogen into plasmin. Both cathepsin B and plasmin are subsequently ready to cleave zymogens of MMPs, producing their active forms. The sequence of the degradation of ECM components seems to be determined as well. Glycoproteins that surround collagen molecules and protect them from proteolysis are degraded first by the action of cathepsins and plasmin. This permits the degradation of collagens by MMPs. As a result, ECM becomes destabilized and the barriers preventing migration of neoplastic cells are removed. Especially difficult to penetrate by cancer cells is a basement membrane with

collagen type IV as a main component. This obstacle can be, however, removed with a help of leukocytes. Leukocyte proteases act on basement membrane, degrade it, and thus facilitate cancer cells migration. Additionally, the contact of leukocytes with neoplastic cells influences the synthesis of other proteases, which further promote the degradation of ECM.

Among other enzymes implicated in ECM remodeling are also ►heparanase and sulfatases, which together with MMPs participate in the alternations of heparin sulfate proteoglycans (HSPGs). HSPGs are interacting with many effector molecules such as FGF, IL-8, and ►VEGF acting as coreceptors, and therefore involved in regulation of biological activities of cells. HSPGs are overexpressed in many cancers. Additionally, the changes occurring in proteoglycan structure upon the action of the three mentioned groups of enzymes result in altered affinity for growth factors and growth factor receptors dramatically affecting transmission of signals. The accelerated hydrolysis observed in some conditions, including cancers, leads to such changes in cell surface proteoglycans that hinder their ability to mediate cell adhesion. Moreover, the shedded fragments were demonstrated to promote tumor growth and metastasis.

The elevated activity of enzymes is an interplay between enzymes and their inhibitors – it can result either from enhanced expression of enzymes or from the reduction of the available inhibitors. Cathepsin B, for example, not only directly activates metalloproteinases but also further enhances their activity by cleaving and thus inactivating their inhibitors TIPM-1

Extracellular Matrix Remodeling. Table 1 Proteases participating in degradation of ECM components

Protease family	Protease	Protease function	Protease inhibitors
Aspartyl protease	Cathepsin D	Degradation of ECM components	
		Conversion of cysteine procathepsins into cathepsins	
Cysteine proteases	Cathepsin B, L, H, K	Degradation of ECM components	Cystatins, stefins, kininogen
		Conversion of pro-MMPs into MMPs	
Serine proteases	Plasmin	Degradation of ECM components	α_2-Antiplasmin
		Activation of uPA	α_2-Macroglobulin
	Urokinase-type plasminogen activator (uPA)	Conversion of inactive elastase into elastase	PAI-1, 2, 3
		Conversion of plasminogen into plasmin	
Neutrophil serine proteases	Elastase	Degradation of ECM	α_2-Antiplasmin
	Cathepsin G	Components	α_2-Macroglobulin secretory leukoprotease inhibitor
Matrix metalloproteinases		Degradation of ECM components	TIMP-1, 2, 3, 4
	Collagenases [MMP-1, 8, 13]	Activation of other pro-MMPs into MMPs	α_2-Macroglobulin
		Degradation of collagens: I, II, III, VII, X and gelatins	
	Stromelysins [MMP-3, 10]	Degradation of proteoglycans, laminin, gelatins collagens: III, IV, V, IX, fibronectin, entactin and collagenases-1	
	Gelatinases [MMP-2, 9]	Degradation of gelatins, collagens: I, IV, V, VII, X, fibronectin, elastin and procollagenase-3	
	Membrane type [MMP-14, 15, 16, 17, 24, 25]	Degradation of collagens: I, II, III, gelatins, aggregan, fibronectin, laminin, MMP-2, 13, tenascin, nidogen	
	Others [MMP-7, 11, 12, 19, 20, 23]	Degradation of proteoglycans, laminin, gelatins, fibronectin, collagens: IV, elastin, entactin, tenascin, α_1-antiproteinase	

From Skrzydlewska et al. [1]

and TIMP-2. Cathepsin B itself can be inhibited by cystatins and ►stefins, and it has been demonstrated that in many pathological conditions, including cancer, the concentration of cystatins has been reduced. An interesting example of interplay between proteases is ►plasminogen activator system. Beside direct degradation of ECM components, it seems to be implicated in tumor cell mobility and ►invasion. It is composed of proactivators, plasminogen, their cell surface receptors, inhibitors, and antiplasmins. uPA activates plasmin, and pro-uPA – its precursor – is activated not only by cathepsin B and elastase, but also by plasmin. uPA and plasmin are inhibited by serpins. The principal role in degradation of ECM is played by MMPs. They are a group of 28 Ca^{2+}- and Zn^{2+}-dependent proteases. Based on their structure and substrate specificity, MMPs were originally classified as collagenases, gelatinases, stromelysins, and matrilysins. Taking into account common functional domains, they are currently divided into eight groups. Under physiological conditions, MMPs are produced in low quantities in zymogene forms. Their expression is induced during ECM remodeling processes by cytokines (IL-4 and IL-10), growth factors (TGF-α, TGF-β, FGF), and cell–cell or cell–matrix interactions. The activation of transcription of MMPs genes can involve either of the three mitogen-activated protein kinases pathways: extracellular signal-regulated kinase (ERK), stress-activated protein kinase/Jun N-terminal kinases (SAPK/JNKs), and p38. Zymogens are activated either by autoproteolysis or by another MMP, or by a serine protease. MMPs are specifically inhibited by TIMPs and small molecules containing TIMP-like domains such as NC1 domain of collagen type IV. Besides inhibiting MMPs, TIMPs themselves express various antioncogenic properties and TIMP-3 is suggested to participate in tumor cell death. A list of the main proteases participating in ECM degradation and their inhibitors is presented in Table 1.

Degradation of ECM is necessary for the migration of neoplastic cells but it also serves other purposes important in tumor cells expansion. It results in unmasking of cryptic sites, production of functional fragments, and in the release of signaling factors. Proteolysis of ECM components reveals new binding sites for interaction with cell surface receptors and in this way increases tumor metastatic potential. Cleavage of ECM and cell surface molecules produces active fragments influencing tumor growth and spread. It has been documented that the degradation of ECM components by MMPs leads to the production of proangiogenic molecules. MMPs are also cleaving E-cadherin producing a fragment that is inhibiting E-cadherin and thus induces tumor cell invasion. On the other hand, the degradation of collagen XVIII by elastase releases a C-terminal fragment, which is a potent inhibitor of angiogenesis and tumor growth. Signaling factors, such as TGF-β, PDGF, or b-FGF, are in many cases stored in an inactive form, bound to ECM components. Hence, elevated activity of matrix proteases results in the release of increased number of growth factors, which can after binding to their receptors activate various signaling pathways. These processes, initiated by tumor cells, are taking place in host tissue and result in altered regulation of intracellular signaling facilitating tumor growth and metastasis.

Synonyms
Oat cell carcinoma; Small cell neuroendocrine carcinoma; Microcytoma; Reserve cell carcinoma; Kulchitsky cell carcinoma; Carcinoma with amine precursor uptake decarboxylation cell differentiation

Definition
Extrapulmonary small cell carcinoma (EPSCC) is a high grade epithelial cancer of neuroendocrine origin composed of small, round to fusiform cells with minimal cytoplasm that arises at various anatomical sites in the absence of a primary lung neoplasm.

Small cell carcinoma (SCC) is a distinct clinicopathological entity first described in the lung. It represents approximately 20% of all bronchogenic carcinoma. Extrapulmonary small cell carcinoma (EPSCC) indistinguishable from small cell ►lung cancer was first reported in 1930. Since its first description, EPSCC has been reported in virtually all anatomical sites. The primary sites most frequently involved are gynecologic organs, especially the cervix; genitourinary organs, especially the urinary bladder; the gastrointestinal tract, especially the esophagus; and head and neck region.

EPSCC often represents a diagnostic and therapeutic challenge. Limited data is available about its clinical behavior and outcome. The available literature is predominantly based on reviews of published cases or analysis of institutional data. The clinicopathological features and general management of EPSCC will be reviewed here, followed by a brief description of SCC specific to the more common sites.

Characteristics
Epidemiology
SCC arising from extrapulmonary sites represents 2–4% of all SCC. Approximately 1,000 cases per year have been reported in the United States, which represents an overall incidence of between 0.1% and

0.4% of all cancer. Patients with EPSCC are generally middle-aged or older similar to SCC of lung, however, women with SCC of cervix tend to be younger. Both genders are affected and predominance of either gender varies according to the primary site of involvement. For example, SCC of esophagus, urinary bladder, and head and neck region are more common in men whereas female preponderance has been noted in patients with SCC of gallbladder. Although cigarette smoking appears to be associated with EPSCC especially of the head and neck region, it has not been clearly identified as a risk factor for EPSCC and role of smoking in the development of malignancy remains speculative.

Pathology

The histologic criteria are the same as those for the pulmonary neoplasm. SCC is composed of sheets and nests of round to fusiform cells with minimal amounts of cytoplasm and granular nuclear chromatin. Nucleoli are absent or inconspicuous. The typical organoid architectural patterns of low-grade ►neuroendocrine neoplasms such as ►carcinoid tumor are generally absent. Mitotic rates are high and necrosis of individual malignant cell is common. It may contain non-SCC elements, varying in type depending on the location.

The pathogenesis of SCC is largely unknown and remained speculative. It exhibits several neuroendocrine features characterized by the presence of enzymes such as of dopa decarboxylase, ►calcitonin, neuron-specific enolase, chromogranin A, and CD56 (neural cell ►adhesion molecule). SCC is thought to originate from totipotent ►stem cells present in all tissues. Others have suggested that it may arise from more differentiated tumors during the clonal evolution of a carcinoma as a late-stage phenomenon.

Clinical Features

The clinical presentation is determined by the site of involvement and extent of the disease. Systemic symptoms, such as anorexia and weight loss, are common especially in patients with advanced disease. Focal symptoms are mostly site-specific and are usually indistinguishable from those of other neoplasms arising from that anatomical site. Though uncommon, similar to SCC of the lung paraneoplastic syndromes such as ectopic ►ACTH production or inappropriate antidiuretic hormone secretion may be the dominant presenting feature. Eaton–Lambert syndrome, thyoxine intoxication, and hyperglucagonemia, have also been reported but are rare.

Diagnosis and Staging

The diagnosis of SCC is primarily rested on morphological assessment. However, ►immunocytochemistry plays an important role and electron microscopy can be of value in difficult cases. The malignant cells are immunoreactive for keratin and epithelial membrane antigen in virtually all cases. Thyroid transcription factor-1 (TTF-1) immunostaining has been proposed by several investigators to differentiate small cell lung carcinoma from EPSCC. However, TTF-1 expression is not specific for SCC of pulmonary origin and should not be used to distinguish primary from metastatic SCC in extrapulmonary sites.

Although no specific staging system for EPSCC has been established most authors have adopted "Two Stage System" originally introduced by the Veterans' Affairs Lung Study Group. This staging system consists of two categories: limited disease (LD) defined as tumor contained within a localized anatomic region, with or without locoregional lymphadenopathy; and extensive disease (ED), defined as tumor outside the locoregional boundaries. Information provided by the "Tumor-Node-Metastases (TNM)" staging system may be valuable in certain anatomical sites such as SCC of large bowel.

The diagnosis of EPSCC requires a normal computed tomographic (CT) study of chest. A primary lung tumor should be excluded. Some investigators have suggested routine bronchoscopy, but this is not widely adopted. Abdominal and pelvic CT scan is a useful test to determine primary site and to assess the extent of the disease. Although there is a lack of data regarding the role of ►positron emission tomography (PET) scan in the management of EPSCC, it can be a useful tool for the detection of primary tumor in SCC of unknown primary site. In the absence of neurologic symptoms, CT scan of head is not routinely performed. Bone marrow biopsy is indicated if there is cytopenia without other evidence of disseminated disease. Other studies such as endoscopic examination are aimed to assess the affected sites and vary accordingly.

Management

Limited data are available about the optimal management of EPSCC. As in pulmonary SCC, the survival of untreated patients is poor. Treatment goals for extensive stage and limited stage disease are different and they should be treated differently. Treatment for LD is potentially curative, whereas that of ED is palliative.

SCC is sensitive to both ►radiation therapy and ►chemotherapy. The unfavorable prognosis and the chemosensitivity of its pulmonary counterpart have persuaded many clinicians to use combined-modality therapy including surgery, radiation and chemotherapy. The response rate varies from 48 to 100%. However, the optimal integration of these modalities and precise sequence is remained to be defined. Whereas chemotherapy can induce major regression of localized disease and concurrently treat occult metastases, surgery and/or radiation therapy represent the best option for ►locoregional therapy at majority of the anatomical

sites. In carefully selected patients with LD and small tumor volume, surgery can be curative. Although the role of ►adjuvant therapy remains to be defined platinum-based adjuvant chemotherapy may be beneficial given the chemoresponsiveness of the disease and the high rate of systemic recurrence. The possible synergism between chemotherapy and radiotherapy supports combined ►chemoradiotherapy and for many patients with LD at various anatomical sites the combination of chemotherapy and radiation therapy can be an effective treatment. Cranial irradiation is not routinely used in the management of these patients who achieved a complete response.

Patients with ED of any site are best managed with systemic chemotherapy. Responses to therapy occur in 60–90% of patients, however, most response are partial and of short duration. The use of surgery or radiotherapy in these patients is restricted for palliation of local symptoms.

Prognosis

SCC follows an aggressive course with early propensity for metastases. EPSCC of various anatomical sites behave differently and outcome varies according to the primary site of the disease involvement. In general the prognosis of EPSCC is comparable to SCC of lung and that extent of disease is an important factor predicting survival. Poor performance status and abnormal white blood cell count are the other important variables that correlate with survival.

In reported series patients with EPSCC are not uniformly treated or comparably staged. The median overall survival of all patients with EPSCC is 9–15 months and 5-year survival is 10–15%. Patients with LD have median overall survival of 25–34 months and 5-year survival of 31% whereas patients with ED have a median overall survival of 2–12 months and 5-year survival of 2%. Despite the generally aggressive behavior of SCC, long-term remission or cure can be achieved in selected patients with a tailored therapy.

Genitourinary Tract

Urinary Bladder

SCC has been reported in the urinary bladder, prostate, and kidney. Although urinary bladder is the most common site of EPSCC in the genitourinary tract, it accounts for less than 1%t of all ►bladder cancers. Patients are usually between the ages of 40 and 60 years, and it is three times more common in men than women. SCC may coexist with ►transitional cell carcinoma and other types of bladder tumors. Majority of patients present with locally advanced or disseminated disease. Surgery is generally recommended for patients with localized disease often followed by adjuvant chemotherapy. Combination of chemotherapy and radiation have been given concurrently in an effort to preserve the bladder in many cases. The overall median survival in most reported series is about 2 years.

Prostate

The incidence of prostate SCC is less than 1% of the total of ►prostate cancer. The median age of the patients is approximately 65 years, which is similar to that of patients with adenocarcinoma of prostate. Prostate SCC may present at initial diagnosis or appear later in the evolution of an adenocarcinoma. Approximately 30% of patients present initially with prostatic adenocarcinoma, 20% present with combined adenocarcinoma and SCC, and 50% of patients presented with SCC. ►Prostate specific antigen (PSA) is not elevated in majority of the patients with prostate SCC and they respond poorly to antiandrogen therapy. Most of the patients have advanced disease at diagnosis and median survival is about 15 months. Patients presenting initially with an adenocarcinoma have a median survival of 25 months compared with a median survival of 5 months for patients presenting with SCC.

Gynecological Sites

Cervix

SCC most commonly involve cervix but may also develop in the endometrium, ovary, vagina, and vulva. SCC represents 0.4–1.4% of all ►cervical cancer. The cervix should always be considered as the site of origin in a woman with a SCC of unknown primary site. Women with cervical SCC tend to be younger with median age of diagnosis is about 40–50 year. The prognosis varies with the stage of the disease. Survival is poor with hysterectomy alone and most patients are treated with a multimodality approach, using chemotherapy regimens that are typically used for small cell lung cancer. Patients with cervical SCC treated with combination of ►chemoradiotherapy had 3-year survival of 60%.

Gastrointestinal Tract

Esophagus

Primary SCC involving the esophagus appears to be the most frequently reported digestive tract site of EPSCC. Stomach, pancreas, ampulla of Vater, gallbladder, small intestine, and colon and rectum are the other sites in gastrointestinal tract where SCC have been reported. SCC of esophagus is rare and incidence has been estimated to range from 0.8 to 2.4% of all ►esophageal cancers. Most cases occur between the ages of 50 and 70 years, and EPSCC is twice as common in men compared with women. Combination chemoradiotherapy is effective against esophageal SCC and may improve survival. ►Adjuvant systemic chemotherapy is recommended following surgery for localized disease although long-term survival has been reported in a few

cases. The reported overall median survival is approximately 5 months, with a median survival for patients with LD is about 8 months and for patients with ED is about 3 months.

Colon and Rectum

SCC arising in the colon and rectum is rare making up approximately 0.2% of all colorectal neoplasms. The epidemiology is somewhat similar to that of adenocarcinoma with a slight male predominance. The majority of the cases are diagnosed between the ages of 50 and 70. Within the large bowel, the most frequent site is the rectum, followed by the cecum and sigmoid. Tumors with mixed histology are often present. The overall prognosis is poor with a median survival of 6 months. Surgery is the primary treatment for localized disease. ►Adjuvant radiation for local control and systemic chemotherapy to treat ►micrometastases are recommended, however, in the absence of clinical trials, the individual contribution of each component to the survival cannot be determined.

Head and Neck Region

Larynx

Although larynx is one of the most common extrapulmonary sites, laryngeal SCC account for only 0.5% of all primary ►laryngeal carcinoma. Most patients are between the ages of 60 and 80 years, and there is a male predominance. Smoking, tobacco chewing, and excess ►alcohol consumption have been associated with SCC of the larynx. The supraglottic region is the most commonly reported site. The majority of patients of localized SCC of the head and neck have been treated with local modality of treatment. Although optimal management for these patients is undefined, several investigators have reported that the use of concurrent chemoradiotherapy regimens for limited-stage disease offer potential for long-term survival. Median survival of patients with primary SCC of the larynx, hypopharynx, and trachea is between 7 months and 11 months.

►BRCA1/BRCA2 Germline Mutations and Breast Cancer Risk.

Familial Cancer

Definition

If a cancer is familiar, it is more common in relatives of an affected individual than in the general population. The level of aggregation is usually measured as a relative risk in affected families as compared to all families. A relative risk of 2.0 implies a two-times higher risk for the offspring of an affected parent.

Breast cancer, for example, is two-times more common in daughters whose mothers had breast cancer. The risks can be measured between parents and offspring, between siblings or between any first-degree relatives.

Familial aggregation is found in all types of cancer. The highest familial risks are observed for thyroid and testicular cancers, with familial risks between 5 and 10. Higher than 3.0 are the risks for ►melanoma, ►prostate cancer, ►endometrial cancer and squamous cell ►skin cancer. The breast and colon cancer the risk is about 2.0.

The reasons for familial cancer are inherited susceptibility. A shared environment and common patterns of behavior also play a role. Familial aggregation of ►lung cancer and ►cervical cancer (relative risk about 2.0) can be partially explained by environmental factors. Inherited cancers are a subgroup of familial cancers where the genetic component is obvious. In

many cases the underlying genes have been identified and gene tests are available for some cancer-related genes. Inherited cancers are often monogenic and confer a high risk in those family members who have inherited the defective gene. The frequency of disease is described by penetrance, which is 100% if all carriers of the defective gene contract cancer. Inherited cancers include cancers at many sites and syndromes at multiple sites.

Synonyms

Familial (constitutional) panmyelocytopathy (type) Fanconi; Familial hypoplastic anemia Fanconi

Definition

Fanconi anemia (FA) is a human inherited disorder clinically characterized by variable congenital anomalies, bone marrow failure and cancer susceptibility. Cellular features include genomic and chromosomal instability and hypersensitivity to DNA-crosslinking agents. FA is a rare recessive disease with an overall prevalence of about 1 in 300,000, but much higher prevalence in selected populations.

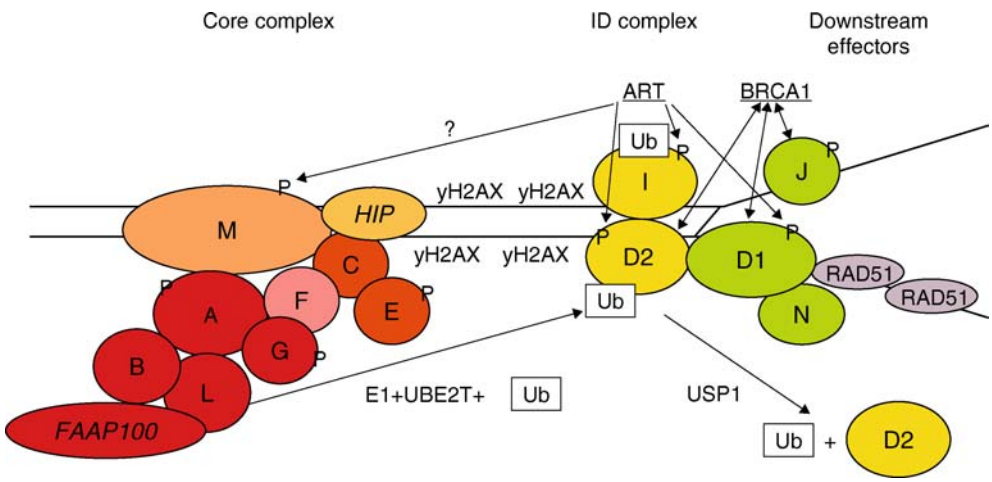
Characteristics

Approximately 70% of FA patients display variable presence of (intrauterine) growth retardation, hyper- and hypopigmentations of the skin, radial ray and external ear defects, microcephaly, microphthalmia, and malformations of the inner organs including most

frequently kidney, gastrointestinal tract, heart and brain. FA is genetically heterogeneous comprising at least 13 ►complementation groups (A to N). Underlying these subtypes are biallelic (in case of the X-chromosomal group FA-B hemizygous) mutations in 13 different genes (*FANCA*, *-B*, *-C*, *-D1*, *-D2*, *-E*, *-F*, *-G*, *-I*, *-J*, *-L*, *-M* or *-N*). The products of the FA genes interact with themselves and with a number of other proteins in a common pathway. The FA pathway for genomic maintenance, also called FA/BRCA pathway (Fig. 1), is a DNA damage-activated signaling pathway, important for the recognition of ►DNA-interstrand crosslinks and the initiation of repair of these lesions by nucleotide excision repair, ►translesion synthesis and ►homologous recombination. FA patients have defects in the FA pathway and share a high risk for the occurrence of characteristic malignancies at relatively young age. Approximately 23% of FA patients develop one kind of neoplasm or more during lifetime. In most cases, there are sharply increased risks for ►acute myeloid leukemia (AML) during childhood and ►squamous cell carcinomas (SCC) becoming effective during young adulthood. These risks are associated with defects of any of the FA genes except *FANCD1* and *-N*. Associated with defects of the latter is a different risk combination with earlier onset. *FANCD1* is also known as ►*BRCA2* and *FANCN* as ►*PALB2*. ►Biallelic mutations in either of them consistently result in a type of FA with strong risks for developmental types of cancer during infancy including ►medulloblastoma and ►nephroblastoma (►Wilms tumor), and AML. In particular defects of *FANCD1* and *-N* include a number of cases with multiple tumors. FA-D1 and -N patients invariably succumb to their malignancies at early age. Given the high degree of genomic instability and elevated mutation rates seen in FA cells, there is little doubt about a causal relationship between the FA-specific defect of genomic maintenance and the emergence of cancer in FA patients.

Myelodysplastic Syndromes (MDS)

In ►myelodysplastic syndromes, bone marrow precursor cells fail to differentiate properly such that not enough mature erythrocytes, leukocytes and thrombocytes arrive at the periphery. MDS is a frequent hematological disorder in FA. It occurs in ~7% of all patients. MDS is generally considered a premalignant condition, but less so in the context of FA. FA-related MDS progresses to ►leukemia more slowly compared to MDS in non-FA patients; it obviously follows a different natural course. Thus, FA patients may suffer from MDS for many years without developing overt leukemia. Nevertheless, the presence of MDS affects the prognosis of FA: The estimated 5-year-survival rate of FA patients with MDS amounts to only 0.09 as opposed to 0.92 in patients without MDS. Wherever



Fanconi Anemia. Figure 1 Model of the FA/BRCA signaling network. A DNA interstrand-crosslink stalls a replication fork. ATR is activated and phosphorylates FANCM, FANCD2, FANCI and FANCD1/BRCA2. The FA core complex (FANCA, -B, -C, -E, -F, G, -L and -M, *orange* to *red*) is assembled and loaded onto double-stranded DNA through FANCM and the Hef-interacting protein, HIP (FAAP24). The active FA core complex translocates along DNA and, as a E3 ligase, monoubiquitates FANCD2 and FANCI by means of UBE2T as the E2 ligase and FANCL as the E3 catalytic subunit. The ID complex (FANCI and -D2, *yellow*) is directed to chromatin at the stalled replication fork via γH2AX. The active ID complex, supported by BRCA1, recruits downstream effector proteins (*green*). While FANCJ/BRIP1 is thought to stabilize the replication fork and enable translesion synthesis, FANCD1/BRCA2 in combination with FANCN/PALB2 uploads RAD51 (*violet*) and is attributed a role in restart of the replication fork after homologous recombination. All of the latter proteins colocalize in repair foci. Adapted from Wang (2007).

possible, MDS is treated by ►hematopoietic stem cell transplantation (HSCT) to diminish the risk of transition to AML.

Leukemia

The most common malignancy arising in FA patients is leukemia. Its overall cumulative incidence is 37% (33% by age 40). The median age of onset is 14 years, thereafter the incidence rate of leukemia levels out at <1% per year. With 94% of all leukemias, AML predominates in FA with the relative risk being about 500- to 800-fold increased. ►Acute lymphoblastic leukemia (ALL) amounts to only 6%, in contrast to 84% of leukemias in the general population being ALL. Chronic myelomonocytic leukemia (CMML) or ►Burkitt lymphoma have been reported in single cases.

All FAB subclasses are represented in FA-associated AML, albeit with different proportions compared to the general population. There are more FA patients in the M4 and M6 and fewer in the M1 and M2 subclasses than in non-FA AML patients. Monosomy of chromosome 7 and partial tri- or tetrasomies of chromosome 3q, occurring as clonal aberrations in bone marrow and detectable also in peripheral blood leukocytes, are proven risk factors for the development of MDS and AML. AML may be the first and only manifestation of FA in otherwise unsuspicious patients.

Solid Tumors

The overall risk of FA patients for the emergence of solid tumors exceeds that of the general population by nearly 50-fold, with higher risks for selected tumors. The rate of solid tumors rises more than linearly and reaches 10% per year by age 45. If the competing death risks of anemia and leukemia could be removed, the estimated cumulative probability of solid tumors in FA patients would amount to 76% by that age.

The median age of onset of cancer in FA, including solid tumors and leukemia, is 16 years, whereas it is 68 years in the general population. In up to 25% of FA cases with all types of malignancies, the diagnosis of neoplasm precedes the diagnosis of FA, an extreme example being a 49-year-old patient with bilateral carcinoma of the breast, who developed MDS and AML following chemotherapy.

The incidence of solid tumors in FA patients increases beyond disease-associated rates after ►HSCT with the rate of tumor development in the HSCT group being 2.8-fold the rate in the untransplanted FA group. Conditioning, especially following regimens including total body irradiation, but also immunosuppression or posttransplant complications such as chronic graft versus host disease or infections, sharply enhance the risk for malignancies with poor survival. Most of these tumors are head and neck cancers, often involving the tongue.

Squamous Cell Carcinoma of the Head and Neck (HNSCC)

The most typical solid tumors in FA are ►HNSCC and ►SCC of the genital region in females. HNSCC in FA includes tumors of the tongue, gingiva, oropharynx and larynx. The cumulative lifetime incidence of HNSCC is about 700-fold increased with a median patient age of 31 years. In addition, there is an ~2,300-fold increased risk compared to the general population to develop carcinoma of the esophagus. FA patients with HNSCC are usually young, non-smokers and non-drinkers. Females are more often affected than males, particularly among those patients, in whom the diagnosis of FA was made after the diagnosis of cancer. This may reflect the overall survival advantage of female FA patients. FA-associated HNSCC is not fundamentally different from sporadic HNSCC, except a potential sensitivity to crosslinking agents. HNSCC initially presents as chronic ►inflammation or just red or white mucosal spots or minor lesions such that the diagnosis is often delayed. This delay leads to poor therapeutic success and no better than 50% 2-year-survival rates with this aggressive tumor type. A sensitive brush method for obtaining cells from the tongue and oral cavity of FA patients may facilitate monitoring of early cell changes and thereby contribute to the prevention of this devastating type of malignancy.

SCC of the Vulva and Cervix

The cumulative probability to develop carcinoma of the vulva is 4,300-fold, that to develop carcinoma of the cervix is 200-fold increased in FA patients. The occurrence of SCC of the vulva, cervix and anus may not only be promoted by FA, but additionally be triggered by human papilloma virus infections. It has been reported that 54% of all FA patients with these tumors had HPV-associated ►condylomas before the occurrence of cancer.

Liver Tumors

Liver tumors are frequent in FA and in the great majority follow androgen therapy for aplastic anemia. They are often multiple and mostly include adenomas (benign focal nodular hyperplasia or peliosis), seldom ►hepatocellular carcinomas (HCC). In rare cases, both adenomas and HCC can be found in the same patient. Adenomas without liver cell dysplasia are not considered premalignant changes and usually regress upon discontinuation of androgen therapy. The median age of onset of these tumors is 13 years and the cumulative incidence is 46% by age 50. The development of liver tumors due to androgen therapy is not specific for FA patients. The risk for HCC may depend on the length of term of therapy and on the specific

type of androgen used. Oxymetholone and methyltestosterone appear to be associated more frequently with the occurrence of HCC, whereas patients treated with danazol develop adenomas, but may be less affected by HCC.

Other Tumors

Solid neoplasms occasionally found in FA patients include ►brain tumors and ►renal carcinomas, ►breast cancer, ►basal cell carcinoma, ►neuroblastoma, ►desmoid tumors, gonadoblastoma, ►melanoma, neurilemmoma and ►osteosarcoma. A major factor thought to promote tumor development in FA is oxidative stress. *In vitro* experiments suggest that FA cells are more sensitive than non-FA cells towards the effects of reactive oxygen species.

FA Gene Involvement in Neoplastic Disease of Non-FA Individuals

Among the known ►breast cancer risk genes, three are authentic FA ►genes. These include the downstream effector genes of the FA/BRCA pathway, *FANCD1* = *BRCA2*, *FANCN* = *PALB2* and *FANCJ* = ►*BRIP1*. *BRCA2* is considered a high-penetrance breast cancer susceptibility gene with heterozygous mutations increasing the risk more than tenfold. Heterozygous *BRCA2* mutations are associated with female and male breast cancer, ovarian cancer and pancreatic carcinoma in familial forms. All of these cancers show allelic loss at the *BRCA2* locus consistent with the tumor suppressor function of the gene.

FANCN = *PALB2* has been identified as a low-penetrance susceptibility gene for female and male breast cancer with ►monoallelic truncating germline mutations causing a 2.3 times higher risk for female breast cancer at all ages and a relative risk of 3.0 for women under 50 years of age. This low-penetrance susceptibility is surprising since PALB2 is functionally associated with ►BRCA2 and biallelic mutations in both genes cause a similar, severe type of FA.

FANCJ = *BRIP1* interacts with the ►BRCT domain of ►BRCA1. Heterozygous inactivating mutations in ►*BRCA1* predispose to breast cancer and inactivation of ►BRIP1 abrogates certain BRCA1 functions. Consistently, heterozygous truncating germline mutations in the *FANCJ* gene *BRIP1* have been shown to represent low-penetrance breast cancer susceptibility alleles and confer an approximately twofold increased risk at all ages and a relative risk of 3.5 for carriers aged less than 50 years.

Studies of *FANCA*, *-C*, *-D2*, *-E*, *-F* and *-G* in familial breast cancer cases did not identify any truncating mutations. However, there are not enough data to date, which would exclude that certain mutations in some of these FA genes might enhance, for instance, breast cancer risk, as has been proposed for three different common mutations in *FANCC* by study of FA families.

Inactivation of the FA/BRCA pathway through hypermethylation of the *FANCF* gene has been reported for a variety of spontaneous malignancies including cervical, ovarian, bladder and ►non-small-cell lung cancer, AML, and HNSCC. The proportion of cases affected by *FANCF* silencing in each of these tumor types is relatively low, a maximum being reported 21% *FANCF*-methylated ovarian carcinomas in one study. Of note, the *FANCF* gene is located adjacent to a hot-spot region for hypermethylation on chromosome 11p15. Functional suppression of imprinted genes in this region has been found in many tumor types. Thus, *FANCF* ►hypermethylation may well occur incidentally due to spreading of the ►epigenetic modification.

The occasional involvement of germline or rare somatic FA gene mutations and ►LOH has also been reported in some sporadic cancers. As with *FANCF* hypermethylation, only a minority of tumors in non-FA individuals reveals mutations in FA genes, with *BRCA2* predominating. In pancreatic carcinoma cell lines, the proximal FA pathway was inactivated in 9.5%, and *BRCA2* in 7% of cases. One explanation is that sporadic disruption of the FA pathway causing genomic instability might be an early event during malignant transformation in a subset of tumors, preferentially among FA-typical cancers that occur in non-FA patients. Alternatively, it could be a later phenomenon during tumor advancement studies of microsatellite instability were incompatible with selective pressure for functional loss of BRCA2 in tumor evolution, but fitted closely with the absence of selection. This suggests that *BRCA2* inactivation occurs at a time when positive or negative selection for or against such event has been lost, implying that disruption of the FA/BRCA pathway in sporadic cancer is rather a stochastic phenomenon with neutral genetic drift during tumor progression. This resembles silencing of *FANCF*. Where it occurs, it is often found in only some proportion of tumor cells. Cancer rates in obligate FA heterozygotes comparable to those in the general population (apart from carriers of mutations in the FA genes mentioned above) also argue against disruption of the FA/BRCA2 pathway as an event initiating tumorigenesis.

The functional consequences of disruption of the FA pathway in sporadic cancer have not fully been explored. Nevertheless, drug-induced inhibition of the FA/BRCA pathway has been suggested as a potential route to sensitization of tumors to DNA-crosslinking agents. It has been proposed as a means of targeted chemotherapy. However, once the cell death pathway is compromised, e.g. by silencing of ►TP53, and disconnected from the FA pathway in tumor cells, no benefit of such therapy is to be expected.

FAS

Definition I

Synonym APO-1, CD95 Fas, also known as APT1, tumor necrosis factor receptor superfamily member 6 (TNFRSF6), CD95, APO-1 and FAS1 is a type I membrane protein of about 40 kD. It was originally identified by mouse monoclonal antibody called anti-Fas or anti-APO-1. In the 6th Workshop and conference on Human Leukocyte Differentiation Antigens (Kobe, 1996), Fas was designated as CD95. The gene maps to 10q24 and is mutated in Autoimmune Lymphoproliferative Syndrome. The protein mediates apoptosis through sequential activation of ICE-like caspases (Casp 4, Casp 5, Casp 3) and may also be involved in autoimmune diabetes.

Synonyms
FAS; FASN

Definition
Fatty acid synthase is a key enzyme which regulates the de novo biosynthesis of long-chain fatty acids.

Characteristics
Structure and Function
Fatty acid synthase (FAS) is a key enzyme that regulates the de novo biosynthesis of long-chain fatty acids from acetyl-CoA and malonyl-CoA in the presence of

NADPH. There are two types of FAS. ►FAS II, found in prokaryotes, plants, and mitochondria, consists of an acyl carrier protein (ACP) and seven structurally independent monofunctional enzymes. Each of these enzymes is encoded by a separate gene that produces a unique protein which catalyzes a single step in fatty acid synthesis. Mammalian FAS, named ►FAS I, consists of two identical multifunctional polypeptides. Each monomer of FAS I contains seven distinct catalytic domains starting from the N-terminal. These catalytic domains including β-ketoacyl synthase (KS), malonyl/acetyltransferase (MAT), dehydrase (DH), enoyl reductase (ER), β-ketoacyl reductase (KR), acyl carrier protein (ACP), and thioesterase (TE).

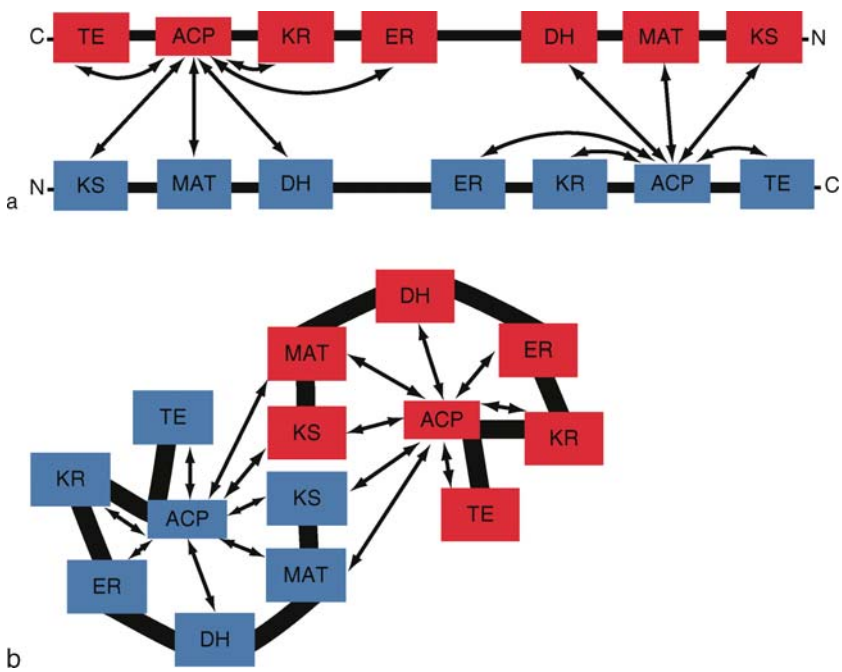
Two models have been proposed for the structure of FAS. The conventional model is based on crosslinking studies with the bifunctional reagent, 1, 3-dibromopropanone (DBP). In this model, two identical monomers are arranged in a head to tail orientation that allows functional interactions across the monomer interface (Fig. 1a). The second model is based on functional mutant complementation and improved DBP crosslinking studies. These studies suggest that the FAS monomers form a coiled conformation that allows for a variety of intra- and intermonomer functional domain interactions (Fig. 1b). In this model, both of KS and MAT domains are located in the center of the FAS dimer and can interact with the ACP groups on either of the monomers.

FAS in Normal Tissues

FAS I plays an essential role during embryonic development and a key role in energy homeostasis in adult mammals. Most normal tissues preferentially use circulating dietary fatty acids for the synthesis of new structural lipids. Thus, FAS expression is generally low to undetectable in most human normal tissues and is high only in the lipogenic tissues, such as liver and adipose tissues. In liver and adipose tissues, fatty acid synthesis occurs when it is necessary to store excess calories from carbohydrates as ►triglycerides. FAS expression is tightly controlled by nutrients through transcriptional induction and regulated by insulin, glucagon, glucocorticoids, and thyroid hormone. During starvation, fatty acid oxidation is activated to produce free fatty acids for survival, and FAS activity is rapidly downregulated. The effect of nutrients and ►hormones on the expression of lipogenic genes is mostly mediated by the sterol regulatory element-binding protein-1 (►SREBP-1). In adipose tissue, the ►transcription factor, ►peroxisome proliferator-activated receptor γ PPARγ, is critical for regulating both adipogenesis and lipogenesis. Activation of PPARγ stimulates fatty acid synthesis and storage.

FAS and Cancer

Elevated expression of FAS has been observed in many human tumors, including carcinoma of the breast,



Fatty Acid Synthase. Figure 1 Two models for the organization of FAS [1].

prostate, colon, ovary, endometrium, mesothelium, lung, thyroid, and stomach. Moreover, overexpression of FAS in breast, prostate, and thyroid ►cancers has been associated with more aggressive malignancies. The differential expression of FAS in normal and tumor tissues has led to FAS being considered as a target for anticancer therapy. Abnormally active endogenous fatty acid metabolism appears to be important for cancer cell proliferation and survival. The data from clinical studies and animal models indicate that tumor cells constitutively express high levels of FAS and undergo significant endogenous fatty acid biosynthesis. In contrast to liver and adipose tissues, the function of elevated endogenous synthesis of long-chain fatty acid in most human cancers is not for energy storage; the new synthesized fatty acids are converted into ►phospholipids, not triglycerides. In cancer cells, overexpression of FAS seems to be independent of the regulatory signals found in normal tissues. Recent studies indicate that ►mitogen-activated protein kinases (MAPKs) and ►PI3 kinases pathways ►(PI3K signaling) are likely involved in FAS regulation via SREBP-1c. Inhibition of MAP and PI3 kinases downregulates SREBP-1 levels, thereby reducing FAS expression and fatty acid synthesis in transformed human cancer cells. Deletion of the major SREBP-binding site from the FAS promoter abrogates the transcription activity of FAS. The constitutive activation of the MAPK and PI3 kinase AKT signaling pathways in cancer cells leads to elevated levels of FAS and sustained fatty acid synthesis.

FAS Inhibitors as Potential Cancer Chemotherapeutic Agents

Several FAS inhibitors have been developed to study the loss of FAS function in tumor cells. These inhibitors include ►cerulenin, the cerulenin derivative, ►C75, the β-lactone, ►orlistat, and the ►green tea polyphenol, epigallocatechin-3-gallate (EGCG). Cerulenin, C75 and orlistat are selective inhibitors of tumor cell growth.

Cerulenin, (2R, 3S)-2, 3-epoxy-4-oxo-7, 10-trans, *trans*-dodecadienamide, was the first identified "specific" inactivator of FAS. It is a natural antibiotic product of the fungus *Cephalosporium ceruleans*. Cerulenin irreversibly inhibits FAS by binding covalently to the active site cysteine thiol in the β-ketoacyl-synthase domain. Cerulenin is selectively cytotoxic to a number of established human cancer cell lines including leukemias, breast, colon, brain, ovary, and prostate. The inhibition of fatty acid synthesis by cerulenin has been shown to be dose-dependent. The cytotoxic effect generally parallels the level of endogenous fatty acid synthesis in human breast tumor cells. FAS inhibition by cerulenin leads to apoptotic cell death in ►breast cancer, ►prostate cancer, ►brain cancer, and ►colon cancer cells. However, cerulenin's chemical instability renders it ineffective as a systemic anticancer agent.

C75, a potent derivative of cerulenin, is a more stable FAS inhibitor. Structurally, it is a cell-permeable α-methylene-γ-butyrolactone, designed to be less reactive and potentially safer than cerulenin. In vivo and in vitro studies have confirmed the selective toxicity of C75 against tumor cells. C75-mediated inhibition of FAS increases malonyl-CoA levels and inhibits carnitine palmitoyltransferase 1 (CPT-1) activity, preventing the oxidation of newly synthesized fatty acids. High levels of malonyl-CoA and low levels of CPT-1 may represent mechanisms whereby FAS inhibition leads to tumor cell death. C75 treatment of mesothelioma and prostate tumor (►Prostate cancer, clinical oncology) ►xenografts in ►nude mice leads to significant inhibition of tumor growth. Subcutaneous xenografts of MCF-7 ►breast cancer cells in nude mice treated with C75 showed fatty acid synthesis inhibition, ►apoptosis, and reduced tumor growth with no normal tissue toxicity. C75 has also been used as an antiobesity treatment in animal models. Treating obese mice with C75 produces a profound reduction in body weight and food intake.

►Orlistat (also known as Xenical or tetrahydrolipstatin), a US Food and Drug Administration (FDA)-approved drug used for treating ►obesity, is a saturated derivative of lipstatin and works by inhibiting pancreatic and gastric lipases in the lumen of the gastrointestinal tract to decrease systemic absorption of dietary fat. Orlistat is also a rather potent and selective inhibitor of FAS. It inhibits the thioesterase domain of FAS which is responsible for releasing palmitate from the ACP of the enzyme. Orlistat has been reported to have antitumor activity in many tumor cell models because of its ability to block the activity of FAS. Cell cycle arrest induced apoptotic cell death and downregulation of the ►Her2/neu (erbB-2) ►oncogene have been observed in orlistat treated breast cancer cells. Orlistat is also able to effectively inhibit the growth of prostate tumor ►(prostate cancer, clinical oncology) ►xenografts implanted in nude mice.

Fatty Acid Transport

Leonard A. Sauer
Bassett Research Institute, Cooperstown, NY, USA

Definition

Is the process through which free fatty acids pass through the membranes of cells. The term may include: uptake of fatty acids from the blood or the extracellular space; release of fatty acids from the cell interior to the extracellular space or blood; and transport of fatty acids within the cell across intracellular membranes during biosynthesis and metabolism. While all three types of transport may occur in tumor cells this essay concentrates on the characteristics and mechanisms for free fatty acid entry into tumor cells.

Characteristics

Fatty acids serve multiple functions in cells and their transport from arterial blood plasma to the cell interior is necessary for cell growth and survival. Fatty acid oxidation is a major source of energy for heat production and generation of ATP for biosynthesis and growth. During metabolism fatty acids are incorporated into several complex lipids required for cell structure and function. Fatty acids also play important roles in cell signaling; they are anchors for attachment of specific signaling proteins to membranes and they are converted to several types of ►lipid mediators involved in intra- and extracellular cell signaling mechanisms. The essential long chain polyunsaturated fatty acids, linoleic (C18:2n6), linolenic (C18:3n3), eicosapentaenoic (C20:5n3) and docosahexaenoic (C22:6n3) acids, which are obtained from dietary sources, play particularly important roles in cell signaling, membrane structure, growth and control of fatty acid transport. If dietary fat consumption exceeds the need, fatty acids are stored in white adipose tissue as triacylglycerols for subsequent release during postprandial and longer periods of food deprivation.

Fatty acids greater than 8 carbons in chain length are not very water soluble and are transported in the blood bound to plasma albumin. The plasma albumin-fatty acid pool is maintained by release of free fatty acids from plasma lipoproteins (catalyzed by endothelial lipoprotein lipase) and by release of free fatty acids from lipid stores. Fatty acids bound to plasma albumin dissociate from the albumin binding sites to maintain a plasma free fatty acid concentration of 7–10 nM. This plasma free fatty acid pool is a major source of free fatty acids for cell consumption. Accumulation of high free fatty acid concentrations inside cells, however, is toxic for cell structure and function and specific intracellular fatty acid binding proteins (FABPs) are present in cells to maintain low free fatty acid concentrations. Specific isoforms of these FABPs are expressed in different organs and tissues.

Characteristics - Tumor

Transplantable solid rodent tumors and human cancer xenografts grown in nude rats have ready access to the free fatty acid pool in arterial blood plasma. Cancers that arise spontaneously undoubtedly also have access to plasma fatty acids. Arteriovenous difference measurements in arterial and tumor venous blood plasma samples collected across solid tumors in vivo or during perfusion in situ indicate that substantial rates of fatty acid uptake occur. Thirty-five to 45% of the total fatty acids in arterial blood plasma is removed during one pass of the arterial blood through a fast-growing rat hepatoma. Similar uptakes (35 to 45%) occur for each of the seven major plasma fatty acids in rat arterial blood: myristic, palmitic, palmitoleic, stearic, oleic, linoleic and arachidonic acids. Consequently, larger amounts of the more abundant plasma fatty acids, oleic, linoleic and arachidonic acids are removed. Since tumor fatty acid uptake is proportional to the arterial plasma fatty content of each fatty acid, there is no preferential uptake of any single fatty acid. Each of five different human cancer xenografts, ER^+ and ER^- MCF-7 breast, PC3 prostate, CFDT1 renal transitional and FaDu pharyngeal carcinomas, grown in nude rats removes fatty acids from the arterial blood plasma. Fatty acid uptake by human tumors also occurs in proportion to the concentration of the individual fatty acid in arterial blood plasma. However, the rates and efficiencies of fatty acid uptake in human cancer xenografts are different and are directly proportional to the tumor growth rate.

Growth and incorporation of [^{3}H]thymidine into DNA in rodent tumors and human cancer xenografts in vivo or during perfusion in situ are directly dependent on the availability and uptake of plasma ►linoleic acid. Plasma linoleic acid concentrations, tumor linoleic acid uptakes and growth rates are increased in tumor-bearing rats fed diets enriched in linoleic acid. Similar stimulations of tumor growth occur when tumor-bearing rats are subjected to an acute fast, except that the elevation in plasma linoleic acid content in the acutely fasted rats is derived from lipolysis of host fat stores. In contrast, the absence of linoleic acid in arterial blood plasma, as occurs in tumor-bearing rats fed a linoleic acid-deficient diet, inhibits growth and the rate of [^{3}H]thymidine incorporation into tumor DNA. Linoleic acid-dependent growth in rodent tumors and human cancer xenografts results from the conversion in the tumor of linoleic acid to

13-hydroxyoctadecadienoic acid (13-HODE). 13-HODE, a mitogen in these tumors, is a product of lipoxygenase activity and is released into the tumor venous blood plasma. Depending on the tumor type 1 to 10% of the linoleic acid removed from the arterial blood is converted to 13-HODE. Thus, tumor growth rates are directly proportional to both linoleic acid uptake and 13-HODE release.

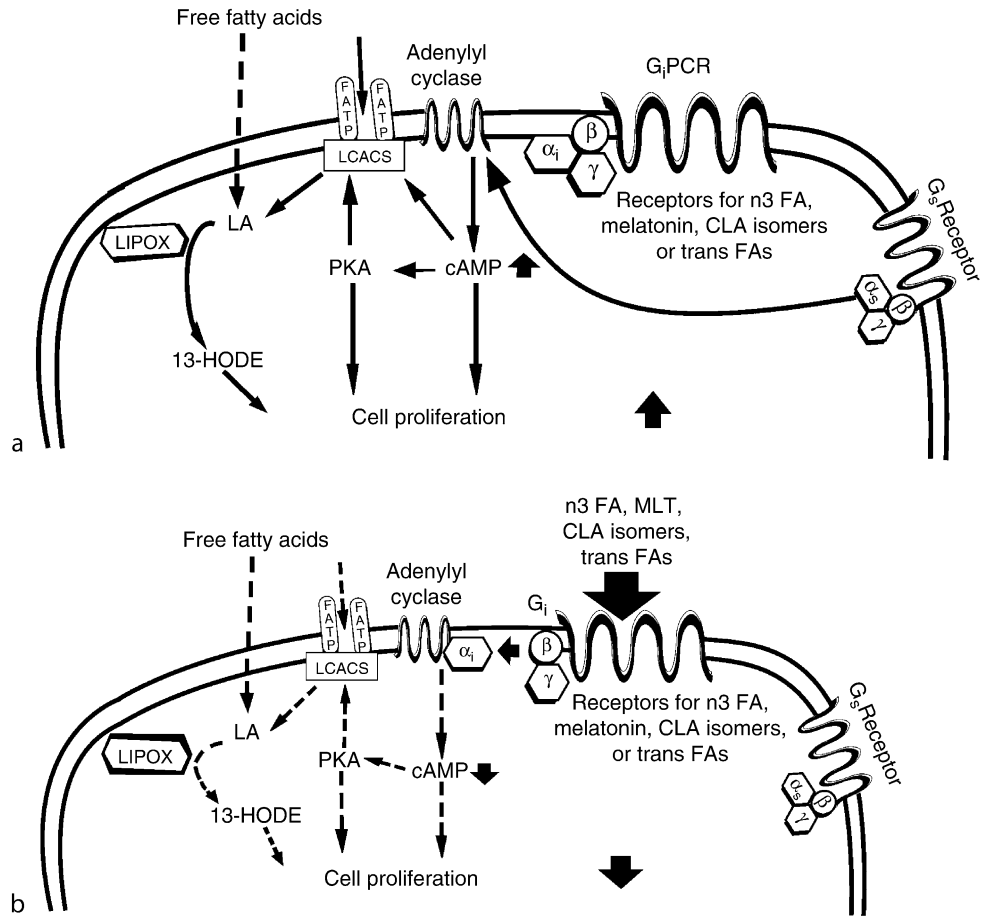
Arterial blood plasma long chain polyunsaturated fatty acids affect tumor growth differently; whereas the n6 fatty acid, linoleic acid, increases tumor growth, the presence of ►n3 fatty acids in arterial blood plasma inhibits tumor growth. In tumor-bearing rats fed a diet containing both linoleic acid and n3 fatty acids, the rates of linoleic acid uptake, 13-HODE production,[^{3}H]thymidine incorporation into DNA and growth are suppressed. Each of the n3 fatty acids, α-linolenic, stearidonic, eicosapentaenoic and docosahexaenoic acids, inhibits fatty acid transport; a 50% inhibition occurs at a plasma n3 fatty acid concentration of about 0.15 mM. Most interesting, uptake of all plasma saturated, monounsaturated and n6 polyunsaturated fatty acids is depressed by n3 fatty acids. However, tumor uptake of n3 fatty acids is not inhibited. Other dietary agents also inhibit tumor fatty acid transport and growth. These include, ►melatonin and some conjugated linoleic acid isomers and *trans* fatty acids. As with n3 fatty acids, the inhibition of tumor fatty acid transport is directly proportional to the arterial blood plasma content of the inhibitor. Melatonin, which is present in the diet and is the natural hormone of the pineal gland, is the most potent inhibitor of tumor fatty acid transport yet discovered. A plasma concentration of 0.1 nM melatonin causes a 50% inhibition of fatty acid transport. In addition to inhibitions of both fatty acid transport and 13-HODE release, these agents cause significant reductions in the intratumor cAMP content, [^{3}H] thymidine incorporation and phosphorylated-MEK and -ERK1/2 (►MAP Kinase). Significantly, these inhibitions caused by n3 fatty acids, melatonin, CLA isomers and *trans* fatty acids are reversed by the addition of either 8-bromo-cAMP or pertussis toxin to the arterial blood containing these agents. [Pertussis toxin catalyzes the ADP-ribosylation of the α subunit of inhibitory heteromeric guanine nucleotide G proteins and reactivates the inhibited adenylyl cyclase activity. 8-bromo-cAMP is a cell-permeable analog of cAMP that is resistant to hydrolysis by phosphodiesterases.] Addition of 13-HODE to the arterial blood restores phosphorylated-MEK and -ERK1/2 and [^{3}H]thymidine incorporation but not fatty acid transport. The results strongly suggest that fatty acid transport and growth in rodent tumors and human cancers are dependent on an elevated intratumor cAMP content and that the inhibition of fatty acid transport is mediated by an inhibitory ►G protein-coupled receptor(s).

Mechanisms

The mechanism for fatty acid transport in eukaryotic cells is not yet clearly resolved. Two hypotheses, transport by passive diffusion and transport by protein–mediated carriers, have been presented and studied extensively in model membrane vesicles and cultured cells. Lipophilic non-ionized free fatty acids rapidly penetrate membrane vesicles and red cells, a process that has been termed flip-flop to describe movement of the fatty acid across the membrane leaflet barrier. The barrier to flip-flop is increased by ionization of the fatty acid and may be further increased by changes in the lipid phases in cell membranes of different cells. These findings strengthen the hypothesis for fatty acid transport via protein-mediated carriers. Three groups of membrane protein carriers that contribute to fatty acid transport have been identified in mammalian cells. Fatty Acid Transport Proteins (FATP1–6) are a family of proteins that have distinct tissue distributions. Several but not all of the FATP isoforms transport fatty acids across cell membranes; several also have long chain fatty acid Co-A synthetase (LCACS) activity, which may be important for retention of the fatty acid inside the cell. Evidence also indicates that the plasma membrane protein Fatty Acid Translocase (FAT/CD36) is involved in fatty acid uptake in heart, skeletal muscle and adipose tissue. Control of fatty acid transport by FATP isoforms and FAT/CD36 may involve movement of the carriers between intracellular membranes and the plasma membrane. A Fatty Acid Binding Protein in plasma membranes (FABPpm) that is present in heart, intestine, liver and adipocytes may also play an important role in fatty acid transport. Since all of these proteins may be present in cells, cooperative activities (as yet undefined) may occur among the different protein carriers.

The requirement for high intratumor cAMP is a unique property that appears to control fatty acid transport in solid tumors. The mechanisms that maintain the high intratumor cAMP content are not known but may be catalyzed by stimulatory G_sPCR(s) (►G proteins). This cAMP requirement is not easily reconcilable with the current understanding of fatty acid transport mediated by either passive diffusion or by protein carriers. Depletion of intratumor cAMP and inhibition of fatty acid transport caused by n3 fatty acids, melatonin or CLA isomers is dose-dependent and complete at high inhibitor concentrations. Despite the fact that arterial blood plasma fatty acid concentrations remain available to the tumor, fatty acid transport into the tumor is inhibited. However, addition of either 8-bromo-cAMP or pertussis toxin to the

F



Fatty Acid Transport. Figure 1 Schematic representations for fatty acid transport (a) and control of transport (b) by dietary inhibitors. (a) The sequence of events associated with elevated intratumor cAMP, uptake of linoleic acid, 13-HODE production and cell proliferation are designated by solid arrows. (b) Attenuation of intratumor cAMP and fatty acid transport caused by binding of n3 fatty acids, melatonin, CLA isomers or *trans* fatty acids to inhibitory G protein-coupled receptors is designated by dashed arrows. Abbreviations are: G_iPCR, inhibitory G protein-coupled receptors; G_sPCR, stimulatory G protein-coupled receptor; 13-HODE, 13-hydroxyoctadecadienoic acid; LCACS, long chain fatty acid acyl-Co A synthetase; LIPOX, lipoxygenase, LA, linoleic acid; PKA, protein kinase A.

inhibitor-containing arterial blood restores intratumor cAMP and fatty acid transport. Reversal of the inhibition by these agents indicates that inhibitory G_iPCR(s) (►G proteins) for n3 fatty acid, melatonin and CLA isomers mediate the reduction of intratumor cAMP and inhibition of fatty acid transport. Rat hepatoma 7288CTC and the human cancer xenografts contain one or both of the inhibitory G protein-coupled melatonin receptors, MT_1 and MT_2. Compound S20928, a specific antagonist for melatonin receptors MT_1 and MT_2, increases intratumor cAMP and mitigates the melatonin inhibition. There is as yet no direct evidence that inhibitory G protein-coupled receptors for n3 fatty acids, CLA isomers or *trans* fatty acids exist in solid tumors. mRNA for FATP1 is over-expressed in a rat hepatoma suggesting that FATP1 may mediate fatty acid transport in hepatomas and other tumors. If that is the case, the activity of FATP1 as a fatty acid transport carrier in these tumors may require cAMP (Fig. 1).

n3 Fatty Acids

Definition

n3 long chain polyunsaturated fatty acids (n3 PUFAs), also known as ω3 PUFAs, are a group of dietary fatty acids that have important roles in several physiological functions. They are characterized by the position of the terminal *cis*-olefinic bond, which is located 3 carbon atoms from the methyl end of the carbon chain. The n3 PUFA, α-linolenic acid (C18:3n3), is present in several plant oils and is a precursor in animal tissues of stearidonic (C18:4n3), eicosapentaenoic (C20:5n3) and docosahexaenoic (C22:6n3) acids. Marine fish and oils derived from them are important dietary sources for the C18 through C22 n3 PUFAs. The position of the terminal cis-olefinic bond in n3 PUFAs distinguishes them from the n6 or ω6 PUFAs in which the location of the terminal *cis*-olefinic bond is 6 carbons from the methyl end of the carbon chain. Dietary n3 PUFAs (►Fatty acid uptake) have a negative effect on growth of established solid tumors, whereas the dietary n6 PUFA, linoleic acid (C18:2n6) [►linoleic acid] has a positive tumor growth effect. The mechanisms for interaction among n3 and n6 PUFAs are a conundrum in cancer biology.

Immunochemical fecal occult blood test; Immunological fecal occult blood test; iFOBT; Fecal occult blood test; FIT

Definition

A fecal immunochemical test for hemoglobin is a test designed to detect hemoglobin in feces using an antibody raised against human hemoglobin. It is one of a class of technologies referred to as ►fecal occult blood test (FOBT).

Characteristics

Fecal immunochemical tests (FIT) incorporate an antibody specific for human hemoglobin; such react with the globin protein moiety of hemoglobin.

Fate of Hemoglobin in the Gastro-Intestinal Tract

The globin moiety of hemoglobin is a protein and as such is rapidly digested in stomach or small intestine such that it is no longer detectable by immunochemical methods. Ingestion of blood volumes of up to 100 mL has not resulted in detectable immunoreactive hemoglobin in feces, based on reports using some of the earlier types of FIT. In other words, FIT are selective for colorectal bleeding, especially where the bleeding is occult (i.e. not visible to the naked eye). This is different from the chemical, specifically guaiac-based, FOBT which can return a positive result for blood derived from the proximal as well as distal ►GI tract.

FIT technology differs from chemical-based FOBT that react to the peroxidase activity of heme (Fig. 1). In feces, hemoglobin is subject to degradation by endogenous digestive enzymes (albeit at a much slower rate than in small intestine and stomach) and by bacterial enzymes. As shown in Fig. 1, this releases heme from globin. FIT technology detects globin and not heme and so is not subject to the factors that interfere with methods that depend on detection of heme. Heme itself is degraded by bacterial enzymes. Globin itself is progressively degraded at widely varying rates in feces.

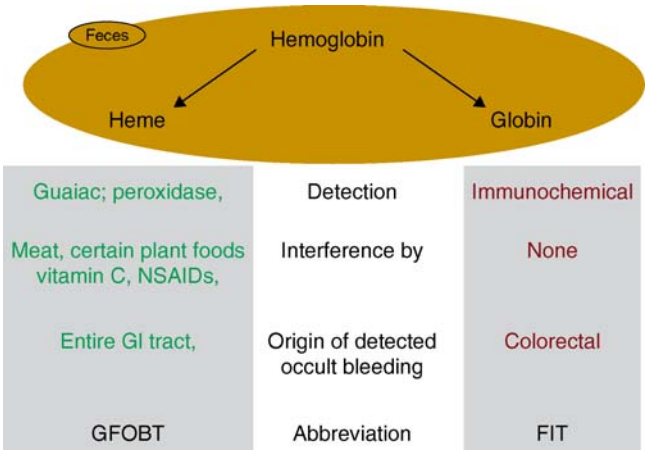
Because fecal immunochemical test technology is so different from that of the chemical methods, because it reacts to a different analyte (i.e. globin not heme) and because it provides the option of quantification of fecal hemoglobin rather than being limited to qualitative assessment as is the case for GFOBT, it is recommended that the terminology "fecal immunochemical test" be applied and abbreviated as FIT, to emphasize that it is a quite different technology and analyte from chemical FOBT.

Uses for FIT

The primary use of FIT is in screening for colorectal cancer. Chemical FOBT have been proven to reduce mortality and incidence in four randomized controlled trials. Comparative studies have shown FIT to be more sensitive for cancer and more sensitive for colorectal adenomas than guaiac-based FOBT. An hemagglutination-FIT has been shown to be superior to a high-sensitivity guaiac-FOBT in that it achieved the same higher sensitivity for cancer but required less than half as many colonoscopies to achieve this. In other words, FIT improve sensitivity for colorectal cancer and adenomas but not at the cost of unacceptable deterioration in specificity.

FITs are not subject to interference by diet or drugs and maintenance of an adequate specificity is not dependent on proscription of certain foods or drugs as is the case for guaiac-FOBT. This, together with the improved stool-sampling methods characteristic of FIT, makes it easier for screenees and improves participation rates in screening.

It is not advisable to use FIT as an all-purpose test for fecal blood as it is selective for colorectal bleeding. If used in this setting, such as in the context of iron-deficiency, it should be combined with a chemical test. However, it is important to note that the negative predictive value of either guaiac-FOBT or FIT is not 100% and many consider their use should be confined to screening for colorectal cancer where they act as an aid to early detection; as such they serve to identify those most likely to have colorectal neoplasia and so in need of a diagnostic procedure such as ►colonoscopy.



Fecal Immunochemical Test. Figure 1 Fate of hemoglobin in feces and detection of products by the various fecal occult blood test (FOBT) technologies.

Quantifiable FIT

Several of the latest FIT allow quantification of fecal hemoglobin. Results show that fecal hemoglobin concentration corresponds to the "stage" of neoplasia. People with cancer have the highest levels on average, those with a normal colon the lowest levels while those with adenomas have intermediate levels. Studies such as these show that patients with advanced adenomas (size greater than 1 cm, villous change or high grade dysplasia) do have occult bleeding. In other words, the higher the level of fecal hemoglobin the more likely that neoplasia is present.

The advantage of fecal hemoglobin measurement is that it returns full control of sensitivity and specificity to the doctor managing screening. It enables the doctor to set the level of fecal hemoglobin that would trigger follow-up diagnostic colonoscopy. At the population level, such an approach allows flexible choice of a test specificity:sensitivity ratio, so controlling the colonoscopy rate to that which is feasible for a health care system.

Types of FIT Currently Available

A variety of test technologies are employed in the currently available tests. This includes latex agglutination, membrane diffusion devices for detecting immunogold- or latex-labeled antibodies, hemagglutination, and magnetic particle agglutination. The end point for some tests are read by eye while others may also be read by a machine designed specifically for the particular technology and its endpoint. Some devices are designed for simplicity and development in an office-setting while others are designed for large scale development in a laboratory – automated processing, development and reading may be available.

Internationally, there are no set criteria that a test manufacturer should follow when setting the specifications for a test. As such, different tests may behave differently with differences in the quantity of hemoglobin to which they react as well as the nature of the hemoglobin antigen that they detect.

A test result may be quantitative, providing a measure of the concentration of hemoglobin in feces, or qualitative, providing an indication as to whether the fecal hemoglobin is considered to have reached a level likely to reflect the presence of neoplastic pathology in the colon or rectum.

Stool-Sampling Procedures

The nature of the fecal sample is an important component of a test. Each test comes with its own characteristic stool-sampling device. These include devices that keep the sample dry and so more likely to keep the antigen stable and others that use devices that include liquid and in which hemoglobin degradation might proceed during specimen transit unless samples are kept cold.

Most devices require the stool to be kept clear of toilet bowl water when sampling while a few require sampling to be undertaken from a stool kept clear of water. The range of sampling devices include wooden spatulas that smear feces onto a card, probes that absorb or wick materials from feces when poked into the stool, probes that trap feces into grooves when poked into the stool, and brushes that sample toilet bowl water from the surface of the immersed stool. Some provide precise control of stool sample quantity while others do not provide such control.

Most manufacturers provide packaging that enables samples to be sent by mail to a processing laboratory.

As hemoglobin can be rapidly degraded in feces especially at room temperature or above, whole stools should never be sent to a laboratory for sampling by the laboratory. Rather, the appropriate stool-sampling device provided for a test must be used. It is likely that different tests vary in their capacity to detect partially degraded hemoglobin. This will be dependent on the antibody used but there is little published material to guide users.

Performing an in-office GFOBT as part of a digital rectal examination has been common practice especially in the USA. However, usually only one rather than the recommended two or three stool samples is obtained. Recently this approach has been evaluated in a large group of asymptomatic subjects where it was found to be unsatisfactory. Screening based on digital sampling of stool as part of a rectal examination cannot be recommended and manufacturer's recommendations for obtaining stool samples should be followed.

Biology of Bleeding from Colorectal Neoplasia

The fact that microscopic bleeding may arise from cancers or adenomas, provides the basis for the use of FOBT to aid early detection of colorectal neoplasia. Blood loss is variable from day-to-day and may fall within the normal range. Furthermore, blood of colorectal origin is not uniformly distributed within a stool and often is found on the surface. Consequently, it is usually recommended that when screening for colorectal cancer, samples from at least two separate stools be collected. It is also recommended that the stool surface be sampled rather than the stool interior or an homogenate.

Fecal Occult Blood Test

Definition

FOBT; A fecal occult blood test finds blood in the stool by placing a small sample of stool on a chemically treated card, pad, or wipe. Then a special chemical solution is put on top of the sample. If the card, pad, or cloth turns blue, there is blood in the stool sample. A fecal occult blood test may be used to check for ►colon cancer, but it is never used to diagnose this condition. Other tests for ►colon cancer include a digital rectal examination, sigmoidoscopy, colonoscopy, or CT scan.

►Fecal Immunochemical Test

Felty Syndrome

Definition

Is a rare disorder that involves rheumatoid arthritis, a swollen spleen, decreased white blood cell count, and repeated infections. The cause of Felty syndrome is unknown. It is more common in people who have had rheumatoid arthritis for a long time. People with this syndrome are at risk of infection because they have a low white blood cell count.

Female Sex Hormones

Definition

Estrogens and progestagens.

►Estrogenic Hormones

Feminization

Definition

Rarely occurs in ►adrenocortical carcinoma and is the result of an increased production of estrogen by the tumor cells. Males usually develop breasts (gynecomastia), and girls present with precocious telarche (isolated unilateral or bilateral breast development).

►ERM Proteins

FERM Domain

Definition

Is name of the protein 4.1 family domain and stands for F (four point one) E (ezrin) R (radixin) M (moesin). It is a unique module involved in the linkage of cytoplasmic proteins to the membrane.

►Neurofibromatosis 2

Fermentation Products

Definition

Dietary fiber including resistant starches, complex carbohydrates and cellulose, have been put forward as cancer protective food components. The theory is that dietary fiber may protect against ►colon cancer through absorption of risk factors and especially through secondary events resulting from the fermentation of carbohydrates by the microflora. These will lead to fecal bulking, increased speed of colon transit, increase of nitrogen metabolism, increased bacterial load in the colon, acidification and finally to the production of short chain fatty acids (SCFA). Butyrate, one of the major SCFA, is considered to be beneficial due to its trophic effects as an essential nutrient to the colon epithelium. Suggested mechanisms of cancer prevention at a cellular level have been reported to be the promotion of differentiation, induction of apoptosis and inhibition of proliferation in colon tumor cell lines. These mechanisms are classified as suppressing activities of cancer preventing agents

Synonyms

Fever of unknown origin; Fever of unexplained origin; Pyrexia of unknown origin; Fever of obscure origin

Definition

Fever of unknown origin is a clinical syndrome of ►fever that does not resolve spontaneously within 3 weeks and the cause remains unknown after extensive workup. Fever is defined as an elevation of the body temperature that exceeds the normal daily variation. The hypothalamus controls the body temperature and a normal body temperature is ordinarily maintained because the hypothalamic thermal regulatory centre balances the excess heat production derived from metabolic activities in the muscles and the liver with heat dissipation from the skin and lungs. Normally, healthy adult individuals have a mean oral temperature of 36.8°C ± 0.4°C. The temperature is a little bit higher in the

evening. Fever of unknown origin is an important clinical challenge. In 1961 Petersdorf and Beeson [1] defined it in their first report as an illness characterized by fever of more than 3 weeks' duration, with temperatures of more than 38.3°C and failure to identify the origin of the fever despite 1 week of hospitalization. Because of the development of diagnostic procedures, increasing costs of hospital care and the increasingly outpatient work-up, the definition was modified in 2003 and a hospital setting was no longer needed for assessment of the illness.

Characteristics

Over the last decades, several case-series have examined the underlying diseases for fever of unknown origin. More than 200 causes have been reported to cause fever of unknown origin.

After work-up, fever of unknown origin has generally been considered to be caused by infections, neoplasms, inflammatory or a heterogeneous group of other diseases. The most common infections reported in the literature are tuberculosis and intra-abdominal abscesses. Other important causes are temporal arthritis and other collagen vascular diseases and venous thromboembolism. One is unable to establish the causal diagnosis in 9–25% of the cases.

In the early case-series, the proportion of cancers varied between 7 and 24%. Although most causes of fever of unknown origin resolve spontaneously, the risk of occult cancer remains a concern. It is important to emphasize that most studies on the origin of fever of unknown origin did not include any control groups or a reference standard and criteria and the final diagnosis was defined in many different ways.

Cancer and Fever of Unknown Origin

Although several studies have been conducted on the association between fever of unknown origin and a subsequent diagnosis of cancer, the studies have been small, based on 40–300 patients, several studies have been based on referral centers and almost all studies lack control groups.

Nearly all common cancers in the literature had a link to fever of unknown origin. In the referral centre, case-series of a proportion of cancer diagnosed in patients with fever of unknown origin has decreased from about 30% of cases in the 1970s to 9–20% in the 1990s. It has been suggested that improved diagnostic imaging with e.g. CT and MRI has improved the detection of otherwise occult solid tumors.

In 2005 a large, Danish population-based study based on health care databases assessed the risk of cancer in 43,205 patients hospitalized from 1977 to 1997 with fever of unknown origin. Data on patients with a discharge diagnosis of fever of unknown origin were linked to the Danish Cancer Registry. The incidence rate of cancer was compared with the expected cancer incidence rate in the general population. The median follow-up was 6.3 years: 9,932 of the patients were more than 60 years old, 399 cancer cases were diagnosed during the first year of follow-up among the 43,205 patients with a relative risk (standardized incidence rate ratio) of 2.3 (95% CI: 2.1–2.5). The relative risk was raised for various types of cancer. Especially for ►Hodgkin disease (relative risk 27.8 95% CI: 15.9–45.1), non-Hodgkin ►lymphoma (relative risk 9.9 95% CI: 7.1–13.3), ►leukemia (relative risk 5.6 95% CI: 3.9–7.8) and ►multiple myeloma (relative risk 4.4 95% CI: 2.1–8.0), as well as sarcoma (relative risk 6.6 95% CI: 3.6–11.1) and solid tumors in the liver (relative risk 6.1 95% CI: 3.2–10.7), gall bladder (relative risk 2.7 95% CI: 0.9–6.3), brain (relative risk 4.1 95% CI: 3.5 – 6.2), kidney (relative risk 2.6 95% CI: 2.6; 95% CI: 1.4 – 4.5), colon (relative risk 2.7 95% CI: 2.0–3.5), and pancreas (relative risk 3.7 95% CI: 2–3–5.6).

During 1–19 years for hospitalization for fever of unknown origin 1,097 cancer cases were observed compared with 977.8 cancer cases expected. During the follow-up period, there was still an increased relative risk of hematological cancer as Hodgkin disease (relative risk 2.1 95% CI: 1.1–3.8), non-Hodgkin lymphoma (relative risk 1.4 95% CI: 1.0–1.9), leukemia (relative risk 1.7 95% CI: 1.3–2.2) and multiple myeloma (relative risk 1.6 95% CI: 1.0–2.4), liver (relative risk 1.9 95% CI: 1.1–2.9), brain (relative risk 1.4 95% CI: 1.0–1.9) and kidney cancer (relative risk 1.5 95% CI: 1.1–2.1). Until publication of the Danish study, the former studies on cancer risk had included a total of 1,200 fever of unknown origin patients. The absolute risks of cancer during the first year of follow-up were low, much lower than those reported in former studies.

Diagnosis

There are no randomized clinical trials in the literature about the clinical utility of different diagnostic strategies. Mourad et al. [2] has suggested the following minimal to qualify as fever of unknown origin: comprehensive history, physical examination, complete and differential blood cell count,, blood film reviewed by hematopathologist, routine blood chemistry, urinanalysis and microscopy, blood and urine cultures, antinuclear antibodies, rheumatoid factor, human immunodeficiency virus antibody, cytomegalovirus IgM antibodies, heterophil antibody test, Q-fever serology, chest radiography, hepatitis serology. To obtain a cancer diagnosis abdominal CT scan is the most central diagnostic test, but further diagnostic work up depends of symptoms and findings.

Prognosis of Cancer Associated with Fever of Unknown Origin

The underlying disease is the main predictor for the outcome of fever of unknown origin. Four studies have shown that 52–100% of patients with fever of unknown

origin and cancer will die within 5 years after the diagnosis. In the Danish database study of the 399 cases of cancer, the extent of cancer was compared for cases associated with fever of unknown origin and similar cancer 3,958 cases that did not have fever of unknown origin. Cancer diagnosed in patients with fever of unknown origin during the first year of follow-up was associated with higher prevalence of metastases and an increased mortality ratio of 1.4. After 1 year of follow-up, the cumulative survival among cancer cases was about 50% and after 2 year about 35%.

A diagnosis of cancer subsequent to hospitalization because of fever of unknown origin does not necessary imply an extremely poor prognosis.

Conclusion

The existing literature has consistently shown that fever of unknown origin is a marker of occult cancer. The last Danish study showed that this association in a population-based setting is weaker than reported in former studies, but the relative risk remains increased many years subsequent to the hospitalization for fever of unknown origin for hematological cancer, liver, brain and kidney cancer. Fever of unknown origin is associated with more advanced cancer disease and a poor prognosis compared with similar cancer patients without fever of unknown origin, but the prognosis is not extremely poor.

Fibrinogen

Yoshikazu Takada
UC Davis School of Medicine, Sacramento, CA, USA

Definition

Is a major plasma glycoprotein (350 kDa) that plays an important role in blood clotting, cellular and matrix interactions, ►inflammation, wound healing, and neoplasia.

Characteristics

Fibrinogen is a 340 kDa glycoprotein that consists of two identical disulfide-linked subunits. Each subunit is composed of three nonidentical polypeptide chains: alpha, beta, and gamma. The beta and gamma chains have conserved C-terminal domains of about 250 amino acid residues (designated βC and γC, respectively). The crystal structure of the isolated γC domain, as well as that of the γC and βC domains in the fibrinogen D fragment, revealed that both domains are similarly folded. A minor 420 kDa form of fibrinogen (fibrinogen-420) has an alternative extended form of the alpha chain (αE), which has a C-terminal domain (designated αEC) whose sequence and fold are highly homologous to those of the βC and γC domains. Fibrinogen binds to CD54 (ICAM-1) through the frist IgG domain (8KVILPRGGSVLVTC21 of CD54). CD54 binds to Fibrinogen γ-chain (117NQKIVNLKEKVAQLEA133).

Fibrinogen is polymerized into fibrin network, and this process is triggered by thrombin. Polymerized fibrin is further cross-linked by factor XIII. Fibrin or fibrinogen is proteolytically degraded into ►fibrin degradation products (FDP) (fibrinolysis). Plasmin, a major extracellular serine protease, plays a role in this process. Fragments D and E are major fibrin degradation products. Fragment D contains C-terminal globular domains (γC of the γ chain and βC of the β chain). Fragment E contains the central portion of fibrinogen (Fig. 1). The γC domain has been shown to interact with several ►integrin cell adhesion receptors (αvβ3, α5β1, αIIbβ3, αXβ2 (p150,95), and αMβ2 (Mac-1)) and the αEC domain binds to avβ3 and aMβ2 (Fig. 2).

Integrins are a family of cell ►adhesion receptors that recognize extracellular matrix ligands including fibrin (ogen) and cell surface ligands. Integrins are transmembrane α–βheterodimers, and at least 18α and 8β subunits are known. It has been well established that integrins transduce signals inside the cells upon ligand binding, and integrin functions are regulated by the signals from inside the cells. According to the crystal structure of the human γC domain, γC has a C-terminal fibrin-polymerization domain, a single calcium-binding site, and a deep binding pocket. Several integrins recognize γC. Integrin αIIbβ3 in platelets, αvβ3 in endothelial cells, and αMβ2 in leukocytes recognize γC and play an important role in thrombus formation, angiogenesis, and inflammation; respectively. This domain does not have an RGD motif, a prototype integrin recognition sequence. αIIbβ3 recognizes the C-terminal sequence ($HHLGGAKQAGDV^{400–411}$) of γC. Deletion of the QAGDV sequence at the C-terminal region of the γC domain in mice induces a defect in platelet aggregation. Integrins αMβ2 and αXβ2 (p150,95) in leukocytes recognize residues 190–201 and 383–395 of γC. The αM I-domain directly interacts with this sequence. αvβ3 is a fibrinogen receptor in endothelial cells and αvβ3-fibrinogen interaction may play a key role in angiogenesis associated with wound healing and tumorigenicity. αvβ3 also recognizes γC. Although αIIbβ3 requires $HHLGGAKQAGDV^{400–411}$ of γC for binding, this sequence is not important for recognition by αvβ3. The residues 190–201 and 346–358 in γC sequences are involved in αvβ3 binding. Although they are spatially distinct sequences, they are adjacent in the three-dimensional structure. Residues 346–358 do not support

Fibrinogen. Figure 2 Integrin binding to the γC domain of fibrinogen.

the binding of αIIbβ3 or αMβ2 to fibrinogen. Thus αvβ3 binds to γC in a manner distinct from αMβ2 and αIIbβ3.

Fibrin(ogen) is found deposited in the majority of human and experimental animal tumors. The deposition of fibrin(ogen), along with other adhesive glycoproteins, into the extracellular matrix (ECM) serves as a scaffold to support the binding of growth factors and to promote the cellular responses of adhesion, proliferation, and migration during ►angiogenesis and tumor growth. Fibrin(ogen) degradation products (FDPs) generated during fibrinolysis have been implicated in tissue inflammation associated with the adult respiratory distress syndrome, disseminated intravascular coagulation, and septic shock. Plasma concentrations of FDP fragment D are markedly elevated in these disorders. Activation of fibrinolysis and the resulting generation of FDPs, including fragment D, contribute to lung vascular injury. Fragment D detaches endothelial monolayers from the substratum, and that fragment D increased endothelial monolayer permeability. FDP fragment D increases secretion of endothelial plasminogen activators and that fragment D may be a critical mediator linking activation of fibrinolysis to vascular endothelial injury in inflammatory disorders.

The isolated γC or its truncation mutant γC399tr, which lacks the αIIbβ3-binding site, induces ►apoptosis of endothelial cells, while native fibrinogen or fragment D does not have such effects. γC or γC399tr blocks tube formation by endothelial cells on matrigel through inducing apoptosis. Colon carcinoma cells that were engineered to secrete γC grow much slower than non-secreting cells in vivo while they grow at comparable rate in vitro, suggesting that γC secretion affects tumor growth through blocking angiogenesis in vivo. γC399tr effectively blocks tumor growth, and suppresses intratumoral microcirculation. Soluble native fibrinogen and fragment D do not bind to fully activated αvβ3, but soluble γC and γC399tr truncation mutant does. Thus the αvβ3-binding site is cryptic in native fibrinogen and fragment D, but is exposed in γC and γC399tr. These findings shed a new light on fibrinogen functions, and γC and γC399tr are potential therapeutics.

At least three integrins bind to the γC domain. The C-terminal AGDV sequence (408–411) is required for αIIbβ3, residues 383–395 are recognized by αMβ2, and residues 346–358 are uniquely involved in binding to αvβ3. In the C-terminal, approximately 20 residues are missing in the crystal structure of the γC domain,

probably because these residues take various conformations due to their flexibility. Truncation of the C-terminal 12 residues (400–411) of the isolated γC domain (γC399tr) eliminates the AGDV motif required for αIIbβ3 binding and exposes the αMβ2-binding site. Our preliminary results suggest that the αvβ3-binding site is not accessible in native fibrinogen and in fragment D, but is exposed in the isolated recombinant γC domain and γC399tr. It is unclear whether the αvβ3-binding site becomes further accessible by the truncation.

Synonyms

HBGF; Heparin-binding growth factors

Definition

Fibroblast growth factors (FGFs) constitute a large family of growth and differentiation factors. The family comprises two prototypic members, acidic FGF (aFGF, FGF1) and the basic FGF (bFGF, FGF2), as well as 21 additionally related polypeptide growth factors that have been identified to date. The designation "FGF" is historical and refers to the fact that the first members of the family stimulated fibroblast proliferation. In fact, FGFs can act on a wide range of cells, especially of mesodermal and neuroectodermal origin.

Characteristics

Common characteristics of members of the FGF protein superfamily are a high affinity for heparin and heparin-like glycosaminoglycans as well as a high sequence homology within a central core domain of 120 amino acids. During embryonic development, FGFs are curcially involved in embroyonic development, and in many processes such as wound healing, hematopoiesis, and particularly angiogenesis. FGFs are also implicated in the maintenance of an undifferentiated state in embryonic stem cells. Most FGFs interact with a family of high-affinity cell surface receptor tyrosine kinases (RTK). Although more than 20 FGFs with different effects on various target cells have been identified, only four different FGF receptor isotypes (FGFR1–4) exist. By expression of different splice variants of FGFR1–3, four *FGFR* genes encode a broad variety of different isoforms which differ in their FGF ligand-binding profiles. For instance, one particular splice variant, FGFR2IIIb, is mainly expressed on epithelial cells and represents the receptor for FGF7 (also named

keratinocyte growth factor, KGF). Within the classical FGF family, FGF11–14, also known as FGF homologous factors (FHF1–4), represent a subclass of FGFs. This subclass is characterized by the fact that, although FHFs can bind heparin like the classical FGFs, they are unable to activate FGFRs and interact with intracellular target proteins.

Regulation

Due to their affinity for heparin-like glycosaminoglycans, the majority of secreted FGFs are bound to ►extracellular matrix (ECM) components. Locally stored FGFs can be released from this extracellular reservoir by at least two mechanisms. One mechanism involves enzymatic degradation of ECM, e.g., during wound repair or tumor cell invasion. Alternatively, the carrier protein FGF-BP (FGF-binding protein) binds FGFs in a noncovalent manner and shuttles them from their ECM storage site to their cell surface receptors.

Clinical Relevance

Besides their ability to regulate proliferation and differentiation, some FGFs are important angiogenic inducers. Increased FGF activity in malignant tumors results from stromal as well as cancer cells and in turn acts on cancer cells as well as the surrounding stroma, and especially the vasculature. In selected cancer types, activating mutations in specific FGFRs or altered expression of isoforms have been described. Due to their multiple effects on tumor growth, FGFs, their receptors, and FGF-BP have been analyzed in various tumor cell types as potential tumor and/or progression markers. Moreover, in the future, selective inhibition of FGF/FGFR-signaling, e.g., by thalidomide, could exploit the crucial function of FGF-signaling in cancer for therapy.

Fibronectin

Rakesh Verma
Antisoma Research Laboratories, St. George's Hospital Medical School, London, UK

Definition

Is a large adhesive glycoprotein and a normal constituent of extracellular fluids, extracellular matrices, most basement membranes and certain cell types. It is implicated in a variety of different biological phenomena such as cell ►adhesion, establishment and maintenance of normal cell morphology, cell ►migration, differentiation, transformation, hemostasis, thrombosis, wound healing, ►transformation and ontogeny.

Characteristics

The molecule consists of two similar but non-identical polypeptide subunits, which are disulphide-linked at the carboxyl terminus. The longer α-chain and shorter β-chain each contain two free SH-groups and 60 cysteine residues, many of which appear to be involved in intrachain disulphide loops. Fibronectin is glycosylated at about 4–6 sites within the protein via arginine (N-linked), which account for 4–5% of the molecular weight of the molecule. Major sugar residues in glycosylation units are mannose, galactose, glucosamine and sialic acid.

Both α and β chains consist of similarly ordered globular domains:

1. Amino-terminus
2. Gelatin-binding domain
3. Cell adhesive/attachment domain
4. Heparin-binding domain
5. Carboxy-terminus (Fig. 1)

Forms of Fibronectin

Cellular fibronectins are secreted by various cell types, such as fibroblasts, epithelial and endothelial cells, chondrocytes, ►macrophages and platelets, which organize them into extracellular matrices. Cellular fibronectins appear to be more interesting, in the context of neoplastic disease, than plasma fibronectin because their expression is affected by oncogenic transformation.

Functions

Fibronectin is implicated in a variety of different biological phenomena such as cell adhesion via its receptors (Fig. 2) and the establishment and maintenance of normal cell morphology as a component of the ►extracellular matrix (ECM).

Fibronectin is also implicated in hemostasis and thrombosis. Fibronectin contains binding domains for cells, gelatin (collagen), heparin and some other proteoglycans, DNA, hyaluronic acid and fibrin.

Structure

Each polypeptide chain consists of internal repeats of three types of homologies termed type I, II, and III repeat. There are 12 type I repeats, 2 type II repeats and 15–18 type III repeats (Fig. 1). Each exon of the single gene encodes one type I or type II repeat. Most type III repeats are encoded generally by two exons, but this pattern is altered at three positions that exist as a single exon, and where alternative splicing occurs. Type I repeats are ~40 amino acids long, type II are ~60 and type III are ~90, as originally shown in bovine plasma fibronectin.

Fibronectin Polymorphism

The diversity observed among fibronectins is due to both alternative splicing of the single primary transcript and due to post-translational modifications.

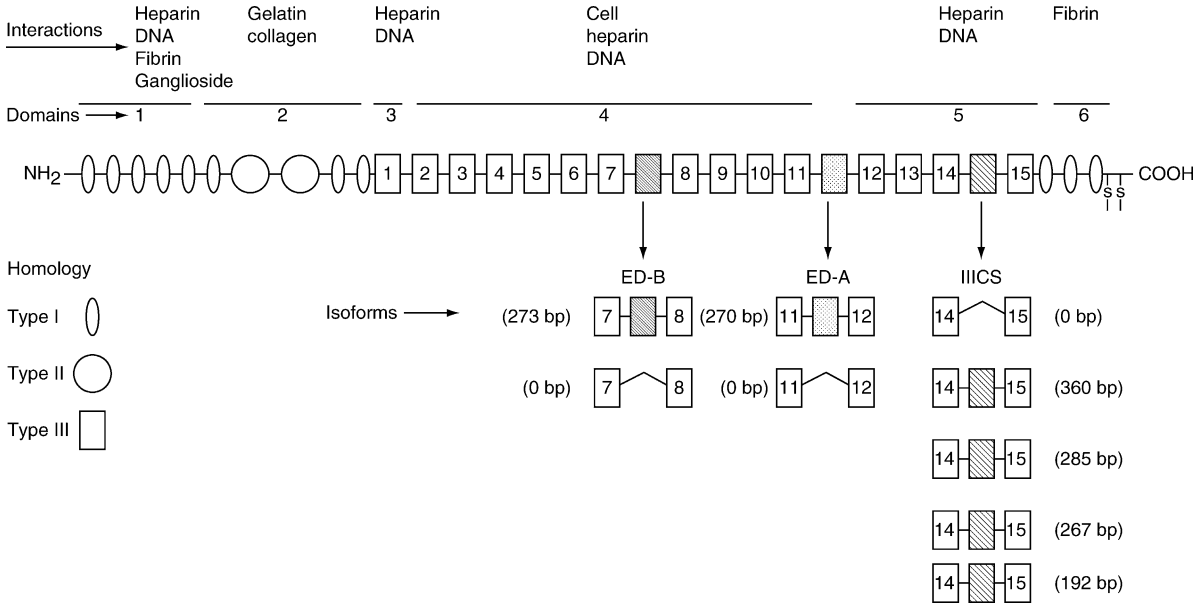
Post-Translational Modifications

Fibronectin undergoes glycosylation that appears to stabilize fibronectin molecules against proteolysis. In addition, the degree of glycosylation may influence the interaction of the protein with cells; for instance, higher amounts of glycosylation decrease the avidity for collagen. Other post-transcriptional modifications of fibronectin include phosphorylation and sulfation. Fibronectin is phosphorylated on a serine residue near the carboxy terminus. Certain fibronectin variants are found to be tyrosine-linked sulfated.

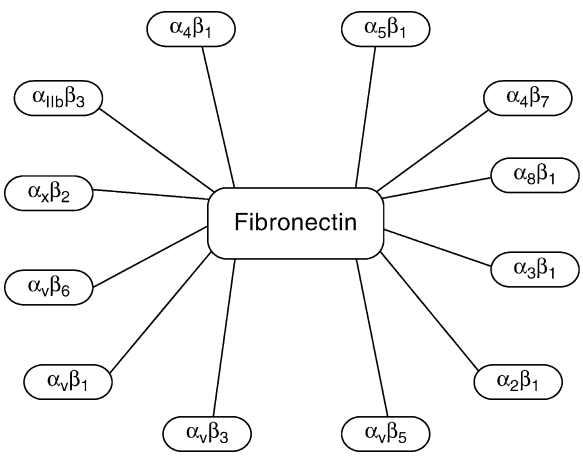
Alternative Splicing

►Alternative splicing is a widespread gene regulation mechanism able to generate diversity in a reversible way and without requiring the expression of new genes. Some eukaryotic genes, such as the gene encoding for

F



Fibronectin. Figure 1 Fibronectin molecule. Diagrammatic representation of the domain structure of fibronectin. Shown are homology repeats and different sites of alternative splicing (ED-B, ED-A and IIICS), giving rise to different isoforms of fibronectin.



Fibronectin. Figure 2 Fibronectin interactions with integrins. Different integrins that interact with fibronectin.

tenascin, produce multiple isoforms by alternative mRNA splicing. In general the exon changes caused by alternative mRNA splicing do not produce radically different proteins. Rather, they produce a set of similar proteins called protein isoforms.

Alternative splicing in fibronectin occurs in three regions of the primary transcript and generates 20 different isoforms that differ in the number of internal repeats. The regions of variation are: type III constant region (IIICS), extra domain A (ED-A) and extra domain B (ED-B). The same regions in rats are known as V, EIIIA and EIIIB, respectively.

Alternative splicing of fibronectin mRNA is regulated in a cell-, tissue- and developmentally-specific manner. Furthermore, it has been demonstrated that the splicing pattern of fibronectin mRNA is deregulated in transformed cells and in malignancies. The fibronectin isoforms containing the IIICS, ED-A and ED-B sequences are expressed more in transformed cells and in tumor tissues than in their normal counterparts. Because of the preferential expression of ED-B and de novo glycosylated fibronectin variants in fetal and tumor tissues, these fibronectin isoforms are known as oncofetal or embryonic fibronectins.

- IIICS region is situated between the last two type III homology repeats. This region of fibronectin undergoes complex patterns of alternative splicing; it may be totally included, partially included or excluded and may yield up to five different isoforms. IIICS domain is also subject to glycosylation. This fibronectin variant results from the addition of an α-N-acetyl-galactosamine to a threonine residue in a hexapeptide segment (Val-Thr-His-Pro-Gly-Tyr) located in the IIICS domain. De novo glycosylation of fibronectin is associated with cellular immaturity, cancer formation and the malignancy of breast, gastric and oral carcinomas.
- ED-A is situated between 11th and 12th type III homology repeats and it is the second region of alternative splicing. It is a single exon that is either included or omitted from the mature mRNA. This variation is tissue specific, and ED-A is not found in the mRNA of liver where plasma fibronectin is

synthesized. In human adult tissues, ED-A fibronectin has a restricted expression in certain tissues such as renal and colonic mucosa. ED-A is also present in normal adult myocardium where it is deposited as spots in the interstitium.

- The third region of variation is ED-B that is localized in the middle of the cell binding domain 4, between seventh and eighth type III homology repeats. ED-B is itself a complete type III homology repeat composed of 91 amino acids and coded by a single exon, which is either included or omitted from the mature mRNA. ED-B is the most conserved fibronectin region with 100% and 96% homology with rat and chicken fibronectin, respectively. ED-B containing fibronectin, with very few exceptions (superficial synovial cells, intima of some vessels and areas of interstitium of ovary, functional layer of endometrium during the proliferative phase and isolated areas of basement membrane of celomic epithelium), is reported to be absent in normal tissues. It has a greater expression in the intima of vessels of fetal brain cortex, stomach, jejunum, thymus and lungs of 8- to 12-week-old fetuses and tumor tissues as established by immunohistochemistry using the monoclonal antibody BC-1 (specific for ED-B containing fibronectin). In tissues from older fetuses (20–22 week old) only basal portions of gastric and duodenal glands were found positive for ED-B fibronectin. This suggests that ED-B fibronectin undergoes a programmed expression during ontogenesis.

Biological Significance of ED-B

The biological significance of ED-B is unknown. Its proximity to the cell-binding region suggests a role in cell adhesion and migration. This is also supported by the expression of ED-B in fetal tissues and during angiogenesis. In both the cases, cell migration and interactions are required. So far, no binding peptide is located to the ED-B repeat. But the ED-B domain seems to enhance cell adhesion and spreading. This adhesion effect of the ED-B may be mediated via conformational changes. It has been reported that insertion of the ED-B in fibronectin causes conformational changes in the molecule. The conformational changes induced by the ED-B in the downstream segment of the fibronectin may improve the access to the integrin binding sites in the ninth and tenth type III repeats. It has been shown that ED-B domain with its neighboring type III repeats is important in promoting cell adhesion.

Fibronectin Isoforms in Disease

Expression of fibronectin isoforms differs in disease. Although the expression of ED-A, ED-B and de novo glycosylated fibronectin is not disease specific, it is correlated with tissue modulation processes and particularly with connective tissue formation (fibroplasia).

Dilated cardiomyopathy (DCM) is a heart muscle disease in which alterations to cardiomyocytes result in changes in the composition of the ECM, including increase in the deposition of fibronectin, laminin and collagens in the intercellular spaces and in the vicinity of blood vessels. In patients with DCM, ED-A is detected as spots in the interstitium like in normal hearts. In contrast, ED-B and de novo glycosylated fibronectin, which are not seen in normal adult myocardium, are expressed in DCM. Re-expression of the ED-B and de novo glycosylated fibronectin in the adult heart was also found in myocardial hypertrophy in the rat. ED-A is synthesized by the synovial lining fibroblast-like (type B) cells. The expression of ED-A seems to be correlated with activated or transformed states of synovium. De novo glycosylated fibronectin was present in the synovial fluid of patients with rheumatoid arthritis. Patients with osteoarthritis also produce the same variant of fibronectin although at lower levels. De novo glycsylated fibronectin was also proposed as a predictor of preterm birth. High levels of this fibronectin variant were detected in the cervicovaginal secretion of women during the second and third trimesters of pregnancy.

Fibronectin Isoforms and Cancer

Fibronectin isoforms are detectable at higher levels in tumors, whereas they are least or not at all expressed in normal adult tissues. In pituitary adenomas the presence of ED-A and ED-B has been reported. They were localized in the adenoma neovasculature, especially in the endothelium and smooth-muscle layers of the vessel walls. Expression of ED-A and ED-B fibronectins was also shown in human colorectal carcinomas and in tumors derived from rat colon carcinoma. ED-A labeling was detected in all the samples of human carcinomas in the stroma separating the tumor glands but also in normal colon stroma. Apart from ED-A and ED-B, the glycosylated isoform of fibronectin is also expressed in colorectal cancer but is absent from the normal tissue. Increased expression of ED-B fibronectin mRNA was observed in different types of ►lung cancer including adenocarcinoma, ►squamous cell carcinoma, small cell carcinoma and large cell carcinoma. These results suggest that in lung cancer alternative splicing of fibronectin mRNA in ED-B domain occurs irrespective of type of cancer or degree of differentiation. In liver cancer both ED-A and ED-B mRNAs are increased in malignant tumors whereas ED-B mRNA was also detected in benign neoplasms.

Definition

Are a family of secreted glycoproteins that are deposited in various extracellular structures such as basement membranes, elastic fibers, proteoglycan aggregates and fibronectin microfibrils. Fibulins have been shown to play an important role in organogenesis and vasculogenesis. Current evidence suggests that fibulins may acts as tumor suppressors or tumor promoters.

Characteristics

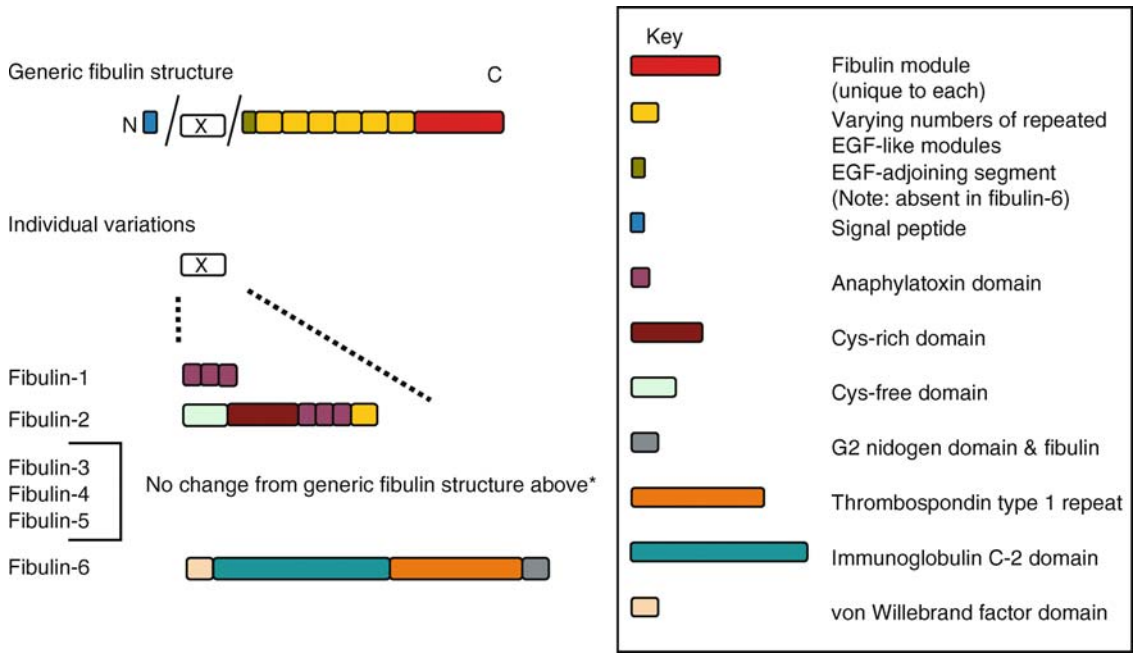
Fibulins arise as products from six distinct genes, termed fibulin 1-6, each residing on separate chromosomes. The fibulin isoforms vary in size from 50 to 200 kDa and are comprised of a collection of repeated calcium-binding epidermal growth factor (cbEGF)-like domains, which consist of rod-like elements with globular domains at the ends, and a unique C-terminal fibulin-type module (Fig. 1). Fibulins are prominently expressed in the blood and blood vessels but have also been found to reside in the lung, heart, liver, brain and other bodily tissues. Of the six fibulins identified to date, cancer-associated linkages have been documented for fibulin-1, -3, -4 and -5.

Fibulin-1

Fibulin-1 was the first member of the fibulin family identified. It consists of an N-terminal signal sequence, three anaphylatoxin (AT) repeats, nine EGF-like domains, eight of them processing the consensus sequence for calcium ligation, and an alternatively spliced fibulin-type C-terminal domain (FIB), giving rise to four possible variants, fibulin-1A to -1D. Variants-1C and -1D have been found to reside in most tissues and cell lines, whilst variants-1A and -1B have been detected at low levels in the human placenta. Current evidence suggests that fibulin-1 may act as a tumor suppressor or ►oncogene, depending on cellular context and/or which splice variant is expressed. Overexpression of fibulin-1D in human fibrosarcoma-derived cell lines suppresses anchorage-independent growth, motility and matrigel invasion *in vitro* and delays tumor formation *in vivo*. Similarly, elevated expression of fibulin-1D or addition of purified protein inhibits cells ►adhesion, spreading and motility *in vitro*. In addition, ectopic overexpression of fibulin-1D inhibits transformation by the papillomavirus E6 gene, possibly through a protein-protein interaction mechanism. Fibulin-1 can interact with positive (fibronectin and laminin) and negative (aggrecan and veriscan) regulators of cell motility, thus influencing cell movement and tumor progression. Elevated expression of fibulin-1 in ovarian and breast carcinomas has been reported (►Ovarian cancer, ►breast cancer), with there being an increased level of fibulin-1C:-1D seen in the former tumor tissue type. Serological screening of cDNAs identified fibulin-1 protein as an immunogen in patients with breast cancer. Similarly, dendritic cells obtained from fibulin-1 seropositive patients demonstrated a T cell response to the presence of fibulin-1. DNA microarray studies of lung adenocarcinomas demonstrated a close association of fibulin-1 and -2 with matrix metalloproteinase-2 expression, a promoter of ►metastasis and tumor invasion. The mechanism by which fibulin-1 promotes or inhibits tumorigenesis is unclear at present. However, available data suggest that there are specific binding functions for fibulin-1D that are not shared by fibulin-1C.

Fibulin-2

Fibulin-2 consists of an additional 400 amino acid long N-terminal domain, which is composed of



Fibulins. Figure 1 Schematic representation of the fibulin family structure. The structure of a generic fibulin is shown, with individual variations between family members represented underneath. The six secreted glycoproteins comprising the family are characterized by a unique fibulin-type module at the C-terminus and repeated epidermal growth factor (EGF)-like domains. Splice variants (known to exist for fibulins-1 to -4) are not illustrated. *Fibulins -3 and -4 have five EGF-like modules followed by a sixth with an insertion. There is no insertion in the sixth EGF-like domain of fibulin-5. Fibulins -3, -4 and -5 share ~50% amino acid homology.

cysteine-rich and cysteine-freesubdomains and nine EGF-like domains, which are a similar type to the EGF domains of fibulin-1. The role of fibulin-2 in cancer is unknown at present; however, recent studies have identified fibulin-2 as an overexpressed metastasis-associated gene in solid tumors of diverse types.

Fibulin-3

Fibulin-3 consists of five ►cbEGF-like modules and a carboxy-terminal domain III. Various alternatively spliced fibulin-3 transcripts have been identified which show a partial or complete deletion of the amino-terminal domain I. Fibulin-3 has been shown to positively and negatively regulate cell proliferation *in vitro*. Expression of fibulin-3 mRNA has been reported during the processes of cell growth arrest and senescence and is also upregulated in transformed cell lines. Microinjection of *in vitro* translated fibulin-3 mRNA into normal human fibroblasts stimulated DNA synthesis of injected cells, as well as some surrounding cells. Endogenous levels of fibulin-3 have been shown to inhibit proliferation, invasion, and angiogenic sprouting of endothelial cells in the presence of vascular endothelial growth factor. The ability of fibulin-3 to inhibit these tumorigenic variables suggests a possible role in reducing tumor angiogenesis and consequently tumor growth both *in vivo* and *in vitro*. Lastly, the rat homologue of fibulin-3 has been shown to associate with DA41, as determined by yeast two-hybrid assay. The DA41 protein interacts with the tumor-suppressor protein DAN, indicating that fibulin-3 might have an indirect role in the regulation of cell growth through a network of molecular interactions. Further work is required to determine the role of fibulin-3 in cancer.

Fibulin-4

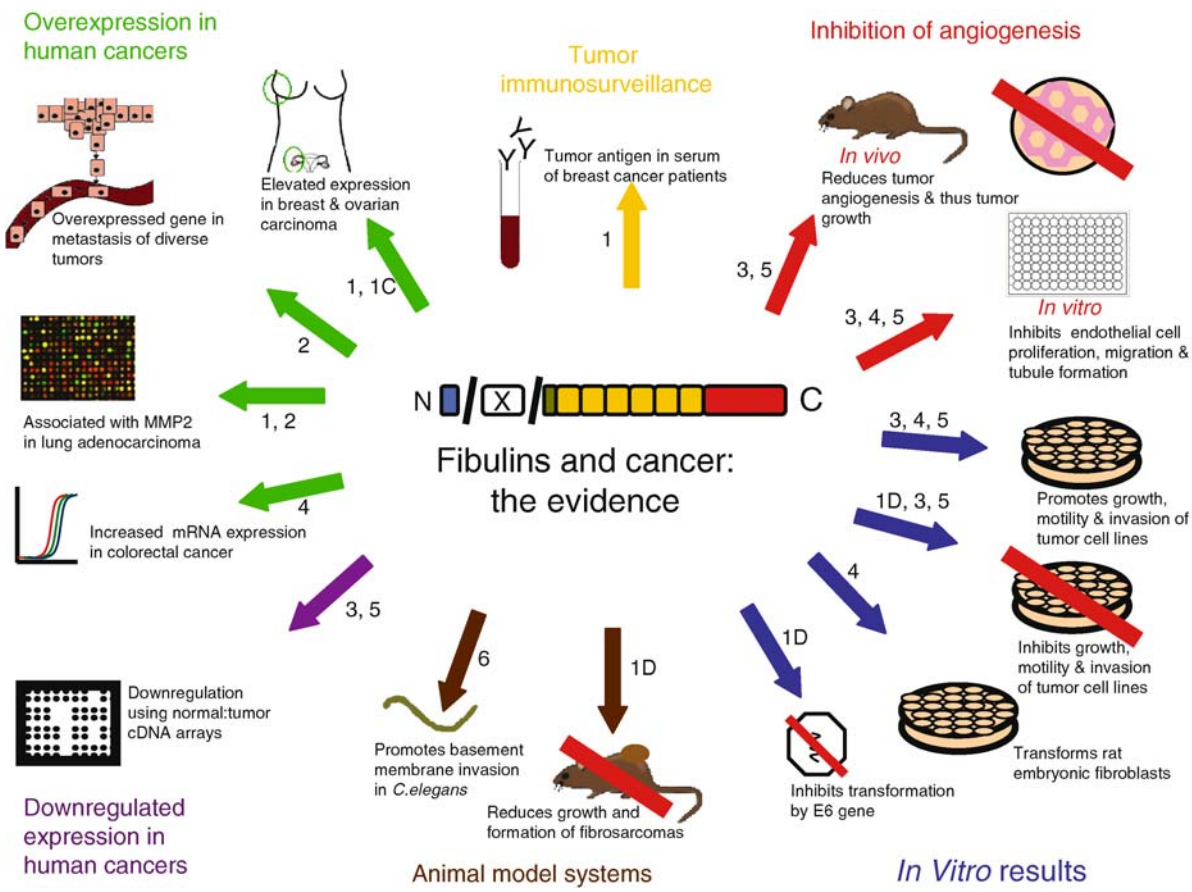
Fibulin-4 also consists of five cbEGF-like modules and a carboxy-terminal domain III. The human fibulin-4 gene is localized to 11q13, a region commonly amplified in a variety of human cancers. Mouse fibulin-4, originally identified as a specific protein partner for mutant p53, displays both mutant p53-dependent and -independent oncogenic properties. Fibulin-4 has been shown to induce cell proliferation and increase rates of neoplastic transformation by synergizing with mutant p53 protein. Elevated expression of fibulin 4 mRNA has been reported in a panel of paired normal/tumor human colon tissue biopsies (►Colon cancer). The exact mechanism responsible for the increased fibulin-4 levels in colorectal tumors is unknown at present. Further work is necessary to determine whether altered fibulin-4 expression is prevalent in other tumor types.

Fibulin-5

Similar in structure to fibulin-3 and -4, fibulin-5 is composed of six cbEGF-like domains followed by a globular C-terminal module which differs from other fibulins by the presence of integrin-binding RGD motif. Recent studies suggest that fibulin-5 may suppress or promote tumorigenesis. In human tissues derived from 68 patients, fibulin-5 mRNA expression was altered in 65% of the tumors, of which 95% showed down-regulation and 5% demonstrated up-regulation. The reduction of fibulin-5 expression was most prominent in cancers of the kidney, breast, ovary and colon. Importantly, fibulin-5 was expressed aberrantly in 68% of metastatic human malignancies (17 of 25 cases), of which 100% showed down-regulated expression of fibulin-5. Paradoxically, fibulin-5 expressing HT1080 cells exhibite enhanced DNA synthesis and increased cell ►migration to fibronectin as compared with control cells. In the presence of synthetic basement membranes, fibulin-5 expressing HT1080 cells invaded significantly better than control HT1080 cells. In addition, vascular smooth muscle cells derived from fibulin-5 knockout mice exhibited increased proliferation and migratory responses to mitogenic stimulus, with these effects being inhibited by the overexpression of fibulin-5. In short, the ability of fibulin-5 to enhance the malignancy of human fibrosarcoma cells and to down-regulate mRNA expression in human tumor tissue suggests that aberrant fibulin-5 may affect cancer cell growth in a context and/or tumor-specific manner.

Fibulin-6

Fibulin-6 was first identified in *Caenorhabditis elegans* (*C. elegans*), with orthologues in human and mice. It consists of a series of predicted cbEGF-like domains, followed by a single unusual EGF-like domain at the carboxy terminal. The ability of cells to invade through basement membranes and enter new tissues is crucial to the spread of cancer. To date, there is no direct evidence linking fibulin-6 to cancer. However, the ability of fibulin-6 to promote invasiveness *in vivo* has been reported using *C. elegans* as a model system. Further studies are necessary to elucidate fibulin-6 participation in invasiveness and possibly in ►carcinogenesis.



Fibulins. Figure 2 Fibulin family and cancer: the evidence. A summary of the available evidence linking members of the fibulin family with cancer. The individual fibulins linked to each process are shown in bold beside an arrow leading to a graphic representation of the findings.

Conclusion and Perspective

Fibulins are emerging as key contributors to carcinogenesis as indicated by their proposed involvement in tumorigenic mechanisms such as proliferation, adhesion, motility and invasion (Fig. 2). Their relevance to diagnosis and therapeutic implications in cancer is not fully clear at present. Fibulin-1, which is highly expressed in the blood and has been identified as an immunogen in patients with breast cancer, could aid in the detection of specific variants or processed forms of this protein via the development of a highly sensitive serum-based assays. Analysis of fibulin levels in more accessible biological materials, such as serum and urine, is warranted. Therapeutically, recombinant forms of fibulin-1, -4 and -5 might have potential as tumor suppressive or anti-angiogenic agents. Fibulin-1 protein can inhibit the adhesion and motility of a broad range of tumor cell types with minimal effects against primary cells. Using a retroviral-based gene-therapy approach, overexpression of fibulin-5 *in vivo* promotes wound closure. Lastly, the ability of recombinant fibulin-4 protein to inhibit angiogenesis *in vitro* suggests a possible therapeutic role in the treatment of cancer. In summary, further work is needed to fully resolve the complex role of fibulins in tumor development and progression.

Field Cancerization

Definition

A concept to explain how multiple primary tumors and recurrences occur in a given tissue. First described for head and neck ►squamous cell carcinoma, but also recognized to occur in many other organs systems including skin, lung, breast, anogenital, colon, bladder. Stem cells exposed to carcinogens may become genetically altered, giving rise to clones of altered daughter cells. These undergo subsequent rounds of cell division, with each individual cell becoming a potential target for further genetic events and, consequently, malignant progression.

Field Defect

Definition

A phenomenon where grossly normal-appearing tissue which has pre-cancerous genetic changes. This tissue can be considered at risk for becoming a pre-malignant lesion and is hypothesized to occur in cancers which are commonly multifocal or locally recur after surgical removal of previously found growths.

►Carcinoid Tumors

Field Effect

Definition

Explanation for induction of multiple abnormalities within a single tissue. Where a "field" of cells is exposed to a given carcinogen, multiple unrelated lesions may arise.

Fine needle aspiration (FNA); Fine needle aspiration cytology (FNAC); Needle biopsy; Needle aspiration biopsy (NAB); Skinny needle; Thin needle; Aspiration cytology

Definition

Is defined as the removal of cells using a fine gauge needle from a lump or mass for diagnostic purposes.

Characteristics

Background

The diagnosis of cancer requires analysis of tissue or cell samples under the microscope. Although physical exam, radiological imaging, and laboratory tests are useful in determining which lumps might be malignant, these tests are not specific and all lesions must be sampled and examined under a microscope to determine the precise nature. The removal of a sample for examination under a microscope is called a *biopsy.* One of the biopsy methods used for cancer diagnosis is called a *needle biopsy.* There are 2 types of needle biopsies: core needle biopsy and fine needle aspiration biopsy (FNAB). *Core needle biopsy* removes a small cylinder of tissue and involves microscopic examination of intact tissue as a slice, called ►histology. FNAB withdraws cells and microscopic pieces of tissue which are evaluated under the microscope as individual cells and clusters of cells. FNAB is easier to obtain, causes less discomfort, is less invasive, and is more cost effective than core needle biopsy. The disadvantage of FNAB is that it cannot always provide the level of information afforded by core biopsy. In many clinical situations, however, both methods are equivalent.

This essay explains the FNAB method.

What is FNAB?

Fine needle aspiration biopsy (FNAB) is a non-surgical diagnostic technique used for the diagnosis of mass lesions. FNAB is not new; it has been successfully practiced in Europe since the 1950s. From Europe, FNAB spread to other parts of the world and is now an established technique used worldwide. The beauty of FNAB is in its simplicity. It requires only needles, syringes, glass slides, stains, a microscope and a skillful operator. Skinny ("fine") hollow needles attached to a syringe are used to extract ("aspirate") cells from a suspicious mass for microscopic examination. Although the procedure is simple, it is not easy, and successful results are obtained only when the procedure is performed and interpreted by a team of experts trained in the art of FNAB. The team optimally consists of a ►cytopathologist, a ►cytotechnologist and for lesions requiring image-guidance, a radiologist. The cytopathologist, a medical doctor with subspecialty training in ►cytology, interprets the results and, in the case of superficial masses, also procures the specimen. The radiologist procures the samples from deep-seated lesions aided by image guidance. The cytotechnologist is responsible for assisting with the FNAB procedure,

the initial microscopic screening, and preliminary diagnosis of slides. He/she may also be responsible for specimen collection, preparation and staining and record keeping. When performed by such a team, FNAB is very sensitive and specific with a diagnostic accuracy approaching that of histology.

FNAB is versatile and can be performed at any body site. Common superficial sites include thyroid, breast, lymph node, salivary gland and subcutaneous tissue. Common deep internal sites include liver, pancreas, kidney, lung, mediastinum, pleura, pelvis, retroperitoneum, bone, brain, retina and deep soft tissue. More recently, a technique called ►endoscopic-ultrasound guided fine needle aspiration (EUS-FNAB) was developed to diagnose tumors in and around the digestive tract.

By using FNAB, a major ►surgical biopsy (►open biopsy) can often be avoided.

What Cellular Characteristics Do Cytologists Study in Order to Make a Microscopic Diagnosis of Cancer?

►Cytologists distinguish normal cells from cancer cells, and recognize the different types of cancer cells by studying the morphologic features of cells. The two components of the cell that cytologists study are the nucleus and the cytoplasm. The nucleus tells the cytologist about the health of the cell and the cytoplasm tells about what kind of cell it is. In cancer, the nucleus looks abnormal. It usually takes up more cell volume and may be darker than a healthy nucleus. It can also have an irregular shape. The abnormal changes in the nucleus are due to the fact that they often contain too much DNA. The cytoplasm gives the cytologist clues about the type of cancer present-whether it is an adenocarcinoma, squamous cell carcinoma, neuroendocrine carcinoma, lymphoma, or sarcoma. The way the cell clusters relate to each other assist the cytologist decide the type of cancer present. Sometimes studying the morphology does not yield enough information to allow the cytologist to decide the type of cancer. In these instances the cytologist uses ancillary ►immunocytochemical stains and other molecular markers on the cellular material obtained from the FNAB procedure to assist in making a definitive diagnosis and distinguish the type of cancer.

Method

Palpation-Guided Aspirates

For superficial palpable lumps, the procedure is optimally performed in a dedicated FNAB outpatient clinic by a cytopathologist with the assistance of a cytotechnologist (Fig. 1). The procedure takes approximately 15 minutes and is performed while the patient is awake. The patient is examined, the mass is localized, and the skin over the mass is cleansed with antiseptic. Local anesthetic may be injected into the skin over the nodule, although many practitioners prefer to perform aspirations without any anesthetic. A fine bore needle (approximately 23–25 gauge) is inserted through the skin and into the mass. A syringe attached to an aspiration device is commonly used to apply suction and the needle is rapidly moved up and down inside the nodule until enough cells and small tissue fragments have been dislodged and drawn up into the needle. The needle is then removed, and a gauze pad is applied with pressure to the biopsy site. After the fine needle aspiration biopsy is completed, a band-aid is applied and the patient is discharged home and can resume usual daily activities.

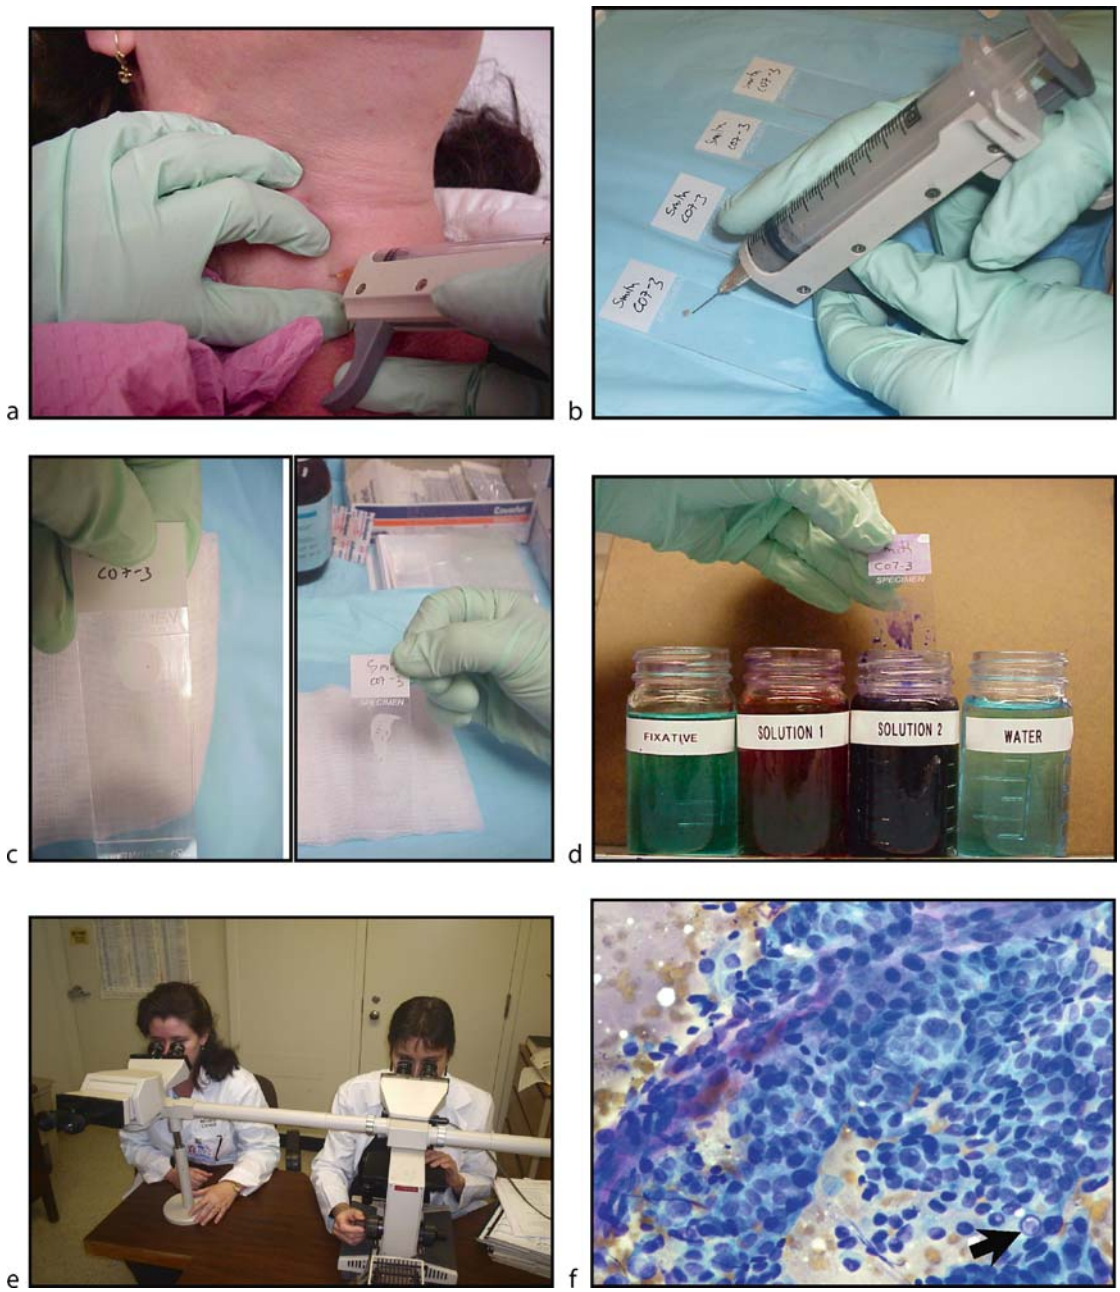
The biopsy material is expelled onto glass slides and smeared into a thin film. A number of samples are usually taken in separate aspirations or "passes" to increase the likelihood that an adequate sample will be obtained. In some facilities, representative smears are selected, stained and microscopically evaluated immediately for adequacy of the sample and for preliminary diagnosis prior to discharging the patient. This is optimal as it assures adequate sampling and appropriate sample triaging. If sufficient diagnostic material is obtained the procedure is terminated, and the patient is discharged. If the immediate microscopic evaluation demonstrates a lesion for which ancillary studies are needed, additional material is obtained immediately to fulfill the specimen requirements. This may include molecular studies (such as flow cytometry, immunocytochemistry, FISH and PCR), microbiology stain and culture, electron microscopy or other studies, as needed. ►Wright-Giemsa and ►Papanicolaou stained smears are routinely prepared in all cases. Cellular material can also be made into a "►cell block" and processed similar to histology.

Deep Seated Aspirations

Deep-seated soft tissue and visceral lesions are amenable to percutaneous FNAB using radiographic image-guidance (CT or ultrasound), which serves to guides the tip of the needle into the mass (Fig. 2). Image guidance can also be useful for difficult to palpate superficial masses or superficial masses located adjacent to vital structures. The technique for deep-seated aspirations is similar to that for superficial masses except that modified longer needles are required and a radiologist, rather than a cytopathologist usually does the FNAB. Optimal diagnostic yield is achieved when a cytologist is present during the procedure. Having the cytologist present allows for microscopic evaluation for adequacy and appropriate triage of the material. As in palpation-guided FNAB, smears are routinely made and if needed, material procured for ancillary studies as determined by the on-site microscopic evaluation.

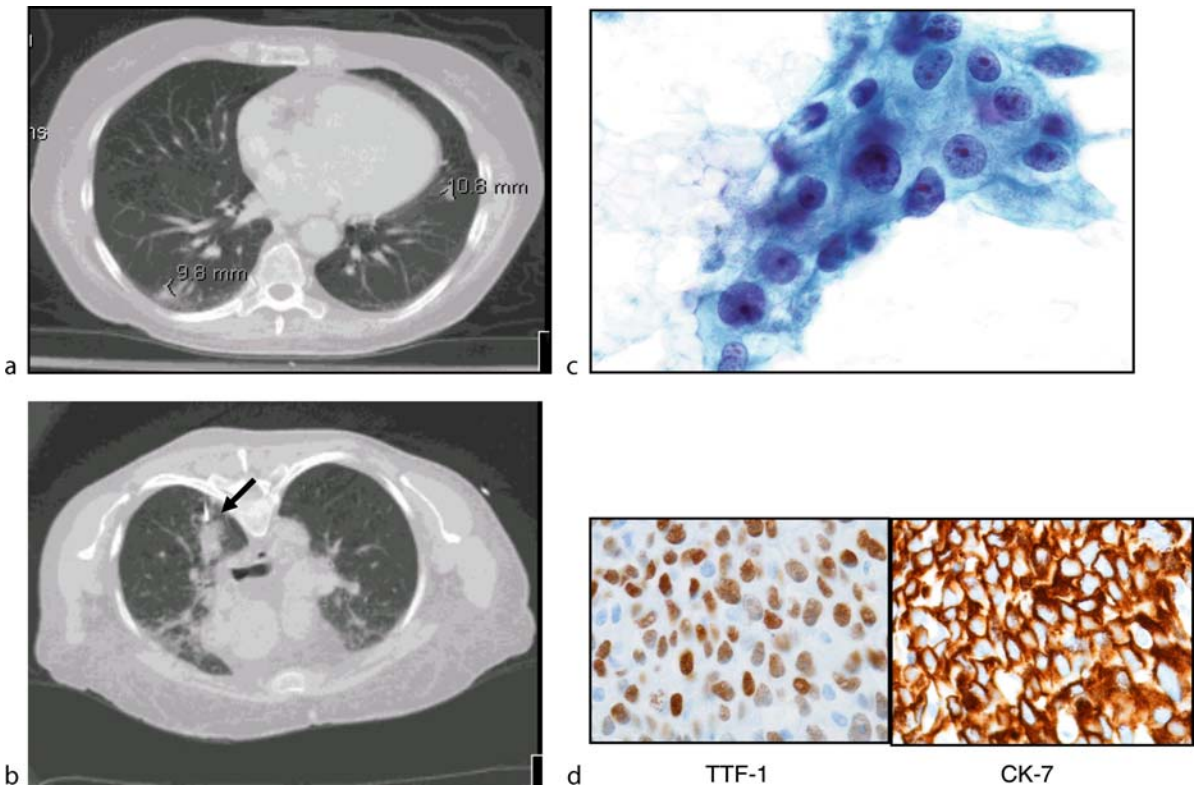
Complications and Contraindications

Complications associated with superficial palpable masses are rare and most commonly consist of minor



Fine Needle Aspiration Biopsy. Figure 1 Example of a palpation-guided FNAB procedure of a 1 cm right thyroid nodule in a 46-year-old female. (a) The needle is shown within the nodule. (b) The needle has been withdrawn from the nodule and the sample is placed in a drop onto a microscopy slide. (c) The specimen is smeared out using a two-slide smearing technique. (d) Representative slides are rapidly stained with a Wright-Giemsa stain. (e) The slides are evaluated microscopically for assessment of adequacy and preliminary diagnosis. Microscopic evaluation in this case demonstrated a papillary thyroid carcinoma. (f) Microscopic view showing the characteristic features of papillary carcinoma. Malignant thyroid cells are arranged in papillary configurations. Note the intranuclear hole (arrow) characteristic of this tumor type. (400× magnification, Wright-Giemsa stain).

bruising at the site. Deep-seated organ aspirations have higher complication rates which include infection, bleeding, peritonitis and pneumothorax. Uncorrected coagulopathy is an absolute contraindication for deep-seated FNAB. Needle tract seeding by tumor cells has also been rarely described in both superficial and deep FNAB; this complication is more commonly seen with core needle biopsy due to the larger needle caliber.



Fine Needle Aspiration Biopsy. Figure 2 Example of a CT-guided FNAB of a lung nodule. This patient was a previously healthy 65-year-old female with multiple pulmonary nodules noted incidentally on a CT scan done for other purposes. (a) CT scan shows bilateral, to numerous to count, pulmonary nodules thought to be suggestive of diffuse involvement of the lung by metastatic carcinoma. (b) CT scan showing the placement of the needle (arrow) within in a right posterior upper lobe nodule. (c) Microscopic view of a smear from the lung nodule demonstrates adenocarcinoma. Note the large malignant appearing cells with abundant cytoplasm and round to irregular nuclei with prominent nucleoli (1000× magnification, Papanicolaou stain). (d) Immunostaining results performed on the cell block shows the tumor to have strong positive nuclear immunostaining for TTF-1 (a marker for lung cells) and cytoplasmic staining for CK7 (also a marker for lung cells). The immunostains confirm that the cancer is actually a primary lung adenocarcinoma and not metastatic.

Generally, there are no absolute contraindications to FNAB of superficial masses.

Diagnostic Accuracy and Yield

When performed and interpreted by a dedicated FNAB team of experts a greater than 95% overall sensitivity and 99% specificity for the detection of cancer can be expected. The failure rate in obtaining a definitive diagnosis is less than 10% in experienced hands. This outcome may occur either when the specimen does not contain enough cells or when the specimen is adequate but overlapping cytologic features between benign and low-grade malignant entities precludes a definitive diagnosis. For such cases, further diagnostic steps such as core or open tissue biopsy are required.

Diagnostic Utility of FNAB

FNAB can provide specific diagnoses for many types of cancers. It is superb for the diagnosis of primary, recurrent and metastatic carcinoma, usually yielding enough information about the carcinoma subtype to start definitive treatment. FNAB is also sensitive for the detection of metastatic melanoma, lymphoma and many sarcomas.

The clinical value of FNAB is not limited to cancers. Most lumps and mass lesions are not cancers and FNAB is very valuable in diagnosing benign tumors, infections, cysts, inflammatory conditions and benign physiological alterations.

Limitations of the FNAB Method of Study

FNAB is a cytological method. In other words, it studies cells rather than intact tissue slices. The study of cells does not allow for evaluation of the relationship of the malignant cells to the supporting tissue as well as histology does. In addition, sometimes the FNAB cannot harvest sufficient cells/tissue for ancillary studies. Due to these limitations,

a histologic diagnosis may sometimes be preferred over a cytologic one.

Examples:

1. Some thyroid tumors require evaluation of the tumor capsule in order to decide if the tumor is benign or malignant; this can only be achieved by histological evaluation.
2. Although ►lymphoma is readily diagnosable by FNAB, sometimes the lymphoma subtype cannot be classified by FNAB to the extent required for optimal oncologic treatment. In this case, a surgical biopsy may be needed.
3. In some centers core needle biopsy is preferred over FNAB for the evaluation of prostatic and non-palpable mammographically detected breast lesions due to the purported higher sensitivity of core biopsy in these instances.

Despite these limitations, FNAB remains the initial diagnostic test of choice in most patients presenting with mass lesions. FNAB has the advantage of decreasing healthcare costs and improving patient care by providing a highly accurate and rapid diagnosis compared to alternative methods.

Fine-Needle Aspiration Cytology

Definition

FNAC; A simple, inexpensive and well-tolerated method that consists in the aspiration of cells present using a fine needle. Smears, containing cells, are prepared immediately and microscopically examined by a cytopathologist. This method has a high sensitivity and a high specificity.

►Fine Needle Aspiration Biopsy

Firestorm Pattern

James Hicks
Cold Spring Harbor Laboratory, Cold Spring Harbor, NY, USA

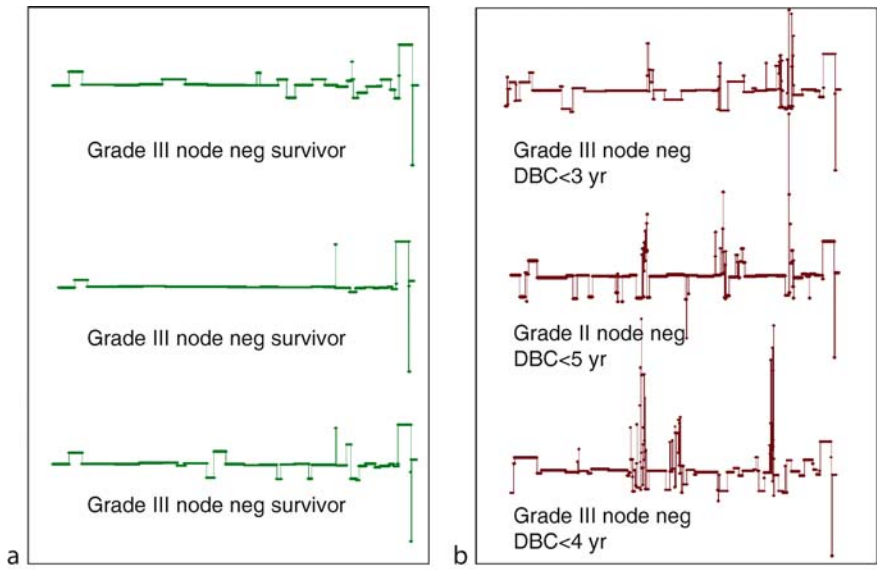
Definition

Firestorm refers to a type of genomic rearrangement, originally identified in breast cancer, characterized by multiple, narrow amplicons on a single chromosome arm usually coupled with deletion of the intervening regions. Firestorm amplicons are usually highly amplified (up to 30x) ►amplification and are maintained contiguously on a single chromosome, but not necessarily associated with their original centromere. There is evidence that firestorms are a marker for poor outcome in breast cancer in patients with otherwise good prognoses.

Characteristics

The term “firestorm” was coined to describe special cases of chromosome rearrangement revealed through high resolution microarray profiling in breast cancer genomes where multiple amplifications and deletions have occurred on a single chromosome arm. Firestorms appear as a series of tightly grouped peaks and valleys in genome profiles of copy number, with the peaks very often containing known or suspected oncogenes. As many as five separate firestorms may be observed in a single tumor genome, yet each one is clearly concentrated on a single arm. This structure is easily contrasted with so-called “simplex” and “saw-tooth” profiles that are characterized by whole chromosome or chromosome arm deletions and duplications distributed among many (“saw-tooth”) or a select few (“simplex”) chromosomes (Fig. 1). Additional information can be found in entries for amplification and amplified in breast cancer in this volume.

Firestorms are characterized by their structure and their potential significance for cancer gene identification as well as for diagnosis and prognosis. Based on the association of amplification and deletion in firestorms, along with their limitation to a single arm, it appears that firestorms are the result of a mechanism based on chromosome mechanics rather than over-replication of a single locus or a genome-wide destabilization of chromosome integrity. Firestorm peaks are frequently associated with known ►oncogenes (e.g. ►MYC, ►CCND1, ►ERBB2) but that the adjacent peaks are non-randomly distributed and may be pointers to novel oncogenes. Finally, based on an analysis of clinical outcomes in Swedish patients from 1985 to the present, there is evidence that a measure of firestorm activity, the



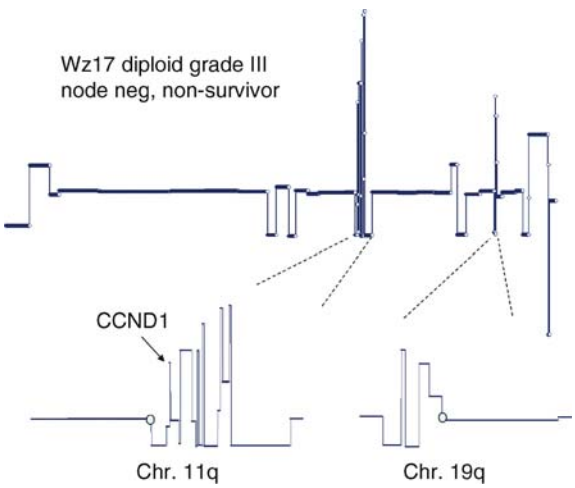
Firestorm Pattern. Figure 1 Comparison of simplex and "firestorm" genomic profiles from patients with similar pathology profiles. DBC: died of breast cancer.

"firestorm index" (F) may be a useful prognostic measure of metastatic disease recurrence.

Contrast with Other Forms of Gene Amplification

Two distinct forms of gene or regional amplification have been known since 1970s. Independently segregating replicons carrying the dihyrofolate reductase gene (DHFR), known as ►"double minutes" (DMs), were described in 1978 by Alt and Schimke and coworkers in murine cells as a result of selection with methotrexate. At about the same time, chromosomal regions carrying tandem copies of a single cytoband (►Homogenously staining region or HSR) were identified in drug resistant lines and later in transformed cell lines and solid tumors In both cases, the interpretation was on amplification of a locus either to overcome drug resistance or, presumably, to advance the replication of a cancer cell.

Firestorms are similar to HSR in that the amplified regions are carried on chromosome arms rather than replicating independently as double minutes. The main distinctions with HSR were revealed through the detailed resolution available with microarray analysis of copy number revealing that firestorms exhibit multiple narrow peaks of amplification and that those amplifications are tightly coupled to deletions of the intervening regions (Fig. 2). Using the ROMA microarray technique on arrays containing 85,000 probes coupled with a breakpoint analysis algorithm it is possible to observe breakpoints in copy number at 50 kbp resolution and to distinguish separate amplifications and deletions spaced less than 100 kbp apart. Thus, HSR refers to a single locus amplified in tandem



Firestorm Pattern. Figure 2 Firestorm amplifications are associated with deletion of the non-amplified regions.

on a chromosome, while firestorm refers to multiple HSR like events on a single chromosome arm.

Figure 1 provides examples of the microarray genome profiles of six pseudo-diploid, node-negative breast tumor samples that contrast the simplex and firestorm types. The genomes are presented in chromosome order, left to right, and represent copy number relative to a standard male primary fibroblast line. The X and Y chromosomes on the right provide scale, the XX/X ratio showing as an increase (duplication) and the Y/0 ratio as a loss. Figure 1a shows typical simplex profiles, most often associated with good prognosis and

long-term survival. Figure 1b provides examples of firestorm profiles in tumors of similar histopathologic status. Irrespective of which chromosome suffers the firestorms there is a similar risk for recurrence, consistent with the common notion that there are multiple pathways toward metastasis.

Figure 2 provides a magnified view of a typical pseudo-diploid genome containing two firestorms along with expanded views of the two firestorms on chromosomes 11 and 19. The expanded views demonstrate the typical pattern in firestorms where multiple, narrow regions are amplified, and, concomitantly, the non-amplified regions are actually deleted. The combination of amplification and deletion has been validated by interphase FISH in all cases tested, revealing one normal chromosome arm and one completely rearranged chromosome arm that is made up of only the amplified regions as has been demonstrated in metaphase chromosomes from cell lines by Gisselsson and co-workers. Thus, firestorms not only result in the gain of up to thirty or more copies of certain loci, but also the loss of the intervening regions, the combination of which may provide both increase in oncogene activity and deletion of tumor suppressors in a single multi-step process.

Mechanism of Firestorm Formation

The genesis of firestorms is very likely through a combination of chromosome breakage and rejoining events of the type first described by Barbara McClintock, based on her cytogenetic observations in maize. She noted that unprotected chromosome ends were likely to fuse after replication creating either a dicentric chromosome or a "ring" chromosome, either of which result in a visible "anaphase bridge" between nuclei at the end of mitosis. These bridged chromosomes would break, either randomly or at preferred sites, resulting in another set of broken ends and a repeat of the process, which she named the breakage-fusion-bridge (BFB) cycle. Elements of this process have been historically been observed in tumor cells as ring chromosomes and other abnormalities and have been implicated in the generation of altered chromosomes visualized cytogenetically.

Breakage-fusion-bridge and related mechanisms such as break induced replication have the power to introduce both amplifications and deletions through repeated rounds of recombination and replication. One of many variations of the way such a mechanism could introduce firestorm patterns is shown in a highly simplified cartoon in Fig. 3. DNA breaks may occur anywhere in the genome, but degradation of telomeres is one way to generate such an unprotected end. Two broken ends may fuse, or a single end may invade its sister (or another chromosome) (Fig. 3a). If linked centromeres separate at nuclear division, the chromosome will eventually break and the daughter nuclei will obtain an unequal complement of loci, along with "invasive" broken ends (Fig. 3b). Subsequent rounds of invasion at random loci, fusion and breakage can lead to repeated amplification of multiple sites (Fig. 3c). Chromosome invasion can also result in pairing and unauthorized DNA replication leading to further amplification of regions near the recombination site (not shown in the figure). Finally, invasion of an unrelated chromosome, perhaps at repeated sequences, may lead to a translocation of the rearranged loci (Fig. 3d).

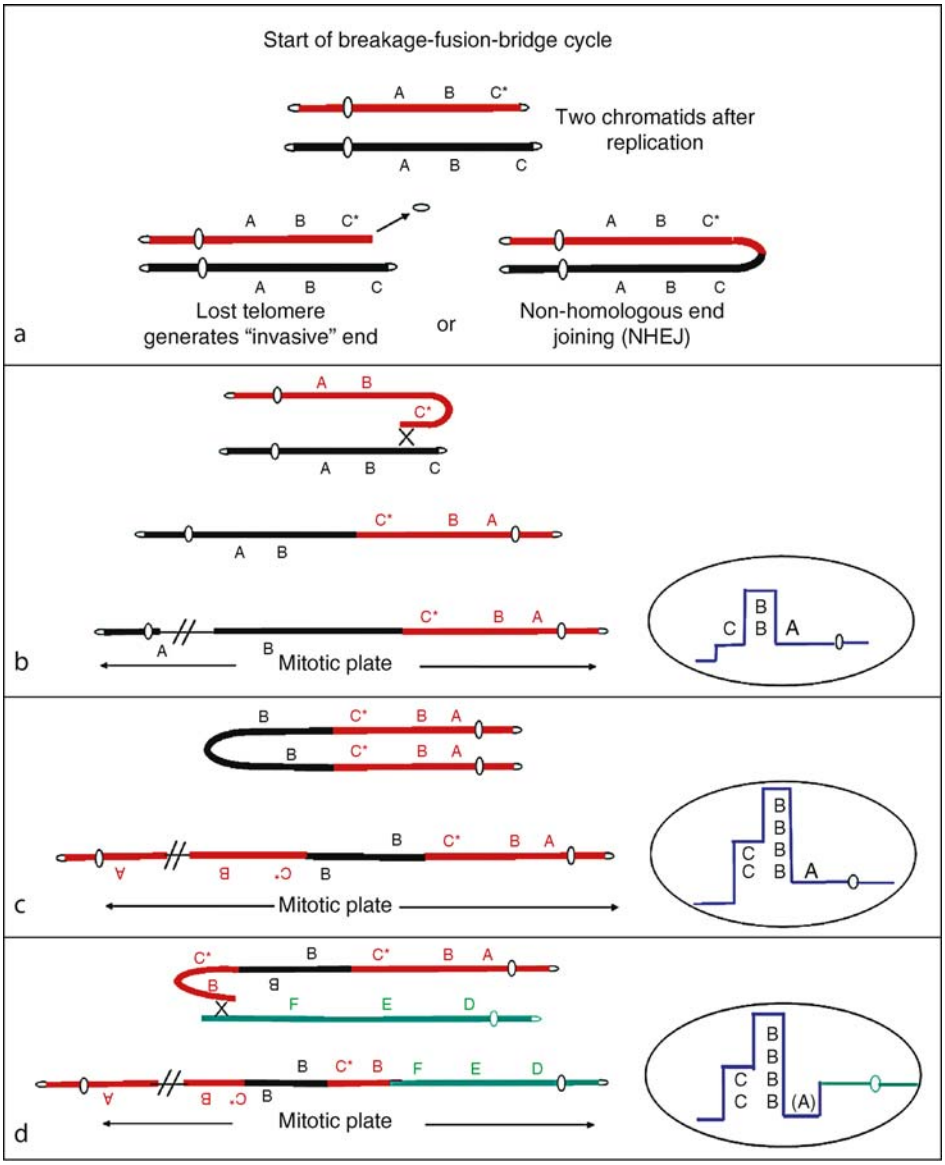
Relation of Patterns to Clinical Outcome

It has long been postulated that complexity of genome rearrangement could serve as a marker for malignant "progression." On first inspection, the highly rearranged "sawtooth" and "firestorm" patterns appeared to correlate with shorter survival in the diploid tumors, presumably due to selection of novel genetic combinations afforded the cancer cells by the opportunity for accelerated recombination. This was documented by developing a mathematical measure of complexity suitable for statistical analysis. Simply using the total number of segments, or events, as a measure does not clearly distinguish a sample with a single firestorm from the simplex pattern with a similar number of events, but the effects of the firestorm appeared by inspection to be much more deleterious to survival. Therefore a measure was chosen that would separate the firestorm patterns from the simplex patterns by scoring the close-packed spacing of the firestorm events, while at the same time incorporating the total number of events. The resulting sum of the reciprocals of the mean of lengths of all adjacent segment pairs ("Firestorm index" or F) accomplished this goal:

$$F = \sum_i \frac{2}{l_i^L + l_i^R} \qquad (1)$$

where i enumerates all the discontinuities with a magnitude above a numerical threshold of 0.1 in the segmented profile, and where $l_i^R (l_i^L)$ denotes the number of probes in the closest neighboring discontinuity on the right (left), or to a chromosome boundary, whichever is closer. The measure works equally well if absolute position in the genome is substituted for probe number. Using this algorithm the firestorm patterns achieve high F values even if only a single arm is affected because of the contribution of event proximity. It has been suggested that adding a factor for amplitude as well as spacing provides an even more effective measure (Anne-Lise Borressen-Dale, personal communication).

Preliminary analyses of a large diploid tumor collection indicated that prognoses in primary breast cancer, measured by the probability of overall survival, was correlated with the morphology of the gene copy



Firestorm Pattern. Figure 3 Example of a mechanism for firestorm formation using the breakage-fusion-bridge (BFB) cycle.

number signature as reflected in F value. Within the balanced group of the samples tested, the magnitude of the signature was independent of such established clinical markers as node status, histologic grade and primary tumor size. It is thus reasonable to expect that the firestorm signature will contribute to the prediction of outcome, perhaps in combination with other known factors.

A clear potential application of such a measure is in the determination of prognosis, with a focus on the identification of patients with such excellent prognoses that systemic therapy is not required or, conversely, such poor prognoses – in spite of clinical measurements that might be misleading in this regard – that systemic treatment is absolutely indicated. For example, a patient with a small, estrogen-receptor positive, node-negative primary breast cancer – all factors that usually indicate a good prognosis – might have an especially poor prognosis as predicted by F.

Five Elements

Definition

The five elements (wood, fire, earth, metal, and water) concept is a philosophical theory developed in ancient China to explain the composition and phenomena of the physical universe. It is used in Chinese medicine to expound the unity between human and nature, as well as the physiological and pathological relationship and interconnection among the internal organs. The five elements match the five viscera, in which liver, heart, spleen, lung, and kidney correspond to wood, fire, earth, metal, and water respectively. The five elements concept explains the interpromoting and interacting relations, as well as the encroachment and violation in illness condition between the five viscera.

Definition

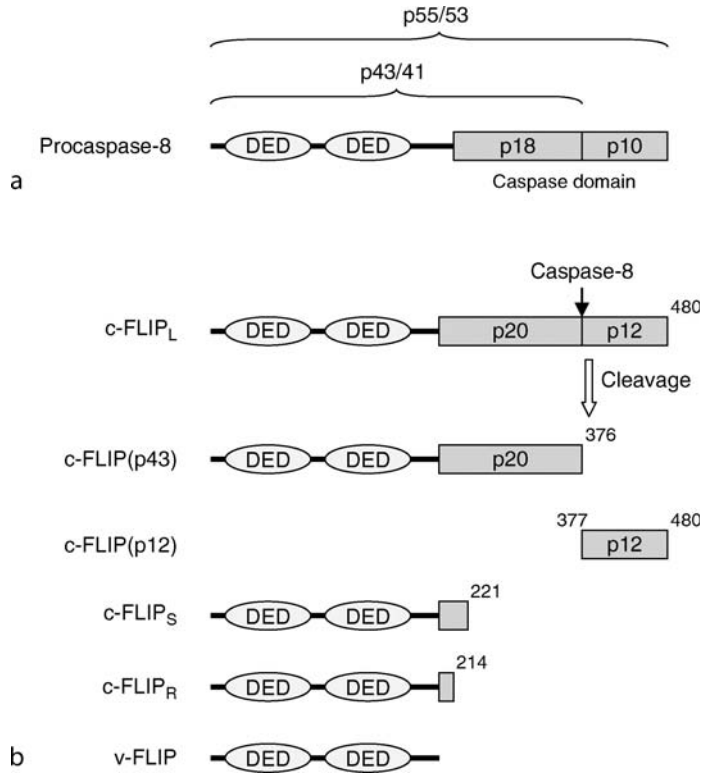
Human cellular FLICE inhibitory protein (c-FLIP) gene shares sequence homology with ►FADD, procaspase-8 and procaspase-10 and is located on chromosome 2q33–34. c-FLIP has eleven splice variants at the mRNA level. Two of these ►splice variants are considered major splicing variants detectable at the protein level in various types of cells and have been extensively studied thus far. One splice variant is designated the long isoform of c-FLIP (c-FLIP$_L$), which is a 55 kDa protein consisting of 480 amino acids, and the other major splice variant is the short isoform of c-FLIP (c-FLIP$_S$), which is a 26 kDa protein consisting of 221 amino acids. The third form of c-FLIP, designated c-FLIP$_R$, which is a 23 kDa protein consisting of 214 amino acids, is primarily expressed in T and B cells. Both c-FLIP$_S$ and c-FLIP$_R$ contain two ►DEDs, whereas c-FLIP$_L$, has two DEDs and a catalytically inactive caspase-like domain and thus shows overall homology with procaspase-8. c-FLIP$_L$ can be processed at Asp376 by caspase-8, yielding the N-terminal 43 kDa and C-terminal 12 kDa fragments which are termed c-FLIP(p43) and c-FLIP(p12), respectively (Fig. 1).

Some viruses such as herpesvirus saimiri, human herpesvirus 8 and moluscum contagiosum virus also produce DED-containing proteins, which are called viral FLICE-inhibitory protein (v-FLIP). Similar to c-FLIP$_S$, v-FLIP consists of two DEDs (Fig. 1).



FLICE Inhibitory Protein. Figure 1 Structures of procaspase-8 (a) and c-FLIP (b). Two major splice variants of c-FLIP, c-FLIP$_L$ and c-FLIP$_S$, have been extensively studied at the protein level. c-FLIP$_R$ and v-FLIP function in a similar manner to c-FLIP$_S$. c-FLIP$_L$ is processed by caspase-8 at Asp376, generating the N-terminal fragment c-FLIP (p43) and the C-terminal fragment c-FLIP (p12).

Characteristics

Function

c-FLIP primarily functions as a specific inhibitor of ►death receptor-mediated ►apoptosis. c-FLIP proteins can be recruited to the ►DISC by DED interaction. Both short forms of c-FLIP isoforms, c-FLIP$_S$ and c-FLIP$_R$, block death receptor-induced apoptosis by inhibiting procaspase-8 activation at the DISC. The role of c-FLIP$_L$ at the DISC is controversial. Some reports demonstrate that c-FLIP$_L$ functions as an anti-apoptotic protein in a way similar to c-FLIP$_S$, whereas others describe that c-FLIP$_L$ acts as a proapoptotic molecule in certain cellular contexts to facilitate the activation of procaspase-8 at the DISC. Endogenous c-FLIP$_L$ functions primarily as an inhibitor of death receptor-mediated apoptosis because ►siRNA-mediated knockdown of c-FLIP$_L$ augmented DISC recruitment, activation, processing, release of caspase-8, and apoptosis in several ►cancer cell lines. In general, c-FLIP$_S$ completely inhibits cleavage of procaspase-8 by preventing the initial cleavage step of procaspase-8 between the p18 and p10 subunit of the caspase homology domain, whereas c-FLIP$_L$ allows the first cleavage of procaspase-8 into caspase-8 (p43/41) but prevents the final cleavage between the prodomain and the p18 subunit of the p43/41 intermediate to generate active caspase-8 (Fig. 1). v-FLIP can function in a similar way to c-FLIPs to bind to the DISC and inhibit death receptor-induced apoptosis.

Besides inhibition of apoptosis, c-FLIP modulates the activity of ►nuclear factor-κB (NF-κB), ►MAP kinase and ►Wnt signaling pathways, suggesting that c-FLIP may play a critical role in many cellular activities. c-FLIP plays an essential role in heart development since disruption of mouse c-FLIP is prenatally lethal probably due to cardiac failure, resembling the phenotype of caspase $8^{-/-}$ and $FADD^{-/-}$ mice.

Modulation of c-FLIP Level

c-FLIPs are short-lived proteins subjected to ubiquitin (►ubiquitination)/proteasome (►protease)-mediated degradation. Many anticancer agents modulate c-FLIP levels through such a mechanism. However, the underlying mechanism including ►E3 ubiquitin ligases responsible for c-FLIP ubiquitination has not been fully elucidated. A recent study has demonstrated that N-terminal c-Jun kinase (JNK)-dependent phosphorylation and activation of the E3 ubiquitin-protein ligase ►Itch specifically ubiquitinates c-FLIP$_L$ and induces its proteasomal degradation.

In addition to the posttranslational modification, c-FLIP expression can be regulated at the transcriptional level. In this regard, the MAP kinase, PI3 kinase (►PI3K signaling)/Akt, NF-κB, p53 (►p53 protein, biological and clinical aspects) and c-Myc (►Myc oncogene) and JAK/STAT pathways have been suggested to be involved in regulation of c-FLIP expression. c-Myc directly represses c-FLIP transcription while other pathways such as PI3 kinase/Akt, NF-κB and p53 increase c-FLIP transcription. Thus, activation of c-Myc sensitizes cancer cells to death receptor-induced apoptosis.

Role in Carcinogenesis

c-FLIP is expressed abundantly in some tissues, such as heart, skeletal muscle and lymphoid tissues. However, c-FLIP is also expressed in a broad spectrum of normal cells such as endothelial cells, keratinocytes, motoneurons, muscle cells, pancreatic cells, dendritic cells and macrophages, suggesting that c-FLIP is an important regulator of many physiologic processes. Accordingly, dysregulation of c-FLIP might lead to development of many diseases including cancer. c-FLIP is up-regulated in many human tumor cells, including colon, gastric, hepatocellular, ovarian, endometrial carcinoma cells, melanoma, leukemia, and Hodgkin lymphoma cells. Increased c-FLIP/►caspase-8 ratio in ►Epstein-Barr virus-transformed cells results in resistance to death receptor-induced apoptosis. High c-FLIP protein expression is associated with a poor clinical outcome in Burkitt lymphoma. Moreover, transfection of c-FLIP into cancer cells promotes cancer ►metastasis. Thus, elevated c-FLIP levels in tumor tissues may allow tumor cells to escape from the death receptor-mediated apoptotic death. Some studies have shown that c-FLIP is involved in mediating the immune escape of tumors *in vivo*.

The Wnt signaling pathway is involved in ►carcinogenesis as mutations in Wnt signaling are associated with many human cancers. It has been shown that c-FLIP$_L$, together with FADD, boosts the Wnt-signaling pathway through inhibiting β-catenin ubiquitination and proteasomal degradation, thereby contributing to carcinogenesis.

Implications in Cancer Therapy

c-FLIP might be a promising target for cancer therapy. In general, c-FLIP expression correlates with resistance against death receptor-induced apoptosis in a variety of cancer types and c-FLIP-transfected cancer cell lines develop more aggressive tumors *in vivo*. Conversely, downregulation of c-FLIP by antisense oligonucleotides (►antisense DNA therapy), siRNA, or ►small molecule drugs sensitize cells to death receptor-mediated apoptosis. Some small molecule drugs with anticancer activity including DNA-damaging agents, ►histone deacetylase (HDAC) inhibitors, COX-2 (►cyclooxygenase in colorectal cancer) inhibitors, and PPARγ (►peroxisome proliferator-activated receptor and cancer) agonists reduce c-FLIP levels in cancer cells. Given that the death ligand ►TRAIL and agonistic anti-TRAIL receptor DR4 and DR5 antibodies (►TRAIL receptor antibodies) are being tested in clinical trials for treatment of cancer, inhibition of c-FLIP expression in cancer cells is of particular importance for TRAIL- or TRAIL receptor-based cancer therapies. Anticancer agents with c-FLIP-inhibitory activity will greatly sensitize cancer cells to TRAIL- or TRAIL receptor-based cancer therapies.

Recent studies have shown that overexpression of c-FLIP also protects cancer cells from apoptosis induced by certain anticancer drugs including chemotherapeutic agents (►chemotherapy of cancer, progress and perspectives) and the COX-2 inhibitor ►celecoxib. In agreement, siRNA-mediated knockdown of c-FLIP sensitizes cancer cells to apoptosis induced by chemotherapeutic drugs including ►cisplatin, 5-fluorouracil (►fluorouracil) and ►taxol. Thus c-FLIP may also play an important role in mediating cell resistance to chemotherapy.

Flow Cytometry

Anurag Saxena
Department of Pathology and Laboratory Medicine, Royal University Hospital, Saskatoon Health Region/ University of Saskatchewan, Saskatoon, Saskatchewan, Canada

Definition

FCM; Is a method for counting, analyzing and sorting particles e.g. cells in a single cell suspension by their light absorbing or fluorescing properties. Flow

cytometry permits assessment of physical (cell size, shape and internal complexity), chemical (expression of proteins and other molecules) and biological (metabolic pathways e.g. calcium ion flux) attributes of single cells in suspension. (►FACS)

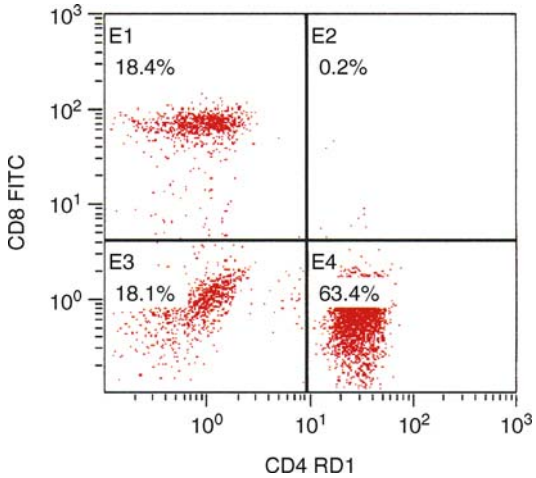
Characteristics

1. The Technology
2. Applications in cancer

The Technology

There are three essential components of a flow cytometer, fluidics, optics and electronics. *Fluidics:* A single cell suspension in a highly controlled fluid stream is forced through a nozzle to induced laminar flow at a high flow rate (meters/sec). A higher-pressure sheath fluid stream surrounds the sample in isotonic fluid and the cells are examined (interrogated) at a point by the excitation light, usually a laser beam. *Optics:* A laser light source generates a monochromatic light beam that passes through the sample stream and gets scattered when it encounters a cell. A simple light scatter plot can identify cells based upon their size, shape and internal complexity. If ►fluorochromes are attached to the cells (either by direct labeling or through conjugated monoclonal antibodies), these absorb the laser light and re-emit a light of longer wavelength (specific to each fluorochrome). Multiple wavelengths can be collected and analyzed at the same time (multicolor analysis). Minimal overlap between generated wavelengths is established prior to collection of the light by a system of filters and dichroic mirrors and later by electronic compensation. ►Epitope density is a major determinant of fluorochromes to be used for conjugating antibodies e.g. low density epitopes can be detected by antibodies bound to phycoerythrin (PE) and high density epitopes would be easily detectable by fluorescein isothiocyanate (FITC). *Electronics:* The light is then collected by photomultiplier tubes and converted into analog electric signals, either in log or linear domains followed by digitization of the signals. Attribution of all the signals associated with a specific cell permits multiparameter analysis. The digital data is collected in a list mode format usually since this allows for complicated analysis and the data can be processed many times. The computer analysis of the data can be performed either by stand-alone software packages or on-line systems with file transfer abilities.

Selection of a subpopulation for further analysis is called gating and can be performed at multiple time-points e.g. live gating- selecting the population at the time of data collection, analysis gating – after the data has been collected in the list mode; other gating strategies include forward and back gating. The data are displayed in graphic formats including histograms, dot plots, contour plots or isometric plots (Fig. 1). Analysis



Flow Cytometry. Figure 1 A dot plot display of two parameters (CD4 and CD8 ►antigens) from a patient with a lymphoproliferative disorder permitting assessment of the expression pattern and the number of positive and negative cells for each ►antigen as well as any co-expression, if present.

of the data requires careful interpretation of the generated histograms and determining an overall pattern of expression of multiple ►antigens. Assessing negative or positive expression of an antigen and viewing co-expression as color-coded histograms requires some basic understanding of binary logic and Boolean gating. Proper instrument setup, calibration, and compensation along with use of appropriate external and internal controls are necessary for misinterpretation of findings.

Flow sorters allow physical separation (sorting) of cells with up to 99% purity for any additional studies such as molecular or functional assays. A comprehensive quality assurance and quality control program has to be established for pre-analytic, analytic and post-analytic stages.

Specimen Issues. Peripheral blood, tumor masses (fine needle aspirates, core biopsies, and incision or excision biopsies) and bone marrow and various body fluids are common specimens analyzed by FCM. Fresh samples are preferred to obtain the cellular population for further analysis, although paraffin embedded tissues have also been analyzed successfully by flow cytometry. An assessment of representative morphology and viability of the single cell suspension allows for a more meaningful interpretation of flow data e.g. by ensuring that the critical tumor cell population has not been lost due to cellular fragility. Dead cells can non-specifically bind antibodies and affect data interpretation.

Applications

Flow cytometry provides an objective measure of multiple attributes of single cells at a great speed

(thousands of cells per second) allowing determination of not only average characteristics of a tumor's cellular population but tumor cell heterogeneity as well. In addition to size, shape and internal complexity determination, Fluorochromes can be used either to directly label molecules inside a cell (e.g. DNA, RNA, thiols) or label monoclonal antibodies directed against specific cell surface or intracellular proteins/molecules. FCM also permits functional assessment e.g. viability, oxidative burst, mitochondrial membrane potential, cell activation using intracellular calcium ion flux, DNA synthesis and cell cycle phase analysis and apoptosis etc. Green fluorescent protein labeling can be used as a gene reporter.

The applications of flow cytometry in cancer include; (i) ►Immunophenotyping of ►hematologic malignancies for diagnosis and prognosis and monitoring ►Residual Disease, (ii) Organ transplantation support, (iii) DNA analysis of S-phase fraction of solid tumors and (iv) determining treatment efficacy.

Immunophenotyping (IP)

Immunophenotypic patterns of cells correspond to different stages of differentiation and function and complement morphologic assessment of tumor cells for correct diagnosis. IP is essential for initial diagnosis and classification, determining certain prognostic variables (e.g. cytokine receptors, multidrug resistance), identifying potential treatment targets and post-treatment follow-up including minimal residual disease assessment.

For lymphoid lesions the FCM provides lineage information (B vs. T-lymphoid) by using antibodies against pan-B antigens (e.g. CD19, ►CD20, CD22) and pan-T antigens (e.g. ►CD3, CD5, CD7). FCM provides information on whether a population is likely to be neoplastic or not. This latter aspect is determined by identifying light chain restriction (clonality) for B-cells and detecting antigen deletion, subset expansion, or aberrant antigen expression for T-cells. Once a population is determined to be neoplastic identifying a relatively unique pattern of antigen expression can be used either to make the diagnosis or complement the diagnostic process by integrating the information with other diagnostic data e.g. morphology and genetics. For lymphoid neoplasms composed of smaller lymphoid cells, immunophenotyping is often considered the gold standard for diagnosis. Expression of certain antigens is related to prognosis e.g. ZAP-70 in ►chronic lymphocytic leukemia and this is optimally measured by FCM.

For ►acute myeloid leukemias, FCM is used in a similar fashion to determine the expression of "immature" (e.g. CD34, TdT, CD117, HLA-DR), "differentiation-related" antigens e.g. CD11b for acute leukemias with monocytic differentiation and "lineage-related" antigens e.g. CD41 and CD61 for megakaryocytic leukemias. The role of FCM in acute leukemia diagnosis includes, a) distinguish acute myeloid from acute lymphoid leukemia, b) correlation with other diagnostic findings such as morphology and genetics, c) recognition of acute biphenotypic subtype and d) prognostic value of antigen expression (e.g. CD7 in AML confers poor prognosis). FCM is also useful in the diagnosis of ►myelodysplastic syndromes e.g. by demonstrating abnormal antigen pattern of myeloid, erythroid and megakaryocytic antigens and accurate blast quantitation.

The presence of antigens on tumor cells is useful in instituting targeted therapy e.g. ►rituximab for CD20+ B-cell lymphomas, alemtuzumab for CD52 expressing chronic lymphocytic leukemia.

The immunophenotype is also useful in follow-up of patients in order to assess residual disease, recurrence and progression/transformation. FCM is extremely useful in differentiating leukemic blasts and hematogones (reactive B-cell precursors), a critical distinction in follow-up marrows of children with B-lineage acute lymphoblastic leukemia. FCM by virtue of its specificity, sensitivity, reliability and established standardization is useful in identifying smaller populations of tumor cells in post treatment specimens, which are below the detection limit of conventional methods (minimal residual disease-MRD); the clinical significance of MRD is established for certain malignancies e.g. childhood acute lymphoblastic leukemia and is being evaluated for others. For follow-up of myeloma patients, abnormal plasma cells (CD19−, CD56+) can be assessed in bone marrow samples, although this technique is somewhat limited by sampling error due to focal distribution of plasma cell clusters.

FCM is not without its limitations. Interpretive errors may be caused by antigens are not always being lineage restricted, non-classic immunophenotypic profile of a tumor, sampling issues (e.g. non-representation of an abnormal plasma cell clusters in the bone marrow aspirate). A better way to interpret the data is not only pay attention to the numbers of cells positive or negative but also the pattern of antigen expression and the composite profile of expression of multiple antigens. The best was is to determine the pattern of antigen expression rather relying on one antigen alone. In expert hands the method is reliable, objective and fast.

Transplant Support

Assessing the numbers and purity of CD34+ stem cells is necessary for stem cell transplant patients since the number of viable CD34+ cells is a crucial factor determining rapid and long-term multilineage engraftment. FCM on ►apheresis products, cord blood or bone marrow ensures adequate numbers of CD34+ cells are present. Harvest products can also be assessed for

F

contamination by tumor cells. Other roles of FCM include, assessment of immune reconstitution by determining numbers of B, T and NK cells and their subsets, graft rejection, graft versus host disease and graft versus leukemia effect. FCM is a highly sensitive technique for pre-transplant ►cross matching, HLA ►antibody screening and monitoring post-transplant antibody levels for solid organ transplantation patients.

DNA Ploidy and S Phase Fraction

DNA content of cells can be determined by determining ►fluorescence intensity of DNA binding dyes such as propidium iodide (PI); three populations G0/G1, S and G2/M are easily discernible. FCM is useful when material cannot be obtained for karyotyping, however, it cannot detect balanced translocations and partial chromosome deletions. Since the measurement is that of total DNA content, rather than actual chromosome numbers, the results are in reference to a normal "diploid" population. The DNA histogram plots fluorescence intensity (x-axis) versus the number of cells (y-axis). A majority of the malignancies have an abnormal DNA content (other than diploid) and aneuploid tumors generally have a bad prognosis with a few exceptions. ►S phase fraction: The proportion of cells in S phase – an estimate of the tumor's proliferative activity- can be determined either by PI labeling or by using a dot plot of anti-bromodeoxyuridine and propidium iodide. S phase fraction generally correlates with increasing DNA amount in tumor cells and the grade of tumors e.g. in lymphomas and a higher S phase fraction is generally considered an adverse prognostic variable. Enthusiasm for DNA ►ploidy and S phase fraction determination in routine oncologic practice has been somewhat limited in view of the technological variations and prognostic and predictive information available from other parameters. Improvement and standardization in methodology may lead to enhanced use of DNA ploidy data by FCM in routine clinical practice. Flow karyotyping refers to the use of FCM to analyze or separate chromosomes on the basis of their DNA content.

Determining Treatment Efficacy

The in vitro prediction of cellular sensitivity to treatment can be assessed by FCM by microdrop encapsulation assay and BrDU incorporation proliferative survival assay. Development of treatment protocols may also take into FCM determination of apoptosis.

Newer and Future Applications

Detection of rare circulating tumor cells and circulating endothelial cells may help in assessing tumor progression and response to treatment, however this application with great potential, at present, is not applicable in routine clinical practice, mainly due to technical issues. Cellular RNA content may be useful for the discrimination of acute leukemias and ►multiple myeloma. As the notion of personalized medicine gets further impetus identification antigens against which treatment can be directed will increase in clinical practice. Biological microbeads are useful for flow cytometric immunoassays.

A relatively recent development has been exploitation of a hybrid technology between flow cytometry and image cytometry, the laser scanning cytometry, to quantify fluorescence intensity of individual cells on glass slides. From a dot plot display populations can be selected and the cells that generated the data can be relocated and then visualized with either bright field or epifluorescence microscopy.

The future of flow cytometry appears to be bright. Technological advances will continue to positively impact the use of FCM. Semiconductor quantum dots (Qdots) are likely to be used as fluorophores in view of their exceptional brightness and large Stokes shifts. Multicolor analysis is likely to expand to use additional colors. Photothermal flow cytometry can be used for detection of label-free detection of cells. Rare event detection including identification of single cells is likely to improve with the use of additional approaches to spectral analysis such as Raman spectroscopy and fluorescence resonance energy transfer measurements.

[2]Peter MacCallum Cancer Center, and the University of Melbourne, Melbourne, VIC, Australia

Synonyms

9-β-D-Arabinosyl-2-fluoroadenine (F-ara-A) monophosphate; FAMP; NSC-312887; Fludarabine phosphate

Definition

Is the ►prodrug of 9-β-D-arabinosyl-2-fluoroadenine (F-ara-A), a synthetic halogen-substituted analogue of deoxyadenosine. Fludarabine and the two other related compounds ►cladribine (2-chloro-2′-deoxyadenosine) and ►pentostatin (2′-deoxycoformycin) are collectively referred to as ►purine analogues, although pentostatin is not actually an analogue, but an inhibitor of ►adenosine deaminase. Fludarabine is widely used in the treatment of indolent lymphoproliferative malignancies, ►acute myeloid leukemia, and as a part of the conditioning regimen for ►non-myeloablative allogeneic stem-cell transplantation.

Characteristics

Clinical and Cellular Pharmacology

The development of fludarabine stemmed from the success of the cytosine analogue ►cytarabine (ara-C) in the treatment of acute myeloid leukemia. A similar adenine analogue, Ara-A (vidarabine), was a successful anti-viral agent that had limited anti-cancer activity due to its rapid clearance by adenosine deaminase. Subsequent structural modifications by Montgomery and Hewson resulted in the development of 9-β-D-arabinosyl-2-fluoroadenine (F-ara-A), an adenosine deaminase-resistant derivative of ara-A. Because F-ara-A is poorly soluble, its 5′-monophosphate prodrug – designated fludarabine – was synthesized as the preferred compound for clinical development. *In-vivo*, fludarabine is rapidly and reliably dephosphorylated to F-ara-A, which is then taken up into cells and phosphorylated to its triphosphate (F-ara-ATP), the active compound mediating the anti-neoplastic properties of fludarabine (Fig. 1). The rate limiting step in this conversion process is the phosphorylation of F-ara-A to its monophosphate (F-ara-MP) by ►deoxycytidine kinase.

The current standard dose and administration of fludarabine is 25–30 mg/m^2 via a short infusion (15–30 min); this is substantially lower than the potentially neurotoxic doses used in the initial phase I trials of fludarabine in advanced malignancies, which was up to 260 mg/m^2 over 2–5 min. Pharmacokinetic data of F-ara-A from this phase I study showed a volume of distribution of 44.2 L/m^2, clearance of 4.08 L/h/m^2 and a triphasic elimination phase comprising a rapid distribution phase (5 min) followed by an intermediate elimination phase (1–2 h) and a prolonged terminal elimination phase (10–30 h). Similar kinetics were observed after the typical 30 min infusion. F-ara-A elimination is predominantly renal, with approximately 60% of a bolus recovered in the urine within 24 h. Dose modification for impaired renal function is required.

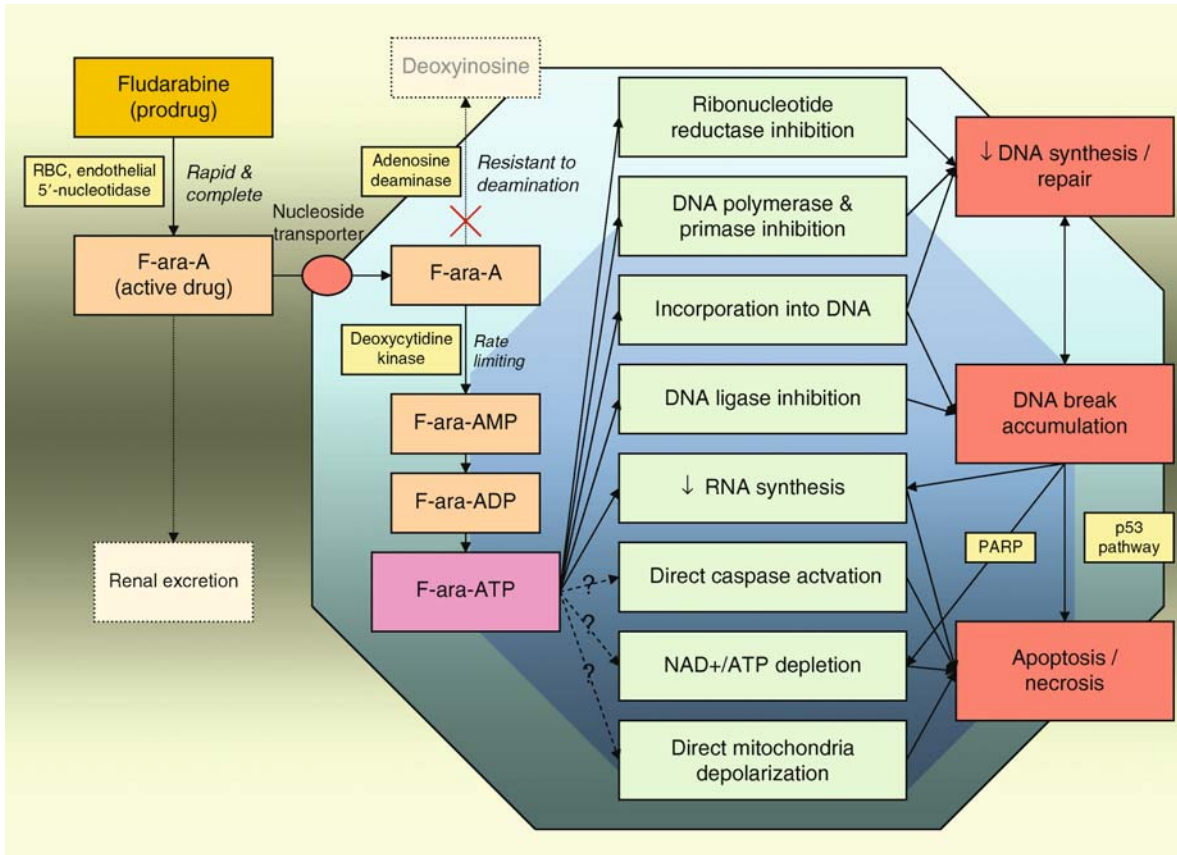
In circulating leukemic cells, peak F-ara-ATP concentrations are reached at about 4 h after the start of fludarabine infusion. There is considerable inter-individual variation in F-ara-ATP elimination: in patients with ►chronic lymphocytic leukemia (CLL), the intracellular F-ara-ATP half-life ranged from a few hours to several days with a median of 15 h. Based on this data, daily administration schedules are commonly employed in clinical practice.

New oral preparations of fludarabine are available. Their bioavailability range between 55% (tablets) to 75% (liquid).

Mechanisms of Anti-Cancer Activity

The main elements of fludarabine action are illustrated in Fig. 1. Most classical anti-metabolite agents, such as cytarabine, are most active against rapidly dividing cells, where they are readily incorporated into newly synthesized DNA and cause chain termination. The initial expectation was that a similar mechanism of action would apply to fludarabine, and therefore the initial phase I-II trial was conducted in patients with acute myeloid leukemia or ►acute lymphocytic leukemia, diseases with rapidly proliferating cell populations. Although fludarabine showed some anti-leukemic activity, the doses explored (up to 150mg/m^2/day) were associated with prohibitive delayed neurotoxicity including cortical blindness and coma. Later, fludarabine was tested in patients with CLL at substantially lower doses (20–30 mg/m^2/day). CLL was traditionally considered be a disease of slowly proliferating, long-lived leukemic cells, and it was therefore somewhat unexpected when fludarabine, an anti-metabolite agent, was found to be highly effective. This clinical observation led to extensive re-consideration of possible mechanisms accounting for fludarabine activity in non-dividing cells, summarized in Fig. 1. Currently the dominant mechanism of fludarabine in indolent lymphoproliferative disorders is unknown. It is likely that most of the indolent lymphoproliferative disorders, including CLL, are more proliferative than initially thought. There is also evidence to suggest that quiescent lymphocytes are continually breaking and rejoining their DNA, and F-ara-ATP may inhibit DNA repair in this situation.

F



Fludarabine. Figure 1 Major components of Fludarabine metabolism and action. Differential toxicity in leukemia cells may be due to relative abundance of the high-affinity nucleoside transporter, efficient phosphorylation of nucleosides to triphosphate, and increased DNA turnover in tumour cells.

Lastly, it is possible that intracellular accumulation of dATP or its analogues (such as F-ara-ATP) activate ►apoptotic pathways directly without the requirement for DNA damage.

There is mounting clinical evidence that *in-vivo* activity of fludarabine depends strongly on the presence of an intact ►p53 pathway. Patients with mutation and/or deletion of the p53 gene respond less well to fludarabine, and any responses achieved are associated with substantially shorter remissions. ►Microarray experiments have shown that *in-vivo* exposure to fludarabine results in activation of genes associated with the p53 pathway.

Clinical Applications

Fludarabine is primarily used in the treatment of indolent lymphoid malignancies, particularly CLL. In CLL, three large randomized trials have established fludarabine as being the most active single agent, achieving more complete remissions and longer responses than ►chlorambucil or alkylator-based combination regimens. Subsequent *in-vitro* studies showed that the combinination of fludarabine and ►cyclophosphamide was synergistic, primarily due to fludarabine inhibition of the repair of cyclophosphamide-induced DNA damage. Translation of this combination of fludarabine and cyclophosphamide (FC) into the clinic has confirmed this preclinical synergy, with FC established as being more effective than fludarabine in three large randomized trials. More recently, the addition of ►rituximab (a monoclonal antibody directed against the CD20 molecule expressed on the majority of indolent lymphoid malignancies) to FC has resulted in a regimen capable of achieving complete response in 70% of patients treated.

Based on the favorable experience with CLL, fludarabine was also tested in patients with other indolent lymphoproliferative maligancies, particularly ►follicular lymphoma and related ►non-Hodgkin lymphomas. In follicular lymphoma, the combination of fludarabine and ►mitoxantrone achieves superior CR rates and remission durations to ►CHOP, an alkylator-based combination commonly employed in patients with histologically aggressive lymphomas.

Analogous to the experience with CLL, combinations with rituximab are being explored in patients with indolent B-lymphomas with promising activity.

In acute myeloid leukemia, fludarabine has inadequate activity at the maximally tolerated dose to be clinically useful as a single agent. However, Gandhi and Plunkett showed through a series of elegant pre-clinical and translational pharmacologic studies that exposure to fludarabine may increase the effectiveness of cytarabine (ara-C), the most important agent in acute myeloid leukemia therapy. Ara-C is converted to its active metabolite, ara-CTP, in leukemic blasts with the rate-limiting step being conversion to ara-CMP by deoxycytidine kinase. A major cellular target of F-ara-ATP is ►ribonucleotide reductase, a critical enzyme for sustaining intracellular levels of dNTPs, and reduction in intracellular dCTP may reduce the negative feedback on deoxycytidine kinase. Indeed, clinical studies have shown that exposure to fludarabine significantly increases leukemic blast accumulation of ara-CTP following administration of cytarabine. The combination of fludarabine and cytarabine is currently being explored in patients with acute myeloid leukemias associated with the t(8;21) or inversion 16 chromosomal abnormalities, the subtypes where dose-intensity of cytarabine are most crucial.

One of the side effects of fludarabine is lymphocyte depletion and associated predisposition to ►opportunistic infections. Indeed, CD4 and CD8 T-cells may be suppressed for 12 months or more following therapy with fludarabine. This immunosuppressive effect of fludarabine has been successfully exploited in allogeneic stem cell transplantation. Traditionally, large ("myeloablative") doses of chemotherapy ►myeloablative megatherapy and/or radiation were required in stem cell transplantation to suppress host immunity sufficiently to prevent graft rejection; such conditioning regimens are highly toxic, and limit the applicability of stem cell transplantation to younger and fitter patients. New approaches to stem cell transplantation using less intensive regimens ("non-myeloablative" conditioning) incorporate fludarabine with ►cyclophosphamide and/or other agents to achieve similar degrees of transient immunosuppression required for successful engraftment, with substantially less toxicity.

The major side-effect of fludarabine at currently clinically used doses (25 – 30 mg/m^2/day) is ►myelosuppression and pre-disposition to infection. Delayed neurotoxicity due to diffuse widespread demyelination, previously a major problem seen in early trials employing high doses of fludarabine (>100 mg/m^2 bolus, or >40 mg/m^2/day continuous infusion), is not encountered at currently used doses. In addition to infections resulting from neutropenia, the use of fludarabine has been associated with a number of "atypical" infections including *Pneumocystis jiroveci* (PCP) pneumonia, systemic listeriosis and reactivation of herpes family viruses. These are commonly attributed to the CD4 lymphopenia caused by fludarabine, but concurrent ►corticosteroid exposure and the effects of previous chemotherapy are also contributory, as these infections are very rarely seen with single-agent fludarabine.

Synonyms

Tissue spectroscopy; Laser-induced fluorescence diagnosis LIFD; Photodynamic diagnostics

Definition

Fluorescence diagnostics are procedures designed to detect neoplastic tissues based upon spectroscopic recognition of tissue-specific accumulations of natural or artificial fluorescing molecules (fluorophores).

Characteristics

Certain fluorescing dyes selectively accumulate in cancer cells and may, since fluorescing molecules are very rare in the biological environment, serve for sensitive detection of early cancerous lesions in human tissues without interfering with tissue integrity. Some of the dyes used for ►photodynamic therapy present a strong fluorescence, and since they localize to malignant tumors, early attempts were made to use these dyes for tumor diagnosis. Polyporphimer sodium (Photofrin®), for example, is a more effective purified fraction of the classical hematoporphyrinderivate (HpD), which has now obtained clinical approval for various indications in several countries. Polyporphimer sodium has to be applied intravenously and reaches a peak tumor:normal-tissue ratio 48–72 h after injection. The possible wavelengths for stimulation are 405 nm (Soret), 505, 525, 565, and 630 nm (Q-bands). The main advantage of this substance lies in the large clinical experience with its use for Photodynamic Therapy. The disadvantages are a long-lasting ►photosensitivity of the skin, still unsatisfactory tumor selectivity, and the relatively unfavorable longer activation wavelength of 630 nm. New dyes have entered the field, one of which is ►5-aminolevulinic acid (►ALA). This substance is unique in the group of photodiagnostic agents, since it is not fluorescent by itself and has to be transformed by a cellular enzymatic reaction to the natural cellular fluorophore protoporphyrin IX. Since ALA can be absorbed after topical application, it is possible to locally apply by endoscopic spraying. The fast photobleaching kinetics of ALA is a disadvantage, however, this substance has actually gained importance as a photodiagnostic drug.

The autofluorescence features of certain tumors may also allow sensitive detection of early cancers. Background subtracting technology has contributed to sensitivity and specificity of point measuring and imaging systems. However, to date, there are few organ sites where such diagnostic modality is truly established.

Application

Detection of Early Lung Cancer by Fluorescence Bronchoscopy

The bronchoscopic detection of severe dysplasia and early invasive ►lung cancer generally requires the expert analysis. Hematoporphyrin-mediated specific fluorescence was early investigated to improve diagnostic sensitivity during bronchoscopy. A group in Vancouver, trying to implement background subtracting techniques realized that the autofluorescence background differed significantly between tumorous and healthy mucosa. Malignant tumors are characterized by a reduction in elastin- and connective tissue-mediated autofluorescence. Thus, instead of using an exogenous tracer, they developed an imaging system based on autofluorescence characteristics only. This system was commercialized in the mean time under the name ►light-induced fluorescence endoscopy (LIFE) and is gaining rather widespread acceptance. In a recently published multicenter evaluation, the relative sensitivity of white light bronchoscopy enhanced by LIFE versus white light bronchoscopy alone was 6.3 for intraepithelial neoplastic lesions and still 2.7 for invasive cancers. The positive predictive value was 0.33. The authors conclude in that report that autofluorescence bronchoscopy, when used as an adjunct to standard white light bronchoscopy, enhances the ability of the bronchoscopist to localize small neoplastic lesions, especially intraepithelial lesions that

may have significant implication in the management of lung cancer in the future.

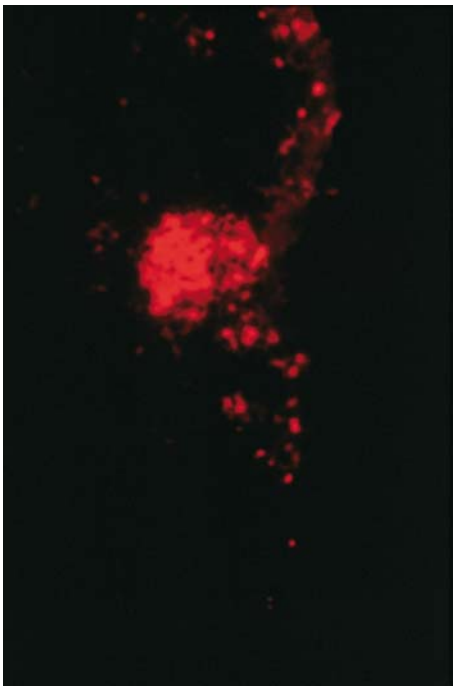
Urinary Bladder

If the success of autofluorescence detection originates from the bronchi, the success of ALA-induced fluorescence detection originates from the urinary bladder. While early attempts had been undertaken with hematoporphyrin fluorescence imaging, the topical use of ALA to induce protoporphyrin IX fluorescence has rapidly set a standard. In their latest assessment, a group from Germany reported in 208 consecutive patients with superficial bladder cancer a best estimate for the sensitivity of ALA-induced fluorescence endoscopy of 93.4% (95% confidence intervals 90–97.3) compared with a value of 46.7% (95% confidence intervals 39.4–54.3) for white light endoscopy. Some autofluorescence based approaches do not find the same acceptance as yet.

Other Organ Sites

Sensitive detection of premalignant conditions or early tumor stages may be considered as the general aim of fluorescence enhanced endoscopic approaches. Based on endoscopic accessibility and upon the presence of a risk group with sufficient incidence of dysplastic or cancerous lesions, research was directed towards patients with ►Barrett esophagus or with ►ulcerative colitis. However, both predisposing conditions are associated with an extended, inhomogeneous chronic inflammatory process that seems to interfere with the homogeneity of the background fluorescence. Neither autofluorescence nor ALA-enhanced fluorescence techniques have been reported to be a worthwhile adjunct to conventional diagnostics. The differentiation of small colonic polyps may be possible by autofluorescence; it is, however, questionable, whether the clinical benefit will justify the effort.

The procedures discussed so far have all dealt with the tissue surface. If microscopic tumor deposits are to be detected at a certain depth in the tissue, more sophisticated techniques are required to isolate the specific fluorescence signal from the abundant autofluorescence originating from the interpositioned normal tissue. Single point measurements may be advantageous over imaging techniques. Using a single point background subtracting measuring device with an excitation wavelength in the red (630 nm), Mang et al [1] were able to detect very small tumor deposits in the skin of breast cancer patients and lymphatic micrometastases (Fig. 1) in a rat model.



Fluorescence Diagnostics. Figure 1 Fluorescence micrograph of a lymph node micrometastases after systemic application of polyhematoporphyrin as photodiagnostic agent. Synonyms

5-Fluorouracil; 5-FU

Definition

Is a drug primarily used in cancer treatment. It is considered a ►pyrimidine analog belonging to the class of drugs known as ►antimetabolites. This ►chemotherapy agent has been used against cancer for about 40 years and appears to have multiple sites of action. As a pyrimidine analog it is activated inside the cell to a cytotoxic metabolite that is incorporated into RNA and DNA. This action causes ►cell cycle arrest and, in many instances, induces ►apoptosis. Because its main actions involve DNA synthesis, this agent is considered an S-phase specific drug and is active during this phase of the cell cycle in actively dividing cells.

Characteristics

Fluorouracil continues to have wide use in the treatment of cancer. Research over the past several years has increased our understanding of how 5-FU inhibits cell growth and this has led to the development of new strategies that have increased the utility of this anti-cancer drug. However, drug resistance continues to limit the usefulness of this antimetabolite as well as limit the use of some of the newer antimetabolite derivatives of 5-FU.

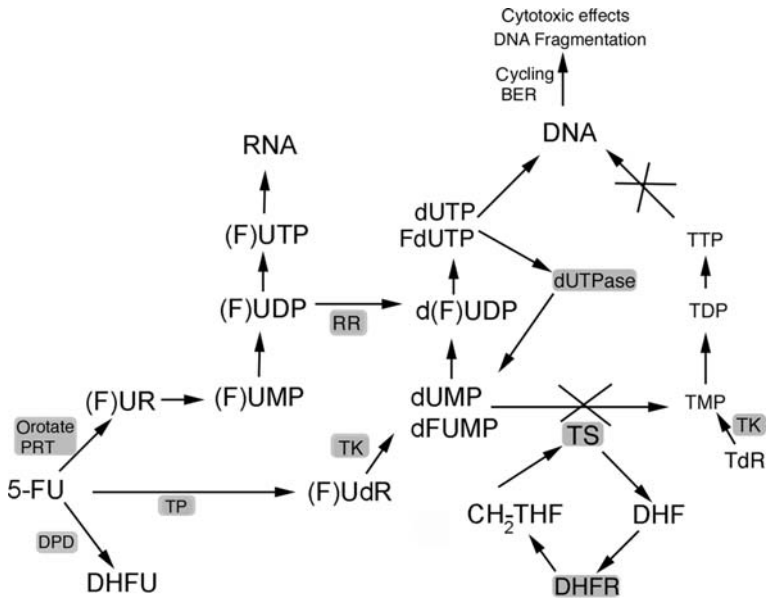
Mechanisms of Action

One of the key actions of 5-FU is the inhibition of thymidylate synthase (TS). Once in the cell 5-FU can be converted to fluorodeoxyuridine by ►thymidine phosphorylase (TP) and then to the monophosphate, FdUMP by thymidine kinase (Fig. 1). FdUMP in the presence of a reduced folate cofactor forms a stable covalent complex with TS, inhibiting activity and blocking de novo thymidylate (TMP) synthesis. Cytotoxic determinants of this mechanism include diminished levels of TMP and TTP. This results in the inhibition of DNA synthesis.

Other pathways that appear to contribute to the cytotoxic action of 5-FU include extensive incorporation of the ribonucleotide metabolite, FUTP into both cytoplasmic and nuclear RNA, disrupting normal RNA homeostasis. The contribution of the RNA pathway to cellular toxicity varies greatly and depends on cell type and the experimental setting. 5-FU can affect ►pre-mRNA processing such as ►polyadenylation as well as mRNA translation, ultimately leading to decreased expression of protein, including key proteins involved in metabolizing 5-FU.

Determinants of Cell Sensitivity to 5-FU

Cancer cells vary widely in their sensitivity to this chemotherapeutic agent, and numerous determinants appear to play a role in whether a cell is sensitive or resistant to 5-FU. Preclinical as well as clinical studies have demonstrated that TS expression is a key



Fluorouracil. Figure 1 Potential pathways for the metabolism of fluorouracil. RR, ribonucleotide reductase; TK, thymidine kinase; DHFR, dihydrofolate reductase; PRT, phosphoribosyltransferase; DPD, dihydropyrimidine dehydrogenase; dUTPase, dUTP nucleotidohydrolase; TS, thymidylate synthase; TP, thymidine phosphorylase.

determinant of 5-FU sensitivity. Quantitation of TS expression in tumors has revealed that low levels of TS correlate with improved response to 5-FU based therapy. Metabolic enzymes also play a role in 5-FU response rates. The catabolic enzyme, dihydropyrimidine dehydrogenase (DPD) initiates the degradation of 5-FU by converting the fluoropyrimidine to dihydrofluorouracil. High levels of DPD in colorectal tumors lead to elevated resistance to 5-FU. Other determinants that play a role include thymidine phosphorylase (TP), which converts 5-FU to an active metabolite known as FUdR (Fig. 1). The ►tumor suppressor ►p53, which regulates gene transcription of a number of key enzymes, is also known to alter cellular sensitivity to 5-FU. Research efforts continue in an attempt to further elucidate the mechanisms of action of 5-FU in the hope of improving its efficacy in the clinic. Results from a number of laboratories have uncovered an additional cytopathic mechanism that is downstream of TS inhibition. This mechanism contributes to 5-FU cytotoxicity through a self-defeating base-excision repair process. Along with the depletion of TTP pools (because of a decrease in de novo TMP synthesis) there is also an increase in dUMP, the normal substrate of TS. Metabolism of dUMP to the triphosphate, dUTP (as well as the conversion of FdUMP to FdUTP) results in elevated pools of these atypical precursors for DNA synthesis. Normally the enzyme, dUTP nucleotidohydrolase (dUTPase) which hydrolyzes dUTP to dUMP, prevents significant dUMP incorporation into DNA. However in the presence of FU metabolites, the efficiency of dUTPase appears to be diminished. It appears that FdUTP effectively ties up the enzyme, allowing dUTP pools to build up. Under these conditions there is a destructive cycle of dUMP (and FdUMP) incorporation into DNA, removal of uracil (and fluorouracil) by the base-excision repair enzyme, uracil-►DNA glycosylase and reincorporation of (F)dUMP, during the synthesis phase of ►DNA repair. The end-point is loss of DNA integrity and cell death. Studies have revealed that levels of dUTPase vary significantly between cell lines. These studies show that elevated dUTPase activity in the cell correlates with lower dUTP pools and diminished DNA fragmentation. Several investigators have also demonstrated that elevated dUTPase correlates with increased resistance to the fluoropyrimidine antimetabolite. Introduction of recombinant vectors, expressing dUTPase, into sensitive cells decreased sensitivity to FUdR (an active metabolite of 5-FU) as well as decreasing dUTP pools and DNA fragmentation. Utilizing ►small interfering RNA (siRNA) strategies, it was shown that suppression of dUTPase, resulted in a significant enhancement of dUTP pools, enhanced DNA fragmentation and a decrease in IC_{50} for FUdR. Clinical evidence points to an association between dUTPase levels, survival and response to 5-FU in colorectal cancer. Higher levels of dUTPase correlate with poorer response to 5-FU therapy. Published studies also provide evidence that dUTPase levels vary widely between individual cancer tumor specimens.

While considerable data has accumulated on the expression characteristics of dUTPase in a number of

cancer cell lines as well as cancer tissues, very little information exists on the expression characteristics of the DNA repair enzyme, uracil-DNA glycosylase (UDG) in cells in relation to 5-FU or its metabolites. It has been estimated that as many as 400 uracil residues could arise in the human genome per day as a result of spontaneous cytosine deamination occurring under physiological conditions. The mutagenic potential of uracil is particularly high because, unlike many other lesions, it can be efficiently used as a template. Like thymine, uracil can base pair with adenine and yield a stable duplex structure. During occurrences of cytosine deamination to uracil, C to T and G to A base substitutions arise. Subsequent rounds of DNA replication lead to transition mutations. Uracil-DNA glycosylases and related enzymes initiate base-excision repair pathways that function to correct misincorporation of dUMP and to correct deaminated cytosine residues in DNA. This process is necessary to prevent the accumulation of mutations, which may lead to genomic instability and pathologic outcomes such as cancer. There are two isoforms of UDG, one located in the nucleus, nUDG (also known as UNG2 or UDG1A) and one that is targeted for ►mitochondrial DNA repair, mUDG (also known as UNG1 or UDG1). Recent evidence indicates that both the nuclear and mitochondrial isoforms of UDG are modulated by 5-FU (and FUdR) treatment in certain cell lines but not in others. Significant modulation occurs at the transcriptional and at least for nUDG at a post-translational level. In normally cycling cells in culture, nUDG protein expression occurs in the G_1 phase of the cell cycle and that during the S to ►G_2 phase transition, nUDG is degraded by a ►ubiquitin-mediated process. Recent evidence also indicates that 5-FU mediates an atypical turnover of nUDG in late G_1/early S phase of the cell cycle. Additional data indicate that for cell lines that do not down regulate nUDG (in response to 5-FU), siRNA-mediated knockdown of nUDG increases resistance to the cytotoxic effects of the FUdR metabolite, increasing the IC_{50} by sixfold. A derived speculation from these findings is that cells can tolerate uracil in DNA (especially base-paired to adenine) much better than they can tolerate DNA strand breaks. So if the cell maintains uracil in DNA until pools of dUTP (and FdUTP) decrease, subsequent DNA repair would be much less deleterious. Therefore it can be inferred that in certain cell lines, damage induced by 5-FU instigates a ►checkpoint mechanism that culminates in the down regulation of UDG. This mechanism protects cells from the destructive, cyclic base-excision repair process created by elevated pools of dUTP. Conversely cells that lack this mechanism, and maintain elevated levels of UDG, are more sensitive to the effects of cyclic base-excision repair and show increased toxicity to fluoropyrimidines. Strategies directed at stabilizing nUDG in cancer cells may provide clinically significant approaches for novel drug development.

Toxic Side-Effects

Toxicity to fluorouracil manifests in several ways. Early symptoms include nausea and anorexia. This is followed by ►stomatitis and diarrhea. Mucosal ulcerations of the gastrointestinal tract may lead to fulminant diarrhea, shock and death. This is most prominent in patients receiving continuous infusion of 5-FU or a combination of 5-FU and ►leucovorin (LV). The major toxicities of IV bolus regimens is ►myelosuppression. Toxicities of infusional 5-FU are a function of dose and duration of exposure. DPD catalyzes the initial step in degrading 5-FU. In a small percentage of the population DPD activity is below average levels for the general population. Administration of 5-FU to these individuals can cause significant life-threatening toxicity. Unfortunately, in most cases this genetic predisposition is not uncovered until administration of 5-FU.

Capecitabine, an Orally Administered ►Prodrug of Fluorouracil

Statistical analyses have indicated that prolonged low-dose infusional 5-FU resulted in higher response rates with some improvement in survival when compared to bolus injection. Because of the labor-intensive nature of prolonged infusional therapy new modes of oral delivery of 5-FU have been formulated. ►Capecitabine is an orally administered fluoropyrimidine carbamate prodrug that is activated to 5-FU by a series of enzymes. Studies suggest that the latter activating enzymes in this series are higher in the tumor relative to normal tissue, rendering a certain degree of selective activation of the prodrug in tumor tissue.

Fluoxetine hydrochloride is a drug used in the clinic for the treatment of depression and for a broad spectrum of psychiatric disorders. Fluoxetine has also been shown to inhibit multidrug resistance extrusion pumps expressed in a variety of cancer cells.

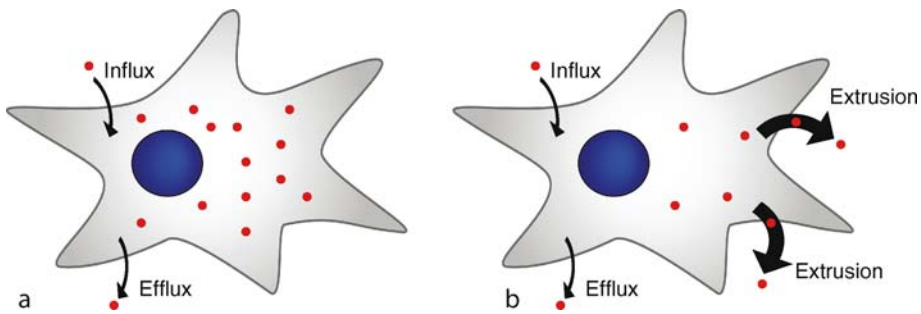
Characteristics

Fluoxetine hydrochloride is a drug used clinically in depression, and in a wide spectrum of psychiatric disorders. Fluoxetine was derived from an antihistamine (diphenhydramine), and found to inhibit reuptake of the neurotransmitter ►serotonin. Fluoxetine is also used (off-label) to treat many other conditions, including Attention-Deficit Hyperactivity Disorder (ADHD). The mechanism by which the drug operates is still unclear. Fluoxetine has been shown to be effective in cancer therapy in two areas; As an anticancer effector inducing apoptosis, as reported *in vitro* for ►Burkitt lymphoma (a type of ►B cell lymphoma), ►glioma and ►neuroblastoma cells, and as a non-selective inhibitor of the ►cancer multidrug resistance (MDR) extrusion pumps.

Multiple Drug Resistance

Multiple drug resistance (MDR) is one of the principal mechanisms by which chemotherapy treatment fails many cancer patients. It affects patients with a variety of blood cancers and solid tumors, including ►breast cancer, ►ovarian cancer, ►lung cancer, lower gastrointestinal tract, liver and ►brain tumors. Tumors usually consist of mixed populations of malignant cells, some of which are drug-sensitive while others are drug-resistant. In a drug-sensitive tumor cell the drug can accumulate to a sufficient level that culminates in cell death (Fig. 1a). The molecular basis of cancer drug resistance is complex and has been correlated to elevated enzymes that can neutralize chemotherapeutic drugs, but more often it is due to the overexpression of extrusion transporters from the ►ABC (ATP-Binding Cassette) Superfamily. These transporters actively pump chemotherapeutic drugs out of the cell, thus reducing the intracellular drug doses below lethal thresholds (Fig. 1b). Chemotherapy kills drug-sensitive cells, leaving behind a higher proportion of drug-resistant cells. As the tumor is recurred, chemotherapy may fail as a consequence of residual drug resistance cells dominating the tumor population.

Among the ►ABC transporters, the most investigated proteins are: ►P-glycoprotein (ABCB1); the multidrug resistance associated proteins (MRPs) of



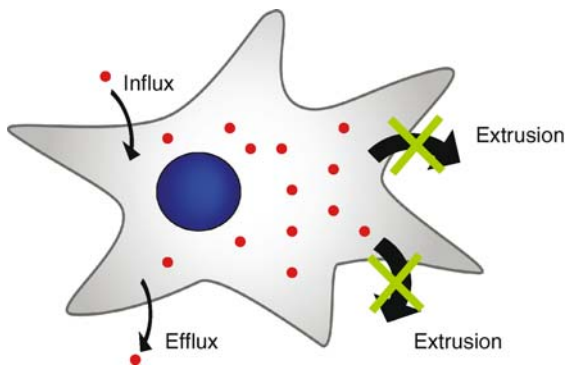
Fluoxetine. Figure 1 Illustration of drug efflux and accumulation in drug-sensitive and in drug-resistant tumor cells. (a) A drug-sensitive tumor cell. Drug molecules (red dots) diffuse across the cell membrane. The influx of the drug is superior to the drug efflux due to the direction of the drug's electrochemical gradient, allowing sufficient drug accumulation inside the cell. The cell nucleus is in blue. (b) A resistant tumor cell combines drug diffusion across the cell membrane with extrusion pumps that expel the drug out of the cell and thus reducing the drug accumulation inside the cell.

which the most studied is the MRP1 (ABCC1); and the breast cancer resistance protein (ABCG2). Those proteins share a similar function – they all expel chemotherapy from the cells, however their structure is different from one another.

Clinical MDR appears in two modes, inherent (intrinsic) and acquired. When the tumor is not responding to the chemotherapeutic treatment, even in the first cycle of administration, it can be defined as an inherent (intrinsic) resistance. The acquired form of drug resistance is defined when the tumor response to chemotherapy treatment is reduced over time (usually after several cycles of administration). Recent findings from cancer ►stem cell research may shed light into our understanding of the biology behind the different modes. High levels of ABC transporters in stem cells (particular ABCG2 in normal stem cells) and the recognition and retention of ABC transporters in cancer stem cells that intrinsically and consistently over-express ABC transporters contribute to the understanding of the phenomena, but still leave the tumor biologist with a vital question: How come some tumors are intrinsically resistance to chemotherapy while others remains sensitive? The role of cancer stem cells in cancer recurrence and in intrinsic vs. acquired MDR needs further studies. It is clear, however, that the impact of cancer stem cells on MDR will become a major factor in designing strategies to overcome drug resistance.

MDR Reversal by Chemosensitization

Drug resistance mediated by extrusion pumps is a problem that holds the key to its solution. In the most direct view, arresting the pump action (Fig. 2) should restore drug accumulation inside the MDR tumor cell to levels comparable to those of a drug sensitive tumor cell (Fig. 1a).



Fluoxetine. Figure 2 A chemosensitized drug-resistant tumor cell. By blocking the extrusion pumps, the drug is allowed to accumulate inside the cell, comparable to the case of a drug-sensitive tumor cell.

Several different names have been given to an agent capable of pump arrest: MDR reversal agent, MDR modulator, chemosensitizer, and pump inhibitor. The ongoing search for chemosensitizers that can apply in the clinic is into its third generation. First-generation chemosensitizers were found among drugs already approved for different indication, such as ►verapamil, cyclosporine A and ►progesterone. Today those drugs are used as *in vitro* benchmarks. They cannot be employed clinically due to dose related adverse effects, toxicity and, in some cases, solubility limitations.

The second and third generations of chemosensitizers were drawn from chemical derivatization of the first-generation molecules and from combinatorial chemistry designed predominantly against ABCB1 (P-glycoprotein). Examples include many compounds that are under development in pharmaceutical companies such as VX-710, XR9051, XR9576, MS-209, GF120918, LY335979, ONT-093, and PSC833 (Valspodar). Some of the compounds reached clinical trials; although they are less toxic and more potent then the first generation compounds, they are still prone to adverse effects, poor solubility, and unfavorable changes in ►pharmacokinetics of the anti-cancer drug. Not all of them fit to blocking different pump proteins. Most of them usually function with one or two pumps and thus are not "multi-pump" blockers. PSC833 (Valspodar) was one of the prominent candidates that reached clinical trials. Valspodar has been extensively investigated both pre-clinically and clinically and found to function as a single-pump blocker (ABCB1). Recently (2006), it has been reported that Valspodar did not improve treatment outcomes and increased the toxicity in a randomize phase III clinical trial in patients with recurring or refractory multiple myeloma. Valspodar treatment was in combination with the chemotherapeutic drugs vincristine, ►doxorubicin and the steroid dexamethasone, compared with treatments that exclude the chemosensitizer.

The diversity among pumps proteins, the heterogeneity of cells in a given tumor as well as variability between patients will probably require treatment with more than one chemosensitizer. Multi-pump blockers, will have distinct self-explanatory advances over single-pump ones. Given the above-discussed need for additional chemosensitizers, it is important to contemplate what it takes to qualify a candidate molecule as an effective chemosensitizer for which pump inhibition is a single or a major mechanism.

We propose that a candidate molecule should meet three *in vitro* criteria prior to investigating its potential *in vivo*. The *in vitro* criteria are based on both functional and mechanistic principles. The most prominent one is cell demise: treatment of a given MDR tumor cell line, with a combination of the candidate molecule

and a chemotherapeutic drug, should significantly enhance cell death, compared with similar treatment with drug alone.

Mechanistic criteria include drug efflux and drug accumulation. Incubating MDR cells with a chemotherapeutic drug, with or without the candidate chemosensitizer, should result in higher intracellular drug accumulation in the latter case. Efflux of a chemotherapeutic drug from MDR cells, preferable under unidirectional conditions, should be significantly faster in the absence of the chemosensitizer candidate, than when it is present. If a candidate chemosensitizer meets all those criteria, there is merit in expanding the evaluation in several directions: testing, in the same cell line, different chemotherapeutic drugs drawn from those known to be substrates of a given MDR pump; testing different additional MDR cell lines; testing MDR cell lines with their parent sensitive lines (upon availability). Comparative studies to known chemosensitizers used as benchmarks, can stringent the evaluation of the candidate molecule.

Fluoxetine as a Multi-pump Chemosensitizer

Fluoxetine belongs among the first-generation of chemosensitizers, namely drugs approved for non-cancer indications and found to act as MDR modulators. Yet, one critical factor sets fluoxetine apart from other first generation members and indicates it may merit a separate category, possibly fourth-generation chemosensitizers. Unlike first-generation chemosensitizers with their drawbacks mentioned above, fluoxetine exerts its ability to chemosensitize MDR cells at low safe doses, well below its human safety range.

In Vitro Studies

Fluoxetine was tested in ABCB1/MDR tumor cells, in ABCC1/MDR tumor cells and in drug-sensitive tumor cells. Test drugs were the chemotherapies: ►Adriamycin (doxorubicin), ►mitomycin C, ►paclitaxel and ►vinblastine. The multi-pump chemosensitizers verapamil and cyclosporine A, shown to affect the ABCB1 and ABCC1 pump proteins, were used as benchmarks. All three criteria were tested.

Cytotoxicity – two measures are useful for evaluation of whether a chemosensitizer candidate meets the *in vitro* cytotoxicity criterion: IC_{50}, the drug concentration that generates 50% inhibition of cell proliferation which, in the case of MDR, is measured in the absence and the presence of a fixed chemosensitizer concentration; RF, the fold change in drug sensitivity, is calculated from the ratio of IC_{50} in the absence to that in the presence of the candidate. Fluoxetine, verapamil, and cyclosporine A were kept at low doses, where they do not affect cell viability. Fluoxetine had no effect on the response of drug-sensitive cells to chemotherapeutic drugs. RF values obtained for human breast cancer, colon cancer, and ►leukemia cell lines as well as mouse leukemia cell line were between 0.9 and 1.1. For doxorubicin, mitomycin C, and paclitaxel, fluoxetine-induced RF values in human ►pancreas cancer cell line and in human brain tumor (both expressing ABCC1 pumps), were in the range of 10–80. The same experiment using the benchmarks yielded RF values of 2–19. In mouse ►melanoma cell lines, and in resistant forms of ►breast carcinoma and ►leukemia (from human source) the RF values with the same drugs span from 20 to 70, where the benchmarks yielded only a minor RF numbers between 2 and 5.

Drug Efflux – The efflux of drugs from drug-sensitive cells was quite slow. Complete depletion of intracellular ►doxorubicin from human breast carcinoma took more than 10 h and was unaffected by fluoxetine or the other benchmarks. Drug efflux from other MDR-expressing pumps (both ABCB1 and ABCC1 proteins) was found to be rather fast. For example, under unidirectional flux conditions it took between 0.5 and 2 h for complete depletion of such cells from intracellular drugs (►doxorubicin, ►vinblastine, ►paclitaxel, and ►mitomycin C). The benchmarks slowed down drug efflux, increasing the time span for complete depletion up to 3–5 h. Fluoxetine showed a remarkable effect by slowing down the efflux, thereby increasing the time for complete depletion, to the range of 8–12 h, close to that of drug-sensitive cells.

Drug Accumulation – Drug accumulation was measured with fluorescent substrate like Rhodamine-123 and actual drugs. The benchmarks were found to increase intracellular drug accumulation compared to cells exposed to drugs alone. This effect was found in inherent and acquired MDR cells, whether the pump-protein was ABCB1 or ABCC1. Fluoxetine increased drug accumulation by three- to sevenfold better than the benchmarks.

In Vivo Studies

Following the *in vitro* findings, fluoxetine was studied in several different mouse tumor models with doxorubicin as the test drug. A number of parameters were unique to these studies: fluoxetine dose was well below human safety limits; it was administrated orally in the drinking water; it was given continuously from tumor inoculation until termination of the experiment. Most of the efforts were on efficacy, but it was initially verified that fluoxetine did not alter the drug's pharmacokinetics, a problem encountered with some previous-generation chemosensitizers. Biodistribution was also tested showing that while fluoxetine generated a 12-fold increase in doxorubicin accumulation in ►lung tumors, it had no effect on drug accumulation in liver, spleen and kidneys of tumor-bearing mice. Several

tumor-bearing mice models have been tested to confirm efficacy. Those included inherent (intrinsically inherent) tumors expressing ABCB1 and separately ABCC1; models of lung metastasis as well as lung tumors (as primary source); human tumors inoculated to immunodeficiency mice and mouse tumors. In all cases fluoxetine attenuated tumor progression and in human tumors it even caused complete regression in 40% of the mice while the other mice from this group showed dramatically decreased tumor size and ►metastatic burden in lung tumors that was mirrored in increased survival rate. The survival rate of animals bearing tumors that was treated with a combination treatment of both chemotherapy and fluoxetine was two- to fourfold more than their controls (including the mice that got only chemotherapeutic drug) in different tumor-bearing mice.

Conclusions

The need to provide cancer patients with an arsenal of clinically approved chemosensitizers that will address the different MDR pump-proteins is still a remaining challenge. Despite the complexity and the multifactorial nature of cancer MDR, encouraging prospects do exist with respect to maturation of the third generation chemosensitizers into established clinical modalities.

Fluoxetine met all three *in vitro* criteria for acting as a chemosensitizer. It is important to emphasize that one criterion may be inconclusive. Fluoxetine also acted as a chemosensitizer *in vivo*. The data indicated that fluoxetine belongs to the category of multi-pump blockers, showing the capacity to reverse MDR generated by two major proteins ABCB1 (p-glycoprotein) and ABCC1 (MRP1), but further studies are required to determine whether MDR reversal is the only or the major mechanism by which fluoxetine works and whether fluoxetine can inhibit other pump proteins such as ABCG2 and other members of the MRP family.

Synonyms

FAK

Definition

The nonreceptor ►protein tyrosine kinase focal adhesion kinase (FAK) was originally isolated as a tyrosine-phosphorylated 125-kDa protein in ►v-Src-transformed

chicken embryo fibroblasts. FAK is a signal transducer of integrins and interact with certain soluble growth factors and chemokines. This kinase is involved in cellular processes like cell ►adhesion and spreading, ►migration, proliferation, and cell survival.

Characteristics

FAK consists of a central kinase domain, a large N-terminal ►FERM domain (protein 4.1, ezrin, radixin, and moesin homology), and of a large C-terminal ►FAT domain (focal adhesion targeting domain). Additionally, it comprises three proline-rich regions. The FERM-domain mediates interactions of FAK with growth factor receptors ►EGFR (epidermal growth factor receptor) and ►PDGF (platelet-derived growth factor receptor), which are often overexpressed in tumors and promote cell ►motility and ►invasion. The activation of the non receptor tyrosine kinase Etk (also called Bmx) by extracellular matrix proteins is regulated by binding to the FERM-domain of FAK. The FAT-domain mediates the binding of integrin-associated proteins such as paxillin and talin leading to the formation of focal contacts. An important C-terminal domain of FAK is the FAK-related nonkinase domain (►FRNK) which functions as a negative regulator of kinase activity. Overexpression of the FRNK segment that is separately expressed in certain cell types inhibits cell spreading and cell migration. The kinase domain induces adhesion-induced activation of FAK through phosphorylations of tyrosine residues at tyrosine residues Tyr397, Tyr576, and Tyr577. Additional phosphorylation sites are Tyr861 and Tyr925 in the C-terminal domain. Two proline-rich regions function as binding sites for ►Src-homology domain containing proteins.

FAK Phosphorylation and Regulation

Following attachment of the cell to extracellular matrix, subsequent integrin clustering results in rapid phosphorylation of FAK at Tyr397 and leads to the formation of phosphotyrosine docking sites for several classes of signaling molecules. So the ►phosphorylation of tyrosine residue 397 of FAK creates a high-affinity binding site for the ►SH2 domain of ►Src family tyrosine kinases and leads to the recruitment and activation of ►Src kinase and of p85 subunit of PI3-kinase, phospholipase C, and the adapter protein Grb7. The association of FAK and ►Src follows further phosphorylations of Tyr576, Tyr577, Tyr407, Tyr861, and Tyr925. A number of signaling proteins are phosphorylated and they are involved in adhesion, invasion, and survival signaling of tumor cells. Proline-rich recognition sites for ►SH3 domain-containing proteins provide binding motifs, for example ►Cas, an adaptor protein, or for ►GTPase activating proteins GRAF and ASAP1, which are involved in regulation of small GTP-binding proteins such as ►Rho and Arf proteins that play important roles in cytoskeletal reorganizations (Fig. 1).

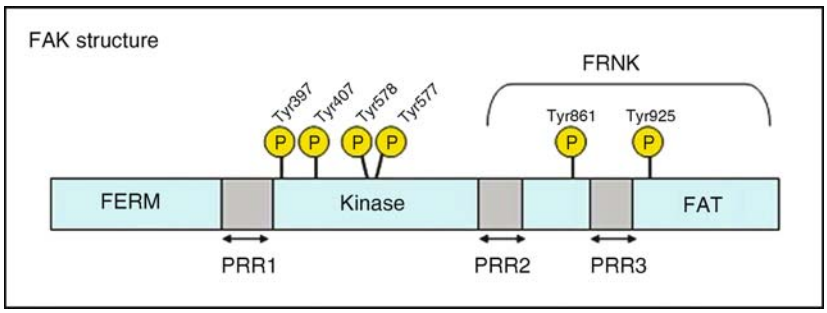
FAK functions in different downstream pathways and some are changed in tumors (Fig. 2).

Focal Contact

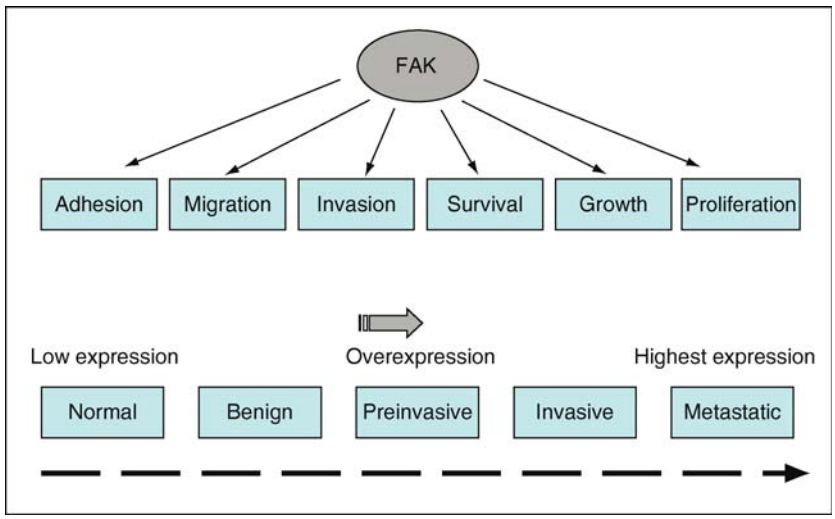
The actin cytoskeleton of cells interacts through integrins with the extracellular matrix. These sites of contact are named focal contacts. Focal contacts are composed of structural and regulatory proteins such as paxillin and talin, which recruit FAK and vinculin to focal contacts. α-Actinin, phosphorylated by FAK, binds to vinculin and crosslinks actomyosin stress fibers, which are further connected to the focal contacts. External signals are transduced into the cell interior that can generate additional cytoskeletal rearrangements.

Regulation of Focal Contacts

The regulation of assembly and disassembly of focal contacts is very important for the motility and migration



Focal Adhesion Kinase. Figure 1 The structure of focal adhesion kinase and tyrosine phosphorylation sites. The schematic illustration demonstrates the important N-terminal (FERM domain), central (kinase domain) and C-terminal domains (FAT and FRNK domains) of FAK with localization of their tyrosine (Tyr) phosphorylation sites and the three proline-rich regions (PRR1–3).



Focal Adhesion Kinase. Figure 2 Overview about the role of FAK signaling in different cellular processes and its overexpression in tumor progression.

of cells. The formation of strong or weak focal contacts is an important determinant whether a cell can migrate or not. It seems to be a cycle between binding of FAK to focal contacts and its release from these structures. The Src-mediated phosphorylation of FAK at Tyr925 leads to a SH2 binding site for ►GRB2 following Ras and ERK2 activation. The ►ERK activation results in the phosphorylation of FAK at Ser910, which subsequently leads to decreased paxillin binding and finally in release of FAK from focal contacts and to its turnover. In contrast, the Erk2-mediated phosphorylation of ►paxillin results in activation and binding of FAK to paxillin at new or growing focal adhesions.

Signaling Pathways in Cancer

Cell Migration

FAK is an important regulator of cell motility and cell migration, which are prominent processes in tumor ►progression and development of ►metastasis. To promote cell movements the FAK/Src complex phosphorylates Cas leading to recruitments of further ►SH2-containing proteins such as the adaptor protein ►Crk. The interaction of Crk with the ►DOCK180/ELMO complex results in ►Rac activation, a small ►Rho family GTPase. ►Rac1 is responsible for plasma membrane protrusions and formation of ►lamellipodia. Paxillin phosphorylation at tyrosines 31 and 118 also leads to Crk binding promoting Rac activation and paxillin is involved in modulation the dynamics of cell adhesion. The activation of RhoA promotes cell contractility and formation of stress fibers, contractile actin-myosin filaments, which are important for focal adhesion assembly. The regulation of RhoA and Rac1 activity is an important step in FAK signaling.

Invasion

To become invasive tumor cells have to degrade the ►basement membrane and migrate into the underlying ►stroma. The invasion of tumor cells through vessel walls and into the surrounding stroma requires the degradation of the ►extracellular matrix. FAK signaling is linked to the production and activity of matrix-degrading metalloproteinases (MMP), which represent important members of degradative proteases that can promote local tissue destruction and tumor-induced neoangiogenesis. For example, the activation of Rac1 and JNK (JUN N-terminal kinase) through the Src–Cas–Crk–DOCK180 complex results in increased MMP2 and MMP9 expression. The focal adhesion turnover is also facilitated by ►calpain-2-mediated cleavage of focal contacts. This protease is activated by ►EGF-induced ►MAPK (mitogen-activated protein kinase) and promotes the migration and invasion of tumor cells. There appears to be a correlation between FAK overexpression in tumors and their invasive and metastatic properties.

Cell Survival

Another role of FAK signaling is to promote the resistance to ►anoikis, a form of ►apoptosis resulting from loss of attachment to the extracellular matrix. The ability to survive in the absence of adhesion is an important characteristic of tumor cells to progress to a malignant phenotype. Several studies showed that inhibition of FAK signaling caused increased apoptosis. In addition, overexpression of FAK increases the adhesion independent growth of several tumor cell types. In contrast, analysis of nontumor cells did not found comparable effects on cell survival. The phosphorylation of tyrosine 397 and the kinase activity

of FAK are required for this process. Binding to the p85 subunit of PI3-kinase and following AKT kinase activation result in prevention of apoptosis. The suppression of anoikis is mediated by binding of FAK to the receptor-interacting protein (RIP), which consequently cannot bind to the dead receptor complex.

Growth and Proliferation

The adhesion-independent growth of tumor cells is an important step in tumor progression. For example, it has been shown that inhibition of FAK reduces the ability of breast cancer cells to grow in an adhesion-independent manner. Furthermore, it was demonstrated that FAK is overexpressed with increased tumor stages. This result was associated with increased rates of cell proliferation. Therefore, FAK may promote tumor growth through inhibition of apoptosis and acceleration of tumor cell proliferation.

Tumor Progression

A ►DMBA/TPA mouse skin carcinogenesis model was used, among others, to investigate the role of FAK in tumor ►progression. The results suggest that FAK expression and FAK-dependent cell signaling are increasingly enhanced with advanced stages of tumor progression and malignant progression. Normal epithelium and benign hyperplastic lesions have low FAK expression, whereas in preinvasive and invasive stages an overexpression of FAK was observed. In metastatic tumors the highest FAK expression was found. This overexpression seems to be a marker for an invasive and metastatic tumor phenotype.

Metastasis

►Metastasis is a process in which circulating tumor cells usually invade into potential host organs by breaking through vessel walls at the primary and secondary tumor site. In the blood flow the cells are exposed to shear forces requiring stabilization of their adhesive interactions under dynamic conditions in fluid flow. Similar to endothelial cells tumor cells can respond to external forces with increased integrin clustering and FAK activation. Exposed to this shear stress, motile cells can show enhanced FAK phosphorylation at the leading edge promoting a number of FAK-mediated tumor cell characteristics, such as migration and survival. This pathway appears to enable metastatic cells to resist shear forces within their target organs, to adhere and successfully colonize target organs.

FAK Overexpression

Many studies reported overexpression of FAK in various tumor types using different detection methods at mRNA, DNA, and protein level. Increased expression was found in patients' specimens of epithelial tumors of colon, liver, breast, ovary, stomach, thyroid, prostate, and oral cavity. Elevated FAK expression was also detected in many tumor-derived cell lines. These expression levels correlate with tumor progression.

Cancer Therapy

Once modified, the involvement of FAK in many cellular processes qualified FAK as a determinating and possibly rate-limiting pathway for tumor progression making this kinase an interesting target for anticancer therapy. In preclinical models, the inhibition of FAK signaling already demonstrated promising therapeutic effects by prevention of tumor cell migration and invasion resulting in higher survival rates. However, further preclinical investigations and clinical studies are necessary to establish FAK as a novel treatment strategy.

Follicular Lymphoma

Definition

FL; is a common low grade ►B-cell lymphoma, which accounts for ca. 40% of B-cell lymphomas. Typically these lymphomas carry a ►translocation t(14;18), which brings the rearranged ►BCL-2 gene (chromosome 18) under the control of the immunoglobulin enhancer (chromosome 14). Tumors usually express B-cell markers

and surface immunoglobulin. Many patients do not require treatment for a long time. A characteristic feature is a spontaneous "waxing and waning" of the enlarged lymph nodes, which may reflect residual but inefficient attempts of the immune system to eliminate the cancer. FL is not considered curable, except for patients in very early stages of disease. Often this lymphoma transforms into a more aggressive form of lymphoma, diffuse large B-cell lymphoma, which carries a poor prognosis.

Synonyms

Follicular adenomas; Papillary carcinoma; Follicular carcinoma; Anaplastic carcinomas

Definition

Are tumors derived from the thyrocyte, the cellular unit of ►thyroid follicle. These tumors include benign adenomas, papillary and follicular carcinomas, two entities considered as differentiated carcinomas, and undifferentiated or anaplastic carcinomas.

Characteristics

Clinical thyroid nodules, that are the consequence of abnormal localized growth of the thyroid tissue, are detected in 4–7% of the general population in a iodine sufficient area. The prevalence is higher in countries affected by moderate or severe iodine deficiency. Infraclinical nodules are even more common, depending on the techniques used for screening, and ultrasonography detects nodules in more than 50% of women older than 60 years. About 5% of thyroid nodules are malignant. The annual incidence of thyroid carcinoma, the most common malignancies of endocrine organs, ranges from 1.2 to 3.8 per 100,000, being twice as high in females as in males. The annual mortality rate ranges from 0.2 to 2.8 per 100,000.

Classification

The clinico-pathological classification of thyroid nodules distinguishes: non-neoplastic nodules, found in patients with either hyperplasia or inflammatory and ► autoimmune thyroid diseases, benign follicular thyroid adenomas, including non-functioning or cold nodules (80% of all nodules) and functioning or hot nodules, and thyroid carcinomas. Most thyroid nodules are benign lesions: a follicular adenoma is defined as a benign encapsulated tumor with evidence of follicular cell differentiation.

Less than 10% of cold nodules are malignant follicular thyroid tumors, i.e. thyroid carcinomas. Among these, 75% present evidence of follicular differentiation and thus are designated as differentiated cancers; they include two distinct histotypes, papillary carcinomas (PTC), characterized by distinctive nuclear features, and follicular carcinomas (FTC). Undifferentiated or anaplastic carcinomas are very rare and defined as highly malignant tumors with undifferentiated cells.

Etiology

Several risk factors for thyroid carcinoma have been identified from epidemiological studies. About 3–5% of Papillary thyroid carcinoma (►thyroid carcinogenesis) have a familial component history, and can occur in the context of rare familial syndromes (►familial polyposis coli, ►Cowden disease). Pre-existing benign thyroid diseases increase risk of developing a thyroid carcinoma. In areas with iodine deficiency compared to those with sufficient iodine intake, the prevalence of nodules is higher but the incidence of thyroid carcinoma is identical; follicular and anaplastic carcinomas are more frequent and papillary carcinoma is less frequent. The role of other dietary factors, such as fish consumption, cyanogens and smoking remains unclear.

Radiation exposure during childhood increases the risk of developing ►PTC later in life, probably by inducing chromosomal rearrangement. This can be related to an exposure to external radiation or to radioactive iodine, as a consequence of Chernobyl accident.

Diagnosis

Thyroid nodules are usually asymptomatic. Most of them are found by the patient himself or during a physical examination. The diagnostic evaluation of thyroid nodules essentially relies on serum TSH determination, ultrasonography which is useful for establishing the size of the lesion and its solid or cystic nature and of ► Fine-Needle Aspiration Cytology. In some cases, cytology cannot differentiate adenoma from carcinoma and the use of immunohistochemical markers contributed only marginally to better defining FTC.

Thyroid scan is performed only in patients with a low serum ►TSH level, to ascertain the presence of a hot nodule. Computerized tomography scans and magnetic resonance imaging are performed only in the rare patients with extensive disease. Thyroid carcinomas may release amounts of thyroglobulin in blood but high levels are also found in a variety of benign thyroid diseases and should not be measured.

Treatment

In the vast majority of cases, follicular adenomas are simply followed up with no therapy. Surgery is indicated only when compression or discomfort is present.

Initial treatment of thyroid carcinomas is based on total thyroidectomy with central lymph node dissection in patients with a PTC. Radioiodine is administered post operatively only in patients with either persistent disease or with poor prognostic indicators, such as age $\geq$ 45 years, poorly-differentiated carcinomas and extended disease.

All patients with thyroid cancer are treated post-operatively with levothyroxine.

Follow-up aims to detect persistent or recurrent disease at an early stage and is based on the combined use of thyroglobulin testing following recombinant human TSH stimulation and of neck ultrasonography. The majority of patients are cured, as demonstrated by the work-up performed at 1 year.

Genetics

The putative relationships between adenomas and carcinomas and the mechanisms of ►thyroid carcinogenesis are not clearly understood. Activating point mutations of the *RAS* gene are detected in 30–40% of benign and malignant follicular thyroid tumors. Chromosomal imbalances are also frequent in FTCs, particularly the PAX8-PPARγ1 rearrangement that is found in about 30% FTCs but also in some follicular adenomas. These observations suggest that FTC proceeds from at least two distinct oncogenic events, namely *RAS* mutations and PAX8-PPARγ1 rearrangement. Papillary thyroid carcinomas are characterized in 70% of cases by the presence of either a ►RET/PTC rearrangement, or an activating point mutation of *RAS* or *BRAF* genes. These genetic alterations are independent and nonoverlapping, and induce a constitutive activation of the MAP-kinase pathway. The higher frequency of RET/PTC rearrangements in radiation-associated PTC and also in some adenomas suggest that they may be directly induced by radiation exposure. Overexpression of several growth factors, such as ►MET, ►VEGF, ►FGF1 and 2 and ►IGF1, is believed to be secondary to other oncogenic events. Finally, inactivating mutations of the ►p53 gene are found only in ►anaplastic thyroid carcinomas.

Synonyms

HFH-11B; Trident; WIN; FKHL-16; MPP2

Definition

FoxM1 is a transcription factor of the Forkhead family. The Forkhead family consists of about 50 transcription factors that share a conserved 100 amino acid (Forkhead or winged-helix) DNA binding domain, which is responsible for DNA binding via the consensus TAAACA site. The human FoxM1 gene contains ten exons, and it expressed as three alternatively spliced variants (a, b, c). FoxM1 is generally expressed in dividing cells and it is required for proper cell proliferation. Furthermore, FoxM1 is essential for the execution of ►mitosis, and it is overexpressed in most human cancers. FoxM1 may directly induce tumorigenesis because of its dominant role in cell proliferation. Therefore, FoxM1 is an attractive target for small molecule inhibition in cancer treatment.

Characteristics

FoxM1 expression correlates with the proliferative state of cells. It is expressed in all embryonic tissues and in proliferating cells of epithelial and mesenchymal origin. FoxM1 expression is not detectable in quiescent cells, but it is induced when these cells are stimulated to re-enter cell cycle. Along these lines, FoxM1 is also expressed in the majority of dividing mammalian cells, but its expression is turned off in terminally differentiated, non-dividing cells. Developmental studies suggest that FoxM1 may play a role in the development of nervous system and it is critical during organogenesis. FoxM1 is required for hepatoblast differentiation toward biliary epithelial cell lineages and for embryonic development of pulmonary vasculature. FoxM1 expression is also induced in proliferating cells following lung and liver injury suggesting that FoxM1 is essential for ►tissue regeneration and repair. Similarly, endothelial cell-restricted FoxM1-deficient mice exhibited a marked impairment in endothelial barrier repair and a significant increase in mortality following acute lung injury. Following vascular injury, FoxM1$^{-/-}$ lungs displayed diminished cell proliferation, increased expression of ►CDK inhibitor p27 and decreased expression of ►cyclin B1 and ►Cdc25. Deletion of FoxM1 in endothelial cells led to decreased expression of cell cycle promoting proteins and Cdk activities suggesting that FoxM1 plays a critical role in the restoration of endothelial barrier function following vascular injury.

FoxM1 is induced early during the G1 phase of the cell cycle and its expression continues through S phase and mitosis. Transcriptional activity of FoxM1 is dependent on its phosphorylation because cyclin-CDK1/2-dependent phosphorylation of FoxM1 during the cell cycle is required for the recruitment of the transcriptional co-activator ►p300/CBP. FoxM1 activation is also dependent on Ras-MAPK pathway, which regulates FoxM1 subcellular localization and transcriptional activity. Overall, it is appears that multiple FoxM1 phosphorylation events may regulate its activity during cell cycle progression. FoxM1 is required for the execution of the mitotic program because FoxM1-depleted cells fail to progress beyond the prophase stage of mitosis. FoxM1 transcriptionally activates ►cyclin B, ►survivin, ►Aurora B kinase, ►Cdc25 phosphatase and Plk1, all of which are implicated in mitosis. In addition, FoxM1 induces cell cycle progression through transcriptional induction of Skp2 and Cks1 genes (specificity subunits of Skp1-Cullin1-F-box ubiquitin ligase complex) that leads to the degradation of cell cycle/►cyclin-dependent kinase inhibitors p21^{WAF1} and p27^{KIP1}. FoxM1c also transactivates ►c-myc, c-*fos*, ►*hsp70* and histone *H2B/a* genes all of which are involved in proliferation and tumorigenesis.

FoxM1 is one of the most significantly upregulated genes in human solid tumors. FoxM1 is overexpressed in non-small cell lung carcinomas, anaplastic astrocytomas, glioblastomas, basal cell carcinomas, hepatocellular carcinomas and intrahepatic cholangiocarcinomas. Furthermore, FoxM1 is overexpressed in primary breast tumors, and its depletion by RNA interference (RNAi) in these cancer cells leads to mitotic catastrophe. Since FoxM1 expression is specifically increased in breast carcinomas relative to normal tissue FoxM1 could be involved in promoting cellular transformation of breast epithelial cells. Approximately 60–80% of all breast cancers overexpress estrogen receptor (ER) and ER plays a key role in breast cancer development. It was shown that FoxM1 is a transcriptional regulator of ER expression in breast cancer cells and silencing of FoxM1 expression in breast cancer cells using RNAi resulted in strong inhibition of ER expression. FoxM1 expression is essential for the

development of liver cancer because it was demonstrated that FoxM1$^{-/-}$ mice livers are highly resistant to developing hepatocellular carcinomas in response to a Diethylnitrosamine (DEN)/Phenobarbital (PB) liver tumor induction protocol. Inhibition of FoxM1 transcriptional activity by a cell-penetrating peptide containing amino acids 24-46 of FoxM1►p19^{ARF} also reduced anchorage-independent cell growth and inhibited development of liver cancer in DEN/PB mouse models.

FoxM1 also contributes to cellular transformation by human papillomavirus HPV-16 by interaction with oncogenic HPV-E7 protein. This interaction increases the transforming activity of HPV-E7 and enhances the transcriptional activity of FoxM1. Increased levels of FoxM1 accelerated prostate cancer development and progression in mouse models. Knockdown of FoxM1 by RNAi in several prostate cancer cell lines led to a significant reduction in cell proliferation and anchorage-independent cell growth in soft agar. FoxM1 was significantly overexpressed in basal cell carcinomas (BCCs), but not in ►squamous cell carcinomas. Constitutive expression of the transcription factor ►Gli1, the known target of ►Sonic Hedgehog (Shh) signaling, led to induction of FoxM1 mRNA expression, and coexpression of Gli1 and FoxM1 proteins was observed within the same BCC tumor sample. Since Shh plays a key role in the development of BCC, FoxM1 may be a putative target of Shh pathway. Similarly, in gliomas where Shh is also implicated in tumorigenesis FoxM1 protein has been overexpressed. The levels of FoxM1 expression in human glioma tissues was directly correlated with the glioma grade and inversely correlated with patient survival. Enforced FoxM1 expression in non-tumorigenic glioma cell lines caused them to form xenograft tumors in nude mice, while inhibition of FoxM1 expression by RNAi suppressed their anchorage-independent growth in vitro and tumorigenicity in vivo.

Since FoxM1 is overexpressed in many types of cancer where it may be required for proliferation of cancer cells, it is an attractive target for drug development. To obtain a screening system for the identification of small molecule inhibitors of FoxM1 transcriptional activity in a high-throughput fashion, we developed a cell line that stably expresses doxycycline/tetracycline-inducible FoxM1-GFP, firefly luciferase under the control of multiple FoxM1 response elements, and a control renilla luciferase under the CMV promoter. We used this cell line to screen for FoxM1 transcriptional inhibitors in libraries of small molecules (Challenge Set and Diversity Set) obtained from NCI. We selected only those compounds that specifically inhibit FoxM1 and we identified a well-known thiazole group antibiotic ►siomycin A (NSC-285116) as an inhibitor of the transcriptional activity of exogenous and endogenous FoxM1. In addition, using quantitative real-time RT-PCR, we found that the mRNA levels of the transcriptional targets of FoxM1, such as ►Cdc25, ►survivin and CENPB were sufficiently reduced after ►siomycin A treatment. Furthermore, Siomycin A may antagonize FoxM1 function by at least two distinct mechanisms – one by blocking its phosphorylation, thereby leading to its reduced transactivation ability, and the other by down-regulating its mRNA and protein levels. Using clonogenic assay, siomycin A may act as an effective inhibitor of FoxM1-based cellular transformation. In addition, siomycin A induced potent apoptosis in human breast and liver cancer cell lines, that correlated with inhibition of FoxM1 expression. Now, it is necessary to determine if inhibition of FoxM1 by siomycin A leads specifically to apoptosis of cancer cells, and to test this drug in animal models of human cancer. FoxM1 inhibitors such as siomycin A or other small molecules may have potential as anticancer drugs.

In summary, FoxM1 is often overexpressed in many types of human tumors and it appears that FoxM1 expression is critical in the process of cellular transformation. FoxM1 function is inhibited by several tumor suppressors, such as ►p19 ARF, pRb, p16 and p53 and may be activated by multiple oncogenic signaling pathways suggesting that FoxM1 may be classified as a proto-oncogene. However, it remains to be elucidated if overexpression of FoxM1 in cancer cells is a result of cell transformation that leads to increased proliferation and FoxM1 expression, or whether FoxM1 directly collaborates with other oncogenes to induce cell transformation. In any case, if cancer cells require high levels of FoxM1 expression for their survival, then FoxM1 appears to be an attractive target for anticancer therapy. Identification of the FoxM1 inhibitor siomycin A suggests that targeting of FoxM1 by small molecules is a feasible alternative and in a short time this approach may help to identify novel anticancer compounds for clinical trials.

Formalin-fixed Paraffin-embedded Tissue

Definition

The usual process needed for a tissue to be studied under the microscope in ►Pathology. Because of this process most high molecular weight DNA is destroyed as well as almost all RNA molecules. Therefore it is a good source of small-sized DNA molecules, and an inconsistent way to get RNA.

Formation of New Blood Vessels

►Angiogenesis

Forward Chemical Genetics

Definition

An approach to studying biology in which a compound that induces a particular biological phenotype is first detected. Subsequently, the affected target and its relationship to the phenotype are identified.

►Small Molecule Screens

FOS

Definition

v-fos FBJ murine osteosarcoma viral oncogene homolog, is a leucine-zipper protein of 380 amino acids and 40 kD. The human FOS gene locus maps at 14q24.3 and the mouse fos gene locus at chromosome 12 (40.00 cM). FOS is a protooncogene and c-Fos is a nuclear phosphoprotein that forms a tight but non-covalently linked complex with c-Jun to the ►AP-1 transcription factor. c-Fos expression increases rapidly upon growth factor stimulation or wounding of cultured cells.

Fossil Tree

►Ginkgo Biloba

F

FOX

Definition

Refers to Forkhead box genes; Encode a family of ►transcription factors that play important roles in regulating the expression of genes involved in cell growth, proliferation, differentiation, and longevity. Many FOX proteins are important to embryonic development and some are implicated in tumorigenesis by their expression level.

►Forkhead box M1

FOXC2

Definition

A forkhead family transcription factor that is expressed in human lymphatic vessels. Studies in mice indicate this transcription factor regulates lymphatic capillary and valve development as deletions of this gene cause aberrant lymphatic vessel development that resembles the human disease ►lymphedema-distichiasis.

►Lymphangiogenesis

FOXO1A

Definition

Is the acronym for forkhead box O1A (►rhabdomyosarcoma), also known as FKHR.

►Beckwith-Wiedemann Syndrome Associated Childhood Tumors

FOXO 3A

Definition
Forkhead box O3A, a member of the forkhead family of transcription factors.

FRA3B

Definition
The fragile site or region at chromosome region 3p14.2. The constitutive fragile site at 3p14.2 (FRA3B) is the most frequently activated constitutive fragile site, with up to 50% of normal lymphocyte derived metaphases showing the characteristic gaps or decondensation at 3p14.2 after ►aphidicolin treatment. Common or constitutive fragile sites are now known to be fragile regions; i.e. the position of the gaps can occur at many different sites within a fragile region, which may extend up to a megabase in size.

►FHIT
►Fragile Sites

FRA16D

Definition
The fragile site or region at chromosome region 16q23.3.

►WWOX
►Fragile Sites

Fragile Histidine Triad

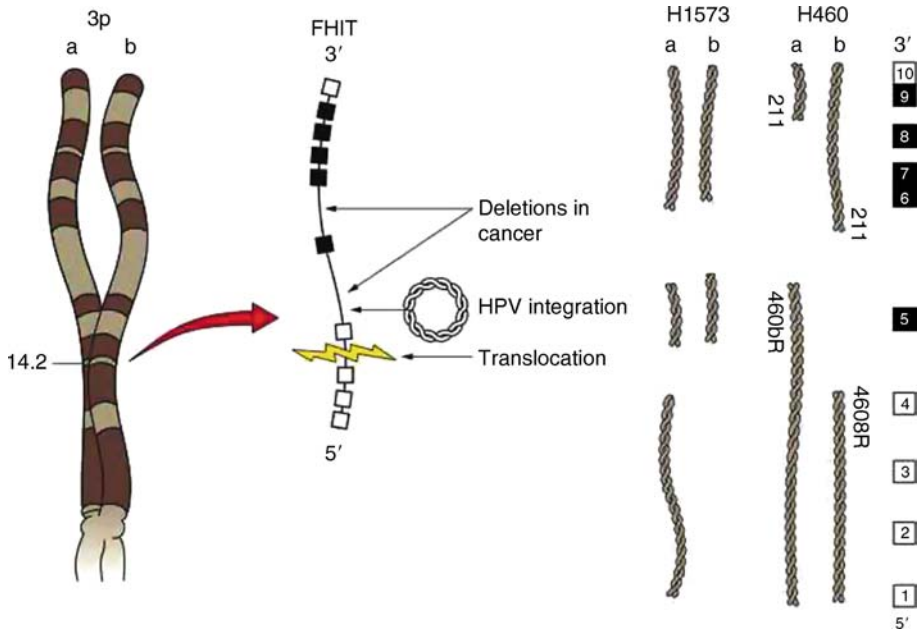
Kay Huebner, Helen Pace
Department of Molecular Virology, Immunology and Medical Genetics, Ohio State University Comprehensive Cancer Center, Columbus, OH, USA

Synonyms
FHIT

Definition
The Fragile Histidine Triad (*FHIT*) gene, at human chromosome region 3p14.2 encompasses a familial ►clear cell renal cancer chromosome translocation breakpoint and the most active chromosomal constitutive ►fragile site, ►*FRA3B*. The gene is inactivated in a large fraction of most types of human cancers, through intragenic ►hemizygous or ►homozygous deletions, ►hypermethylation of regulatory region ►CpG islands, or a combination of these mechanisms, probably as a result of ►DNA damage to the *FRA3B* fragile region.

Characteristics
The Gene
The *FHIT* genomic locus spans >1.6 Mb of DNA, while the *FHIT* cDNA is 1.1 kb. Fig. 1 illustrates the structure of this ►tumor suppressor gene and the positions of fragile region landmarks such as the familial renal cancer translocation and the ►human papillomavirus integration site. The right side of Fig. 1 illustrates the types of biallelic deletions observed in this locus in lung cancer and other cancer-derived cell lines. Sequencing of the gene and isolation of cancer cell deletion endpoints revealed that many deletion endpoints are within recombined LINE-1 repeats, suggesting that ►carcinogen damage to the fragile region is repaired through recombination between LINE-1 (►LINE element) sequences flanking the damaged region, with concomitant loss of portions of the *FHIT* gene. The murine *Fhit* locus is also fragile and the mouse Fhit protein is more than 90% identical to human Fhit. One *Fhit* allele was inactivated in murine ►embryonic stem (ES cells) to create *Fhit* ►knockout mice in which the gene is functionally inactive. Mice heterozygous or homozygous for the mutant *Fhit* locus are fertile, long-lived and exquisitely sensitive to tumor induction by carcinogens.

The Protein
The amino acid coding region begins in exon 5, ends in exon 9 (Fig. 1) and encodes a protein of 147 amino acids.

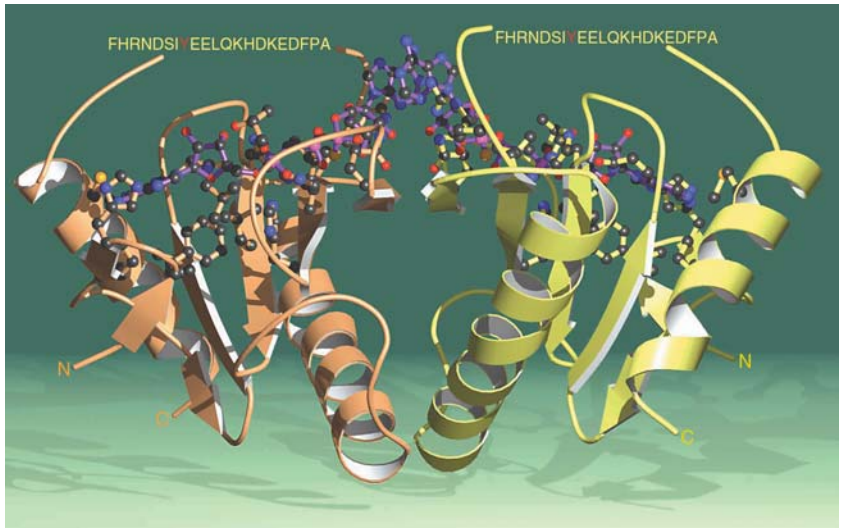


Fragile Histidine Triad. Figure 1 The *FHIT* gene at chromosome region 3p14.2. The gene encompasses *FRA3B* where numerous chromosomal alterations are observed in cancer cells. This locus is highly susceptible in all individuals to carcinogen-induced breakage. As a consequence chromosomal alterations including deletions, insertions and translocations occur. The chromosome alterations frequently lead to loss of parts of the Fhit protein-coding sequence and the consequent loss of Fhit protein expression (on the right are examples of alleles in lung cancer-derived cells). The *FHIT* gene is hemi- or homozygously deleted in the majority of lung, stomach, esophageal and kidney cancers and in a large fraction of many other cancers; point mutations are almost never observed. Fhit protein is absent or reduced in lung, stomach, kidney and other cancers, consistent with a role as a tumor suppressor and fulfilling the prediction that fragile site alterations contribute to the neoplastic process.

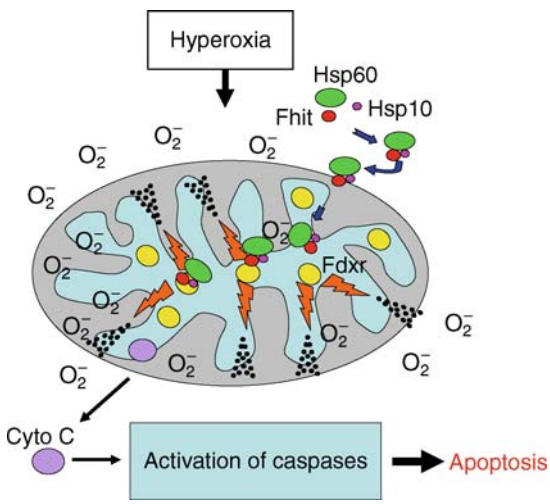
The Fhit protein is a member of a large Histidine Triad (HIT) gene family of nucleotide binding proteins with four conserved histidine residues, three of which occur in a histidine triad, HxHxHxx (where "x" is hydrophobic). There are more than thirty HIT genes in species representing all branches of life. Fhit and its orthologs form a closely related subfamily of HIT proteins, found only in eukaryotes, that bind and hydrolyze dinucleoside oligophosphates, especially diadenosine tri- or tetraphosphates (Ap3A, Ap4A), to produce a nucleoside monophosphate plus a nucleoside di- or tri-phosphate. Site-directed mutagenesis of the conserved Fhit histidine residues to asparagines results in decreased enzymatic activity for each mutation, with the largest change occurring with replacement of the central histidine, H96. Thus, H96 is essential for hydrolysis of the diadenosine tri- or tetra-phosphate but the Fhit H96N mutant still acts as a tumor suppressor, in accord with the proposal that the Fhit-substrate complex sends the tumor suppression signal. Fhit is constitutively dimeric, existing as a highly curved, ten-stranded antiparallel-sheet, which presents nucleotides on the top surface. Amino acids 107-127, following the catalytic site, form an unstructured loop (Fig. 2) within the loop, amino acid Y114 can be phosphorylated by ►Src family kinases and FhitY114 mutant proteins lose apoptotic and tumor suppressor functions. Protein cross-linking and ►proteomics methods were used to characterize a Fhit protein complex involved in triggering Fhit-mediated apoptosis. This complex includes ►Hsp60 and Hsp10 that mediate Fhit import into mitochondria, where it interacts with ►ferredoxin reductase (Fdxr), responsible for transferring electrons from NADPH to cytochrome P450 via ferredoxin (Fig. 3). Fhit restoration significantly increases the production of ►reactive oxygen species (ROS) and the rate of ►apoptosis of lung cancer cells under oxidative stress conditions; conversely, Fhit-negative cells escape apoptosis, carrying serious oxidative DNA damage that may contribute to an increased mutation burden.

Bioactivity

The biological functions of Fhit have been studied in human cancer cell lines stably over-expressing exogenous Fhit. Tumorigenicity was suppressed in gastric, lung, renal and breast cancer lines. Similarly, cancer cell lines infected with adenovirus carrying the *FHIT* gene were killed by apoptosis. Fhit sends signals for apoptosis



Fragile Histidine Triad. Figure 2 Architecture of Fhit–substrate complex. View of the Fhit dimer with bound substrate. Monomers of Fhit are yellow and copper; substrate molecules are purple. Atoms are colored as follows: carbon, black; nitrogen, blue; oxygen, red; phosphorus, magenta; sulfur, orange. The amino acid sequence of the unstructured loop is also shown. (adapted from Pace et al. (1998) Proc Natl Acad Sci USA 95:5484–5489).



Fragile Histidine Triad. Figure 3 Model depicting proposed Fhit signal pathway induced by hyperoxia. Fhit protein binds the Hsp/Hsp10 complex in the cytosol, and is carried to the mitochondria; in the mitochondria Fhit interacts with Fdxr protein and in the presence of H_2O_2, which creates hyperoxic conditions, ROS is generated, leading to release of cytochrome C, followed by apoptosis. Reduced Fhit leads to reduced ROS and reduced apoptosis.

in response to various types of cellular stress: in response to DNA damaging agents such as ►UVC light and ►mitomycin C, Fhit-deficient cells escape apoptosis and accumulate mutations; over-expression of wild-type Fhit leads to reduced expression of activated ►Akt and ►Survivin, reduced expression of cyclophilin A, and reduced expression of phospho ►Chk1; Fhit, when over-expressed, enters mitochondria, interacts with Fdxr protein and causes an increase in Fdxr protein level, associated with generation of ROS and followed by programmed cell death (Fig. 3). Fhit does not affect the *FDXR* transcriptional level but may affect stability of the protein. Fhit localizes in both cytosol (where it interacts with Hsp60 and Hsp10) and mitochondria where it interacts with main mitochondria chain respiratory proteins. Interestingly, Fhit restoration significantly increases the production of ROS in lung and colon cancer-derived cells in response to stressful treatments. Study of Fhit deficient mouse tissue-derived and human cancer-derived cells *in vitro* has led to several important conclusions: Fhit is not a cell cycle regulated gene; repair protein-deficient cancers are more likely to be Fhit-deficient; Fhit-deficient cells show enhanced resistance to UVC, ►mitomycin C and ►ionizing radiation-induced cell killing, possibly due to strong activation of the ►*ATR/CHK1* pathway following DNA damage; Fhit-deficient cells show higher efficiency of homologous recombination repair, a major double-strand break repair pathway. The DNA damage-susceptible *FRA3B/FHIT* chromosome fragile region paradoxically encodes a protein that is necessary for protecting cells from accumulation of DNA damage, through modulation of ►checkpoint proteins and inactivation of Fhit contributes to accumulation of abnormal checkpoint phenotypes in cancer development.

Clinical Relevance

More than 640 reports describe the involvement of Fhit loss in development in nearly every type of cancer. Important findings are that: (i) large fractions of kidney, lung, gastric, colon, pancreatic, breast, cervical and other cancers show absence of expression of Fhit protein, suggesting that its inactivation is critical in the progression of many human cancers, especially cancers of organs directly exposed to environmental carcinogenic agents; (ii) loss of Fhit expression in cancers can result from hemi or homozygous deletion or translocation within the *FHIT* gene or hypermethylation of CpG islands in the promoter region or a combination of these mechanisms; (iii) Fhit loss is a very early step in development of some types of cancers and can be associated with prognostic features or survival; (iv) loss of Fhit protein is associated with loss of other fragile genes in breast cancer; (v) an ►SNP within the *FHIT* locus is associated with development of ►prostate cancer in some families with increased prostate cancer susceptibility; (vi) *FHIT* restoration in a number of malignant cell lines triggers ►apoptosis *in vitro* and in preclinical models; (vii) *Fhit* knockout mouse strains show approximately tenfold enhanced susceptibility to carcinogen-induced tumors and have been useful in development of tumor models for prevention and therapeutic studies; oral Fhit gene therapy can prevent and reverse tumor growth in Fhit-deficient mice; (viii) Fhit enhances ROS-related apoptotic effects of chemotherapeutic agents.

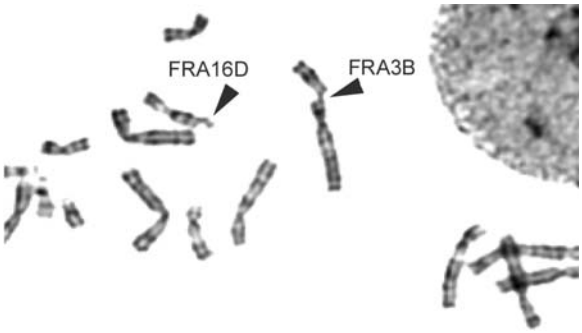
Fragile Sites

Ryan L. Ragland, Thomas W. Glover
Department of Human Genetics, University of Michigan, Ann Arbor, MI, USA

Definition

Fragile sites are specific chromosomal loci that are especially prone to forming gaps and break as seen on ►metaphase chromosomes under conditions of replication stress.



Fragile Sites. Figure 1 Examples of the common fragile sites FRA3B (3p14.2) and FRA16D (16q23) on human chromosomes.

Characteristics

Expressed fragile sites are seen as gaps and breaks on metaphase chromosome preparations of cultured cells. Fragile sites are not usually expressed on chromosomes under normal replication conditions, but rather become detectable under conditions that partially inhibit DNA replication. The formation of gaps and breaks at fragile sites is thought to represent an underlying unusual aspect of chromosome structure or function.

Categories of Fragile Site

Fragile sites are broadly classified into two main categories, rare and common based on their population frequency, pattern of inheritance and method of induction.

Rare Fragile Sites

►Rare fragile sites are seen in a small proportion of individuals and are inherited in a Mendelian manner. Some, such as FRAXA, are associated with human genetic disorders, and their study led to the identification of nucleotide-repeat expansion as a frequent mutational mechanism in humans. There are currently 31 known rare fragile sites. Nine of these have been cloned: FRAXA (Xq27.3), FRAXE (Xq28), FRAXF (Xq28), FRA10A (10q23.3), FRA10B (10q25.2), FRA11B (11q23.3), FRA12A (12q13.1), FRA16A (16q13.11), and FRA16B (16q22.1).

The major group of rare fragile sites is the folate-sensitive group, associated with CGG-repeat expansion. This group includes FRAXA, in the *FMR1* gene, which is responsible for the ►fragile-X syndrome, and FRAXE in the *FMR2* gene, which is associated with nonspecific mental retardation. In addition, an autosomal folate-sensitive fragile site, FRA12A, in the *DIP2B* gene has recently been associated with mental retardation. Other non-folate sensitive rare

fragile sites, characterized by expanded AT-rich minisatellite repeats, are induced by ►bromodeoxyuridine or ►distamycin-A.

Common Fragile Sites

►Common fragile sites (CFSs), comprise the largest class of fragile sites. These sites are found in all individuals and are considered to be a normal component of chromosome structure. Unlike rare fragile sites, CFSs are not caused by expansion of ►trinucleotide repeats. CFSs form gaps and breaks on metaphase chromosomes when DNA synthesis is partially inhibited by folate stress or using compounds such as ►aphidicolin, an inhibitor of DNA polymerases. In addition to forming gaps and breaks on metaphase chromosomes, CFSs exhibit additional features of unstable DNA. They are hot spots for deletions, sister ►chromatid exchanges, ►chromosomal translocations, integration of transfected and viral DNA sequences, and chromosome breaks associated with initiation of gene ►amplification.

There are over 76 different CFSs with one or more seen on most human chromosomes. However, just 20 of these sites account for more than 80% of all gaps and breaks seen in aphidicolin-treated lymphocytes. The most highly expressed of these sites are FRA3B (3p14.2) and FRA16D (16q23). CFS regions span several hundred kilobases to over a megabase of DNA. Despite their size, a number of these sites are fully contained within large genes such as the tumor suppressor genes ►*FHIT* (fragile histidine triad gene) at 3p14 and ►*WWOX* (WW domain containing oxidoreductase) at 16q23.

CFSs appear to be highly conserved during mammalian evolution. ►Orthologs of human CFSs have been found in the ►syntenic regions of a number of other mammalian species, including other primates, cat, dog, pig, horse, cow, Indian mole rat, deer mouse, and laboratory mouse strongly suggesting an underlying function for these sites in the normal functioning of the cell.

Molecular Basis of Fragile Site Expression

Rare Fragile Sites

The expression of all rare fragile sites studied at the molecular level is dependent on an expansion of repeat DNA sequences. Most, such as the folate sensitive fragile site FRAXA (Xq27.3) in the 5′ non-coding region of the *FMR-1* gene, are caused by an expansion of CGG trinucleotide repeats. Normal individuals have anywhere from 1–50 CGG repeats. Whereas, in the disease state the number of repeat units increases dramatically, to 200–2,000 repeats. Trinucleotide repeats are inherited in a Mendelian manner but also follow a phenomenon known as ►anticipation whereby an increase of severity of symptoms and an earlier age of onset of disease is seen in succeeding generations. Other rare fragile sites are associated with an expanded AT-rich minisatellite repeat sequence. The rare fragile sites FRA16B (16q22.1) and FRA10B (10q25.2) are examples in which expansion of the existing AT-rich minisatellite repeats, to 33 and 42 base pairs respectively, is the cause of fragility.

Common Fragile Sites

Less is currently known about the molecular basis of expression of common fragile sites. While similar in appearance to rare fragile sites at the cytogenetic level, common fragile sites are not caused by expansion of trinucleotide or other simple repeat sequences. All common fragile sites are AT-rich and contain numerous repeat elements such as, LINES, SINES, and other long repeat elements. Common fragile sites contain clusters of sequences with a potential for high ►DNA flexibility and formation of unusual DNA structures that could impede DNA replication. Furthermore, these sites are among the last sites in the genome to replicate and late or incomplete DNA replication may contribute to their fragility. Despite these findings there is no clear answer as to why these sites are more sensitive to replication stress than other none fragile loci.

Cellular Regulation of Common Fragile Site Instability

Mechanisms of fragile site expression provide important clues about the consequences of stalled or perturbed replication in mammalian cells. It has been shown that the ►ATR (►ataxia-telangiectasia and rad3-related) protein kinase is crucial for maintaining fragile site stability. ATR is a major cell cycle checkpoint protein that responds to replication stress and stalled replication forks by blocking cell cycle progression. Deficiency of ATR leads to a spontaneous expression of fragile sites that is amplified 8–10 fold when cells are treated with aphidicolin. Consistent with these findings, it has been shown that individuals with the genetic disease ►Seckel syndrome 1 have a hypomorphic mutation in *ATR* and show increased fragile site breakage following exposure of cells to aphidicolin. It has also been shown that the ►*BRCA1*, the ►Fanconi anemia family gene *FANCD2*, *CHK1*, *HUS1* and *SMC1* also play important roles in sensing and ►repair of DNA damage at common fragile sites and that loss of any of these genes leads to an increase in common fragile site expression.

Once broken, CFSs are repaired by a variety of cellular mechanisms. It has been shown that ►*RAD51*, *DNA-PKcs*, and *Ligase IV* are all important for repair of broken sites and that loss of any of these genes causes an increase in detectable gaps and breaks on metaphase chromosomes.

It is hypothesized that increased ►replication stress leads to collapsed or delayed replication forks,

incomplete replication of the associated regions, and large single-strand gaps, some of which can escape ►G2/M checkpoints. CFSs are more prone to forming gaps and breaks under replication stress than are other sites in the genome. When checkpoints are perturbed or absent, as is the case when ATR is lost, instability increases dramatically through out the genome but common fragile sites are more strongly affected. Furthermore, loss of genes that would normally function to repair damaged sites can also lead to an increase in visible gaps and breaks at CFSs on metaphase chromosomes. Thus, breaks at CFSs can serve as "signatures" of increased replication stress and are valuable cytological markers for the study of checkpoint and repair pathways that respond to replication stress.

Clinical Relevance

Rare Fragile Sites

The FRAXA rare fragile site at Xq28 is a cytogenetic manifestation of the expanded CGG repeat mutation in the promoter region of the *FMR1* gene associated with the ►fragile-X syndrome, a leading cause of mental retardation in humans. Large repeat length leads to methylation and transcriptional inactivation of *FMR-1* and thus phenotypic expression of any associated disease. Individuals with a moderate repeat length, 50–100 repeats, are considered to have premutations of the disease. In this moderate repeat expansion state clinical manifestations of the associated disease are possible, including the recently described FXTAS (fragile-X tremor ataxia syndrome) however, symptoms are less severe and less frequent than in the full mutation state. A similar fragile site on the X chromosome, FRAXE (Xq28), is associated with the genes *FMR2* and *FMR3* and can lead to mild mental retardation in some families. FRA11B (11q23.3) on the long arm of chromosome 11 is believed to lead to terminal deletions of chromosome 11 in a small number of cases of Jacobsen syndrome. In addition, an autosomal folate-sensitive fragile site, FRA12A, in the *DIP2B* gene has recently been associated with mental retardation. It is likely that other rare fragile sites will be found to be associated with specific genes and genetic diseases.

Common Fragile Sites

At least two of the thirteen cloned common fragile sites lie within known ►tumor suppressor genes. FRA3B (3p14.2) spans over 500Kb of sequence and is centered on exon 5 of the *FHIT* gene. Deletions within FRA3B (3p14.2) have been found in solid tumors and are associated with loss or alteration of the *FHIT* gene. Specifically, alteration or deletion of the *FHIT* gene has been found to frequently occur in ►Barrett esophagus, gastric, colon, lung and other types of cancer cells. FRA16D (16q23) is centered on exons 6, 7, and 8 of the *WWOX* gene. The *WWOX* gene has been implicated in both ►apoptosis and tumor suppression, and deletions of *WWOX* have been found in a number of gastric adenocarcinomas and multiple myelomas. Consistent with the finding that fragile sites are sensitive to replication stress, there is evidence that deletions at common fragile site regions appear very early during tumorigenesis and precede more global genomic deletions and ►LOH in cells with activated DNA-damage checkpoint response genes such as *ATR* and ►*ATM*. In addition, two groups have reported that the ATR checkpoint pathway is activated very early during tumorigenesis in response to unknown factors that lead to replication stress

These and many similar data suggest that common fragile sites are frequently unstable in cancers and can lead to the deletion or alteration of tumor suppressor genes associated with them. Lower expression or loss of tumor suppressor genes such as *FHIT* or *WWOX* may increase susceptibility for development of certain cancers. Because of this, it is probable that the expression of common fragile sites plays a significant role in the early stages of tumor formation. Additionally, due to the frequency of deletions at common fragile sites early in tumorigenesis, deletions at these sites can be used as signatures of increased replication stress and early tumorigenesis.

Fragile-X Syndrome

Definition

A genetic disease associated with the rare fragile site FRAX and caused by an expanded CGG trinucleotide repeat in the *FMR1* gene. This is the most common cause of inherited mental retardation.

►Fragile Sites

Fragilomics

Definition

Referring to a systematic large scale study to identify the repertoire of ►fragile sites of the genome, to define the genes disrupted by fragile site activation and to determine the role they might have in human chronic diseases including cancer; the term fragilome was coined in the early 2004s as a linguistic equivalent to the concept of genomics.

Fragment Analysis

Definition

Method for the detection of ►polymerase chain reaction (PCR) fragments. Fluorescence labeled primers enable the detection and exact length calculation of PCR amplificates on sequencing machines.

►Leukemia Diagnostics

Frameshift Mutation

Definition

Is a genetic mutation that inserts in or deletes from a DNA sequence a number of nucleotides not evenly divisible by three. Consequently, the insertion or deletion disrupts the reading frame, or the grouping of the codons, resulting in a completely different translation from the original DNA.

Free Radicals

Definition

Are chemical species that possess at least one unpaired electron and are therefore unstable and highly reactive. The presence of unpaired electrons confers a considerable degree of reactivity upon a free radical. Free radicals can cause cellular damage by reacting with proteins, lipids, carbohydrates and DNA, and they are thought to be involved in the etiology of many human diseases including cancer, cardiovascular disease, and age-related diseases.

Fucosylation

Eiji Miyoshi
Department of Biochemistry, Osaka University Graduate School of Medicine, Suita, Japan

Definition

Is one of the most popular modifications with ►oligosaccharides on glycoproteins or glycolipid, which is involved in cancer. Fucosylation involves the attachment of a fucose residue to *N*-glycans, *O*-glycans, and glycolipids. *O*-fucosylation, which is a special type of fucosylation, is very important for ►Notch signaling. Increased levels of fucosylation have been reported in a number of pathological conditions, including ►inflammation and cancer. Therefore, certain types of fucosylated glycoproteins or antibodies, which recognize fucosylated oligosaccharides, have been used as tumor markers. The regulatory mechanisms of fucosylation are complicated.

Characteristics

Regulation of Fucosylation

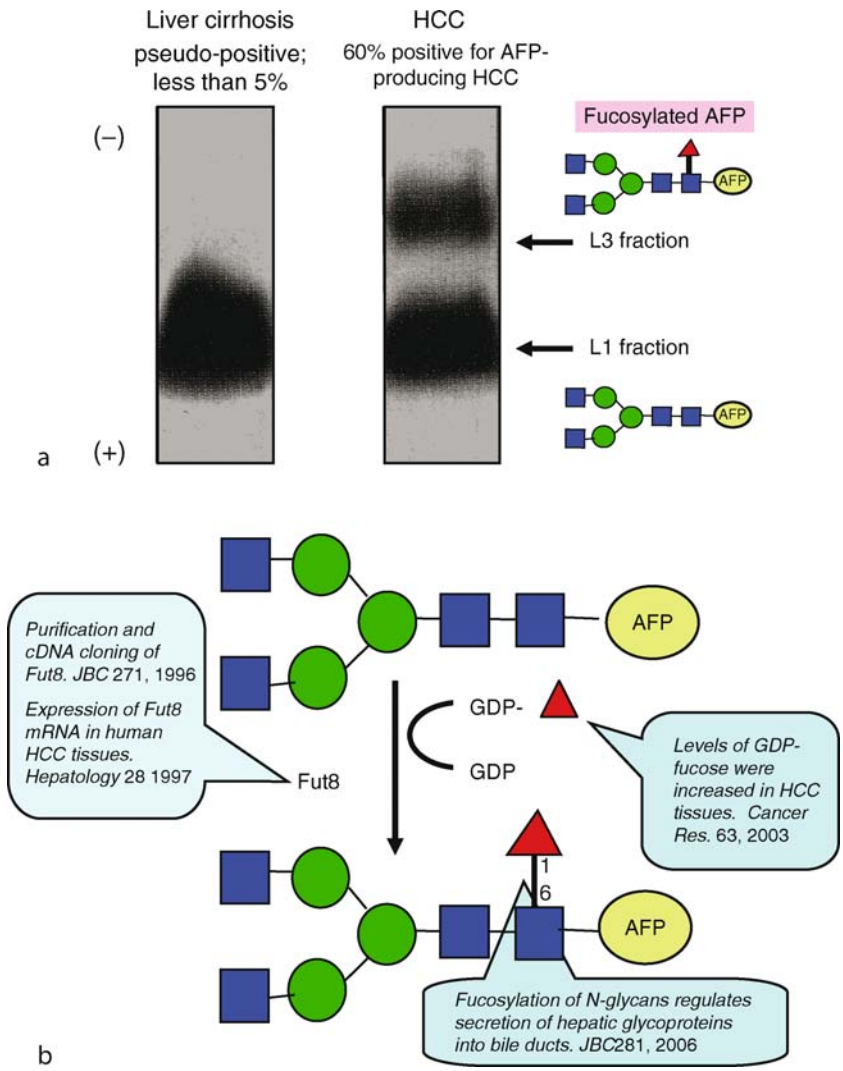
The regulation of fucosylation appears to be complicated, and depends on the type of cells or organs under consideration. Basically, fucosyltransferases, ►GDP-fucose synthetic enzymes, and GDP-fucose transporters are involved in the fucosylation pathway. There are 11 different, known fucosyltransferases (Fut) that have been identified to date, and they are divided into four groups. Fut1 and Fut2 are involved in the synthesis of α1-2 fucose, Fut3, 4, 5, 6, 7, and 9 in the synthesis of α1-3/α1-4 fucose, ►α1-6 fucosyltransferase (Fut8) in the synthesis of α1-6 fucose (►core fucose), and enzymatic activities as fucosyltransferases have not been confirmed in both Fut10 and Fut11. Fut8 has little homology with other fucosyltransferase members and plays an essential role in many biological phenomena because most Fut8 knockout mice die after birth. This drastic change is not observed in other Fut1~9 knockout mice. Core fucose, a product of Fut8 regulates the functions of many growth factor receptors and adhesion molecules. For example, depletion of the core fucose on the EGF receptor inhibits binding to its ligand, leading to the suppression of cell growth and the depletion of core fucose from α3β1 integrin suppresses that attachment of cells to laminin.

►Core Fucosylation and α-Fetoprotein

The expression of Fut8 is quite low in normal liver and increased levels of fucosylated proteins in serum can be used as a tumor marker because numerous serum proteins are produced in the liver. A representative of such a case is fucosylated ►α-fetoprotein (AFP), which can be detected by LCA (lens culinaris) lectin affinoelectrophoresis. AFP is a well-known tumor marker for ►hepatocellular carcinoma (HCC), but it is sometimes also increased in benign liver diseases such as chronic hepatitis and liver cirrhosis. In contrast, fucosylated AFP, referred to ►AFP-L3 (Fig. 1a), is very specific for HCC and was approved as a tumor marker for HCC by the FDA (Food and Drug Administration) in 2005. The molecular mechanisms underlying the production of fucosylated AFP in HCC are complicated. The enhancement of Fut8 is required to produce fucosylated AFP, but this enhancement is insufficient for the production of fucosylated AFP in HCC. GDP-fucose, a donor substrate for many fucosyltransferases is also a key factor in the production of fucosylated proteins. There are two different synthetic pathways for producing GDP-fucose in hepatocytes. One is a de novo pathway and the other is a salvage pathway. The de novo pathway is particularly dominant in hepatocytes and ►FX and GMD plays a pivotal role in the de novo pathway. While the expression of Fut8 is increased in both HCC and liver cirrhosis, the levels of FX are significantly increased in HCC tissues. The levels of GDP-fucose in cells or tissues can be measured using a novel ►HPLC assay and significant increases in GDP-fucose are observed in HCC tissues, compared to the surrounding tissue. In terms of the fucosylation pathway, many factors including fucosyltransferases, GMD, FX, and the GDP-fucose transporter appear to be coregulated. More importantly, fucosylated glycoproteins produced in hepatocytes are secreted into the bile, which is on the apical side of hepatocytes. When the oligosaccharide structures of bile and serum glycoproteins are compared by a lectin blot or 2D mapping, dramatic increases in fucosylation are observed in bile glycoproteins. Fut8 ►knockout mice show a decreased level of hepatic glycoproteins such as α1-acid glycoprotein and α1-antitrypsin in their bile, suggesting that fucosylation regulates the secretion of certain types of hepatic glycoproteins into the bile. The disruption of this system could be one of the mechanisms underlying the increases in fucosylated protein levels, including AFP-L3 in the serum of patients with HCC (Fig. 1b).

Fucosylation and Lewis Antigen

Fut3, 4, 5, 6, 7, and 9 are involved in the synthesis of the Lewis antigen. They function in a cell- or organ-specific manner. Sialyl Lewis X or sialyl Lewis A are used as tumor markers for certain types of cancer. Increases in these Lewis antigens in cancer tissues are correlated with a poor prognosis in colon cancer, due to the high incidence of liver metastasis. The reason for this is that Sialyl Lewis X is a ligand for selection which is expressed in endothelial cells. The first step of tumor metastasis is weak binding through an oligosaccharide and a lectin, followed by strong binding via integrins.



Fucosylation. Figure 1

Although these ►Lewis antigens are fucosylated oligosaccharides, other glycosyltransferases except fucosyltransferases are involved in its synthesis. The donor substrate, GDP-fucose is also important for the synthesis, but the Km values for these Lewis enzymes are different from that of Fut8. This type of fucosylation is also a signal for sorting hepatic glycoproteins into the bile. In the human liver, Fut6 is involved in the synthesis of Lewis types of fucosylation and hepatic glycoproteins with this oligosaccharide structure are present in the bile. In the case of mice, Fut6 is a pseudogene, and therefore the secretion of certain kinds of hepatic glycoproteins into the bile is disrupted in Fut8 knockout mice.

Fucosylated Haptoglobin and Pancreatic Cancer

In terms of glycomics, fucosylated glycoproteins are recognized by several types of ►lectins. These lectins include AAL, UEA, LCA, and AOL. AAL recognizes α1-3/α1-4 and α1-6 fucose, UEA recognizes α1-2 fucose, LCA recognizes the native form of α1-6 fucose with a mannose arm, and AOL recognizes α1-6 fucose more specifically. These lectins could be applicable to a diagnosis of cancer. In western blotting of the AAL lectin using serum from patients with ►pancreatic cancer, approximately 40 kD proteins were found to be highly fucosylated. The N-terminal sequence revealed that this protein was the haptoglobin β chain. The positive rate of fucosylated haptoglobin is 60–80% and the ratio is increased with the progression of the stage pf the disease. Increases in fucosylated haptoglobin levels have been observed in several types of cancer (20–40%) and, it was reported that high levels of fucosylated ►haptoglobin were produced in the advanced stage of ovarian cancer, lung cancer, and breast cancer. Basically, haptoglobin is produced in the

liver and has a low level of fucosylation on its glycans, since the expression of Fut8 is quite low in a normal liver. The ectopic expression of haptoglobin is observed in special conditions such as infections, inflammation, and cancer. The question herein is where fucosylated haptoglobin is produced in patients with pancreatic cancer. A special pancreatic cancer cell, PSN-1 expresses haptoglobin mRNA and produces fucosylated haptoglobin into conditioned medium. However, this case is very rare in comparison with the positive rate for fucosylated haptoglobin (60–80%). If white blood cells infiltrated around pancreatic cancer cells produce haptoglobin, they would be fucosylated, because blood cells express high levels of Fut8. The third hypothesis is that fucosylated haptoglobin produced in the liver is miss-sorted into the blood due to a factor that is secreted from pancreatic cancer cells. To determine which theory is correct, detailed analyses of oligosaccharide structures including the site-directed analysis of haptoglobin oligosaccharides need to be performed. Collectively, fucosylation is highly associated with cancer and additional, detailed information regarding its mechanism would be highly desirable, since it could be a target for novel cancer therapy.

Fucoxanthin

Kazuo Miyashita
Department of Bioresources Chemistry, Faculty of Fisheries Sciences, Hokkaido University, Hakodate, Japan

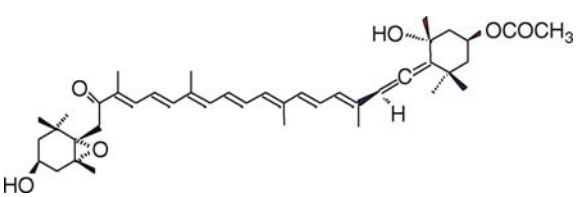
Definition

Is a xanthophyll that contains allenic bond, two hydroxy, keto, and epoxy groups. It is one of the most abundant ►carotenoids accounting for >10% of estimated total natural production of carotenoids. Further, fucoxanthin is the characteristic pigments of brown seaweeds (phaeophyceae) which are the largest occurring group among seaweeds. In South East Asian countries, some brown seaweeds containing fucoxanthin are often used as a food source (Fig. 1).

Characteristics

Effect on Cancer Cell Growth

Cell proliferation is the key in promoting and further progression of carcinogenesis. In a study screening the antiproliferative activity of seaweed extracts on tumor cells, fucoxanthin from the brown seaweed,



Fucoxanthin. Figure 1 Structure of fucoxanthin.

Undaria pinnatifida, is found to be the active principle. When several cancer cells are cultured with fucoxanthin, the cell viability decreases. The antiproliferative activity of fucoxanthin on human cancer cells is generally higher than other carotenoids. Fucoxanthin exhibits the higher activity than β-carotene and astaxanthin on human ►colon cancer cells (Caco-2, HT-29, DLD-1) and human leukemia cell (HL-60). Treatment of Caco-2 cells with fucoxanthin induces morphological changes such as a diminished size and rounded shape. Also, the cell membrane has shrunk with a condensed cytoplasm. The stronger inhibitory effect of fucoxanthin is found in human prostate cancer cells (PC-3, DU 145, LNCap). In this case, the effect of 15 kinds of carotenoids (phytoene, phytofluene, ξ-carotene, lycopene, α-carotene, β-carotene, β-cryptoxanthin, canthaxanthin, astaxanthin, capsanthin, lutein, zeaxanthin, vioaxanthin, neoxanthin, and fucoxanthin) present in foodstuffs is evaluated on the grown of the cancer cell lines. Among the carotenoids, neoxanthin and fucoxanthin cause a remarkable reduction in the growth of prostate cancer cells.

Apoptosis

There is a wealth of information pertaining to apoptosis in anticancer research. ►Macrophages recognize the cells undergoing apoptosis and engulf them without adversely affecting or damaging the neighboring cells. Apoptosis-inducing activities provide a novel means of ►chemoprevention and chemotherapy in the treating cancer. In an investigation on the apoptosis-inducing activity of fucoxanthin, a DNA ladder, which is a characteristic feature of apoptotic cells, is clearly visible in HL-60 cells treated with fucoxanthin. Similar results can be obtained with ►camptothecin, which is known to be a strong apoptosis-inducing agent. The fragmented DNA content designated as the enrichment factor as estimated by sandwich ►ELISA, increases with the concentration of fucoxanthin in the medium. DNA fragmentation, indicating by in situ ►TUNEL (Terminal deoxynucleotidyl transferase-mediated dUTP nick end-labeling), reveals that fucoxanthin reduces cancer cell viability by inducing apoptosis. Some apoptosis-inducing agents are known to arrest a specific cell phase. Therefore, it can be presumed that fucoxanthin affects cell cycle.

Mechanism

Fucoxanthin suppresses expression of ►Bcl-2 protein, which is responsible for suppression of programmed cell death as a survival factor. This is indicative of the fact that downregulation of Bcl-2 protein may contribute to fucoxanthin-induced apoptosis in cancer cells. DNA fragmentation induced by fucoxanthin is partially inhibited by a ►caspase inhibitor Z-VAD-fmk. Further, fucoxanthin also regulates the redox signals, and then facilitates the progression of apoptosis through Bcl-2 protein suppression, and caspase-dependent and-independent pathway.

Combination with Troglitazone

►Troglitazone is known to inhibit cell growth and induce apoptosis through the activation of ►PPARγ. Oral administration of troglitazone inhibits the early stage of colon tumorigenesis. On the other hand, preincubation of cancer cells with fucoxanthin remarkably enhances the effect of troglitazone. Therefore, the combined action of PPARγ ligand such as troglitazone and fucoxanthin is more effective on chemoprevention of cancer than troglitazone, and possibly other agents, alone.

Fulvestrant

Anthony Howell
CRUK Department of Medical Oncology, University of Manchester, Christie Hospital NHS Trust, Manchester, UK

Synonyms

Faslodex

Definition

Was originally known as ICI 182,780 and is now marketed by AstraZeneca under the trade name Faslodex®. The chemical formula of fulvestrant is 7α-[9-(4,4,5,5,5-pentafluoro-pentylsulfinyl)nonyl]estra-1,3,5(10)-triene-3,17β-diol.

Fulvestrant, a steroidal 7α-alkylsulfinyl analog of 17β-►estradiol, is an ►estrogen receptor antagonist with no agonist effects. It is used as an endocrine treatment for postmenopausal women with hormone-sensitive ►advanced breast cancer.

Characteristics

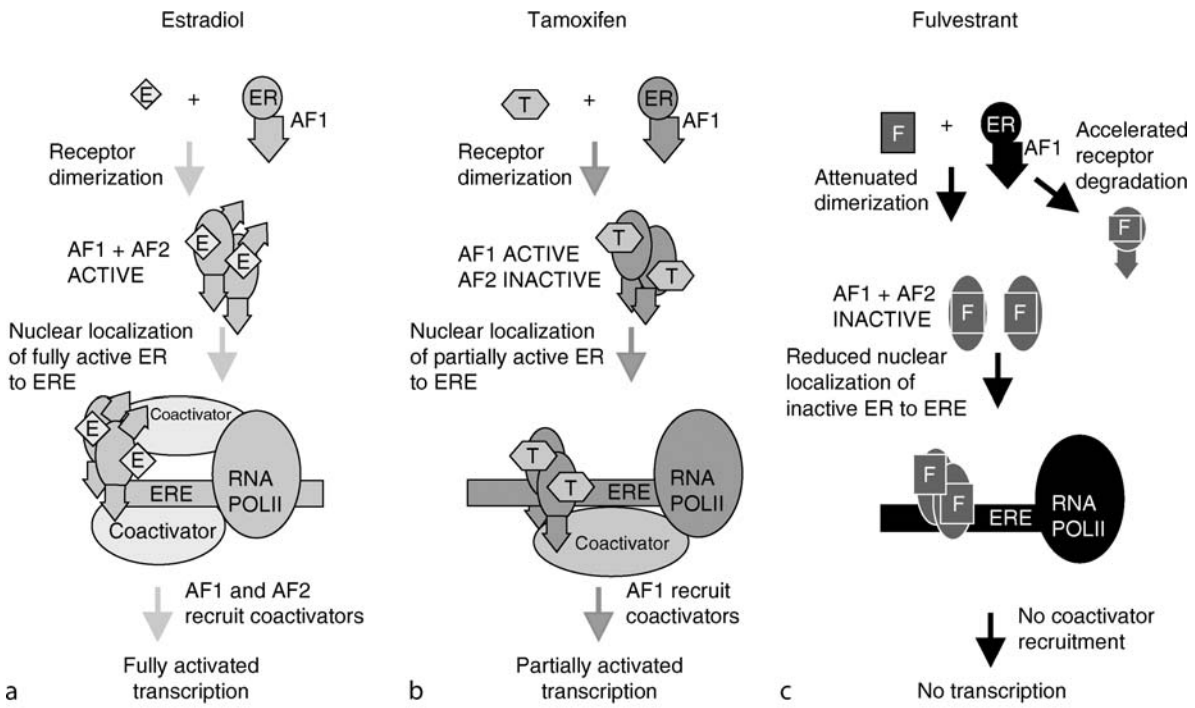
Mode of Action

Currently, more than one million women worldwide are diagnosed with ►breast cancer each year. In postmenopausal women, approximately 75% of breast tumors are hormone sensitive, expressing the estrogen receptor and/or progesterone receptor, and are stimulated to grow in the presence of estrogen. To understand the treatments for hormone-receptor positive breast cancer, we must first understand the role of ►estrogen, a natural circulating hormone that has been shown to drive tumor growth. Once estrogen has bound to the ►estrogen receptor, the receptors dimerize, before translocation to the nucleus, where the complex binds to specific DNA sequences (estrogen response elements) in target genes. Activating functions on the estrogen receptor (AF1 and AF2) recruit protein cofactors, allowing the transcription and expression of the target genes, resulting in increased cell division and tumor progression (Fig. 1).

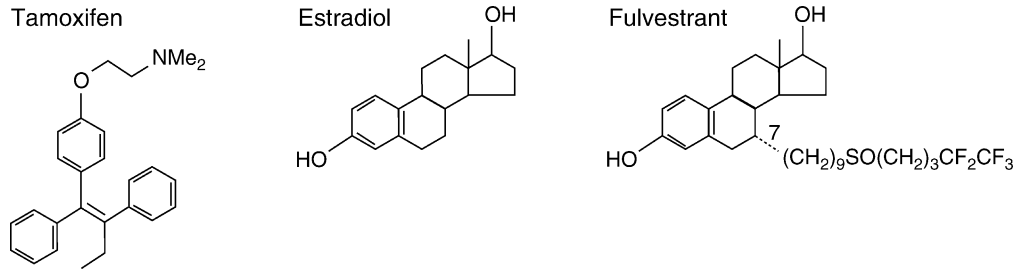
As an estrogen receptor antagonist, fulvestrant exhibits a high estrogen receptor binding affinity and produces a complete receptor blockade. Following binding of fulvestrant, dimerization of the estrogen receptor is impaired and the bound receptor is rapidly degraded, a process unique to fulvestrant amongst the ►antiestrogen receptor agents. Nuclear localization is also disrupted, and both AF1 and AF2 are inactivated, leading to complete abrogation of estrogen signaling through the estrogen receptor (Fig. 1). This also means that fulvestrant has no estrogen agonist activity, which is important, since even partial agonist activity can lead to an increased incidence of endometrial abnormalities and cancer.

As a steroidal analog of estradiol, fulvestrant is structurally distinct from the non-steroidal ►tamoxifen, a selective estrogen receptor modulator, which is also used in the treatment of hormone receptor-positive breast cancer (Fig. 2). Although tamoxifen binds to the estrogen receptor, and permits dimerization and translocation, AF2 is not activated and so the transcription of estrogen-responsive genes is blocked (Fig. 1). However, this block is not complete, since AF1 continues to function, and therefore tamoxifen retains partial agonist activity, with the associated endometrial risks.

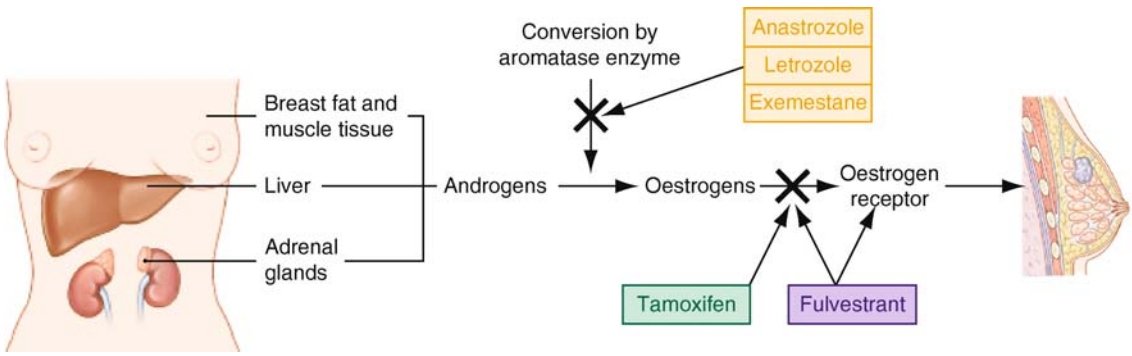
Fulvestrant, with its unique mode of action, is fundamentally different from the third-generation ►aromatase inhibitors such as anastrozole, letrozole or exemestane, which are used to treat breast cancer in an increasing proportion of postmenopausal women.



Fulvestrant. Figure 1 The mode of action of fulvestrant, tamoxifen and estradiol. (Reproduced from Dowsett et al. [2, Fig. 1]. Breast Cancer Res Treat 93:S11–S18 (2005). With kind permission of Springer Science and Business Media.)



Fulvestrant. Figure 2 Chemical structure of fulvestrant.



Fulvestrant. Figure 3 Scheme showing how different endocrine therapies (fulvestrant, tamoxifen, aromatase inhibitors) work in breast cancer.

Following the menopause, most endogenous estrogen is produced via the conversion of adrenal androgens in peripheral tissues. Aromatase inhibitors work by blocking the aromatase enzyme, which catalyzes this conversion, thus reducing the levels of circulating estrogen available to bind to the estrogen receptor (Fig. 3).

Current Utilization of Fulvestrant

While treatment for hormone-sensitive early breast cancer aims to remove the tumor by surgical or radiological techniques followed by adjuvant ►endocrine therapy, treatment for advanced disease is essentially palliative rather than curative, with the emphasis on extending life and preserving quality of life amongst patients. In postmenopausal women with hormone-sensitive advanced breast cancer, it is now standard practice to employ a sequence of endocrine agents, to slow the progression of the disease and delay for as long as possible the requirement for cytotoxic chemotherapy treatment. Consequently, novel endocrine agents that are both effective and lack cross-resistance with existing therapies are required to extend the duration of the sequential treatment regimens.

Fulvestrant is a new therapeutic option that can be added to the hormonal treatment sequence. Results from Phase III clinical trials showed that in postmenopausal women with hormone-responsive advanced breast cancer who had progressed on previous antiestrogen therapy, fulvestrant was at least as effective as anastrozole, in terms of time to progression, objective response rates and survival. This evidence led to its regulatory approval and fulvestrant is currently licensed for use as a second-line endocrine treatment agent for advanced breast cancer after progression or recurrence on an antiestrogen. More recently, Phase III trial data have confirmed fulvestrant activity in the post-aromatase inhibitor setting. Reflecting all these data, fulvestrant is considered in the National Comprehensive Cancer Network guidelines as an option after the failure of first-choice endocrine treatment (tamoxifen or an aromatase inhibitor). Thus, fulvestrant is a valuable addition to the endocrine armory.

Importantly, due to its unique mechanism of action, analyses of patients progressing on fulvestrant have demonstrated continued sensitivity to subsequent endocrine therapies, indicating that fulvestrant lacks cross-reactivity with the ►aromatase inhibitors and tamoxifen.

Administration and Tolerability

Instead of the daily oral dosing used with other endocrine therapies, fulvestrant is given as a monthly

250 mg/5 mL intramuscular injection, which provides slow release of the drug and sustained pharmacologic activity over the dosing interval (28 ± 3 days). The injection is well tolerated locally and may also help to assure treatment compliance. Once in the body, fulvestrant is predominantly bound to plasma proteins and metabolized by the liver, with negligible renal excretion, and it is not implicated in clinically significant drug–drug interactions, making it suitable for use in patients receiving polypharmacy for co-morbid conditions.

Fulvestrant is well tolerated, with most adverse events being mild to moderate in intensity. In clinical trials, the most commonly reported adverse events were nausea, asthenia and pain. Fulvestrant has potential tolerability benefits over some existing treatments, e.g. it is associated with less hot flashes than tamoxifen, and a lower incidence of joint disorders than anastrozole.

Future Uses of Fulvestrant

In recent years, the third-generation aromatase inhibitors, have been shown to be superior to tamoxifen for the treatment of both early and advanced breast cancer. Treatment guidelines currently recommend that an aromatase inhibitor should be used as either the primary endocrine therapy in postmenopausal women, or after 2–3 years of tamoxifen. However, even in this estrogen-deprived environment, some tumors will become resistant to treatment and begin to progress. Therefore, if cytotoxic chemotherapy is to be further delayed, an alternative endocrine therapy must be used. Indeed, as aromatase inhibitors continue to replace tamoxifen in the first-line setting, it is becoming increasingly important to identify agents that are effective after recurrence or progression on these drugs. As previously described, results from both Phase III and Phase II studies suggest that fulvestrant may be active after progression on aromatase inhibitors.

Fulvestrant's unique mode of action and lack of cross-reactivity also invites the possibility of potentially synergistic combinations with other treatment agents. Preclinical data suggest that the combination of fulvestrant with aromatase inhibitors will offer a more effective anti-tumor effect than either agent alone, and Phase III trials are underway to fully evaluate this treatment strategy.

In addition, the epidermal growth factor (EGF) receptor-mediated pathway of gene transcription, which can provide an alternative growth stimulus for breast tumors in the absence of hormone receptors, has also been shown to cross-talk with the estrogen receptor-mediated pathway. This, in turn, has important implications for the development of resistance to endocrine therapy. As fulvestrant increases degradation of estrogen receptors, it may limit the potential for cross-talk with other pathways. Combination treatment with fulvestrant and an agent targeting growth factor receptors (such as gefitinib, lapatinib or trastuzumab) may therefore further limit cross-talk and potentially delay the time of onset of treatment resistance. Currently, several clinical trials are ongoing to investigate the activity of such combination therapy in patients with advanced breast cancer.

Summary

Fulvestrant, a steroidal analog of ►estradiol, is an effective treatment for postmenopausal women with hormone-sensitive advanced breast cancer who have progressed on previous endocrine therapy. With its unique mode of action, fulvestrant provides a valuable addition to the endocrine treatment sequence, with significant benefits for patients. It is administered as a monthly intramuscular injection, and is well tolerated and associated with few adverse events. Fulvestrant may also have a potential use in combination treatment strategies, as the partner of choice with ►EGF receptor inhibitors.

Fumarase

►Fumarate Hydratase

Fumarate Hydratase

Sakari Vanharanta, Virpi Launonen
Department of Medical Genetics, Biomedicum Helsinki, University of Helsinki, Helsinki, Finland

Synonyms

FH; Fumarase

Definition

Fumarate hydratase is an enzyme that functions in the mitochondrial citric acid cycle, catalyzing the reversible hydration/dehydration reaction in which fumarate is converted to malate.

Characteristics

The human gene encoding fumarate hydratase is located in the chromosome segment 1q42.3-q43. It consists of ten exons that span over 20 kb of genomic DNA. The transcript is approximately 1.8 kb long and is predicted to encode a 510 amino acid polypeptide. The first exon of *FH* encodes a signal peptide that directs the protein to the mitochondrion. There the signal peptide is cleaved, and the remaining mature FH protein forms a functional homotetramer in the mitochondrial matrix. Some processed FH is also present in the cytosol, although the function of this cytosolic FH is unclear. In addition to the mitochondrial signal, the processed FH contains other domains such as alpha-helical and lyase domains. The alpha-helixes form a superhelical core for the tetramer. The functionally active FH enzyme converts fumarate to malate. This hydration reaction is a part of the citric acid cycle (also known as the tricarboxylic acid cycle or the Krebs cycle) which is an essential component of cellular carbohydrate metabolism. In the cytosol, fumarate is produced in the urea cycle and therefore FH is connected to protein metabolism as well. FH is well conserved, human FH sharing a 57% amino acid identity with the *Escherichia Coli* FumC protein, and it belongs to a protein superfamily which includes mostly other enzymes such as aspartase, adenylosuccinate lyase, and argininosuccinate lyase.

The first clues as to the role of FH in human disease came from the identification of two siblings that presented with progressive encephalopathy, dystonia, ►leucopenia, and ►neutropenia. They had elevated levels of lactate in their cerebrospinal fluid and high fumarate excretion in their urine. A ►homozygous mutation was discovered in a conserved region of the *FH* gene in both of these patients. Also, FH deficiency was shown to be present in all tissues studied in the patients, and their healthy parents were shown to carry the mutation in a heterozygous form. Since then, about 20 families with FH deficiency have been reported in the literature. The symptoms are severe and the affected individuals usually die within a few months of birth.

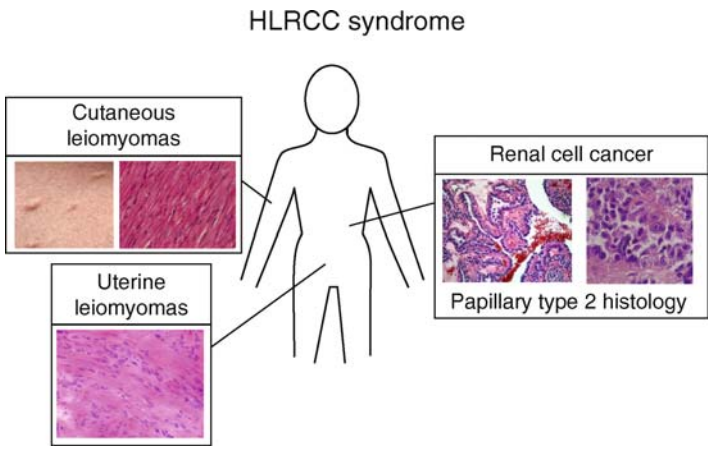
Evidence for yet another role of FH in human disease came from quite a different line of research. The genomic locus harboring the *FH* gene was independently mapped by genetic linkage analysis to segregate with inherited predisposition to ►leiomyoma and ►renal carcinoma; ►Hereditary leiomyomatosis and renal cell cancer (HLRCC), and to ►multiple cutaneous and uterine leiomyomatosis (MCUL). Soon after, these two conditions were shown to be variants of the same syndrome and the underlying gene was identified as *FH*. The tumors showed loss of heterozygosity (►LOH) and retention of the mutated allele, therefore suggesting that the gene acted as a ►tumor suppressor. Also, FH enzyme activity was shown to be reduced in the leukocytes and absent in the tumors of mutation carriers.

Clinical Features of HLRCC/MCUL

Since the first reports indicating the involvement of FH in tumorigenesis, more than 100 families with the HLRCC/MCUL phenotype have been reported in the literature (Fig. 1). Although no population-based studies have been carried out, it seems clear that the prevalence of HLRCC/MCUL is very low. There are reports of HLRCC/MCUL from all around the world, and there seem to be population differences in the phenotype. For example, HLRCC seems to be more common in Finland and North America, whereas in the UK, renal cell cancer is rarely detected in the families segregating heterozygous *FH* mutations. The most common manifestation of HLRCC/MCUL is cutaneous and/or ►uterine leiomyomas. Early-onset renal cell cancer is significantly rarer and is typically of the papillary type II histology.

Cutaneous leiomyomas are small benign tumors of the skin that show as multiple 0.5–2 cm skin-colored nodules, and their tissue of origin is thought to be the arrectores pili muscle of the hair follicle. They can manifest clinically as pain and paresthesias already in childhood, and the age of onset ranges from 10 to 50 in the HLRCC/MCUL families.

Uterine leiomyomas (also known as ►myomas or ►fibroids) are smooth muscle cell tumors that arise within the smooth muscle lining of the uterus, the myometrium. They are some of the most common neoplastic tumors of women, and estimates of affected individuals range from 25% to up to 77% depending on the methods used for the diagnosis. Even though they are benign, they can cause severe morbidity such as aberrant bleeding, abdominal pain and even infertility. In families affected by HLRCC/MCUL, the onset of leiomyomas seems to be earlier than in the general



Fumarate Hydratase. Figure 1 Hereditary leiomyomatosis and renal cell cancer (HLRCC) is an autosomal dominant tumor predisposition syndrome caused by germline mutations in the *fumarate hydratase* gene. The most common features are cutaneous and/or uterine leiomyomas. Predisposition to renal cell carcinoma is present in a subset of families. Typically, HLRCC renal cell carcinomas display papillary type 2 histology.

population. In these families, leiomyomas are also more often symptomatic and therefore they more commonly result in hysterectomy (i.e. the surgical removal of the uterus). In addition to typical leiomyomas, some HLRCC/MCUL patients develop atypical leiomyomas. These are rare variants of leiomyomas which are sometimes hard to discern from uterine leiomyosarcomas. Whether HLRCC/MCUL predisposes to malignant leiomyosarcoma is still a somewhat open question, although some studies suggest that this might indeed be the case.

Familial clustering of ►renal cell cancer was the key finding in the identification of the syndrome HLRCC. In the first family reported, four patients aged 33–48 were identified. Since then, additional cases of renal cell cancer have been detected in some HLRCC/MCUL families, the median age of onset being around 40. The natural history of HLRCC/MCUL renal tumors is malignant with early metastasis often leading to the demise of the patient. In the early reports, all renal cell cancers related to HLRCC/MCUL displayed a distinctive papillary type II histology, although other types of renal tumors, such as collecting duct and clear-cell carcinoma, have been later associated with HLRCC/MCUL as well. HLRCC/MCUL renal tumors are typically unilateral, which is in contrast to other inherited forms of renal cell cancer such as von ►Hippel-Lindau Syndrome (VHL), Hereditary Papillary Renal Carcinoma, and ►Birt-Hogg-Dubé Syndrome (BHD), in which tumors often affect both kidneys.

FH-mutation carriers might be at risk of developing ►Leydig cell tumors and ovarian cystadenomas. Incidental cases of other tumors, such as breast and prostate cancer and some hematological malignancies, have also been reported in HLRCC/MCUL families, although it remains unclear whether any of these are true manifestations of the germline *FH* mutations.

Mutations in the *FH* Gene

The syndrome HLRCC/MCUL is transmitted in an ►autosomal dominant manner, and germline *FH* mutations have been detected in ~85% of all the families displaying the HLRCC/MCUL phenotype. Altogether, ~60 different mutations have been identified. The vast majority (~70%) are single base pair substitutions, of which ►missense mutations comprise about 60%; the rest are non-sense mutations. Small deletions and insertions as well as ►splice site changes have been reported. In addition, whole gene *FH* deletions have been detected in some families. Mutations occur throughout the gene. The mutation R58X has been detected in four families of diverse ethnic and geographical backgrounds in North America. ►Haplotype analysis has suggested that the mutation has occurred independently in these families, indicating that this might represent a mutational hot spot. The same mutation has also been detected in families from the United Kingdom and Australia. Other mutations that have been detected in several families of different geographical backgrounds are, for example, N64T and R190H, and these may represent mutational hot spots as well. The mutations in families with the renal cell cancer phenotype do not differ from those seen in families without these malignant tumors and, in fact, the same mutations have been detected in families with either of the two phenotypes. This has raised the question of whether an additional genomic locus could act as a modifier together with *FH* mutations.

A ►founder effect has been detected at least in populations of the Finnish and Iranian origin. Two

mutations, H153R and a 2-bp deletion in codon 181, have both been identified in three different families in Finland. Similarly, a splice site mutation IVS6-1G>A has been detected in a common haplotype in several families of Iranian origin. Most tumors arising in HLRCC/MCUL families have a second somatic inactivating hit in the *FH* gene. This is often acquired through the loss of the wild-type *FH* by a partial or whole genomic deletion of chromosome arm 1q.

FH mutations are also rarely seen in sporadic tumors. Inactivation of the *FH* gene has been detected in three tumors from the Finnish population, one soft-tissue sarcoma of the lower limb, and two uterine leiomyomas, all showing loss of the wild-type *FH*. However, despite mutation screens comprising hundreds of tumor specimen, no other somatic changes in *FH* have been detected in various tumor types including prostate, breast, colorectal, lung, ovarian, thyroid, head and neck cancers, pheochromocytomas, gliomas, and melanomas. Therefore, it is safe to say that, in general, somatic inactivation of the *FH* gene is a very rare occurrence in human tumors.

As determined by microarray based gene expression analysis, as well as by traditional immunohistochemical methods, ►uterine fibroids carrying *FH* mutations have distinct biological properties which seem to require two hits in the *FH* gene. The molecular mechanisms through which mutations in *FH* lead to tumorigenesis are still far from being well understood. Some evidence suggests that the disruption of FH activity would lead to the stabilization of the ►hypoxia inducible factor-1 (HIF1) under normoxic conditions, thus activating several growth-promoting signaling cascades.

The mutations detected in the recessively inherited developmental disorder FH deficiency are also mostly missense mutations, and they occur throughout the *FH* gene. The mutational spectrum of FH deficiency does not seem to be different from that of HLRCC/MCUL and, indeed, a phenotype compatible with HLRCC/MCUL has been reported in some of the parents of the children affected by FH deficiency.

Funnel Factors

Gemma Armengol, Santiago Ramon y Cajal
Department of Pathology, Vall d'Hebron University Hospital, Barcelona, Spain

Definition

Is a molecule where several oncogenic signals converge and drive the proliferative signal downstream. This transformation-inducing signal inexorably passes and is canalized through the funnel factor. Funnel factors provide a clear reflection of the tumor's transforming potential regardless of the triggering genetic alteration upstream. The level of expression of these factors should correlate with the degree of malignancy of the tumor and the most relevant clinical parameters, such as ►metastasis and survival. Therefore, they may reflect the molecular information and transformation potential for each tumor.

Characteristics

Background of Molecular Human Carcinogenesis

Funnel factors are those final effectors that channel the malignant cellular growth signals, which are transduced through pathways or cascades that induce and mediate changes into the cell physiology. Several of these pathways or cascades are redundant, that is they can trigger a similar cellular effect. There are six acquired capabilities considered to be necessary for the malignant cellular growth: ►self-sufficiency in growth signals, insensitivity to anti-growth signals, limitless replicative potential, resistance to ►apoptosis, sustained ►angiogenesis and, finally, the ability to infiltrate the surrounding tissue and metastasize. Each of these changes in cellular physiology can be brought about through dozens of signaling pathways or cascades, each implicating various genes or proteins. Many different oncogenic alterations may be involved in each biochemical route. This intricate molecular background and its biochemical consequences can help us to understand the great heterogeneity observed in tumors, with over 250 types of malignant human tumors with distinctive clinical and pathological characteristics and thousands of morphological and pathological tumor subtypes.

So far, up to 300 mutated genes implicated in oncogenesis have been identified as human cancer genes. Many oncologists and pathologists ask whether all this information is really important for the management of individual cancer patients. The answer is unknown because only a few molecular targets have been identified in a small number of tumor types. For example, ►amplification of ERBB2 is seen in 25–30% of ►breast carcinomas, ►*EGFR* mutations in less than 10% of ►lung carcinomas, and ►*c-KIT* in the rare ►gastrointestinal stromal tumors; but in most carcinomas, there is no distinctive oncogenic target. In the near future, technological advances will allow us to study the complete genetic background, ►mRNA profiling, and protein expression of individual tumors, and identify a myriad of genetic and biochemical alterations. But even then, attempts to inhibit or counteract single genetic alterations with the use of multiple specific agents would probably be chaotic. Nevertheless, dissection of the biochemical pathways is progressing. We now know which factors are the final growth signaling effectors that can control ►transcription and protein synthesis. Then, it is logical to think that the level of expression of these final effectors, which channel the proliferation signal, can be associated with the real oncogenic role of a pathway in individual tumors.

Cell Signaling in Human Tumors

Among the acquired capabilities of tumor cells, a funnel factor has been described for self-sufficiency in growth signals. This essential oncogenic capability is one of the most extensively studied characteristics of tumor cells, and one that is constitutively activated in nearly all tumors. The process of converting extracellular signals into cellular responses, in this case cell growth and division, is called signal transduction. The growth signal transduction pathway is comprised of ►growth factors, ►growth factor receptors, factors transmitting the growth signal, and the final effector factors, some of which are located in the nucleus to activate ►transcription factors and some in the ►ribosomes to activate protein synthesis. The neoplastic cell, however, may be able to generate signals for survival or proliferation through various mechanisms without depending on exogenous signals. These mechanisms include alterations in the growth factors or receptors, or in the signaling pathways, themselves. Among the latter, the most highly recognized and important are the ►RAS-►RAF-►MAPK (ERK1/2) and ►PI3K-►AKT pathways, which regulate ►mTOR. Specific molecular alterations are detected in these signaling cascades in the majority of tumors. Usually these are single alterations with an oncogenic impact, such as growth factor mutations or RAS mutations; other concomitant genetic alterations are not usually found in these biochemical pathways.

Searching for Funnel Factors: p-4E-BP1

In studies performed in various tumor types, the expression of key cell-signaling factors, including Her1 and Her2 growth factor receptors, as well as the RAS-RAF-MAPK and the PI3K-AKT-mTOR pathways were correlated with the associated clinico-pathological characteristics of these tumors. The downstream factors p70, S6, 4E-BP1, and EIF4E, which play a critical role in the control of protein synthesis, survival, and cell growth, were also analyzed. It was found that ►phosphorylated ►4E-BP1 (eukaryotic ►translation initiation factor 4E binding protein 1) levels in breast, ovary, and prostate tumors were associated with malignant progression and an adverse prognosis, regardless of the upstream oncogenic alterations. Thus, p-4E-BP1 seems to act as a funnel factor for an essential oncogenic capability of tumor cells, self-sufficiency in growth signals, and could be a highly relevant molecular marker of malignant potential. The results showing that 4E-BP1 is associated with the prognosis in breast, ovary and prostate tumors, are supported by other data. In breast cancer, ►phosphorylation of AKT, mTOR and 4E-BP1 has been associated with tumor development and progression; and in prostate cancer, one of the best biomarkers of the mTOR pathway is 4E-BP1, since overexpression of this factor has been highly associated with this type of tumor. Moreover, experimental studies have shown that 4E-BP1 is essential for cell transformation. Transfer of 4E-BP1 phosphorylation site mutants into breast carcinoma cells suppressed their tumorigenicity.

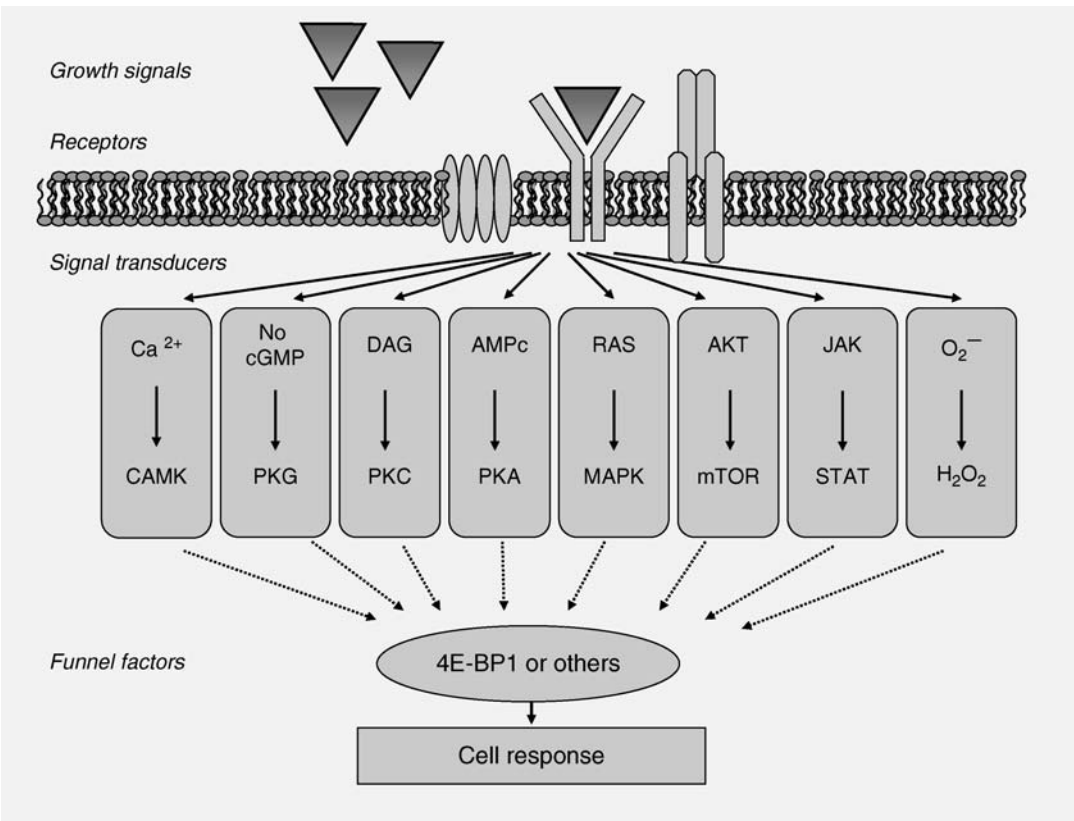
4E-BP1 is a eukaryotic translation initiation factor 4E (EIF4E)-binding protein that plays a critical role in the control of protein synthesis, survival, and cell growth. During ►cap-dependent translation, EIF4E binds to the mRNA ►cap structure and promotes formation of the ►translation initiation complex and ►ribosome binding. When 4E-BP1 is active (non-phosphorylated 4E-BP1) it binds to EIF4E and impedes formation of the initiation complex; translation is then blocked, favoring apoptosis. However, when 4E-BP1 is phosphorylated, the affinity for EIF4E binding is reduced, EIF4E is released, and cap-dependent translation can initiate.

4E-BP1 has seven phosphorylation sites. It is likely that mTOR is the main phosphorylation pathway of 4E-BP1, although other ►kinases may be implicated, such as ►CDK1, ►ATM, ►PI3K-AKT, ►ERK1/2, and perhaps other, still unidentified, kinases. Therefore, 4E-BP1 phosphorylation can be the consequence of many different oncogenic events occurring in several biochemical pathways, including amplification or mutation of growth factor receptors, loss of function or mutations in ►PTEN, ►ATM, ►p53, ►PI3K or ►RAS, or other collateral mechanisms of cellular oncogenic activation (Fig. 1). Because of the elevated number of genetic alterations that regulate 4E-BP1, we propose that the phosphorylated form of this protein can act as a "bottleneck" or funneling factor through which the transforming signals converge, channeling the oncogenic proliferative signal regardless of the upstream specific oncogenic alteration.

The role of other 4E-BP ►isoforms, such as 4E-BP2 and 4E-BP3, in human tumors is still unclear, and it is not known whether they can be activated in 4E-BP1-negative tumors. Study of the EIF protein family will also be determinant when reliable antibodies allow us to analyze their expression in large series of tumors. Recent data have provided novel perspectives into the proliferative and oncogenic properties of EIF4E, since it has been shown to have an impact on nearly every stage of cell cycle progression. Earlier studies have shown that EIF4E levels are substantially elevated in several types of cancers.

Funnel Factors in Other Oncogenic Pathways

Extending the concept of funnel factor, there might be several funnel factors where the final biochemical effect converges for each of the oncogenic capabilities of tumor cells. For example, in the apoptosis pathways,



Funnel Factors. Figure 1 Schematic diagram showing how funneling factors channel the proliferation signal.

where the expression of certain proteins that inhibit apoptosis, such as survivin and livin, might be associated with resistance to apoptosis regardless of the activation of other antiapoptotic or proapoptotic genes that might be present.

Study of the expression profiles of funnel factors from all the cell transformation pathways would allow us to obtain an individual functional-molecular signature for each tumor. This signature, combined with clinical and pathological data would help us to establish the malignant potential of each individual tumor and deduce its potential resistance to conventional chemotherapy and radiotherapy. Obviously, in addition to molecular characterization of tumors for prognostic purposes, it is necessary to study factors that might be potential therapeutic targets, currently one of the most promising areas in the field of cancer treatment. With this functional approach it seems worthwhile to investigate whether these funnel factors can be critical targets for cancer treatment.

Furin; PACE; SPC1; PCSK3; Dibasic processing enzyme; Prohormone convertase; Paired basic amino acid cleaving enzyme

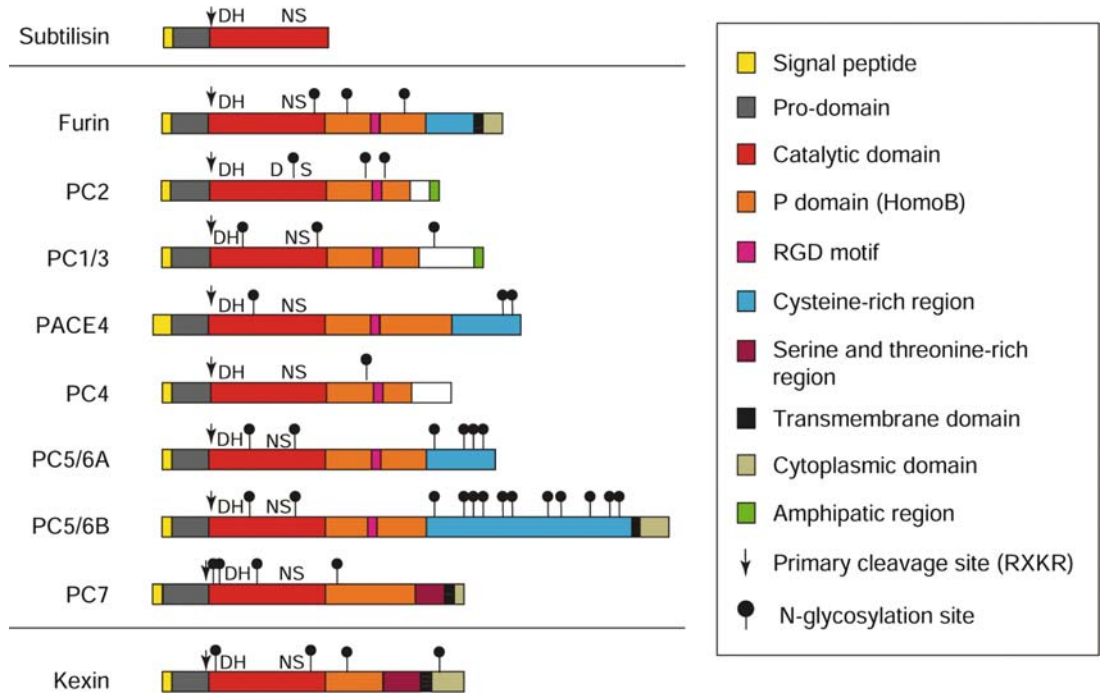
Definition

Furin (E.C. 3.4.21.75) is a highly specialized proteinase that cleaves the unique sequence motifs in a variety of proteins. Normally, following furin cleavage, the target protein is activated and, therefore, it can exhibit its biological activity. Because furin has been discovered first, currently it is the most studied enzyme of the proprotein convertase (PC) family of serine proteinases. Seven distinct proprotein convertases of this family (furin, PC2, PC1/3, PC4, PACE4, PC5/6, and PC7) have been identified in humans, some of which have ►isoforms generated as the result of ►alternative splicing. Structurally and functionally, furin resembles its evolutionary precursor: the prohormone-processing enzyme, kexin (EC 3.4.21.61), which is encoded by the KEX2 gene of yeast *Saccharomyces cerevisiae*. The polypeptide sequence of the furin ►catalytic domain is homologous to that of *Bacillus* subtilisin, an evolutionary precursor of PCs. Furin and related PCs are involved in the limited ►endoproteolysis (►protease activated receptor) of inactive precursor proteins which occurs at the sites marked by paired or multiple basic amino acids.

Characteristics

A wide variety of proteins are initially synthesized as parts of higher molecular weight, but inactive, precursor proteins. Specific endoproteolytic processing of these ►proproteins is required to generate the regulatory proteins in a mature and biologically active form. A large majority of these active proteins, including ►matrix metalloproteinases, growth factors, and ►adhesion molecules are essential in the processes of cellular transformation, acquisition of the tumorigenic phenotype, and metastases formation. The enzyme furin, which is encoded by the *fur* gene, was the first and can be considered the prototype of a mammalian subclass of subtilisin-like proteases. The localization of the gene immediately upstream from the FES ►oncogene (V-FES feline sarcoma viral oncogene homolog) generated the name FUR (for FES upstream region). Furin is similar to other PCs in that it contains a signal peptide, a prodomain, a subtilisin-like catalytic domain, a middle P domain, a cysteine-rich region, a transmembrane anchor, and a cytoplasmic tail (Figs. 1 and 2). Furin and PCs are normally N-glycosylated ►glycoproteins (►glycosylation). Phosphorylation of the cytoplasmic tail is required for the trans-Golgi localization of furin which in vivo exists as di-, mono- and non-phosphorylated forms. Propeptide cleavage is a prerequisite for the exit of furin molecules out of the ►endoplasmic reticulum. The second cleavage in the propeptide occurs in the ►trans-Golgi network, which is followed by the release of the propeptide bound to furin and the activation of furin.

Furin is expressed in all examined tissues and cell lines and is mainly localized in the trans-Golgi

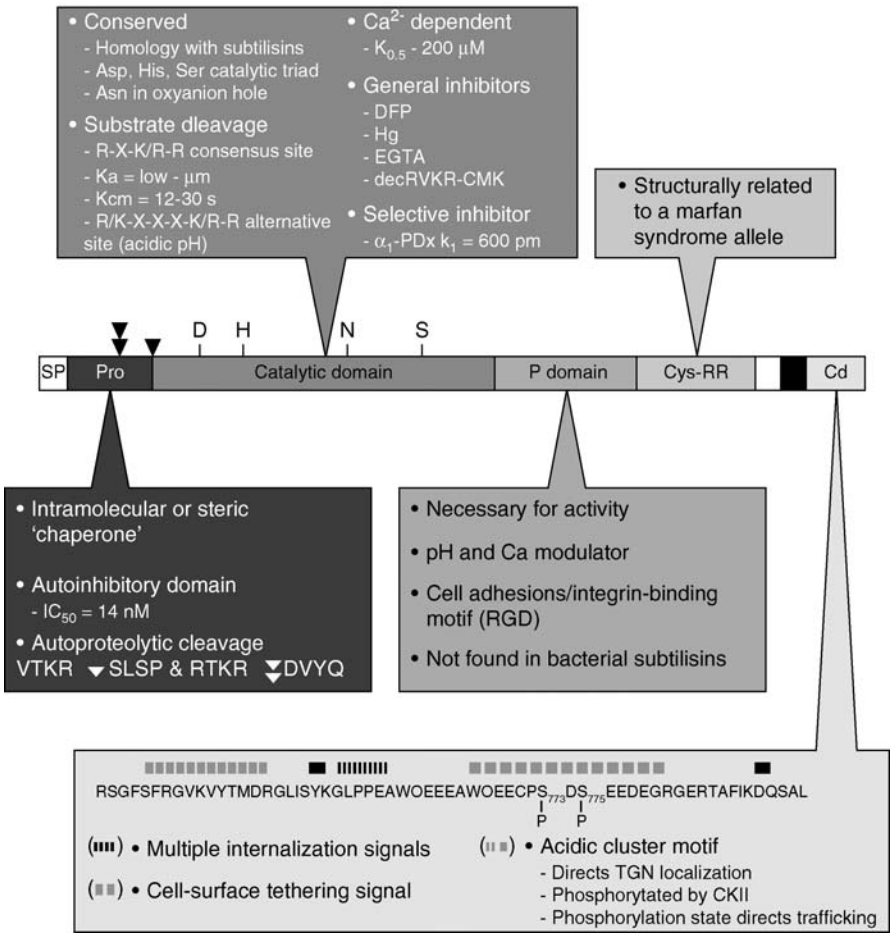


Furin. Figure 1 A modular domain structure of furin and six related PCs. The A and B isoforms of PC5/6 are encoded by the same gene. The structure includes (i) the N-terminal signal peptide, which directs proteins into the secretory pathway, (ii) a pro-domain, which maintains the inactive zymogen state of PCs and which also acts as an intramolecular chaperone for the proper folding, (iii) a catalytic domain with the active site that exhibits an Asp (D)-His(H)-Ser(S) catalytic triad and an additional Asn(N), (iv) a barrel-like structured P domain that regulates enzyme stability, (v) a C-terminal domain that contains membrane attachment sequences, a Cys-rich region and intracellular sorting signals. Adapted from [4].

network. Some proportion of the furin molecules cycles between the trans-Golgi and the cell surface. Furin represents the ubiquitous endoprotease activity within constitutive secretory pathways and normally it is capable of cleaving the Arg-X-(Lys/Arg)-Arg consensus motif, where X is any amino acid type (Table 1). Furin and related PCs are activating proteases and normally they do not inactivate polypeptides. Because of the overlapping substrate preferences and cell/tissue expression, there is a substantive level of redundancy in the PC functionality, albeit certain distinct functions of the individual PCs have also been demonstrated. Furin knockout, however, is lethal in mice. Furin null embryos die because they fail to accomplish ventral closure successfully and to form a looping heart tube. These processes require cellular migration and proliferation, both of which are regulated by furin. Through regulation of cellular migration and proliferation, furin plays an important, albeit incompletely understood role, in cellular transformation, acquisition of the tumorigenic phenotype, cancer progression and metastasis. The expression of furin, however, discriminates sharply between small cell lung cancers, which have no expression, and non-small cell lung cancers, in which furin is overexpressed.

The roles of furin and other PCs in cancer have been characterized as the result of many studies of gene expression and enzyme inhibition. Because of the redundancy, it is not always clear if all PCs present in cancer cell/tissue are directly relevant to tumorigenicity. An enhanced expression of furin and related PCs in cancer is not necessarily an indicator of a poor clinical outcome. There is, however, evidence that high levels of furin-related PCs contribute to tumor growth and metastasis by controlling the activation of key cancer-associated proteins, including matrix metalloproteinases and growth factors such as ►VEGF, ►TGFβ and ►PDGF. The multiple effects of PCs on cell proliferation, motility, adhesion and invasion have led to a concept that in the course of tumor development and progression PCs act as "master switches" of the key tumorigenic protein functionality. If this concept is valid, then PCs could be identified as important therapeutic targets in a number of cancer types. The challenge remains to identify the functionally-relevant, target PC in each cancer type, because it is unlikely that broad-range PC inhibitors would have significant clinically beneficial effects.

No natural protein inhibitors of furin are known. D-Arg-based peptides, α1-anti-trypsin Portland and,



Furin. Figure 2 Furin structure. The 794-residue pre-profurin sequence contains a 24-residue signal peptide, an 83-residue prodomain, a 330-residue subtilisin-like catalytic domain, a 140-residue middle P domain (also termed the "homo B," a 115-residue cysteine-rich region, a 23-residue transmembrane anchor, and a 56-residue cytoplasmic tail. Adapted from [1].

especially the synthetic peptidic inhibitor decanoyl-Arg-Val-Lys-Arg-chloromethylketone, are used to inhibit furin in the cleavage reactions in vitro and in cell-based tests. Inhibition of furin results in a significant reduction in tumor cell invasion. This reduction appears to be associated with a processing blockade of proteins directly involved in the mechanism of invasion including matrix metalloproteinases, growth factors and adhesion signaling receptors such as integrins.

PCs including furin are implicated in many pathogenic states because they process to maturity membrane fusion proteins and pro-toxins of a wide variety of both naturally occurring and weaponized bacteria and viruses, including anthrax and botulinum toxins and H5N1 bird flu, Marburg and Ebola viruses. After processing by furin and the subsequent internalization inthe complex with the respective receptor followed by acidification of the ►endosomal compartment (►endocytosis), the processed, partially denatured, infectious proteins expose their membrane-penetrating peptide region and escape into the cytoplasm. The intact toxins and viral proteins, however, are incapable of accomplishing these processes. Normally, the low pathogenicity viral subtypes have mutations in the cleavage site sequence and thus a reduced sensitivity to furin. Accordingly, proteolytic processing by furin is an important determinant in the overall pathogenicity of viruses and bacterial toxins. Based on these data, PCs, including furin, are promising targets for drug design in a variety of acute and chronic diseases including cancer and infectious diseases.

Fusion Genes

Patrizia Gasparini
Molecular-Cytogenetic Unit, Department of Experimental Oncology, Istituto Nazionale Tumori, Milano, Italy

Synonyms

Fusion proteins; fusion oncogenes; chimeric genes; chimeric oncogenes; chimeric transcripts; hybrid genes

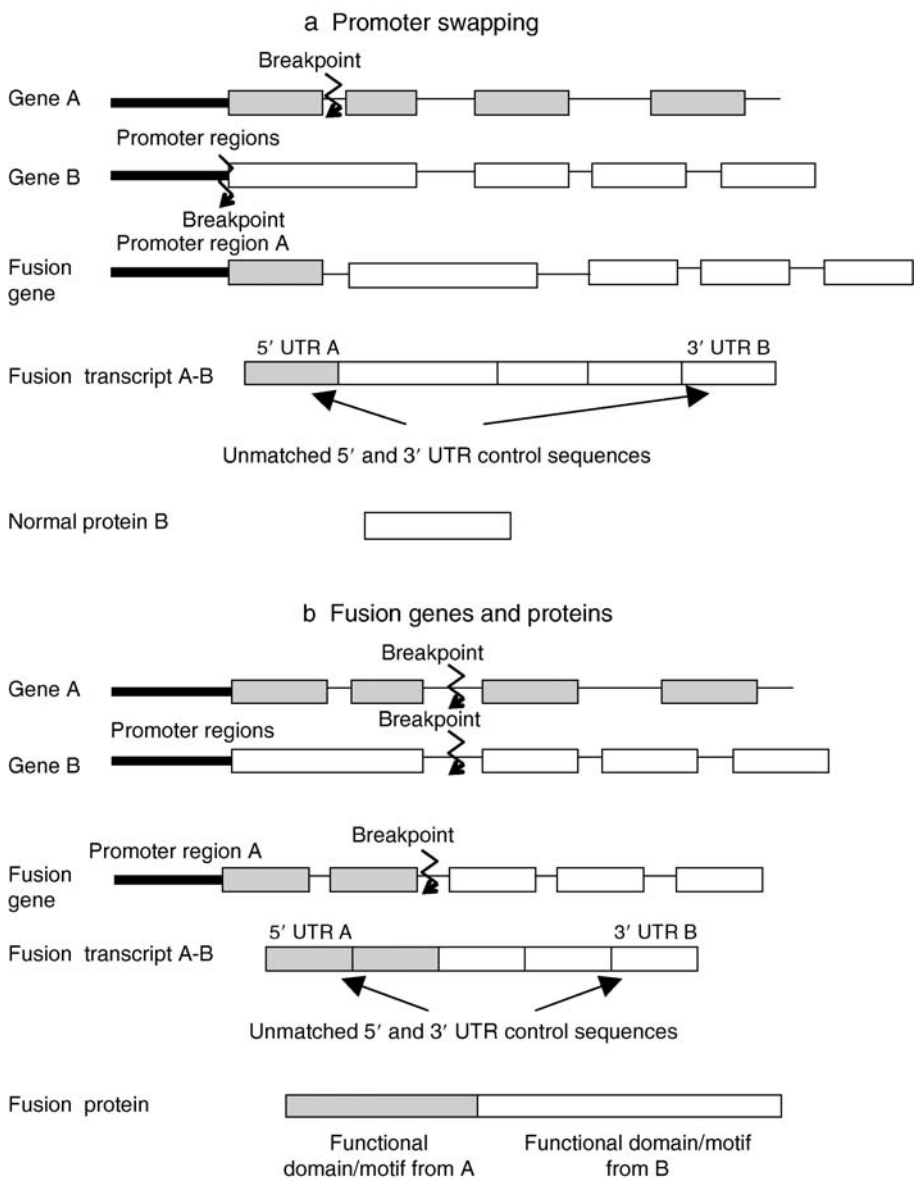
Definition

A hybrid gene created by joining portions of two different genes (to produce a new protein) or by joining a gene to a different promoter (to alter or deregulate a gene transcription).

Characteristics

A wide variety of recurrent molecular alterations has been associated with cancer including ►polymorphisms, changes in gene copy number (amplifications and deletions), point mutations, ►epigenetic modifications and gene fusions due to structural ►chromosomal rearrangements, such as translocations and less frequently inversions. As for these last ones, the genes located at the breakpoints of the rearrangement may be structurally changed with dramatic effects on their products. Molecularly, two events of structural aberrations can be generated: "promoter swapping" (the exchange of promoter control regions) or fusion gene.

In detail (Fig. 1a) "promoter swapping" occurs when the regulatory elements of a gene (promoter and/or enhancer) become aberrantly juxtaposed to a proto-oncogene, thus driving deregulated expression of an oncogene. Molecularly, the breakpoints of the rearrangements occur upstream from the coding region of the partner gene resulting in two chimeric genes which have exchanged their promoter regions, and less frequently noncoding exons. At the genomic level, the



Fusion Genes. Figure 1 A schematic representation of two events of stuctural aberations: (a) Promoter swapping and (b) Fusion genes and Fusion proteins.

3′ partner gene B is placed downstream of the 5′ gene A promoter region. The chimeric transcript contains 5′ ►untranslated regions (UTR) from the A gene and a coding region B that is intact and encodes a normal protein B. This mechanism can be exemplified by the three translocations that characterize Burkitt lymphoma: t(8;14), t(8;22), and t(2;8). All these rearrangements lead to the activation of *MYC*, located on 8q24, by juxtaposing the coding sequences of the gene to one constitutively active immunoglobulin (Ig) genes promoter or regulatory regions (IgH at 14q32, IgK at 2p12, and IgL at 22q11).

Fusion genes (Fig. 1b) arise when the coding regions of the two genes are juxtaposed, resulting in a chimeric transcript that produces a fusion protein with a new altered activity. In detail, in the majority of cases, fusion genes are formed when DNA breaks occur within two different genes mainly within the introns, A and B, and the gene fragments are joined in erroneous combinations. In most cases, the results are two fusion genes: A-B and B-A. On genomic level, the 3′partner gene B is placed under the 5′ gene A promoter control region which dominates the transcription control of the fusion gene. As a result, in the fusion protein the functional domains from the A and B proteins are brought together in a new abnormal combination. In cancer, the genes that are often interrupted by a chromosomal rearrangement are oncogenes , thus harboring fusion oncogenes. An appropriate example of a fusion oncogene is ►BRC/ABL characterizing chronic myelogenous leukemia which is driven by t(9;22)(q34;q11), also known as the ►Philadelphia chromosome, the first translocation to be molecularly characterized. In particular, the translocation fuses the *ABL* gene normally located on 9q34, with the *BCR* gene at 22q11. The BCR/ABL fusion created on the derivative chromosome 22 encodes a chimeric protein with an increased ►tyrosine kinase activity and abnormal localization. Table 1 enlists molecularly characterized recurrent chromosomal rearrangements found in cancers.

Formation Of Fusion Genes

Several factors influence the formation of fusion oncogenes and their role in tumorigenesis. Firstly, the rate at which fusion genes are formed is important. Literature suggests that at least some fusion genes are found in healthy individuals, implying that at least some gene fusions emerge at a notable rate. The mechanisms behind fusions are unknown but the occurrence of several double strand breaks that coincide in time and space are important. The proximity of damaged partner genes at the moments of repair is critical and the localization of chromatin and genomic regions in the interphase nuclei may be critical. Secondly, the presence of a fusion gene in a cell is not enough to cause cancer. Additional genetic or epigenetic changes are also needed and the risk for these additional events to occur affects the outcome. Thirdly, once the fusion is formed, its penetrance, i.e. the proportion of fusion carriers that develop tumors, is determined by selected mechanisms. Interestingly, many fusion oncogenes demonstrate a strict specificity for tumor type. The risk of getting a certain translocation could depend on cell type-specific processes that make the specific genes or DNA regions involved vulnerable to the translocation. It is clear that tumor development in different cell types and tissues locations involves many pathways, distinct genes, and also exogenous factors. A common mechanism for early genetic changes can however be distinguished in a number of different tumor types by specific chromosome rearrangements.

Moreover, the transcriptional orientation of fusion partner genes is essential in order to harbor functional fusion genes. At times, the partner genes are not oriented in the correct direction with regards to their transcriptional orientation, and more complex rearrangements are needed to fuse the partner genes into functional fusion genes. For instance, the EWS-ERG fusion is found in about 10% of Ewing sarcomas and it is the result of a complex rearrangement, a ►translocation and an ►inversion, given that the genes involved are not transcribed in the same centromeric/telomeric direction. This requirement and the necessary presence of critical functional protein parts seem to influence how frequently variant fusion genes are present in tumors. Moreover, to produce a functional fusion gene is necessary that the exons flanking the breakpoints can give rise to splicing events that maintain their reading frames. Overall, the factors that generate double-strand breaks are largely unknown.

Clinical Relevance

Studies over the past decades have revealed that recurring chromosome rearrangements leading to fusion oncogenes are specific features not only of leukemias and lymphomas, but also of certain epithelial tumors. Presently, over 600 recurrent balanced tumor-associated chromosomal rearrangements have been molecularly characterized. However, the data are strongly biased in favor of hematologic malignancies and sarcomas. An important example of a recurrent rearrangement which leads to the development of a targeted therapy is the t(15;17)(q22;q21) in ►acute promyelocytic leukemia which fuses the ►*PML* gene (15q22) with *RARα* gene at 17q21. The PML protein contains a zinc-binding domain called a “ring” finger that may be involved in protein–protein interaction. RARα protein encodes the retinoic acid alpha-receptor protein (►retinoic acid receptors a member of the nuclear steroid/thyroid hormone receptor superfamily. Although retinoic acid binding is retained in the fusion protein, the PML/RARα may confer altered DNA-binding specificity to the RARα ligand

complex. Leukemia patients with the *PML/RARα* gene fusion have an excellent response to the all-trans retinoic acid treatment, which stimulates the differentiation of promyelocytic leukemia cells. Similarly, the molecular characterization of the t(9;22)(q34;q11) in chronic myelogenous leukemia, which generates the fusion oncoprotein BCR/ABL, lead to the development of a successful targeted treatment of imatinib.

In contrast to hematological neoplasia, our knowledge regarding fusion genes in solid tumors is very limited, due to the complexity and poor quality of their ►cytogenetic karyotypes, yet they constitute only the 10% of known recurrent balanced chromosome rearrangements. However, fusion oncogenes may be more common in epithelial tumors than previously thought. Usually, translocations in solid tumors result in gene fusions that encode chimeric oncoproteins. The first chromosome abnormalities to be molecularly characterized in solid tumors were an inv(10)(q11.2; q21.2), as the more frequent alteration, and a t(10;17)(q11.2;q23), in ►papillary thyroid carcinoma. These two abnormalities represent the cytogenetic mechanism which activate the proto-oncogene ►*RET* on chromosome 10, by generating the fusion genes forming the oncogene RET/PTC1 and RET/PTC2, respectively. Moreover, other chromosomal rearrangements leading to *RET* activation were recently described and listed in Table 1. A great impact in the study of solid tumors is foreseen by the recent identification of a large subset of ►prostate cancer harboring ►TMPRSS2/ERG, fusions, TMPRSS2/ETV1 and TMPRSS2/ETV4, generated by inv(21)(q22.2;q22.3), t(7;21)(p21.2;q22.3) and t(17;21)(q21;q22.3) respectively. In particular, the gene *fusion* of the 5′ UTR of TMPRSS2 (a prostate-specific gene) to *ERG* or *ETV1* (genes of the ►ETS family), was identified in the majority of prostate cancer. Although the clinical significance of those fusions is unknown, recent investigations indicate that the expression of TMPRSS2/ERG among prostate cancer patients is a strong prognostic factor for disease progression.

Although fusion proteins play an important role in oncogenesis, additional genetic alterations are essential in order to transform cells. Silencing the specific fusion genes that play fundamental roles for the corresponding tumor, blocking targets of fusion proteins and repressing the cooperating events are all promising therapeutic strategies that need to be further investigated. The detection of the intracellular targets of these fusions will harbor new and important insights into molecular pathways that underlie tumor development. Ultimately, a combination of these approaches with

conventional treatments may provide a powerful new approach to treat these fusion-positive tumors.

Institute of Pharmacology, University of Heidelberg, Heidelberg, Germany

Synonyms

Heterotrimeric GTP-binding proteins; Heterotrimeric guanine nucleotide-binding proteins

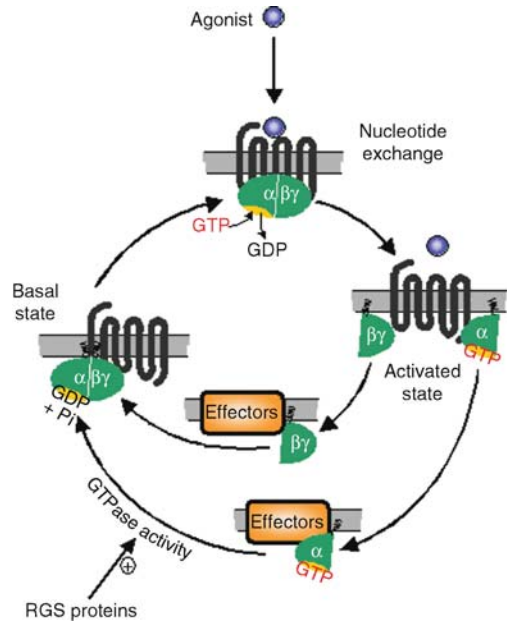
Definition

G-proteins are named for their ability to bind and hydrolyze the guanine nucleotide ►GTP. In the widest sense, the superfamily of guanine nucleotide-binding proteins comprises two structurally distinct classes, the monomeric GTP-binding proteins (also called ►monomeric GTPases) which are involved in a variety of cellular processes, and the heterotrimeric GTP-binding proteins which are primarily involved in transmembrane ►signal transduction by coupling membraneous receptors to various effector molecules. Traditionally, the term "G-protein" is only applied to the latter group, the heterotrimeric GTP-binding proteins.

Characteristics

Cellular functions in a living organism are regulated and coordinated by a huge variety of extracellular

signals including ►hormones growth factors, paracrine factors, neurotransmitters, or sensory stimuli. Many of these signals are received by cells through receptors on the plasma membrane which convey the incoming information by coupling to G-proteins which are attached to the inner side of the plasma membrane. More than 1,000 genes coding for G-protein-coupled receptors (►GPCR) have been identified making GPCRs one of the largest gene families of the mammalian genome. G-proteins activated through GPCRs regulate various effectors like enzymes and ion channels which produce intracellular signals resulting in specific cellular responses. G-protein functions are highly diverse due to their composition of different α-, β-, and γ-subunits, each of which are products of different genes. The α-subunit of the heterotrimeric G-protein possesses structural and functional homologies to other members of the guanine nucleotide-binding protein superfamily. The β- and γ-subunits of heterotrimeric G-proteins form an undissociable complex and represent a functional unit. Some G-proteins are very specialized like those expressed only in sensory cells; others appear to have functions in a wide variety of cells and tissues. Many G-proteins seem to have overlapping distributions and functions indicating that complex functional relationships exist among different G-proteins.



G-Proteins. Figure 1 The G-protein cycle. Upon activation of a G-protein-coupled receptor by binding of an agonist, GDP is released from the α-subunit of the heterotrimeric G-protein and replaced by GTP. This in turn leads to the dissociation of the α-subunit and the βγ-complex which are now able to interact with effector proteins. A GTPase activity inherent to the G-protein α-subunit terminates the G-protein activation. The hydrolysis of GTP to GDP can be accelerated by regulators of G-protein signalling (RGS) proteins as well as by various effectors.

Molecular and Cellular Regulation

In order to convey a signal from an activated receptor to an effector, the heterotrimeric G-protein undergoes an activation–inactivation cycle which allows the G-protein to function as a regulatable molecular switch (Fig. 1). In the basal state, the βγ-complex as well as the GDP-bound α-subunit is associated. In this form, the G-protein can be recognized by an appropriate activated receptor which interacts with the G-protein heterotrimer.

This interaction results in the dissociation of GDP from the α-subunit of the heterotrimeric G-protein. GDP is then replaced by GTP. Binding of GTP to the α-subunit induces a conformational change, which in turn leads to the dissociation of the α-subunit and the βγ-complex. The GTP-bound α-subunit as well as the βγ-complex is now able to interact with effector proteins. A ►GTPase activity inherent to the G-protein α-subunit terminates the G-protein activation. The formed GDP remains bound to the α-subunit which now reassociates with the βγ-complex. The reassociation of the heterotrimeric G-protein induced by the hydrolysis of GTP represents the inactivation mechanism for the βγ-complex. Two bacterial toxins specifically interfere with the G-protein activation–inactivation cycle and have been useful tools in studying G-protein-mediated signaling. ►Pertussis toxin blocks the interaction of activated receptors and various G-proteins whereas ►cholera toxin leads to the constitutive activation of some G-proteins. A physiological regulation of the GTPase activity of the α-subunit occurs by several effector proteins which interact with the GTP-bound α-subunit and accelerate their GTPase activity leading to G-protein inactivation. In addition, a family of proteins called "regulators of G-protein signaling" (►RGS proteins) are also able to increase the GTPase rate of the G-protein α-subunit.

More than 20 G-protein α-subunits have been described in the mammalian system, and they can be divided into four subfamilies based on structural and functional homologies (Table 1). The main properties of individual G-proteins appear to be primarily determined by the identity of the α-subunit of the heterotrimeric G-protein. While some G-protein α-subunits show a very restricted expression pattern others are expressed in a wide variety of tissues and some G-protein α-subunits like $G\alpha_s$, $G\alpha_q$, $G\alpha_{11}$, $G\alpha_{12}$, and $G\alpha_{13}$ appear

G-Proteins. Table 1 Mammalian G-protein α-subunits

?, Regulation not shown directly.

to be expressed more or less ubiquitously. An individual cell expresses up to ten different G-protein α-subunits.

Five G-protein β-subunits and 11 γ-subunits have been described in the mammalian system. With the exception of the β_5-subunit which is expressed mainly in the central nervous system, the currently known β-subunits exhibit a high level of sequence homology (79–90%). In contrast, G-protein γ-subunits are much more heterogeneous. Similar to GTP-bound Gα, βγ-complexes can also regulate various effectors. The best examples of βγ-regulated effectors are particular isoforms of ►adenylyl cyclase and ►phospholipase C, as well as ion channels and ►phosphoinositide-3-kinase isoforms. With a few exceptions, there appear to be no major differences between different βγ-combinations with regard to their ability to regulate effector enzymes.

Stimulatory regulation of adenylyl cyclases through GPCRs involves G-proteins of the G_s-family of which two main members are known, G_s and G_{olf}.

The $G\alpha_{i/o}$-family members have been shown to mediate receptor-dependent inhibition of adenylyl cyclases. Since the cellular levels of these G-proteins are usually relatively high, they also represent an important source for βγ-complexes which can regulate a variety of cellular effectors. The G-protein G_o is the most abundant G-protein in the mammalian nervous system. G_o is involved in the inhibitory regulation of voltage-dependent Ca^{2+} channels, a process which appears to be mediated by the βγ-complex of G_o.

Several G-protein α-subunits are primarily expressed in sensory cells and have been involved in the signal transduction of sensory stimuli. Rod-transducin ($G_{t\text{-}r}$) and cone-transducin ($G_{t\text{-}c}$) play well established roles in the phototransduction cascade in the outer segments of retinal rods and cones where they couple light receptors to downstream signaling components of the retinal phototransduction cascade. In contrast to the transducins, the function of gustducin ($G\alpha_{gust}$) in taste cells is less well understood. Among the five taste qualities (sweet, umami, bitter, sour, and salty), sweet, umami, and bitter tastes appear to be transduced through heterotrimeric G-proteins.

$G\alpha_q$-family members mediate the pertussis toxin insensitive regulation of phospholipase C β-isoforms. The G_q-family consists of four members whose α-subunits are expressed from individual genes with different expression patterns. $G\alpha_q$ and $G\alpha_{11}$ appear to be expressed more or less ubiquitously and are primarily responsible for coupling of receptors to phospholipase C β-isoforms. In contrast, the murine G-protein α-subunit $G\alpha_{15}$ and its

human counterpart $G\alpha_{16}$ are only expressed in a subset of hematopoietic cells, and the expression of $G\alpha_{14}$ is restricted to several organs, e.g., kidney, testis, and lung. Receptors activating G_q-family members in mammalian systems do not discriminate between G_q and G_{11}.

The G-proteins G_{12} and G_{13} constitute the G_{12}-family and appear to be expressed ubiquitously. $G_{12/13}$ regulate the actin cytoskeleton through the activation of the monomeric GTPase Rho (►Rho-family proteins). This activation is mediated by a subgroup of guanine nucleotide exchange factors (►GEFs) for Rho including p115-RhoGEF, PDZ-RhoGEF, and LARG.

In recent years, genes of almost all G-protein α-subunits have been inactivated in mice. The resulting phenotypes of Gα-deficient animals have provided insights into the biological role of G-proteins demonstrating that G-protein-mediated signaling processes are crucially involved in multiple processes during development as well as in the adult organism.

Clinical Relevance

G-protein-mediated signaling processes are operating in all cells of the human organism. They are involved in many physiological and pathological processes. Many clinically relevant drugs function as agonists or antagonists of GPCRs and exert their effects through G-protein-mediated signaling pathways. Some diseases have been found to be caused by distinct defects in single G-protein α-subunits. Emerging experimental data indicate that GPCRs, e.g., the receptors for ►thrombin (►Protease-activated receptor), ►prostaglandin E_2 (PGE_2) (►Prostaglandins), lysophosphatidic acid (LPA), and sphingosine-1-phosphate (S1P), are crucially involved in tumor growth and ►metastasis.

►Gain-of-function mutations of the gene encoding $G\alpha_s$ (*GNAS*) give rise to the *gsp* oncogene (►Oncogene) which has been found in almost 30% of thyroid toxic adenomas as well as in some thyroid carcinomas (►Thyroid carcinogenesis) and growth hormone producing pituitary adenomas. The sporadic somatic mutation leads to the substitution of Arg201, the same residue which is ADP-ribosylated by cholera toxin, and results in a constitutively active form of $G\alpha_s$ by blocking its GTPase activity. This leads to activation of adenylyl cyclase independent of receptor agonists. The same sporadic mutation occurring early in embryogenesis results in a ►mosaicism which is responsible for the ►McCune-Albright syndrome characterized by polyostotic fibrous dysplasia of the bone, precocious puberty, and café-au-lait pigmentation of the skin.

An analogous mutation of the gene encoding $G\alpha_{i2}$ (*GNAi2*) (the *gip2* oncogene) has been found in human ovarian sex cord stromal tumors and adrenal cortical tumors (►Adrenocortical cancer).

In vitro studies indicate that expression of constitutively active forms $G\alpha_q$ and $G\alpha_{11}$ can lead to transformation of fibroblasts when expressed at low levels. No transforming mutants of $G\alpha_q$ and $G\alpha_{11}$ have been detected in human tumors, but various G_q/G_{11}-coupled receptors have been shown to be involved in the stimulation of proliferation in small lung cancer cells. The ►Kaposi sarcoma-associated herpesvirus (KSHV/HHV8) is suppose to encode a G_q/G_{11}-coupled receptor and signaling via this receptor has been shown to lead to cell transformation, tumorigenicity, and angiogenesis, and thus to critically contribute to KSHV-mediated oncogenesis.

GNA12 the gene encoding $G\alpha_{12}$ was identified as an oncogene (the *gep* oncogene) in soft tissue sarcoma. Constitutively active mutants of $G\alpha_{12}$ and $G\alpha_{13}$ have been shown to exhibit potent transforming activity in different systems. No activating mutation of $G\alpha_{12}$ or $G\alpha_{13}$ has been found in human tumors so far, however, increased expression levels of both proteins have been detected in various human cancers. In addition to their role in the regulation of cellular growth and their transforming ability, signaling via $G\alpha_{12/13}$-proteins has recently been implicated in the control of ►invasion and metastasis of breast and prostate cancer cell lines. By regulating a subgroup of RhoGEF-proteins, both $G\alpha_{12}$ and $G\alpha_{13}$ can activate the small GTPase RhoA which has been suggested to play an important role in cancer ►progression and invasion.

[2]Department of Oncology, Odense University Hospital, Odense C, Denmark

Synonyms

CT4; G antigen

Definition

Belong to the ►cancer testis antigen (CTA) family and consist of at least 16 highly homologous proteins (GAGE 1, GAGE2A-E, GAGE10, GAGE12B-J, GAGE13).

Characteristics

The 16 genes that encode GAGE proteins are located in an equal number of tandem repeats on chromosome X (p11.2-p11.4 region). GAGE 1 is unique among the GAGE proteins because of an exclusive C-terminal encoded by an exon that is interrupted in the other GAGE genes. The remaining GAGE members are composed of five exons encoding 116–117 amino acids with 98% identity, while GAGE1 consist of 138 amino acids. The molecular size of GAGE proteins is 26–29 kDa.

In contrast to other CTAs, the expression of which in adult normal tissues is restricted to germ cells of testis, GAGE is also expressed in a subset of oocytes of resting primordial follicles and in maturing oocytes of ovaries. In the testicular seminiferous tubuli, GAGE expression is restricted to the spermatogonia and, to a lesser degree, the primary spermatocytes. GAGE gene transcripts have been found in numerous cancers, most frequently ►malignant melanoma (24–42%), ►lung cancer (19–54%) ►thyroid cancer (30%) ►breast cancer (26%) ►hepatocellular cancer (38%) and ►ovarian cancer (30%) sarcomas (19%) (►Osteosarcoma, ►rhabdomyosarcoma), and ►bladder cancer (12%). Immunohistochemical studies have also identified GAGE in many cancers, but generally at a lower frequency than that observed by ►RT-PCR, including bladder cancer (40%) [00187], ►malignant melanoma (17%), ►lung cancer (16%) ►breast cancer (12%), and ►thyroid cancer (10%). The staining pattern varied significantly among and within specimens, and most GAGE-positive tumors also contained cancer cells lacking GAGE expression. GAGE has been correlated to poor prognosis in ►gastric cancer, ►esophageal carcinoma and ►neuroblastoma.

G

In vitro studies have shown that GAGE expression in tumors can be induced by the DNA methyltransferase inhibitor 5-aza-2′-deoxycytidine (►Methylation), but the transcription of individual GAGE genes seems to be differently regulated, since the GAGE members are not always co-expressed.

GAGE proteins are immunogenic and lead to anti-GAGE antibody and ►cytotoxic T lymphocyte (CTL) responses in some cancer patients. The GAGE 1 gene was originally identified as encoding an antigenic peptide, YRPRPRRY, which was presented on a human melanoma by the MHC class I molecules HLA-Cw6 and recognized by a CTL clone derived from the melanoma patient. From the same patient, another CTL clone recognizing the peptide YYWPRPRRY, which is encoded by GAGE2A-E and presented by HLA-A29 molecules, was also isolated. Anti-GAGE antibodies are present in 6% of melanoma patients, but not in pancreas cancer patients.

Subcellular localization of GAGE in normal cells (e.g. germ cells) and cancer cells is similar; exhibiting weak cytoplasmic staining and variable nuclear staining. This suggests that GAGE, when expressed in cancer cells, is expressed in the natural context and thus may play a functional role therein. The nuclear localization of GAGE in spermatogonia and cancer cells suggests that GAGE may be a regulator of germline gene expression.

Due to the restriction of GAGE expression to immunoprivileged normal tissues and their relatively frequent expression in different types of cancer, GAGE proteins are considered attractive candidates for T cell-mediated, cancer-specific ►immunotherapy. However, the lack of GAGE expression in subsets of cancer cells within GAGE-positive tumors, as also observed for other CTAs, may limit its value as a therapeutic target. Combining different CTA targets may compensate for the heterogeneous expression of each CTA within cancers and improve the therapeutic potential.

The function of GAGE members remains largely unknown, although one study has reported anti-apoptotic properties of GAGE12 (formerly known as GAGE7). GAGE12-transfected cells were shown to be resistant to ►apoptosis induced by ►interferon-gamma or by the death receptor ►Fas/APO-1/CD95. In the Fas pathway, the anti-apoptotic activity of GAGE12 maps downstream of ►caspase-8 activation, and upstream of poly (ADP-ribose) polymerase (PARP) cleavage. Furthermore, GAGE12 renders the cells resistant to the chemo- and radio-therapeutic agents (►Chemotherapy of cancer, progress and perspectives, ►radioimmunotherapy), ►Taxol and gamma-irradiation.

Gain of Function p53

Giovanni Blandino
Rome Oncogenomic Center, Department of Experimental Oncology, Regina Elena Cancer Institute, Rome, Italy

Definition

Gain of function is the property of some proteins whose alterations determine the acquisition of novel functions mainly opposite to those exerted by the ►wild-type counterparts.

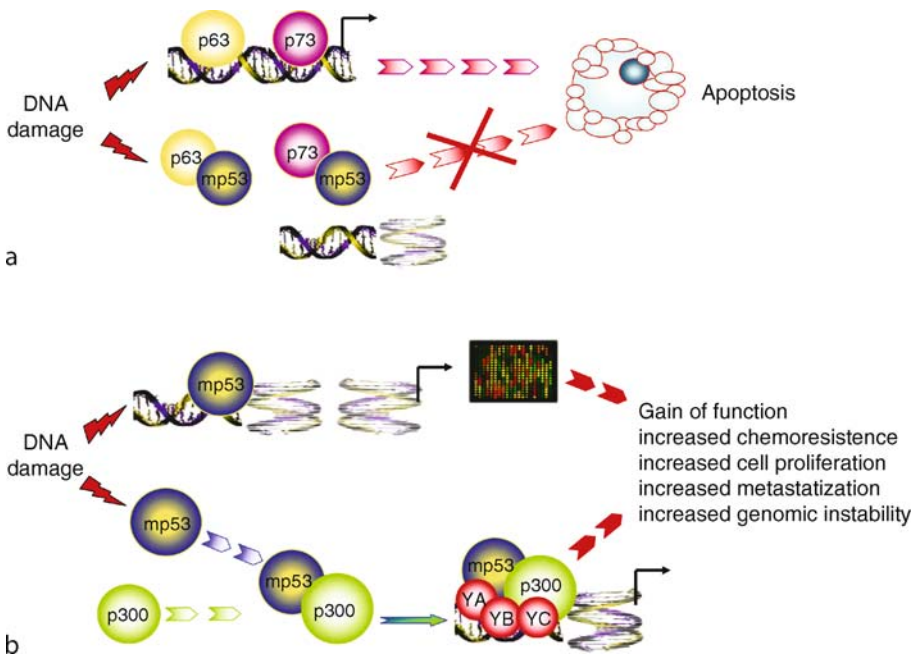
Characteristics

The gene product of the tumor suppressor ►p53 represents a paradigm of a protein whose alterations, mainly missense mutations, cause the acquisition of novel functions that contribute to the insurgence, the maintenance, the spreading and the ►chemoresistance of certain tumors. p53 is a ►transcription factor that can be roughly divided in three functional domains: (i) the N-terminus where resides the transcriptional activity; (ii) the central DNA binding domain that is responsible for the specific recognition of p53 binding sites; and (iii) the C-terminus domain that exerts oligomeric and autoregulatory activities. Half of human cancers bear p53 mutations that mainly occur within the specific DNA binding domain. The resulting proteins are characterized by the loss of the antitumoral activities of wild-type p53 (wt-p53) and, at least, for some of them by the gain of novel oncogenic activities. Many in vitro and, very recently, in vivo studies have shown that, at least, some of these mutant p53 proteins gain novel oncogenic functions that range from increased proliferation to enhanced chemoresistance to anticancer treatments. To date, the diverse mutant p53 proteins have been classified accordingly to their structural features. Indeed, they can be divided in two large classes: (i) DNA contact defective mutants whose missense mutation impacts on the region of the protein that contacts the DNA. The prototypes of this class of mutants are p53His273 and p53Trp248 that are also the

most frequent p53 mutations found in human cancers. (ii) Defective structure mutants whose missense mutation resides within the region of the stabilization of the internal loops (L2 and L3) of p53 and consequently their overall structure is quite different than that of wt-p53. Despite many ongoing attempts, a functional classification of p53 mutations that resembles their structures features has not been identified yet. By comparing wild-type versus mutant p53 two peculiar differences can be revealed. While wt-p53 is a short-living protein capable to activate target genes transcriptionally through the recognition of specific binding sites on their regulatory regions, mutant p53 is a very stable protein that is unable to bind wt-p53 consensus. There is scarce evidence on the molecular basis of the prolonged half-life of mutant p53 compared with that of wt-p53, but this peculiar feature might play a key role in gain of function.

Molecular Mechanisms

The molecular mechanisms underlying gain of function of mutant p53 proteins need to be clarified yet. To date, two scenarios can be proposed as molecular basis for mutant p53 gain of function. The first one relies on the prolonged half-life of mutant p53 proteins that are consequently very abundant in tumor cells. Thus, mutant p53 proteins can be engaged in many and multiple physical protein–protein interactions. One of the most studied is that with the newly discovered ►p53 family members, p73 and p63 (Fig. 1a). The latter, despite their critical roles in development and differentiation, have been shown to recapitulate most of the wt-p53 tumor suppressor activities when exogenously expressed in $p53^{+/+}$ and p53 null cells. Floating protein complexes involving mutant p53 and p73 or p63 have clearly evidenced in diverse tumor cell lines. The net result of these protein complexes is the severe impairment of p73/p63-mediated growth suppression and ►apoptosis. Chromatin immunoprecipitation experiments have clearly shown that mutant p53 severely impairs the in vivo recruitment of both p73 and p63 to the regulatory regions of their target genes. The polymorphism at position 72 of mutant p53 has been shown to be a critical determinant of the strength of the protein complex mutant p53/p73. Indeed, the 72R (Arg) forms of p53Ala143 and p53His175 mutants bind to p73 and impairs p73-mediated gene target transcriptional activation more efficiently than the equivalent 72P (Pro) mutants. The biochemical analysis of the protein complex mutant p53/p73 has revealed that the interaction surface is composed by the core domain of mutant p53 and the specific DNA binding



Gain of Function p53. Figure 1 Schematic representation of two molecular scenarios underlying gain of function of mutant p53. (a) Mutant p53 proteins form protein complexes with the newly discovered p53 family members, p73 and p63 (►p53 protein biological and clinical aspects). This results in the impairment of p73 or p63 recruitment on the regulatory regions of their target genes and of p73/p63-mediated apoptosis in response to DNA-damaging agents. (b-*upper part*) Mutant p53 binds directly to DNA through a consensus that remains to be identified yet; (b-*lower part*) Mutant p53 takes part to large protein complex facilitating the recruitment of the acetylase, p300. The final outcome is the transcriptional modulation of target genes responsible for the indicated biological effects.

domain of p73. These findings have discovered a novel function for the core domain of mutant p53, such as, its ability to function as a protein–protein interaction platform.

Is there any link between the selective pressure for p53 missense mutations in the core domain and gain of function activity of mutant p53 proteins? There is no sufficient evidence to make a conclusion. The vast majority of p53 mutant proteins are unable to bind wt-p53 binding sites present on the regulatory regions of its target genes and consequently are inefficient in the activation of wt-p53 mediated antitumoral effects. Opposite to such loss of function, mutant p53 proteins may acquire, through its mutated core domain, new properties that contribute to their gain of function. Despite many efforts, the presence of wt-p53/p73 protein complexes has not been identified in tumor cells. This might suggest that mutant p53 binds to a pool of selected proteins diverse than those bound by wt-p53. The presence of mutant p53 or wt-p53 in large and multiple protein complexes might represent a key determinant of their biological outputs. A paradigmatic example has been recently provided by the analysis of the transcriptional cross-talk between mutant p53 and the transcription factor NF-Y. The latter binds to both wt- and mutant-p53 but the transcriptional effects on NF-Y target genes are repression or activation, respectively. Is mutant p53 a bona fide transcription factor? (Fig. 1b) There is growing evidence accounting for transcriptional activity of mutant-p53 as molecular mechanism underlying its gain of function activity. This possibility mainly resides on the assumption that the N-terminus of mutant p53 in functionally intact and might exert specific transcriptional activity. To date, one of the key features of a bona fide transcription factor such as a specific DNA binding site for mutant p53 proteins has not been identified yet. This might suggest that mutant p53 can exert its transcriptional activity by engaging with DNA binding proteins, acetylases, deacetylases, and other proteins in the context of large protein complexes. If this hypothesis will be further demonstrated, as occurred for the transcriptional cross-talk mutant p53/NF-Y, it will mean that the plethora of the putative mutant p53 target genes is rather large, thereby providing the molecular basis underlying the diverse mutant p53-mediated oncogenic effects. There is scarce evidence on the role of mutant in these large protein complexes and specifically the contribution of its N-terminus transcriptional activation domain. It was originally shown that mutant p53 proteins, whose residues 22 and 23 were mutated, lost their oncogenic activity as well as their ability to transactivate specific target genes. Despite the molecular details need to be clarified yet, these findings strongly support a direct involvement of the N-terminus of mutant p53 in the activity of the large transcriptional competent protein complexes. The biochemical analysis of the spatial and temporal events regulating the cross-talk between mutant p53 and NF-Y has revealed a different transcriptional contribution of mutant p53 proteins (p53 protein biological and clinical aspects). Indeed, it was found that mutant p53 facilitates the recruitment of p300 acetylase, thereby indicating that it might serve as scaffold protein whose contribution results in the stabilization and proper activation of the transcriptional competent protein complex. Recent evidence has shown an additional molecular mechanism for mutant p53 gain of function activity. It is based on the tight association of mutant p53 with the nuclear matrix in vivo, and with high affinity to nuclear matrix attachment region (MAR) DNA in vitro. These findings suggest that mutant p53 interacting with key structural components of the nucleus, exerts its gain of function activity through the perturbation of the nuclear structure and function. As described earlier, the molecular scenario(s) underlying gain of function of mutant p53 are rather complex. It might be reasonable that a combination of specific protein–protein interaction and direct transcriptional activity takes place in driving gain of function of mutant p53. Many questions regarding the contribution of cell context, type of p53 mutations, posttranslational modifications are still unanswered and might be determinant in the final outcome of mutant p53 activities.

Clinical Aspects

Many in vitro and in vivo evidences have shown that the status of p53 is a key determinant of tumor aggressiveness and chemosensibility to common anticancer treatments. Tumors carrying p53 mutations are more resistant to the killing of anticancer agents and relapse more frequently than those bearing wt-p53. As a consequence of it, the overriding of mutant p53 gain of function might be extremely useful for treating mutant p53 tumors. Diverse approaches ranging from reactivation of mutant p53 to its wt-conformation as well as the elimination of mutant p53 have been undertaken in the last few years. In addition to them, the use of short peptides capable to specifically disassemble oncogenic protein complexes involving mutant p53 protein might be attempted to increase the chemosensibility of tumor cells. The well-established mutant p53/p73 protein complex could be a preferential target to be tackle with such approach. The amount of free and available p73 to be recruited in activating proapoptotic pathways in response to different anticancer treatments might be significantly increased by pretreating mutant p53 cells with short interfering peptides capable to disrupt the protein complex mutant p53/p73. These effects might render mutant p53 cells more prone to the killing of anticancer treatments.

Gallbladder Cancer

Giorgia Randi
Department of Epidemiology, Institute for Farmacological Research Mario Negri, Milan, Italy

G

Definition

The biliary tract consists of an interconnected system of intra- and extrahepatic ducts that transport ►bile secreted from the liver to the digestive tract. The gallbladder is an important organ of the biliary system lying just under the liver, receiving, storing and then releasing the bile through bile ducts into the duodenum to help digesting fat. Gallbladder cancer (GC) is the most common type of cancer of the biliary tract.

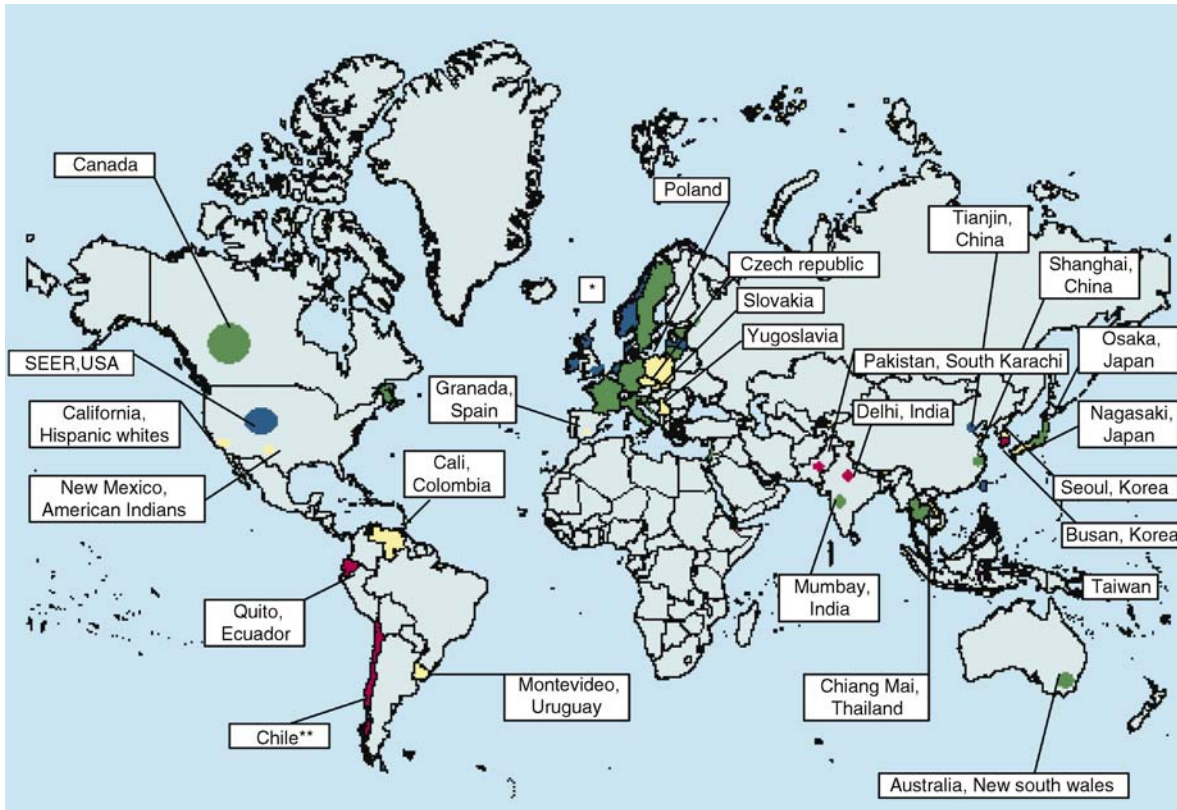
Characteristics

GC is a relatively rare neoplasm and despite being a non sex-related cancer is several-fold more frequent among women than among men. Detection of GC is quite difficult because symptoms and signs of GC are not specific and often appear late in the clinical course of the disease. For this reason, diagnosis is generally made when the cancer is already in advanced stages, and prognosis for survival is less than 5 years in 90% of cases.

Descriptive Epidemiology

GC incidence is characterized by a wide worldwide variation (Fig. 1) being low in several European countries and the United States of America (USA), relatively high in selected central European countries, and very high in some countries of Latin America and Asia. GC has been shown to be the first cause of cancer death among women in some areas of Chile.

According to ►incidence rates recorded by cancer registries in mid-1990s, the highest incidence rate worldwide was shown by women from Delhi, India (21.5/100,000), followed by South Karachi, Pakistan (13.8/100,000) and Quito, Ecuador (12.9/100,000). Cancer registries reporting high GC incidence rates were in Far East Asia (Korea and Japan), Eastern Europe (Slovakia, Poland, Czech Republic and Yugoslavia), and South America (Colombia). In Western Europe, elevated incidence rates were shown in Granada, Spain. Although



Gallbladder Cancer. Figure 1 Worldwide incidence of gallbladder cancer among women. Geographic areas according to incidence rates of mid-1990s from 40 selected cancer registries: areas in red are characterized by very high incidence rates (age-standardized rates ≥ 10 per 100,000 women); areas in yellow are characterized by high incidence (age-standardized rates between 6 and 10 per 100,000 women); areas in green are characterized by medium incidence rates (age-standardized rates between 2 and 6 per 100,000); areas in blue are characterized by low incidence rates (age-standardized rates < 2 per 100,000 women). *Countries in Europe were not specified because of space reasons: Germany, Italy, France, Slovenia, Croatia, Lithuania, Russia, Estonia shown medium incidence rates; Latvia shown low incidence rate. **No official incidence rate was available for Chile, but GC has been shown to be the first cause of cancer death among women in some areas of the country.

systematically lower than in women, high incidence rates among men (ranging between 4.4 and 8.0/100,000) were found in some areas of Asia and Eastern Europe.

Low incidence rates (below 3/100,000 women and 1.5/100,000 men) emerged for most registries from Northern Europe, with the partial exception of Sweden, and from the USA (SEER), and Canada.

The female to male (F/M) incidence ratio of GC incidence rates varied greatly: it was more than 5 in several high-risk areas (e.g., Pakistan, India, Colombia and Spain) as well as in low-risk areas (e.g., Denmark), but was typically between 2 and 3 in the majority of countries. F/M ratio was close to 1 in Korea, Japan and some part of China.

Incidence rates of GC in various ethnic groups from selected cancer registries in the USA confirmed the worldwide pattern, as GC was substantially more frequent among Hispanic than non-Hispanic white women and remarkably elevated among Korean and Chinese men. Very high incidence was also reported by men and women among American Indians in New Mexico. Also the F/M ratio reflected the worldwide situation being high among Hispanic whites, and close to 1 among Koreans, Filipinos, Japanese and Chinese.

Risk Factors

►Carcinogenesis of gallbladder is still poorly understood, and limited number of ►epidemiologic studies have been published on this issue because of (i) the rarity of GC in countries where most medical research is funded and performed, (ii) the difficulties of histological identification of GC, (iii) the lack of relevant animal models and tumor cell lines for GC, (iv) the lack of comprehensive national or international registries

for information on GC cases. ►Risk factors for GC include genetic predisposition, geographic variation and ethnicity, increasing age, female gender, chronic inflammation, congenital abnormalities, low socio-economic status, low frequency of ►cholecystectomy for gallbladder diseases and exposure to certain chemicals.

History of ►gallstones and ►cholecystitis are considered the major risk factors for GC. Several cohort and case-control studies found strong association between history of benign gallbladder diseases (mainly gallstones) and GC risk. Cholesterol and mixed gallstones (containing more than 50% of cholesterol) account for 80% of the all gallstones found, and pigment stones (composed largely of calcium bilirubinate) account for the remaining fraction. The etiology of cholesterol gallstones is thought to involve the interaction of genetic factors (e.g. modification of MDR3 and CYP7A1 genes, and numerous lithogenic genes) and several environmental factors (age, female gender, ►obesity, multiple pregnancies, a family history of gallstones and low levels of physical activity).

The worldwide distribution of gallstone prevalence shows a strong geographic and ethnic variation, and a positive correlation with the incidence rates of GC. High gallstone prevalence (≥50%) among women was found among American Indians in the USA, and among Mapuche Indians in Chile, both populations presenting very high GC incidence rates. Other areas with high or medium prevalence of gallstones were identified in South America, in Eastern and Western Europe. Very few is known about some regions of the world like India where high incidence of symptomatic gallstones has been observed, but results from ultrasound-based studies are not available. Low-risk areas for gallstones (i.e., prevalence <10% among women) included African countries, but also Thailand, China, Korea and Japan that reported high GC incidence rates.

Only a small proportion (1–3%) of patients with gallstones develops GC, thus other risk factors have been proposed to play a role.

Obesity and overweight are major risk factors for gallstones and large cohort studies showed that the association of GC with obesity is one of the strongest seen for any cancer sites. The influence of obesity, however, like the influence of belonging to certain ethnic groups, seemed to be at least in part mediated by an increased predisposition to develop gallstones.

The overall increased frequency of GC in women suggests a possible role for hormonal factors, especially in the formation of cholesterol gallstones. According to the results published by epidemiologic studies, high parity and high number of pregnancies, again recognized risk factors for gallstones, have been related to increased GC risk. Among parous women, older age at first birth or pregnancy has been associated with reduced risk of GC. The effect of oral contraceptive use was not materially related to GC risk, neither were duration of use and time since first and last use. Inconsistent results were obtained for the association of GC risk with menopausal status and HRT use. The exact role of women's hormones is thus still not clear.

Chronic infection of the gallbladder may contribute to the onset of GC, *per se* or via gallstone formation. Most available evidence implicates ►*Salmonella typhi* and *paratyphi* and *Helicobacter* species. All epidemiologic studies on *S. typhi* and *paratyphi* and GC based on ►biological markers, such as serum Vi antigen or the presence of the bacteria in bile specimens, found a significant positive association between carrier state of *S. typhi* and *paratyphi* and GC risk. Also *Helicobacter bilis* and *Helicobacter pylori* have been identified in bile specimens and associated with risk of biliary tract cancer. Unfortunately, most studies of infection and GC to date have been small (no more than 15 exposed cases), have lacked well matched controls (with or without gallstones) and have been hampered by the lack of standardized and non invasive methods for the detection of these infectious agents in large epidemiologic studies.

The association between dietary factors and GC has been also evaluated in some studies. Strong direct association has been found between risk of GC and total carbohydrate intake and total energy intake, and inverse one with fibers, vitamin V6, E, and C. However, apart from obesity, there is no nutritional nor dietary factor consistently related to GC risk. Life-style factors such as smoking and drinking alcohol have been found to be associated with obesity, gallstones and the risk of developing GC in some studies. Due to paucity of results and complexity of the issue, it is still difficult to derive consistent associations.

It has been proposed that two main pathways to GC exist worldwide. The predominant pathway involves gallstones and resultant cholecystitis and affects women to a greater extent than men. The other pathway involves an anomalous pancreatobiliary duct junction (APBDJ), a congenital malformation of the biliary tract that is more frequent in Japan, Korea, and possibly China, than in Western countries. With APBDJ, the pancreatic and common bile ducts join together before reaching the duodenal wall allowing reflux of secretions of the esocrine pancreas into the gallbladder. APBDJ seems specifically related to papillary carcinoma of the gallbladder, rarer in Western countries than in Japan, less invasive and fatal than other carcinomas of the gallbladder.

Conclusions and Perspectives

GC is a highly lethal and aggressive disease with a poor prognosis, but radical surgery can be curative when

proper investigations are done. For the time being, diagnosis of gallstones and removal of gallbladder currently represent the keystone to GC prevention in the majority of the population at high risk. Indeed, a strong inverse association between number of cholecystectomies and GC incidence and mortality rates can be found in many countries.

Behavioral interventions meant to prevent overweight and obesity are difficult to implement, but have the added benefit of preventing diabetes mellitus, cardiovascular diseases and a range of cancer sites in addition to GC, especially among women. If the etiologic role of *S. typhi* and *paratyphi*, *Helicobacter* species or other agents were better demonstrated, the benefits of prevention and treatment of these infections may be substantial.

Gallstones

Definition

Are crystalline bodies formed within the gallbladder by accretion or concretion of normal or abnormal bile components. There are three main types: cholesterol gallstones, mixed gallstones, and pigment gallstones. Cholesterol and mixed gallstones account for 80% of the total, and pigment stones comprise the remaining 20%. Gallstones form when cholesterol and minerals in the bile clump together and form "stones" in the gallbladder. If a gallstone is large enough it can block the bile duct causing severe pain and cholestasis.

Center for Cancer and Immunology Research, Children's Research Institute, Children's National Medical Center and The George Washington University School of Medicine, Washington, DC, USA

Synonyms

Glycosphingolipids (sialic acid-containing)

Definition

A family of complex amphiphatic molecules, consisting of a carbohydrate and a lipid portion. The carbohydrate portion is comprised of one or more sialic acids linked to an oligosaccharide. The complex carbohydrate in turn is linked to ►ceramide, a lipid that consists of ►sphingosine and a fatty acyl residue.

Characteristics

Gangliosides, in addition to being ubiquitous components of normal cell membranes, are highly associated with tumors. A diverse group of molecules, marked structural differences characterize many gangliosides of tumor origin in comparison with gangliosides of normal tissues. Ganglioside biological activities can be highly dependent upon ganglioside molecular structure.

Structure

The ganglioside molecule consists of an oligosaccharide core to which is attached one or more sialic acids, and a hydrophobic lipid (ceramide) consisting of sphingosine (Sph, a long-chain base) and a fatty acid (FA) (Fig. 1), and is a product of ►sphingolipid metabolism. As an example, GM1, and major brain ganglioside, is shown in Fig. 1.

Individual carbohydrate species can be classified in ganglioside biosynthetic pathways. Their biosynthesis, in a sequential order of glycosylations, occurs via two main and several minor pathways. The major pathways are "a" (GM2, GM1a, GD1a) and "b" (GD3, GD2, GD1b, GT1b, GQ1b), stemming from a common precursor (GM3) derived from lactosylceramide. Each ganglioside is structurally more complex than its precursor molecule, and the stepwise addition of monosaccharide or sialic acid residues by specific membrane-bound glycosyltransferases in the Golgi apparatus, is catalyzed by the same glycosyltransferases in both pathways.

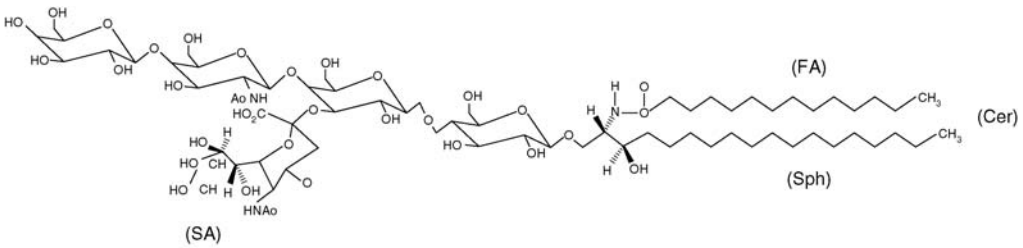
Oligosaccharide heterogeneity is complemented by structural diversity of the ceramide portion of the molecule, especially of tumor gangliosides. Ceramide structural differences may occur both in the sphingosine and in the fatty acyl group, and consist of at least three types of variations: length of the carbon chain, degree of unsaturation, and substitution by hydroxyl groups. All these have been shown to influence ganglioside biological activities. The predominant alteration in tumor ganglioside ceramide structure is significant variation in fatty acyl chain length. This complexity of structure, especially in tumor gangliosides, has implications for biological activity, and the particular importance of ceramide structure is suggested by studies showing differential functional effects of ceramide subspecies of tumor gangliosides.

Cellular Ganglioside Expression in Cancer

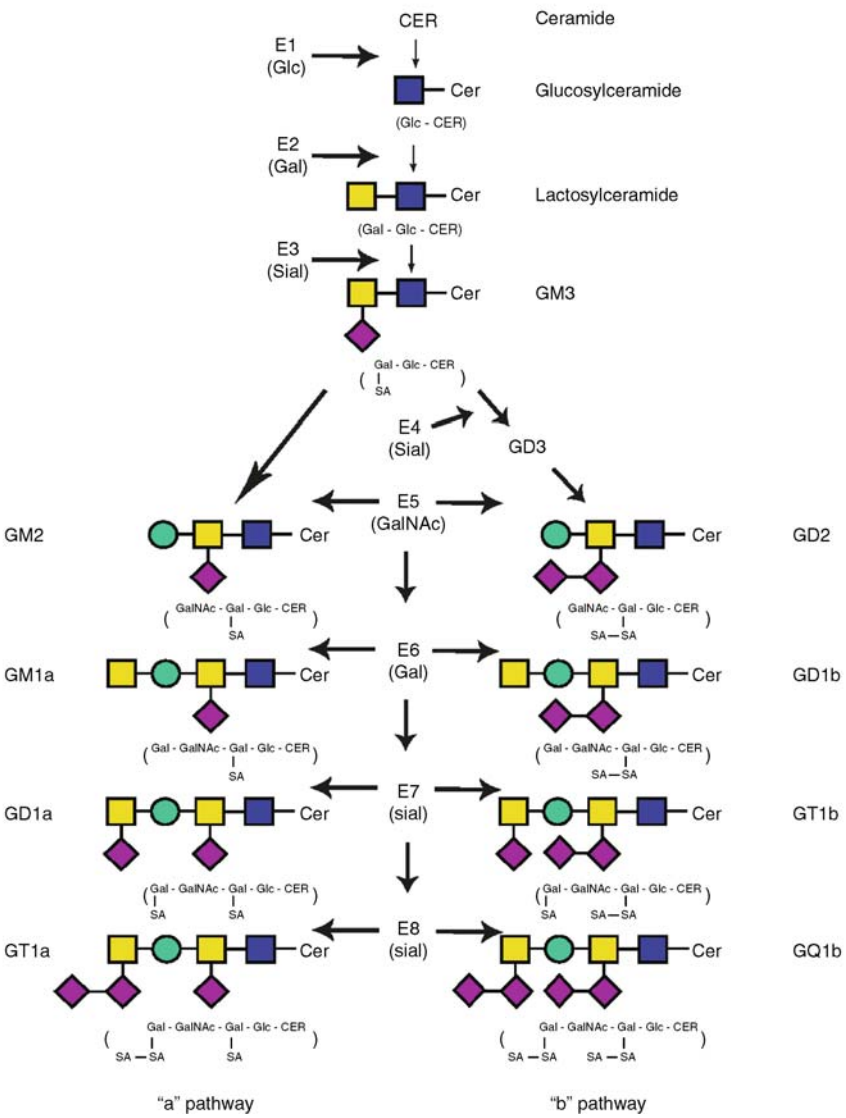
Gangliosides are normally found in all tissues and cells, in varying concentrations. They are present in highest concentrations in brain tissue. In cancer, there are both quantitative and qualitative changes in gangliosides (compared to analogous normal tissues) and these may serve as markers for tumors. The highly heterogeneous expression of gangliosides in normal and tumor tissues raises the possibility of their value as cell surface epitopes. Many monoclonal antibodies against specific gangliosides have been raised, one of the early examples being a monoclonal antibody to ganglioside GD2. GD2 was subsequently shown to be a universal marker for ►neuroblastoma as well as for other neuroectodermal tumors. Antibodies to gangliosides aid in identification of tumor cells and immunohistochemical analysis of tissues. When the expression of a ganglioside is operationally unique to a tumor type (such as GD2 in neuroblastoma), this may also have therapeutic application, such as ►monoclonal antibody therapy for the elimination of residual disease in partially treated patients. Finally, delineation and quantification of expression of specific ganglioside molecules on tumor cell surfaces (such as GD2 in neuroblastoma) has established their value as diagnostic and prognostic markers.

Ganglioside Shedding in Cancer

A striking characteristic of tumor cell ganglioside metabolism is the rapid rate of shedding from the cell surface. This is characteristic of many types of tumor cells, including, among others, neuroblastoma, lymphoma, melanoma, leukemia, and brain tumors. In humans, shed gangliosides can be detected in the peripheral circulation (e.g., in neuroblastoma, in which shedding of tumor-derived gangliosides correlates with the subsequent incidence and rate of tumor ►progression) and in cerebrospinal fluid (e.g., ►medulloblastoma and ►astrocytoma). Also extensively characterized in in vitro systems, this shedding process alters the tumor ►microenvironment: The release of specific gangliosides from tumor cells results in ganglioside enrichment of this ►microenvironment. In turn, these gangliosides



GM1 (Monosialoganglioside)



Gangliosides. Figure 1 The major pathways of ganglioside biosynthesis. GM3, derived from lactosylceramide, is the common precursor for both "a" and "b" pathway gangliosides. Each ganglioside consists of a ceramide back bone (CER), and a carbohydrate chain (glc = glucose, gal = galactose, GalNAc = N-acetylgalactosamine) containing one or more sialic acid (SA = sialic acid) residues. Parallel steps in both pathways are catalyzed by the same glycosyltransferases: (E1): Glucosylceramide synthase, (E2): Lactosylceramide synthase, (E3): GM3 synthase, (E4): GD3 synthase, (E5): GM2/GD2 synthase, (E6): GD1b/GM1a synthase, (E7): GT1b/GD1a synthase, (E8): GQ1b/GT1a synthase.

can be intercalated into the membrane of normal cells and alter their function.

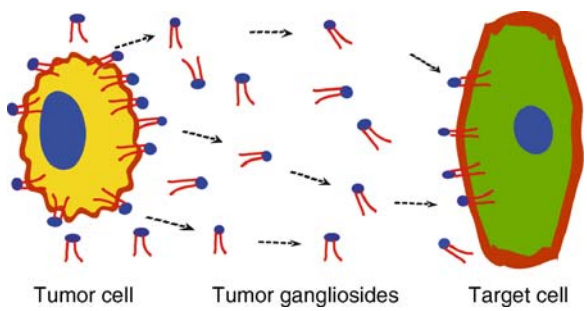
Functional Properties

Elucidating the functional properties of gangliosides has been a challenge facing investigators for over half a century. A role in brain function has long been suspected because of the high concentrations in brain tissue, and the critical role of gangliosides in brain development has been clearly shown through the use of ►knock-out mouse models, in which ganglioside biosynthetic enzymes shown in Fig. 1 have been deleted. Resulting consequences include a myriad of defects ranging from subtle neurologic defects to embryonic lethality. Defined human genetic ganglioside metabolic defects, with one recent exception, are catabolic defects, resulting in ganglioside storage. These diseases (e.g., Tay-Sachs disease) also have serious central nervous system consequences, including seizure disorders, mental retardation, etc.

More subtle functional properties of gangliosides have been uncovered through the study of the modulation of cell function by the addition of exogenous gangliosides, or by their depletion in cultured cells, using pharmacological inhibitors. These studies at the cellular level are delineating functional properties of gangliosides that may relate particularly to cancer progression, by the presence of tumor gangliosides in the tumor microenvironment (Fig. 2). Three such functional properties are highlighted:

Immunosuppression

More than two decades ago inhibition of mitogen and antigen-induced lymphoproliferative responses by normal brain gangliosides was observed. The first studies of tumor-derived gangliosides, in a mouse model, showed that tumor gangliosides markedly suppress cellular immune responses in vitro. A number of specific effects of exogenous gangliosides on the immune response have subsequently been characterized. A partial list includes inhibition of: ►antigen-presenting cell (e.g., ►dendritic cell) function, cytokine production, dendritic cell costimulatory molecule (e.g., CD80/CD86) expression and ►IL-12 production, ►T cell responses including cytotoxic effector function and proliferation of mitogen-activated lymphocytes, and interference with nuclear translocation of ►NFκB in monocytes and lymphocytes. The immune response to tumor in vivo is also significantly affected, immunosuppressive activity is influenced by ganglioside structure, and certain ganglioside structures, which are only minor components in normal tissue but are frequently major species in tumors (such as GD3 and GD2 ganglioside in neuroectodermal tumors), are in fact biologically very active ganglioside species. It is quite possible that certain shed tumor gangliosides function as intercellular signaling molecules, downregulate the cellular immune response, and thereby enhance tumor formation and progression according to the model in Fig. 2.



Gangliosides. Figure 2 Tumor cells rapidly synthesize gangliosides and shed them into their microenvironment, where they interact with, bind to, and affect the function of, normal cells within this tumor microenvironment.

Growth Factor-Induced Cell Signaling

It is modified by gangliosides because of the specific localization of gangliosides within the cell membrane, in glycosphingolipid-enriched domains. Existence in these domains puts gangliosides into close proximity with numerous biologically active cell surface molecules (such as growth factor receptors) with which they can then interact. The modification of cell surface ganglioside content, by the addition of exogenous gangliosides or by the inhibition of their synthesis and therefore depletion from cell membranes, has resulted in modification of ►signal transduction triggered by a number of different growth factors. Given the diversity of ganglioside molecules and the large number of biologically active growth factor receptors in the membrane, it is not surprising that a comprehensive unified understanding of the mechanisms of these interactions and their effects is still lacking. Nevertheless, some general characteristics have emerged, and these included that some simple gangliosides, such as GM3, may be inhibitory in their effects on growth factor signaling, whereas more complex gangliosides, such as GD1a, have an enhancing activity. In the tumor microenvironment, these effects may be highly significant with respect to promoting (or impeding) tumor growth, since a substantial number of ►receptor tyrosine kinases (►EGFR, ►VEGFR, ►FGFR, ►insulin receptor) have been affected by ganglioside modification of cell membranes, clearly pointing to a role of gangliosides as modulators of cell signaling.

Cell Proliferation and ►Angiogenesis

These are examples in which ganglioside modulation of cell signaling may affect a biological function critical

to tumor formation and progression. In this case, enrichment of normal fibroblast and vascular endothelial cell membranes by certain gangliosides, as they would be derived from tumors by shedding, results in significant upregulation of normal cell EGF and VEGF receptor dimerization, activation, and downstream signaling. In turn, this caused enhancement of EGF-induced fibroblast proliferation and ►VEGF-induced vascular endothelial cell proliferation and ►migration. Ganglioside enrichment of human umbilical vein vascular endothelial cells also caused even very low, normally barely stimulatory, VEGF concentrations to trigger robust VEGFR dimerization and autophosphorylation, downstream signaling, and cell proliferation and migration. By dramatically lowering the threshold for growth factor activation of contiguous normal stromal cells, shed tumor gangliosides may promote tumor progression by causing these normal cells to become increasingly autonomous from growth factor requirements.

Conclusions

In addition to being generally recognized as important in the central nervous system and its development, gangliosides, especially as derived from tumors, may be viewed as a new class of intercellular signaling molecules, associating with antigen-processing/presenting cells to inhibit accessory cell function interacting with lymphokines to inhibit cytokine-mediated lymphocyte proliferation, altering the expression of cell surface receptor molecules such that the cell has altered responsiveness to proliferative stimuli, and enhancing receptor-mediated cell signaling and function. These potentially protumorigenic effects of gangliosides suggest that targeting glycosphingolipid synthesis with pharmacologic inhibitors might impede tumor progression, a hypothesis currently being tested in view of striking inhibition of tumor progression observed using inhibitors of glycosphingolipid synthesis, which have been shown to decrease ganglioside synthesis and shedding.

Definition

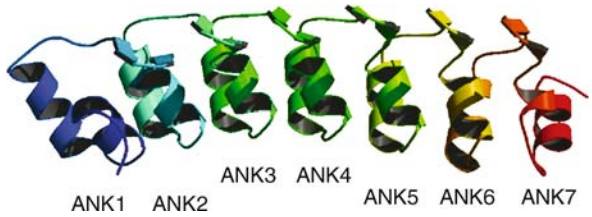
Gankyrin (Gann ankyrin-repeat protein; "Gann" in Japanese means cancer) is a small, 25kD, 226 amino acid protein originally identified as the product of an oncogene commonly overexpressed in human ►hepatocellular carcinoma (►HCC). Independently, it was purified as the p28 component of the 19S regulator (PA700 complex) of the ►26S proteasome. The gene is localized on human chromosome Xq22.3, and produces at least nine transcript variants encoding nine distinct proteins. Gankyrin associates with cyclin dependent kinase 4 (►CDK4) to control the phosphorylation of the ►retinoblastoma protein pRB and with the ►E3 ubiquitin ligase ►MDM2 to control the ubiquitylation and degradation of ►p53 (and possibly ►pRB).

Characteristics

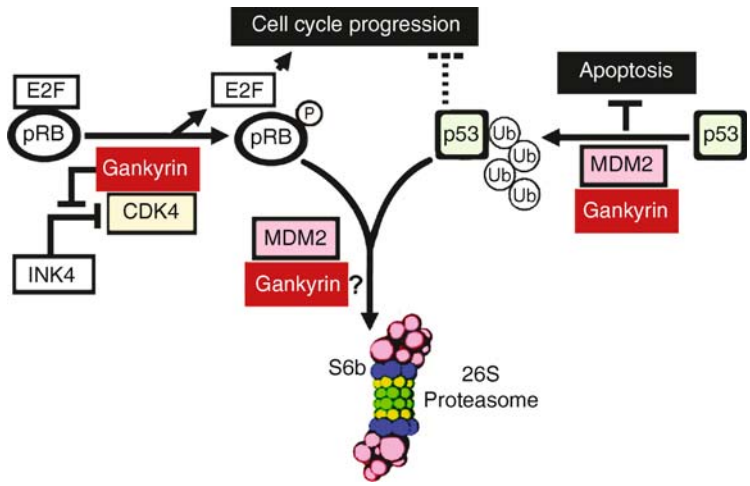
Gankyrin is a small cytoplasm–nucleus shuttling protein highly conserved throughout evolution (~40% identity to yeast Nas6p). Structurally, gankyrin consists of seven, not five or six as originally suggested by its amino acid sequence, ►ankyrin repeats (Fig. 1). Ankyrin repeat is the functional domain involved in protein–protein interactions, and gankyrin has been shown to interact with multiple proteins including the S6b ATPase (also known as Rpt3, TBP7, or PSMC4) of the 19S regulator of the 26S proteasome.

pRB and Gankyrin

Gankyrin plays a key role in regulating the cell cycle. Gankyrin contains the pRB-recognition motif LxCxE (178LACDE182) in the C-terminal domain, and binds pRB, but not pRB-related protein p107 or p130, in vitro and in vivo. Enforced expression of gankyrin in immortalized mouse fibroblasts and human tumor cells



Gankyrin. Figure 1 Structure of gankyrin: A ribbon representation. The polypeptide chain is color-ramped from its N-terminus in blue to the C-terminus in red. ANK1–7 indicates the seven ankyrin repeats.



Gankyrin. Figure 2 Activities of gankyrin on cell cycle control and apoptosis: In the presence of gankyrin, CDK4 is protected from the inhibitory effect of INKs (p16INK4A and p18INK4C). pRB is hyperphosphorylated and degraded, whereas E2Ftranscription factors are released to trigger expression of DNA synthesis genes and progression of cell cycle. p53 is polyubiquitylated by MDM2 and degraded to inhibit p53-dependent apoptosis and cell cycle arrest. P, phosphate; Ub, ubiquitin.

confers growth in soft agar and tumor formation in ►nude mice. The transforming activity of gankyrin correlates with its ability to bind pRB (e.g., the LxCxE point mutant E182A is inactive). Binding of gankyrin to pRB increases the rate of pRB degradation, suggesting that increased expression of gankyrin promotes tumorigenicity by targeting pRB to the ►proteasome. Gankyrin deactivates the pRB tumor suppressor pathway at multiple levels (Fig. 2). Gankyrin also binds CDK4, competing with p16►INK4A and p18INK4C, inhibitors of cyclin-dependent kinases (INKs), for binding to CDK4. Gankyrin displaces INKs, which results in active CDK4, hyperphosphorylation of pRB (together with other G1/S kinases), and release of the ►E2F transcription factor to activate DNA synthesis genes. Gankyrin does not bind to CDK6.

Gankyrin seems to play a role in cell cycle progression in normal cells as well. The upregulation of gankyrin correlates with cell cycle progression in normal rat primary hepatocytes and oval cells after mitogenic stimulation. Upregulation of gankyrin is also observed in the liver tissue of patients with fulminant hepatic failure, a model of active proliferation of human hepatocytes associated with liver regeneration.

p53 and Gankyrin

When overexpressed, gankyrin inhibits ►apoptosis in tumor cells that have been exposed to DNA-damaging agents. This antiapoptotic activity is, at least partly, due to increased degradation of p53, resulting in the reduced transcription of p53-dependent proapoptotic genes. Gankyrin binds to the E3 ubiquitin ligase MDM2 in vitro and in vivo, which increases p53–MDM2 association, thereby increasing the ubiquitylation and subsequent proteasomal degradation of p53. The mechanism by which gankyrin increases the binding of p53 to MDM2 and facilitates the ►ubiquitylation of p53 is currently unknown. However, it is known that gankyrin binds to a region of MDM2 (amino acids

411–438) just N-terminal to the ►RING finger domain. This puts the gankyrin-binding region in a central position, as the N-terminus of MDM2 binds p53 and the C-terminus contains a RING site that enables association with an E2 ubiquitin conjugating enzyme. Although not definitively proven, the fact that gankyrin binds to both the proteasomal S6b ATPase and MDM2 suggests a mechanism for the degradation of p53 by linking the ubiquitin ligase (MDM2) via gankyrin directly to the 19S regulator of the 26S proteasone. Such a mechanism could extend to other key cell-cycle regulators including pRB.

Gankyrin also controls MDM2 autoubiquitylation, especially in the absence of p53. Gankyrin does not bind to other p53 ubiquitylating enzymes, Cop1, Pirh2, p300 or the HECT ubiquitin ligase E6 AP.

Miscellaneous

In the yeast *Saccharomyces cerevisiae*, gankyrin (known as Nas6p) is a part of the multisubunit complex containing Sem1p (►DSS1 in mammals). Sem1p is also a proteasome subunit. Together with ►BRCA2 (breast cancer susceptibility gene 2), DSS1 regulates the activity of ►RAD51 recombinase and the formation of RAD51-positive DNA repair foci in response to ►DNA damage. These findings suggest a role of gankyrin in the ►DNA repair response.

In the hyperplastic liver of the transgenic zebrafish larvae overexpressing either one of the Bcl-2-related genes, zfBLP1 and zfMcl-1a, gankyrin is one of several genes that are upregulated.

Gankyrin upregulation is implicated in ►RAS-mediated transformation in rodent cells. Gankyrin is a promiscuous small ankyrin-repeat protein. In addition to binding S6b ATPase, pRB, CDK4, and MDM2 described earlier, gankyrin binds to or form a complex with MAGE-A4, Rel A, Tat, Integrase, and Vif of the ►human immunodeficiency virus 1, and probably others. Biological significance of these bindings is presently unknown.

Clinical Aspects

Gankyrin was discovered by constructing subtracted cDNA libraries from human noncancerous liver and ►HCC. The initial and subsequent studies have demonstrated that gankyrin mRNA is overexpressed in most HCCs.

The importance of the dual inactivation of both the pRB and p53 pathways for oncogenesis has been demonstrated, and gankyrin inhibits both of them. In a rodent hepatocarcinogenesis model, hypermethylation of the p16INK4A gene and p53 mutation appear at a late stage, whereas gankyrin is overexpressed from early stage after carcinogen treatment, preceding the loss of pRB protein and adenoma formation. Clinically, gankyrin mRNA is upregulated in early HCCs compared with dysplastic nodules in ►HCV ►cirrhosis. p53 mutation is not so frequent in HCCs, especially in low-grade or low-stage HCCs. These results suggest that gankyrin has important roles from early stages of hepatocarcinogenesis.

Whether gankyrin expression is deregulated in cancers other than HCC has not been extensively studied, but the ►SAGE analyses suggest its ubiquitous low expression in normal tissues and overexpression in several tumors including those of the brain, breast, lung, ovary, prostate, and stomach.

Overexpression of gankyrin is suggested to be of use as one of the diagnostic and subclassification markers for ►hyperdiploid ►acute lymphoblastic leukemia (ALL) with more than 50 chromosomes. Pediatric ALL is a heterogenous disease, with individual leukemia subtypes differing in their response to chemotherapy. Patients with hyperdiploid ALL with more than 50 chromosomes, one of the six prognostic subtypes, have an excellent prognosis.

As a dual-negative regulator of pRB and p53, gankyrin is a rational cancer therapeutic target. Overexpression of ►MAGE-A4, one of the melanoma antigens and a gankyrin interactor of unknown function, suppresses the tumorigenic activity of gankyrin. When overexpressed, gankyrin has antiapoptotic activity. Conversely, downregulation of gankyrin expression by small interfering RNA (►siRNA) or ►antisense oligonucleotides increases p53 protein levels and function, increases ►caspase activities, and promotes ►apoptosis of tumor cells in vitro. Growth of human HCC cells transplanted to nude mice is suppressed by intratumoral injection of ►adenovirus delivering siRNA against gankyrin ►Drug Delivery Systems for Cancer Therapy. These findings illustrate the importance of gankyrin functions for proliferation of HCC. Currently, response rate of HCC to systemic chemotherapy is only 0–25%, and has never been shown to prolong survival of the patients. Blocking expression and/or function of gankyrin might be a valuable therapeutic and preventive strategy against human HCC.

Gap Junctions

Angel Alonso
Deutsches Krebsforschungszentrum, Heidelberg, Germany

Definition

Are intercellular channel structures located in the ►plasma membranes of neighboring cells that mediate transfer of materials up to a molecular weight of 1,000 Da.

Characteristics

Transferred materials comprise ions, growth factors, and second messengers, among others. This transfer seems to be passive and nonselective. Channels (►Ether à–go–go potassium channels) are formed by two hemichannels or ►connexons, every one embedded in the plasma membrane of adjacent cells and connected to each other to form hydrophilic, tube-like pores that allow transfer of material from one cell to another. In some cases, only one hemichannel is present allowing material to pass from the cell into the intercellular space. Individual channels accumulate in regions of the plasma membrane forming the typical ►plaques observed in the microscope. One plaque may contain up to 1,000 channels.

The connexons are formed by six molecules of ►connexin proteins, each of which contains four transmembrane regions. Connexins are a family of at least 20 members in humans, with similar structures and different molecular weights. Both, the N-terminal and the C-terminal end of the proteins are located intracellularly, with the C-terminal end being of different length in the different connexin types.

The capacity of gap junctions to mediate cell–cell communication (coupling) can be measured by ►metabolic cooperation, ►electrical coupling, or by estimating the transfer of a diffusible dye from a cell to their neighbors. Dye transfer is the most commonly used method of gap–junction analysis. In this method, one cell is microinjected with a solution of a low molecular weight fluorescence material like ►Lucifer yellow and diffusion to neighbor cells is recorded under the microscope after defined times.

Coupling between cells is dependent on connexin phosphorylation. In general it can be postulated that increased phosphorylation results in decreased coupling.

The main function of gap junctions is probably to maintain ►homeostasis in cells and tissues. This includes growth control, differentiation, or death through the pass of signaling molecules from one cell to their neighbors.

Gap junctions play the most important role during experimental carcinogenesis as well as in primary human tumors. Essentially, cellular ►transformation is associated with a decrease in gap junctions-mediated cell–cell communication. This decrease is due not only to the failure of formation of channels, but also to the downregulation of connexin expression at the protein and RNA levels. Some tumoral cell lines seem to display average amounts of connexins and show regular cell–cell communication between the malignized cells, but not between malignant and normal cells. This implies that malignant cells will grow independently of the homeostatic control mechanisms displayed by the normal, neighbor cells.

A similar reduction of gap junction-mediated cell–cell communication is observed in cells treated with carcinogens or tumor promoters, but not in cells treated with mutagenic (noncarcinogenic) substances. ►Oncogenes like ►ras or ►src or growth factors like ►EGF close gap junctions through different molecular mechanisms. Consequently, growth inhibitors like ►retinoids or dexamethasone increase cell–cell communication.

In some cases, a noticeable reduction in gap–junction communication is observed in ►preneoplastic changes, being the reduction in connexin expression stronger with increased malignancy of the lesion, as found in prostate tumors. In other cases, like the larynx, no such differences have been found between normal and premalignant lesions. In some experimental models, restoration of gap junction is associated with loss of malignancy and cell differentiation, which suggests that connexin proteins are tumor suppressors. In vitro transfection of connexin genes into malignant cells results in restoration of the gap junctions and growth inhibition. Nevertheless, under in vivo conditions, and using mice deficient in connexin expression, no direct correlation between gap–junction communication and spontaneous malignant growth has so far been established.

Most of these studies have been performed using cell lines derived from human tumors but reliable information concerning the situation in primary human tumors is not yet available. In several of these studies, the

amount and localization of connexins has been taken as a measure for cell–cell communication, an assumption that is not always valid.

Clinical Relevance

The property of the cells to communicate through gap junctions has been used as the basis for a cancer treatment strategy. The theory behind this strategy is that cells may pass toxic, low molecular weight substances to their neighbors through gap junctions. This will result in a bystander effect increasing the efficiency of the standard therapies. Although under *in vitro* conditions the strategy seems to be promising, no results have so far been obtained in primary human tumors.

Stomach cancer; Gastric carcinoma

Definition

Gastric cancer includes a variety of tumors that develop in the stomach. The vast majority of these tumors, more than 95%, are from epithelial origin and are named as gastric carcinomas. There are also less frequent none-pithelial tumors in the stomach, including ►lymphomas, and ►mesenchymal tumors.

Characteristics

Carcinomas of the stomach are heterogeneous tumors from the morphologic standpoint. This heterogeneity is reflected in the histopathologic classifications of the tumors. The most common classifications are the Lauren classification and the World Health Organization (WHO) classification.

The Lauren classification recognizes two major types of gastric carcinomas, the “intestinal” and the “diffuse,”

which display different clinicopathological characteristics and occur in different epidemiologic settings. Microscopically, the "intestinal" type gastric carcinoma retains a glandular structure and cellular adhesion/polarity. Grossly, it usually displays a sharp margin and an expansive growth. The "diffuse" type gastric carcinoma often displays an invasive growth pattern. Scattered clusters of malignant cells frequently infiltrate the submucosa. However, it has little glandular formation. The "diffuse" type shows an infiltrative growth pattern which often results in the absence of mass. Endoscopically, this carcinoma may be difficult to identify without the presence of ulceration or mass. In advanced forms of this carcinoma, infiltration of the gastric wall leads to linitis plastica (leather-bottle-like stomach).

The WHO classifies gastric carcinoma in several groups. The WHO papillary and tubular groups correspond with the intestinal type of gastric carcinoma in the Lauren classification. The mucinous and signet-ring cell WHO groups correspond with the diffuse type in the Lauren classification. The undifferentiated type lacks features that further identify its origin.

Epidemiology

Worldwide, there are currently over 900,000 new diagnosis of gastric cancer each year making it the third and fifth most common form of cancer in males and females, respectively. There is a tenfold variation in incidence between the highest and lowest risk populations. Populations with high incidence rates (more than 40 cases/100,000/year) occur in Eastern Asia, South America, and Eastern Europe. The Lowest incidence rates (around 15 cases/100,000/year) occur in North America, Northern Europe, and most countries in Africa. Incidence rates in most populations show a declining trend over several decades. There is also a variation in incidence among different ethnic groups within the same area. Blacks, Hispanics, and Native Americans in the US are 1.5–2.5 times more likely than whites to develop a gastric cancer. Migration studies show that the risk of cancer changes within two generations when people move from high-incidence to low-incidence countries. For example, Japanese immigrants to the US maintain their original risk of gastric cancer, whereas the subsequent generations show a decline in incidence reaching the incidence rate of the host country.

Etiology

A variety of host-related, environmental, and infectious causes have been implicated in sporadic gastric cancer. Environmental factors, particularly early in life, appear to influence the risk of the disease. The main identified environmental risk factor for gastric cancer is the infection by the bacteria ►*Helicobacter pylori*. *H. pylori* infection is a prevalent chronic infection in humans. The infection is generally acquired during childhood and in most individuals the infection results in asymptomatic gastritis. Later in life, chronic infected individuals can progress through chronic atrophic gastritis, intestinal metaplasia, and dysplasia, towards gastric carcinoma, especially in high-incidence areas. Patients with *H. pylori* infection have three- to fivefold increased risk for noncardial cancers as indicated by prospective studies. Progression to more severe diseases occurs in a fraction of infected individuals and seems to depend on several factors, including host susceptibility, environmental factors, and differences in *H. pylori* strains. Recent studies in animal models, particular the development of gastric cancer in Mongolian gerbils infected with human isolates of *H. pylori* have also provided conclusive evidence to the etiologic role of *H. pylori* in gastric cancer development.

Eradication of *H. pylori* has been shown to reverse premalignant lesions and significantly decreases the rate of development of gastric cancer providing additional evidence for the role of *H. pylori* in gastric carcinogenesis. *H. pylori* exhibit a high level of genetic diversity among strains which contribute to different degrees of virulence among strains. Two of the most studied virulence-associated genes are *vacA*, present in all *H. pylori* strains and encoding a bacterial toxin; and cagA, not present in all strains and a marker for the cag pathogenicity island (PAI). The genotyping of these *H. pylori* genes allowed the identification of *H pylori* strains that are associated with a higher degree of inflammation and epithelial damage in the gastric mucosa, as well as with increased risk for development of gastric carcinoma.

Several host-related factors have also been shown to be associated with the development of gastric carcinoma. Human ►genetic polymorphisms conditioning host variable expression of ligands for bacterial adhesins may be crucial for successful and persistent infection. In addition, polymorphisms in proinflammatory ►cytokine genes, such as *IL-1B, IL-8, IL-10,* and ►*TNF*-α, and ►mucin gene *MUC1*, have been shown to be associated with the risk of development of gastric cancer and its precursor lesions. In summary, infections with certain *H pylori* strains combined with host genetic susceptibility lead to increased risk of developing severe gastritis, chronic atrophic gastritis, and gastric carcinoma.

Additionally, other factors have been implicated. Inadequate consumption of fresh fruits and vegetables,

high salt intake and consumption of smoked or cured meat, and fish are considered dietary risk factors. There is also evidence that refrigeration of food may contribute for the protection against this cancer by facilitating year-round consumption of fresh fruits food and by reducing the use of salt and exposure to various carcinogens present in smoked and cured meat and fish. Finally, various studies suggest a twofold increased risk in smokers.

Molecular Biology of Gastric Cancer

The large majority of gastric carcinomas are sporadic. There is evidence that indicates that sporadic gastric carcinoma appears after a carcinogenesis process that begins with chronic *H. pylori* infection and a series of histopathological changes in the gastric mucosa that often develops over a long period of time. The available evidence support the existence of two main histogenetic pathways of carcinogenesis: one leading to the "intestinal" carcinoma developing after a pathway which includes chronic atrophic gastritis, intestinal metaplasia, particularly the incomplete type III intestinal metaplasia, and adenomatous dysplasia; and the other leading to the "diffuse" carcinoma, either de novo or via hyperplastic changes. Both pathways appear to develop in the setting of *H. pylori*-associated gastritis.

H. pylori might contribute for the development of gastric carcinomas by the converging effects of two main types of molecular events: (i) collateral damage of inflammatory by-products causing mutational events in gastric epithelial cells and (ii) direct effects on gastric epithelial cells by *H. pylori* organisms or released bacterial products. At the molecular level this events include: direct toxic effects on epithelial cells, alteration of the apoptosis–proliferation balance, alterations on transduction pathways and gene expression, impairment of DNA mismatch repair, and alterations in cell adhesion.

Various genes have been analyzed in attempts to understand the molecular basis for human gastric carcinoma development, but only a few with frequent alterations have been identified.

The homeobox *CDX2* gene has been identified as crucial for the transdifferentiation process leading to intestinal metaplasia, a precursor lesion observed in the gastric carcinogenesis pathway that is characterized by the a modified expression of ►*mucin* genes. The use of mucins as molecular differentiation markers allows the identification and classification of various subtypes of intestinal metaplasia, contributing for the identification of subtypes with higher risk of evolving to gastric carcinoma.

In addition, ►amplification of ►ERBB2 and the ►MET genes have been found in ~10% of intestinal and diffuse types of gastric carcinoma. Oncogenic activation of K-ras (0–18% in both histological types) have also been found. In addition, mutations in the tumor-suppressor gene ►*p53* have been reported in the diffuse type (0–21%) and intestinal type (36–43%). ►*APC* tumor-suppressor gene mutations are usually found in gastric adenomas but are rarely found in gastric carcinomas. This is different from the frequent mutations of APC in both colorectal adenomas and carcinomas. Furthermore, somatic mutations of ►E-cadherin are observed in 33–50% of the diffuse type of gastric carcinoma.

►Microsatellite instability (MSI) is observed in 5–10% of diffuse type and in 15–40% of intestinal type of gastric carcinomas. The major mechanism for the MSI in gastric carcinomas is inactivation of the mismatch repair gene *hMLH1* resulting from the ►hypermethylation of its ►promoter.

The presence of ►Epstein-Barr virus (EBV) has been observed in some cases of gastric cancers. EBV is a ubiquitous human herpesvirus which establishes a lifelong infection of B-cells in the human population. While in the vast majority of individuals the infection remains asymptomatic, a small proportion of individuals may develop virus-associated tumors, mainly ►lymphomas. EBV has also been detected in a range of tumors on nonlymphoid lineages. EBV is found in the tumor cells of the undifferentiated type of gastric carcinoma often with lymphoid stroma.

Familial Clustering of Gastric Cancer

A small number of gastric cancer patients show a heritable risk gastric cancer, with familial predisposition and apparent independence of environmental factors. Familial clustering has been reported in ~1% of gastric cancers.

Hereditary Diffuse Gastric Cancer

►Germline mutation of the E-cadherin gene (*CDH1*) in families with history of gastric cancer was first described in 1998 by Guilford et al. describing a germline truncating E-cadherin mutations in three Maori kindreds. Since then, multiple families with a history of gastric cancer ►HDGC and *CDH1* mutations have been identified, and the HDGC syndrome has been established. E-cadherin is a cell adhesion molecule predominantly expressed in epithelial tissues. E-cadherin molecules are generally localized at the basolateral surface of the epithelial cell, in regions of cell–cell contact. Truncating and ►missense germline mutations in the *CDH1* gene have been reported in HDGC. Affected individuals inherit one copy of the defective

E-cadherin gene. Somatic mutation, deletion, or promoter ►methylation inactivates the other copy. The cancer appears with an ►autosomal dominant pattern with high ►penetrance. When prophylactic gastrectomy is performed, multifocal early gastric diffuse gastric carcinoma is often found in the resected specimen.

Diagnosis and Detection

Gastric cancer often does not cause major symptoms in the early stages. Most patients with gastric cancer are diagnosed when they undergo endoscopy and biopsy after exhibiting symptoms. About 50% of patients may have nonspecific gastrointestinal complaints, such as dyspepsia. This is one of the reasons why about 80% of patients are diagnosed with advanced tumors. Diagnosis may also be obtained by double-contrast Barium X-ray. Other methods for diagnosis include endoscopic ultrasound, computed tomography, positron emission tomography, and magnetic resonance imaging. Serological assays screening, including serum pepsinogen, is a potentially useful method for detection of gastric cancer. Other molecular mechanisms for early diagnosis are currently under investigation.

Management

Surgical resection remains the primary treatment for gastric cancer. Prognosis of GC is poor with a 5 year survival rate closely related to the stage of the carcinoma when diagnosis and surgical resection is performed. Surgery with curative intent remains the only way to improve survival. Poor results in survival may be explained by the fact that when symptoms occur, and diagnosis is made, the cancer has often already spread. Presently, only a small percentage of patients are eligible for curative surgery. Management of advanced stage cancer also includes surgical resection, with chemotherapy. Novel drugs and treatments are currently under investigation.

Gastrin

Definition

A gastrointestinal peptide hormone that regulates gastric acid secretion and motility

►Gut Peptides

Gastrin-Releasing Peptide

Oneel Patel, Arthur Shulkes, Graham S. Baldwin
Department of Surgery, University of Melbourne, Austin Health, Melbourne, VIC, Australia

Synonyms

Bombesin amphibian gastrin-releasing peptide

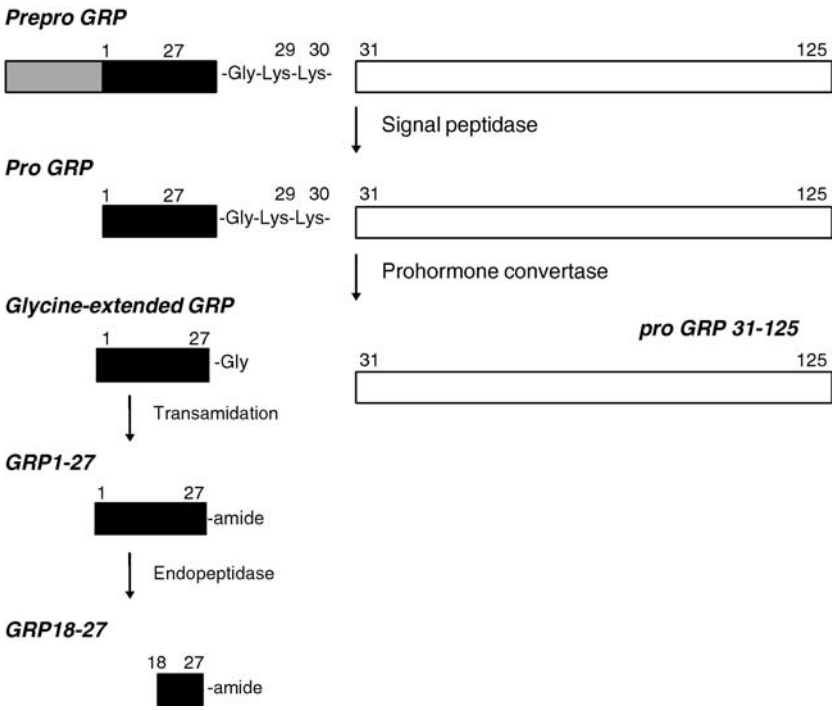
Definition

GRP; Is a peptide hormone of 27 amino acids, with the sequence VPLPAGGGTVLTKMYPRGNHWAVGHL-Mamide.

Characteristics

The tetradecapeptide ►bombesin was first isolated and characterized from the skin of the frog *Bombina bombina* in 1970. A decade later, the mammalian counterpart of bombesin was identified using an anti-bombesin antibody and named gastrin-releasing peptide (GRP). The name GRP arises from the first known activity of inducing gastrin secretion from G cells in the gastric antrum.

The human GRP gene maps to chromosome band 18q21. The three GRP mRNAs, which arise from a single nascent mRNA by alternate splicing at the junction between exons 2 and 3, encode peptides of 148, 141, and 138 amino acids. Like many neuropeptides mature amidated GRP arises by a series of well-defined processing steps from these initial large translation products. All three GRP mRNAs encode



Gastrin-Releasing Peptide. Figure 1 Processing of proGRP. PreproGRP (148 amino acids in human) is converted to proGRP (125 amino acids) by removal of the signal peptide. The sequential actions of a prohormone convertase that cleaves on the C-terminal side of the sole pair of lysine residues, and a carboxypeptidase B-like enzyme that removes the lysines, convert proGRP to glycine-extended proGRP1–27. The C-terminus of proGRP1–27 is then amidated to form mature GRP1–27. An additional cleavage between amino acids 17 and 18 yields GRP18–27.

GRP1–27 and GRP18–27, but differ in sequence at their C-termini. Multiple cleavages of the C-terminal extension peptide proGRP31-125 also occur in a tissue specific manner (Fig. 1).

GRP Receptors

The three different receptor subtypes (GRP-R, NMB-R and BRS-3) for the GRP family of peptides all belong to the seven-transmembrane family. The human genes encoding GRP-R, NMB-R and BRS-3 are located at chromosome bands Xp22.2-p22.13, 6q21-qter and Xq26-q28, and encode proteins of 384, 390 and 399 amino acids, respectively.

The different GRP receptor subtypes can be readily distinguished on the basis of agonist and antagonist affinities. The GRP-R has high affinity for bombesin and GRP and very low affinity for NMB. Conversely the NMB-R has a higher affinity for NMB than GRP. No natural ligand has been found for the BRS-3 receptor which has low affinity for both GRP and NMB. All the GRP receptors characterized to date are coupled to guanine nucleotide binding proteins (►G-proteins), and activate ►phospholipase C to increase intracellular concentrations of inositol phosphates, diacyl glycerol and calcium. Other intracellular mediators activated by GRP receptors include ►mitogen-activated protein kinase, ►focal adhesion kinase, and ►phosphatidylinositol 3-kinase.

Physiological Functions of GRP

One of the first biological actions of GRP described was the stimulation of ►gastrin release, which in turn results in the stimulation of gastric acid secretion. In addition to gastrin, GRP stimulates the release of a variety of hormones including secretin, ►somatostatin and cholecystokinin, but the physiological relevance of such changes is not known. GRP also stimulates pancreatic exocrine secretion, smooth muscle contraction, gastrointestinal motility, and the healing of damaged gastric mucosa, and delays gastric emptying.

The availability of potent and selective receptor antagonists and of blocking antibodies, together with the generation of ►knock-out mice lacking individual members of the GRP-R family of receptors, has allowed further investigation of the physiological functions of GRP. Such studies have demonstrated that GRP improves learning and memory performance in rats and mice and alters appetite. In addition growth of the colonic mucosa was attenuated in GRP-R deficient mice, in agreement with previous reports that

administration of GRP stimulated growth of the gut mucosa and pancreas.

GRP and Cancer

Apart from its physiological roles, GRP has been shown to stimulate growth of a number of cancerous tissues. The field was initiated by the demonstration that a monoclonal anti-GRP antibody blocked the binding of GRP to cellular receptors and inhibited the growth of ►small cell lung cancer (SCLC) cells both *in vitro* and as ►xenograft *in vivo*. The conclusion that GRP might be an ►autocrine growth factor in SCLC prompted various research groups to investigate the role of GRP in cancer development and progression.

GRP and Lung Carcinoma

Human ►SCLC cells as well as tumors have been shown to express both the GRP peptide and the GRP-R mRNA. GRP18-27, proGRP31-98 (the C-terminal flanking peptide of proGRP) and GRP mRNA have been detected in several small cell, but not in ►non-small cell, ►lung carcinoma cell lines. In patients with SCLC, GRP mRNA and peptide were detected in samples of blood, marrow, and ►pleural effusion. Several groups have reported increased circulating concentrations of proGRP31-98 in SCLC patients and suggested that proGRP may be useful as a prognostic marker. GRP-R mRNA is commonly expressed in both small cell and non-small cell lines.

GRP is ►mitogenic for SCLC cell lines *in vitro* and *in vivo,* but not for cell lines derived from either a squamous lung carcinoma or a lung adenocarcinoma. Subcutaneous GRP treatment of nude mice xenografted with a human SCLC cell line significantly increased tumor weight and DNA content and the increase was blocked by a GRP antagonist.

GRP and Prostate Carcinoma

GRP expression was detected by ►immunohistochemistry in both biopsy and radical prostatectomy specimens from patients with prostatic adenocarcinomas and benign prostatic hyperplasia (►prostate cancer). Circulating proGRP31-98 was increased in some patients with prostatic cancer although there was some overlap with patients with benign prostatic hyperplasia. Using ►RT-PCR and in situ hybridization, widespread but variable GRP-R mRNA expression was demonstrated in specimens of prostate carcinoma and benign prostate hypertrophy, while normal tissue consistently displayed a low GRP-R mRNA concentration. Using ^{125}I-Tyr^{4}-bombesin as a radioligand, GRP-R was detected in prostatic intraepithelial neoplasms and invasive prostate carcinomas. GRP receptors have also been demonstrated on several prostate carcinoma cell lines.

GRP antagonists inhibit the growth of a prostate adenocarcinoma in rats and of human prostate cancer cell lines *in vitro* and as xenografts in mice. An anti-bombesin antibody significantly inhibits both bombesin-stimulated and basal growth of these cell lines. Invasion and migration of several prostate cancer cells is also accelerated by GRP.

GRP and Breast Cancer

GRP immunoreactivity has been detected in human breast carcinoma biopsies. Similarly GRP mRNA was detected in primary breast carcinomas but not in breast cancer cell lines. Using radiolabeled bombesin the GRP receptor was shown to be expressed by neoplastic mammary epithelial cells in many invasive ductal carcinomas and ductal carcinomas in situ.

Bombesin increases cell growth in both estrogen-dependent and -independent human breast cancer cell lines. These effects are blocked by a GRP antagonist. In addition, the GRP antagonists significantly decrease the final tumor volume and weight of xenografts of breast cancer cell lines in female nude mice.

GRP and Gastric Carcinoma

Although there have been no reports of GRP expression in gastric adenocarcinoma, GRP-R expression has been detected in 40% of non-antral gastric adenocarcinomas, and in human gastric carcinoma cell lines. Growth of some gastric cancer cell lines is significantly inhibited by treatment with a GRP-R antagonist. Bombesin significantly increases the incidence of peritoneal metastases from gastric cancers induced in rats by treatment with a chemical carcinogen.

GRP and Pancreatic Carcinoma

GRP immunoreactivity was detected in over 50% of pancreatic ductal adenocarcinomas, and in both well- and poorly differentiated pancreatic carcinoma cell lines. Both GRP-R mRNA and protein were detected in peri-tumoral small veins, but not in the tumor tissue of ductal adenocarcinomas. The mRNAs encoding both GRP-R and NMB-R have been detected by RT-PCR in several ►pancreatic cancer cell lines.

Several groups have reported that GRP stimulated growth of human pancreatic cancer cell lines and that the stimulation was reversed by a GRP antagonist. The presence of an autocrine loop involving GRP and the GRP-R was suggested by the observation that GRP antagonists inhibited xenograft growth of human pancreatic adenocarcinoma cell lines.

GRP and Colorectal Carcinoma

GRP and GRP-R are expressed in many colorectal adenocarcinomas, but not in uninvolved normal mucosa or in tumor metastases. GRP and GRP-R mRNAs have also been detected in many colon cancer cell lines, although functional receptors are frequently absent.

GRP significantly increases the number of ►colorectal cancers and peritoneal metastases induced in rats by treatment with chemical carcinogens. GRP is a mitogen for several colorectal cancer cell lines *in vitro* and GRP antagonists block the proliferative effect of GRP. GRP may also have a morphogenic role in colorectal cancer. A recombinant peptide derived from the C-terminal region of proGRP (proGRP42-98) has been shown to be biologically active in colon cancer cells.

GRP and Gastrointestinal Carcinoid Tumors

Gastrointestinal ►carcinoid tumors are low grade, malignant epithelial neoplasms showing neuroendocrine differentiation. GRP is frequently expressed in carcinoids from the stomach, small intestine and appendix, but rarely in colonic carcinoids.

Clinical Significance

A large proportion of human small-cell lung, prostate, gastric, breast, pancreatic and colorectal cancers express GRP receptors. Sixty-three percent of all human cancers of the types mentioned are GRP-R-positive by PCR-based techniques, and this figure compares favorably with the figure of 56% from ligand binding studies. The frequent expression of GRP-R in tumors makes the receptor an attractive target for cancer treatment.

The observations that GRP stimulates ►angiogenesis, and that GRP-R antagonists block tumor growth and angiogenesis, present new therapeutic options. GRP-R ligands are also receiving considerable attention as vehicles to deliver cytotoxic agents. Cytotoxic bombesin analogues have been used to inhibit the growth of cancers and cell lines of different origins including ovarian, gastric, prostate, small-cell lung and pancreatic carcinoma, and glioblastoma. Tumor imaging and detection is the other area which has exploited the fact that GRP receptors are over-expressed in a number of tumors. GRP-like peptides labeled with β- and/or γ-emitting radionuclides are currently being investigated for their ability to bind to cell-surface GRP receptors, and hence for their potential utility for detection and/or therapy of tumors.

Gastrinoma

Irina A. Lubensky
National Cancer Institute, National Institutes of Health, Bethesda, MD, USA

Synonyms

Zollinger-Ellison syndrome; Islet cell tumor

Definition

Gastrinomas are functioning ►gastrin-producing tumors of the neuroendocrine cells that are located in the duodenum, pancreas and/or "gastrinoma triangle" and cause clinical ►Zollinger-Ellison syndrome (ZES).

Characteristics

Gastrinoma is a functioning ►neuroendocrine tumor of high malignant potential that follows an indolent clinical course. Neuroendocrine tumor cells release gastrin into the blood stream causing clinical symptoms, i.e., ZES.

Annual incidence of ZES in the US is estimated at 1 in 2.5 million people. It may occur in sporadic and familial forms. Twenty to 25% of ZES cases are associated with familial ►multiple endocrine neoplasia type 1 (MEN1; ZES-MEN1) (►Endocrine-related cancers; ►Carcinoid tumor; ►Hereditary cancer syndromes). Sporadic ZES can develop at any age, but the majority of cases are diagnosed between the fourth and sixth decade of life (mean age 50.5 years). ZES-MEN1 patients have multiple gastrinomas and are younger than those with sporadic ZES. Sixty percent of the patients are men.

Diagnosis

The diagnosis of ZES is usually established clinically and then confirmed by demonstration of the specific tumor type (gastrin-positive neuroendocrine tumor) in a pathology specimen. Clinical diagnosis of ZES is based on the finding of concurrent ►hypergastrinemia (increased serum gastrin produced by the tumor) and ►hyperchlorhydria (increased gastric acid secretion by hyperplastic parietal cells secondary to the trophic action of gastrin) in patients with ulcer disease (►Gastrin-releasing peptide; ►Gut peptides). Because ZES symptoms overlap with those of much more common peptic ulcer disease, the diagnosis of gastrinoma (ZES) may be delayed for many years. Multiplicity and unusual (low duodenal and intestinal) location of ulcerations, resistance to medical therapy, frequent and early recurrence of ulcers, prolonged and unexplained diarrhea or steatorrhea, enlarged gastric or duodenal folds, and negative tests for Helicobacter

pylori, when they occur raise a suspicion for ZES. The diagnosis is established by positive results with two or more of the following: elevated fasting serum level of gastrin (>100 ng/l), abnormal secretin stimulation test (increment in fasting serum level of gastrin >200 ng/l after intravenous secretin), and an elevated basal level of gastric acid output (>10 mEq/h).

Gastrinomas are thought to originate from gastrin-producing (G) cells that are normally dispersed in gastric antral and upper duodenal mucosa (►Gastrointestinal tumors; ►Gastrointestinal hormones). However, there is no direct correlation between the distribution of G cells in the digestive system and frequency of gastrinoma location. The tumors commonly arise in ectopic sites such as pancreas (the second most common location) that is normally devoid of G cells. More than 50% of gastrinomas arise in the duodenum. Ninety percent of all gastrinomas are located in the "gastrinoma triangle" (the anatomic junction of cystic and common bile ducts, second and third portion of the duodenum, and neck and body of the pancreas). Solitary pancreatic or duodenal gastrinomas are characteristic for sporadic ZES cases. Location of the tumors in proximal duodenum and their multiplicity are common in ZES-MEN1 patients. Cases of gastrinoma located solely in periduodenal and peripancreatic lymph nodes have been reported, and clinical cure has been achieved following surgical excision of regional lymph nodes in some of such cases.

Microscopically, gastrinomas are composed of small, uniform cells with abundant eosinophilic cytoplasm, and small uniform nuclei with inconspicuous nucleoli. Correlation between histologic features and malignant behavior is poor. Mitotic activity and nuclear pleomorphism, when rarely present, are unreliable predictors of prognosis in gastrinoma. Despite their small size and lack of invasion into adjacent organs, duodenal gastrinomas demonstrate high malignant potential with propensity for regional lymph node and distant metastases.

Because gastrinoma may be an initial manifestation of ►MEN1 in up to one third of familial ZES cases, it is currently recommended to evaluate all ZES patients for medical and family history of the endocrine neoplasms and assess their parathyroid and pituitary function. The differentiation of patients with familial ZES-MEN1 from patients with sporadic ZES is important because of the differences in natural history of ZES, need for family screening, difficulty in controlling acid hypersecretion, and need for exploratory laparotomy for cure.

Gastrinomas are reported to be malignant in 60–90% of cases. About 34% of patients with ZES have metastatic disease at the time of diagnosis. Periduodenal and peripancreatic lymph nodes, liver, and bone are the most common sites of metastases. Gastrinomas in MEN1-ZES and sporadic ZES patients have similar rates of metastases.

Therapy

Since ZES can be cured only by excision of a gastrinoma in the early stage of the disease, the exact tumor localization may be crucial in successful management of ZES patients. Duodenal gastrinomas are frequently small in size (less than 1.0 cm) and are difficult to find preoperatively. Tumor localization studies (►CT, ►MRI, and ►octreotide scanning) are necessary for preoperative localization. Exploratory ►laparotomy with intraoperative ultrasonography, transduodenal endoscopic illumination, duodenotomy, and surgical resection of the tumor is currently recommended for patients with sporadic ZES patients. The usefulness of surgery varies for patients with ZES-MEN1 who usually have multiple tumors.

Treatment of patients with ZES is also directed at reducing gastric acid hypersecretion. Total gastrectomy or vagotomy has been used. However, over the past 15 years a highly potent antisecretory proton pump inhibitor, ►omeprazole, has been effective in suppression of gastric acid output and has significantly decreased the early mortality of patients due to complications of ulcer disease. With the increased ability to control hyperchlorhydria, the progression of gastrinoma and metastases are becoming the primary factor in long-term survival of patients with ZES. The clinical course of gastrinoma is indolent and the prognosis is directly related to the spread of the tumor. Patients with liver metastases have only a 20–30% chance of surviving for 5 years, whereas patients without liver metastases have an excellent long-term prognosis (>90% 5-year survival rate).

Genetics

The role of the *MEN1* gene as an early event in gastrinoma tumorigenesis has been established in *MEN1*-associated gastrinomas as well as in 33% of sporadic gastrinomas regardless of metastases. In both familial and sporadic gastrinomas the *MEN1* gene, located on chromosome 11q13, is thought to act as a tumor suppressor based on the presence of inactivating mutations in the normal tissue/blood DNA, accompanied by the loss of the wild type allele in the tumor. Either ►homozygous deletion or ►hypermethylation at the 5′ region of the *p16/MTS1* or ►$p16^{INK4a}$ tumor suppressor gene on chromosome 9p21 was demonstrated exclusively in sporadic gastrinomas and not in other pancreatic neuroendocrine tumors. The finding suggests that *p16/MTS1* or $p\ 16^{INK4a}$ defect is restricted to gastrin-producing tumors. Somatic genetic changes associated with the development of most sporadic gastrinomas and as well as with the progression to malignancy are currently unknown.

Gastrointestinal Stromal Tumor

Chi Tarn, Andrew K. Godwin
Department of Medical Oncology, Fox Chase Cancer Center, Philadelphia, PA, USA

Synonyms

GIST

Definition

GastroIntestinal Stromal Tumor (GIST) is a type of sarcoma (i.e., a connective tissue neoplasia). GIST is a rare cancer affecting the digestive tract or nearby structures within the abdomen.

Characteristics

Epidemiology and Clinical-Pathological Features of GIST

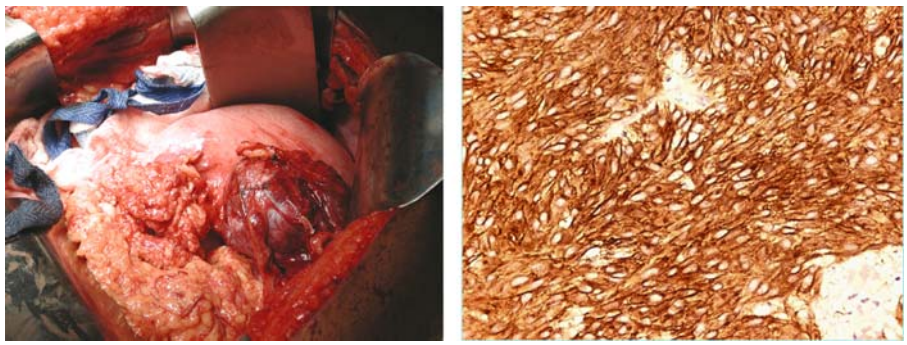
GISTs are believed to arise from the ►Interstitial Cells of Cajal (ICCs), the pacemaker cells for the autonomous movement of the GI tract. Other studies have suggested that GISTs arise from interstitial mesenchymal precursor ►stem cells; however, pinpointing the progenitor cell has been difficult. Although it is considered a rare tumor, nearly 4,500–6,000 new cases are diagnosed annually in the United States. The peak incidence of GIST occurs later in life with a median age of 58 years; however, there are also reports of pediatric GISTs. The most common sites of origin for GIST are the stomach (39–70%) and small intestine (31–45%). Other primary sites include the large bowel, rectum, appendix, and rarely the esophagus. A small percentage of GISTs arise outside the tubal gut, i.e., within the mesentery, gallbladder, and omentum. These tumors are known as extra-gastrointestinal GIST. The symptoms of GIST include bloating, gastrointestinal bleeding, or fatigue related to anemia. The common metastatic sites for GIST include the liver and omentum, and less frequently, the lung and bone.

Diagnosis

Approximately 95% of GISTs express the antigen CD117 (better known as ►KIT) when examined by ►immunohistochemistry (IHC) (Fig. 1). The c-*KIT* gene is the normal cellular homologue of a viral oncogene (v-Kit, Hardy Zuckerman 4 feline sarcoma viral oncogene homologue). There is a small subset of GISTs that lack KIT expression.

Oncogenic Signaling Pathways in GIST

KIT is a 145-kDa transmembrane glycoprotein and is a member of the tyrosine kinase family of receptors. Other members in this family include PDGFRα and β (Fig. 2a). KIT is normally expressed in hematopoietic stem cells, ►mast cells, melanocytic cells, germ cells, and the ICC. The normal function of KIT is dependent on binding to its ligand, ►Stem Cell Factor (SCF), and is essential in embryonic development. Acquired mutations in the c-*KIT* gene are referred to as "►gain-of-function" or "activating" mutations, which lead to constitutive ligand-independent activation of the tyrosine kinase activity of the receptor. Molecular genetic studies have shown that the vast majority of GISTs (70–80%) possess a c-*KIT* mutation in either exon 9, 11, 13,



Gastrointestinal Stromal Tumor. Figure 1 GIST. *Left*: Surgically resected gastric GIST; *right*: Immunohistochemical staining of a paraffin-embedded GIST tissue section for KIT protein expression.

or 17, and that a subset of GIST (~10%) possesses a *PDGFRα* mutation in either exon 12, 14, or 18. Even though c-*KIT* or *PDGFRα* mutations are detected in GIST, approximately 10% of GISTs lack mutations in either of these genes. Therefore, other yet to be discovered genetic and potentially epigenetic mechanisms, independent of c-*KIT* and *PDGFRα* activation, may contribute to the pathogenesis of GIST.

KIT gain-of-function mutations result in autoactivation of the receptor, and consequently transmit the KIT oncogenic signal to downstream targets such as phosphatidylinositol 3-Kinase (►PI3K), ►AKT (as known as protein kinase B), and mitogen-activated protein kinases (►MAPK). These signaling proteins influence proliferation, ►apoptosis, differentiation and/or cell ►adhesion (Fig. 2b). Clinical observations and laboratory research have shown that different gain-of-function mutations within the same receptor can affect different down-stream pathways and clinical response to therapy.

Cytogenetics and Molecular Cytogenetic Alterations

Even though mutations in c-*KIT* or *PDGFRα* appear to be the primary driving force in the pathogenesis of GIST, several other genetic and genomic changes have been documented which contribute to the development of this disease. ►Monosomy for chromosome 14 is one of the most frequent (>60%) genomic alterations detected in GISTs. Other common changes in metastatic GISTs include loss of chromosome arms 1p, 9p, 10, 14q, 15q, and 22, and gains involving 5p and 20q.

Therapy

►Cytoreductive surgery is the standard of care for patient with primary GIST. This surgery seeks to remove the entire gross tumor, and may require total or subtotal organ resection, depending on tumor location and size. However, surgery has limited success for locally recurrent or metastatic GIST and clinical response of patients to systemic therapy using conventional chemotherapies is abysmal. ►Chemotherapy response rates in patients with metastatic disease are less than 5% for all tested cytotoxic agents with a median survival of 10–20 months.

►Imatinib mesylate (STI571 or Gleevec™), is an oral 2-phenylaminopyrimidine derivative that acts as a selective inhibitor against several ►receptor tyrosine kinases including KIT, PDGFRα, and ►BCR-ABL (which is the causative ►chromosomal translocation in ►chronic myelogenous leukemia). Based on a high percentage of metastatic GIST patients demonstrating clinical response to imatinib in phase I/II ►clinical trials, the FDA granted Novartis approval of imatinib for the treatment of advanced GIST in 2001. Clinically, it has been reported that patients with metastatic or localized GIST possessing a mutation in exon 11 (i.e., involving the juxtamembrane domain of the receptor) of c-*KIT* mutations have a longer ►progression free survival and overall survival when treated with imatinib as compared to patients with tumors with other types of c-*KIT* mutations. Likewise, mutations in exon 12 (juxtamembrane domain) of *PDGFRα* are more sensitive to imatinib treatment than patients with other types of mutations in *PGDFRα*.

In summary, GISTs are the most common mesenchymal tumors of the digestive tract and possess mutations in either c-*KIT* or *PDGFRα*. For patients with localized resectable GIST, surgery remains the treatment of choice, whereas, for patients with metastatic disease, imatinib-based therapy is providing benefit for long-term disease control.

Gastrulation

Definition

Is the formation of a gastrula from a blastula during embryogenesis.

►Homeobox Genes

Gatekeeper

Definition

Type of tumor suppressor gene; Refers to a subgroup of gene products, whose major cellular function is in the control of cell division, death or lifespan. Inactivation of gatekeeper genes favors, through a variety of mechanisms, the unrestrained growth typical of cancer cells. Multiple gatekeeper mutations may be required for the neoplastic transformation of a cell. Gatekeeper gene products often participate in the control of ►cell cycle (for example, the Rb gene product [►retinoblastoma protein, cellular biochemistry]) or in the signals that regulate proliferation (for example, the ►APC gene product). It is possible that large proteins with several functional domains (pleiotropic genes), such as ►BRCA1 and ►BRCA2 proteins originally described as gatekeepers may also have caretaker functions.

Gelsolin

Christine Chaponnier[1], Helen L. Yin[2]
[1]Department of Pathology and Immunology, University of Geneva, Geneva, Switzerland
[2]Department of Physiology, University of Texas Southwestern Medical Center, Dallas, TX, USA

Definition

Is a widely expressed 82–84 kDa ►actin-binding protein that is found inside the cells and also in a secreted form in extracellular fluid. Gelsolin severs actin filaments ►actin filament severing by breaking the ionic interactions between actin molecules within the filament and it caps the fast growing (+) end of actin filaments. Filament severing and capping are regulated by Ca^{2+}, the ►phosphoinositide phosphatidylinositol 4,5 bisphosphate (PIP2) and pH.

Characteristics

Cytoplasmic gelsolin was discovered in 1979 and named for its ability to activate gel–sol transformation of actin filaments in a Ca^{2+}-dependant manner. Gelsolin is the founding member of a ►gelsolin family of ►actin filament severing and/or capping proteins. Other members include villin, scinderin, adseverin, CapG, and flightless I. Among these, gelsolin and CapG have been implicated as ►tumor suppressor.

The ►actin cytoskeleton is remodeled dynamically during cell movements. Gelsolin contributes to dynamic remodeling by promoting the disassembly and subsequent reassembly of the actin cytoskeleton in response to changes in intracellular signals. Disassembly is mediated through filament severing and reassembly is mediated by filament uncapping. Gelsolin is activated by micromolar Ca^{2+} to bind to the side of actin filaments and to sever them. After severing, gelsolin remains attached to the (+) ends of these short filaments

even as Ca^{2+} level decreases to submicromolar level. Gelsolin is detached from the (+) ends (uncapping) by PIP2. It is hypothesized that the combination of severing to generate large number of short capped actin filaments and subsequent uncapping can account for explosive actin filament growth. The importance of gelsolin for cell motility has been demonstrated by gelsolin overexpression and depletion by RNA interference in tissue culture cells and by gelsolin gene knockout. For example, although the gelsolin ►knockout mice are viable, their ►neutrophils and ►fibroblasts have decreased motility.

Gelsolin has also been implicated in ►apoptosis, either as an enabler or a protector. Gelsolin is cleaved by ►caspase-3 into two halves and the resulting amino terminal half severs actin filament in a Ca^{2+}-independent manner. This may contribute in part to the morphologic changes associated with apoptosis in some type of cells. However, a protective role of gelsolin has been suggested in Jurkat cells and in neuronal cells. Thus, blockage or enhancement of gelsolin cleavage might retard or enhance apoptosis depending on the cellular context.

The relation between gelsolin, apoptosis and tumorigenesis probably reflects a complex balance between the multiple effector functions of gelsolin.

Gelsolin and Cancer

The role of gelsolin in reorganizing the actin cytoskeleton suggests that it may be involved in promoting tumor cell ►invasion and dissemination. The first study investigating the distribution of gelsolin in ►breast cancer showed that, in ►ductal carcinoma, it is notably downregulated in epithelial cells compared with normal breast tissue. However, gelsolin is expressed at a high level in stromal ►myofibroblasts. Therefore, cytoplasmic gelsolin is expressed in normal epithelial cells, in some tumor cells and importantly in intratumoral and peritumoral stromal myofibroblasts, and in vessel smooth muscle cells. The function of gelsolin in these highly contractile cells is not yet understood.

Since the initial study, there have been many other investigations to determine if gelsolin has a role in tumorigenesis. These studies suggest that depending on the type of tissue and the stage of cancer growth, gelsolin may act as a tumor suppressor or a tumor enhancer. In some cases, gelsolin is a reliable prognostic marker. In this general and short chapter, it is not possible to review of all reports in the field. We therefore took the liberty of selecting only studies that investigate both in vitro and in vivo conditions; these studies should be most relevant for understanding the role of gelsolin in tumor development.

Gelsolin Considered as a Tumor Suppressor

►Immunohistochemistry studies showed that gelsolin expression is downregulated in many types of cancer including breast, stomach, colon, bladder, prostate, lung, kidney, and ovary. For example, 78% of ►bladder tumor tissues and six bladder cancer cell lines displayed low or undetectable gelsolin compared with their normal counterparts. Furthermore, transfection of exogeneous gelsolin cDNA into a bladder cancer cell line reduced colony-forming ability and tumorigenicity in vivo. Loss of gelsolin was also observed in human ►ovarian cancer cell lines and in ovarian carcinoma compared with normal ovaries and benign adenoma. As in the case of bladder cancer cells, reexpression of gelsolin in ovarian tumor cell lines resulted in a reduction in colony formation.

Knockdown of gelsolin using small interfering (si) RNA has given contradictory results. For example, gelsolin depletion in the human immortalized mammary epithelial cell line MCF10A unexpectedly increased cell motility and induced overexpression of the small ►GTPase ►Rac, which has been implicated in dynamic ►lamellipodia formation. Gelsolin depletion also converted ►cadherin from E- to N-type via the induction of the ►transcription factor Snail, whose expression is inversely correlated with E-cadherin mRNA levels in several epithelial tumor cell lines. These unexpected results suggest how a decrease in gelsolin expression can nevertheless lead to enhanced tumor ►cell motility.

The molecular basis for the decrease in gelsolin expression in tumor cells is not known. There are suggestions that gelsolin mRNA level may decrease due to ►epigenetic modifications resulting from DNA ►methylation and ►histone deacetylation, in ►ovarian cancer and in ►breast cancer cell lines. Paradoxically, although gelsolin can suppress tumor progression, it was also shown that overexpression of gelsolin in malignant tumors was associated with poor prognosis. Gelsolin has been suggested to be a motility marker for tumor cells, although its prognostic value has so far only been examined in a small number of malignant tumors. Furthermore, there is surprisingly little information about the possibility that other members of the ►gelsolin family may substitute for the depleted gelsolin in cancer cells.

Gelsolin Considered as a Tumor Enhancer

Besides acting as a tumor suppressor, gelsolin has also been implicated as a tumor enhancer, particularly in lung and breast carcinomas. For example, ►non-small cell lung carcinoma (NSCLC), which comprises 70–80% of all lung carcinomas and has a 5-year survival rate of about 15%, is usually associated with decreased gelsolin level in about 70% of the cases

examined. However, the decrease in gelsolin is not associated with adverse prognostics. Instead, the small percent of cells with high focal gelsolin expression was correlated with the highest risk of cancer recurrence compared with tumors that had no or low gelsolin expression.

Likewise, the expression of gelsolin in breast cancer is variable and may involve only a few cells in the issue. Although gelsolin is absent in many breast cancers, about one third of cases have detectable gelsolin. In some cases, gelsolin expression was focally localized and accentuated in cell clusters or in single invasive cells that show transendothelial migration or are embedded in the stroma. Interestingly, an overexpression of gelsolin, when associated with ERBB2 and EGFR expression, resulted in a more agressive tumor phenotype. Altogether, these results suggest that although gelsolin can be extinguished during cell transformation, its focal high expression in a subpopulation of tumor cells can facilitate tumor dissemination and metastasis by promoting tumor cell locomotion.

In summary, the current findings are consistent with the hypothesis that gelsolin functions in a complex manner in the development and progression of tumors.

Gelsolin Family

Definition

A superfamily of ►gelsolin-like proteins that has a conserved modular motif. Gelsolin is the founding member; other members include villin, scinderin, adseverin, supervillin, CapG, and flightless I. With the exception of flightless I, all are shown to be Ca^{2+}-activated ►actin severing and/or binding proteins. Some of these proteins have also been implicated in transcriptional regulation.

Gemcitabine

Graziella Pratesi
Fondazione IRCCS Istituto Nazionale dei Tumori, Milan, Italy

Synonyms

dFdC; 2′,2′-Difluoro-2′-deoxycytidine; GEMZAR

Definition

Is an antitumor drug belonging to the class of antimetabolites. Antimetabolites are agents that interfere with normal metabolism due to their structural similarity to normal intermediates in the synthesis of RNA and DNA precursors. Due to differences in metabolism between normal and cancer cells, antimetabolites have the potential to act with a certain degree of specificity in cancer cells. Antimetabolites target the synthetic pathway of pyrimidines (uracil, cytosine, thymine) and purines (guanine, adenosine) nucleotides, where they can serve as substrates for enzymes, or can inhibit enzymes, or both. As a consequence of their interference, either by incorporation or inhibition, antimetabolites induce cell damage leading to apoptotic cell death.

Several cytidine and deoxycytidine analogs have been synthesized in the past and tested for antitumor efficacy. The first successful agent in clinical practice was ara-C (1-β-D-arabinofuranosylcytosine) which is currently used as first-line treatment in acute myeloid leukemia and ►non-Hodgkin lymphoma.

Characteristics

Mechanism of Action and Resistance

Is a potent and specific fluorine substituted ara-C analog with pronounced activity against solid tumors. Gemcitabine presents advantages in ►pharmacokinetic and ►pharmacodynamic properties over ara-C. Its mechanism of action is well characterized. Gemcitabine exhibits cell-phase specificity, primarily killing cells undergoing DNA synthesis (S-phase) and also blocking the progression of cells through the ►G1/S transition. Membrane transport is mediated by facilitated diffusion catalyzed by human equilibrative nucleotide transporter 1, a carrier for physiologic nucleosides. The molecule itself is inactive and needs to be metabolized

intracellularly to its mononucleotide by deoxycytidine kinase, and then by nucleotide kinases to the active diphosphate (dFdCDP, gemcitabine-DP) and triphosphate (dFdCTP, gemcitabine-TP) nucleotides. The activity of gemcitabine is strongly correlated with the extent of gemcitabine-TP. Once incorporated into the DNA strand, an additional natural nucleotide is added, masking gemcitabine, preventing ►DNA repair by base pair excision, and eventually resulting in chain termination. Such process is self-potentiated by the inhibitory effect of gemcitabine-DP on the reaction generating normal deoxycitidine-TP, thus favoring the incorporation of gemcitabine-TP into DNA. Gemcitabine is also incorporated into RNA and induces cell ►apoptosis. Ribonucleotide reductase can be inhibited by gemcitabine-DP, resulting in depletion of deoxycitidine-TP and deoxiadenosine-TP. Deoxycitidine-TP is a feedback regulator of nucleotide kinase, thus favoring the activation of gemcitabine. The depletion of deoxiadenosine-TP will inhibit DNA repair. Collectively, the various effects of gemcitabine result in a unique pattern of self-potentiation.

Inactivation of gemcitabine can occur by deamination into its inactive metabolite difluoro-deoxyuridine by cytidine deaminase (CDD) or dephosphorylation of nucleotide-MP by 5′-nucleotidase (5′-NU), which exerts the opposite function of deoxycitidine kinase.

Three general mechanisms of resistance to nucleotide analogs have been described. The first one arises from insufficient intracellular concentration of nucleotides-TP, which may result from inefficient cellular uptake, reduced levels of activating enzymes, increased degradation by increased 5′-NU or CDD activity, or expansion of the natural deoxynucleotide-TP pool. The second mechanism may be due to inability to achieve sufficient alterations in DNA strands or deoxynucleotide-TP pool. The third mechanism may be a consequence of defective apoptotic pathways, which can impair the activity of antitumor drugs of various mechanistic classes.

Clinical Profile

For clinical use gemcitabine is administered intravenously. The standard administration of gemcitabine is a 30 min infusion of 1,000 mg/m^2/week up to 7 weeks, followed by 1 week rest.

Toxicity

The dose limiting toxicity is ►myelosuppression, with 25 and 5% of patients experiencing severe (G3-4) ►neutropenia and ►thrombocytopenia, respectively. At the standard regimen hematological toxicity is of short duration, and mild gastrointestinal toxicities (nausea, vomiting), alteration in liver and renal functions, diarrhea and stomatitis are also observed. Serious renal or liver toxicities are rare but not reversible. Other toxicities include edema, cutaneous toxicity associated to pruritus, fever, neurotoxicity and dyspnea (uncommon but severe).

Indications

Gemcitabine is approved for the treatment of several solid tumors such as pancreatic cancer, advanced ►non-small cell lung carcinoma (NSCLC), ►bladder cancer, ►ovarian cancer and ►breast cancer.

NSCLC. Gemcitabine is approved for use in combination with ►cisplatin for first-line treatment of patients with inoperable, locally advanced (Stage IIIA or IIIB) or metastatic (Stage IV) NSCLC. Two schedules have been investigated and the optimal schedule has not been determined. The combination with cisplatin was investigated on the basis of preclinical studies showing inhibition of repair of platinum-induced DNA damage, and of the results of Phase II studies with single agent gemcitabine in more than 400 patients producing response rates consistently above 20%. Promising results are reported in a Phase III study combining gemcitabine to carboplatin, a platinum-analog less myelotoxic than cisplatin. The combination produced better results, in terms of response rate and time to progression than gemcitabine alone. Several Phase II trials have investigated the combination with non-platinum derivatives such as ►docetaxel, ►paclitaxel or vinorelbine, but no one has proven advantages when compared to the standard platinum-based regimen. Due to the low toxicity profile gemcitabine is under investigation in elderly patients with advanced NSCLC, either as single-agent or in combination with other drugs.

Pancreatic Cancer. Gemcitabine is approved for the treatment of patients with locally advanced (non-resectable Stage II or III) or metastatic (Stage IV) ►adenocarcinoma of pancreas both for first-line treatment and for patients previously treated with a ►5-fluorouracil-containing regimen. The approval for first-line treatment was based on the results of a randomized study showing improvement in median survival, 1-year survival and clinical benefits over weekly 5-fluorouracil. Several randomized trials have compared gemcitabine with a gemcitabine-based combination, none of which having shown any incremental benefit in terms of survival or quality of life. Improvement in survival might be achieved by prolonged infusion strategy of gemcitabine and is currently under evaluation.

Breast Cancer. Gemcitabine is approved for use in combination with ►paclitaxel for the first-line treatment of patients with metastatic breast cancer after failure of prior ►anthracycline-containing adjuvant chemotherapy. The combination of gemcitabine and ►taxanes (docetaxel or paclitaxel) was tested in clinical

trials based on the good single-agent activity of each drug. In a Phase III study gemcitabine in combination with paclitaxel significantly improved response rate, time to progression and survival versus paclitaxel in metastatic breast cancer, with no significant increase in toxicity. The best schedule for administration of gemcitabine-taxane combination and the relevance of the combination in ►Her-2/neu positive patients are currently under investigation.

Bladder Cancer. Systemic chemotherapy has reached a plateau in the treatment of ►transitional cell carcinoma of the bladder. Gemcitabine is approved for such disease in combination with cisplatin. Such regimen has equivalent response rate and survival, but improved toxicity profile, compared to the previous standard regimen including ►methotrexate, ►vinblastine, ►adriamycin and ►cisplatin. Promising results have been observed with intrabladder infusion of gemcitabine.

Ovarian Cancer. Gemcitabine is approved in combination with ►carboplatin in several European countries for the treatment of recurrent epithelial ovarian cancer. It has been recently approved also in the USA on the basis of a randomized trial comparing the combination against carboplatin alone in 356 women with recurrent ovarian cancer, whose tumors had previously responded to first-line therapy. The median progression-free survival was 8.6 months for patients taking carboplatin and gemcitabine, and 5.8 months for patients taking carboplatin alone. Quality-of-life was comparable in the two groups of patients. Multicenter Phase III trials are ongoing comparing paclitaxel plus carboplatin with gemcitabine plus carboplatin. The results of a single-institution Phase II study in 24 patients, indicate an acceptable toxicity (with bone marrow toxicity as dose-limiting) with high overall response rate (91%) for the combination gemcitabine plus carboplatin.

Clinical Pharmacology

Pharmacokinetic studies indicate that the drug is eliminated in the urine. Gemcitabine is rapidly converted to the inactive uracil metabolite (recovered in the urine for more than 90%), which has a long half life. Gemcitabine pharmacokinetic is linear and described by a 2-compartment model. ►Clearance and ►volume of distribution vary with duration of infusion, age and gender. Gemcitabine plasma protein binding is negligible.

Future Perspective

Due to its low bone marrow toxicity, gemcitabine might be a suitable drug to be combined with ►immunotherapy, and preclinical studies support such expectation. Gemcitabine can induce massive tumor-cell apoptosis both in in vitro and in vivo systems. Uptake of dead cells by ►antigen presenting cells, still alive after gemcitabine treatment, will result in increase of cross presenting tumor antigens to T lymphocytes in tumor draining lymph nodes. Moreover gemcitabine, which is particularly toxic for B lymphocytes, by impairing the antitumor antibody response might favorite the generation of ►cytotoxic T lymphocytes, which have to be generated for immunotherapy to be effective. Again, chemotherapy may upregulate cellular death receptors, which are used by T cells to kill targets. Gemcitabine followed by CpG-oligodeoxynucleotide, a modulator of the natural ►immune response, results in a strong therapeutic synergism in a pancreatic tumor model.

Thus, in addition to more combination studies with established or novel antitumor drugs, future clinical studies should address the role of gemcitabine in combination with various immunotherapies for the treatment of cancer.

Gene Expression Cassette

Definition
Stretch of recombinant DNA typically comprising a ►promoter, a gene and a polyadenylation signal; often used in ►gene therapy.

Gene Expression Profile

Definition
Messenger-RNA from relevant cells is copied to labeled (with fluorescence dye or radioactive nucleotide) complementary cDNA probes. The probes are incubated on a DNA array containing spots of DNA from known genes being investigated. Hybridization of a given probe signifies the presence of the mRNA in question in the cell or tissue studied, i.e., the gene is active. The method allows estimation of activity genes in one assay. Firstarray many was developed in early 1980 as "Oncogip" for profilin of ►oncogene expression.

►Microarray (cDNA) Technology

Gene Expression Profiling

Definition
A microarray-based methodology to study gene expression (RNA) patterns. Parallel analysis of the expressed transcriptome of a given cell line or tissue sample, first developed in early 1980ies for ►oncogene profiling.

►Microarray (cDNA) Technology

Gene Gun

Definition
Is a way for in vivo transformation of cells or organisms used for gene therapy and genetic immunization. This gun uses particle bombardment where DNA- (or RNA-) coated gold particles are loaded into the gun. A low pressure helium pulse delivers the coated gold particles into virtually any target cell or tissue.

►DNA Vaccination

Gene Knockout

Definition
Is a genetically engineered organism that carries one or more genes in its chromosomes that have been made

inoperative (have been "knocked out" of the organism). This is done for research purposes. Also known as knockout organisms (►knock-out mice) or simply knockouts, they are used in learning about a gene that has been sequenced, but which has an unknown or incompletely known function. Researchers draw inferences from the difference between the knockout organism and normal individuals.

Gene Profile

Definition

A extensive survey of genes leading to RNA encompassing known coding sequences in the genome.

►Gene Expression Profile

Gene Therapy

Valerie Bosch
Forschungsschwerpunkt Infektion und Krebs, F020, German Cancer Research Center (DKFZ), Heidelberg, Germany

Definition

Directed introduction and expression of new genetic information in cells of an organism for therapeutic purposes. Only somatic gene therapy is presently permitted, and the introduction of genetic material into germ-line cells is not allowed.

Characteristics

The science of gene therapy has its beginnings in the early 1980s, subsequent to the identification of several disease-related genes and the development of technologies for gene isolation, purification and transfer to cells in culture. Many different human diseases represent theoretical targets for gene therapeutic intervention and the strategies developed depend on the nature of the disease to be treated. Table 1 illustrates several classes of human disease and the respective treatment strategies currently being followed. It goes without saying that detailed knowledge of the molecular mechanisms of disease development and progression is a prerequisite for the development of gene therapeutic intervention strategies.

Transfer of Genes

Very many different methods have been developed to transfer therapeutic genes to patient cells. A consideration which is central to the choice of gene transfer vehicle (►vector) is whether stable or only transient gene expression is required. Stable gene expression is necessary for the treatment of hereditary genetic defects whereas transient gene expression is sufficient, and may even be desirable, when employing genes encoding toxic gene products e.g. in the treatment of cancer. Many gene transfer vehicles employ components of viruses (viral vector-mediated gene transfer) since viruses have evolved to efficiently transfer their own genes to cells and to express the respective gene products at high levels. Since it may not be possible to completely eliminate potential safety problems with viral vectors, non-viral gene transfer vehicles have been developed in parallel. These transfer vehicles are based on lipids/►liposomes (lipoplexes), on polycations (polyplexes), on branched polymer structures (dendriplexes) or consist simply of naked DNA (►Non-viral vectors for cancer therapy). In general, the transfer efficiencies and gene expression levels achieved with non-viral vectors are poorer than with viral vectors. The commonly used gene transfer vectors, their advantages and their disadvantages are summarized in Table 2.

In many situations, in addition to high gene transfer efficiency, it is necessary that the transfer vector is selective i.e. mediates expression of the therapeutic gene exclusively in targeted diseased cells. Achieving selectivity is a major hurdle which is being approached in several ways. Gene vectors are being manipulated (on the surface of the gene vector particle) such that targeted cells are exclusively accessed. Selectivity can be achieved by ensuring that, even in the situation in which many cells have been accessed, expression of the therapeutic gene can only occur in specific targeted cells (e.g. by employing tissue-specific promoter/enhancer elements to control therapeutic gene expression).

Clinical Relevance

Therapeutic genes can be introduced into patient cells either ex vivo or in vivo (see Fig. 1). In the ex vivo application, a patient biopsy is genetically manipulated outside the body and subsequently reinjected or transplanted. This procedure has the advantage that only the cells in the biopsy come in contact with the transfer vector. Furthermore, the circumstances in cell culture generally allow more efficient gene transfer than on in vivo application. In addition, in some cases it is possible to expand the cells in the biopsy and create a pool of genetically modified cells which can be

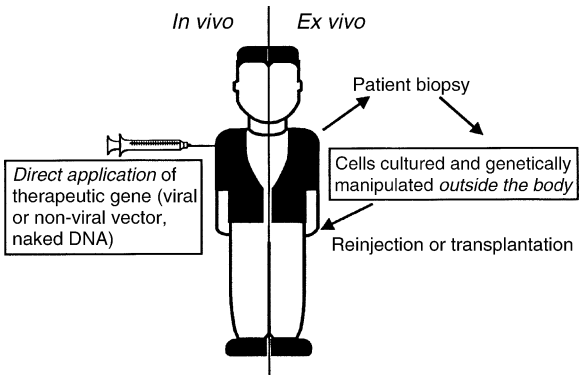
Gene Therapy. Table 1 Examples of gene therapeutic strategies for different disease groups

Disease group	Genetic basis of disease	Strategy
Hereditary monogenic disease e.g. haemophilia, cystic fibrosis	Defective gene which results in a single gene product being missing or non-functional	Introduction of wild-type gene (e.g. into liver or muscle for the production of a protein in the blood circulation, into lung in the case of cystic fibrosis)
Multifactorial disease e.g. cardiac disease, diabetes	Many genes and their gene products directly or indirectly involved	At present too complex. However, restenosis. (i.e. tissue proliferation after surgical dilation of a blood vessel) can be treated by locally expressing genes which inhibit cell proliferation
Cancer	Somatic mutation of cellular genes (several)	1. Induction of cell death employing genes encoding toxic gene products 2. Stimulation of the immune system to recognise and destroy cancer cells. (►Cancer vaccines ►DNA vaccination) 3. Inhibition of "cancer genes." (►Cell-cycle targets for cancer therapy) 4. Prevention of tumor ►angiogenesis
Infectious diseases e.g. AIDS	New genetic material from the infectious agent (e.g. virus) induces pathogenic processes	1. Inhibition of expression of genes encoded by the infectious agent employing e.g. antisense, ribozyme or small-interfering (si) RNA approaches. (►Antisense DNA therapy) 2. Vaccination against viral gene products expressed from transferred heterologous viral vectors or from naked DNA i.e. infection prevented or eliminated by the patient's immune system

Gene Therapy. Table 2 Gene transfer vehicles, their advantages and disadvantages

Gene vehicle	Advantages	Disadvantages
Retrovirus vectors including those based on lentiviruses	1. Integration of vector into host genome leading to stable gene expression 2. No cellular toxicity 3. Lentiviral vectors also infect (transduce) differentiated non-dividing cells	1. Titer not as high as e.g. adenoviral vectors 2. Vector integration into host genome is potentially mutagenic
►Adenovirus vectors	1. Very high titers (10^{13}/ml)	1.Only transient gene expression
	2. Very high, but transient, gene expression	2. Immune response to vector and transgene
Adeno-associated virus (►AAV) vectors	1. AAV is not pathogenic in humans	1. lower coding capacity than with retroviral and adenoviral vectors
	2. Non-toxic	2. Gene expression in proliferating tissue only transient
	3. Infects non-dividing cells	
Lipoplexes, polyplexes and dendriplexes	No viral genes, no toxic effects	Mostly lower and transient gene expression
Naked DNA	No viral genes, no toxic effects	Mostly lower and transient gene expression

reapplied to the patient as required. The main disadvantage of the ex vivo procedure is that it is technically cumbersome, time-consuming and very expensive. The most straightforward and desirable situation would be to apply the gene transfer vehicle in vivo either directly into specific tissues or organs (e.g. directly into tumor tissue) or by injection into the blood circulation. In vivo application requires that the transfer vector efficiently



Gene Therapy. Figure 1 Application routes for gene therapy.

reaches the appropriate diseased cells and at present, this is very often not the case. In fact, major problems hampering gene therapeutic approaches today concern the efficiency and the selectivity of the transfer vectors when applied in vivo. Further problems are related to the induction of host immune reactions towards the (viral) vector and the transgene.

Permission for the first clinical gene therapy study was granted in 1989 and since then numerous ►clinical trials, for the most part with only relatively small numbers of patients, have been carried out. Lack of sufficient selectivity and efficiency of transfer as well as lack of stability of transgene expression, the results of most of these trials did not establish any statistically verified positive effects on disease progression or mortality. Recently, however, more favorable results have been obtained. Thus, as a result of a gene therapeutic intervention with a retroviral vector, several individuals were cured of severe X-linked combined immunodeficiency. Unfortunately, however, within this same trial, severe adverse side-effects were observed in three treated patients. In the meantime, the reasons for these adverse effects have been largely elucidated and subsequent protocols will be adjusted accordingly. At present, basic research is focussed on improving gene vector properties and on gaining a better understanding of the interactions between the gene vector, the transgene and the patient's immune system. It is to be anticipated that the combined knowledge gained from these efforts will allow gene therapeutic protocols to be developed which will represent valid treatments for diseases which have been difficult or impossible to therapy up until now.

Gene Transfection

Definition

Synonym Gene Transduction, Gene Transfer; Introduction of genes into cells.

►Transfection

Gene-Environment Interaction

Definition

The combined effect of genetic susceptibility and exposure to non-genetic factors, broadly defined as "environmental."

►Cancer Epidemiology

Genetic Association

Definition

Studies of genetic association test whether ►allele or ►genotype frequencies are different between groups of individuals (for example, subjects with and without cancer).

►Linkage Disequilibrium

Genetic Association Study

►Case Control Association Study

Genetic Epidemiology

Definition

The branch of epidemiology which aims at elucidating and quantifying the genetic causes of cancer. Genetic epidemiology investigates the aggregation of cancers in

families (linkage studies), and the presence of high-risk genetic variants in sporadic cases (association studies).

►Cancer Epidemiology
►Epidemiology of Cancer

Genetic Haplotype

Definition

Is a term used in the context of ►case–control association study where instead of analyzing the association between trait and each genetic marker singly, multiple markers are analyzed simultaneously for a combined effect. These multiple markers when combined together are called a haplotype. There are two rationales for examining haplotypes. First, using haplotypes allows multiple potentially causal markers to be tested simultaneously for association. However, for haplotypes to be superior to individual markers, multiple functional markers must have a strong interaction when combined and yet have no detectable effect when considered individually. Second, haplotypes can be tested for association because they may be a proxy for untyped causal markers. Some have pointed out that the additional association tests entailed in haplotype-based analyses can actually result in a loss of power, and hence lower efficiency, once corrections for multiple testing are taken into account.

►Case–Control Association Study
►Haplotype

Genetic Immunization

►DNA Vaccination

Genetic Instability

Definition

Synonym genomic instability, seems to be the hallmark of cancer cells, in contrast to the normal cells that, with few exceptions such as e.g. telomeres (►telomerase) or ►V(D)J-recombination, are genetically stable. The principal concept here is that when genes involved in the maintenance of genetic stability of the cellular genome undergo mutation, the repair of ►DNA damage often will be incomplete, due to impaired DNA repair (►repair of DNA) systems. As the consequence, during tumor ►multistep development, tumor cells assume a ►mutator phenotype and will accumulate mutations leading to the evolution, by Darwinian selection, of tumor cells that escape cellular growth signals and become more and more malignant. This process is not necessarily related, as often postulated, to very rapid tumor cell proliferation. Cells of many types of tumors actually multiply rather slowly and, in contrast, normal cells in various sites, like the epithelium of the intestine, multiply very rapidly but still remain normal. The ensuing genetic instability drives tumor ►progression by generating mutations in ►oncogenes and ►tumor-suppressor genes. These mutant genes provide cancer cells with a selective growth advantage, thereby leading to the clonal outgrowth of a tumor.

Genetic instability can be at the level of the chromosome (►chromosomal instability; CIN) or can be expressed as ►microsatellite instability (MIN; also referred to as MSI). Chromosomal instability (CIN) is a defining characteristic of most human cancers. Mutation of CIN genes increases the probability that whole chromosomes or large fractions of chromosomes are gained or lost during cell division. The consequence of CIN is an imbalance in the number of chromosomes per cell (►aneuploidy) and an enhanced rate of ►loss of heterozygosity. Microsatellite instability is a condition manifested by damaged DNA due to defects in the normal DNA repair process. MSI is a key factor in several cancers including ►colon cancer, ►endometrial cancer, ►ovarian cancer and ►gastric cancer. For colon cancer, a prominent form is hereditary non-polyposis colorectal cancer (HNPCC) or ►Lynch Syndrome, where an inherited mutation in a ►mismatch repair gene causes ►microsatellite instability. The replication error results in a ►frameshift mutation that inactivates or alters ►tumor suppressor genes.

Genetic changes in genetically unstable cells will occurs at random possibly affecting, in humans, any of the estimated 30,000 genes present in the genome. Because of this randomness, genomic instability eventually will lead to tumor cell populations that are genetically different, both within a given tumor in the individual patient and in the same tumor type of different patients. Because the biological behavior of tumor cells is dictated by the profile of genetic changes, the heterogenous populations of cells will respond differently to therapeutic treatments, such as ►chemotherapy or any other form of therapy. Very often, large populations of tumor cells, due to the pattern of genetic changes, may disappear by therapy-induced ►apoptosis. Still, minor populations, again because of their

particular genetic pattern, may be inherently ►drug resistant and may develop into a new tumor that now is fully resistant against therapeutic drugs. For the same reason, tumors in different patients may respond differently.

►Chromosomal Instability

Genetic Knock-out

Definition

A gene knockout is a genetically engineered organism that carries one or more genes in its chromosomes that have been made inoperative (have been "knocked out" of the organism). Also known as knockout organisms or simply knockouts (►knock-out mice), they are used in learning about a gene that has been sequenced, but which has an unknown or incompletely known function. Researchers draw inferences about gene function from the difference between the knockout organism and normal individuals.

►Orphan Nuclear Receptors

Genetic Polymorphism

Definition

Genetic polymorphism is the presence of multiple inheritable forms of a gene within the population; a genetic trait where the least common ►allele is found in approximately at least 1% of the population

►Detoxification
►Modifier Loci
►Pharmacogenomics in Multidrug Resistance

Genetic Recombination

Definition

Is the process whereby DNA from one chromosomal location is exchanged for, or replaces, another region of the genome.

Genetic Susceptibility

Definition

An inherited increase in the risk of developing a specific disease.

►Mutagen Sensitivity

Genetic Toxicology

Joseph R. Landolph Jr.
Cancer Research Laboratory, USC/Norris Comprehensive Cancer Center, Keck School of Medicine/School of Pharmacy, University of Southern California, Los Angeles, CA, USA

Synonyms

Chemical mutagenesis; Clastogenesis; Chemical carcinogenesis

Definition

The study of the processes and mechanisms by which chemicals or radiations cause damage, including ►mutations, DNA single-strand breaks and double-strand breaks, ►gene rearrangements and gene ►amplifications, and ►chromosome damage in prokaryotes or eukaryotic cells. This includes aspects of mutagenesis, i.e., the process by which specific chemicals induce changes in the sequence of DNA bases in genomes. It includes also ►chemical carcinogenesis, i.e., the molecular mechanisms by which chemicals carcinogens induce mutation in ►tumor suppressor genes, inactivating them, and induce mutations, rearrangements, or amplifications of ►oncogenes, deregulating them, causing fifteen such changes. These five to eight changes, consisting of inactivation of tumor suppressor genes and activation of oncogenes, leads to further derangements in the expression of ►numerous genes, which results in the cell acquiring a tumorigenic phenotype and the eventual development of cancer.

Characteristics

Genetic Toxicology

Genetic Toxicology, or the science of the study of chemicals and radiations (►Radiation-induced cancer) that can cause damage to genes and the genome, is now a very advanced science. There are now many

assay systems, both in bacteria, yeast, *Drosophila*, mice, and in cultured murine and human cells, which can be used to detect ►DNA damage. Such damage includes mutations induced by chemicals or radiation, gene rearrangements, gene amplification, chromosome damage (gaps, breaks, fragments, dicentrics, and satellites), single-strand breaks in DNA, and double-strand breaks in DNA. Important assay detection systems include the ►Ames assay that detect reversion of His − *Salmonella* back to His + *Salmonella*, and which also utilizes addition of exogenous ►cytochrome P450 to metabolically activate premutagens, such as ►polycyclic aromatic hydrocarbons to epoxides and diol epoxides. Mutation and recombination can also be studied in yeast. In addition, there are assays to study mutation in mice, using the "spot test." Plasmids can also be added to mice and retrieved from mice treated with suspect chemical mutagens, and then analyzed to detect mutations in these plasmids.

There is now an extensive body of data indicating that specific chemicals and radiations can be assayed in mammalian cells, both rodent cells (murine, rat, and hamster cells) and cultured human cells, for their ability to cause mutation. Examples of these assays include the assay for mutation to 6-thioguanine (or 8-agazguanine) resistance, which detects base substitution, frameshift, and deletion mutations caused by chemicals and radiations. There is an assay for mutation to ouabain resistance, which detects base substitution mutations in the (Na, K) adenosine triphosphatase (ATPase) in rodent and human cells. There is also an assay in L5178Y mouse lymphoma cells that detects large chromosomal mutations and also point mutations, in which the cells are assayed that are resistant to bromodeoxyuridine. These cells have mutations in or deletions of, the thymidine kinase gene. There is also a simple assay in which cells are exposed to chemical mutagens or radiations, and then the cells are lysed, and DNA damage is assayed in a gel electrophoretic assay ("►COMET assay").

From results of these assays, we now know that we can easily detect chemicals that cause genetic toxicity, in the form of DNA damage, mutations, gene amplification, or breaks in the single- or double-strands of DNA, or damage to chromosomes (gaps, breaks, fragments, dicentrics, satellites) (►Clastogenesis). In terms of correlations of genetic toxicity with cancer-causing ability, it has also been established that ~45% of all chemical carcinogens are mutagens. Hence, these assays detect mutagenesis/DNA damage, and will therefore detect mutagenic chemical carcinogens and radiations. Many chemical carcinogens are also clastogenic agents. The other classes of carcinogens involve those that cause ►methylation of tumor suppressor genes, rendering them transcriptionally quiescent, or demethylation of oncogenes rendering them transcriptionally active at inappropriate times. Another group of carcinogens are certain hormones (►Hormonal carcinogenesis), such as ►diethylstilbestrol, estrogen, and ►testosterone, which act by inducing cell division. Inappropriately high numbers of cell division can lead to spontaneous mutations in cells, or can drive cell division to replicate the DNA of cells that have been adducted by chemical mutagens or damaged by radiations, leading to fixation of chemical mutations.

Chemical, Viral, and Radiation Carcinogens

Broadly defined, a ►carcinogen is any material, whether radiation, chemical, or virus, which can induce tumors in lower animals or in humans. ►Tobacco contains ~4,500 different chemicals, and over 20 different known strong human carcinogens, as well as ►tumor promoters and ►cocarcinogens. Exposure to tobacco and tobacco products is thought to account for ~30% of all human cancers. These include ►lung cancer, ►bladder cancer, ►oral cancer, ►pharyngeal cancer, ►laryngeal cancer, ►nasopharyngeal cancer, ►esophageal cancer, ►kidney cancer, ►liver cancer, and ►pancreatic cancer, according to the latest US Surgeon General's report. ►Second-hand tobacco smoke, or environmental tobacco smoke, also causes cancer in exposed individuals.

A second grouping of human cancers is thought to be due to exposure to excess levels of normal hormones, including ►estrogens and ►testosterone. Excess estrogen is believed to lead to ►breast cancer by causing an excessive stimulation of cell division, leading to spontaneous mutations in the oncogenes and tumor suppressor genes of breast epithelial cells. An excessive level of cell division in the epithelial cells of the prostate, driven by testosterone and its metabolites, is thought to contribute to the induction of prostate cancer. Human ►endometrial cancer is thought to be caused by estrogens without progestogens. ►Ovarian cancer can be induced by ovulation and the accompanying hormonal changes. Exposure to excess levels of hormones is estimated to induce ~30% of new human cancer cases.

Dietary influences are very important in human cancer induction. Dietary influences are estimated to contribute to ~15% of human cancers. Cancers influenced by diet include ►stomach cancer, ►colorectal cancer, and nasopharyngeal cancer. Consumption of an excess of animal fat and excess caloric intake predispose to cancer induction. Conversely, high consumption of green leafy and yellow vegetables and fresh fruits and a diet high in fiber inversely correlate with cancer induction. There are also a number of dietary mutagens formed by pyrolysis of foods. These include the tryptophan metabolites, TRP P1 and TRY P2, and other metabolites such as PhiP and MeIQX. ►Colon cancer in particular is thought to be induced by an excess of animal fat and deficiency of dietary fiber. Caloric excess in the diet correlates with

endometrial cancer induction. Excessive ►alcohol consumption correlates with increased risk of induction of pharyngeal cancer, laryngeal cancer, liver cancer esophageal cancer, oral cancer, colon cancer, and breast cancer (►Alcohal-rediated Cancer). Another specific example of a known human chemical carcinogen occurring during food consumption is ►aflatoxin B1, a biocidal metabolite of the mold, *Aspergillus flavus*. *A. flavus* biosynthesizes and then utilizes aflatoxin B1 as a biocide against other microorganisms in order to establish its own ecological niche. Aflatoxin B1 is metabolized by cytochrome P450 in mammals to a mutagenic metabolite, aflatoxin B1 2,3-epoxide, which binds covalently to DNA and induces mutations in the ►*p53* tumor suppressor gene and in other genes. This process leads liver cancer in humans. Aflatoxin B1-induced liver cancer is common in The People's Republic of China, Taiwan, Africa, and Mozambique, where hot, wet climates favor the growth of *A. flavus*, and this fungus contaminates fruits and grains, which are ingested by humans, leading to liver cancer.

Exposure to oncogenic viruses is estimated to induce ~10% of all human cancers. Notable and well-studied viruses that are oncogenic include the ►human papillomaviruses, including HPV16 and 18, which induce human ►cervical cancer. ►Hepatitis B virus and ►hepatitis C virus induce human liver cancer in Taiwan, in The People's Republic of China, and in Mozambique. The ►human T cell leukemia virus (HTLV) induces human T cell leukemias in Japan and the Caribbean. Infection of humans with the human immunodeficiency virus (HIV) is known to lead to ►lymphomas. Exposure to ►Epstein-Barr Virus can lead to benign conditions such as mononucleosis, and also at lower incidences, to Burkitt Lymphoma in Africa and to ►nasopharyngeal carcinoma in The People's Republic of China.

A fifth category of agents that induce human cancer are drugs, ►x-rays, and ►UV radiation. This combined category of carcinogens is estimated to induce 10% of all human cancers. Certain medically approved drugs, such as a fraction of cancer chemotherapeutic agents, including ►alkylating agents, ►adriamycin, and ►tamifoxen, can induce secondary malignancies (►secondary tumor). Certain analgesics, such as phenacetin, can induce renal pelvic cancer. Prominent examples of radiation carcinogens include ►ultraviolet light associated with ►skin cancer and ionizing radiations – gamma rays, x-rays, beta particles, alpha particles, and neutrons. Studies of the atomic bomb blasts in Hiroshima and Nagasaki during World War II have provided the best estimates of dose–response curves for radiation-induced carcinogenesis. UV light from the sun and in tanning salons can induce skin cancer.

The sixth broad category of carcinogens that can induce human cancer occurs in the occupational setting. Occupationally induced cancer is estimated to contribute ~5% of all human cancers. In this context, exposure to ►benzene has been linked in epidemiological studies to the induction of ►acute myelogenous leukemia, ►non-Hodgkin lymphoma, ►chronic myelogenous leukemia, and many other types of leukemia in rubber workers and in workers in shoe factories in the past. Exposure of nickel refinery workers to mixtures of soluble and insoluble ►nickel compounds as aerosols has been correlated with increased incidences of nasal sinus and respiratory cancers. Similarly, exposure of workers to hexavalent ►chromium compounds in the chromate manufacturing industry and in the chrome plating industry correlates with induction of lung cancer. Vinyl chloride exposure has led to human lung, liver, and brain cancer, and to the immune-mediated disease, vinyl chloride disease, which is similar to scleroderma.

Other examples of occupational carcinogens include bis-chloromethyl ether (lung cancer), ►asbestos (lung cancer and ►mesothelioma), and trichloroethylene (cancer at multiple sites) and perchloroethylene. ►Dioxin (TCDD, or 2,3,7,8-tetrachloro-p-dibenzo-dioxin), a by-product of paper manufacturing, is a potent carcinogen and tumor promoter. ►Arsenic, a by-product of copper smelting, is also found as an environmental carcinogen in drinking water contaminated by arsenate leached from iron sulfide-bearing rocks.

Environmental carcinogenesis is thought to be important also. However, at the present time, no solid estimates of the amount of human cancer that environmental pollution with carcinogens causes can be made with confidence due to our lack of knowledge in this area.

Chemical Carcinogenesis

Chemical carcinogenesis is the process by which chemical carcinogens (and radiations) can induce tumors in lower animals or in humans. Broadly viewed, chemical carcinogenesis begins as the process in which the very complicated series of ►signal transduction pathways mediating cellular growth and proliferation and their negative regulators are disrupted and deregulated. Chemical carcinogenesis is clearly a multistep process.

Chemical carcinogenesis has been divided conceptually and experimentally in the l930s by Isaac Berenblum, of the Weizmann Institute in Israel, into two stages, initiation and promotion (►Tumor promotion), when studying carcinogenesis on the backs of shaved mice. Berenblum used small doses of the ►polycyclic aromatic hydrocarbon 7,12-dimethylbenza(a)anthracene (►DMBA) as the initiator and the mixture croton oil, a biocide isolated from the plant, *Euphorbia lathyris*, as a promoter. Initiation is thought to be a mutation, likely in an oncogene such as the ►*RAS* cellular oncogene. Stimulation of the initiated

cells bearing mutations in the *RAS* or other cellular oncogenes with croton oil stimulates the cells to grow. With repeated croton oil stimulation, the initiated cells form a benign tumor called a ►papilloma. With further croton oil stimulation, the cells convert into a malignant tumor, called a ►carcinoma. Further damage to the cells of this carcinoma can result in a metastatic carcinoma. For many decades, investigators have used tetradecanoyl-phorbol acetate (►TPA), a chemical purified form croton oil, as the tumor promoter. TPA is one of the most potent tumor promoters known, and it binds to ►protein kinase C to stimulate cell division of initiated cells. Studies of how tumor cells interact with fibroblasts and immune effector cells to enable them to continuously grow and break free of the homeostatic mechanisms of the host that mediate tissue integrity are subjects of intense current interest.

Chemically Induced Morphological and Neoplastic Transformation and the Molecular Biology of Carcinogenesis/Cell Transformation and Human Cancer

At the cellular level, chemical carcinogenesis first involves the conversion of a normal cell into a tumor cell. There are a number of in vitro cell culture systems in which this process can be studied in a systematic way. They involve studying the loss of contact inhibition of cell division, the loss of anchorage dependence of cell division, escape from calcium ion-induced terminal differentiation, and the eventual acquisition of the property of tumorigenicity. These include C3H/10T1/2 Cl 8 mouse embryo fibroblastic cells, Balb/c 3T3 cells, Syrian hamster cells, mouse epidermal keratinocytes, and rat tracheal hamster epithelial cells among the rodent cell systems. Additional human cell systems involve diploid human fibroblasts and human epidermal keratinocytes.

This process of malignant cell transformation proceeds first through a series of mutations, rearrangements, or amplifications of oncogenes, or in epigenetic changes involving methylation status of oncogenes, leading to inappropriate expression of the normal oncogene product, or to expression of a mutated oncogene product. Such expression can lead to inappropriately high expression of various proteins involved in signal transduction pathways downstream of the oncogene product in the signal transduction pathway. A number of oncogenes contribute to cellular progression chemical carcinogenesis. Oncogenes are a set of genes controlling cellular growth and proliferation, and consist of a large number of gene families. Prominent members of these families include the ►*RAS* gene family, the ►*MYC* gene family, ►*ABL*, ►*FOS*, ►*JUN*, ►*ERBB2*, *FMS*, ►*KIT*, *RAF*, *SIS*, *ERBA*, *ETS*, *REL*, ►*HER2/neu*, ►*SRC*, ►*BCL-2*, *BCL-3*, *BCL-6*, *HOX1*, *RHOM-1*, *RHOM-2*, *TAL-1*, *TAL-2*, *TAN-1*, and many others.

Secondly, this process involves the inactivation of a number of ►tumor suppressor genes. Tumor suppressor genes are negative regulators of cell growth and proliferation. Prominent members of this large group of genes include the genes ►*RB1*, ►*FHIT*, ►*VHL*, ►*APC*, ►*WT1*, ►*NF1*, ►*NF2*, ►*TP53*, ►*MEN1*, ►*PTEN*, and many others. Inactivation of the *RB1* tumor suppressor gene leads to release of the transcription factor EF-2 from the Rb–EF2 complex, which can cause cell cycle progression. Mutational inactivation or deletion of *TP53* can lead to failure to stop cell cycle progression and allow DNA repair to proceed, leading to an accumulation of mutations in cells. Additionally, inactivation of *TP53* can lead to a failure of cells bearing many mutations to undergo ►apoptosis. This allows accumulation of cells bearing mutations, and allows these cells to progress toward malignancy.

The accumulation of mutations, gene amplifications, gene rearrangements, or deletions is thought to lead to conversion of a normal cell into a malignant cell. These include events that activate a number of cellular oncogenes, and that inactivate tumor suppressor genes. Hence, a number of cellular oncogenes would be mutated and activated, or amplified, or rearranged and placed under the control of strong promoters. This would lead to expression of mutant oncogene product, or to higher steady-state levels of normal oncogene product. These protein products then would impact upon signal transduction pathways to stimulate these pathways. In the same manner, mutational inactivation of tumor suppressor genes, methylation of the promoters of these genes to transcriptionally inactivate them, and breakage and loss of part of the chromosome bearing these genes, or loss of the entire chromosome bearing these genes, can also contribute to carcinogenesis. It is thought that fifteen events, including activation of oncogenes and inactivation of tumor suppressor genes, lead to carcinogenesis. What has only recently become known is that fifteen such events can have far-reaching effects on global gene expression, leading to aberrant expression of 100–300 genes in cells, which results in the malignant phenotype. This is because mutation or overexpression of each oncogene can lead to increased expression of ~10 additional genes in signal transduction pathways in which this gene participates. Similarly, each tumor suppressor gene may control expression of approximately an additional 10 genes. When this suppressor gene is inactivated, stimulation of its expression of these additional 10 genes is also lost. Hence, physiologically, tumor cells suffer global derangement of gene expression. Our knowledge of this complexity paradoxically provides many opportunities for therapeutic intervention to kill tumor cells, cause them to apoptose, or to cause them to differentiate into nontumorigenic cells.

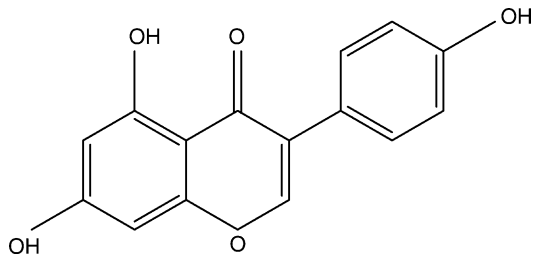
Genistein

Ruiwen Zhang
University of Alabama at Birmingham, Birmingham, AL, USA

Synonyms

4′,5,7-Trihydroxyisoflavone; Soy phytoestrogen



Genistein. Figure 1 The chemical structure of Genistein.

Definition

Genistein is an ►isoflavone, derived principally from soybeans, that has cancer preventive and therapeutic effects (see Fig. 1).

Characteristics

Soy and Cancer

Numerous epidemiological studies have indicated that a diet high in soy products can decrease the risk of developing cancers, including ►breast cancer, ►prostate cancer, ►colon cancer, ►lung cancer and ►skin cancer. In countries where soy products are frequently consumed, there is a lower incidence of these and other cancers. A study of more than 600 women in Singapore (420 healthy controls and 200 women with confirmed breast cancer) demonstrated that ingestion of soy products correlated with a decrease in cancer risk. Moreover, a similar study with men showed that soy consumption decreased prostate cancer mortality.

Two isoflavones, genistein and daidzein, appear to be the major mediators of the cancer preventive activity of soybeans. For genistein, which is probably the primary active component, a body of work related to its cancer preventive and therapeutic effects, as well as to its mechanisms of action, has emerged.

Cancer Prevention by Genistein

Studies of ►chemical carcinogenesis and cancer development in transgenic animals have demonstrated that administration of genistein can decrease the incidence of cancer and decrease the multiplicity of tumors that develop. For example, treatment of transgenic adenocarcinoma of the mouse prostate (TRAMP) mice with 100–500 mg genistein/kg diet reduced the incidence of advanced-stage prostate tumors in a dose-dependent manner. A high-isoflavone diet also inhibited methylnitrosourea-induced prostate tumors in Lobund-Wistar rats. Treatment of mouse mammary tumor virus (MMTV)-neu mice with diets containing 250 mg/kg of genistein or daidzein increased the latency for spontaneous breast tumors but did not affect tumor size or multiplicity. Topically applied to ►DMBA-initiated and ►TPA-promoted Sencar mice,

genistein reduced the incidence and multiplicity of skin tumors by 20% and 50%, respectively.

In addition to its chemopreventive effects, genistein can be used therapeutically. It increases the survival of animals bearing ►xenograft, chemically induced and spontaneous (transgenic) tumors and improves the response to conventional therapies. Genistein can act additively or synergistically with chemotherapeutic agents, hormone therapy, ►immunotherapy or ►radiation therapy. Epidemiological studies with cancer patients suggest that increased soy consumption may increase survival. Moreover, while randomized trials are still ongoing (or have yet to be performed for many types of cancers), genistein appears to have little or no toxicity.

Mechanisms of Action of Genistein

Although the mechanisms of action for the anticancer effects of genistein have not been established, there are a number of candidate pathways. Reported *in vitro* and/or *in vivo* activities of genistein include estrogen agonism/antagonism; inhibition of protein tyrosine phosphorylation; ►topoisomerase inhibition; suppression of ►angiogenesis; scavenging of free radicals; and inhibition of ►matrix metalloproteinases, ►NF-κB and oncogenes, such as ►MDM2. Any or all of these effects can decrease carcinogenesis and tumor progression, lead to the induction of apoptosis and cell differentiation, and suppress ►metastasis.

Bioavailability and Safety

The ►bioavailability of genistein appears to be greater than that of many other natural compounds. Plasma concentrations of genistein in tumor-bearing ►nude mice fed a diet containing 1 mg/g genistein were 3.4 μmol/L; in humans, a single oral dose of 460 mg resulted in peak plasma concentrations of 20–25 μmol/L. In most commercially available products, isoflavones are present as glycosides, which may require hydrolysis by intestinal beta-glucosidases. After absorption, ►phytoestrogens are primarily converted to glucuronic acid derivatives. Extensive metabolism, accomplished by bacteria in the gut, leads to the formation of equol and lignans.

Although genistein is generally regarded as safe, and toxic effects of genistein do not occur when cells are exposed to physiologically relevant levels of the compound, there are some undesirable effects, most of which have been observed in animal models and are due to its hormone-like properties. Because there is evidence from *in vitro* and animal studies that it can stimulate the growth of hormone-dependent cancers (especially ►estrogen receptor alpha positive breast cancers), use of genistein to treat these cancers is controversial.

Other Indications

Because of its estrogenic effects, genistein has been used to ameliorate the effects of menopause. Studies so far have been inconclusive, although some suggest that genistein can improve the symptoms. Future studies, especially those involving use of randomized placebo controls, will be needed to determine its efficacy.

Based on its estrogenic, anti-oxidant and other properties, genistein has also been suggested to prevent osteoporosis, improve cognitive function, decrease cholesterol, and improve cardiovascular health.

Genomic Imbalance

Roberta Vanni
Department of Biomedical Science & Technology, University of Cagliari, Monserrato (CA), Italy

Definition

Refers to a genome showing any loss or gain of DNA sequences compared with the reference DNA whole sequence of the genome of interest. The term usually indicates extensive disequilibrium in the number of chromosomes or chromosome segments per cell.

Characteristics

Genomic Imbalance Concept

The relative dosage of genes governing cell physiology, is the product of evolution. Human somatic cells have evolved their "genome balance" as ►diploid, and variation in the number of chromosome copies as compared to the euploidy which has evolved, leads to genomic imbalance. This affects gene dosage and, consequently, promotes imbalances in cellular pathways. Most cancer cells acquire genomic imbalance as a consequence of ►aneuploidy, i.e. an abnormal copy number

of genomic elements, identified as gain and/or loss of whole chromosome(s) (aneuploidy) or chromosome segment(s) (partial aneuploidy). Genomic imbalance reflects the ►karyotype complexity of the cancer cells.

Cancer as a Genetic Disease

Cancer as a genetic diseasse involving genomic imbalance is a concept that has been explored since the end of the nineteenth century. In 1890 Paul von Hansemann (1858–1920), noticed that chromosomes in carcinomas segregate in unbalanced fashions, and at the beginning of the twentieth century, in 1914, Theodor Boveri (1862–1915) proposed his "chromosome theory of cancer," according to which cancer results from abnormal chromosomal composition within cells. Nowadays, this concept is widely accepted, based on molecular evidence, according to which cancer is a biological process characterized not only by accumulation of chromosome changes, but also by gene mutations, all contributing to the cell transformation process. The loss of critical cellular checks and balances throws proliferation processes into disorder by means of sequential steps, broadly including ►initiation, ►progression, ►invasion and ►metastasis.

Cause of Genomic Imbalance in Cancer

Genomic imbalance is the product of a phenomenon called ►chromosome instability (CIN), resulting in the increased probability that during cell division, whole chromosomes or chromosome segments will be acquired or lost. CIN is actually an ongoing process, responsible for variation in the rate of chromosome changes according to Darwinian selection, and may end with the production of stable aneuploid cells having proliferative advantages. A certain degree of cytogenetic heterogeneity within a tumor is maintained by CIN, and cytogenetically related or unrelated clones often persist alongside the favored one, contributing to intratumoral genomic imbalance. Many aggressive cancers, such those of the bladder, brain, breast, bone, cervix, colon, gallbladder, head and neck, liver, lung, ovary, pancreas, prostate, and testis show an accumulation of complex rearranged chromosome patterns, which may include, in addition to aneuploidy, ►double-minutes and the formation of ►homogeneously-staining regions. CIN, and the consequent genomic imbalance, calls for the interaction of various outcomes, including, abnormal mitotic segregation, abnormal shortening of ►telomeres and ►mitotic checkpoint deficiency.

- *Abnormal mitotic segregation*. Chromosome segregational defects may be due to different mechanisms, such as ►multipolar spindles formation, loss of ►sister chromatid cohesion, ►kinetochore defects during spindle attachment.

Multipolar spindles may develop in the presence of supernumerary ►centrosomes. Centrosome amplification is frequently seen in almost all types of solid tumors, and to a lesser extent in leukemia and lymphoma. Its occurrence is strongly associated with a high degree of aneuploidy. Amplification of *STK15/* aurora kinase*A* gene, inactivation of tumor suppressor genes, such as TP53 (Tumor Protein 53), *RB1* (Retinoblastoma), and *BRCA1* (breast cancer1) as well as overexpression of cyclins D and E, play a prominent role in this process.

Loss of sister chromatid cohesion is crucial in the metaphase-to-anaphase transition and the correct separation of genetic material in the cell. Cohesion is maintained by proteins called ►cohesins, which have to be degraded to lead to sister chromatid separation. Cohesins are released through a number of catabolic steps driven by the anaphase-promoting complex (APC), a ►ubiquitin ligase, targeting proteins for degradation. In yeast, APC acts on ►securin proteins, which in turn prevent ►separin (a cysteine protease, also called separase) from promoting sister chromatid separation. Human homologs of yeast separin and securin are respectively ESP1 (Extra Spindle Poles-like1) and ►PTTG1 (Pituitary Tumor-Transforming Gene1) proteins, and their inactivation interferes with the correct distribution of genetic material at ►anaphase.

►Kinetochore defects during spindle attachment may also have a major impact on chromosome malsegregation. Kinetochore is a highly-complex proteinaceous structure located in centromeric DNA and providing dynamic attachments to spindle microtubules, mediating the chromosome bi-orientation necessary to facilitate accurate segregation. Disturbances in this process result in aneuploid cells.

- *Abnormal shortening of telomeres*. This phenomenon is observed in both benign and malignant tumors. Shortening of ►telomeres during normal cell development and aging is the rule; however, in somatic cells that have lost proliferation control, it gives rise to genome instability and abnormal cell proliferation. Such abnormal shortening causes telomeres to lose their ability to protect chromosome ends from fusion. The products of chromosome fusion contribute to CIN by the formation of anaphase bridges, leading to structural and numerical chromosome changes or, through cell division inhibition, to poliploydization and subsequent multipolar spindle formation.
- *Mutations at mitotic checkpoint*. The regular mitotic phase of the ►cell cycle involves an orderly set of events, subdivided into phases: the prophase, prometaphase, metaphase, anaphase and telophase. In a normal cell, anaphase can start only when all chromosomes have congressed to the metaphase plate and achieved bipolar attachment to the mitotic

spindle. This scenario requires a powerful ►mitotic checkpoint, based on a dynamic balance of ►ubiquitination (by APC) and deubiquitination (possibly by ►USP44, Ubiquitin-Specific Protease44) of target proteins. Breakdown of mitotic checkpoint signaling brings on cell death, whereas its weakening, i.e. minor changes in checkpoint protein levels, does not compromise cell viability but promotes aneuploidy, since the mitotic checkpoint does not recognize a single or a few chromosomes lacking spindle attachment.

Although the role of genomic imbalance in tumorigenesis is recognized, and for some tumors diverse genomic imbalances correlate with prognosis, whether or not it may actually initiate tumorigenesis is still being debated.

Genomic Imprinting

Andrew P. Feinberg
Department of Medicine and Center for Epigenetics,
Institute for Basic Biomedical Sciences,
Johns Hopkins University School of Medicine,
Baltimore, MD, USA

Definition

Is an ►epigenetic alteration (i.e., not involving a change in base sequence) of a specific parental ►allele of a gene, or the chromosome on which it resides, in the gamete or zygote, leading to differential expression of the two alleles of the gene in somatic cells of the offspring. Genomic imprinting challenges two assumptions of conventional Mendelian genetics applied to human disease: that the maternal and paternal alleles of a gene are equivalent, and that two functional copies of a gene always are associated with health (Table 1).

Characteristics

Imprinted genes probably account for many examples of developmental malformations in humans, as uniparental disomy (UPD) of several chromosomes is associated with a variety of recognized defects, but UPD affecting most or all of a chromosome is rarely seen. Imprinting may have arisen in mammals as a result of an evolutionary conflict between maternal and paternal genomes. There is a strong and sometimes surprising relationship between imprinted genes and growth, including both prenatal growth and postnatal growth related to nurturing ability. Imprinting is also thought to underlie some quantitative trait loci for growth, with considerable potential commercial application in animal husbandry, and imprinting may be a potential barrier to stem cell transplantation. For all these reasons, genomic imprinting has generated intense interest.

Imprinted Genes and their Regulation

Despite this interest, the comprehensive identity of all imprinted genes remains unknown. At present over 80 imprinted genes are suspected in one or more species (see http://www.geneimprint.com). Imprinted genes appear to be organized within genomic domains. Evidence for this idea comes from studies of the region of 15q11-13 involved in Prader-Willi and Angelman syndromes, which cause mental retardation and neurological problems. This region harbors at least six imprinted genes and the region of the IGF2R gene contains at least three. Similarly, band 11p15 contains a domain of imprinted genes distributed over ~1 Mb. These genes play diverse roles including hormone-mediated growth stimulation (insulin-like growth factor II, or IGF2), control of the cell cycle (p57KIP2) and ion trafficking (KVLQT1). Both cis-acting and trans-acting factors appear to be important in the regulation of genomic imprinting. It is believed that cis-acting sequences can regulate imprinting over large distances. Evidence for this idea comes from the identification of patients with microdeletions involving upstream exons of the small nuclear ribonucleoprotein N gene (SNRPN), in the Prader-Willi region of chromosome 15. These deletions lead to disrupted imprinting extending over several megabases. This deletion site has therefore been termed an "imprinting center" for this chromosomal region. However, the molecular basis for the function of the imprinting center is as yet unknown.

Genomic Imprinting. Table 1 Key ideas of genomic imprinting and cancer

	Specific disorders (PWS, AS)
	Human cancer
Imprinting in cancer	Loss of imprinting (LOI) in childhood and adult tumors
	Both gene silencing and gene activation
	Link to cancer risk
Mechanisms	DNA methylation
	Conserved regulatory elements and genomic domains
	Modifier genes

Imprinting and DNA Methylation

Cytosine DNA ►methylation also appears to be important in the regulation of genomic imprinting, as loss of the cytosine DNA methyltransferase I gene (Dnmt1) disrupts normal genomic imprinting in mice. DNA methylation is a covalent modification of DNA in which a methyl group is transferred from S-adenosyl methionine to the C-5 position of cytosine. DNA methylation occurs almost exclusively at CpG dinucleotides. CpG islands, which are sequences unusually rich in ►CpG dinucleotides, are usually found in the vicinity of imprinted genes.

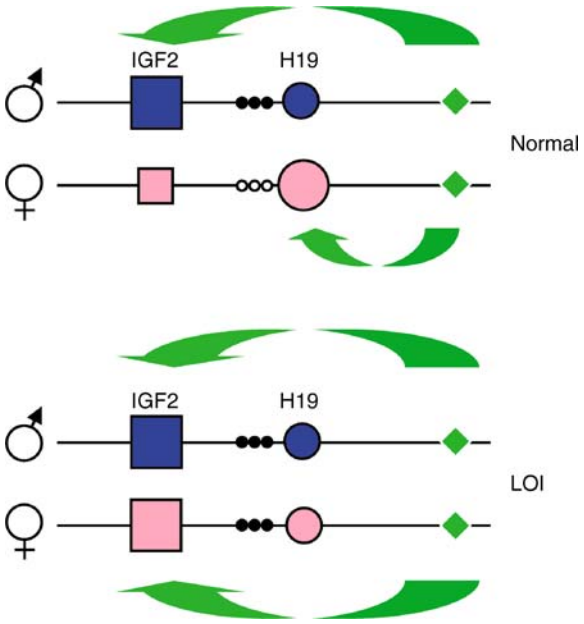
Recently, one mediator of imprinting was discovered. It is the CCCTC-binding factor (►CTCF), a transcription factor that binds to an unmethylated, GC-rich sequence ~2kb upstream of the H19 gene. The latter has previously been shown to be necessary for normal imprinting of H19 and ►IGF2. The same CTCF does not bind to methylated DNA. CTCF is known to be an insulator binding protein, and its binding prevents access by IGF2 to a shared enhancer 3′ to H19 (and about 200 kb telomeric to IGF2 itself).

Loss of Imprinting (LOI) in Cancer

In 1993, it was discovered that IGF2 can undergo loss of imprinting (LOI) in cancer, with abnormal expression of the normally silent maternal allele. LOI of IGF2 has been found in a wide variety of tumors, including embryonal tumors and adult malignancies. In the case of ►colon cancer, LOI was found not only in the tumors but in the normal tissues of patients with colon cancer. Furthermore, multiple well-controlled studies have now shown an association of LOI with a positive family history and personal history of colorectal tumors, both benign and malignant. Studies of mouse models with LOI and a gene mutation causing intestinal tumors show that LOI increases tumor initiation, and acts by increasing and altering the tissue stem cell compartment. Thus, tests for LOI may eventually prove useful for identifying patients at risk of cancer, thereby reducing overall cancer mortality (Fig. 1).

In the case of embryonal tumors, this activation of the maternal allele of IGF2 is coupled to silencing of the maternal H19 allele and methylation of a normally unmethylated maternal H19 ►CpG island. However, LOI of IGF2 occurs independently of H19 in adult tumors, such as ►cervical cancer and ►brain cancer. LOI of IGF2 is now recognized as one of the most common genetic alterations in human cancer. LOI of IGF2 is also found in about 15% of patients with ►Beckwith-Wiedemann syndrome (BWS). BWS is a disorder of prenatal overgrowth, birth defects and cancer, which is transmitted as an ►autosomal dominant trait, although most cases arise sporadically. In addition, LOI of the LIT1 gene, also on 11p15, is found in about 40% of BWS patients. This gene is particularly interesting, as it is an antisense transcript normally expressed from the paternal allele, that lies entirely within the maternally expressed KVLQT1 gene. A link between LOI and DNA methylation is also suggested by studies using the drug 5-aza-2′-deoxycytidine, which inhibits DNA methylation. This drug can restore a normal pattern of imprinting to tumor cells with LOI, suggesting that this or other pharmacological agents might eventually be used to treat cancers specifically with LOI or as chemopreventive agents in patients with LOI in their normal tissues.

Frequent loss of heterozygosity (►LOH) of 11p15 has also been observed generally in embryonal tumors, including ►Wilms tumor, ►rhabdomyosarcoma and ►hepatoblastoma. LOH of 11p15 is one of the most common genetic changes in cancer and is found in many adult malignancies, including those of the stomach bladder, ovary, breast and lung. Further strong support for the existence of an embryonal ►tumor suppressor gene on 11p15 derives from genetic complementation experiments. ►Microcell-mediated chromosome transfer of a human chromosome 11 suppresses the growth of rhabdomyosarcoma cells



Genomic Imprinting. Figure 1 Upper panel shows a normally imprinted IGF2 and H19 gene, with IGF2 expressed (drawn large) from the paternal allele, and H19 from the maternal allele. A shared enhancer (green) cannot cross an unmethylated CpG island (small open circles) upstream of the maternal H19 allele, presumably because of binding of CTCF to this island. The lower panel shows loss of imprinting (LOI) in cancer, with a switch of the paternal chromosome to a maternal epigenotype. Here the H19 CpG island is also methylated on the maternal chromosome, allowing the enhancer to interact with IGF2, with activation of the maternal IGF2 allele and silencing of the maternal H19 allele.

in vitro. Furthermore, subchromosomal transferable fragments limited to 11p15 do suppress tumor cell growth. However, in the investigation of an 11p15 tumor suppressor gene it is puzzling that in virtually all cases of LOH of 11p15 in embryonal tumors it is the maternal allele that is lost, an observation made before the discovery of human imprinted genes or such genes on 11p15 in particular. To address this problem, Sapienza argued that a gene that is not normally imprinted might become so aberrantly. According to Sapienza, a specific parental allele (in this case the paternal) would become silenced in some individuals. One or more of the maternally expressed genes on 11p15 might fulfill this role.

One of the most exciting frontiers in the study of genomic imprinting and its role in cancer is the identification of sequences that lie between genes, which might serve a regulatory role in the maintenance of normal imprinting of large genomic domains, such as on 11p15. One recent approach to identifying such sequences is by comparative genomics, in which the mouse sequence is obtained and compared to human sequence, in order to identify species conserved orthologous elements. These elements can then be tested in functional assays and be analyzed for mutations or deletions in patients with cancer or ►BWS. Proteins that interact with such sequences could include as yet unidentified modifiers of DNA methylation and/or genomic imprinting. Thus, one of the most important implications of the study of imprinting is that the lessons learned may be applicable to understanding the regulation of genomic domains generally, and their dysregulation may provide novel insights into the mechanism of cancer.

Genomic Instability

Definition

►Genetic Instability

Genomics

Definition

Denotes the complete study of the hereditary material of living beings: both the coding and noncoding portions. Structural genomics involves creating "maps" of genomes, carrying out DNA sequencing, and determining the localization and the regulatory regions of genes on ►chromosomes. Functional genomics is the branch of genomics that studies the biological function of the

genes and their products, the coded proteins, their expression and regulation, as well as the interactions between different genes.

Genotoxic

Definition

Causes damage to DNA. Examples of genotoxic agents are chemicals or radiations that cause mutation to cells, chromosome breakage in cells, gene ►amplification in cells, or single-stranded or ►DNA-double strand breaks.

►Chemically Induced Cell Transformation
►Chemical Carcinogenesis
►DNA Damage

Genotoxic Carcinogen

Definition

A carcinogen capable of causing a change to the structure of the genome.

►Toxicological Carcinogenesis

Genotoxicity Tests

Definition

These represent a range of standardized assays designed to test chemicals for interaction with DNA, i.e. genotoxicity or mutagenicity. These comprise a number of different tests both *in vitro* and *in vivo*. The most usual study conducted early in the development of a new drug is the ►Ames Assay that utilizes mutants of *Salmonella typhimurium*. Various mammalian cell culture systems are also employed such as Chinese hamster ovary (CHO) cells. Clastogenic activity is assessed by exposing cells to chemicals and examining cells microscopically for chromosome damage. An *in vivo* study is also often performed examination of the bone marrow in treated rodents.

►Preclinical Testing
►Clastogen

Genotype

Definition

Catalog of individual's two alleles at a particular DNA location. Refers to the complete genetic composition of a single cell or organism. It also can refer to the specific allelic composition of a particular gene or group of genes.

►Arylamine *N*-Acetyltransferases (NAT)
►Biomonitoring
►Linkage Disequilibrium

Geranylgeranyl

Definition

C20 isoprenoid lipid, an intermediate in the HMG-CoA reductase mevalonate biosynthetic pathway, used in the biosynthesis of geranylgeranylated proteins.

►Rho Family Proteins

Geranylgeranylation

Definition

Post-translational modification of proteins by the attachment of an isoprenoid to C-terminal cysteine residues.

►Statins

Germ Cell Layers

Definition

Collection of cells formed during embryogenesis into the mesoderm, endoderm and ectoderm that go on to form specific organs of the body.

►Cowden Syndrome
►Germ Cell Tumors

Germ Cell Tumors

Synonyms

Testicular tumors; Gonadal neoplasms; Dysgerminomas

Definition

►Testicular cancer represents a group of histologically heterogeneous neoplasms typically arising in gonadal tissue and, uncommonly, arising in extragonadal sites such as the retroperitoneum or mediastinum. A disease of young men which, when metastatic was previously uniformly fatal, testicular cancer is now usually cured.

Characteristics

Incidence

Germ cell tumors represent the most common cancer in young men between the ages of 20 years and 40 years. These tumors have a bimodal age distribution being most common in men ages 15–25 with a second, smaller peak at about age 60. It is estimated that ~8,000 new cases of testicular cancer were diagnosed in the United States in 2005. During the past century, the worldwide incidence of testicular neoplasms has nearly doubled, with the highest increases reported in the United States, Great Britain and Northern Europe.

Risk Factors

Numerous case-control and cohort studies have established cryptorchidism as the major identifiable risk factor, although only about 10% of cases are associated with this phenomenon. This increased risk is true for the contralateral testicle even if it is normally descended. Additional risk factors include a personal history of testicular cancer as well as the presence of a first degree relative with the disease. Scrotal trauma and toxic exposures have not clearly been associated with the occurrence of germ cell tumors.

Histological Classification

The main histological categories of germ cell tumors are seminomas (►Seminomatous Germ Cell Tumor) and non-seminomas (►Non-seminomatous Gene Cell Tumor). Non-seminomas are further subcategorized as embryonal carcinomas, endodermal sinus tumors (also known as yolk sac tumors), choriocarcinoma and ►teratoma. Tumors that contain more than one histological subtype are termed mixed germ cell tumors. For classification and treatment purposes, any tumor not histologically a pure seminoma is classified as a non-seminoma.

Clinical Presentation and Diagnosis

The majority of patients with testicular cancer presents with a painless testicular swelling or a palpable mass. In many cases, testicular swelling can be accompanied by pain secondary to bleeding or infarction within the tumor. Systemic symptoms at presentation such as abdominal pain, decreased appetite with or without associated weight loss, night sweats, chest pain, shortness of breath or hemoptysis usually indicate either an advanced stage of disease or an extragonadal primary tumor. If the diagnosis of a germ cell tumor is suspected, a bilateral high-resolution testicular ultrasound should be performed. In addition, the tumor markers human chorionic ►gonadotropin (hCG), ►alpha-fetoprotein (AFP) and lactate dehydrogenase (LDH) have unique diagnostic and prognostic significance in germ cell tumors and levels should be obtained on all patients with suspected germ cell tumors. Though not specific for germ cell tumors, AFP is produced by tumors with endodermal sinus or embryonal components as well as by immature teratomas. HCG is a hormonal product of syncitiotrophoblasts and can be expressed by choriocarcinomas, mixed germ cell tumors and, sometimes, by seminomas. LDH is a cellular protein expressed in numerous tissues and can be produced by non-seminomas. These markers are important for ►staging of tumors, monitoring therapy, deciding when to apply surgical consolidation as well as to sensitively detect residual or recurrent disease. Additional preoperative workup typically includes a chest radiograph and discussion of sperm banking with the patient. When a testicular mass is found on ultrasonography, a radical inguinal ►orchiectomy should be performed, unless the patient is ill, and initiation of systemic therapy is deemed urgent. In this instance, it would be appropriate to proceed with ►chemotherapy without tissue diagnosis, if the markers are elevated and the clinical picture is compatible with the diagnosis of germ cell tumor. Trans-scrotal biopsies should be avoided as they can disrupt regional lymphatics, potentially altering the typically predictable lymphatic spread of these tumors. Postoperatively (or preoperatively if this will not delay surgery) an abdominal and pelvic computed tomography (CT) scan should be obtained and, if clinically indicated, brain magnetic resonance imaging (MRI) and a bone scan. CT scans can reveal clinically significant adenopathy

that will be important in clinical decision-making. The preferred sites of initial spread for right-sided tumors are typically the infra-renal paracaval, inter-aortocaval and possibly paraortic nodes. In contrast, left-sided tumors preferentially spread to the infra-renal paraortic nodes initially.

Staging and Risk Stratification

As with all staging systems, the purpose is to classify patients with respect to prognosis and to allow one to offer treatments having a toxicity profile commensurate with the burden of disease and risk of recurrence. Given the importance of tumor markers in the management of germ cell tumors, the staging for germ cell tumors takes these into account along with histology, site of origin and anatomic extent of disease. The standard risk stratification used for these tumors is that developed by the International Germ Cell Cancer Consensus Group (IGCCCG). Through a retrospective multivariate analysis of nearly 6,000 patients with germ cell tumors, this group identified the clinical features strongly associated with prognosis: primary site of disease, the presence of non-pulmonary visceral metastases and marker levels at the initiation of therapy. Using these features, they divided non-seminomatous germ cell tumors into good-, intermediate- and poor-risk categories and seminomas into good- and intermediate-risk categories (Table 1). This risk stratification system provided the basis for the most recent American Joint Commission on Cancer (AJCC) TNM staging system for germ cell tumors. In general, Stage I disease is confined to the testis, stage II disease is disease that does not spread beyond the retroperitoneum and stage III disease involves the nodal regions beyond the retroperitoneum or non-nodal metastatic disease. Elevated serum tumor markers can help to define higher stages of disease.

Management

As the biology and management of seminomas and non-seminomas are quite different, we will consider the management of these distinct histologies separately.

Seminomas

By IGCCCG risk stratification, all patients with seminomas without non-pulmonary visceral metastates are categorized as having good-risk disease. Amongst these patients are those with Stages I and II disease and some with Stage III disease. The majority of patients with Stage I disease will be cured with radical inguinal orchiectomy alone, however, ~15–20% of patients with Stage I seminoma will have recurrent disease. As a result, there exists a need to identify those features of Stage I disease that would indicate a higher risk of relapse so that such patients could be offered adjuvant therapy. It has been reported that there is a subset of patients with Stage I seminoma with a primary tumor

Germ Cell Tumors. Table 1 International germ cell cancer consensus group classification prognostic risk stratification

	Seminoma	Nonseminoma
Good risk	Any primary site	Testis/retroperitoneal primary and
	No non-pulmonary visceral metastases	No non-pulmonary visceral metastases and
	Normal AFP, any hCG, any LDH	AFP < 1,000 ng/mL and
		hCG < 5,000 mIu/mL and
		LDH < 1.5 × upper limits of normal range (ULN)
	82% 5-year PFS; 86% 5-year OS	86% 5-year PFS; 90% 5-year OS
Intermediate risk	Any primary site	Testis/retroperitoneal primary and
	Non-pulmonary visceral metastases	No non-pulmonary visceral metastases and
	Normal AFP, any hCG, any LDH	AFP 1,000–10,000 ng/mL and
		hCG 5,000–50,000 mIu/mL and
		LDH 1.5–10 × ULN
	67% 5-year PFS; 72% 5-year OS	75% 5-year PFS; 80% 5-year OS
Poor risk	–	Mediastinal primary or
		Non-pulmonary visceral metastases or
		AFP > 10,000 ng/mL or
		HCG > 50,000 mIu/mL or
		LDH > 10 × ULN
		41% 5-year PFS; 48% 5-year OS

less than 4 cm in size and without rete testis involvement who have a relapse free survival of 88%, and thus may constitute a group of patients most appropriate for surveillance. At present, surveillance is considered a reasonable option for highly motivated patients with Stage I seminoma after orchiectomy, though given the fact that nearly one third of patients with recurrent disease will require systemic chemotherapy, this has not been the most commonly used approach. At present, the majority of patients with Stage I seminoma are treated with infra-diaphragmatic radiotherapy (20 Gy) to the para-aortics. Such treatment results in 5-year survival rates of 98–99%. Data exists to support the use of a single dose of ►carboplatin as ►adjuvant therapy in Stage I seminoma, but this practice has not been widely adopted at present. Recently published retrospective data from the Princess Margaret Hospital in Toronto, Canada, showed comparable long-term results for patients with stage I seminoma treated with radiation prophylactically versus those with stage I who elected to be followed with active surveillance with initiation of therapy at the time of recurrence.

Patients with Stage II disease are divided into those with non-bulky disease (those with nodal metastases no larger than 5 cm) and those with bulky disease (those with nodal metastases greater than 5 cm). For patients with non-bulky disease (Stage IIA-B), infra-diaphragmatic radiation therapy (20 Gy) to include the para-aortics and ipsilateral iliac nodes with a boost (6–10 Gy) to the involved site is the standard therapy. Residual abnormalities are sometimes encountered following radiation therapy, but observation is generally recommended.

For patients with advanced seminoma, defined as having Stage IIC or Stage III disease, chemotherapy is the treatment modality of choice. For those patients with good-risk disease, chemotherapy with four cycles of ►etoposide and ►cisplatin (EP) is generally offered. ►Bleomycin is generally excluded as the risk of pulmonary toxicity outweighs the small incremental benefit afforded by its use. In the same light, ►carboplatin has been demonstrated to be inferior to cisplatin and is thus not substituted in this scenario. For those patients with intermediate-risk disease, chemotherapy is usually administered with four cycles of ►bleomycin, ►etoposide and ►cisplatin (BEP). After completion of chemotherapy, patients with advanced seminoma are restaged with chest, abdominal and pelvic CT scans as well as serum tumor markers. If no residual mass is found, or the residual mass measures <3 cm in size and tumor markers are normal, a surveillance schedule is initiated. If the residual mass measures >3 cm in size, a ►positron emission tomography (PET) scan is performed, if available, to assess for the presence of viable tumor. In the presence of a positive PET scan, salvage radiation therapy is offered at our institution. For those patients unable to undergo PET scan, the size of the residual mass guides post-chemotherapy management, with masses greater than 3 cm having a higher risk of relapse. In this case, a surgical biopsy or consolidative radiation therapy are the interventions of choice. Patients who are found to have progressive disease after initial therapy are generally treated with salvage chemotherapy.

Non-Seminomatous Germ Cell Tumors (NSGCT)

NSGCT are risk stratified according to the IGCCCG classification schema based on the location of the primary tumor, the presence of non-pulmonary visceral metastases and the level of tumor marker elevation. Treatment options vary by stage and can include observation, chemotherapy and/or retroperitoneal lymph node dissection (RPLND).

Patients with Stage IA NSGCT (tumor limited to the testis and epididymis without lympho-vascular invasion and normal post-orchiectomy tumor markers) are generally managed with either surveillance (in reliable patients) or RPLND. The reason for surveillance as an option is that the majority of patients with Stage I NSGCT will not have recurrence and of those approximately 30% who do have recurrent disease, there is effective chemotherapy which can result in long-term survival for most patients. RPLND is often used because it usually leads to accurate staging and can be curative in the majority of patients. The presence of N1 or N2 disease found at RPLND can then be managed either with surveillance or two cycles of EP or BEP chemotherapy. Patients with N3 disease found at RPLND are typically managed as good-risk advanced stage patients and are treated with EP for four cycles or BEP for three cycles. Patients with Stage IB NSGCT are generally managed with RPLND, although either active surveillance (for T2 disease only) or chemotherapy with two cycles of BEP is also appropriate. Post-RPLND management is as stated above for Stage IA disease. Patients with Stage IS disease (persistent marker elevation after orchiectomy) are managed with chemotherapy (either four cycles of EP or three cycles of BEP).

Stage IIA NSGCT in the presence of negative post-orchiectomy tumor markers are generally approached with either RPLND or primary chemotherapy with EP for four cycles or BEP for three cycles. Those patients with Stage IIA disease who have persistent tumor marker elevations are managed with chemotherapy alone. Patients with Stage IIB disease and negative markers may undergo RPLND as long as lymph node metastases are within lymphatic drainage sites. Post-RPLND management is the same as for those patients who have RPLND for Stage I disease. If the patient

has multi-focal lymph node metastases, adjuvant chemotherapy is considered the management option of choice. For patients who have received chemotherapy and have a residual retroperitoneal mass post-treatment, RPLND is generally performed to look for viable tumor, or teratoma.

Patients with advanced disease (Stage IIC and III) disease are risk stratified by the IGCCCG into three categories (good, intermediate and poor). Those with good-risk disease (testis or retroperitoneal primary; no non-pulmonary visceral metastases as well as AFP <1,000 ng/mL, hCG <5,000 mIU/mL and LDH <1.5 times upper normal range) are initially managed with chemotherapy (EP for four cycles or BEP for three cycles). Patients with intermediate-risk (testis or retroperitoneal primary; no non-pulmonary visceral metastases and AFP 1,000–10,000 ng/mL, hCG 5,000–50,000 mIU/mL or LDH 1.5–10 times upper normal range) or poor-risk disease (mediastinal primary or non-pulmonary visceral metastases or AFP ≥10,000 ng/mL, hCG ≥50,000 or LDH ≥10 times upper normal range) are managed initially with four cycles of BEP chemotherapy. For patients with advanced stage disease, who have a complete response to chemotherapy, the approach at MD Anderson Cancer Center is surveillance as the next step in management. If there is any residual disease (as long as tumor markers have normalized), all sites of residual disease are resected. The presence of non-viable tumor or teratoma allows for standard observation. For those patients with residual viable tumor >10%, salvage chemotherapy is initiated, generally with either a combination of vinblastine, ifosfamide and platinum (VeIP) or paclitaxel, ifosfamide and platinum (TIP). Approximately one-third of patients with persistently elevated tumor markers after multiple chemotherapy regimens may achieve long-term survival with "desperation surgery," if they undergo complete resection of their residual disease.

Conclusions

Germ cell tumors were amongst the first solid neoplasms to show remarkable response rates with chemotherapy. The successful management of most patients with testicular cancer has established a paradigm for the use of multi-agent chemotherapy regimens integrated with surgery, radiation and tumor marker evaluation. It has also allowed for risk-adapted treatment strategies, sparing patients with lower risk disease the therapies with greater short- and long-term risk, while treating patients with higher risk disease more aggressively. However, it must be remembered that despite remarkable successes in the management of germ cell tumors, there remains a population of patients with advanced, chemo-refractory disease for whom more effective salvage therapies are still needed.

Germinal Center

Definition

Secondary lymphoid follicle present in the lymph node cortex that serves as the site of B cell maturation to antibody-producing cells. Germinal centers are histological structures in lymphoid organs like lymph nodes, spleen, and ►Peyer patches. They are mainly composed of proliferating ►B cells and smaller numbers of ►T cells, ►macrophages and ►dendritic cells. In germinal centres, T cell-dependent immune responses take place, giving rise to high affinity memory B cells and plasma cells. Many mature B cell lymphomas derive from malignant transformation of germinal center B cells.

►Hodgkin and Reed/Sternberg Cell
►Hodgkin Disease, Clinical Oncology

Germinal Stem Cells

Definition

Pluripotent stem cells derived from so-called primordial germ cells, which are the cells that give rise to the gametes (sperm and eggs) in adults.

►Adult Stem Cells

Germinoma

Definition

Germinomas are rare malignant primary ►brain tumors thought to be arising from primordial germ cells of the yolk sac endoderm. They form part of the spectrum of ►germ cell tumors (GCTs) and are the commonest type of GCT in the central nervous system (CNS). in the CNS the histopathological appearances are termed germinoma and account for approximately 60% of all primary intracranial GCTs. Intracranial GCTs are histopathologically identical to their gonadal counterparts with a testicular primary being referred to as a ►seminoma and an ovarian primary as a ►dysgerminoma.

Characteristics

Germinomas account for 1–3% of all intracranial neoplasms and commonly arise in midline structures adjacent to the third ventricle. The most common regions involved are the pineal (~45%) and suprasellar (~35%) areas. In around 15% of cases concurrent lesions are detected in both the pineal gland and the suprasellar area or very rarely the basal ganglia or the brainstem. These tumors are termed bifocal or multiple midline GCTs.

Germinomas have a tendency to spread through the subependymal lining and cerebrospinal fluid (CSF). Approximately 5–10% of patients present with either microscopic or macroscopic metastatic disease in the CSF at the time of diagnosis. Extraneural metastases at diagnosis are extremely uncommon.

There is a marked geographical variation in the incidence of germinomas. In the West, they account for 0.4–3.4% of primary central nervous system tumors while in Japan and the Far East they are five to eight times more frequent.

Germinomas are more commonly found in males with a male to female ratio of approximately 2:1 and predominantly affect patients in their teens with approximately 75% of patients' diagnosed with a primary CNS GCT being in the age range of 10–20 and are a recognized tumor entity in CNS ►childhood cancer. The WHO classification divides germ cell tumors into subtypes depending on the final differentiated cell. With regards to their management they are divided into three major subgroups: pure germinomas, secreting (malignant) non-germinomatous germ cell tumors and teratomas. Classically Germinomas consist of large uniform cells with clear cytoplasm. Syncytiotrophobastic cells can be present and may secrete low levels of beta human chorionic gonadotrophin (β-HCG). Despite this, germinomas are often referred to as non secreting germ cell tumors if β-HCG levels are ≤50 IU/l in either serum or CSF. There is no evidence to suggest that a slight elevation of β-HCG levels is associated with a worse outcome.

Presenting symptoms of a germinoma depend on the anatomical site of the primary tumor and its growth rate. The classical symptom of pineal primaries is Parinaud syndrome (paralysis of upward gaze, headache and impaired pupillary constriction to light with preservation of accommodation). In addition tumors in this location frequently compress the Sylvian aqueduct leading to obstructive hydrocephalus, indicated by symptoms of raised intracranial pressure (diurnal headache, vomiting and lethargy). The commonest presenting symptoms of suprasellar tumors are obstructive hydrocephalus, endocrine and visual field defects and/or reduced visual acuity. The frequent involvement of the pituitary stalk and the proximity of the tumor to the hypothalamopituitary axis leads to diabetes insipidus (DI). This symptom can precede the radiological and pathological diagnosis of a suprasellar germinoma sometimes by up to a few years. Other symptoms include hypothalamic damage e.g. anorexia or weight gain, somnolence, mood swings, disrupted sleep pattern, electrolyte imbalances, temperature disregulation, failure to thrive, precocious puberty, secondary amenorrhea, and panhypopituitarism.

Diagnosis

When a germinoma is suspected based on the clinical history and physical examination, ►magnetic resonance imaging (MRI) with intravenous contrast enhancement of the brain and spine is the diagnostic imaging of choice to establish the precise location and extent of the disease. The classic appearance of a germinoma on MRI is an iso- or hyperdense well defined lesion that uniformly enhances with contrast. If the clinical picture and radiological findings are suspicious of a primary CNS GCT, tumor marker analysis is important to differentiate between secreting GCTs and germinomas as pathologically elevated tumor markers establish a diagnosis without the requirement for tissue diagnosis. When the tumor marker assays are negative, a histopathological verification of primary tumor is mandatory. In addition an examination of the CSF must be performed in all patients, to confirm or refute microscopic tumor dissemination (M1 disease), and establish the presence or absence of elevated CSF tumor markers (αFP, β-HCG). An isolated elevation of ►CSF tumor markers in the presence of negative serum markers establishes the diagnosis of a secreting germ cell tumor and

subsequently defines the appropriate management strategy. If CSF cannot be obtained intraoperatively a lumbar puncture should only be performed at diagnosis, if the ventricles are not obstructed or an adaeuate CSF diversion has been performed in patients with obstructive hydrocephalus. Alternatively, a lumbar puncture should be performed within 1–2 days of the surgical intervention to relieve raised intracranial pressure as the half-life of βHCG is only 5 days after complete macroscopic resection. It has to be acknowledged that there is currently no uniformly validated laboratory test for the measurement of CSF tumor markers although this is an internationally agreed mandatory requirement for staging CNS germinomas. To complete staging, a CSF analysis for cytology should be performed 14 days after the surgical intervention to avoid false positive results.

The differential diagnosis of a pineal mass includes pinealoblastoma, pineocytoma, glioma or benign cysts. At a suprasellar location, the possible differential diagnoses include, predominantly, optic chiasm and hypothalamic gliomas, craniopharyngiomas and Rathke's pouch cysts.

Treatment

Surgery

In an emergency situation, an endoscopic ventriculostomy or ventriculo-peritoneal shunt with or without a prior external ventricular drainage (EVD) will alleviate raised intracranial pressure, secondary to obstructive hydrocephalus, and/or could be used to obtain diagnostic tissue. Otherwise the standard diagnostic neurosurgical procedure is an open biopsy of the mass lesion. There is, however, increasing use of less invasive techniques such as stereotactic and endoscopic biopsy. Modern neuro-surgical techniques using a stereotactic approach are deemed safe and mortality is in the region of 0.5% in experienced hands with similar diagnostic yield rates.

There is no advantage in attempting a gross total resection in intracranial germinomas as it does not alter management or outcome, but it can be associated with significant surgical related morbidity. Radical surgery is reserved for the very few patients with a significant residual mass following completion of treatment which usually represents a residual mature teratoma component on histopathological assessment.

Histological subtype is the single most important prognostic factor for outcome as the natural history and treatment of different histopathological subtypes are quite distinct.

Radiotherapy

In excess of 90% of germinomas are radiocurable when treated in a tertiary specialist neuro-oncology unit with close links to an endocrine service. Historically the gold standard treatment for germinomas has been conventionally fractionated craniospinal ►radiotherapy (using external beam ►ionizing radiation therapy) followed by a boost to the primary site given the extremely high ►radiation sensitivity of these tumors. The pattern of relapse in localized germinomas is dominated by ventricular recurrences and it is unusual to develop an isolated spinal cord relapse. A recent literature review confirmed that there is good evidence to suggest that in completely staged patients with localized germinomas irradiation of the ventricles, followed by a boost to the primary tumor area gives equivalent long term control rates compared to wide field craniospinal radiotherapy. Originally the craniospinal axis was treated with a dose of 30–35 Gy followed by a boost of 10–20 Gy in 7–12 fractions to the primary site. Over the last two decades consecutive studies have demonstrated that a reduction of the dose to the craniospinal axis to 24 Gy is equivalent with respect to long term disease free survival. In addition, there was no loss of local control when reducing the primary tumor dose from 50–54 to 40–45 Gy. The use of three-dimensional planning and conformal radiotherapy, in conjunction with reduced volumes is likely to minimize the amount of normal tissue irradiated to high doses of radiotherapy. This is likely to reduce treatment related late sequelae e.g. growth impairment, neurocognitive disabilities, cerebrovascualr events and second malignant neoplasms.

There is some evidence to suggest that the primary tumor dose can be further reduced if a complete response can be demonstrated following multiagent induction chemotherapy in primary localized germinomas. However, there is controversy as to what volume requires irradiation in these patients. In addition controversy exists how to classify bifocal tumors. In Europe bifocal tumors are regarded as localized disease whilst in the States these patients are treated using strategies designed for primary metastatic disease.

There is currently no controversy over the volume that should be irradiated in patients with proven evidence of metastatic germinoma at diagnosis. CSF-positive disease is a risk factor for spinal seeding but it does not predict for recurrence when treated with craniospinal radiotherapy. Long term control in excess of 90–95% at 5 years is achieved even in the presence of widespread macroscopic metastatic disease (M 2/3) when craniospinal irradiation to dose levels of 24–30 Gy, and boosts to all sites of macroscopic disease up to a dose of 40–45 Gy is used.

Chemotherapy

Germinomas are inherently chemosensitive. As primary radiotherapeutic strategies in very young children are associated with noticeable late morbidity, focus in the scientific pediatric oncology community for a long time has been to develop chemotherapeutic strategies

for germinomas. This is either as a primary treatment strategy or in combination with risk adapted reduced doses or irradiation. However, despite being chemosensitive, only a limited number of patients with localized germinoma are primarily chemocurable as the delivery of conventional chemotherapy is to a degree limited in these patients by the ►blood brain barrier. Most patients require salvage treatment including radiotherapy. In addition a chemotherapy only approach comes at the expense of significant treatment related morbidity and mortality, not associated with radiotherapy alone. It might be anticipated that with continuing improvements in research and supportive care, as well as the availability of novel chemotherapeutic agents, some of the current limitation maybe overcome in the future.

At present chemotherapy has been successfully used in a number of combined modality treatment approaches (►chemoradiotherapy) for patients with localized disease. This aims to reduce the volume and/or the dose of radiotherapy with a reduction of late morbidity associated with radiotherapy in very young children. There is no proven benefit for using chemotherapy with respect to event free or overall survival in patients with metastatic disease at diagnosis.

The backbone of most reported multiagent chemotherapy are platinum derivatives (particularly ►carboplatinum), epipodophyllotoxins (e.g. ►etoposide), alkylating agents (e.g. cyclofosfamide, ifosfamide) and/or antibiotics (e.g. ►bleomycin). The commonest chemotherapy associated side effects are short term but can be life threatening. These include hematological morbidities with the risk of bleeding and infection (particularly neutropenic sepsis), renal and hearing impairment, hemorrhagic cystitis, electrolyte disturbances (particularly in patients with known DI) and infertility to name a few. While recurrences are rare, after combined modality treatment (~15%) they are potentially salvageable by further chemo and/or radiotherapy.

Genetics

Little data is available regarding critical genetic mutations in pathogenesis of intracranial GCTs. Speculation regarding a genetic link has arisen due to case reports of intracranial GCTs occurring in children with Downs syndrome. Cytogenetic studies have repeatedly demonstrated abnormalities of chromosomes 1 and 12, mirroring the changes seen in extracranial GCTs. Very rarely, patients with intracranial GCTs have been reported to subsequently develop gonadal GCTs, perhaps indicating an unidentified genetic predisposition. CNS germinomas, in particular, often display sex chromosome abnormalities, usually an increased number of copies of chromosome X. Along with the increased incidence in peri-pubertal patients and its association with the site of origin being near the diencephalic nuclei, which regulates gonadotropin activity, has formed the basis for a speculated link to gonadotropins. For example an excess of intracranial GCTs has been reported in patients with Klinefelter's syndrome, which is associated with high levels of gonadotropins. However, this association may possibly be more likely linked to the underlying chromosomal anomalies rather than the endocrine stimuli.

Recent studies demonstrated frequent mutations of in germinomas (~25%). ►KIT is a ►tyrosine kinase whose mutations may result in constitutive activation and has been implicated in ►chronic myelogenous leukemia (CML) and ►gastrointestinal stromal tumors (GISTs). Such a mutation may offer new therapeutic opportunities in this tumor group in the future.

Germline Mutation

Definition

Is a heritable variation in the DNA that occurred in the lineage of germ cells (in the egg or the sperm). Mutations in germline cells when transmitted to offspring, gets incorporated in every cell of the body while those in somatic cells are not.

GI

Definition

►Gastrointestinal

Giant Cell Tumor

Definition

A locally destructive primary ►bone tumor in skeletally mature individuals consisting of proliferating mononuclear cells and large multinucleated ►osteoclast-like giant cells.

Gilbert Syndrome

Definition

Is frequently seen in Caucasians and is an inherited disorder, normally without serious consequences, that affects the glucuronidation of bilirubin in the liver. This results in an increase in the level of (unconjugated) bilirubin levels in the bloodstream and can lead to ►jaundice, in particular a yellow skin and eyes.

Ginkgo Biloba

Jane C.-J. Chao
School of Nutrition and Health Sciences, Taipei Medical University, Taipei, Taiwan

Synonyms

Salisburia adiantifolia; *Pterophyllus salisburiensis*; *Salisburia macrophylla*; Ginkgo tree; Maidenhair tree; Kew tree; Fossil tree; Japanese silver apricot; Yinxing

Definition

Ginkgo biloba is originally from Asia and has been utilized as an herbal remedy for thousands of years in the traditional Chinese pharmacopoeia. *G. biloba* is known for its antioxidant, anti-inflammatory, and neuroprotective properties. Extract from *G. biloba* leaves is commonly prescribed medicine to improve circulation and cardiovascular health.

Characteristics

Ginkgo, a unique medium-large deciduous tree with no close living relatives, is classified in the division of Ginkgophyta, consisting of the single class Ginkgoopsida, order Ginkgoales, family Ginkgoaceae, genus *Ginkgo* and the only one species – *G. biloba*. Ginkgo, the world's oldest living tree on earth for 270 million years (the Permian period), was referred to as a living fossil by Charles Darwin in 1859. They spread throughout Laurasia during the middle Jurassic and Cretaceous, but became much rarer thereafter. Ginkgo was discovered in China in 1691 and is now widely dispersed throughout the world. Ginkgo trees are common and widespread in Asia, Europe and North America. Once thought to be extinct, ginkgo trees disappeared from North America about 7 million years ago and from Europe about 2.5 million years ago.

Ginkgo is characterized by its unique two-lobed fan-shaped leaves and naked seeds (gymnosperms). Unlike most gymnosperms, ginkgo is a dioecious tree, male and female are separate plants. Ginkgo trees grow at a moderate rate, and can reach a height of about 100–130 ft and a spread of 25–30 ft at full maturity. The trunk can become approximately 10–13 ft wide in diameter. Ginkgo trees are straight columnar and sparingly branched. The leaves have a unique open dichotomous venation pattern. They are bright to dark green during the summer, and turn golden yellow in the fall. The seed has a silvery shine and is called silver apricot (nut). The seeds have been considered as a delicious food by the Chinese and Japanese. Green algae live in symbiosis with the ginkgo embryo and reproductive tissue, which is not known to occur in any other tree and only occurs in the animals. Ginkgo has a long life span, 1,000 or more, and may live as long as over 3,000 years. The oldest ginkgo is about 3,500 years old in China. *G. biloba* has been widely utilized in herbal medicine and as a dietary supplement. In the Far East, ginkgo has been used as a health-promoting supplement for over 3,000 years. The seeds are used in traditional Chinese medicine, and standard extract of the leaves is used as a phytomedicine in Europe and as a dietary supplement in the United States.

G. biloba Seeds

G. biloba seeds are called bai-guo (white nut) in Chinese or ginnan in Japanese. The seeds are considered to be beneficial to asthma, cough, irritability of the bladder, and uterine flux. Ginkbilobin, a protein isolated from *G. biloba* seed, has potent antifungal activity. Recently, *G. biloba* seeds have been discovered to have anticancer activity. *G. biloba* seed polysaccharide, isolated by ethanol and purified by Sephadex G-200 chromatography, potentially stimulates ►apoptosis of human hepatoma SMMC-7721 cells. However, 4-*O*-methylpyridoxine, a ginkgotoxin of *G. biloba* seed, is poisonous when a large amount is consumed.

G. biloba Extract

Ginkgo leaf, known as bai-guo-ye in Chinese medicine, was first mentioned in 1436 for the external use

to treat skin and head sores as well as freckles, and for internal use in 1505 during the Ming dynasty of China. *G. biloba* extract has been available in Europe since the early 1990s. Dried *G. biloba* leaves are extracted by organic solvent, concentrated under reduced pressure, washed by liquid–liquid extraction, and finally dried. Extract is composed of 1 part extract from 50 parts raw leaves. The German Commission, one of Europe's most respected herbal standard authorities, has defined the active components of *G. biloba* extract (trade names: EGb 761, Ginkgold, Cerenin, Ginkocer Ranbaxy, Tebonin, LI 1370, Rökan, and Tanakan) as 22–27% ginkgo-flavone glycosides (primarily glycosides of kaempferol, quercetin, and isorhamnetin with glucose or rhamnose) and 5–7% terpene lactones (2.8–3.4% ginkgolides and 2.6–3.2% bilobalide) (Fig. 1) At least seven flavonoid components, including quercetin, isorhamnetin, kaempferol, bilobetin, ginkgetin, isoginkgetin, and sciadopitysin, have been isolated from *G. biloba* extract using reversed phase HPLC. Ginkgolides are only present in *G. biloba* and not in other living species, and are composed mostly of A, B, C, and a very small quantity of J and M, which are only different in the number and position of hydroxyl groups. Ginkgolide B and bilobalide account for about 0.8 and 3% of the total extract, respectively. Other components include proanthocyanidins (4.2–5%), glucose, rhamnose, organic acids, D-glucaric acid, and ginkgolic acid (anacardic acid, less than 5 ppm).

G. biloba extract is well known for its antioxidant activity to scavenge free radicals, especially oxygen-centered free radicals, such as $OH^{\bullet}$, $O_2^{\bullet -}$, $RO^{\bullet}$, and $ROO^{\bullet}$, and to neutralize ferryl ion-induced ►lipid peroxidation. The antioxidant activity can contribute from its ginkgo-flavone glycosides and bilobalides. *G. biloba* extract and bilobalide exert their protective effects by upregulating mitochondrial NADH dehydrogenase gene expression, decreasing state 4 respiration and increasing respiratory control ratio, which leads to the elimination of oxidative damage. Additionally, terpene lactones in *G. biloba* extract are potent antagonists of platelet activating factor (PAF) by blocking the binding of PAF to its receptors. The overall actions of terpene lactones inhibit platelet aggregation and improve blood circulation of the brain and other tissues. Of these ginkgolides, ginkgolide B has shown to be the most potent PAF inhibitor (10 times more potent) with the longest duration of action. Due to the antioxidant and antiaggressive actions, *G. biloba* extract exerts its therapeutic activity primarily in cerebrovascular dysfunctions and peripheral vascular disorders, such as age-related dementia, Alzheimer's disease, failing memory, poor cerebral and ocular blood flow, congestive symptoms of premenstrual syndrome, as well as the prevention of altitude sickness. Additionally, *G. biloba* extract may provide a useful preventive or therapeutic treatment for peptic ulcer, intermittent claudication, drug-induced retinopathies, injured retinal cells from spontaneous hypertension, gentamycin-induced cochlear damage, and reperfusion-induced ventricular fibrillation.

Besides the antioxidant and antiaggressive actions of *G. biloba* extract, it has been reported to have antiviral and anti-inflammatory properties. Ginkgetin, a biflavonoid from *G. biloba* extract, has antimicrobial effect on inhibiting the growth of the fungi, the influenza virus sialidase, and herpes simplex virus type 1, and anti-inflammatory effect on suppressing the expression of proinflammatory molecules, such as ►phospholipase A2, ►cyclooxygenase-2, 5-lipoxygenase, inducible nitric oxide synthase, and interleukin-1β, to protect against inflammatory diseases, such as arthritis and chronic skin ►inflammation.

b

Ginkgo Biloba. Figure 1 Structure of (a) ginkolides and (b) bilobalide.

G. biloba extract may be considered a possible chemopreventive or anticancer agent and useful in preventing or treating cancer invasiveness and ►metastasis. In vitro or animal studies have shown that *G. biloba* extract inhibits proliferation of cancer cells, such as ►breast cancer, ►glioblastoma, ►colon cancer, ►ovarian cancer, and ►hepatocellular carcinoma, and induces ►apoptosis of cancer cells, such as oral cavity cancer, ►ovarian cancer, and ►hepatocellular carcinoma. A clinical study has demonstrated that oral administration of *G. biloba* extract in the patients with upper digestive tract malignant tumors decreases tumor size, improves the patients' clinical symptoms, and prolongs the survival period. Additionally, *G. biloba* extract alleviates the inhibited hematopoietic function and weight loss due to ►chemoradiotherapy. The anticancer mechanisms of *G. biloba* extract may involve (i) the inhibition of cell proliferation through decreasing the overexpression of peripheral-type benzodiazepine receptor and proliferating cell nuclear antigen, (ii) the induction of ►apoptosis through stimulating ►caspase-3 activity and ►p53 protein expression, (iii) the cytotoxic effect through modulating the ►apoptosis and/or ►necrosis, and (iv) the stimulation of carcinogen metabolism through increasing the detoxifying enzyme activity of ►cytochrome P450, ►glutathione S-transferase, and quinine reductase in the liver. Certain components in *G. biloba* extract have been identified to participate in the anticancer action. Quercetin, an important flavonoid of *G. biloba* extract, suppresses cell proliferation of human ►hepatocellular carcinoma cell lines BEL-7402, HuH-7, and HLE with a peak inhibition at 50 μM. Ginkgetin inhibits the proliferation of human ►ovarian cancer OVCAR-3 cells via the induction of ►apoptosis in a dose-dependent manner. Ginkgolide B inhibits cell proliferation of highly aggressive human ►breast cancer MDA-231 cells but not affects nonaggressive ►breast cancer MCF-7 cells. Ginkgolic acid not only reduces the growth of tumor cells in vitro without the influence the growth of normal cells, but also exerts the cytotoxic effect to induce death by ►apoptosis and necrosis possibly via the mediation of protein phosphatase 2C.

Gleason Grading

Mutsuo Furihata, Tamotsu Takeuchi
Department of Pathology, Kochi Medical School, Kochi, Japan

Definition

The Gleason grading system of prostate adenocarcinoma is the principal grading system recommended by a the WHO consensus conference. The system is based on the histological pattern of arrangement of glandular architecture of carcinoma cells in hematoxylin&eosin; (H&E)-stained sections (►H&E stain). Five basic histological patterns or grades are recognized to generate histological scores ranging from 2 to 10. ►Gleason score is directly correlated with virtually pathological variables, including tumor volume and margin status in radical prostatectomy specimens, as well as serum ►prostate-specific antigen (PSA) levels. Gleason score is a powerful predictor of clinical and pathological stage, progression (►Tumor progression) to metastatic disease, and survival. Models are used to predict responses to specific therapies, such as surgery, radiotherapy, and androgen ablation therapy.

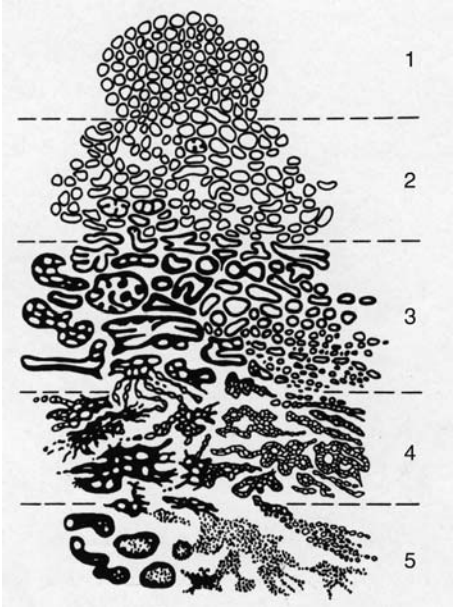
Characteristics

The Gleason grading system is the one predominantly used in both research and daily clinical practice, and is routinely used for grading of all prostate tissue samples, including needle-core biopsies and samples from radical prostatectomy. The Gleason grading system was devised by Dr. Donald F. Gleason, a pathologist, and a member of the Veterans Administration Cooperative Urological Research Group.

The Gleason grading system is based on the histological pattern of arrangement of glandular architecture of carcinoma cells in H&E sections. The system defines five histological patterns or grades with decreasing differentiation illustrated in a standard drawing observed at relatively low magnification (10–40×) (Fig. 1). The primary and secondary patterns, i.e., the most prevalent and second most prevalent patterns on simple visual inspection, are added to obtain the Gleason score or sum.

Gleason pattern 1 (Grade 1) is composed of very well circumscribed nodular growth of separate, closely packed glands without any infiltration into adjacent normal prostate tissue. The glands are uniform, rounded to oval, and of intermediate size (Fig. 2). This pattern, which is usually seen in the transition zone in incidental cancers, is exceedingly rare. Atypical adenomatous hyperplasia should be excluded before diagnosing a pure pattern of this type.

Gleason pattern 2 (Grade 2) features less well-defined masses that are not as circumscribed as pattern 1, and is composed of round or oval glands (Fig. 2). Compared to those of pattern 1, pattern 2 glands display increased variability in size and shape,



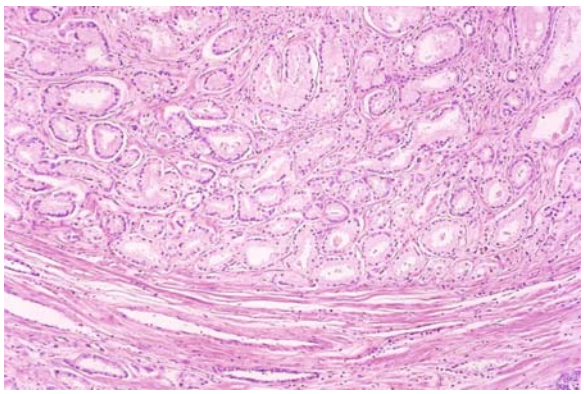
Gleason Grading. Figure 1 Five histological patterns or grades with decreasing differentiation illustrated in a drawing by Dr. Gleason.

with a degree of separation by stroma. There is minimal and limited invasion by neoplastic glands into the stroma. Pattern 2 is usually found admixed with pattern 3 to yield a Gleason score of 5. Gleason pattern 2, like pattern 1, is often found in transition-zone carcinomas, but may occasionally be found in the peripheral zone.

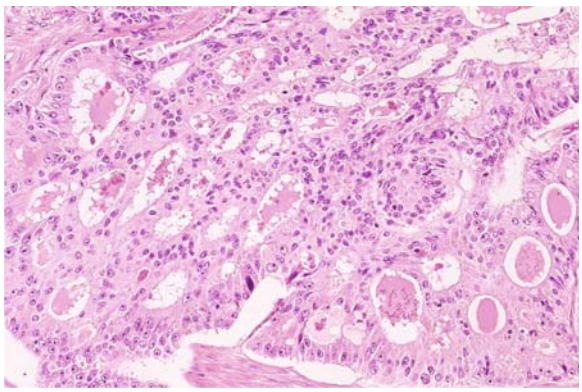
Gleason pattern 3 (Grade 3) is the most common pattern of growth of prostate adenocarcinoma, and is found in pure form in the large majority of cases. The glands are more infiltrative, and the distance between them is more variable than in patterns 1 and 2. Pattern 3 is characterized by small- to medium-sized single glands of irregular shape extending into the stroma (Fig. 3). Small glands forming glandular luminal spaces are typical of pattern 3. Each gland has an open lumen and is circumscribed by stroma. Shape, especially of medium-sized glands, is quite variable with angular and elongated forms. Cribriform or papillary growth, which is rarely observed in pattern 3, is recognized by the smooth, pushing edges of the invasive periphery.

Gleason pattern 4 (Grade 4) involves poorly differentiated growth of high-grade tumor with fused or cribriform glands appearing as raggedly infiltrative masses. The hypernephroid or hypernephromatoid pattern is a rare variant of fused glands with clear cytoplasm. Cribriform pattern 4 glands are large or irregular, and are recognized by their ragged edges compared to the smooth borders noted in pattern 3 (Fig. 4). Most cribriform invasive adenocarcinomas should be considered pattern 4 rather than pattern 3. Pattern 4 is often combined with pattern 3 to yield a score of 7, which is currently one of the most commonly assigned Gleason scores.

Gleason pattern 5 (Grade 5) involves the most poorly differentiated growth of tumor, which is almost completely lacking in glandular lumina, with only occasional lumina observed. The tumor cells form ragged sheets or exhibit anaplastic single cell proliferation invading the stroma (Fig. 5). Comedo appearance in pattern 5 is associated with smooth, rounded masses, cords, or cylinders of carcinoma with the presence of



Gleason Grading. Figure 2 Gleason grade 2 + 1 = score of 3 adenocarcinoma.



Gleason Grading. Figure 4 Gleason grade 4 adenocarcinoma showing cribriform pattern.

Gleason Grading. Figure 5 Gleason grade 5 adenocarcinoma comprised of ragged sheets of anaplastic tumor cells.

necrosis. Gleason score 9 (Gleason grade 4 + 5) and Gleason score 10 (pure pattern 5) are less common, and noted in association with ►prostate cancer of high clinical stage.

Clinical Aspects

Increasing Gleason grade is directly associated with pathological and clinical end points, including lymphatic and vascular invasion, tumor size, local recurrence, and lymph node or distant metastasis in patients receiving no treatment, radical prostatectomy, radiation therapy, or other types of treatment. Although Gleason grading by needle biopsy can be used to predict pathological stage, it is not completely accurate in each patient. Several studies have addressed the discrepancies between Gleason score in needle biopsies and corresponding radical prostatectomy specimens. Perhaps the most important factor in such discrepancies is sampling error, which is related to the small amount of tissue removed by thin-core needle biopsies. In order to predict pathological stage clinically, needle-biopsy Gleason grade needs to be combined with other pretreatment factors, such as serum PSA, local clinical T stage, and amount of tumor included in the needle biopsy.

The Gleason score assigned to the tumor at radical prostatectomy is the most powerful predictor of progression after resection. Gleason scores 2–4 are rarely noted in stages T1c or T2. All patients with Gleason scores of only 2–4 are cured. Gleason scores 5–6 are associated with relatively low rates of progression after definitive therapy. Most patients with tumors with these Gleason scores are cured, whether they exhibit extraprostatic extension or positive margins or not. Tumors with Gleason scores 7–10 are associated with a worse ►prognosis. Tumors with a Gleason score of 7 have a significantly worse prognosis than those with a Gleason score of 6. Several studies have addressed whether Gleason scores 3 + 4 or 4 + 3 have different prognoses, with somewhat conflicting results. Patients with Gleason score 8–10 tumors present at an advanced stage, and are not amenable to local treatment. The National Comprehensive Cancer Network (NCCN) has presented guidelines for the management of recurrence of prostate cancer, and recommends that decisions regarding treatment be based on risk stratification. Patients are characterized as at low, intermediate, high, or very high-risk of recurrence according to their clinical stage, Gleason score, and PSA value. The low-risk category includes men with T1 to T2 disease, Gleason score 2–6, and a PSA value φ 10 ng/ml. The intermediate-risk category includes those with any T2b to T2c disease, or any Gleason 7 score, or PSA value 10–20 ng/ml. Treatment decisions in both of these categories are stratified by life expectancy. The high-risk category includes men with T3a to T3b disease, Gleason score 8–10, or PSA value >20 ng/ml. The treatment strategy for these patients is based on expected patient survival. Finally, the very-high-risk category includes all patients with T3c or T4 disease or nonlocalized disease. Radical prostatectomy is not considered for these patients, and treatment should consist of hormone therapy or observation.

Gleason score is the most powerful predictor of clinical and pathological stage, progression to metastatic disease, and survival, and should be routinely reported for adenocarcinoma of the prostate. In the future, markers discovered by gene expression profiling will be prognostically useful if they yield added value beyond established prognostic factors including Gleason grade.

GLFG Bodies

Definition

Glycine–leucine–phenylalanine–glycine (GLFG) repeats. These FG rich areas are found on ►Nucleoporin 98 (NUP98) and NUP98 chimeric proteins arising from translocations in leukemia. They act as docking sites for importins, exportins and transportins involved in nuclear pore function. GLFG repeats have transcriptional-activation potency that is mediated in part by its

interaction with the transcriptional co-activator CBP/p300. The GLFG domain itself is responsible for targeting NUP98 from the nuclear pore to novel GLFG bodies in the nucleus. The GLFG motif may also regulate the localization of NUP98 chimeric proteins.

University of Salzburg, Salzburg, Austria

Synonyms

GLI-Kruppel family member; Glioma-associated oncogene homolog 1 (zinc finger protein) (GLI1); Tax helper protein (GLI2)

Definition

GLI proteins belong to the family of zinc finger transcription factors and act at the distal end of the Hedgehog (HH) signaling pathway to control HH target gene transcription.

Characteristics

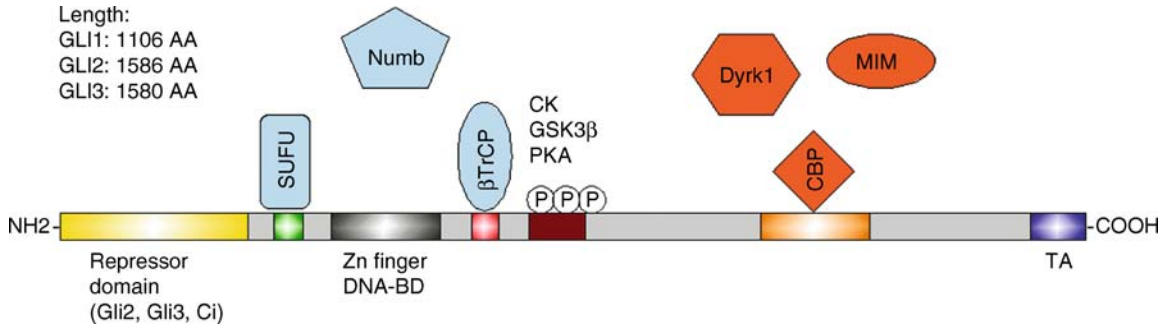
In vertebrates, three GLI homologs, GLI1, GLI2 and GLI3 have been identified.

GLI proteins belong to the family of zinc finger transcription factors and play key roles in development and disease as they mediate HH signaling in numerous embryonic processes such as pattern formation and cell fate decisions as well as in cancer and developmental anomalies.

All GLI proteins including the fly homolog Cubitus interruptus (Ci) have in common a highly conserved DNA binding domain composed of five zinc finger domains of the C2-H2 class, which mediates specific binding to the consensus GLI binding sequence GACCACCCA in promoters of HH target genes (Fig. 1). GLI1 and GLI2 encode the main activators of HH-target genes, while GLI3 acts mainly as transcriptional repressor in the absence of HH-signaling. Transcriptional activation of GLI target genes involves the C-terminal trans-activation domain. Repression of target genes by GLI3 requires proteolytic processing of full-length GLI3 into a fragment encompassing the N-terminal repressor and the DNA binding domain, a process that depends on phosphorylation by multiple kinases such as ►PKA, CK and ►GSK3β.

Regulation of GLI Activity in Response to HH Signaling

Activation of GLI transcription factors is initiated by binding of HH protein to its trans-membrane receptor ►Patched (PTC). This allows another trans-membrane protein, Smoothened (SMO), to relay the signal towards the nucleus. The question of how GLI proteins are activated by SMO has not yet been answered completely. Unlike GLI1, which is a direct transcriptional target gene of the pathway, GLI2 and GLI3 are considered latent transcription factors whose activation requires pathway activity. The identification of several intraflagellar transport (IFT) proteins as regulators of GLI protein activity has shed new light on the mechanisms of signaling and GLI activation. IFT proteins play a critical role in the growth and maintenance of cilia. In fact, several components of the HH signaling pathway including GLI are specifically localized in the primary cilium, a microtubule-based organelle that protrudes from the surface of most mammalian cells. In the absence of HH ligand, the latent activator forms of GLI2 and GLI3 are kept inactive by SUFU (see below) and another protein termed Iguana. Further, absence of ligand promotes the generation of GLI3 repressor, which also depends on proper function of the cilium. Binding of HH protein to its receptor PTC leads to re-localization of SMO to cilia, where it activates



GLI Proteins. Figure 1 Schematic illustration of the basic domain architecture of GLI proteins and interacting proteins. Based on sequence comparison studies, GLI1 neither contains a CBP binding domain, nor a N-terminal repressor domain; as the GLI domains that interact with Numb, MIM, Dyrk1 have not yet been mapped, these GLI binding proteins are not shown as directly associated with GLI. Negative regulators of GLI activity are shown in light blue, positive regulators in orange; phosphorylation by Protein Kinase A (PKA), Casein Kinase (CK) and Glycogen Synthase Kinase-3β (GSK3β) is critical for proteolytic processing of GLI3, Ci and probably of GLI2. DNA-BD: DNA-binding domain; TA: transactivation domain; AA: amino acids.

GLI proteins in a cilia-dependent manner, though the molecular details are not fully understood. Proteolytic processing of GLI3 into its repressor form is also inhibited in the presence of HH ligand.

Regulation of GLI activity at the post-translational level also involves interactions with co-factors, integration with other signaling systems and signals affecting protein stability.

Suppressor of Fused (SUFU) encodes a key negative regulator of GLI proteins. SUFU has been shown to bind GLI proteins and loss of SUFU function results in constitutive HH signaling and tumor development. Further, interactions of GLIs with co-factors such as Creb binding protein (CBP), Dyrk1 or Missing in Metastasis (MIM) are crucial for full transcriptional activation of HH targets.

The complexity of regulation of GLI proteins is further underlined by studies showing that signal cross-talk between HH/GLI and major intracellular signaling cascades such as RAS/RAF/MEK/ERK and PI3K/AKT modulates the transcriptional activity of GLI proteins.

The activity of GLI proteins is also tightly controlled by several mechanisms regulating GLI protein stability. Binding of beta-TrCP to GLI marks GLI for degradation by the ubiquitin-proteasome pathway. Similarly, binding of Numb, a developmental protein involved in binary cell fate decisions, to GLI1 protein triggers itch-mediated ubiquitination and degradation of GLI1 via the proteasome machinery, thereby promoting growth arrest and differentiation of neuronal cells.

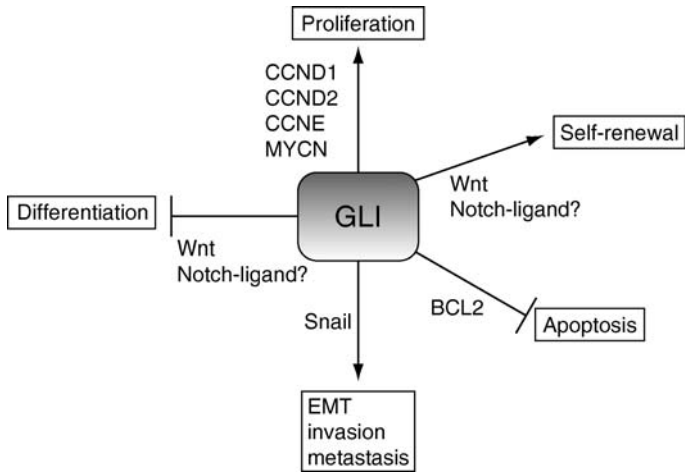
GLI Proteins in Cancer

Aberrant activation of the Hedgehog/GLI signaling pathway leads to the development of a number of human malignancies ranging from semi-malignant tumors of the skin (Basal cell carcinoma) to fatal cancers of the brain, lung, upper gastrointestinal tract, pancreas and prostate.

HH-associated cancers display elevated expression levels of one or more GLI transcription factors, particularly GLI1 and GLI2, suggesting a key role for both GLI proteins in HH-driven cancers. The oncogenic activity of GLI1, and probably also that of GLI2, has multiple facets (Fig. 2). GLI1 can transform rodent cells and promote cell cycle progression of several epithelial cell types. In agreement with these oncogenic properties, inhibition of GLI1 or GLI2 function has been shown to slow down tumor cell proliferation and to increase apoptosis. Enhanced expression of GLI1 also augments the metastatic potential of prostate cancer cells.

The identification of direct GLI target genes with a putative role in cancer development and growth has shed light on the molecular mechanisms underlying Hedgehog-driven tumorigenesis. GLI1 and GLI2 have been shown to increase the expression of key regulators of G1/S and G2/M transition of the cell cycle. The Cyclin D genes CCND1 and CCND2 are up-regulated in HH-associated cancers and both are likely to be directly controlled by GLI proteins. In Drosophila, Cyclin E is directly regulated by the fly GLI homolog Ci. HH-induced proliferation also involves direct activation of the N-MYC (►MYCN) proto-oncogene. In neuronal cells, overexpression of MYCN mimics the proliferative effect of Hedgehog, while inhibition of MYCN abrogates Hedgehog-induced proliferation.

GLI transcription factors also promote cell survival by directly activating transcription of the key anti-apoptotic factor BCL2. Of note, Wnt and Notch ligands have also been described as direct GLI targets, which may play a role in stem cell renewal and inhibition of cell differentiation.



GLI Proteins. Figure 2 GLI proteins regulate multiple oncogenic mechanisms. Direct GLI target genes that have been implicated as key mediators of the respective oncogenic process are listed. EMT: Epithelial-mesenchymal transition.

Furthermore, GLI proteins have been implicated in the control of the invasive and metastatic behavior of prostate cancer cells, as overexpression of GLI can convert cells with low metastatic potential into highly malignant cells. This may well be mediated through direct transcriptional activation of Snail, a transcription factor with a critical role in ►epithelial-to-mesenchymal transition (EMT) and in the down-regulation of the ►cell adhesion molecule ►E-cadherin, two hallmarks of increased invasiveness and metastasis.

Glioblastoma

Definition

A member of the group of ►brain tumors, the most malignant astrocytic tumor, composed of poorly differentiated neoplastic astrocytes with areas of vascular proliferation and/or ►necrosis. Typically affects adults and is preferentially located in the cerebral hemispheres. Glioblastomas may develop from low-grade diffuse or anaplastic ►asrocytoma, but most frequently they present after a short clinical history with no evidence of a less malignant precursor lesion.

►Glioblastoma Multiforme

Glioblastoma Multiforme

Weiling Zhao
Department of Radiation Oncology and Brain Tumor Center of Excellence, Wake Forest University School of Medicine, Winston-Salem, NC, USA

Synonyms

Glioblastoma; GBM; Grade IV astrocytoma; WHO grade IV astrocytoma

Definition

Glioblastoma multiforme (GBM) is a highly aggressive central nervous system (CNS) tumor derived from glial cells.

Characteristics

Introduction

GBM is the most aggressive and life-threatening CNS tumor. Although predominately found in the brain, it can also develop in the other tissues of the CNS, such

spinal cord and optic nerves. Primary GBM tumors usually develop de novo. However, sometimes a lower grade, less malignant ►brain tumor can evolve into a higher grade secondary GBM. GBM tumors are the most malignant primary brain tumor, accounting for about 60% of brain tumor cases in adults over 50 years old. Rapid proliferation, aggressive ►invasion, infiltration, and destruction of neighboring normal tissues are the dominant characteristics of GBM tumors. ►Metastasis of the tumor to other tissues beyond the CNS is rarely, if ever, observed clinically. GBMs occur predominately in the subcortical white matter of the cerebral hemispheres. Tumor infiltration often extends into the adjacent cortex, basal ganglia, and contralateral hemisphere. The occurrence of GBMs in the brainstem is rare in adults, but not in children.

The Genomic Abnormalities in GBM Tumors

Similar to other malignant tumors, ►genomic instability, such as chromosomal abnormalities that result in the ►loss of heterozygosity (►LOH), and gene mutations are frequently detected in GBM tumor cells. The most frequently observed mutations are found in the genes of ►p53 (►TP53), ►EGFR, ►mdm2 and ►PTEN. EGFR is a regulatory protein involved in the control of cell proliferation. Amplification/overexpression of EGFR has been identified as one of the most common characteristics of GBM tumors. The truncated, ligand-independent and constitutively activated isoforms of EGFR are frequently found in GBM tumors. It has been demonstrated that the overexpression of EGFR correlates positively with increased tumor growth rate and decreased survival. Approximately half of GBM patients have elevated EGFR expression.

Mutations in the ►tumor suppressor gene, p53 (TP53), were one of the first genetic abnormalities identified in gliomas. Frequently, p53 mutations have been observed in low-grade gliomas and secondary GBM tumors, suggesting that inactivation of p53 (TP53) is an early event in GBM pathogenesis. ►Amplification of the gene mdm2 is also frequently detected in GBMs. This protein forms a complex with p53 (TP53), resulting in an inhibition of p53 (TP53) function. Thus, amplification of mdm2 in tumor cells constitutes an alternative mechanism for facilitating uncontrolled cell growth. Clinically overexpression of mdm2 is observed in 10–15% of GBM patients, and is usually associated with poor prognosis.

The most frequent gene alterations occur on chromosome 10 for both primary and secondary GBM tumors. These mutations appear to be specific for GBMs, are rarely found in the lower grade brain tumors, and are generally accepted as a ►biomarker of poor prognosis. The tumor suppressor gene, PTEN, located at 10q23.3 encodes a tyrosine phosphatase and plays a significant regulatory role in the AKT signaling pathway. Loss of the PTEN function causes increased phosphorylation of the inositol phospholipids that activate the AKT serine/threonine-kinase, leading to enhanced cell cycle entry and aberrant proliferation. The PTEN mutation is found in about 20–40% of GBM patients.

Treatment of GBM Tumors

Nearly all GBM tumors are treated with a combination of surgery, ►radiotherapy, and ►chemotherapy. All of these treatments are difficult because the location of GBM tumors in the brain and spinal cord present unique challenges that require a balance between the safety and effectiveness of the treatments. The development of sophisticated noninvasive techniques such as ►computed tomography (CT), ►positron emission tomography (PET), and ►magnetic resonance imaging (MRI) has allowed surgeons to locate the tumor more precisely so that stereotactic surgery can remove more of the tumor without damaging nearby critical normal brain structures. This has not only led to increased survival, but also to improved posttreatment quality of life.

Even when it appears that the entire tumor has been surgically removed, GBM tumors usually regrow from the few GBM tumor cells that remain in the surrounding brain tissue. Postoperative ►radiotherapy is usually recommended in an attempt to kill the remaining tumor cells that could not be surgically removed. Both conventional radiotherapy (fractionated radiotherapy) and ►stereotactic radiosurgery (single fraction radiotherapy) are used to kill the remaining tumor cells. Conventional radiotherapy uses external radiation beams to treat either large volumes of the brain or the whole brain. This approach is usually recommended for large infiltrating tumors or those that have multiple foci throughout the brain. Stereotactic radiosurgery and ►Gamma Knife radiosurgery, have been developed to allow one to precisely target radiation directly to small, well localized tumors. These radiosurgery techniques can deliver large doses of radiation to an area no bigger than 4–5 mm in diameter in a single treatment, thereby increasing tumor cell kill while drastically reducing the radiation damage to the surrounding normal brain tissue. These radiosurgery techniques have not only led to an increase in the median survival of GBM patients, but also improved their posttreatment quality of life.

Chemotherapy has also been used as a primary treatment for GBM tumors, and as an adjuvant to surgery and radiotherapy for recurrent GBM tumors. However, the existence of the blood–brain barrier (BBB) complicates the use of chemotherapeutic agents for treating CNS tumors. Water soluble (hydrophilic) molecules and molecules with molecular weights greater than 600 do not cross the BBB very efficiently, if at all. While this is unimportant for treating cells in the center of a GBM tumor where there is no BBB, it is

critical for treating the cells at the edge of the tumor where the BBB is still intact.

For many years, the lipophilic nitrosoureas, BCNU and CCNU, were the most effective systemic chemotherapeutic agents for treating GBM tumors. When used as single agents, they increased the lifespan of GBM patients by 2–3 months. In combination with other chemotherapeutic agents and/or radiation, they increased the lifespan of GBM patients by 3–6 months. Nevertheless, until recently, the best combinations of nitrosourea-based chemotherapy, radiotherapy, and surgery resulted in an increase in the median lifespan to only about 12 months, probably due to very little of the systemically administered drugs getting to the viable tumor cells in the CNS.

To overcome the problem of delivering substantial concentrations of these chemotherapeutic agents to the tumor, a biodegradable polymer wafer containing BCNU was approved by FDA in 2002. These wafers can be inserted during surgery so that they line the entire tumor cavity. As these wafers degrade, they release BCNU in a controlled fashion to maintain a higher concentration of the drug in the tumor over a longer period of time than can be achieved if the drug is administered systemically. A phase III randomized trial that included 240 GBM patients compared the results from implanting the BCNU-containing polymer wafers with the results from implanting a placebo wafer. All patients received the standard treatment consisting of tumor resection followed by fractionated external radiation. The median lifespan of the group treated with the BCNU-containing polymer wafers was 13.9 months, while the median lifespan of the group treated with placebo wafer was 11.6 months. Although the wafer results were better than the results obtained with systemic administration of BCNU, the increase in the medium lifespan was not as dramatic as expected, suggesting that new chemotherapeutic agents need to be developed for the treatment of GBM tumors.

In 2005, temozolomide (Temodal, Temodar, TMZ), an alkylating agent that can be given orally, was approved by the FDA for the treatment of GBM tumors. After oral administration, TMZ is rapidly absorbed with almost 100% bioavailability. It readily crosses the blood–brain barrier and achieves effective concentrations in the cerebrospinal fluid. A phase III clinical trial performed by the European Organization for the Research and Treatment of Cancer (EORTC) used temozolomide combined with radiation to treat patients with new diagnosed GBM. GBM patients in the arm treated with temozolomide and radiation had a significant increase in their median lifespan (14.6 months) over those treated in the control arm (12.1 months). More importantly, the patients treated with temozolomide and radiation had a large increase in their two-year survival rate (26.5%) compared to the control group (10.4%). Consequently, the current standard of care for GBM patients is now surgery followed by treatment with temozolomide and radiation.

Current Status of GBM Research

Despite the best efforts of neurosurgeons, radiation oncologists, and medical oncologists, the median lifespan of patients with GBM tumors has not been changed very much. Although the 2 year survival of GBM patients has more than doubled using surgery, temozolomide chemotherapy, and radiotherapy, the 5 year survival is still less than 1%. Thus, new therapeutic approaches that can selectively enhance tumor cell killing while sparing normal brain cells are still urgently needed. Currently, researchers are studying new therapeutic modalities including ►immunotherapy, stem cell therapy, ►gene therapy and anti-angiogenesis therapy. Many researchers have been successful in treating GBM tumors in animal models, but there has been only limited success when these new treatments have been translated to the clinic. The key factors that have hindered clinical therapeutic progress are the lack of appropriate animal models that predict the response of human GBM tumors to treatment, the inability to deliver effective doses of chemotherapeutic agents to the tumor, and the genetic heterogeneity of human GBM tumors that make them among the most difficult tumors to treat.

Glioma

Definition

Is a primary brain tumor derived from transformed glial cells. Malignant glioma (GBM) is the most common primary brain tumor and is uniformly fatal despite aggressive surgical and adjuvant therapies.

►Brain Tumors

Glioma Retinae

►Retinoblastoma

Glivec

Definition

The first of a new class of antiproliferative agents that interfere with growth signaling pathways in tumor cells. Is targeted to kill cells that harbor the specific leukemia-causing ►BCR-ABL1 fusion protein found predominantly in ►chronic myeloid leukaemia (CML), while having little effect on the growth of normal cells that do not carry the mutant protein.

►Gleevec
►Imatinib
►STI-571

γ Globulins

Definition

Plasma proteins can be separated on the basis of electrophoretic mobility into albumin and the α, β, and γ globulins. Most antibodies migrate in electrophoresis as γ globulins (or gamma globulins), and patients who lack antibodies are said to have ►agammaglobulinemia.

►Sjögren Syndrome

Glucagon

Definition

Has a major role in maintaining normal concentrations of glucose in blood, having the opposite effect of ►insulin. That is, glucagon has the effect of increasing blood glucose levels.

Glucagonoma

Definition

Is a functioning ►islet cell tumor that produces excessive amounts of the hyperglycemic hormone glucagon, causing elevated blood sugar levels. This tumor can be associated with characteristic skin lesions (necrolytic migratory erythema).

►Neuroendocrine Carcinoma

Glucocorticoids

Definition

Are a class of steroid hormones, characterized by an ability to bind with the cortisol receptor and trigger many biological effects. Glucocorticoids are distinguished from mineralocorticoids and sex steroids by the specific receptors, target cells, and effects.

►Anti-Inflammatory Drugs
►Estrogenic Hormones

Glucose

Definition

A 6-carbon monosaccharide used by cells as a source of energy and metabolic intermediate.

►Warburg Effect

Glucuronic Acid

Definition

Is a polar, very water soluble sugar containing a carboxlic acid group that is chemically attached to a drug in a phase II metabolism reaction.

►ADMET Screen

β-Glucuronidase

Definition

β-Glucuronidases are enzymes produced by common intestinal microflora and are capable to deglucuronidate glucuronidated compounds, such as SN-38G. β-glucuronidases may play a role in the pathogenesis of ►irinotecan-induced delayed-type diarrhea.

Glucuronidation

Definition

Is the formation of hydrophilic glucuronides catalyzed by uridine diphosphate-glucuronosyltransferases. Glucuronidation facilitates the excretion of both endogenous and exogenous (lipophilic) molecules.

Glut1

Definition

Glucose Transporter 1. Expressed in fetal tissues and adult blood-brain barrier endothelia and erythrocytes. One of the carrier proteins of glucose along the cellular membrane. It is the first glucose transporter that has been characterized. In the adult, Glut 1 is expressed at highest levels in red cells and in the endothelial cells of barrier tissues such as the blood-brain barrier.

►Polycythemia

Glut4

Definition

Insulin-regulated glucose transporter. Found in adipose and skeletal muscle tissues, it is responsible for insulin-regulated glucose disposal.

►Insulin Receptor

Glutamate Carboxypeptidase II

Definition

A type of carboxypeptidase that is a transmembrane protein oriented such that the C-terminus of the protein is in the extracellular space outside of the cell membrane (i.e. type II transmembrane protein) and that is capable of sequentially hydrolyzing peptide bonds between adjacent glutamate amino acids starting at the carboxy-terminus of a peptide.

►Prostate-Specific Membrane Antigen

γ-Glutamylcystein Synthetase

Definition

Enzyme that catalyzes the first step in which an amide linkage is formed between the amino group of cysteine and the γ-glutamyl group of glutamate.

►Pharmacogenomics in Multidrug Resistance

Glutathione

Definition

A tripeptide of glutamic acid, cysteine, and glycine, which exist in reduced (GSH) and oxidized (GSSG) forms and functioning in various redox reactions, in the destruction of peroxides and free radicals, as a cofactor for enzymes, and in the ►detoxification of harmful compounds. Glutathione is an antioxidant and protects cells against free radicals. It is also involved in the formation and maintenance of disulfide bonds in proteins and in transport of amino acids across cell membranes.

Synonyms

Ral interacting protein 76kDa; RLIP76

Definition

RLIP76 is a multifunctional protein important for utilizing the energy currency adenosine triphosphate (►ATP) to transport various chemical materials outside the cell. Through this transport process this transporter protein converge many cell signaling processes through the modulation of substrate levels or the contribution of protein–protein interactions to stimulate cell signaling. Overexpression of RLIP76 has been correlated to contribute to the phenomenon known as ►multidrug resistance. This protein is also known to have a clinical impact in addition to multidrug resistance toward ►inflammation, heat and ►oxidative stress, radiation, and a culmination of these stressors allowing it to contribute to general stress resistance.

Characteristics

►Ral Interacting Protein 76 kDa (RLIP76), a known Ral effector, is a 655 amino acid long protein capable of the ATP-dependent transport of ►glutathione conjugates (GS-E, adducts of glutathione and electrophiles) and amphiphilic ►xenobiotics. In addition to this ATP-dependent transport this protein has been well established as a known Ral-binding protein and ►Rho-►GAP protein that participates in ►endocytosis. RLIP76 is the predominant GS-E transporter and current studies have established a link with this protein between glutathione metabolism and a myriad of signaling pathways (Fig. 1).

Expression of RLIP76 is everywhere in mammalian tissues including kidney, liver, brain, muscle, eye, erythrocytes, and leukocytes. Its presence has also been demonstrated in cancer cell lines of various tissue origins. In cells, RLIP76 is primarily associated with the membrane but its presence in cytosol has been demonstrated, which is consistent with its known functions.

The primary structure of RLIP76 using N-terminal sequencing revealed that RLIP76 possess a GAP activity for cdc42 and the Ral-binding domain. In addition, it also contains a GTP binding domain. RLIP76 was demonstrated to function as a Ral GEF (►guanidine exchange factor), Rho-►GAP (GTP-activating protein) and is responsible for signal propagation downstream to proteins such as POB1 (partner of RalBP1).

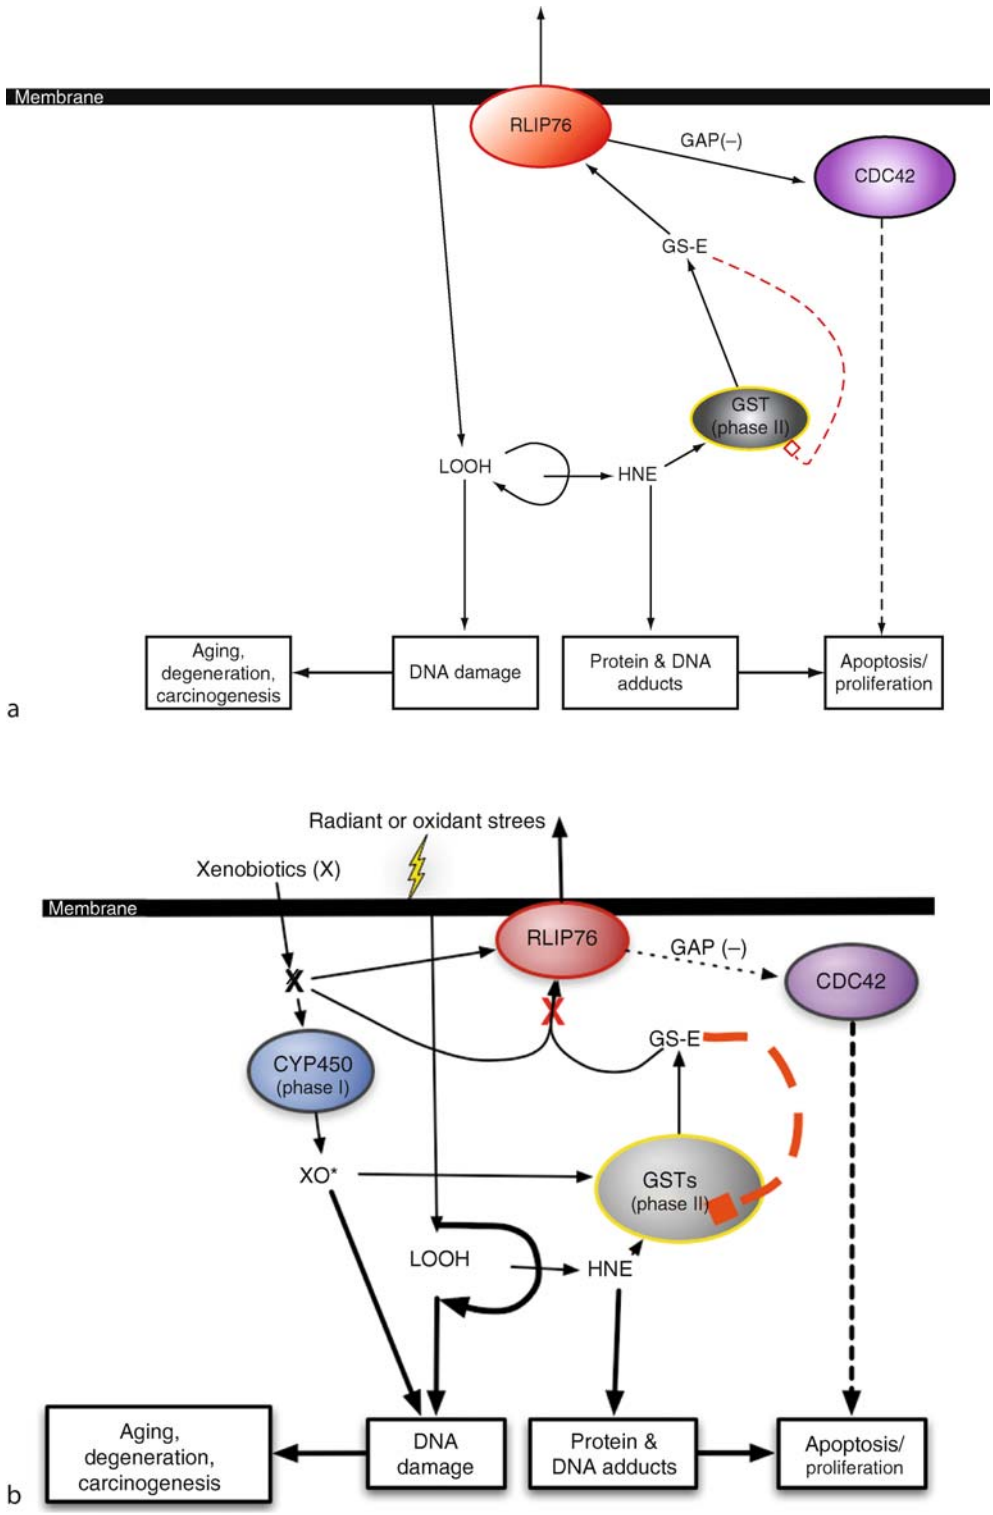
Discovery of RLIP76

A protein initially discovered as an ATP-dependent GS-E transporter was designated as DNP-SG ►ATPase. This protein stimulated ATPase activity in the presence of DNP-SG (dinitrophenyl *S*-glutathione a known conjugate of the cofactor glutathione and 1-chloro-2, 4-dinitrobenzene). ATP-dependent transport of DNP-SG and other GS-E was demonstrated in liposomes reconstituted with purified DNP-SG ATPase protein. Immunoscreening of a human bone marrow cDNA library using antibodies specific to DNP-SG ATPase resulted in cloning of a previously described protein RLIP76. It was established that that the structural, immunological and kinetic properties of tissue purified DNP-SG ATPase were identical and that in addition to DNP-SG, other GS-E including LTC4, GS-HNE, and various chemotherapeutic drugs such as doxorubicin also stimulated the ATPase activity of RLIP76. Proteoliposomes reconstituted with recombinant RLIP76 catalyzed the ATP-dependent transport of these chemicals with kinetic parameters similar to that of DNP-SG ATPase. Additional immunological studies with tissue-purified DNP-SG ATPase and recombinant RLIP76 established the identities of these two proteins and that this transporter was distinct from the known transporters including the classical family of transporters that are members of the ATP binding cassette transporter superfamily (►ABC transporter proteins).

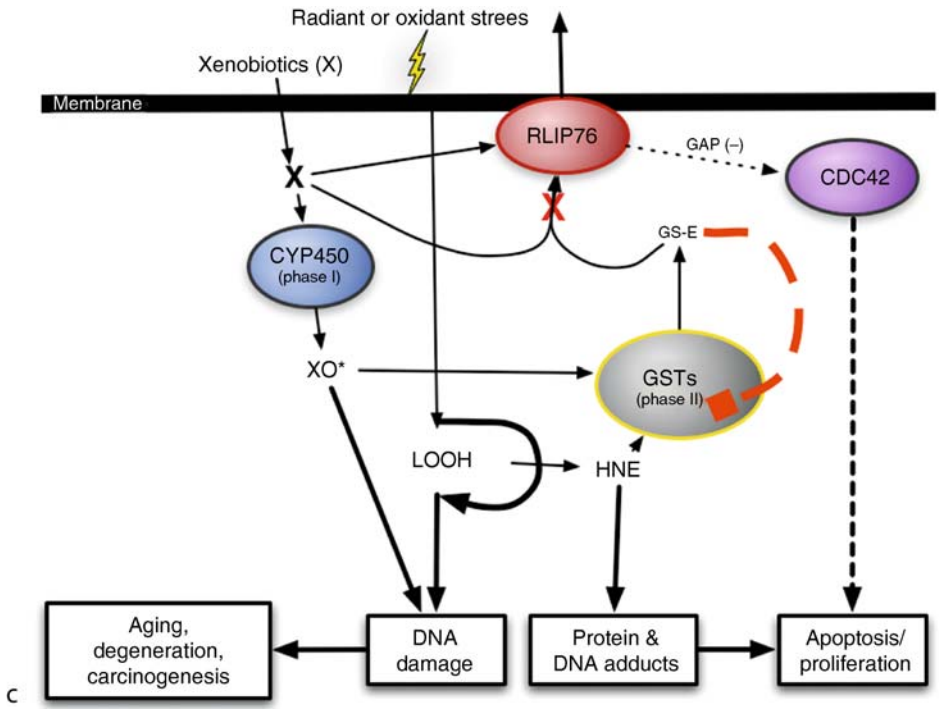
Clinical Significance

Drug Resistance

The role of RLIP76 in ►drug resistance of cancer cells is suggested by studies showing that its over-expression confers resistance and drug accumulation by increasing the rate of transport from cancer cells. In contrast, inhibition of RLIP76 by antibodies reverses the protein's overexpression effects. More importantly, depletion of the normal levels of RLIP76 in cancer cells by ►small interfering RNA (siRNA) sensitizes these cells to chemotherapy treatment and promotes ►apoptosis. The ability of RLIP76 to transport foreign material as well as their metabolites suggests that it is one of the major



Glutathione Conjugate Transporter RLIP76. Figure 1 (Continued)



Glutathione Conjugate Transporter RLIP76. Figure 1 (a) At normal levels or absence of increased stress, a baseline level of lipid hydroperoxide generation from membrane lipids gives rise to radicals. 4-hydroxynonenal (4-HNE) and other lipid aldehydes as well as peroxides are processed by GSTs to glutathione conjugate (GS-E) which are transported in an ATP-dependent manner by RLIP76 and other transporter proteins. The concentration of GS-E is low. Because of low concentration of GS-E, RLIP76 is balancing between transport and GAP (toward cdc42), thus inhibiting this proapoptotic pathway. Under conditions of low HNE, formation of DNA adducts is kept low and cell proliferation (marked bold) is favored. (b) Under the conditions of stress, lipid peroxidation is increased resulting in greater amount of toxicity and greater amount of HNE formation, which is catalyzed to GS-E by the various GSTs. Because of the rise in GS-E product, some product-inhibition of GSTs occurs until RLIP76 activity is increased. If xenobiotic toxins (chemotherapy drugs, carcinogens) are also present under these condition, a competition arises between lipid metabolites and activated P450 metabolites (XO*) for GST-mediated conjugation with GSH, the concentration of XO* rises more rapidly and genotoxicity is enhanced, particularly because XO* can propagate themselves via lipid peroxidation. Because of increased transport substrate, GS-E, the transport activity of RLIP76 is favored over its GAP activity toward cdc42, partially releasing that inhibition. The net effect, depending on the severity of stress would result in decreased proliferative signals and increased tendency to apoptosis (marked bold), both as a result of loss of cdc42 inhibition, and as a result of increased electrophilc lipid or xenobiotic oxidation products. (c) If RLIP76 is inhibited under conditions of stress, not only is there rapid accumulation of GS-E, but inhibition of GSTs by GS-E results in accumulation of XO*, which are also formed more rapidly because of increased substrate xenobiotic due to lack of the xenobiotic efflux activity represented by RLIP76. Under these conditions, genotoxicity and apoptosis signaling are greatly increased and proliferation is diminished.

components of the phase III ►detoxification systems. This contention is supported by studies showing that in mice as well as in cancer cells in culture, RLIP76 is responsible for more than 70% of the total ►doxorubicin transport as opposed to ►MRP1 and other transporters which are responsible for transporting only less than 30% of the drug.

Heat-shock and Oxidative Stress

Increases in oxidants can cause genomic insult leading to carcinogenesis. ►Oxidative stress usually leads to enhanced generation of endogenous electrophiles, which are metabolized to ►GS-E by ►GSTs. Besides being toxic, GS-E metabolites are known to be important contributors to cell signaling. Competitive inhibition of GS-E transport by xenobiotics implies that cell signaling pathways may be modulated by such compounds, particularly during oxidative stress-induced signaling. Alternatively, pharmacological effects of such xenobiotics could be modulated by oxidative stress. A major role of RLIP76 in defense against oxidative stress is suggested by studies showing that short exposure

of mild heat shock, oxidative stress, or ►UV radiation, to human cell lines leads to induction of RLIP76 as an early stress responder even prior to the proteins known for stress response (e.g., the ►heat-shock proteins). Under stress conditions, formation of electrophilic products (e.g., ►4-HNE) from the breakdown of lipids is observed and consequently GS-E levels rise. With induced expression of RLIP76, the stress-preconditioned cells acquire at least threefold higher capacity to transport endogenous GS-E as compared with untreated controls. This increased efflux of GS-E can be blocked by coating the cells with antibodies against RLIP76, indicating that GS-E are specifically transported by RLIP76. Cells, preconditioned to stress, display an enhanced ability to exclude GS-E due to induced RLIP76. Preconditioned cells are resistant to ►4-hydroxynonenal (4-HNE), superoxide anion (O_2-), ►hydrogen peroxide (H_2O_2), or ►UV radiation-mediated toxicity. These cells also acquire resistance to apoptosis by suppressing ►Jun N-terminal kinase and ►caspase-3. Inhibiting GS-E transport can abrogate the protective effect of this stress preconditioning. These studies suggest that the intracellular concentrations of endogenous GS-E, such as the conjugate between glutathione and 4-hydroxynonenal (GS-HNE), can affect stress-mediated signaling and that RLIP76 and GSTs are the major determinants of the intracellular levels of 4-HNE and GS-HNE.

Radiation Toxicity

Generation of ►reactive-oxygen species is one of the common effects of using high-energy radiation on biological tissues. RLIP76 is capable of providing protection against oxidative stress, primarily due to its ability to remove various electrophilic toxicants generated during ►lipid peroxidation caused by the reactive oxygen species. This implies that RLIP76 should provide protection against radiation toxicity because lipid peroxidation is an unavoidable consequence of exposure to radiation. It has been demonstrated that purified RLIP76 incorporated into liposomes is eagerly taken up by cultured cells resulting in increased cellular RLIP76 levels. When lung cancer cell lines in culture were treated with RLIP76 liposomes prior to the exposure to radiation, these cells with increase levels of RLIP76 were found to be more resistant to radiation toxicity as compared with the control cells. Efflux of GS-E formed from the reactive products of lipid peroxidation contributes significantly to radiation toxicity and that the increased efflux of GS-E from RLIP76-enriched cells rendered these cells resistance to radiation. Significance of GS-E efflux and role of RLIP76 against X-radiation has also been confirmed in the in vivo model.

The ability of RLIP76 to modulate stress from chemical, heat, radiation sources in addition to amphiphilic xenobiotic toxins such as ►vinca alkaloids used in chemotherapy indicates that RLIP76 plays a positive role in preventing oncogenesis but a negative role as the major contributor to resistance in cancerous cells.

Definition

GSTs; Refer to a family of ►Phase 2 detoxification enzymes that catalyse the conjugation of glutathione

(GSH) to a wide variety of endogenous and exogenous electrophilic compounds, thereby decreasing their reactivity with cellular macromolecules. This detoxification ability plays a pivotal role in cellular protection from ►oxidative stresses.

Characteristics

GSTs are divided into three distinct super-families: cytosolic, mitochondrial, and membrane-bound microsomal. Microsomal GSTs play a key role in the endogenous metabolism of leukotrienes and prostaglandins. The mammalian cytosolic GSTs are highly polymorphic and could be divided into six classes: alpha (A), mu (M), omega (O), theta (T), sigma (S) and pi (P). Classification is based on sharing greater than 60% identity within a class and focuses mainly on the more highly conserved N-terminal domain that contains a catalytically active tyrosine, cysteine or serine residue. The catalytic residue interacts with the ►thiol group of glutathione (G-site), and crystal structure has confirmed a substrate binding site (H-site) that facilitates catalysis and is in proximity to the G-site. GSTs have been found in virtually almost every living species, including mammals, plants and bacteria.

Catalytic function

GSTs catalyze a general reaction:

$$GSH + R - X \rightarrow GSR + HX$$

The function of the enzyme is to bring the substrate into close proximity with GSH by binding both GSH and the electrophilic substrate to the active site of the GSTs, and active the sulfhydryl group of ►glutathione, then allowing for nucleophilic attack of GSH on the electrophilic substrate (R-X). Lots of diverse chemicals and compounds serve as substrates for GSTs, and differences in expression of specific GSTs isoforms could be an important determinant of target organ and species sensitivity.

Signaling regulation

Though GSTs were early investigated because of their pivotal role in detoxification of ►reactive oxygen species (ROS) and maintenance of the cellular redox state, they were then discovered as "ligandins" owing to their abilities to interact covalently and noncovalently with various compounds that were not substrates for enzymatic activity, including steroids, thyroid hormones, prostaglandins and bile acid. As the ligand-binding characters of GSTs were confirmed, the regulatory effects of GSTs on stress- and anticancer drugs-activated cellular signaling pathways were revealed in various studies.

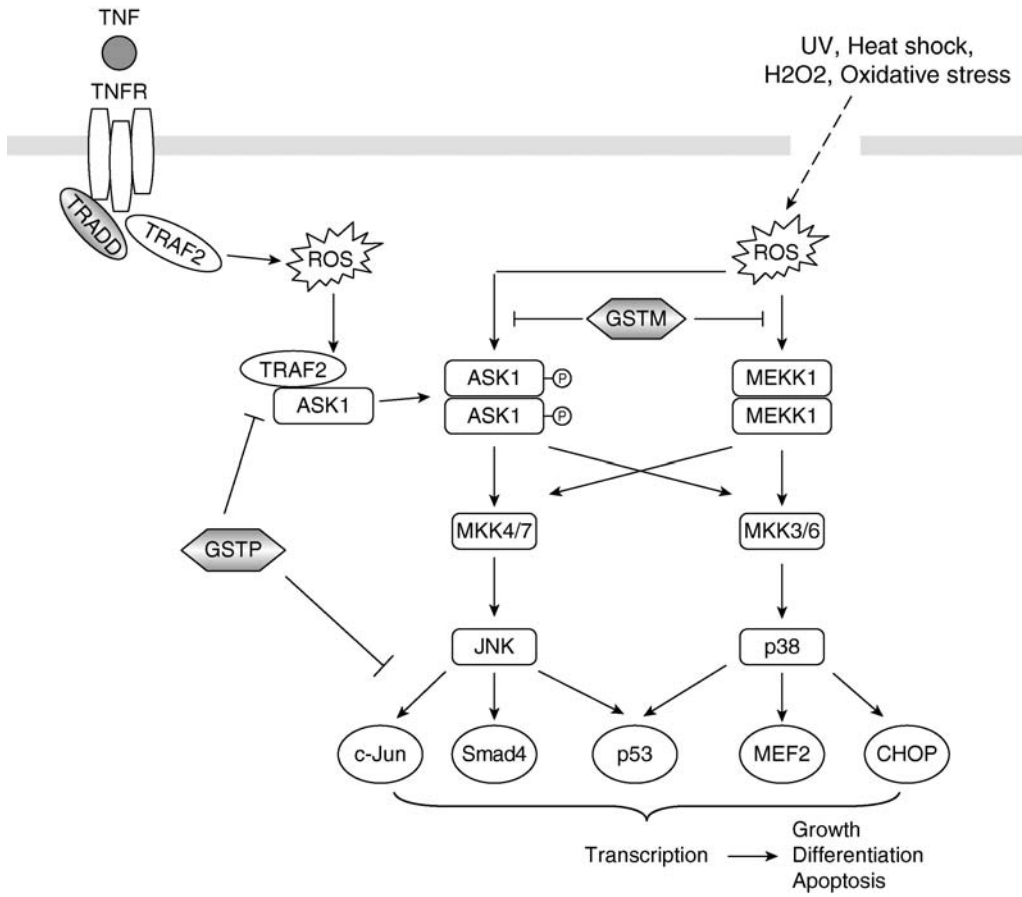
The Pi and Mu classes play an important role in regulating mitogen-activated protein kinase (►MAPK) signaling pathway via their noncatalytic, ligand-binding activity. GSTP functions as an endogenous inhibitor of ►JNK, which interact with the C-terminal of that kinase. GSTP also regulates TNF-α-induced MAPKs signaling by forming ligand-binding interactions with ►tumor necrosis factor – associated factor and suppressing TRAF2-enhanced activation of ►apoptosis signal-regulating kinase1, thereby attenuated TNF-α-TRAF2-ASK1-triggered cancer cell apoptosis. GSTM also has been identified as a negative regulator of ASK1 through direct protein-protein interaction (Fig. 1). All of these findings suggested that the cell death inhibition role of GSTs may provide a novel strategy for antitumor therapy.

Cancer related

For more than a decade, GSTs have generated interest as a neoplastic marker based on its elevated expression in many tumor tissues relative to matched normal tissue. Elevated expression of GSTs have been implicated in cellular response to oxidative stress and protect tumor cells from apoptosis elicited by a variety of cytotoxic agents, such as ►hydrogen peroxide, ►UV radiation, ►cisplatin, ►arsenic trioxide and ►etoposide. Chemotherapeutic-resistant tumor cell lines also have been shown to overexpression GST isozymes. A primary cause of cancer treatment failure and patient relapse is an acquired or intrinsic resistance to anticancer therapies. Acquisition of drug resistance can be attributed to various factors that include avoidance of apoptotic cell death, altered expression of multidrug resistance-associated proteins, altered drug metabolism or uptake, and/or overexpression of GSTs.

Deletion of GSTM1 and GSTT1 genes results in 'null' genotype and increased risk for malignancies as a consequence of a decreased capacity to detoxify possible carcinogens. GSTM1 and GSTT1 phenotypes were also been examined in patients with ►acute myelogenous leukemia (AML). Patients null for GSTT1 exhibited an increased toxicity and reduced survival rate following chemotherapeutic treatment. In contrast, patients null for GSTM1 or GSTT1 showed a twofold reduction in cancer relapse during remission.

The literature is replete with correlative epidemiological reports, where small sample size precludes definitive conclusions of cause and effect between GST expression and cancer incidence. Many studies have provided epidemiological linkage of polymorphic expression of GSTs with cancer incidence and prognosis. As a single enzyme, GST is unlikely to act in isolation, nevertheless, the elevated expression of GSTs in many tumor tissues and cause of cancer treatment failure is well accepted and GSTs have been selected as plausible pharmaceutical targets.



Glutathione-S Transferase. Figure 1 GSTP and GSTM act as regulators of cellular signalings. GSTP interacts and inhibits JNK activity by sequestering JNK/c-Jun, whereas GSTM binding MEKK1 and ASK1 directly. These protein–protein interactions negatively regulate oxidative stresses-induced cell growth, differentiation and apoptosis. GSTP also inhibit TNF-α-triggered cancer cell apoptosis through TRAF2, thereby represses the TRAF2–ASK1 complex.

GSTs have emerged as a promising therapeutic target because specific isozymes are overexpressed in a wide variety of tumors and may play a role in the etiology of other diseases, including neurodegenerative diseases, multiple sclerosis, and asthma. An initial approach was the design of GST inhibitors to act as reasonably non-toxic modulatory agents, useful in situations where conventional anticancer agents are detoxified by GSTs. A variety of GST inhibitors were shown to modulate drug resistance by sensitizing tumor cells to anticancer drugs. The first clinical modulatory studies focused on an approved drug, ethacrynic acid (EA). The therapeutic value of EA as a chemosensitizer has been used in patients. TLK199 is a peptidomimetic GSH analogue that is a low micromolar inhibitor of GSTP. TLK199 was shown to potentiate the toxicity of numerous anticancer agents in different tumor cell lines. Alternatively, compounds designed to disrupt the protein–protein interactions of GSTs with TRAF2 or stress kinases also provide a possible therapeutic approach with respect to modifying proliferative responses.

N-Glycan Chain

Definition

Glycan covalently linked to an asparagine residue of a polypeptide chain in the consensus sequon-Asn-X-Ser/Thr.

►Mucins

Glycans

Definition

Are composed of carbohydrate units covalently linked together via glycosidic bonds.

►Glycobiology

Glycobiology

Göran Larson, Ammi Grahn, Jonas Nilsson
Department of Clinical Chemistry and Transfusion Medicin, Institute of Biomedicine, Sahlgrenska academy at Göteborg University, Göteborg, Sweden

Definition

A discipline of natural sciences covering studies of the structure, biosynthesis and biology of glycans and glycoconjugates, and proteins that specifically interact with these. It is involved in almost every aspect of cancer; transformation, progression, ►metastasis, diagnosis, monitoring, and therapy. Still, the general awareness of the potential and clinical use of discoveries in glycobiology among oncologists, or in oncology among glycobiologists, is limited.

Characteristics

Glycan Structural Diversity is Theoretically Immense but Genetically Restricted

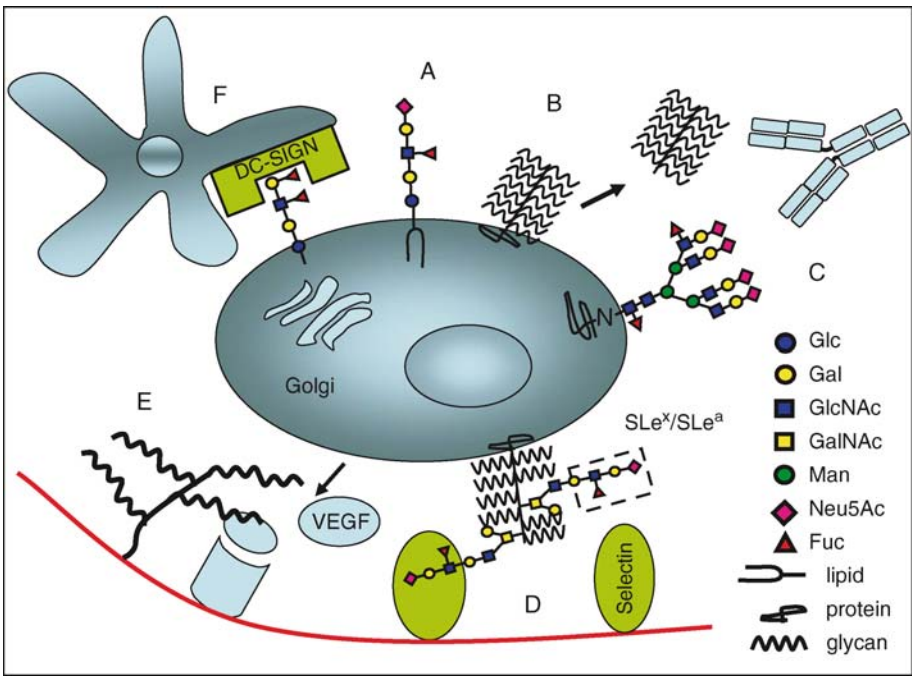
The field of glycobiology has evolved from mainly structural characterization of naturally occurring carbohydrates (sugars or ►glycans) to functional studies of the biology and interaction of such compounds with both endogenous and exogenous proteins, ►lectins typically equipped with carbohydrate recognizing domains (CRD). The glycans (Fig. 1) may occur as free oligosaccharides but are usually covalently linked at the reducing end to an aglycone part being either lipid (in ►glycolipids) or protein (in ►glycoproteins, ►mucins, or ►proteoglycans). The aglycone part as well as the glycan part is of fundamental and often mutual importance for the biosynthesis, localization, and function of the resultant ►glycoconjugates. Carbohydrates of proteins are either O-linked or N-linked and may, as in glycolipids, be either neutral or acidic due to presence of carboxyl and/or sulfate groups.

The structural variability of glycans in nature is, although theoretically immense compared with proteins and oligonucleotides due to the many possible monosaccharides and the many ways these may be linked together, restricted by the number of genes responsible for biosynthesis, and degradation of such glycans. The biosynthesis of glycans is typically localized to the Golgi system whereas preassembly and trimming typically appear in the cytoplasm and the ►endoplasmic reticulum (ER). Some biosynthetic steps even occur in the nucleus. The general requirement for enzymatic ►glycosylation, i.e., initiation or extension of a carbohydrate chain, is a glycosyltransferase, a nucleotide activated sugar donor, an acceptor molecule and an appropriate divalent metal ion. Enzymatic glycosylation is, in contrast to oligonucleotide and protein synthesis, not template driven. Instead glycosylation is characterized by the specificity, redundancy, and promiscuity of the enzymes and the local competition between enzymes which together determine the final glycan structures.

Glycans Evoke Antibody Responses

Since glycans decorate the cell surface of all living cells they may be used both as tags for identity and as molecular sensors of the environment. Glycan structures are cell- and species-specific and typically change during embryogenesis, differentiation, and growth. Cancer development, progression, and spread are distorted or unforeseen series of events that, under the pressure of the innate and acquired immune systems, continuously selects the most aggressive malignant clones. Thus, successful malignant cells will have to adapt to the host physiology, evade the immune defense and take advantage of common cellular and molecular processes that may increase their possibility for survival. Glycans play important parts in such phenomena as will be exemplified later.

The human ABO(H) histo-blood group system, originally identified on red blood cells but now known to occur on many other cells, is of carbohydrate nature. This system, detected due to transfusion complications caused by ►naturally occurring antibodies toward nonself structures, has been the raw model for how ►tumor associated carbohydrate antigens (►TACA) may be utilized to evoke B-cell-mediated antibody



Glycobiology. Figure 1 Tumor cell glycan-mediated interactions with antibodies and lectins. Glycans are biosynthesized by enzymes in the Golgi system, using activated monosaccharides (Glc, Gal, etc.) and typically show aberrant glycosylations not normally found in differentiated cells of that cell type. Glycans appear as membrane bound glycolipids (a), mucins (b, d), glycoproteins (c), or as secreted mucins (b). Antibodies raised against tumor-associated carbohydrate antigens (TACA) are used for serum tests, immunohistochemistry, nuclear imaging, and radioimmunotherapy. Tumor cells overexpress specific glycans, e.g., SLe^x and SLe^a, and use these in the first steps of selectin-mediated adhesion to vascular endothelium facilitating haematogenous metastasis (d). Angiogenesis, defined as the sprouting of blood-vessel endothelial cells, is crucial for local growth of tumor cells in tissues and is dependant on the interactions of proangiogenic factors (e.g., VEGF), proteoglycans, and endothelial cell receptor tyrosine kinases (e). Recognition of TACA by antigen-presenting cells is mediated by C-type lectins (e.g., DC-SIGN) interacting with specific glycans (f). Glc: glucose, Gal: glactose, GlcNAc: *N*-acetylglucosamine, GalNAc: *N*-acetylgalactosamine, Man: mannose, Neu5Ac: neuraminic, Fuc: fucose, SLe^x/SLe^a: Sialyl Lewis x or Sialyl Lewis a structures, VEGF: vascular endothelium growth factor, DC-SIGN: dendritic cell-specific ICAM-3 grabbing nonintegrin.

response. In the classical literature there were encouraging reports of how illegitimate or ►aberrant glycosylation occurred in various adenocarcinomas. The most spectacular clinical report was perhaps the description in 1951 by Levine et al. of a woman of blood group *pp*, i.e., a rare subgroup of the glycan-based histo-blood group P system, who survived for 25 years after a minor incompatible blood transfusion and an incomplete resection of a gastric adenocarcinoma, later shown to contain glycolipids reactive with her own hyperimmune serum (anti-Tja).

A long-standing debate has been whether aberrant glycosylation is a result or a cause of cancer. Many recent reports indicate that some, if not all, aberrant glycosylations are part of the initial oncogenic transformation as well as key events in defining the malignancy (invasive and metastatic phenotype) of tumors. Apart from the examples given in some detail below glycans also play important parts in apoptosis, motility, growth, and angiogenesis (Fig. 1).

Glycans are Clinically Useful as Cancer Markers

With the advent of monoclonal antibody techniques many groups challenged mice with human tumor cells in order to produce antitumor antibodies of potential use for diagnosis and therapy (Fig. 1). Many tumor-associated antigens have been shown to be carbohydrates typically expressed both in carcinomas but also on other, often embryonic or immunocompetent cells (►CA19–9 and SPan-1 recognizing SLe^a; CA50, and DU-PAN-2 recognizing SLe^c, the nonfucosylated precursor of SLe^a; CSLEX-1, and FH6 recognizing ►SLe^x and $SdiLe^x$; B72.3 and CC49 recognizing STn etc). Some of these antibodies are in clinical use worldwide for screening, diagnosis, prognosis, and follow-up after tumor treatment. Only in Japan almost

10 million serum tests for CA19–9 are performed each year, comparable to the number of tests for ►CEA and more than those for ►α-fetoprotein. Other well-known biomarkers of malignancy such as ►PSA for ►prostate cancer and ►CA125 for ►ovarian cancer are also glycoproteins. Thus, although ►TACA appearing in plasma is of considerable advantage for diagnostic use, circulating glycans being either shed or secreted by the tumor cells and mainly as large mucins, may also block antibodies injected for therapy. The clinical use of therapeutic antibodies has so far been limited, partly also due to the immune responses raised against mice monoclonal antibodies, but new strategies for humanizing such antibodies are now under way which will facilitate the use of labeled antibodies e.g., for ►nuclear imaging and for ►radioimmunotherapy.

TACAs are Recognized by Lectins on Antigen-Presenting Dendritic Cells

►Dendritic cells (DC) are specialized ►antigen-presenting cells that express a wide variety of receptors for antigen presentation and uptake. The cells play a key role in controlling ►T-cell responses directing them either to activation or to tolerance. Recent reports reveal that TACA (e.g., CEA or MUC-1 mucin) interact with the calcium dependant proteins (►C-type lectins), DC-SIGN (Dendritic Cell-specific ICAM-3 grabbing nonintegrin), MR (mannose receptor), and MGL (macrophage galactose-type lectin) on dendritic cells (Fig. 1). Both tumor cell-associated and circulating mucins may become internalized, processed, and presented on ►MHC class II molecules, provided their glycans show the aberrant glycosylations recognized by these lectins (e.g., Le^x, Le^y, and Tn antigens). This system may seem to be adequate for early detection and removal of malignant cells. However, TACA may manipulate dendritic cells through their C-type lectins to allow tumor cells to evade the immune system if no other danger signals are provided in parallel. A further understanding of these processes will probably be necessary for understanding why *in vivo* immune responses against TACA are so difficult to obtain but also to pave the way for new antitumor vaccine strategies.

Human Retrovirus HTLV-1 (►Human T-cell Leukemia Virus) Induces Specific Glycan Biosynthesis

Fundamental questions are why certain glycans typically appear in tumors, what advantages do they give the tumor cell and what proteins are there to recognize such glycans? ►DNA methylation or ►histone deacetylation is supposed to mediate decreased expression of glycosyltransferases and errors in alternative splicing has been described for the ABO gene as a plausible explanation for the appearance of TACA in tumor tissues. Several viral infections have been shown to drastically alter the expression of host glycans and corresponding glycosyltransferases in infected cells. Of particular interest is the elevated expression of SLe^x in leukemia cells of patients with adult ►T-cell-leukemia (ATL), a rare but fatal malignancy of helper T-cells. This disease is an endemic leukemia induced by the virus ►HTLV-1. The leukemia cells typically infiltrate various organs and tissues including the skin and the level of infiltration correlates significantly with the level of SLe^x expression on the surface of the leukemia cells. The *pX* gene of HTLV-1 codes for an oncogenic protein, called ►Tax, which has a transactivating effect on several important cellular genes including *hFUT7* which actually codes for the glycoyltransferase responsible for the final step in the biosynthesis of SLe^x. The description of this mechanism is a significant contribution and was the first proof of principle where aberrant glycosylation was directly linked to a genetic mechanism of malignant transformation. The significance of genetic regulation of glycosyltransferase genes in the many cancers of epithelial origin, where the SLe^x and its structural analog SLe^a are characteristically overexpressed, awaits further elucidation.

Selectin–Glycan Interactions Initiate Adhesion of Malignant Cells to Vascular Endothelium

The infiltration of tumor cells from the circulating blood stream into the tissues, as exemplified by leukemia cells in ATL-patients, is for white blood cells (granulocytes and lymphocytes) a physiological homing process which starts with the tethering, rolling, adhesion to, and finally infiltration through the endothelium lining the vessel wall. This process is strictly sequential and initiated by specific calcium-dependant protein–carbohydrate interactions mediated by a family of three ►C-type lectins called E-, P-, and L-selectins and their glycan counter-receptors. These lectins all recognize a common carbohydrate structure, SLe^x, although their receptor specificities vary as to the detailed glycan structures and to the dependence of critical sulfate groups on the core protein or on the glycan itself. E-selectin is typically expressed on endothelial cells at sites of inflammation. P-selectin is constitutively expressed on platelets, on endothelium of lung and brain choroid plexus microvessels and on activated endothelial cells. L-selectin is typically expressed on leukocytes i.e., myeloid cells, naïve T-cells, and some activated and memory T-cells. The revelation of the homing process of myeloid cells, necessary for a normal immune defense, has been possible only through the combined efforts of many outstanding groups using both *in vitro* and *in vivo* studies particularly single and double knock-out mice defective for various cytokines, selectins, glycosyltransferases, mucins, or mucin-like selectin ligands.

Drugs may Inhibit Metastases by Blocking Selectin–Glycan Interactions

Malignant cells misuse the selectin–glycan interactions to metastasize into vascularized distant tissues by presenting at their surfaces increased levels of mucins or mucin-like proteins with multivalent expression of SLe^x, SLe^a, and related glycans (Fig. 1). In a study over a 10-year period it was shown that, 80% of colorectal cancer patients died if there were high levels of SLe^a in their primary tumors, whereas 90% of these patients survived if their tumors lacked expression of SLe^a. The process of metastasizing should not be regarded only as a 1:1 cell interaction since platelets, monocytes, neutrophils, and malignant cells circulating in the blood often produce microparticles which allow for additional networks of selectin–ligand interactions. Many studies have successfully demonstrated the use of blocking the selectin–glycan process for treatment of inflammatory and malignant conditions in animals but so far there has been no break-through in humans. A particularly remarkable effect was however recently shown in a 10-year follow-up of ►colon cancer patients, expressing high levels of SLe^a and postoperatively treated with cimetidine, a histamine-2 receptor blocker usually prescribed for the therapy of gastroduodenal ulcers, where survival increased from 20 to 90%, probably due to the suppressive effect of cimetidine on E-selectin expression on vascular endothelial cells. Glycomimetics, drugs of noncarbohydrate nature but imitating the bioactive conformation of native glycans, are now being tested to selectively block selectin–glycan interactions. Other ways of strategies may be through the antisense cDNA and more recently through the ►siRNA approach.

Concluding Sweet Remarks

The field of glycobiology has generally been considered "harder and less accessible" than other fields dealing directly with proteins and their genes in defining cancer cell phenotypes. This may have been caused by the structural complexity, nomenclature, and methodology of glycans being less straightforward than linear protein or genetic profiling. However, glycoconjugates are intimately involved in most processes of cancer development and research and should be considered essentials for future prevention and treatment of cancer. Improvements in methodology and mutual transfer of basic and clinical knowledge will undoubtedly bridge the gaps between the different fields.

Glycocalyx

Definition

Is a general term referring to extra cellular polymeric material (protein and carbohydrate) produced by cells. The term was first used to describe the polysaccharide matrix excreted by epithelial cells and forming a coating on their surface. A pericellular coat of polysaccharides including hyaluronan, which surrounds the plasma membrane.

►Hyaluronan Synthases
►Carcinoembryonic Antigen

Glycoconjugates

Definition

Type of compounds consisting of one or more ►glycans covalently linked to other types of chemical constituents, such as lipids and proteins.

►Glycobiology

Glycoforms

Definition

Different molecular forms of a ►glycoprotein, resulting from variable glycan structure and/or glycan attachment site occupancy.

►Mucins

Glycogen Synthase Kinase-3

Definition

Is a serine/threonine kinase, which phosphorylates certain cellular substrates involved in various signaling pathways usually causing functional inhibition. Phosphorylation of the substrates often leads to their inactivation.

►BCL3
►Protein Kinase C Family

Glycolipids

Definition

Common name for membrane bound ►glycans linked to a lipid being either ►ceramide (glycosphingolipids) or diacyl-glycerol (glycoglycerolipids).

►Glycobiology

Glycolysis

Definition

Is a series of biochemical reactions by which a molecule of glucose is oxidized to two molecules of pyruvic acid and can occur in the absence of oxygen. A catabolic cellular cascade generating ►ATP and various other metabolites from glucose.

►Warburg Effect

Glycoprotein

Definition

Is a protein modified by the addition of relatively short sugar chains. Is a macromolecule composed of a protein and carbohydrate(s). The carbohydrate is attached to the protein during ►post-translational modification. The addition of sugar chains can happen either at asparagine and is termed N-glycosylation, or at hydroxylysine, hydroxyproline, serine, or threonine, and is termed O-glycosylation. The sugar group(s) can assist in protein folding or improve proteins stability.

►Mesothelin
►Glycobiology
►Gastrointestinal Stromal Tumor

Glycoprotein-340

►Deleted in Malignant Brain Tumours 1

Glycosaminoglycans

Definition

GAG; Gel-forming polysaccharides of the ►extracellular matrix. These polysaccharides are composed of repeating disaccharide units in which one sugar is either N-acetylgalactosamine or N-acetylglucosamine. Typically each disaccharide carries a carboxyl group and often one or more sulfates so that most glycosaminoglycans have a high density of negative charges. The negatively charged molecules can bind strongly to positively charged regions of proteins in a manner similar to heparin. The glycosaminoglycans are often combined with protein to form proteoglycans. Glycosaminoglycans are an important component of the extracellular matrix in vertebrates.

Glycoside

A form of a molecule with a sugar moiety attached to its anomeric carbon via an *O*-glycosidic bond. Plants frequently store molecules as glycosides, which are inactive until they are enzymatically processed.

►Genistein

Glycosphingolipids

Definition

Are ►ceramides with one or more sugar residues.

►Lipid Mediators

Glycosyl Phosphatidyl Inositol

Definition

A GPI anchor or glycosylphosphatidylinositol is a phosphate containing glycolipid that can be attached to a protein during ►post-translational modification. It is linked to the C-terminal amino acid of a mature protein.

►Carcinoembryonic Antigen

Glycosylation

Synonyms

Carbohydrate part of glycoconjugates

Definition

Glycosylation is defined as the covalent attachment of a carbohydrate to a protein, lipid, carbohydrate, or other organic compound, catalyzed by glycosyltransferases, utilizing specific sugar donor substrates.

Characteristics

The type of glycosylation of the different biomolecules can be used to classify the following families of glycoconjugates: The asparagine-linked (*N*-linked) oligosaccharides of many glycoproteins; The serine or threonine-linked (*O*-linked) oligosaccharides that are present on many glycoproteins and that predominates on secreted or membrane-bound ►mucins; the glycosaminoglycans (GAG), which are ►glycans present as free polysaccharides or as part of proteoglycans (such as heparin sulfate and chondroitin sulfate); the ►glycosphingolipids, which consist of oligosaccharides linked to ceramide; the glycosylphosphatidylinositol (GPI)-linked proteins, which are proteins that bear a glycan chain linked to phosphatidylinositol; and nuclear and cytoplasmic proteins, which bear the monosaccharide *O*-linked *N*-acetylglucosamine (*O*-GlcNAc) linked to serine. Glycans can exist as membrane-bound glycoconjugates, for example, forming the glycocalix, or as secreted molecules, for example, as components of the ►extracellular matrix. Gycans mediate key cellular functions such as cell–cell interactions, ►adhesion and ►motility, as well as intracellular signaling events.

Glycosylation Alterations and Functions in Cancer

Altered glycosylation is a common feature of cancer cells. These modifications have been observed both histologically using lectins or monoclonal antibodies, and by mass spectrometry. Changes in glycosylation in cancer include both under- and overexpression of naturally occurring glycans, as well as novel expression of glycans normally restricted to other adult tissues, or structures that arise during development in embryonic tissues. The biosynthesis of these altered glycans generally arises from changes in the expression of the glycosyltransferases. Glycosyltransferases are Golgi-resident enzymes that are responsible for the biosynthesis of oligosaccharide chains. Modification of the set and the level of expression of glycosyltransferases can lead to changes in the structures of protein *N*-linked and *O*-linked gycans as well as glycolipids. Glycans play main roles in the biology of the tumor cells.

Glycosylation and Cell Signaling. *N*-linked glycans participate in the control of protein folding, and play a crucial role in the protein half-life and quality control systems. *N*-glycans may also interfere cellular receptors and tumor growth. *N*-glycosylation on insulin-like growth factor 1 receptor (IGF1R) affects its phosphorylation and therefore influences cell-surface receptor translocation, leading to modification of the signaling and affecting the growth and survival of melanoma and sarcoma cells. Inhibitors of *N*-glycosylation can reduce the survival of cells from tumors that depend on IGF1R signaling.

Glycosphingolipids, particularly ►gangliosides frequently overexpressed in tumors, are also involved in cell signaling and tumor cell growth. Gangliosides are capped with sialic acid, a negatively charged acidic saccharide, on the terminal tip of the glycan. In normal cells, gangliosides are often associated with certain cell membrane ►tyrosine kinases receptors, such as EGF receptor and ►IGF receptor, modulating their phosphorylation and interfering with their growth-promoting functions. The ganglioside G_{M3}, which is commonly expressed in lung cancers, melanomas, and neurogenic tumors, is able to regulate growth signaling through the receptor tyrosine kinases. Gangliosides also contribute for the molecular organization of receptor complexes in lipid rafts. Ganglioside G_{M1} contributes for ERBB3 and ERBB4 receptors to form heterodimers

on lipid rafts on ►breast cancer cell membranes, facilitating ERBB signaling and functions.

Protein *O*-Glycosylation. Another good example of glycoconjugates interfering with cell signaling and promotion of proliferation comes from mucins. Mucins are secreted or membrane-associated glycoproteins that contain clusters of *O*-glycans in a central domain of the core protein. The ►mucin (*MUC*) gene family includes several members of glycoproteins that are expressed in a tissue- and cell-specific manner. Most carcinoma expresses mucins with altered *O*-glycan chains. Membrane-associated mucins can interfere with signal transduction. MUC4 mucin is overexpressed in mammary tumors, contains an epidermal growth factor (EGF)-like motif on its extracellular (juxtamembrane) domain which interacts with the ►ERBB2, initiating phosphorylation of the receptor tyrosine kinase in the absence of other ligands. In breast carcinomas, ERBB2 is frequently overexpressed or mutated in an active form. Experimental studies have showed that MUC4 overexpression increases cell growth and that MUC4 overexpressing cells can autophosphorylate ERBB2, contributing for the inhibition of ►apoptosis. *O*-glycans on MUC4 play an important role in the protein folding leading to the exposure of the EGF-like domain and its activity in cancer cells. Another membrane-associated mucin, ►MUC1 shows an altered *O*-glycosylation carrying several cancer-associated carbohydrate antigens. The cytoplasmic tail of MUC1 can be phosphorylated following mucin interactions with other partners. This may modify signaling pathways and affect β-catenin signal transduction by two mechanisms: MUC1 might be cleaved in the cytoplasm and move with β-catenin to the nucleus thereby influencing transcription, or it might sequester β-catenin in the cytosol and therefore prevent it from interacting with the cadherins or other complexes, thereby influencing ►WNT signaling. Mucin *O*-glycans are also involved in the invasive and metastatic properties of adenocarcinomas by simultaneously configuring the adhesive and antiadhesive cell-surface properties of tumor cells. Mucin *O*-glycans contain domains that mediate both antiadhesion and adhesion effects, and might block proteolytic activity.

Proteoglycans may function as coreceptor for soluble growth factors. The structure of ►Proteoglycans consists of a core protein and one or more GAGs. GAGs are linear polysaccharides composed of repeating disaccharide units (GlcNAc in heparan sulfate or GalNAc in chondroitin sulfate) linked to uronic acid (GlcA or IdoA). Most mammalian cells produce proteoglycans that may be secreted to the extracellular matrix, inserted into the plasma membrane or stored in secretory granules. GAG binding to a protein ligand may cause: (i) immobilization of the protein ligand at site of production, (ii) interference with enzyme activity, (iii) interaction with signaling receptors, (iv) protection of ligands against degradation, and (v) reservation of ligand for future mobilization. These interactions lead to profound physiological effects, affecting processes such as: cell–matrix (interaction with ►fibronectin, ►laminin, and ►thrombospondin), growth (interaction with ►fibroblast growth factors, ►transforming growth factor-β), ►angiogenesis (interaction with vascular endothelium growth factor), and ►inflammation (interaction with selectins, ►interleukin-8, and others). The tumor ►microenvironment often shows significant alterations in content of proteoglycans. Cancer cells seem to usurp GAG mediated functions to promote tumor growth, progression, and ►invasion. For example, ►breast cancer, ►ovarian, ►pancreatic cancer, and ►hepatocellular cancer cells modulates sulfation of proteoglycans in a manner that promotes their binding capability for growth factors and inducing receptor tyrosine kinase activation.

Glycans in Tumor Cell Adhesion and Invasion. *N*- and *O*-glycosylation of glycoproteins controls different tumor cell biological properties. One of the best studied modification observed in cancer cells is the increased expression of complex β1,6-branched *N*-linked glycans on their cell surface. This alteration is caused by an increased expression of the enzyme *N*-acetylglucosaminyltransferase V (GnTV). This enzyme transfers a GlcNAc residue onto growing *N*-linked glycans so that the subsequently glycosylation results on multiantennary chains. This increased branching creates additional sites for terminal sialic acid residues, which, together with the corresponding upregulation of sialyltransferases, may lead to an increased sialylation. The expression of complex β1,6-branched *N*-glycans has been shown on tumor cell ►E-cadherin – an adhesion molecule that mediates cell adhesion through homotypic interactions and β1-integrin. Increased β1,6-branched *N*-glycans on tumor cell E-cadherin reduces cell–cell adhesion, and promotes tumor cell detachment and invasion. The coordinated control of expression of GnTV and other molecules, such as E-cadherin, contributes for the modulation the adhesion and invasion phenotype of tumor cells.

Alterations in *O*-glycosylation are common feature observed in glycoproteins expressed in tumors cells. These alterations include the expression of simple mucin-type *O*-linked carbohydrate antigens, such as the Tn, sialyl-Tn, T, and sialyl-T antigens, which are rarely expressed in normal cells. The biosynthesis of these glycans may occur due to different reasons, such as: altered expression and cellular mislocalization of glycosyltransferases, imbalanced competition among glycosyltransferases for acceptor substrates, and overexpression of acceptor substrates. The sialyl-Tn antigen is a good example of a simple *O*-linked glycan that is abnormally expressed in membrane-associated and

secreted glycoproteins, mainly mucins, from tumor cells. Sialyl-Tn expression is associated with an aggressive phenotype. ►Transfection of ►gastric cancer and ►breast cancer cells with the cDNA that encodes the sialyltransferase responsible for sialyl-Tn biosynthesis (ST6GalNAc-I) modifies cell–cell aggregation, and increases migration and the cell invasion potential. These observations are in agreement with the association of sialyl-Tn expression and the increased metastatic potential and poor prognosis observed in colorectal, gastric, and ovarian carcinoma.

In addition to changes in the core structures of glycans, alterations of terminal structures are also associated with malignant phenoptype. Glycosyltransferases involved in the biosynthesis of terminal structures, such as sialyltransferases and fucosyltransferases, frequently show altered expression in tumors. The altered expression of these enzymes leads to overexpression and/or neoexpression of terminal glycans, namely: sialyl-►Lewis X (S-Le^x), sialyl-Lewis A (S-Le^a), among others. These terminal structures can be carried on *O*- and *N*-linked glycans on proteins as well as on glycolipids.

The expression of S-Le^x and S-Le^a in cancer cells can promote ►metastasis through the interaction with Selectins. Selectins normally mediate adhesion between ►leukocytes (which express L-selectin), ►platelets (P-selectin) and ►endothelial cells (E- and P-selectins) that bear the appropriate glycosylated ligand. This ligand consists of oligosaccharides containing the terminal S-Le^x structure. The presence of such ligand on blood cells (such as monocytes or neutrophils) or in endothelial cells induces the transmigrations of leukocytes to sites of inflammation and/or infections, as well as of platelets to sites of vascular damage. In contrast to their normal counterpart, tumor cells from ►gastric cancer, ►colon, ►pancreatic cancer, and ►lung carcinoma, frequently overexpress S-Le^x, or S-Le^a on glycoproteins and glycosphingolipids. The expression of these glycans is associated with poor prognosis for the patients. These glycans have been shown in metastatic tumor cells in the blood of colon carcinoma patients and demonstrated to bind to ►E-selectin. Likewise, overexpression of E-selectin in a transgenic mouse liver induced redirection of the metastatic patterns of syngenic carcinomas that normally metastasizes the lung. Furthermore, the use of a specific disaccharide decoy that acts as a competitive substrate of glycosyltransferases reduced the levels of S-Le^x on colon carcinoma cells. In comparison to untreated cells, these S-Le^x-deficient cells showed decreased interactions with selectins, increased susceptibility to leukocyte-mediated lysis, and reduction of lung ►metastasis in a murine tumor model. These studies, together with the clinical data, indicate that interactions between glycans and selectin molecules play a role in the metastatic process of some carcinoma cells. In summary, this may fit with the classical observation that cancer cells entering the bloodstream tend to form thromboemboli with platelets and leukocytes, probably facilitating the transport to distant sites, contributing to evasion of the immune system, and finally participating in the process of extravasation in the distant metastatic site.

Alterations in the levels of sialylation, namely oligosaccharide chains containing terminal sialic acid are also often observed in tumor cells. This is the case of sialic acid capping terminal galactose in *N*-linked glycans by the enzyme ST6Gal-I, which is upregulated in colon and breast cancers. Hypersialylation of glycans on β1-integrins augment colon tumor progression by altering cell preference for certain extracellular matrix milieus, as well as by stimulating cell migration. In addition, Polysialilation controlled by polysialyltransferases can modulate the sialylation of molecules, such as NCAM in human tumor cells, which has been linked to cancer development and dissemination.

Glycans Used as Serological Markers in Cancers

The most widely used serum diagnostic assays for carcinomas are based on serum measurement of certain glycans. These serological assays are currently used to facilitate diagnosis, track tumor recurrence or tumor burden or provide a surrogate measure for therapeutic response. For example, the serological marker ►CA125 detects the MUC16 glycoprotein and its detections in the serum of ovarian cancer patients is associated with tumor burden and prognosis. Another useful serological assay is the ►CA19-9, which recognizes the S-Le^a carbohydrate antigen present on mucins and glycolipids. CA-19-9 can be used in pancreatic, gastric, and colorectal carcinomas. The CA15-3 assay, which recognizes the MUC1 mucin glycoprotein, is also a useful marker commonly overexpressed in breast carcinomas with serum levels also associated with tumor burden and prognosis. In an attempt to improve their clinical application of the serological assays, a combination of the existing assays against carbohydrate structures detected in the serum have improved the sensitivity with a concomitant loss of specificity. Other assays with higher specificity are under investigation.

Therapeutic Applications of Glycans in Cancers

Various therapeutical approaches are being developed targeting glycans. These strategies include the targeting of glycans that affect tumor proliferation, such as the interference with the coreceptor activity of proteoglycans on tumor cells. In addition, various approaches are targeting glycan during invasion using methods to block specific *N*- and *O*-glycosylation steps as well as the use of competitors of proteoglycans that, once again interfere with tumor cell invasion.

Tumor cell dissemination is another step in which glycans can be targeted. Agents that can interfere with selectin – carbohydrate interactions have been considered for the treatment of metastatic disease. These interactions can be targeted through the administration of neutralizing antiselectin antibodies or small molecules that mimics the SLeX or SLeA selectin ligands. The applicability of such experimental therapies to clinical tumor biology and metastasis remains challenging but the importance of this strategy warrants further development of this class of therapeutic agents, which might work best in combination with conventional chemotherapy.

In addition, several immunotherapy based approaches are being tested in preclinical and ►clinical trials targeting cancer-associated mucin glycans expressed on adenocarcinomas. These trials include ►monoclonal-antibody-based therapies – either ►radioimmunoconjugates or passive ►immunotherapy and ►antitumor vaccines.

Monoclonal-antibodies directed to cancer associated glycans, such as S-Tn, and glycan carriers, such as MUCl mucin have been used as radioimmunoconjugates. Second generation approaches are under development, such as the use of humanized forms of the murine antibodies as well as recombinant single-chain variable fragments, which have a much smaller mass than full antibodies and therefore are capable of reaching most cells in a tumor.

Another immunotherapy based approach aims at augmenting the immunity against tumor mucin glycans. A tumor's ability to generate and overexpress unique mucins and glycans is now being used to improve or augment the immune system's ability to recognize and destroy tumor cells. Methods to destroy tumor cells using vaccines that target the tumor mucins MUC1 or MUC16, or the cancer-associated S-Tn glycan, have been introduced. Vaccines of this type are typically prepared by conjugating the glycan to a carrier protein, and then injecting the compound into the patient together with an adjuvant that boosts T-cell responses. Vaccines that contain these epitopes are currently being used in breast, colorectal, and ovarian cancer patients to augment antitumor immune responses. In addition, peptide mimetics of tumor carbohydrates, such as SLeX, SLeA, or SLeY, have also been shown to stimulate tumor immunity in animal models. In another promising strategy, antitumor immunity has been generated by making unique alterations to tumor-cell surface sialic acids (which are normally tolerated by the immune system). This might be accomplished by introducing unnatural sialic acid precursors to tumors whereby metabolic incorporation leads to the generation of unnatural sialic acid epitopes, forming the basis for the induction of novel antitumor immune responses.

Other approaches have targeted at augmenting immunity against tumor glycosphingolipids. Some tumors express very high levels of immunogenic gangliosides, and often shed them into the bloodstream. Paradoxically, this can lead to immune silencing, by inhibition of costimulatory molecule synthesis and by the arrest of dendritic-cell maturation, resulting in the inability to generate effective antitumor T-cell immune responses. Although glycosphingolipids are relatively poor immunogens, certain glycosphingolipids might be manipulated to generate both passive and active immunity by eliciting a host response to a tumor glycan. Immunization with purified GD2 or GM2 gangliosides are being used in current clinical trials against melanoma (using GD2–KLH), neuroblastoma (using anti-GD2 small immunoproteins), breast (using NeuGcGM3 proteoliposomes that contain the *N*-glycolyl form of sialic acid), and prostate carcinomas (using a conjugate between KLH and Globo-H hexasaccharide, a glycan expressed on prostate and breast cancer glycolipids).

Finally, liposomal drug-delivery techniques such as ►antisense oligodeoxynucleotides directed to inhibit the synthesis of ►oncogenes have been delivered to human ►neuroblastomas by encapsulation in cationic ►liposomes that have been covalently coupled to monoclonal antibodies against the GD2 ganglioside expressed in the tumor cells.

G2/M Arrest

Definition

Stop of ►cell cycle at G2 or M phase.

►Thiazolidin
►G2/M Transition

G_2/M Checkpoint

Definition

Is a point in the G2 phase of the ►cell cycle where cells become arrested in response to ►DNA damage. The G2/M ►checkpoint is regulated by proteins that modify or sequester the components of the ►Cyclin B/Cdc2 kinase complex, the principal enzymatic activity responsible for the initiation of ►mitosis. It is one of two major checkpoints (G1/S and G2/M) at which the transition from one phase of the cell cycle to the next can be stopped. The initiation of mitosis is subject to a number of checkpoint controls. These controls serve to arrest cell-cycle progression, if progression

would otherwise result in progeny with incomplete or damaged genomes. To progress into mitosis, the nuclear DNA of a cell has to be completely replicated and be in an undamaged state so it can condense into complete chromosomes. Cells in G2 phase that sustain DNA damage will arrest prior to entering mitosis. This arrest continues until their DNA is sufficiently repaired. If damage cannot be repaired, ►apoptosis is induced. Other conditions such as separation of ►centrosomes to allow spindle pole formation are also necessary for a cell to begin the G2/M transition. As transformed cells typically lack some G2/M checkpoint mechanisms and most studies have been carried out using such cells, it is likely that there exist additional checkpoint conditions yet to be identified.

►G_2/M Transition
►Oxidative DNA Damage
►Trefoil Factors
►G2/M Transition

G_2/M Cyclins

Definition

The ►cyclin family members can be divided into G1/S and G2/M subfamilies depending on when their associated ►cyclin-dependent kinase (CDK) activity peaks. Cyclins B1, B2 and A are all G2/M cyclins. In humans these cyclins localize CDK1 to different parts of the cell as it enters ►mitosis. This probably confers some degree of substrate specificity and allows them to be differentially regulated, by keeping CDK1 away from or in contact with its respective regulators. Cyclin A/CDK2 is localized to the nucleus. Its role in inducing G2/M events is unclear, however its activity peaks at this point of the cell cycle.

Cyclin B1/CDK1, translocated to the nucleus at G2/M, can initiate ►NEBD, inactivate the nuclearly localized inhibitory kinase wee1 and activate nuclearly localized phosphatase cdc25C. The abundance of this complex (cyclin B1/CDK1) enables it to efficiently phosphorylate many other substrates at the G2/M transition.

Cyclin B2CDK1, present at much lower amounts within the cell as compared to cyclin B1/CDK1, is localized to the Golgi apparatus and is involved in breaking up of this organelle during mitosis.

►G_2/M Transition

G_2/M Transition

Mark Jackman
Wellcome/CRC Institute, Cambridge, UK

Definition

The G2/M transition is a decisive point in a cells life cycle. The point at which, after successfully completing a second growth phase (G2 phase) following the replication of its DNA (S phase), it begins ►mitosis (M phase), the phase during which it physically separates itself into two daughter cells (Fig. 1).

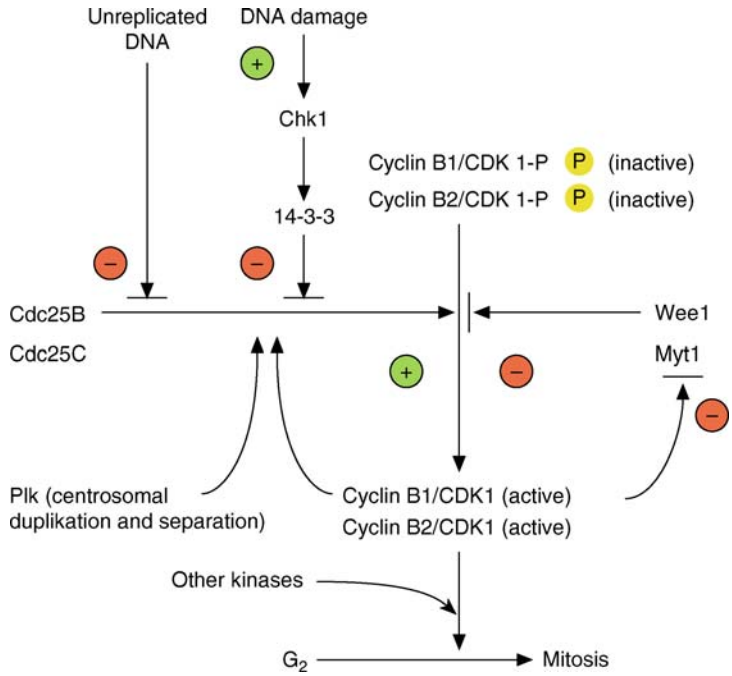
Characteristics

To divide itself equally into two daughter cells a cell must fundamentally change almost all of its structures. These dramatic structural changes become apparent at the G2/M transition. In addition to these structural changes, RNA processing stops and majority of mRNA ►translation is repressed (there are some specific mRNA sequences that can overcome this inhibition allowing them to be translated during mitosis). The G2/M transition occurs because of a pivotal shift in the balance of kinase and phosphatase activities within the cell. A cell will not usually commit to such big changes unless a number of criteria have been met, such as accurate replication of its DNA or separation of its centrosomes. Such criteria are sensed and acted upon via ►G2/M checkpoint pathways.

Structural Changes at the G2/M Transition

One of the first visible signs that a cell is about to enter mitosis is the increasing compaction of its DNA. Cells stained with fluorescent DNA-binding dyes typically show a more granular nuclear staining pattern than is normally seen. As DNA becomes more condensed (a process known as ►chromosome condensation), the nuclear envelope surrounding it disassembles (a process called ►nuclear envelope breakdown or NEBD). NEBD effectively breaks the down nuclear-cytoplasmic compartmentalization within the cell. The ►nucleolus within the nucleus also disassembles causing RNA synthesis and processing to stop.

In the cytoplasm, membrane trafficking and sorting between the ►endoplasmic reticulum, Golgi apparatus and ►plasma membrane ceases. At the same time the endoplasmic reticulum and Golgi apparatus fragment, enabling these organelles to distribute themselves easily between the two daughter cells. Anchored cells grown in culture begin to round up at G2/M; this is due to profound changes in the ►cytoskeleton seen in all cells as they enter mitosis. Actin and intermediate filament networks are reorganized. ►Microtubules undergo a



G_2/M Transition. Figure 1 Regulating the G2/M transition.

dramatic change in their dynamic stability i.e. the rates at which they grow and shrink in length. The number of microtubules nucleated from each centrosome increases approximately tenfold, but the length of these more abundant microtubules decreases by tenfold. This change in microtubule dynamics together with the separation and moving apart of the two centrosomes allows the formation of a ►spindle apparatus. The spindle apparatus functions to organize the chromosomes into an aligned configuration, a stage in mitosis known as metaphase. Following metaphase, the pairs of ►sister chromatids can separate from one another and migrate to the opposite poles of the spindle apparatus (a stage known as anaphase), allowing the final stage of mitosis (telophase) to proceed.

Triggering G2/M Transition

Many kinases and phosphatases are needed for a cell to complete its G2/M transition. The best characterized and most important of these being the cyclin B1/cyclin-dependent kinase (►CDK1), sometimes called ►maturation promoting factor (MPF). Cells injected with active cyclin B1/CDK1 can be induced to enter mitosis. Cyclin B1/CDK1 activity, often taken as a measure of the mitotic state of a cell lysate, can be measured by its ability to phosphorylate exogenously added histone H1 as this is a very good in vitro substrate of cyclin B1/CDK1. The importance of cyclin B1/CDK1 in its activity for driving a cell into mitosis is reflected in the many ways in which its activity is regulated.

Members of the cyclin protein family each bind to a specific member of the ►cyclin-dependent kinase (CDK) family of serine/threonine kinases. CDK's alone are inactive, however when bound to a cyclin, the conformation of CDK changes to an active one. Thus the amount of cyclin within the cell regulates the amount of potential CDK activity. Cyclin B1 is the most abundant ►G2/M cyclin protein and it associates with only one member of the CDK family, CDK1. It accumulates throughout S and G2 phase, rapidly associating with CDK1 as it is synthesized (CDK protein levels are usually in excess of that of cyclin B1). This would cause a slow increase in CDK1 kinase activity as the cell progresses through S and G2 phases, but CDK1 is rapidly made inactive by an inhibitory phosphorylation that blocks the active site of the CDK. This inhibitory phosphorylation is carried out by two kinases, wee1 and myt1, which are localized in the nucleus and cytoplasm, respectively. Wee1 and myt1 kinases allow the cyclin B1/CDK1 complex to stockpile in an inactive state. Removing the inhibitory phosphate masking the active site, rapidly activates accumulated cyclin B1/CDK1 causing the cell to enter mitosis. Cdc25C is the major phosphatase that removes the inhibitory phosphate on CDK1 and thus triggers cyclin B1/CDK1 activation. Cdc25B, another cdc25 family member, is also activated at G2/M, although there is much less of this in the cell relative to Cdc25C. Positive and negative feedback loops reinforce the quick activation of cyclin B1/CDK1; cdc25 phosphatase activity and wee1 kinase activity can be activated and

inhibited respectively by phosphorylation by cyclin B1/CDK1. It is also likely that the timely destruction of the wee1 kinase helps to trigger and maintain activation of cyclin B1/CDK1.

Cells in G2 phase that sustain DNA damage delay activation of their cyclin B1/CDK1 and thus their progression into mitosis. G2/M checkpoint controls converge to a point where the phosphorylation state of CDK1 complexed to ►G2/M cyclins is regulated. Cells expressing a mutated CDK1 that cannot be inhibited by Cdc25 can partially by-pass a DNA damage induced checkpoint arrest. Chk1 and cds protein kinases are two conserved nuclearly localized kinases needed for the DNA replication and DNA damage G2/M ►checkpoints. When activated by the presence of inappropriate DNA breaks or incomplete DNA replication, both phosphorylate cdc25C phosphatase and in doing so create a ►14–3–3 protein-binding site. 14–3–3 protein bound to cdc25p blocks cyclinB1/CDK1 activation by inhibiting the phosphatase's activity and exports nuclearly localized cdc25C protein to the cytoplasm.

The dynamic localization of key enzymes involved in the G2/M transition is important in regulating entry into mitosis. During interphase, cyclin B1 shuttles between the nucleus and the cytoplasm, but at steady state it is primarily cytoplasmically localized. A defining moment in the G2/M transition is the rapid nuclear translocation of cyclin B1/CDK1. This is brought about both activating its rapid nuclear import and inhibiting its nuclear export. Shifting cyclin B1/CDK1 into the nucleus is thought to expose it to nuclearly localized activating cdc25 protein. Thus the movement of cdc25 protein out of the nucleus by 14–3–3 protein stops cyclin B1/CDK1 from being activated in the nucleus.

Although Cyclin B1/CDK is the most important kinase in triggering the G2/M transition, many other kinases and phosphatases are active upon mitotic entry making it difficult to ascribe specific substrates to each kinase. ►Polo-like kinase (Plk) functions in multiple stages of mitosis. During G2 phase of the cell cycle and early phases of mitosis it is localized to centrosomes and spindle poles where its activity is necessary for centrosome separation and bipolar spindle formation. It may also play a role upstream of cyclin B1/CDK1 activation by helping to activate the cdc25 phosphatase.

Synonyms

LRF, luteinizing hormone (LH)-releasing factor; LHRH, LH-releasing hormone; GnRH, gonadotropin-releasing hormone

Definition

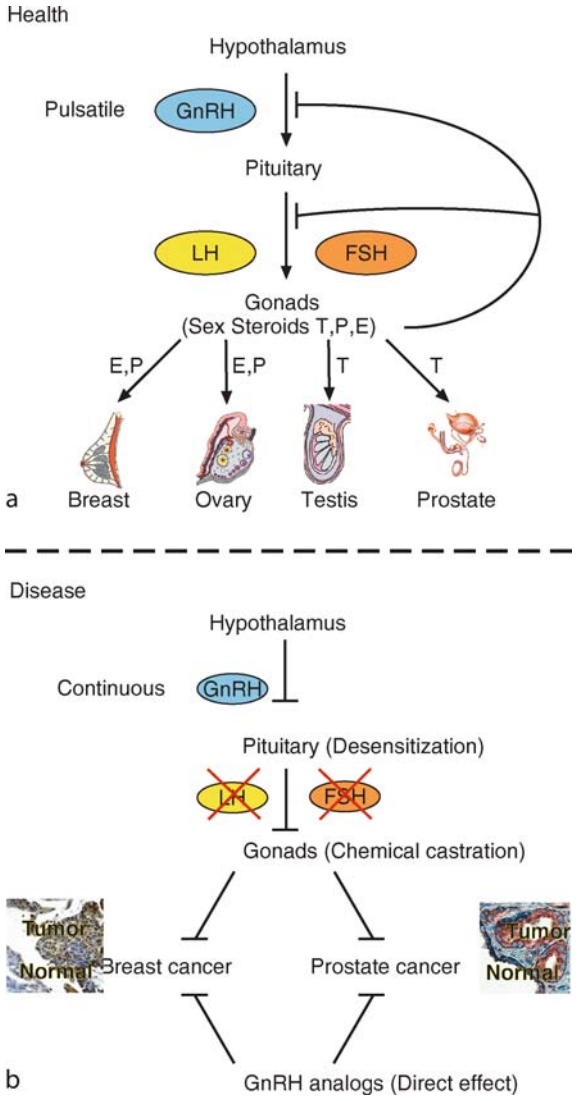
GnRH is the central regulator of reproduction. GnRH binds and activates its cognate receptor in pituitary ►gonadotropes, resulting in the synthesis and release of luteinizing hormone (LH) and follicle stimulating hormone (FSH) that control ovulation and spermatogenesis.

Characteristics

To isolate GnRH, Andrew Schally's group collected 2.5 million pig brains, while Roger Guillemin's group collected 5 million sheep brains, and while competing, both groups have announced in 1971 the isolation and structure of GnRH as pGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly.NH_2. For their outstanding work, both Guillemin and Schally received the Nobel Prize for Medicine in 1977.

The pulsatile nature of hypothalamic GnRH secretion is absolutely required for physiological maintenance of ►gonadotropin (LH and FSH) secretion. Continuous exposure of the pituitary to GnRH results in desensitization of gonadotropin secretion. This homologous desensitization will result in reduction in LH and FSH levels and gonadal steroid sex hormone (►progesterone, ►estrogen, and ►testosterone) levels. Since the steroid sex hormones are required for the functioning of the gonads and many of their cognate cancers, their removal causes malfunction of dependent organs (breast, ovary, testis, and prostate). This phenomenon is known as ►chemical castration (Fig. 1) and is the basis for the wide use of stable and long acting ►GnRH analogs (GnRH-A) in fertility regulation, precocious puberty, ►uterine leiomyoma, ►endometriosis and ►sex hormone-dependent cancers, such as ►prostate cancer and ►breast cancer.

As "chemical castration" agents, GnRH-A (e.g., Leuprorelin, Buserelin, Goserelin, Histrelin, Deslorelin, Nafarelin, and Triptorelin) have a drawback since they initially stimulate gonadal functions before desensitization occurs (castrate levels of testosterone (<50 ng/dl)



Gonadotropin-Releasing Hormone. Figure 1 GnRH actions in the pituitary, the normal physiological actions (a), the "chemical castration effect" and the direct effects of GnRH analogs upon cancer cells (b) are depicted in this model. LH, luteinizing hormone; FSH, follicle stimulating hormone; T, testosterone; P, progesterone; E, estrogen.

take at least 15 days of treatment). This "tumor flare" effect has first promoted the additional use of antiandrogens for prostate cancer (e.g., Bicalutamide, Flutamide, Nilutamide, Megestrol, and Cyproterone) and later the use of several generations of GnRH peptide antagonists (e.g., Abarelix, Antarelix, Cetrorelix, Ganirelix, Antide, Teverelix, FE 200486, and Nal-Glu), which compete with endogenous GnRH for binding to its receptor (castrate levels of testosterone can be achieved after 4 days of treatment). For example, abarelix (the first GnRH antagonist that was approved for clinical use in the USA), became a good alternative to surgical castration, or GnRH agonists plus antiandrogen. The high dose of the antagonists required for cancer treatments, the high cost, side effects (allergic reactions), and low solubility prompted the synthesis of further generations of peptide antagonists, long acting delivery systems and the development of nonpeptide, orally active GnRH antagonists, which are in clinical trials (e.g., TAK-013, TAK-810 and NBI-42902). GnRH agonists are mainly created by substituting the Gly6 with a D-amino acid (Leu, or Ser, or His, or Trp) and the Gly-NH_2 at the 10 position with N-Et-NH_2. The GnRH antagonists require substitution of the 1–3, 6, and the 10 positions in order to be pharmacologically effective. The nonpeptide, orally active GnRH antagonists are based on the structure and/or derivatives of tetracyclic benzodiazepine, ketoconazole, spiroamines, thienopyridines, indole, quinolone, erythromycin A, and imidazolpyrimid-5-ones, which conform to a basic structure of a basic protonable nitrogen group, one or two aromatic groups, and an aliphatic lipophilic group. These nonpeptide GnRH antagonists show marked species selectivity, which is a hindrance in the actively ongoing drug discovery progress. Unlike surgical castration, the use of GnRH agonists plus antiandrogens, or the use of GnRH antagonists, or the treatment with nonpeptide, orally active GnRH antagonists is reversible. This is of great importance in the treatment of young adults. For example, in breast cancer patients who are estrogen and progesterone receptor positive, treatment with GnRH agonists (e.g., goserelin) was found to be as effective as surgical oophorectomy in premenopausal women.

Sex hormone ablation by GnRH-A is achieved during prolonged treatments. However, prostate cancer, which is initially hormone-dependent, may become eventually hormone-refractory, and is no longer sensitive to the GnRH-A-mediated reduction in androgen levels. Similarly, removal of sex hormones by GnRH-A is not relevant to hormone-insensitive breast and ovarian cancer (►Hormones). GnRH-A may also be useful in treating these types of tumors by direct binding to them. The actions of GnRH are mediated by the GnRH receptor (GnRHR), a type A ►G-protein coupled receptor (►GPCR), (►G-proteins) that is expressed in both the pituitary and extrapituitary sites, including normal tissues and tumors. Expression of GnRH and GnRHR, as well as direct growth regulatory effects of GnRH-A in sex hormone-dependent tumor cells, has been reported for cancers of the breast, ovary, and prostate. Interestingly, in these cells, GnRH-A reduce proliferation and induce ►apoptosis, which is mediated by the GnRHR via ►signal transduction mechanisms that are distinct from the classical pituitary pathways. The understanding that GnRH-A can be used not only to reduce androgen levels but also as a direct antiproliferative factor, as well as the binding of

GnRH-A to some cancer cells, may open a new vista into the design of novel GnRH-A for the treatment of hormone-refractory cancers.

The direct effects of GnRH-A may influence a large portion of sex hormone-dependent cancers. Some 85% of human prostate cancers, 80% of endometrial cancers, and 50% of breast cancers express GnRH and GnRHR (type I, the same as in pituitary gonadotropes). Obviously, hypothalamic GnRH does not reach the tumors. It is thought that GnRH is expressed in the tumors and might act in an autocrine/paracrine fashion by binding to local GnRHR. In these tumor cells, the activated GnRHR transmits its signal via Gαi and activation of the ►protein kinase C (PKC) and the ► Map kinase (MAPK) pathways, culminating in an antiproliferative and/or apoptotic effect. Hence, cancer cells are under the influence of opposing survival (e.g., ►EGF, ►IGF-1), versus apoptotic (e.g., GnRH) signaling pathways, which are elicited by hormones produced in the tumors and which are acting in an ►autocrine/►paracrine mechanism. As the cancer progresses, it is obvious that the survival arm is prevailing. It is the researcher role to find the means to increase the apoptotic arm. GnRH-A seem ideal for this task as they can act as "chemical castration" effectors in sex hormone-dependent tumors, or by inducing either direct or toxin-amplified antiproliferative and/or apoptotic actions in sex hormone-independent tumors.

One way that is currently used to employ the direct binding of GnRH-A to tumor cells is the GnRH-toxin therapy. As mentioned above, the expression of GnRHR in tumor cells provided the option for GnRH based targeted toxins. Conjugates of GnRH were prepared by adding various toxins such as: *Pseudomonas* exotoxin, diphtheria toxoid, glutaryl-2-(hydroxymethyl)-anthraquinone, and 2-pyrrolinodoxorubicin, and were shown to be effective in animal models and initial clinical trials in humans. This approach is based on the assumption that the number of GnRHRs in the targeted tumors will be higher than in normal tissues. The second assumption is that the GnRH-toxin conjugate will bind to GnRHRs, followed by internalization of the hormone-receptor complex and release of the hormone-toxin in the cell to exert its killing effect. The third assumption is that the GnRH-toxin conjugate will be provided once to destroy pituitary gonadotropes and cancer cells, a great advantage over the life-long therapy with GnRH-A. Obviously, pituitary gonadotropes have the highest receptor density and will be the prime target of the GnRH-toxin. The conjugate will therefore destroy the gonadotropes and lower gonadotropin (►LH and ►FSH) levels, resulting in "chemical castration" due to lowering of gonadal sex steroids (progesterone, estrogen, and testosterone) (Fig. 1). Thus, the GnRH-toxin conjugate will act at both the pituitary levels and also directly on the GnRHR-expressing cancer cell. This is of advantage during the hormone-sensitive state of the cancer (breast and prostate), while the direct effect of the conjugate will be beneficial during the hormone-resistant phase. The direct effect will be important also in ovarian cancer, since ovarian cancers are less dependent on gonadal steroids as compared to breast and prostate cancer. GnRH-toxin conjugates can be prepared by chemical synthesis or by recombinant fusion proteins (e.g., GnRH + *Pseudomonas* exotoxin). However, while natural GnRH is used for the fusion protein, GnRH-A with D-amino acid (e.g., Lysine) are used for chemical synthesis. Various studies have utilized GnRH-toxin conjugates in rat and ovine pituitary cells, as well as in human cancer cell lines. Once established in cells, the conjugates were tested successfully in various nude mice xenograft models, in dogs (to demonstrate the ability of the GnRH-conjugates to destroy pituitary gonadotropes), and initial clinical trials in humans with advanced prostate cancer have been initiated.

Studies in various laboratories are underway to evaluate the effects and signaling involved in the direct growth suppressive effects of GnRH-A in cancer cells. It seems that GnRH stimulates a "life" signal in pituitary gonadotropes and a "death" signal in cancer cells. Identification of the "death" signal, in particular for sex hormone-insensitive cancer cells, may enable an increase of the beneficial effect of GnRH-A in cancer patients by the combined treatment with GnRH-A and the "death" signal regulator. As second messengers mediate hormone action, the idea is to use GnRH-A and to "kill the messenger," particularly for advanced sex hormone-insensitive cancers.

In summary, GnRH-A can be multifaceted drugs in the cure of ►sex hormone-dependent tumors. GnRH-A can act as "►chemical castration" effectors, or by inducing either direct or toxin-amplified antiproliferative and/or apoptotic and killing actions in sex hormone-independent tumors. However, more studies are required in order to optimize and design future generations of GnRH agonists and antagonists for the treatment of hormone-independent tumors, for which there is no cure to date.

Good Laboratory Practices

Dennis F. Michiel
Biopharmaceutical Development Program, SAIC-Frederick, Inc., National Cancer Institute-Frederick, Frederick, MD, USA

Definition

GLPs; Are the legal requirements delineated by the FDA in 21 CFR Part 58 governing testing laboratories to ensure the quality of nonclinical laboratory studies related to safety of regulated health care products.

Characteristics

Principles

Following incidents of scientific fraud and laboratories not following their protocols in drug testing, the FDA issued Good laboratory Practices in December 1978 as 21 CFR Part 58 (Major Revision 1987) to govern nonclinical safety studies for food, drugs and medical devices. The US Environmental Protection Agency adopted two sets of GLPs in 1979 as part of the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA), which was codified as 40 CFR part 160, and as part of the Toxic Substances Control Act (TSCA), codified as 40 CFR 792. In 1980 the Organization for Economic Cooperation and Development (OECD, www.oecd.org) also issued a set of international GLPs (revised in 1997) applicable to non-clinical safety studies, pesticides and chemicals. Similar to the US, Japan has three sets of GLPs, covering drugs, industrial chemicals and pesticides. Fortunately, the basic principles of GLPs are similar and accurate documentation is the foundation of GLPs and other GXPs. As with GMPs, when working with a contract laboratory the ultimate responsibility for GLP compliance resides with the study sponsor.

The core of the FDA's GLPs are divided into the following major sections in 21 CFR Part 58 that individually address the general requirements for GLP operations:

Subpart A: General Provisions

Subpart B: Organization and Personnel

To be GLP compliant, a laboratory has to have a quality assurance unit, qualified and properly trained personnel and a study director must be appointed for each nonclinical study. Personnel should have adequate education, experience and training to carry out their function. Additionally, it is important that the management organizational structure be defined and personnel aware of their position and responsibilities within the organization. A study director must be appointed for each study and they have the responsibility for the conduct of the study and for the interpretation and review of the results. The Quality Assurance unit is charged with the interpretation and enforcement of GLPs and ensuring that studies are performed in compliance with standard operating protocols and GLPs. Internal audits carried out by Quality Assurance are a major part of a good quality system verifying compliance with GLPs.

Subpart C: Testing Facility

Facilities must be adequate in size and construction to be able to perform the studies. Special attention is paid to animal care facilities to ensure studies are not compromised by cross contamination, either from diseased animals, infestations or other poor animal handling.

Subpart D: Equipment Design

Laboratory studies generally rely on sophisticated equipment and this equipment should be suitably designed and used to perform its lab function. For example, weighing to an accuracy of ± 1 mg of a compound on a balance that is only accurate to 0.01 grams would not be allowed. Additionally, this equipment must be cleaned, maintained and calibrated at regular intervals and this maintenance must be documented.

Subpart E: Testing Facility Operation

As with GMPs, the main business mechanism for compliance with GLPs is through the drafting of well-written Standard Operating Protocols (SOPs) that define how processes are to be performed. This includes management processes, animal care and handling, handling of samples, standards and reagents, maintenance and calibration of equipment, performance of tests and analyses, and handling of data with an emphasis on ensuring the quality and integrity of data generated by a study.

Subpart F: Test and Control Article Characterization

Samples that are to be placed on a test and the control articles are to be characterized as to their identity, strength, purity, composition and method of fabrication as well as other considerations such as stability. Since GLP testing is often performed at contract laboratories, the contract laboratories generally include a statement in their report that these characterizations are the responsibility of the study sponsor.

Subpart G: Protocol and the Conduct of the Non-clinical Laboratory Study

Each study is required to have an approved study protocol or study plan that clearly indicates the purpose of the study and describes the methods used to conduct the study, including reference to the appropriate SOPs. The study needs to be performed in accordance with its study protocol, all data recorded promptly and according to good documentation practices. Any changes or deviations to an approved study protocol need to be documented, with reasons for the changes, and approved by the study director. If data is to be collected or maintained in an electronic format, then this should be done according to 21CFR Part 11, although compliance with Electronic Documents Part 11 is an area of ongoing revision.

Subpart H & I: (Reserved)

Subpart J: Records and Data Reporting

The accuracy and integrity of GLP study records are crucial for the validity of future work performed on the test article. A final report is prepared for each study and approved by the study director and the quality assurance unit. Protocols, data, specimens (if possible), and all records and reports for the study must be securely archived, in a fashion that insures future retrieval.

Subpart K: Disqualification of Testing Facilities

The FDA conducts routine periodic inspections of GLP laboratories (Surveillance Inspections) and "for cause" audits if there is a perceived problem (Directed Inspections). If non-compliance with GLPs is found, then the FDA has the right to disqualify laboratories.

21CFR Part 58 is a relatively short document and should be read in its entirety. The most recent version is available at http://www.access.gpo.gov/nara/cfr/waisidx_07/21cfr58_07.html. Access to this and other related documents is easily obtained through the Internet as most regulatory agencies post these documents at their web site, so readers are encouraged to refer to the original documents. The FDA web site (www.FDA.gov) also provides access to regulations, guidance papers and warning letters. Guidelines for FDA Office of Regulatory Affairs inspectors are also available (www.fda.gov/ora/compliance). Other documents are available from OECD (www.oecd.org) and the European Agency for the Evaluation of Medicinal Products (EMEA, www.emea.europa.eu) web sites.

Basic good practices are the foundation of both GLPs and GMPs. Staff should be qualified and well trained. Only established, approved procedures should be used and all activities should be recorded. Records and samples should be archived and available. As with GMPs, the future will see increased automation and use of computers in analytical techniques and the use of quality management systems to ensure improvements in quality and compliance with GLPs.

This project has been funded in whole or in part with federal funds from the National Cancer Institute, National Institutes of Health, under contract N01-CO-12400. The content of this publication does not necessarily reflect the views or policies of the Department of Health and Human Services, nor does mention of trade names, commercial products, or organizations imply endorsement by the US Government.

Good Manufacturing Practices

David F. Nellis, Dennis F. Michiel
Biopharmaceutical Development Program, SAIC-Frederick, Inc., National Cancer Institute-Frederick, Frederick, MD, USA

Definition

GMPs; Are the legal requirements governing manufacturers of regulated health care products. For drug products, GMPs are the regulations defining the documentation, procedures and process controls that must be followed so the manufacturers can assure that the product produced has the required safety, identity, strength (or potency), purity and quality. Pharmaceutical Quality Systems will play an increasingly important role in the future of GMPs.

Characteristics

The purpose of GMPs is to protect patients by insuring that drug products are safe and effective. In most countries, GMPs are legally proscribed with legislation delegating the interpretations and enforcement to an administrative "inspecting authority" within the government. In the United Kingdom this agency is the Medicine Control Agency (MCA), similar in function to the FDA in the United States (US). In the US the main statute underlying GMPs is the Federal Food, Drug and Cosmetic Act (FD&C Act of 1938). USFDA, International Conference on Harmonisation

(ICH, www.ich.org), World Health Organization (WHO, www.who.int), European Agency for the Evaluation of Medicinal Products (EMEA, www.emea.europa.eu) and Pharmaceutical Inspection Cooperation Scheme (PIC/S, www.picscheme.org) all have versions of GMPs, generally with similar approaches. Although there is not yet an agreed on worldwide version of GMPs, the FDA and other agencies are pursuing international harmonization of GMPs through ICH and PIC/S.

Under the FD&C Act, the Federal Food and Drug Administration (FDA) has promulgated the Current Good Manufacturing Practices (CGMP) regulations as found in 21 CFR 210-226 of the Code of Federal Regulations. The FDA emphasizes the "current" aspect of GMPs and so the regulations are often structured as broad expectations, lacking in specific details. This is done to encourage manufacturers to continually update and improve practices and methods as better systems are developed to control the manufacturing process.

The regulations for pharmaceuticals are covered in 21 CFR Parts 210 and 211, with additional regulations for biological products in Parts 600 and 610. The GMPs as found in 21 CFR 211 for finished pharmaceuticals are divided into the following major sections that individually address the general requirements for GMP operations:

- Subpart A: General Provisions
- Subpart B: Organization and personnel
- Subpart C: Buildings and facilities
- Subpart D: Equipment
- Subpart E: Control of components and containers
- Subpart F: Production and process control
- Subpart G: Packaging and labeling
- Subpart H: Holding and distribution
- Subpart I: Laboratory controls
- Subpart J: Records and reports
- Subpart K: Returned and salvaged drug products

Failure to follow GMPs will be interpreted by the FDA as equivalent to adulteration of the product, as improperly made drugs have killed people.

Quality Assurance

It is the manufacturer's responsibility to turn the quality principles of GMPs into business practices. In most companies the "Quality Assurance" organization is charged with the interpretation and enforcement of GMPs. A major part of a good quality system is the use of internal audits carried out by Quality Assurance, which is recorded, with a follow-up CAPA (Corrective And Preventative Actions) system to make sure deficiencies are noted and fixed. There are three main concepts to any quality CAPA system: (i) Remedial action to correct the problem, (ii) a root cause analysis to determine the cause(s) of the problem, and (iii) based on the analysis, including a preventative action to avoid recurrence of the problem. The FDA does not have access to internal audit files but will want evidence that they are taking place. Audits by Quality Assurance and contract auditors are also good training of personnel for FDA inspections.

Documentation and SOPs

In the GMPs "written procedures shall be established and followed for…" appears at least 100 times. This means that a documentation control system is a standard GMP expectation. The main business mechanism for compliance with GMPs is through the drafting of well-written Standard Operating Protocols (SOPs) that define how processes are to be performed. Approximately half of all FDA warning letters are for GMP violations and the most common GMP violations are for the absence of a critical SOP or that SOPs were not being followed. SOPs are equivalent to commitments by the company and the expectation is that personnel will follow their instructions. By following well-written SOPs, workers are adhering to GMPs as interpreted by their company. Change control is another fundamental of cGMPs that requires thorough evaluation (CAPA) and documentation to assure that any process or equipment changes do not have negative unintended consequences. If records or data are to be collected or maintained in an electronic format, then this should be done in accordance with 21CFR Part 11, although compliance with Electronic Documents Part 11 is an area of ongoing revision.

FDA Quality Initiatives

In the last few decades there has been an increase in the number of drugs manufactured using biological processes, with inherently more process variability. This gradually led to a realization that the basis of GMPs suitable for the production and purification of small molecules may not be optimum for the governing of processes for biologicals. Along with this has been a drive for cost-effective ways to improve quality in every phase of a pharmaceutical product. Quality systems stemming from the management studies of Juran and Deming have been used in other manufacturing sectors for process improvements for several years. The FDA recognized the value of quality systems in the Quality System Regulations for Medical Devices (21 CFR Part 820, 1996). The FDA Modernization Act of 1997 further stimulated a review in the thinking of cost-effective ways for quality improvement, followed by changes in policies governing GMPs. This led to a number of initiatives and guidance documents to guide drug manufacturers into a modern more flexible pharmaceutical quality systems approach to GMPs embracing Quality by Design (QbD), risk assessment and risk management. Once it is understood what is

critical to quality in a process and its acceptable limits or design space, then quality can be designed into the manufacturing process. Continual improvement to process (via CAPA) and product understanding can lead to continual process improvement. The major themes running through these guidances are process understanding, understanding risk, and continual improvement. All the details of these documents cannot be abstracted into a concise review, so readers are encouraged to refer to the original documents. All these initiatives, guidance papers and also warning letters are available at the FDA web site (www.FDA.gov).

Pharmaceutical Quality for the Twenty-First Century

In 2002, the FDA announced a significant 2-year initiative entitled "Pharmaceutical cGMPs for the twenty-first century – A Risk-Based Approach" (final report issued in 2004) to modernize the FDA systems for reviews and inspections of manufacturing practices for drugs and vaccines. Risk-based and science-based approach to quality with an emphasis on using quality systems and risk management approaches. In an era of increased numbers of pharmaceuticals and decreasing resources, the FDA went through a reappraisal of how they review product quality regulations to change to a focus on manufacturers' quality systems. This document encourages innovation by manufacturers such as applying the concepts of risk management and quality systems approaches to the manufacture of pharmaceuticals. This requires a thorough understanding of the manufacturing process to evaluate the procedure variables to determine which critical variables are of highest risk to product quality and allow manufacturers to selectively spend more effort controlling critical parameters, with the goal of continually improving the process. These ideas have been further defined in ICH Q8 Pharmaceutical Development, ICH Q9 Quality Risk Management, and ICH Q10 Pharmaceutical Quality Systems (currently at Step 2).

Process Analytical Technology (PAT)

The US FDA began encouraging use of automated process control technology with the issue of its 2004 "*Guidance for Industry, PAT – A Framework for Innovative Pharmaceutical Development, Manufacturing, and Quality Assurance*" document (http://www.fda.gov/cder/guidance/6419fnl.pdf). Until the PAT guidance was issued, product quality was monitored by testing of process intermediates and final products and the optimum strategy for pharmaceutical manufacturing was to duplicate the steps performed in a process as closely as possible to eliminate variables. PAT calls for a change from end-stage testing and monitoring of a process to the use of analytical techniques for continuous monitoring. With PAT technology, the focus is on both the process and the product. Instead of unchangeable processes, the process variables can be monitored, and controlled, in real-time to define the quality of the product. With the understanding that in biological systems there is always a degree of variability in the process, the idea behind PAT is to promote automated process control to monitor the important process variables in real-time and make adjustments to keep critical process variables at their optimum level as the process proceeds, thus allowing process changes that improve final product quality while reducing overall manufacturing costs. This idea of designing quality into the process has come to be known by the term Quality by Design or QbD. Principles of PAT are being implemented internationally (see EMEA web site http://www.emea.europa.eu/Inspections/PAThome.html) and included in later initiatives and guidances such as ICH Q8: Pharmaceutical Development.

ICH Q8 Pharmaceutical Development

http://www.fda.gov/cder/guidance/6746fnl.pdf Adopted by the FDA May 2006 under Revision, Jan 2008, …/8084dft.pdf

During pharmaceutical development the limits of the process parameters that produce a quality product are defined to establish the "*design space*." Once the manufacturer's design space has been accepted by the FDA, working within the design space would not be considered a process change. Movement of the process outside the design space would be considered a process change and would require regulatory approval as a post-approval change.

Essentially pharmaceutical development would perform extensive robustness experiments on the process variables using design of experiments (DoE) to determine the limits to the variables that produce product of consistent quality. Once the acceptable range for the critical operating parameters is known, then process controls within this design space would not require regulatory review or approval. The idea of design space complements PAT, as it allows use of process technology to monitor and control the process parameters within the design space variables.

ICH Q9 Quality Risk Management

http://www.fda.gov/cder/guidance/7153fnl.pdf Adopted by the FDA June 2006

Q9 provides the Quality Risk Management tools [such as Failure Modes and Effects Analysis (FMEA), hazard analysis critical control point (HACCP)] that can be applied across the product lifecycle. Risk management means taking a systematic approach to assess, control and review possible risks to the quality of a product. This process works with quality by design methods to remove common process errors that could affect product quality.

Quality System Approach to Pharmaceutical Good Manufacturing Practices

This FDA Guidance for Industry, issued in 2006, is one of the major outcomes of the Pharmaceutical Quality for the twenty-first century initiatives. The guidance document recommends that manufacturers meet CGMP requirements by using a comprehensive quality approach based on continuous improvement and risk management.

ICH Q10 Pharmaceutical Quality Systems

http://www.fda.gov/cder/guidance/7891dft.pdf Currently in Draft (ICH Step 2). Similar to the Quality System Approach Guidance, Q10 provides guidance on the quality system framework to continually improve process understanding and for process improvement. The ideal Pharmaceutical Quality System would include knowledge management and quality risk management, process performance monitoring (PAT), CAPA, change management and management review. The FDA has applied a quality systems approach to the way that inspections are done. Their Systems-Based Inspections are now focused on the following six manufacturing systems: Quality System, Production System, Facilities and Equipment System, Laboratory Controls System, Materials System, and Packaging and Labeling System.

To summarize, regulatory agencies are taking a new approach to GMPs as exemplified in ICH Q8, Q9, and Q10, and are shifting their focus to expecting compliance by demonstration that that manufacturers have quality systems in place to prevent and resolve issues of quality, safety and efficacy.

This project has been funded in whole or in part with federal funds from the National Cancer Institute, National Institutes of Health, under contract N01-CO-12400. The content of this publication does not necessarily reflect the views or policies of the Department of Health and Human Services, nor does mention of trade names, commercial products, or organizations imply endorsement by the U.S. Government.

Government Drug Regulatory Agencies

Definition

These are government departments that govern the marketing licence applications and monitor the adverse effects of marketed drugs. In the United States, this agency is the Food and Drug Administration (FDA) and the Ministry of Health and Welfare (MHW) in Japan. In the European Union, each country has its own agency but there is also an agency in the European Union, the European Medicines Agency (EMEA) based in London. Often these government agencies may be responsible for monitoring of Good Laboratory Practice (GLP) regulations in their respective territories.

GPI PLD

Definition
A glycosyl-Phosphatidyl-inositol-specific phospholipase D (GPI-PLD) specifically cleaves GPI anchor to generate phosphatidic acid and the soluble protein. GPI-PLD physiological role is completely unknown. Up-regulation in GPI-PLD expression has been observed in immortalized and malignant tumor cell lines and appears to correlate with malignancy and tumor progression.

►Mesothelin

GPI-Anchored Protein

Definition
A GPI (glycosyl-phosphatidyl-inositol) anchored protein is a protein that was post-translationally modified at its C-terminus by a glycolipid called GPI anchor. GPI anchors are hydrophobic and serve to attach membrane proteins to the lipid bilayer of cell membranes.

►Mesothelin

GPI-Linked

Definition
Refers to a type of membrane association whereby proteins are anchored to the cell surface through glycosyl-phosphatidylinositols attached to their carboxy terminus.

Grading of Tumors

Ivan Damjanov
Department of Pathology, University of Kansas School of Medicine, Kansas City, KS, USA

Synonyms
Tumor grading; Histologic grading; Assessment of the degree of tumor differentiation; Assessment of anaplasia of a tumor

Definition

Grading is a system of histopathologic tumor analysis in which a numerical or semiquantitative descriptive value ("*grade*," or *gradus* in Latin) is assigned to a neoplasm, taking into account its histologic level of ►differentiation and/or resemblance to the tissue of its origin, as well as the extent of ►anaplasia.

Characteristics

Basic Principles

More than one hundred years ago it was noticed by several pathologists that some tumors resemble histologically their tissue of origin, whereas others have lost most of such tissue specific traits and have become anaplastic or undifferentiated. It was suggested by von Hansemann in the 1890ies that one could predict the prognosis of many tumors by examining them microscopically and by taking into account their microscopic properties. This basic concept was refined subsequently by numerous pathologists worldwide until the current grading systems were developed for most malignant tumors.

The tumor grade is formulated by the pathologist who compares the microscopic features of the tumor with those of the tissue from which it has arisen. On the basis of such subjective evaluation, or by following specific systems based on points assigned to each morphologic variable, the pathologist may classify a tumor as well differentiated, moderately differentiated, or poorly differentiated. *Well-differentiated tumors* resemble to a great extent the tissue of their origin. *Moderately differentiated tumors* have retained some of the features of the tissue of their origin, but have also acquired some anaplasia, or differ significantly in some respects from the tissue of their origin. *Poorly differentiated tumors* are anaplastic neoplasms that have retained only some vague resemblance to their tissue of origin. Alternatively, the pathologist may assign to the tumor under study a numerical grade. For example, in the above three tiered system grade 1 would correspond to well differentiated, grade 2 to moderately differentiated, and grade 3 to poorly differentiated tumors. Other more complex systems have been developed for specific tumors.

Methods of Grading

Tumor grading is performed by pathologists analyzing various characteristics of tumors under the light microscope. The most common characteristics evaluated are cytologic features and architectural features.

Cytologic features include size and shape of the nucleus, the ratio of the volume of the nucleus to the volume of the cytoplasm, and the relative number of dividing cells called the mitotic index. *Architectural features* include the histologic organization of the tumor (e.g., percentage of glands on one side and solid areas on the other, as a part of the entire tumor in an adenocarcinoma), and the boundaries of the tumor. A well-differentiated tumor typically has small and regular-shaped nuclei, small nuclear volume relative to the rest of the cellular volume, a relatively low number of dividing cells, shows orderly organization with well formed glands, and has well defined tumor boundaries. A poorly differentiated tumor has large and pleomorphic nuclei (i.e., irregularly shaped nuclei of variable size and shape), large nuclear volume compared to the rest of the cellular volume (i.e., high nucleus: cytoplasm (N/C) ratio), a high number of dividing cells, disorganized tumor architecture including broad solid areas, and poorly defined tumor boundaries.

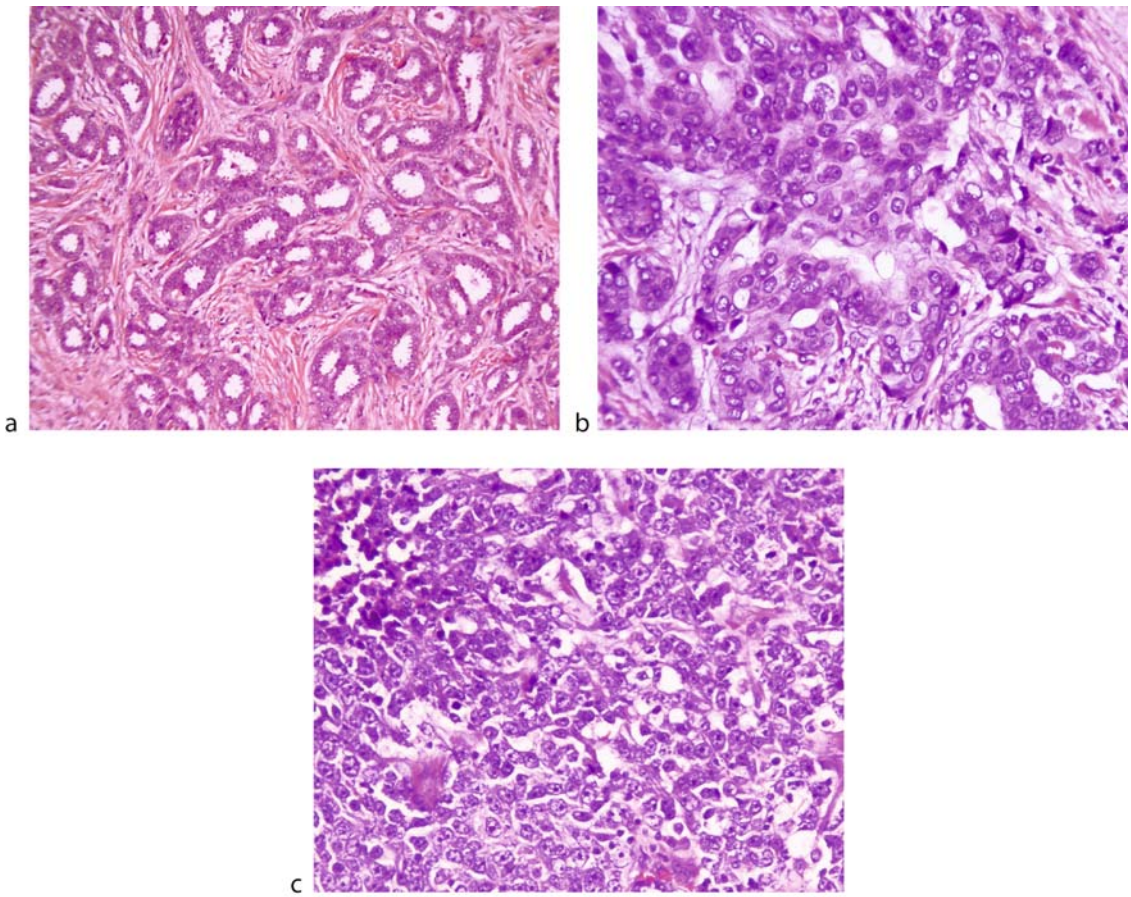
Depending on the number of malignant characteristics present, the American Joint Commission on Cancer (AJCC) has recommended that most malignant tumors be given a grade using a scale from well differentiated on one end to undifferentiated on the other. The most widely used scale is the one from GX through G4, with equivalent descriptors as follows:

- Grade X (GX) – Grade cannot be assessed
- Grade 1 (G1) – Well differentiated (Low-grade and less aggressive)
- Grade 2 (G2) – Moderately differentiated (Intermediate-grade and moderately aggressive)
- Grade 3 (G3) – Poorly differentiated (High-grade and moderately aggressive)
- Grade 4 (G4) – Undifferentiated (High-grade and aggressive)

Similar systems have been recommended by the experts of the World Health Organization (WHO) for most tumors in the human body. Alternatively, Roman numerals I through IV may be used, as is common in the WHO classification of brain tumors. For some tumors grade 3 and grade 4 are combined, and thus a three tiered system may be more practical.

Special grading systems are used for several types of cancer, most notably ►prostate cancer and ►breast cancer. Adenocarcinoma of the prostate is graded by most pathologists using the ►*Gleason grading system*. Gleason score, ranging from 2 to 10, is obtained by separately grading the most prevalent ("primary") and the next most common ("secondary") pattern and then adding the two values. *Scarff-Bloom-Richardson system* is the most widely used semiquantitative system for grading breast carcinomas. It is based on giving points on a scale from 1 to 3 to each of the following features: nuclear grade, tubular/glandular differentiation, and mitotic count (Fig. 1a–c).

To achieve consistency and uniformity, and to assure that the tumors are properly registered for epidemiologic purposes, the pathologists grade tumors by following



Grading of Tumors. Figure 1 Invasive breast carcinoma. (a) Well-differentiated carcinoma (grade 1) composed of well formed glands lined with cells that have uniform small nuclei. (b) Moderately differentiated carcinoma (grade 2) composed of glands and some solid sheets. Tumor cell nuclei are slightly enlarged and show mild pleomorphism. (c) Poorly differentiated carcinoma (grade 3) composed predominantly of solid cords and sheets. Tumor cell nuclei are enlarged and show pleomorphism.

the guidelines and criteria recommended by WHO or JCCC. Such tumor grades are entered into the data base of tumor registries. The pathologists should specify which grading system they have used to avoid confusion and achieve greater comparability of data from one medical center or country to another. Certain forms of preinvasive carcinoma in situ and closely related epithelial dysplasias, such a cervical intraepithelial neoplasia, are also routinely graded.

Grading is of limited use for tumors of endocrine glands such as the parathyroids, adrenals or ►islets of Langerhans. For some tumors, such as ►melanoma, ►seminoma, embryonal carcinoma or ►retinoblastoma, there are no useful grading systems and accordingly, these tumors are not graded histologically. Some tumors are by definition high grade and are automatically given the designation G4, which is typically used for cancer registry purposes. This group of tumors includes small cell carcinomas of the lung or any other site, large cell carcinoma of the lung, and several sarcomas such as ►Ewing sarcoma, ►rhabdomyosarcoma and malignant fibrous histiocytoma. Tumors that have been treated are not graded.

Future Perspectives

Currently, tumor grading is based on a subjective evaluation of routine histologic sections by a trained pathologist. In some instances, as is the case with carcinomas of the breast or prostate, semiquantitative methods have been devised. Still, all these approaches are subjective and there is considerable intra- and interobserver variation. It is hoped that this variation will be reduced in the future, by a more extensive use of immunohistochemical, molecular biologic methods, and the application of image analysis and computer technology.

Graft Acceptance and Rejection

Jeffrey L. Platt
Transplantation Biology and the Departments of Surgery, and microbiology and Immunology, University of michigan, Ann Arbor, Michigan USA

Definition

Refers to the fate of cells, tissues or organs transplanted between different individuals or from one individual to oneself.

Characteristics

The fate of grafts, whether they are accepted or rejected, is a subject of relevance for cancer. Grafts of various types such as bone marrow, stem cell or organ grafts may be carried out for the treatment of cancer and because the rules governing the outcome of grafts explains in part the survival and surveillance of tumors.

Graft acceptance and rejection depends on two factors. One factor reflects the extent to which the source of the graft and the recipient differ genetically. The second factor reflects whether the graft consists of isolated cells or tissue or an intact organ.

The genetic relationship between the donor and the recipient determines whether or not a graft is accepted. Grafts from one individual to themselves are referred to as ►autografts. Autografts are always accepted if they are placed in the correct location. Grafts between genetically identical individuals are called ►isografts. Isografts are usually accepted unless the donor has acquired antigen through infection, chemical modification or mutation. Grafts between different individuals of the same species are referred to as ►allografts. Allografts are almost always rejected unless the immune system of the recipient is defective or the donor and recipient are highly inbred and closely related. Grafts between individuals of different species are called ►xenografts. Xenografts are always rejected unless the recipient of the graft is immuno-incompetent.

Graft Acceptance and Rejection. Table 1

Graft type	Source of vasculature	Source of growth factors
Cells	Recipient	Recipient
Tissues	Recipient and donor	Recipient and donor
Organs	Donor	Donor

Xenografts may also fail if growth factors of the recipient do not support engraftment.

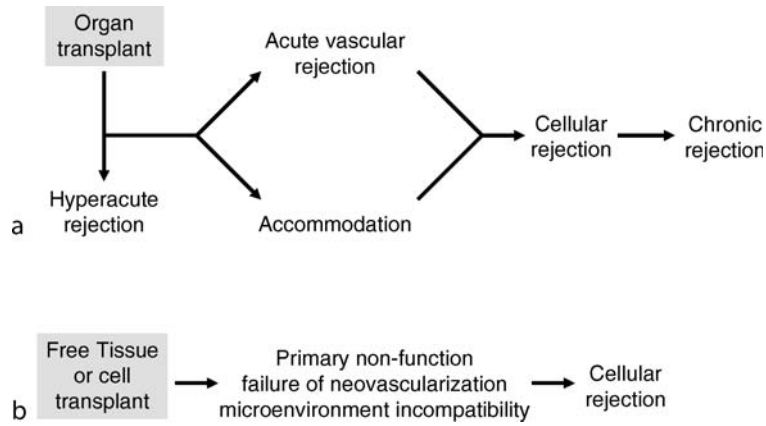
The susceptibility of a graft to rejection and the type of rejection that occurs depend on how the graft receives its supply of blood. Transplanted cells, such as bone marrow cells or hepatocytes, derive their vascular supply, nutrition and growth factors mainly by the in-growth of blood vessels of the graft recipient (Table 1). Transplanted tissues, such as tumor fragments, pancreatic islets and skin, are in part by in-growth of blood vessels of the recipient and in part by spontaneous joining of blood vessels of the recipient with existing blood vessels in the tissue. Transplanted organs are fed entirely by blood vessels formed by the joining of graft and recipient blood vessels.

The ability of cell and tissue grafts to undergo ►neovascularization and to be supported by growth factors of the recipient determines graft acceptance over a period of days to weeks. The acceptance of grafts also depends on the location and the biological compatibility between the donor and the recipient. For example, bone marrow cells may survive transplantation into some locations, such as in bone marrow or in the blood stream, but not others, such as into muscle. As another example, bone marrow cells may fail to engraft across species because the growth factors of the recipient are incompatible with the graft.

The biological responses to transplantation are summarized in Fig. 1. Cell and tissue grafts are subject to ►graft primary non-function or failure of engraftment, owing to the resistance mounted by ►natural killer cells, ►macrophages or other leukocytes. If this hurdle is bypassed, cell and tissue grafts are subject to cellular rejection mediated by ►T lymphocytes. Organ transplants may be subject to immediate or ►graft hyperacute rejection caused by antibodies specific for the transplant donor that bind immediately upon transplantation and activate the complement system. Antibodies forming after transplantation of organ grafts may cause ►graft acute vascular rejection or ►graft chronic rejection. Organ grafts between different individuals are, like cell and tissue grafts, subject to ►graft acute cellular rejection.

Cellular and Molecular Mechanisms

Differences between the ►major histocompatibility antigens of a graft donor and graft recipient are the most



Graft Acceptance and Rejection. Figure 1 The immunological response to transplantation. The immune response to transplantation can be classified according to whether the graft consists of isolated cells or free tissues, such as islets of Langerhans or of a primarily vascularized organ such as the kidney or heart. (a) Vascularized organ grafts are subject to hyperacute and acute vascular rejection caused by the action of antidonor antibodies on donor endothelium. If hyperacute or acute vascular rejection are averted, the graft may undergo accommodation, a condition in which the graft appears to resist injury despite the return of anti-donor antibodies to the circulation and the presence of an intact complement system. A vascularized organ graft may also be subject to cellular rejection and chronic rejection more or less like the corresponding types of rejection observed in allografts. (b) Free tissue grafts are subject to failure caused by primary non-function, failure of neovascularization or failure of the microenvironment to support the survival and function of the foreign tissue. If the free tissue or isolated cells engraft, they are then subject to cellular or humoral rejection.

important determinant of acceptance or rejection ►(MHC). Major histocompatibility antigens are highly polymorphic; thus, all individuals other than identical twins in an outbred population are likely to differ in major histocompatibility antigens, and these differences trigger potent immune responses. Major histocompatibility antigens can be recognized directly by T lymphocytes; thus, intact foreign cells can provide a strong stimulus. Recognition of major histocompatibility antigens by T lymphocytes provokes a severe and very rapid immune response, which accounts for the inevitable rejection of allografts if the recipient does not receive immunosuppressive therapy (T-cell response). Major histocompatibility antigen may also stimulate the production of antibodies. Alloantibodies, as such, can cause vascular rejection of organ grafts and can be used in tissue typing (Fig. 1), but antibodies have little impact on most cell and tissue grafts unless they are placed in the circulation.

Antigens that provoke slower and less severe responses are referred to as ►minor histocompatibility antigens. Any protein or carbohydrate that distinguishes two individuals can potentially serve as a minor histocompatibility antigen. Minor histocompatibility antigens are generally processed by antigen-presenting cells and presented to a very small fraction of T cells, thus accounting for the slower immune response.

Bone marrow transplants engender several distinct aspects of graft acceptance and rejection. Engraftment of bone marrow depends to some extent on the number of hematopoietic stem cells transferred, more stem cells hastening and increasing the frequency of engraftment. When the bone marrow cells are from a non-autologous (that is allogeneic) source, the cells can be rejected by T cells of the recipient. Natural killer cells are particularly important in resisting foreign bone marrow (►Natural killer cells). Natural killer cells are lymphocytes that can act against a variety of foreign cells that lack self-MHC molecules or are targeted by antibodies.

A special type of immune response known as ►graft versus host disease can occur after transfer of mature T cells from one individual to another, as in bone marrow transplantation. The mature T cells attack the recipient of the transplant, damaging skin, intestine, liver and other organs affected by graft versus host disease. Graft versus host disease may be directed against major or minor histocompatibility antigens.

One basis for graft acceptance may be immunological ►graft tolerance. Tolerance refers to the specific non-responsiveness of the immune system when an individual is confronted with a graft or an antigen that is generally considered capable of triggering immunity. Tolerance to self-antigens is acquired by developing T cells in the thymus and developing B cells in the bone marrow and by maturity in B cells through various mechanisms and in various locations. Tolerance to foreign cells and antigens may be induced by various means; however, the induction of tolerance often requires severe treatments that lower the ability to respond broadly to foreign antigens.

Clinical Relevance

Cell, tissue and organ grafts are often carried out as to address the consequences of organ and tissue failure brought about by chemotherapy, cancer, or the surgical removal of tumors. Bone marrow or hematopoietic stem cell transplantation is frequently undertaken to enable chemotherapy. Organ transplantation may be undertaken if the removal of the primary tumor or the complications of chemotherapy dictate; however, organ transplantation is avoided as much as possible because the immunosuppression needed to retain an organ allograft may hasten the recurrence of a tumor.

Graft Acute Cellular Rejection

Definition

Severe damage or destruction of engrafted organs, cells and tissues, usually within days to months after transplantation, caused by T-cell-mediated immune responses.

►Graft Acceptance and Rejection

Graft Acute Vascular Rejection

Definition

Severe damage or destruction of engrafted organs, usually from days to several months after transplantation, probably caused by several humoral factors including antibodies and complement, which may result in unwanted activation of donor endothelium.

►Graft Acceptance and Rejection

Graft Chronic Rejection

Definition

Severe damage and ►inflammation to engrafted organs, usually from several months to several years after transplantation, caused by humoral and cellular responses to donor endothelium.

►Graft Acceptance and Rejection

Graft Hyperacute Rejection

Definition

The destruction of engrafted organs, usually within 24 h of transplantation, caused by preformed antibodies and activation of complement on donor cells.

►Graft Acceptance and Rejection

Graft Primary Non-Function

Definition

Failure of cells and tissues to engraft due to harmful interactions with recipient ►leukocytes.

►Graft Acceptance and Rejection

Graft Tolerance

Definition

A specific non-responsiveness of the recipient's immune system to graft antigens that would normally elicit a rejection reaction.

►Graft Acceptance and Rejection

Graft-Versus-Host Disease

Definition

GVHD; is a life-threatening complication of allogeneic hematopoietic stem-cell transplantation in which donor T cells attack the tissues of the transplant recipient after perceiving host tissues as antigenically foreign. GVHD is mainly directed against epithelial tissues of the skin, liver, and gastrointestinal tract.

►Allogeneic Cell Therapy
►Graft Acceptance and Rejection

Graft-Versus-Leukemia/Tumor

Definition

(GvL/GvT) effects, in adoptive immunotherapy, involve the recognition and elimination of the recipient's residual leukemia/tumor cells by donor lymphocytes derived from hematopoietic cell transplantation. The targets of GvL/GvT responses are the major and minor histocompatibility antigens, which differ between donor and patient.

►Immunotherapy

Granulocyte Elastase

►Neutrophil Elastase

Granulocyte-Colony Stimulating Factor

Definition

G-CSF, is a cytokine produced by a number of different tissues to stimulate the bone marrow to produce granulocytes and hematopoietic stem cells. In ►hematopoietic stem-cell transplantation, G-CSF is used to mobilize hematopoietic stem cells into the peripheral circulation where they can be harvested by ►apheresis.

►Allogeneic Cell Therapy
►Cytokines
►Macrophages

Granulocytes

Definition

White blood cells filled with granules containing potent chemicals that allow the cells to digest microorganisms, or to produce ►inflammation reactions. ►Neutrophils, ►eosinophils, and ►basophils are examples of granulocytes.

Granulocytopenia

►Neutropenia

Granulosa Cell Tumors

Alan L. Johnson, Dori C. Woods
Walther Cancer Research Center, University of Notre Dame, Notre Dame, IN, USA

Definition

Granulosa cell tumors (GCTs) are rare ovarian tumors derived from the somatic cells that immediately surround the developing ►oocyte. Initial prognosis is favorable, yet a propensity for late relapse requires prolonged observation. GCTs represent only 2–5% of all ovarian tumors, yet are the most common type of malignant sex cord-stromal cell tumor. This latter, broad classification of heterogeneous tumors includes epithelial cells derived from the ►ovarian stroma, the ►rete ovarii and developing ovarian follicles.

Characteristics

GCTs typically represent slow growing neoplasms, with 5–25% of these tumors exhibiting malignant

potential. In particular, GCTs can be differentiated from cancers originating from the ►ovarian surface epithelium (OSE) in that the former typically exhibit enhanced steroidogenic potential associated with gonadotropin-responsiveness, and thus are considered an endocrine tumor. GCTs frequently produce elevated levels of estrogen that initiates symptoms typical of estrogen excess, such as ►metrorrhagia and/or endometrial ►hyperplasia. Patients with GCTs also experience an increased risk of developing ►breast cancer or ►uterine cancer. Occasionally, GCTs may produce ►androgen that promote ►virilization or ►hirsutism. Although there are no known risk factors (including genetic) for developing GCTs, there may exist an association with infertility and treatment for infertility.

In addition to monitoring steroid (estradiol or testosterone) production, elevated serum levels of ►inhibin (inhibin A and B), and ►Mullerian Inhibiting Hormone (MIH) can serve as useful diagnostic indicators of this disease. The predominant factor associated with overall survival is detection at ►FIGO stage I. More advanced stages (FIGO stages II-IV) have a poor prognosis, with a five-year survival rate similar to ►OSE cancer. Significantly, relapses are common after a mean of 6 years from initial diagnosis, and 5% of relapses will occur following 20–30 years without symptoms. Rupture of the initial tumor is a primary factor related to propensity for relapse.

From histological and etiological perspectives, GCTs include distinct juvenile and adult types. The juvenile type typically occurs during premenstrual ages, often before age 10 and almost always before age 30. Prepubertal patients present with abdominal pain and swelling together with precocious pseudo puberty, while after puberty symptoms of juvenile GCTs include menstrual irregularities or ►amenorrhea. Relapses from the juvenile type are almost always observed within 3 years of the original diagnosis. By comparison, adult-type GCTs occur predominantly during or subsequent to ►menopause (median age of diagnosis is 50–55 years), and represent the major incidence (95%) of GCTs. Even more rarely, testicular GCTs of both juvenile and adult type have been documented in XY genotypic males.

Clinical Aspects

The low incidence and consequent paucity of information pertaining specifically to the genetics and cellular biology of GCTs has limited the development of optimal and targeted treatment protocols, particularly compared to cancers of OSE origin. A unilateral presence occurs in greater than 95% of adult and juvenile type GCTs. Accordingly, the standard treatment following early detection is ►surgical debulking. There is currently little evidence to support more effective outcomes combining surgery with adjuvant radiation or hormonal therapies. ►Platinum-based ►chemotherapy is commonly utilized for relapsing or metastatic GCTs, with some of the highest reported response rates obtained with ►cisplatin, ►vinblastine and ►bleomycin (PVB) therapy. While the positive response to platinum-based therapies is estimated at 63–80%, the well recognized persistence of relapse is indicative of the need for more efficacious adjuvant therapies.

Granzymes

Definition

Granzymes are a family of serine ►proteases, that are stored in the granules of ►cytotoxic T lymphocytes and ►natural killer cells (NK cells). They are components of the immune system that protect higher organisms against viral infection and cellular transformation. Following receptor-mediated conjugate formation between a granzyme-containing cell and an infected or transformed target cell, granzymes enter the target cell via ►endocytosis and induce ►apoptosis. Granzyme B is the most powerful pro-apoptotic member of the granzyme family.

Grape Seed Extract

Manjinder Kaur, Rajesh Agarwal, Chapla Agarwal
Department of Pharmaceutical Sciences, School of Pharmacy, University of Colorado Health Sciences Center, Denver, CO, USA

Definition

Is a ►nutraceutical rich in ►grape seed proanthocyanidins. It is widely consumed for its beneficial health effects attributed to its high proanthocyanidin(s)

content. Extract is prepared from the seeds of the grapes (*Vitis vinifera*), and seeds are usually procured from wine or juice industry where they are generated as major by-product and/or waste product. Standardized preparations are sold throughout the world and are usually marketed as health supplement.

Characteristics

►Grape seed extract is a complex mixture of ►polyphenols (includes phenolic acids, colored ►anthocyanins, ►flavonoids, and complex flavonoids). It is particularly rich in proanthocyanidins. Chemically, proanthocyanidins in turn encompass two major chemical constituents: procyanidins and procyanidin gallates. Procyanidins are basically oligomeric or polymeric flavonols, consisting of (+)-catechin and (−)-epicatechin, whereas, procyanidin gallates are mainly (−)-epicatechin acetylated with gallic acid. The degree of polymerization (process in which monomers link together to form long chains or network) in proanthocyanidins in grape seed extract falls in the range of 2–15.

Biological Activity

The chemical constituents such as phenolic acids, flavonoids, and proanthocyanidins present in grape seed extract exhibit antiradical (scavenge free radicals), antioxygen (scavenge oxygen free radicals), antilipid peroxidation (halt the process which makes fatty acids/lipids go rancid), as well as metal chelating (bind metal ions) properties and are largely responsible for strong antioxidant capacity of this extract. It has been found that grape seed extract is even more potent scavenger of oxygen-free radicals as compared to known antioxidants, such as ►vitamin C and ►vitamin E succinate.

Health Beneficial Effects

Grape seed extract possesses health beneficial effects, which in part are due to its high antioxidant capacity especially in those diseases where ►reactive oxygen species (ROS) are involved in the pathogenesis of the disease. Even though, grape seed extract is widely consumed as health supplement throughout the world, its health beneficial effects have been proven scientifically and conclusively only in animal models of various human diseases. Such studies have not only unraveled the beneficial effects, but also provided insight into the mechanism of action of grape seed extract in particular disease scenario as listed later.

Cardiovascular Diseases

Grape seed extract has been shown to prevent the development of aortic atherosclerosis in animal model by scavenging the ROS in plasma and interstitial fluid of the arterial walls leading to inhibition of oxidation of LDL (►Low density lipoproteins, in common terms, as bad cholesterol, oxidized LDL contributes to development of atherosclerosis). Additionally, proanthocyanidins from grape seed have been shown to exert antithrombotic effect, which can be of benefit in disease conditions such as venous thrombosis, atherosclerosis, and coronary thrombosis (thrombosis: formation of blood clot). It even protects cardiomyocytes from exogenous as well as endogenous oxidative stress by scavenging ROS and chelation of iron. Grape seed extract not only prevents atherosclerosis (plaques formed by lipids inside the artery) but also has been found to improve the cardiac recovery from reperfusion-induced injury by free radicals generated during reperfusion (restoration of blood flow) after ischemia (restriction in blood supply/flow). Similarly, it exerts protective effect against ischemia-reperfusion-induced renal damage.

Other Health Conditions

Grape seed extract prevents the progression of cataract formation in hereditary cataractous rats as well as experimental cataract induced by selenite treatment, and thus can be used as an effective preventive agent against the development and progression of cataract formation.

Use of grape seed extract has been scientifically proven to treat stress-induced disorders. It exerts nootropic (improvement in brain functions such as cognitive ability and mental agility) effects in animal models, thereby underscoring the importance of using grape fruits and seeds as advocated in traditional system of medicine “ayurveda” for treatment of stress-related disorders.

Grape seed extract exerts inhibitory effects on the fat-metabolizing enzymes, pancreatic lipase and lipoprotein lipase (enzymes which aid in digesting fat), which have important implication in limiting the dietary absorption of fat, and thus consumption of grape seed extract can be an effective, safe, and cost effective weight control strategy. In gastrointestinal disorders, grape seed extract exhibits the antiulcer activity as studied in rats. It also affords protection against acute and chronic stress-induced gastrointestinal injury, primarily by scavenging ROS.

Another important biological activity of grape seed extract is its capacity to lighten the UV-induced pigmentation of skin in guinea pigs. When applied topically, grape seed extract improves dermal wound healing.

Grape seed extract also exhibits endothelial-dependent relaxing activity, which can have profound effect in conditions where nitric oxide/nitric oxide synthase system dysfunction is involved in pathogenesis, such as atherosclerosis, erectile dysfunction.

Owing to antioxidant capacity, it prevents gentamicin-induced nephrotoxicity and bone marrow chromosomal

aberrations in animal model. Grape seed extract also inhibits the production of ►nitric oxide (NO) and ROS along with expression of inducible nitric oxide synthase (iNOS) in ►macrophages stimulated with lipopolysaccharide (LPS) of periodontopathogens; thereby it can also act as a potential preventive agent against periodontal diseases.

Oxidative stress is one of the major contributory factors in the process of aging. Consumption of grape seed extract reduces the accumulation of age-related oxidative damages in central nervous system in experimental animals. It even protects and maintains membrane integrity of erythrocytes in aged animals.

Another important activity associated with grape seed extract is its ability to act as insulinomimetic, and it can activate glycogen and lipid synthesis.

Grape seed extract affords multi organ protection against toxicities of various chemicals such as chemotherapeutic drugs, carcinogens, and acetaminophen.

Grape seed extract also exhibits anti-HIV effects possibly by downregulating the expression of HIV-1 entry coreceptors in normal peripheral blood monocytes and lymphocytes.

Anticancer and Cancer Preventive Efficacy

Another important biological activity of grape seed extract is its anticancer activity against cancers of varying phenotype. Grape seed extract shows cytotoxic effects (killing of cells) against human ►breast cancer, ►prostate cancer, ►skin cancer, ►lung cancer, gastric adenocarcinoma, ►chronic myelogenous leukemic and ►colonic carcinoma cells, importantly here, without affecting the viability of other type of normal cells, such as normal gastric mucosal cells and murine macrophages. Anticancer effects were also observed with grape seed extract against carcinogen-induced liver tumorigenesis. In two-stage skin carcinogenesis mouse model (in this model, development of tumor requires two critical events; initiating event which usually occurs with chemical carcinogen and promoting event which usually occurs with chemicals known as tumor promoters), grape seed extract exerted antitumor promoting effects as evident by significant inhibition of tumor incidence, tumor multiplicity (average number of tumors per tumor bearing mouse), and tumor volume (measure of size also).

Another very important biological activity in context to its anticancer activity is its ability to act as an inhibitor of enzyme ►aromatase. This enzyme converts ►androgen into ►estrogen, and is normally expressed in many tissues such as ovary, placenta, bone, and adipose. Most of the breast tumors are sensitive to estrogen, and there is an increased expression of enzyme aromatase in breast cancer tissues as compared with normal breast tissue. Targeting of this enzyme either by inhibiting its activity or by inhibiting its expression can have important implications in arresting the growth of estrogen-sensitive breast tumors. Additionally, estrogen is primarily synthesized by ovaries, however after menopause, its synthesis declines tremendously, therefore in those women, who have breast cancer after menopause, aromatase inhibitors are much more effective in controlling the progression of this disease. Studies conducted with grape seed extract in preclinical ►xenograft model and breast cancer cell line have revealed that it can be a potential chemopreventive agent against breast cancer because of its ability to inhibit the activity as well as expression of this enzyme.

Aberrant activation of signaling pathways is frequently observed in cancer. In prostate cancer, ►epidermal growth factor receptor (EGFR) and ►insulin-like growth factor receptor-type-I (IGF-IR) are constitutively active (do not need signal/stimuli for activation) along with the increased production of growth factors. This provides an autocrine loop for constitutive activation of both mitogenic and survival signaling in these cancer cells, thereby causing their abnormal proliferation. Grape seed extract inhibits the growth and induces apoptotic death of both androgen-dependent and -independent prostate cancer cells; in part by via inhibition of EGFR-mediated mitogenic signaling. Another important event involved in the growth and spread of cancer is ►angiogenesis (formation of new blood vessels from preexisting ones) and neovascularization. Grape seed extract inhibits the growth of prostate cancer cells tumor xenograft by decreasing the proliferation of these cells, increasing the apoptotic index, and by strong inhibition of tumor angiogenesis. Grape seed extract strongly inhibited the release/secretion of proangiogenic factor ►vascular endothelial growth factor (VEGF) in this preclinical xenograft model. It also inhibited the constitutively activated IGF-I (ligand)/IGF-IR signaling in these cells, thus shutting off the mitogenic and survival mechanism for these cells.

Grape seed extract has shown anticancer activity against not only carcinogen-induced intestinal and colorectal cancers in animal models but also against colorectal carcinoma cell lines of human origin. Even growth of colorectal cancer cells as tumor in xenograft model was strongly inhibited by grape seed extract. Uncontrolled proliferation due to loss of cell cycle checkpoint controls is one of the underlying defects in cancer. Grape seed extract inhibited this abnormal growth of colorectal cancer cells by upregulating the levels of ►cyclin-dependent kinase inhibitors (cyclins, cyclin-dependent kinases, and cyclin-dependent kinase inhibitors control the cell cycle progression) to halt these cells at G1 phase (normal cell goes through different phases before next division of cell occurs). In colorectal tumors grown as xenograft in ►nude mice, grape seed extract inhibited the markers of cell

proliferation and induced apoptotic death leading to overall inhibition of tumor growth. Additionally, cancerous cells have growth advantage over normal cells due to increased levels of nucleotide synthesis by using the salvage (alternate pathway to procure precursors for nucleotide synthesis) pathway. Extract from whole grapes including seed inhibited the activity of enzymes involved in the salvage pathway, thus diminishing the survival advantage of colon cancerous tissues, and this might be plausible mechanism of anticancer effects of grape seed extract in general.

Clinical Studies

Even though all the earlier listed beneficial effects have been proven scientifically in animal models, there are few studies that have explored the mechanism of health beneficial effects in humans. In this context, grape seed extract reduced the inflammatory response as well as oxidative stress in systemic sclerosis (a systemic connective tissue disease) patients as evidenced by decreased expression of ►adhesion molecules (ICAM-1, VCAM-1, E-selectin: endothelial adhesion molecules and their expression is upregulated in this disease) and reduced levels of malondialdehyde (end product of peroxidation of lipids by ROS) in the plasma of the patients indicating a beneficial effect of consuming grape seed extract in this disease.

Hypercholesterolemia is a major risk factor for cardiovascular diseases. Consumption of grape seed extract in conjunction with niacin-bound chromium altered the lipid profile of hypercholesterolemic patients, especially lowered LDL levels and decreased the circulating levels of autoantibodies to oxidized LDL (auto antibodies to oxidized LDL are involved in the pathogenesis of coronary artery disease, atherosclerosis) and thus can have potential role in lowering the risk of cardiovascular diseases in such patients. Consumption of grape seed extract-supplemented meal by humans reduced the postprandial (time after meal consumption) oxidative stress by increasing the plasma levels of antioxidants, thereby decreasing the oxidant levels in the plasma and consequently protecting LDL from deleterious oxidative modification to some extent. Similarly, consumption of grape seed extract by young healthy volunteers improved the total serum antioxidant activity, which may have beneficial effects especially in hypercholesterolmic patients who are at increased risk of cardiovascular diseases.

Grape seed extract consumption in humans has been shown to lower the 24-h energy intake without affecting the satiety, mood, or tolerance, and thus can be an effective therapy to control body weight.

Grape seed extract, not only by itself, but in conjunction with other drugs can have beneficial effects, such as it exerted protective effect on various symptoms of Syndrome X when given in conjunction with niacin-bound chromium complex. Similarly, when given orally to patients with chloasma, it improves on the symptoms of chloasma (a skin condition involving hypermelanosis).

Results of preliminary study conducted in patients with chronic pancreatitis symptoms revealed that oral consumption of grape seed extract reduced the index of pain and incidence of vomiting in such patients. Together, it is evident that grape seed extract possesses multiple health beneficial effects, and thus can be an excellent health supplement.

Conclusions

With the increased acceptance of anything natural by patients or human population in general, recent years have seen rapid growth of nutraceutical industry. These ►nutraceuticals are commonly used as health supplements and/or as alternative complementary medicine. In this context, grape seed extract with high ►antioxidant capacity has shown excellent health beneficial effects especially in those disease conditions where oxidative stress is involved in the etiology. Even though numerous reports are available regarding the health beneficial effects of consuming grape seed extract, yet comprehensive studies in humans are required to be conducted further to completely understand the mechanism of its action under different disease scenarios and to term its usage as absolute safe in humans, especially under those disease conditions where adverse drug interactions when used in combination with this extract are suspected.

Grape Seed Proanthocyanidins

Definition

GSP; A mixture of oligomeric procyanthocyanidins extracted from grape (*Vitis vinifera*) seeds. GSP exhibits

potent antioxidant, anti-inflammatory, anticarcinogenic and antiatherogenic activities.

►Chemoprotectants
►Grape Seed Extract

Graves Disease

Definition

Is a thyroid disorder characterized by goiter, exophthalmos, "orange-peel" skin, and hyperthyroidism. It is caused by an antibody-mediated auto-immune reaction, but the trigger for this reaction is still unknown. It is the most common cause of hyperthyroidism in the world, and the most common cause of general thyroid enlargement in developed countries. In some parts of Europe the term Basedow disease or Graves-Basedow disease is preferred to Graves disease.

►Thyroid Carcinogenesis

GRB2

Definition

Growth factor receptor bound protein 2, plays a central role in signaling by receptor protein tyrosine kinases, where its ►SH2 domain binds to the receptor and the two ►SH3 domains link to effectors.

►Focal Adhesion Kinase

Grb2 Adaptor Protein

Definition

An adaptor protein comprised only of one ►SH2 domain and two ►SH3 domains. For example, upon activation of ►EGF, SH2 domain of Grb2 is used to bind to the receptor through its, while SH3 domain binds to SOS, the guanine nucleotide exchange factor for ►Ras, causing Ras activation leading to activation of the Raf-MAPK(Erk) pathway.

►Membrane-Linked Docking Protein

Green Tea

Definition

A natural product with anti-cancer, cardiovascular disease and neurologic disease properties. Active ingredients include polyphenolic ►catechins. Green tea has potent anti-inflammatory properties.

►Inflammation
►Anti-Inflammatory Drugs

Green Tea Catechins

Definition

Are the flavan-3-ols found in green tea leaves (*Camellia sinensis*). The major four catechins in green tea leaves are (−)-►epigallocatechin gallate (EGCG), (−)-epicatechin gallate (ECG), (−)-epigallocatechin (EGC) and (−)-epicatechin (EC). The potential health benefits of green tea catechins include antioxidant, anticarcinogenic, anti-inflammatory, antiatherogenic and antimicrobial activities.

►Chemoprotectants

Green Tea Polyphenol

►Epigallocatechin

Groucho

Definition

Class of proteins that are co-repressors of a vast number of transcription factors. The prototype of this conserved family is the Drosophila Groucho protein, which is expressed throughout development and plays important roles in various developmental processes.

Growth Arrest

Definition

Is the inhibition of cell division of cells. Growth arrest can be induced by e.g. chemotherapeutics by modulating proteins essential for cell cycle division.

►Apoptosis-Induction for Cancer Therapy

Growth Factor

Definition

A growth factor binds to and signals, through a plasma membrane receptor, to stimulate cellular growth and/or cell division. They bind to specific cell surface receptors and stimulate cellular proliferation, e.g. ►PDGF or ►TGF. Growth factors are important for regulating a variety of cellular processes. Growth factors typically act as signaling molecules between cells.

►Signal Transducers and Activators of Transcription in Oncogenesis
►Stress Response

Growth Factor Receptors

Definition

Cell surface receptors that transduce growth factor signals into the cell interior. They often carry tyrosine kinase activities in their cytoplasmic domains and are overexpressed in many cancers. As a result, cancer cells are stimulated to proliferate in the presence of very low concentrations of growth factor molecules.

►Receptor Tyrosine Kinases

Growth Guidance Cue

►Semaphorin

Growth Hormone

Definition

(GH); synonym somatotropin; Is a protein hormone of about 190 amino acids that is synthesized and secreted by cells called somatotrophs in the anterior pituitary. It is a major participant in control of several complex physiologic processes, including growth and metabolism. Stimulates growth and cell reproduction in humans and animals.

G-SE

Definition

Glutathione (GSH) Conjugates of Electrophiles.

GSH

Definition

►Glutathione
►Hepatic Ethanol Metabolism

GSK3

Definition

►Glycogen synthase kinase 3; serine/threonine protein kinase important in ►Wnt signaling and insulin signaling; phosphorylates ►β-catenin, ►Axin, ►APC and ►LRP5/6.

GSL

Definition

Glucosphingolipid, a class of glycosphingolipids based on glucosylceramide.

►Sphingolipid Metabolism

GSP

Definition
Guanine nucleotide binding adenylate cyclase-stimulating protein; ►G-proteins. GNAS1 (guanine nucleotide binding protein, alpha stimulating activity polypeptide 1).

►Thyroid Carcinogenesis

GST

Definition
►Glutathione S-transferase, is a family of drug-metabolizing enzymes. Its main function is to catalyze the conjugation of glutathione with electrophilic ►xenobiotics and endobiotics, giving rise to usually less electrophilic, more water soluble, and more disposable products.

►Phase 2 Enzymes

GTP

Definition
Guanosine triphosphate.

►RAS

GTP-Binding

Definition
GTP, guanosine triphosphate, is a phosphate-group transferring coenzyme that activates ►RAS proteins and other GTP-binding proteins. RAS proteins possess an intrinsic hydrolytic activity which cleaves guanosin-triphosphate (GTP) to guanosindiphosphate (GDP) and a phosphate group. GDP-bound RAS proteins are inactive.

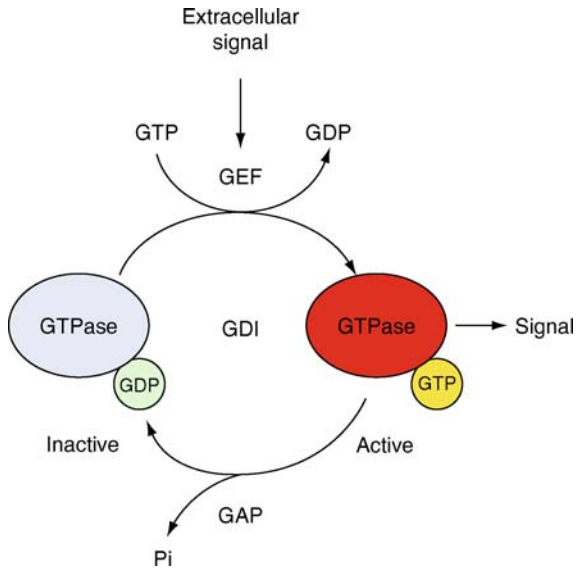
Synonyms
GTP-binding proteins

Definition
GTPases, also known as GTP-binding proteins, ►G-proteins or small GTP-binding proteins are members of the ►Ras superfamily. They are enzymes that catalyze the hydrolysis of GTP to GDP and inorganic phosphate. They are important intermediaries in signal transduction.

GTPases are proteins that work as molecular switches in the regulation of cell responses to extracellular signals. Their function is regulated by GDP/GTP-cycling, where GDP/GTP exchange promotes formation of the GTP-bound protein and GTP hydrolysis promotes formation of the GDP-bound protein. The intrinsic GDP/GTP exchange and GTP hydrolytic activities are typically low and are further accelerated by regulatory proteins. For some GTPases, the GTP-bound form represents the active form (e.g., ►Ras and ►Rho family proteins), whereas for others GDP/GTP cycling is required for activity.

Characteristics
The function of GTPases is regulated by an alternating cycle of on/off states depending on their binding to either GTP or GDP, respectively (Fig. 1). Thus, when bound to GTP, these molecular entities acquire a structural conformation that enables them to interact with other proteins called ►effectors. Effectors are then able to activate specific signaling pathways. When bound to GDP, the conformation of GTPases return back to an inactive state and the signal is interrupted. Frequently, a specific GTPase has the ability to regulate several effectors making their role plastic, versatile and complex (Fig. 2).

Ras protein is the founding member of a large superfamily of small GTPases composed of ~150 members identified with some degree of similarity to the Ras protein. All these molecules have been grouped into at least five major branches according to their

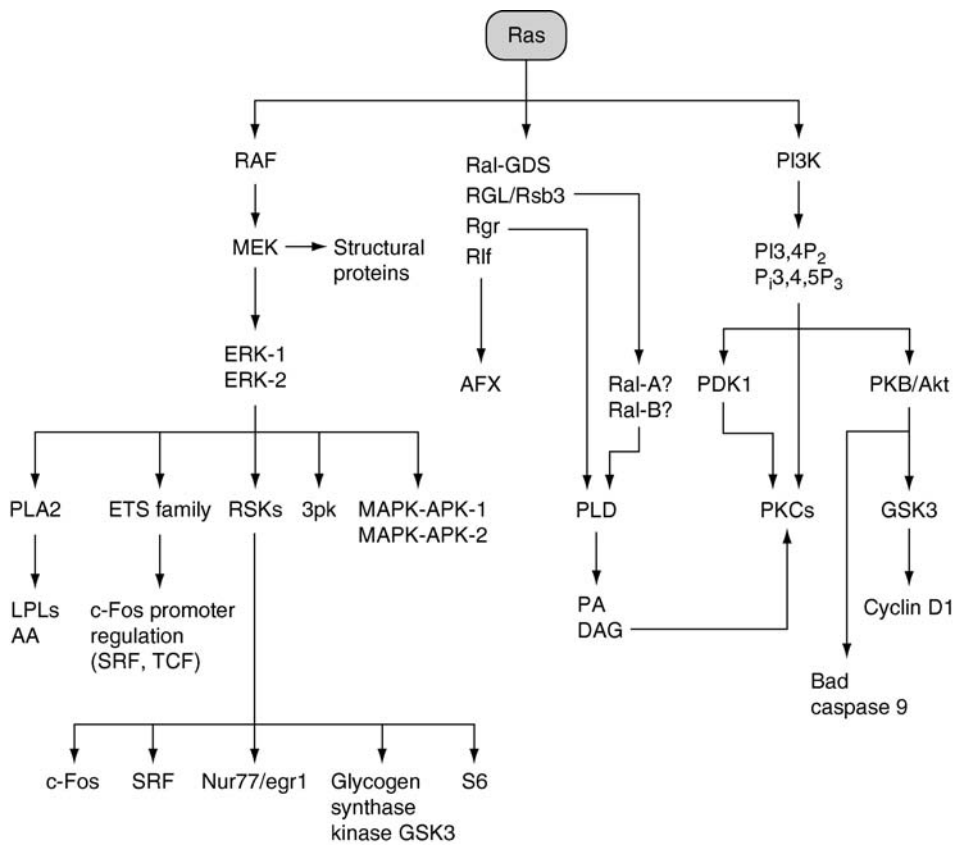


GTPase. Figure 1 Activation/inactivation cycle of GTPases.

sequence homology and functional similarities: Ras, Rho, Rab, Ran and Arf (Table 1). Three of these branches, Ras, Rho, and Rab, include most of the best characterized members of the superfamily. Variations in structure, post-translational modifications that dictate specific subcellular locations and the proteins that serve as their regulators and effectors allow these small GTPases to function as sophisticated modulators of a remarkably complex and diverse range of cellular processes.

The Ras Family

The Ras sarcoma (Ras) oncoproteins are the founding members of the Ras superfamily. This family comprises 36 members, and has been the subject of intense research, in large part because of their critical roles in human oncogenesis. Ras proteins serve as signaling nodes activated in response to diverse extracellular stimuli. Once activated, Ras proteins interact with multiple downstream effectors, which regulate cytoplasmic signaling networks



GTPase. Figure 2 Specific GTPases can interact with a number of different effector molecules. Here mammalian effectors of the Ras protein and their activated signaling pathways are depicted.

GTPase. Table 1 The Ras superfamily

that control gene expression. Ras proteins govern cell proliferation, differentiation, and survival.

The best characterized Ras signaling pathway is activation of Ras by the epidermal growth factor receptor tyrosine kinase. Activated Ras binds to and promotes the translocation of the ►Raf serine/threonine kinase to the plasma membrane, where additional phosphorylation events promote full Raf kinase activation (Fig. 2). Raf phosphorylates and activates the MEK1/2 dual specificity protein kinase, which phosphorylates and activates the ERK1/2 mitogen-activated protein (MAP) kinase. Activated ERK translocates to the nucleus, where it phosphorylates Ets-family transcription factors, which in turn activate Ets-responsive promoters.

Other Ras family proteins, including Rap, R-Ras, Ral and Rheb proteins also regulate signaling networks. Finally, although biochemically similar to Ras, several Ras family proteins appear to act as ►tumor suppressors, rather than as ►oncogenes (e.g., Rerg, Noey2 and D-Ras).

The Rho Family

Ras homologous (Rho) proteins control key signaling and structural aspects of the cell in response to diverse stimuli. They regulate actin organization, cell cycle progression and gene expression. Currently available information from the human genome sequence project has suggested the presence of a total of 22 Rho family members, RhoA, Rac1 and Cdc42 being the best characterized. Rho GTPases are key regulators of actin reorganization. Consequently, these proteins have been implicated in the regulation of cell polarity, cell

movement, cell shape, and cell-cell and cell-matrix interactions, as well as in regulation of ►endocytosis and exocytosis.

The Rab Family

First described as Ras-like proteins in brain (Rab), Rab proteins constitute the largest branch of the superfamily, with 61 members. Rab GTPases are regulators of intracellular vesicular transport and the trafficking of proteins between different organelles of the endocytic and secretory pathways. These proteins facilitate each of the major steps in membrane traffic: vesicle formation and budding from the donor compartment, transport to the acceptor compartment, and vesicle fusion and release of the vesicle content into the acceptor compartment.

Rab proteins localize to specific intracellular compartments consistent with their function in distinct vesicular transport processes. This localization is dependent on prenylation, and specificity is dictated by divergent C-terminal sequences.

The Arf Family

The ADP-ribosylation factor (Arf) family proteins have been found to be ubiquitous regulators of membrane traffic and phospholipids metabolism. The biological effects of Arfs are thought to occur on membranes and to result from their specific interactions with a large number of effectors that include coat complexes, adaptor proteins, lipid-modifying enzymes, and others. The Arf family includes 27 members arranged into three different groups: the Arfs, Arf-like (Arls), and SARs. Arf1 is the best characterized member. Arf1 regulates the formation of vesicle coats at different steps in the exocytic and endocytic pathways.

The Ran Family

The Ras-like nuclear (Ran) protein is the most abundant small GTPase in the cell and is essential for the translocation of RNA and proteins through the nuclear pore complex. The Ran protein is also involved in control of DNA synthesis and cell cycle progression. Ran regulates formation and organization of the microtubule network independently of its role in the nucleus-cytosol exchange of macromolecules. Although related to the Rab proteins in sequence, it has features that distinguish it. Unlike other small GTPases, Ran function is dependent on a spatial gradient of its GTP-bound form. This results in a high concentration of Ran-GTP in the nucleus, which facilitates the directionality of nuclear import and export.

Regulation of GTPases

Regulation of GTPases is achieved both by positive and negative mechanisms (Fig. 1). GDP/GTP cycling is controlled by two main classes of regulatory proteins. Specific guanine-nucleotide-►exchange factors (GEFs) promote formation of the active, GTP-bound form, catalyzing the exchange of pre-bound GDP for GTP (more abundant in the cell cytoplasm). Exchange factors are regulated by extracellular signals such as receptor tyrosine kinases for growth factors, receptors coupled to ►heterotrimeric GTP-binding proteins or lipid metabolites-sensitive exchange factors (such as RasGRP). There are exchange factors with a highly specific activity towards members of the superfamily of GTPases, and other exchange factors with a broad spectrum, able to activate efficiently several members of the superfamily.

►GAPs (►GTPase activating proteins) catalyze, by a factor of at least 100-fold, the intrinsic ability of GTPases to hydrolyse GTP into GDP+Pi, rendering the protein inactive and ready for the next cycle of activation.

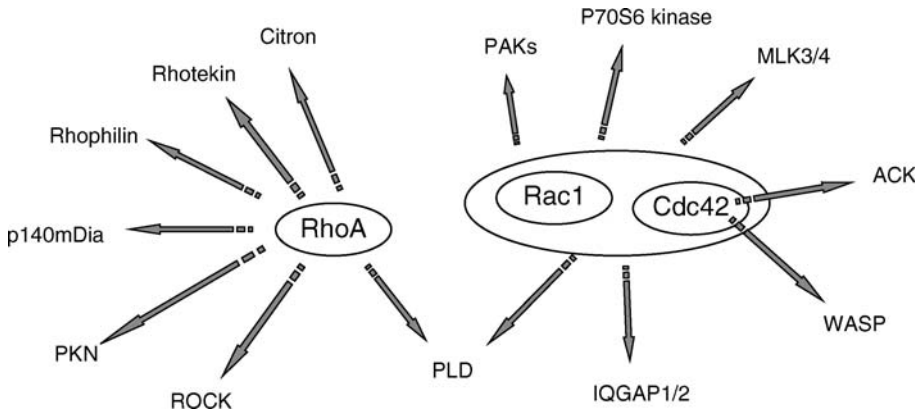
In some cases, cycling of GTPases is modulated by other proteins in addition to exchange factors and GTPases, such as GDI (GDP dissociation inhibitor) that can block both nucleotide hydrolysis and exchange, and participate in Rho GTPase movement between cytosol and membranes. In this case, exchange of GDP by GTP must be accompanied by removal of this inhibitor.

Although the GTP-bound form is the active form for all Ras superfamily GTPases, the cycling between the GDP-bound and GTP-bound states, in which distinct functions are associated with each nucleotide-bound form, is also critical for the activities of Rab, Arf and Ran GTPases.

Clinical Implications

The activity of several GTPases have been implicated in human diseases like cancer, immunodeficiency such as Wiscott-Aldrich syndrome, developmental disorders such as Aarskog-Scott syndrome or X-linked mental retardation. Alterations at both upstream regulatory elements (exchange factors) and defects on the inactivating process (GTPases) have been described as responsible for the dysfunction of the pathway.

Alternative mechanisms for activation of the oncogenic potential of GTPases have been found. ►Point mutations that reduce their GAP-stimulated GTPase activity would render proteins with a much lower efficiency to catalyze GTP hydrolysis. Such point mutations are found frequently in human tumours where members of the Ras branch are involved. Alternatively, cancer-promoting mutations can also affect components of the regulatory cycle, such as GAPs and exchange factors. This is found in proteins involved in the regulation of Ras such as in the case of ►neurofibromatosis type 1 (neurofibromin or NF1) and Rho activity (Dbl, Vav, Ost, Ect2, etc). In some cases, point mutations can promote Ras proteins to



GTPase. Figure 3 The main effectors for the archetypes of Rho proteins, RhoA, Rac1 and Cdc42, are represented. Most effectors are shared by both Rac1 and Cdc42.

spontaneously exchange GDP for the more abundant GTP. In all cases, the endpoint result of these alterations is the same: a larger proportion of the GTPase, and for longer periods of time, will be bound to GTP, rendering the protein permanently in their activated state. Thus, it can interact and activate the corresponding signaling effectors. Recently, it has become evident that Rho family participates in the carcinogenic process by either overexpression of some of the members of the family with oncogenic activity, or by down-modulation of those members with tumor suppressor activity.

Signaling Pathways

GTPases control a large number of signaling pathways involved in regulation of cell growth, cytoskeleton structure, secretion, transcription and ►apoptosis. Specific effectors that are under the control of the specific GTPase mediate all these cellular functions. The GTPases most closely related to the carcinogenic process belong to the Ras and Rho branches.

In the case of Ras proteins, at least three major effectors have been identified in mammalian cells (Fig. 2). The Raf kinase, which is connected to the MEK/ERK kinases pathway, impinges on transcriptional regulation of factors mediating cell proliferation such as ETS. Also, ►PI3K is involved in the regulation of survival signaling through activation of the PDK/PKB pathway. Finally, the Ral-GDS family of exchange factors, including Ral-GDS, Rlf, Rgr and Rgl/Rsb3 participate in important signaling processes such as transcriptional regulation (AFX transcription factors) and lipid-derived signaling through the Ral/PLD pathway, which have implications in cell growth control. Evidence has been generated that a combination of any of two from these three signaling pathways may be sufficient to acquire the transforming phenotype. In addition, cross talking among Ras-dependent and Rho-dependent signaling is an absolute requirement for full transformation.

Regarding the Rho branch, which is also implicated in the carcinogenic process, several effector molecules have been identified (Fig. 3). These include the kinases PKN, ROKα/Rho kinase (Rock), PAKs, p70-S6K, ACKs and MLKs, lipid-related enzymes such as ►phospholipase D (PLD) and PI3K, and other molecules such as p140mDia, citron, rhophilin, rhotekin or WASP. Activation of these effector molecules results in changes in cell morphology and ►motility, as well as transcriptional activation of the ►AP-1, SRF, ►NFκB and STAT transcription factors (►signal transducers and activators of transcription in oncogenesis). Finally, Rho proteins play a role in the acquisition of the metastatic phenotype. The precise effector that is involved in each of these biological effects and in particular its relationship to cancer, has yet to be assigned.

GTPase-Activating Protein

Definition

Negative regulatory protein that accelerates the intrinsic ►GTP hydrolysis activity of a GTP-binding protein, to convert the protein from its active, GTP-bound form to the inactive GDP-form.

►Rho Family Proteins

Guanine Nucleotide Exchange Factor

Definition

Positive regulatory protein that accelerates the intrinsic guanine nucleotide exchange activity of a GTP-binding protein to favor formation of the active GTP-bound form of the protein.

►Rho Family Proteins

Guanylate Cyclase

Definition

GC; Activation of GC leads to formation of cyclic guanosine monophosphate (cGMP).

►Nitric Oxide

Guidance Cues

Definition

A group of secreted or membrane associated proteins that function in the steering of axonal growth cones. The known guidance cues belong to one of four different gene families: the slit, netrin, ephrin and ►semaphorin gene families. Many growth guidance cues are involved in cancer.

Gut Peptides

Sara M. Johnson, B. Mark Evers
Department of Surgery, The University of Texas Medical Branch, Galveston, TX, USA

Synonyms

Neuropeptides; Gastrointestinal hormones; Secretagogues

Definition

Are chemical messengers that regulate gastrointestinal (GI) functions such as secretion, motility, absorption, digestion, and cell proliferation. These ►polypeptides are produced by endocrine cells in the stomach, pancreas, or intestine and act locally through ►autocrine or ►paracrine mechanisms, or at distant sites in a classical endocrine manner. The gut peptides are also produced in the central and peripheral nervous systems, where they function as neurotransmitters.

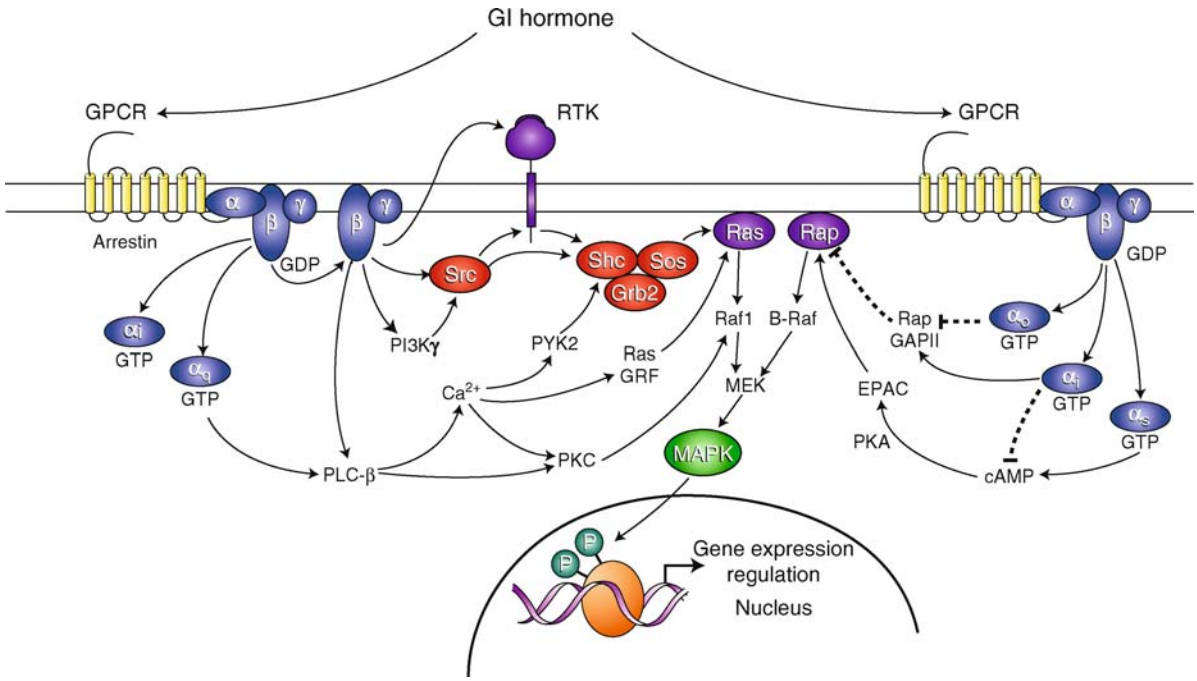
Characteristics

Overview

The best characterized gut peptides include ►gastrin, ►gastrin-releasing peptide (GRP)/►bombesin (BBS), ►somatostatin, ►neurotensin (NT), and ►cholecystokinin (CCK). Glucagon-like peptide 2, ghrelin, vasoactive intestinal peptide, and peptide YY are other examples in this class of dual-function hormones/neurotransmitters. Most of the gut peptides have more than one active form which results from initial synthesis as a large prohormone, and subsequent cleavage to shorter polypeptides.

Messages from the gut peptides are converted to intracellular signals through heterotrimeric ►G-protein coupled receptors (GPCRs), also known as seven-transmembrane domain receptors. The complex functioning of these receptors is incompletely understood, but mechanisms such as heterodimerization of receptors, activation of varying G-proteins, and receptor internalization and desensitization probably allow for the diversity in effects seen in different tissues by each hormone. There are 4 known G_α subunits, 6 G_β subunits, and 12 G_γ subunits; the β and γ subunits form a heterodimer.

Upon peptide binding to the extracellular portion of the receptor, the intracellular G-protein subunits G_α and $G_{\beta\gamma}$ dissociate to activate phospholipases, adenylyl cyclases, protein kinases, membrane ion channels, and the Ras family of small ►GTPases. The proliferative effects of the gut peptides are mediated predominantly through the ►mitogen-activated protein kinase/extracellular-regulated kinase (MAPK/ERK) family of



Gut Peptides. Figure 1 Overview of gut peptide signaling cascades.

proteins. After phosphorylation by serine-threonine kinases, the activated MAPK product translocates to the nucleus where it phosphorylates transcription factors, thereby influencing expression of genes regulating growth (Fig. 1). In cancer, activation of $G\alpha_q$-type GPCRs may transactivate tyrosine kinase pathways (e.g., Src, FAK, EGFR) to further contribute to the mitogenic effects.

Each gut peptide has a unique role in regulating gastrointestinal function and growth of normal and neoplastic tissues.

Gastrin

Gastrin regulates gastric acid production and gastric cell proliferation. Gastrin is produced in the pituitary gland and by G cells in the antrum of the stomach. Its release is stimulated by certain amino acids (AAs) in food and inhibited by the presence of acid in the stomach. The precursor forms of gastrin are 101 and 80 AAs in length, and the active forms are 34 and 17 AAs (G-34 and G-17). The gastrin receptors are the same as those for the peptide CCK and are therefore called CCK-A and CCK-B (also CCK-1 and CCK-2). There is a third receptor which binds gastrin with low affinity, CCK-C.

Gastrin has a role in promoting tumor growth in some neoplasms of the GI tract. Gastrin (G17), glycine-modified forms (Gly-G17), and both of its receptors have been found in human ►gastric cancers, including mutated gastrin receptors. Patients with gastric cancer have higher serum levels of G17; hypergastrinemia is also known to occur as a result of ►*Helicobacter pylori* infection of the stomach, which carries an increased risk for gastric adenocarcinoma. Pancreatic adenocarcinomas generally express both CCK-A and CCK-B. A vaccine directed at G17 (Gastrimmune) has been tested in Phase II trials for advanced pancreatic cancer and as an adjuvant to cytotoxic chemotherapy in patients with gastric and gastroesophageal carcinoma.

The relation between gastrin and ►colorectal cancer (CRC) is less clear and is an area of active investigation. Elevated gastrin levels increase the risk of colon adenocarcinoma. While relatively few CRCs express gastrin receptors or G17, many demonstrate increased expression of the prohormone. Gly-G17 promotes tumor cell growth in CRC cells through a unique and as of yet, uncharacterized receptor which is not blocked by pharmacologic inhibitors of CCK-A or CCK-B receptors. Activation of the gastrin gene is induced by the ►RAS oncogene, and has also been recently related to activation of the ►β-catenin pathway. The gastrin gene may therefore play a role in early CRC tumorigenesis.

Aberrant expression of gastrin receptors may also play a role in GI cancers. A CCK-2 ►splice variant has been detected in colon and pancreatic cancers. This receptor is constitutively active, it triggers intracellular signals without requiring activation by one of its ligands, gastrin or CCK, and may represent an autocrine type of growth stimulation in neoplastic tissue. Its role in human cancers requires further investigation.

Gastrin-Releasing Peptide

Gastrin-releasing peptide (GRP) is the mammalian homolog of the hormone bombesin, originally isolated from the skin of the frog *Bombina bombina*. GRP is found in nerves throughout the GI tract and other organs such as lungs, thymus, prostate, and the pregnant uterus. GRP has stimulatory effects throughout the GI tract; it stimulates gastric acid, gastrin, and pancreatic secretion, intestinal motility, and growth of the gastrointestinal mucosa and pancreatic cells. The precursors to GRP consist of 148 and 125 AAs, and some of the final products are amidated or modified with a glycine residue. The active forms are composed of peptides 1–27, 18–27, and 18–27gly.

GRP stimulates growth and activates nuclear oncogenes in many human cancers and holds potential as a therapeutic target in certain neoplasms. Small cell lung cancers (►SCLC) often both over-express GRP receptors and secrete GRP—the hallmark of autocrine signaling which feeds neoplastic growth. GRP receptor antagonists slow the growth of SCLC cells and enhance efficacy of treatment with cytotoxic chemotherapy. Similarly, androgen-insensitive prostate cancers often demonstrate elevated expression of GRP receptors and also secrete active peptide.

Certain ►neuroblastomas express GRP and their growth is inhibited by receptor antagonism *in vitro*. GRP receptors are expressed in a subset of ovarian cancers, but the role of this peptide is unclear since the tumors have not been found to produce GRP.

Neurotensin

Neurotensin (NT) was originally isolated from brain tissue and subsequently found in the intestine, particularly the distal small bowel. NT is secreted in response to ingested fat and stimulates pancreatic secretion and fat absorption, inhibits gastric and intestinal motility, and stimulates growth of normal intestinal mucosa as well as colorectal and pancreatic cancers with NT receptors (NTR).

NT functions as an endocrine or autocrine/paracrine factor in some of the most prevalent and least curable types of human cancer. Many neoplastic tissues express NTRs, but fewer also possess the ability to produce active NT peptide. Studies suggest that activation of the ERK pathway mediates the trophic effects of NT in various cancers.

NTRs are expressed in 75–90% of pancreatic cancers, but not normal pancreas; *in vitro* and *in vivo* data demonstrates increased pancreatic cancer cell growth in the presence of NT. This gut peptide also plays a role in a subset of breast and colon cancers. While normal breast and colon tissues do not express NTRs, many cancer cell lines express the receptors (e.g., 50% of colon cancer cell lines), and NT expression has been detected a subset of breast and colon cancer tissues. There is limited data to suggest that NT is a growth factor in other GI neoplasms such as stomach and liver; NT may be synergistic with carcinogens in promoting tumorigenesis based on animal studies, but its effect in human stomach and liver cancers is not known.

The autocrine effects of NT are well-established in cancers containing neuroendocrine cells, including a subset of prostate and lung cancers. In particular, many small cell lung cancers and androgen-insensitive prostate cancers both produce NT peptide and express high-affinity NTRs, and *in vivo* studies suggest that inhibition of this trophic pathway holds significant therapeutic potential.

Somatostatin

Somatostatin is universally recognized as an inhibitory GI hormone. It inhibits release of growth hormone, all known GI hormones, inhibits GI motility, gastric acid secretion, intestinal absorption, pancreatic secretion, splanchnic blood flow, and growth of normal and neoplastic tissues. It is produced throughout the central and peripheral nervous systems, in the D cells of pancreatic islets of Langerhans, and mucosa of the stomach and intestine. Peptides of 14 and 28 AAs as well as precursor forms of more than 120 AAs have varying potency. There are five sub-types of somatostatin receptors.

Somatostatin generally has an anti-proliferative effect in neoplastic tissues, but little is known about the specific mechanisms. Its effect has been studied in pancreatic and colon cancers, where its role in tumor cell growth inhibition may depend on the specific receptor subtypes present. It may also modulate growth by inhibiting secretion of the trophic gut peptides described in this review, or by influencing expression of growth factor receptors. The somatostatin analog, octreotide, has a well-established role in the treatment of ►carcinoid tumors.

Synonyms

Gynaecomastia; Gynecomazia; Hypertrophy of male breast

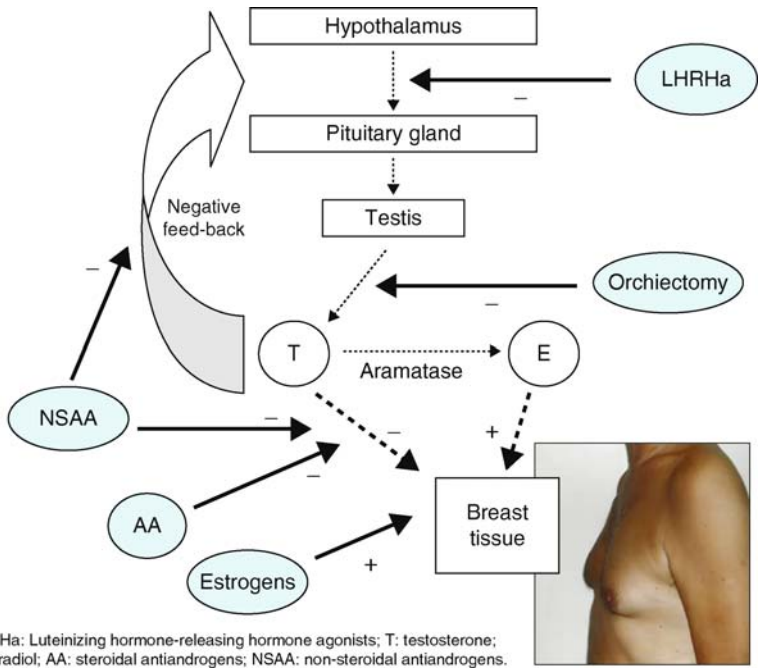
Definition

Gynecomastia is a benign proliferation of the glandular component of the male breast caused by an increased ratio of estrogen to androgen activity. Gynecomastia can be unilateral or bilateral and consists of a palpable mass of tissue with a diameter of at least 0.5 cm, usually presenting as a disk of tissue underlying the nipple. This condition is diagnosed clinically and radiologically, even if there is no consensus on which method should be used to define gynecomastia. Therefore, a careful history of the patient and a good clinical examination represent the first approach to diagnosis. Radiographic investigations using mammography or ultrasound are recommended to confirm the diagnosis. The severity of gynecomastia can be evaluated by using a four-grade score on the basis of the largest diameter: grade 1, <2 cm; grade 2, 2–4 cm; grade 3, 4–6 cm; and grade 4, >6 cm. Recently, Van Poppel et al. introduced a questionnaire (Breast Symptom Questionnaire, BSQ) that correlates well with patients' subjective perceptions of gynecomastia.

Characteristics

Gynecomastia is the most common breast abnormality in the male population. It can result from physiological changes in growth and development, or it can be caused pathologically by a chronic disease (e.g., chronic liver disease due to alcohol abuse) or a tumor (e.g., choriocarcinoma). Gynecomastia also can be induced by drug treatments affecting the balance between estrogens and androgens, such as hormonal therapies for ►prostate cancer.

The incidence of gynecomastia following treatments for prostate cancer varies. Antiandrogen monotherapy is associated with a higher incidence of gynecomastia than other prostate cancer treatments. The mechanisms of induced gynecomastia in prostate cancer patients are shown in Fig. 1.



Gynecomastia. Figure 1 Mechanisms of induced gynecomastia in prostate cancer patients.

The profile of patients with prostate cancer has significantly changed in recent years. Men are being diagnosed at earlier stages of the disease and at younger ages. Consequently, prostate cancer patients are still physically and sexually active, and quality of life has become an important issue in their management.

Hormonal therapies that have a more favorable impact on quality of life than castration are clearly required. Antiandrogen monotherapy with ►bicalutamide (150 mg) offers potential quality-of-life benefits over other treatment modalities for prostate cancer. Gynecomastia with or without breast pain is a recognized adverse effect of bicalutamide, with an incidence of ~70% of patients within the first 6–9 months of hormonal therapy. This adverse event can be a major concern for the patient, sometimes causing treatment withdrawal. Because gynecomastia may compromise treatment outcome, simple and safe methods of managing this condition are needed.

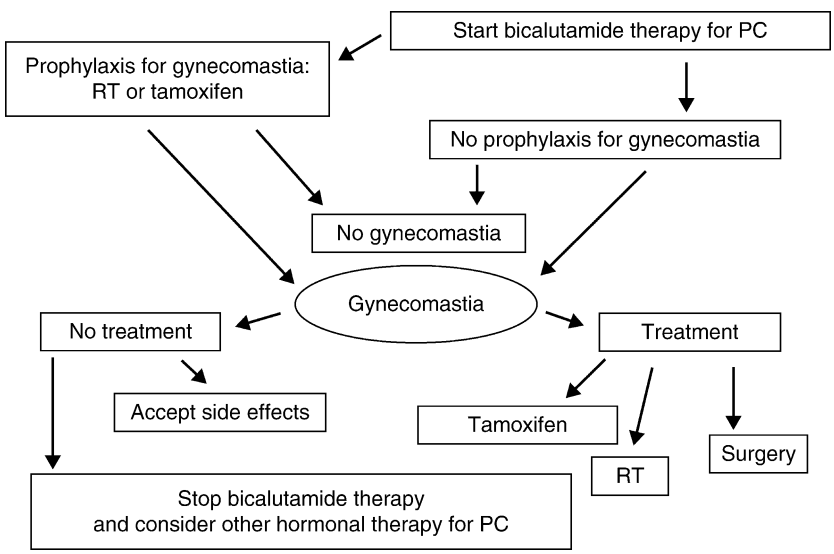
Therefore, clinicians who treat ►prostate cancer need information on the management of gynecomastia in their patients. In this setting, three options can be considered: surgery, ►radiation therapy, and medical therapy as prophylaxis or treatment. Although surgery has been used prophylactically, it is generally reserved for patients who have advanced gynecomastia. Recent data have shown that prophylactic, low-dose (10–12 Gy) breast irradiation is an effective and well-tolerated strategy for prevention or treatment of bicalutamide-induced gynecomastia.

In an interesting comparative study by Perdonà et al., the efficacy of ►tamoxifen (10 mg/day) versus ►radiotherapy (12 Gy) in the management of gynecomastia/breast pain due to bicalutamide (150 mg) monotherapy was investigated. Tamoxifen was extremely effective in preventing the development of bicalutamide-induced gynecomastia/breast pain and was significantly more effective than radiotherapy. These positive findings were in agreement with previous reports of different treatment schedules, such as those by Boccardo et al. and Saltzstein et al. using 20 mg tamoxifen daily and the report by Eaton et al. using 20 mg tamoxifen weekly.

Fradet et al. have conducted a trial to define the optimal tamoxifen dose for treating gynecomastia without compromising disease control. In this double-blind, parallel-group, multicenter trial, 282 patients with PC were randomized to receive bicalutamide (150 mg/day) plus either daily tamoxifen (1, 2.5, 5, 10, or 20 mg) or placebo for 12 months. At 6 and 12 months, tamoxifen decreased the incidence of breast events in a dose-dependent manner. These findings suggest that the optimal prophylactic dose of tamoxifen is 20 mg/day.

However, other issues remain unresolved:

- There may be some concerns regarding the use of tamoxifen in PC. Although blocking the effects of estrogen may effectively prevent or treat gynecomastia, the consequences of such treatment are unknown. Indeed, such therapy might be expected to increase androgen secretion by blocking the negative feedback of estradiol on the hypothalamic-pituitary axis. However, it is reassuring that most studies have reported no detrimental effects of tamoxifen on bicalutamide-induced ►PSA suppression.
- The optimal duration of medical therapy is unknown. Clinical trials addressing longer treatment duration and follow-up are necessary, although ethical concerns may be raised.



Gynecomastia. Figure 2 Management options for bicalutamide-induced gynecomastia. PC, prostate cancer; ►RT, radiation therapy.

- Tamoxifen is generally well tolerated at all doses. However, there are some minor, reversible side effects in tamoxifen-treated patients, and this should be discussed with the patient before therapy is initiated.
- There are financial considerations associated with the use of tamoxifen to prevent gynecomastia because the cost is not reimbursed by health insurances/systems in Europe. However, this is not a serious problem for most patients because tamoxifen is available as a relatively cheap generic drug.
- At present, a consensus on the most suitable method to assess gynecomastia is lacking. In the absence of a standardized parameter of evaluation, any comparison among different trials is of questionable value.

In conclusion, two approaches for the management of gynecomastia are recommended, a prophylactic and a therapeutic approach. The first approach aims to prevent this embarrassing condition, and the second avoids unnecessary treatment of those patients who would not have suffered from gynecomastia. Radiotherapy and medical therapy with tamoxifen are both applicable and effective. When unsatisfactory results are obtained with one therapy, the other can be offered as a second-line option. In this setting, the role of surgery remains limited. Switching to a different hormonal treatment for prostate cancer is another option that can be considered by clinicians and patients (Fig. 2).

Hamartin

Jaroslaw Jozwiak
Department of Histology and Embryology, Medical University of Warsaw, Warsaw, Poland

Synonyms

TSC1; Tuberous sclerosis complex 1

Definition

One of the two tumor suppressor proteins (the other is called ►tuberin or TSC2) forming an intracellular ►heterodimeric complex is called ►tuberous sclerosis complex (TSC). Both proteins are needed for the normal activity of TSC. Mutation of the hamartin gene with the consequence of altered protein leads to the development of a neurological disorder ►tuberous sclerosis, associated with the formation of usually benign tumors, or ►hamartomas, in different organ systems.

Characteristics

TSC is responsible for the inhibition of ►mammalian target of rapamycin (mTOR) kinase, whose pathway is involved in numerous cell processes linked to cell growth control, like cell cycle progression, transcription, and translation control as well as nutrient uptake. mTOR detects signals of nutrient availability, hypoxia, or growth factor stimulation and, in favorable environmental conditions, its activity leads to phosphorylation of ►eIF4E-Binding Protein 1 (4E-BP1, PHAS-I) and ribosomal ►p70 S6 kinase (S6K1), having direct effect on mRNA translation efficiency. Thus, mTOR controls cell growth through general protein biogenesis. When TSC complex is not functional, mTOR is hyperactive and leads to potentiation of cell growth and formation of hamartomas.

The TSC complex does not act directly on mTOR, but inhibits a ►G protein, ►Ras homologue enriched in brain (►Rheb). Rheb is a member of the Ras superfamily of GTPases, sharing the highest homology with Ras and Rap. ►GTPase-activating protein (GAP) region inhibiting Ras-related family of small G proteins, such as Rap1, Rab5, and Rheb, has been found in tuberin, thus explaining the link between tuberin mutations and strong phosphorylation of mTOR target proteins (S6K1 and 4E-BP1).

Although the GAP domain is only found in tuberin, mutations of hamartin result in the same clinical presentation of tuberous sclerosis, although in this case the severity of the disease may be slightly lower. Thus, although the specific activity is exerted by tuberin, hamartin can also influence signal transduction from Rheb to mTOR.

The *TSC1* gene is located on chromosome 9q34. It has 23 exons and an 8.6 kb mRNA transcript. Protein product, hamartin, is an 1164-amino-acid/130 kDa protein expressed in most human tissues, including the brain, kidney, heart, liver, small and large intestine, prostate, or testes. The protein is hydrophilic and has a single ►transmembrane domain at amino acids 127-144, and a predicted coiled-coil region at residues 719-998.

Cytosolic hamartin forms ►homomeric complexes. Whether this interaction is important for the proper formation of the TSC complex or for the development of the disease is not clear. It seems, however, that

tuberin acts as a chaperone, preventing formation of homomeric hamartin complexes. It is postulated that hamartin inhibits tumor formation by regulating actin dynamics and cellular adhesion through the actin-binding proteins of the ►ezrin-radixin-moiesin (ERM) family as well as the small G protein Rho. Importantly, interaction of hamartin with the ►ERM proteins is required for the activation of Rho by serum or lysophosphatidic acid. Moreover, hamartin was found to bind neurofilament-light chain (NF-L) and colocalize with NF-L and ERM proteins in neuronal growth cones of primary cortical neurons. As the binding of NF-L and ERM proteins by hamartin may play an important role in neuronal migration which could explain disturbances of this process that are often postulated to underlie characteristic brain lesions found in tuberous sclerosis, sometimes defined as "neuronal migration disorder."

Hamartin can be phosphorylated by ►cyclin-dependent kinase 1 (CDK1 or cdc2), activated in late cell cycle phases, at three residues: T417, S584, and T1047, one of which lies in the hamartin/tuberin interaction domain. It seems that complexing with tuberin protects hamartin from being phosphorylated, although on the other hand, such a phosphorylation does not influence the interaction with tuberin. Hamartin phosphorylation by CDK1 activates TSC, which strongly suggests specific regulation of this complex during cell cycle progression.

Haploinsufficiency

Lubomir B. Smilenov, David J. Brenner
Department of Radiation Oncology, Columbia University, New York, NY, USA

Definition

Reduced expression levels of a protein as a result of a mutation in one allele of the corresponding gene, leading to phenotypic effect.

H

Characteristics

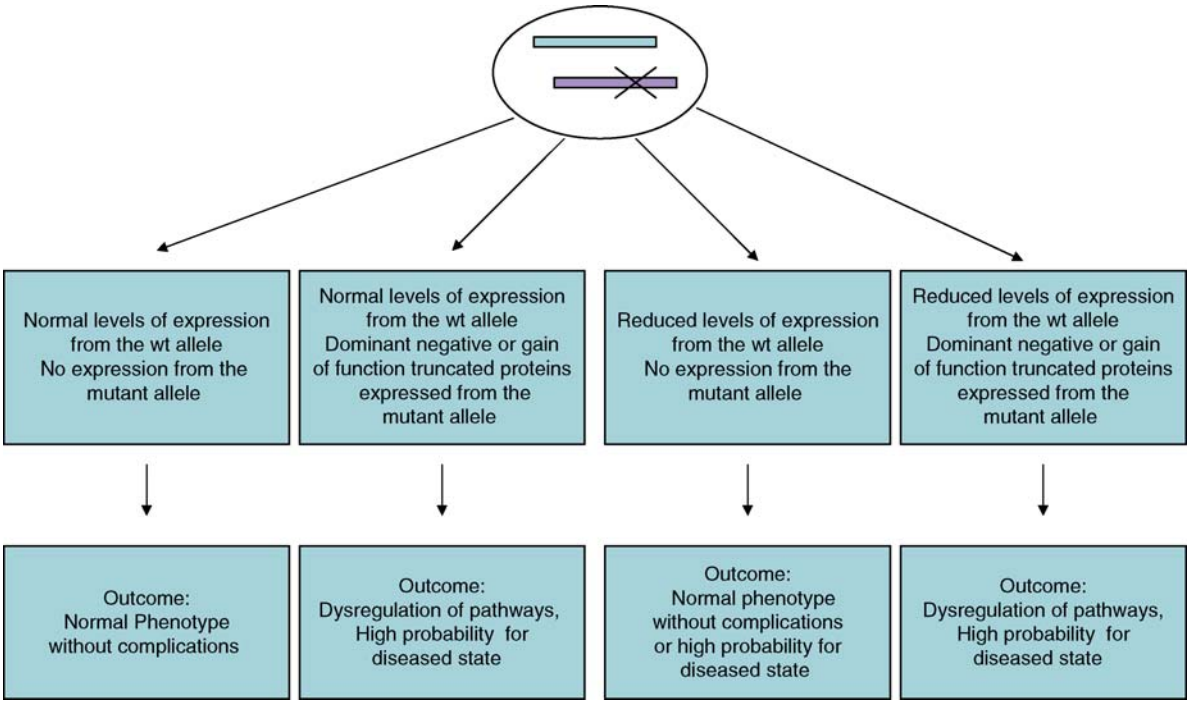
In the early 1920s, shortly after Morgan's chromosome theory of heredity became generally accepted, Calvin Bridges from Columbia University characterized a mutant type of *Drosophila melanogaster* known as "Diminished". He showed that the "Diminished" character is not due to the mutation of an ordinary gene, but to haploidy of the entire fourth chromosome. The elimination of one allele of the genes residing on this chromosome resulted in a complex of mutant characters, including somatic changes, and high rates of sterility and mortality.

During the next two decades several studies were focused on the role of gene haploidy in the generation of specific phenotypes. It became clear that gene dosage plays an important role in cell function and organism development. The word "haploinsufficiency" was credited to Otto Mohr by Curt Stern in the latter's seminal article "Genic Action as studied by means of the effects of different doses and combinations of alleles," published in 1943.

Despite this early evidence for the significance of haploinsufficiency, the dominant thinking from Mendel to the last decade of the twentieth century was that gene expression is a discrete event, i.e. genes are either expressed or not, either dominant or recessive. A general assumption also was that mutations in one allele of a gene does not have a phenotype. Even as late as 1971, these concepts were central to Knudson's two hit theory of carcinogenesis, which suggested that inherited mutations in one allele of a ►tumor suppressor gene increase the probability of early onset of tumors, but do not functionally contribute to it. Initial characterizations of Rb and p53 mutations in human tumors appeared to confirm that heterozygote mutations did not have a phenotype. However, with the development of knockout ►mouse models in the 1990s, it became obvious that mutation in one allele of a tumor suppressor gene could indeed have phenotypes, in some cases significantly different from the wild type.

Mutations in one allele of a tumor suppressor gene (the most studied case), or in any other gene, may result in reduced expression level of the corresponding protein. These mutations may lead to a complete absence of a protein product from the mutant allele (null genotype) or to the synthesis of a truncated protein. Since many of the regulatory proteins are complex, consisting of different functional domains, a truncated protein may retain some functional domains, therefore competing with the wild type protein for some functions (dominant negative or gain of function mutations). Therefore a mutations in one allele may lead to four principle outcomes, illustrated in Fig. 1.

Dominant negative or gain of function mutations often result in early onset of disease state. These are the well documented studies, for example, of the consequences of haploinsufficiency for *WT1*, *p53*, *BRCA1* and *BRCA2* genes. An expanding number of



Haploinsufficiency. Figure 1 Possible effect of mutations in one allele of a gene.

epidemiological studies, as well as mouse models, show that haploinsufficiency in null allele background is also often a major factor in tumor formation. For example, haploinsufficiency for the tumor suppressor genes *APC*, *BML*, *FEN1*, *MSH2*, *p27*, *p53*, *Rb*, *SMAD4* and *NF1* has been shown to be associated with increased incidence of sporadic human cancers including colorectal and gastric cancers, leukemia and lymphoma, breast cancer, retinoblastoma, and others (for a more complete list see Refs. [3] and [4]).

The difficulties in the estimating of the functionality of proteins coded by mutant genes as well as the problems associated with precise defining of the genetic background in large epidemiological studies have been a strong motivating factor in the development of mouse models. The role of haploinsufficiency was particularly well demonstrated in 1996, when three laboratories independently created *p27* null and heterozygous mice. The $p27^{-/-}$ mice had increased growth rate, as well as early mortality as a result of benign pituitary adenoma. As might be expected based on gene dosage concepts, $p27^{+/-}$ heterozygous mice had intermediate growth rate and intermediate mortality compared with the wild type and null genotype. Expression level analysis for the p27 protein also show that it is haploinsufficient in heterozygous animals. These results clearly show that the expression level of p27 may determine phenotype, a conclusion also reached from mouse model studies for *p18*, *PTEN*, *Plk4*, *TGF-b1*, and other genes.

Heterozygous mice typically also have an intermediate response to DNA damaging agents, such as ionizing radiation or some chemical carcinogens, compared with the wild type and null genotype. For example, tumor development in *p27* deficient mice induced by a 1 Gy X-ray dose show distinctive characteristics based on the genotype. $p27^{-/-}$ mice had significantly reduced life span as a result of multiple tumor types. $p27^{+/-}$ mice again show intermediate phenotypic susceptibility to tumors and survival. These tumors in $p27^{+/-}$ mice retain the wild type allele and were less severe than those from the knockout background. Similar results have been obtained in mouse models haploinsufficient for *p53*, *Nbn*, *DMP1* and *TGF-b1*.

Another remarkable result from these mouse-model experiments is that different mouse strains which haploinsufficient for the same protein developed different type of tumors; for example, p53 haploinsufficient mice developed strain-specific tumors after chemical carcinogen treatment. Such observations show the critical importance of the genetic background. In a related set of experiments, it was shown that mice double heterozygous for two genes (for examples *Fen/Apc*, *Cdh1/Apc* and *Xpc/Trp53*) show an increased frequency of tumor incidence in comparison with single heterozygous mice. Such results point to the importance of the genetic background for familial cancers known to arise as a result of heterozygosity for *BRCA1*, *BRCA2*, *ATM*, *CBFA2*, *Smad4* and *Cdh1*. The key conclusion is that heterozygosis for a single gene can contribute to tumor formation.

There are indications that in the general population the number of individuals who are heterozygote for some genes is quite substantial; for example, 0.5–3% of the US population are heterozygote for the *ATM* gene, and recent large-scale epidemiological studies suggest that relative risk of breast cancer in ATM heterozygotes is about 2 compared to the general population, and about 5 in women under 50 years of age. To date, *BRCA1*, *BRCA2*, *TP53* (high risk), and *CHEK2* and *ATM* (moderate risk), have been shown to be involved in enhanced breast cancer predisposition in humans. To what extent these and other heterozygous carriers may have increased cancer risks in other sites is a key question which can probably only be resolved through a better understanding of the mechanisms underlying the role of heterozygosity in tumor formation.

Mechanism of Disease Initiation Involving Haploinsufficiency

Defining the role of haploinsufficiency in the cases where there is expression of dominant negative or gain of function protein from the mutant allele is much easier than when there is no protein expression. Generally, the truncated protein competes with the wild type protein for specific function, or as shown for p53, it may form non functional complexes with the wild type proteins. This can result in partial or complete lost of function for the wild type protein, and often accelerates progress toward a disease state. The mechanisms acting in a null allele background are less well understood. In this case, the only differences between the wild type and haploinsufficient organism are the expression levels of the corresponding proteins. In fact, expression levels of a single protein may have negative effect on the efficiency of a pathway, and haploinsufficiency for two or more proteins can have further negative effects. The effects of this type of haploinsufficiency shows significant interdependence between the proteins involved in cell regulation and tumor formation. Thus, realistic analysis of possible mechanisms inevitably involves analysis of biological networks in which many (if not all) regulatory proteins are linked with each other. Understanding such networks is not easy, even for the known pathways where, for example, the exact yields and activities of the involved proteins are not easy to estimate. Nevertheless, it is now clear that biological networks are complex, hierarchical and, on a local level, are usually modular or motif based. The relatively new discipline of systems biology hold a great deal of promising for elucidating these networks, and one particular mode of organization, the scale free

network, has been shown to be a powerful descriptor of the interrelationships between different cellular components. Scale free networks involve different levels of connectivity between their nodes – a few highly interconnected nodes (hubs) communicate with the remaining larger number of less interconnected nodes. This hierarchy is highly tolerant of inactivated nodes, since the likelihood that one of the few hubs will be affected is small. Even if such an event occurs, the network may not completely lose its connectedness. In analyzing haploinsufficiency, the nodes would represent the status of proteins, and low concentrations of only one of the highly interconnected hub proteins could negatively influence the network response as a whole. The general principles that apply to complex networks require some modifications for biological networks. Mathematical or computer networks are usually analyzed as already connected structures of elements, whereas biological networks are often self assembly/disassembly networks. The requirement for assembly in response to an event at an unknown location in a relatively large (on molecular scale) region, introduces spatial and quantitative constraints. DNA double-strand breaks (DSB), for example, are local events that may appear at any place in the nucleus. In response to a DSB, a network has to be assembled locally in order to signal and initiate the repair. Proteins that are potential members of such local networks have to be in close proximity, or be able to rapidly translocate to the site. Several experiments confirm this scenario. Immunofluorescence analyses of cells subject to radiation induced DSB show that many DNA repair proteins, such as ATM, p53, MRE11, Rad50 and NBS1, ATR, colocalize and form discrete foci near the sites of DNA damage. Migration of DNA repair proteins toward the site of DNA damage has also been analyzed by FRAP. By measuring diffusion rates, it has been shown that translocation and transient immobilization of RAD51, RAD52, RAD54, as well as the NER repair complex ERCC1-XPF, occurs near DNA repair sites in mammalian cells. Haploinsufficiency for ATM or BRCA1 (which recruits proteins toward the BRCA1-associated surveillance complex, BASC) can lead to incomplete assembly of the BASC complex, and diminution or loss of its function. As a result, such cells may contain more unrepaired or misrepaired DSB, or may be more prone to failure of apoptosis, all of which could lead to mutation accumulation and subsequent disease progression. This mechanism suggest an important role for haploinsufficiency in tumor development. Furthermore, the role of combined haploinsufficiency emphasizes that individual predisposition to tumor may be a result of a combination of haploinsufficiencies for different genes. These observations may, in part, account for the higher than predicted rate of cancer in humans.

Haplotype

Definition

A haplotype is a linked set of genes associated with one haploid genome. The term is used mainly in connection with the linked genes of the major histocompatibility complex, which are usually inherited as one haplotype from each parent. Some MHC haplotypes are overrepresented in the population, a phenomenon known as linkage disequilibrium.

►Linkage Disequlibrium
►HLA Class I

Haptens

Definition

Are molecules that can bind antibody but cannot by themselves elicit an adaptive immune response. Haptens must be chemically linked to protein carriers to elicit antibody and ►T-cell response.

Haptoglobin

Definition

One of the acute phase proteins produced in the liver. Haptoglobin binds to oxidized hemoglobin, which is

produced in hemolytic diseases. Haptoglobin is also involved in arteriosclerosis and the immune system. The ectopic production of haptoglobin was observed in several diseases, including infections, ►inflammation and cancer.

►Fucosylation

Haptotaxis

Definition

Haptotaxis is type of chemoattraction where the chemical gradient of the ligand is presented to the cell bound to the substrate. Movement of cells in response to a biochemical gradient on a surface. Attraction indicates on a positive haptotaxis whereas repellence indicates on negative haptotaxis.

►Laminin Signaling
►Chemoattraction

Hardy–Weinberg Law

Definition

First described by G. H. Hardy and Wilhelm Weinberg, it mentions that, under certain conditions, after one generation of random mating, the genotype frequencies at a single gene locus will become fixed at a particular equilibrium value. It also specifies that those equilibrium frequencies can be represented as a simple function of the allele frequencies at that locus.

In case of a single locus with two alleles A and a with allele frequencies of p and q, respectively, it predicts that the genotypic frequencies for the AA homozygote to be p^2, the Aa heterozygote to be $2pq$, and the other aa homozygote to be q^2. In other words, it is predicting genotypic frequencies from allele frequencies.

Deviations from the HWE can be due to Genotyping errors.

HARP

►Pleiotrophin

HAS

►Hyaluronan Synthases

HAS1

Definition

Hyaluronan Synthase 1 – An integral multipass plasma membrane protein that catalyses hyaluronan synthesis, and is associated with maintenance of a basal level of hyaluronan. Exhibits low catalytic activity and synthesises high molecular weight hyaluronan.

►Hyaluronan Synthases

HAS2

Definition

Hyaluronan Synthase 2 – An integral multipass plasma membrane protein that catalyses hyaluronan synthesis. High expression levels are observed in developmental processes involving tissue expansion and growth which may require rapid changes in matrix composition. Exhibits high catalytic activity and synthesises high molecular weight hyaluronan.

►Hyaluronan Synthases

HAS3

Definition

Hyaluronan Synthase 3 – An integral multipass plasma membrane protein that catalyses hyaluronan synthesis and is associated with high catalytic activity and synthesis of low molecular weight hyaluronan. Produces hyaluronan that contributes to the glycocalyx and initiates cell signal transduction via interaction with hyaluronan-specific cell surface receptors.

►Hyaluronan Synthases

Hashimoto Thyroiditis

Definition

Is an thyroid ►autoimmune disease in which the immune system attacks and destroys the cells of the thyroid gland. The thyroid helps set the rate of metabolism, which is the rate at which the body uses energy. Hashimoto hyroiditis stops the gland from making enough thyroid hormones for the body to work the way it should.

►Chronic Lymphocytic Thyroiditis
►Marginal Zone B-Cell Lymphoma
►Chronic Lymphocytic Thyroiditis

HAT

Definition

1. Histone acetyltransferases. Enzymes that transfer acetyl groups from acetyl-CoA to histone tails. Transcriptional coactivators often have HAT activity. Three superfamilies of HATs are known: GNAT, MYST and p300/CBP.
   ►Histone Deacetylases
   ►Epigenetic silencing
   ►P300/CBP Co-Activators

2. Hypoxanthine-aminopterin-thymidine.
   ►Microcell-Mediated Chromosome Transfer

HAUSP

Definition

Herpes-associated ubiquitin-specific protease, a deubiquitinase that interacts with p53 and promotes its accumulation.

►HAUSP De-ubiquitinase

HAUSP De-Ubiquitinase

►Herpesvirus-Associated Ubiquitin-Specific Protease De-ubiquitinase

γH2AX

Definition

A histone variant called H2AX is phosphorylated at serine 139 when double- stranded breaks (DSBs) occur in cells. This phosphorylated form of H2AX is called γH2AX, a hallmark for DSBs.

HB-EGF

Michael R. Freeman
Urological Diseases Research Center, Children's Hospital Boston, Harvard Medical School, Boston, MA, USA

Definition

Heparin-binding epidermal growth factor-like growth factor; is a high-affinity, activating ligand for the ►epidermal growth factor receptor (EGFR/HER1/ErbB1) and for the related receptor tyrosine kinase, ►ErbB4. HB-EGF was originally identified by a combination of biochemical and bioactivity-based in vitro assays. Following biochemical purification, the protein was recognized as a member of the epidermal growth factor (EGF) family by molecular cloning. The HB-EGF gene resides on chromosome 5 (5q23) in the human genome.

Characteristics

HB-EGF is a ►mitogen, morphogen, motility and cell survival factor. The protein is initially expressed in a

membrane-anchored form (proHB-EGF), with a single membrane-spanning domain, a structural characteristic shared by other ErbB family ligands. HB-EGF was initially observed as a mitogenic activity recognizable in cell culture medium conditioned by macrophage-like cells. The protein was recognized to have a high affinity for immobilized heparin and heparin-affinity chromatography was used in its purification. The heparin-binding property of HB-EGF, which is conferred by a region of basic residues that precedes (reading from the N-terminus) the EGF-like motif, distinguishes it biochemically from EGF and most other EGF-like growth factors. HB-EGF most closely resembles one other EGF-like growth factor and EGFR ligand, ►amphiregulin, which exhibits a similar affinity for heparin and has a similar overall primary structure. The results of a variety of studies indicate that cell surface heparan sulfate proteoglycans play a role in the control of HB-EGF bioactivity. Hence, the heparin-binding property of the protein is likely to be physiologically relevant. The heparin-binding region may also serve as a nuclear localization motif.

The soluble form of HB-EGF is mobilized from the cell surface form by regulated proteolytic cleavage. Several membrane-associated proteases, including ►matrix metalloproteinase (MMP)-3, MMP-7, and several proteases of the disintegrin and metalloproteinase (►ADAM) family have been implicated as HB-EGF sheddases in various cell types and physiologic contexts. The specific protease involved in a particular physiologic or pathologic process is likely to reflect cell- and tissue-dependencies that may not apply to other settings.

An interesting property of HB-EGF, unique among the EGF growth factor family, is that the ectodomain and mature form of the protein bind diphtheria toxin with high affinity. The membrane form of the protein (proHB-EGF) is the physiologic receptor for diphtheria toxin. ProHB-EGF is internalized by normal endocytic processes after toxin binding. Hence, HB-EGF is a mediator of the clinical effects of diphtheria toxin by serving as a means of transporting the active toxin into cells.

Clinical Relevance

Experimental and translational studies indicate that HB-EGF plays a role in formation of the vascular system during development, in muscle hypertrophy, in angiogenic tissue reactions, and as an autocrine, paracrine and juxtacrine signaling molecule. Published information suggests that HB-EGF may play a functional role in ►bladder cancer and ►ovarian cancer.

Homology to the E6-associated protein C terminus; ►Itch.

Hedgehog

Definition

Abbreviated Hh in mouse, HH in human; In vertebrates there are three hedgehog genes (*Sonic*, *Indian* and *Desert*) that encode secreted proteins involved in embryonic patterning of a wide range of tissues.

►Hedgehog Signaling

Hedgehog Signaling

Carol Wicking
Institute for Molecular Bioscience, The University of Queensland, St Lucia, Australia

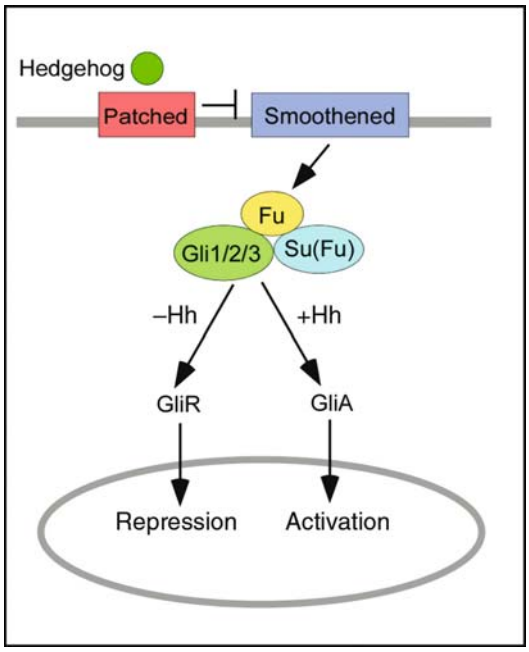
Definition

The Hedgehog pathway is a signaling cascade that plays a crucial role in the embryonic development of a wide range of vertebrate organs and systems. Mutations in members of the hedgehog pathway have been found in a number of tumor types including ►basal cell carcinoma (BCC) and ►medulloblastoma. More recently, ligand-dependent activation of the pathway has been demonstrated in a wider range of tumors. Although some differences exist, the overall pathway has been conserved from *Drosophila* through to human.

Characteristics

The ►Hedgehog proteins are secreted molecules that act through a receptor complex involving two additional proteins ►Patched and ►Smoothened. The current model for hedgehog signaling suggests that, in the absence of Hedgehog, Patched inhibits Smoothened and thus prevents signaling. When Hedgehog binds to Patched, the inhibition of Smoothened is released and intracellular signaling is activated. The ultimate regulation of Hedgehog target genes in the nucleus is mediated in mammals by the three ►Gli zinc finger transcription factors. Gli1 and 2 act primarily as transcriptional activators, while Gli3 is also involved in transcriptional repression. The repressor function of Gli3 is mediated by cleavage of the full-length activator form of the protein into a truncated repressor form (see Fig. 1 for model).

Recent years have seen the identification of many additional proteins that regulate Hedgehog signaling both at the cell surface and at various points in the intracellular signaling cascade. Likewise cilia, microtubule base



Hedgehog Signaling. Figure 1 Simplified representation of the Hedgehog signaling pathway in vertebrates. In the absence of Hedgehog, the transmembrane protein Patched inhibits signaling from the Smoothened molecule. In this state full-length Gli is cleaved to its repressor form (GliR) and enters the nucleus where it represses transcription of target genes. Of the three vertebrate Gli genes, Gli3 plays the major role as a transcriptional repressor in vivo. On Hedgehog binding to Patched, inhibition of Smoothened is relieved, cleavage of Gli is inhibited and the full-length activator (GliA) form enters the nucleus and activates transcription of target genes. A complex of molecules including Suppressor of fused (Su(Fu)) and Fused (Fu), regulates the cytoplasmic/nuclear translocation of Gli, although the precise role of these proteins in vertebrates remains unclear. A number of other molecules have been shown to regulate signaling at various points in the pathway, but these have not been shown for simplicity.

organelles present in virtually all vertebrate cells, have recently been linked to hedgehog signaling in higher vertebrates. For simplicity these aspects of hedgehog signaling will not be addressed in detail here.

Hedgehog Signaling and Cancer

The pivotal role of the Hedgehog signaling pathway in tumor formation was first realised with the discovery that the *Patched* gene is mutated in a rare inherited cancer predisposition syndrome known as ►naevoid basal cell carcinoma syndrome (NBCCS) or Gorlin's syndrome. NBCCS is characterized by a range of developmental defects in addition to cancer predisposition. While the major tumors seen in NBCCS patients are BCCs, other neoplasms that occur at an increased incidence in this syndrome include medulloblastoma, ovarian fibroma, meningioma, fibrosarcoma, rhabdomyosarcoma and cardiac fibroma.

In addition to being responsible for NBCCS, mutations in the *Patched* gene also occur in a large percentage of the common sporadic forms of BCC that occur in the general population. *Patched* acts as a tumor suppressor gene with inactivation of both copies required for tumor progression. NBCCS individuals are born with one copy of the *Patched* gene inactivated either by mutation or genomic deletion in every cell of their bodies, and tumor formation results when the other copy is inactivated in a given cell throughout life. By chance this will occur more frequently and at a younger age than inactivation of both copies in the same cell during the life of a non-NBCCS individual. In addition to BCCs, mutations in *Patched* have also been demonstrated in a subset of sporadic medulloblastomas, tricoepitheliomas (TEs), esophageal squamous cell carcinomas and transitional cell carcinomas of the bladder. Inactivating mutations in the ►*Suppressor of Fused* (*SU(FU)*) gene, which like *Patched* encodes a negative regulator of Hedgehog signaling, have also been detected in medulloblastomas and BCCs. Contrary to the action of *Patched* and *SU(FU)*, *Smoothened* has been shown to act as an oncogene, with activating mutations detected in both BCCs and medulloblastomas. The net result of all of these mutations is the ligand-independent activation of the Hedgehog pathway.

Until relatively recently our knowledge of the involvement of Hedgehog signaling in cancer was restricted primarily to tumors associated with Gorlin's syndrome. However, a wider spectrum of tumors has now been shown to be associated with ligand-dependent activation of the pathway. These tumors include small cell lung cancer, oesophageal, stomach, biliary tract, pancreatic, and prostate cancer.

Hedgehog, Stem Cell Renewal and Cancer

The underlying mechanisms linking the Hedgehog pathway to cancer remain elusive but a number of theories exist. Recent evidence supports the view that tumors arise from ►cancer stem cells, a minor population of cells within a tumor that are characterized by an inherent capacity for self renewal. In this context a number of signaling pathways, including the Hedgehog cascade, have been implicated in tissue regeneration and stem cell renewal. In a number of tissues, injury is associated with stem cell expansion and Hedgehog pathway activation. It has been suggested that cancer may result when this state of tissue repair remains unregulated, thus retaining the stem cell in a continuously activated state.

Targeting Hedgehog Signaling for Therapeutics

A number of studies have investigated antagonists of Hedgehog signaling as potential cancer therapeutics.

In particular, the plant alkaloid ►cyclopamine inhibits signaling at the level of Smoothened and has been shown to inhibit growth of certain Hedgehog-associated tumors in mouse models. Synthetic small molecule antagonists of Hedgehog signaling have also been investigated as potential therapeutics. These studies have demonstrated that inhibition of Hedgehog signaling can block tumor growth and suggest this approach as a promising treatment for a number of cancers. However, issues surrounding blockage of a key developmental pathway re-activated in tissue repair need to be carefully considered before safe effective therapies are developed.

HEK 293

Definition

A cell line derived form human embryonic kidney. Frequently used for adenoviruses production.

►Oncolytic Adenovirus

HeLa Cells

Definition

Are ►immortalized human epithelial cells from a cervical carcinoma transformed by ►human papillomavirus 18 (HPV18). The name of the cell line is derived from the woman who had developed the cancer, Henrietta Lacks. HeLa cells are adherent cells (they stick to surfaces) and maintain contact inhibition *in vitro*, i.e. as they spread out across the culture flask, when two adjacent cells touch, this signals them to stop growing. Loss of contact inhibition is a classic sign of cancer cells, i.e. cells which form tumors in experimental animals.

Helicase

Definition

Is an enzyme that separates the complementary strands of a DNA duplex.

Helicobacter Pylori

Definition

A noxious bacterium responsible for gastrointestinal injury including duodenal ulcer and ►gastric cancer.

►Chemoprotectants
►Gastric Cancer

Helix-Loop-Helix Domain

Definition

HLH domain; A structural motif consisting of two helices connected by a loop sequence. It is found in diverse transcription factors and is involved in homo- or heterodimerization.

►Early B-cell Factors

Helper CD4 T Cells

Definition

Are CD4 T cells that can help B cells to make antibody in response to antigenic challenge. The most efficient helper T cells are also known as Th2 cells, which make the cytokines IL-4 and IL-5. Some experts refer to all CD4 T cells, regardless of function, as helper T cells; we

do not accept this usage because function can be determined only in cellular assays, and some CD4T cells kill the cells they interact with.

Helper T (Th) Cells

Definition

Like CTL, helper T cells bear an αβ TCR that recognize fragments of antigenic proteins. However, these fragments are bound to MHC class II molecules, which are usually found only on cells of the immune system and specifically on specialized antigen presenting cells such as B cells, macrophages and dendritic cells Helper T cells bear CD4 receptors that also bind to MHC class II. Activated CD4 T cells can differentiate into two main phenotypes that differ depending on the cytokine subset they secrete. Th1 cells secrete IFN-γ and are important in activating and maturing CTL whereas Th2 cells secrete cytokines important in maturing antibody secreting B cells. Both Th1 and Th2 are required to maintain long lived memory CTL or B cells. They thus function to help other arms of the immune response, hence their "helper" designation.

►HVJ

Hemangioblastoma

Definition

Is a benign tumor of the nervous system that may occur sporadically or in association with ►von Hippel-Lindau disease. It accounts for approximately 2% of intracranial tumors, arising most frequently in the cerebellar hemispheres and vermis.

►Angioblastoma

Hemangioendothelioma

Definition

A tumor of unpredictable behavior comprised of proliferating endothelial cells. It may be multifocal in the same bone or even in the same limb bud.

►Bone Tumors

Hemangioma

Definition

Benign tumor composed of newly formed blood vessels.

►Hepatic Epithelioid Hemangioendothelioma
►Bone Tumors

Hemangiosarcoma

Definition

Malignant tumor of mesenchymal origin arising from endothelial cells.

►Bovine Papillomavirus

Hematological Malignancies, Leukemias and Lymphomas

Jesper Jurlander
Department of Hematology, The Finsen Centre, Rigshospitalet, Copenhagen, Denmark

Definition

Hematological malignancies are a collective term for neoplastic diseases of the hematopoietic and lymphoid tissues, with clinical presentation as leukemia, lymphoma or myeloma.

Characteristics

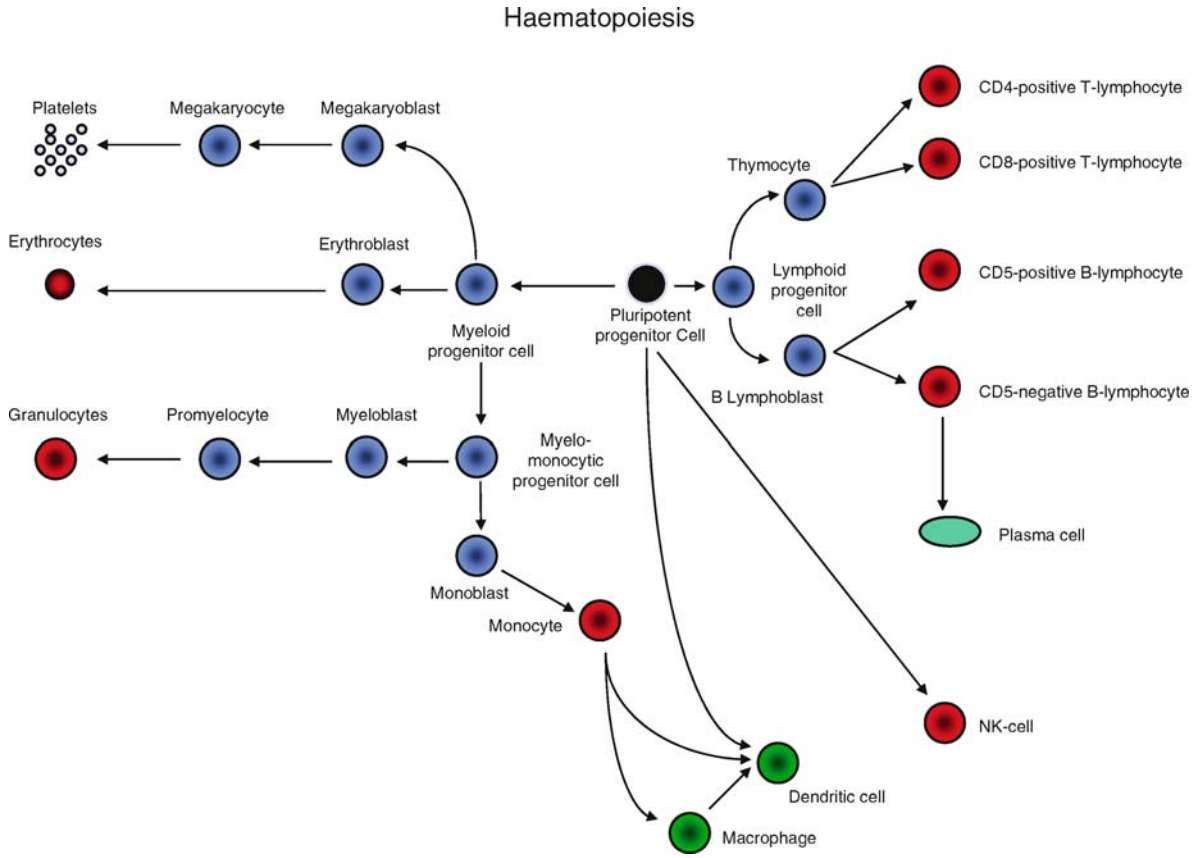
The Hematopoietic System

The blood contains a number of different cell types, which can be divided into cells with and without a nucleus. The unnucleated cells are red blood cells (erythrocytes) and platelets (thrombocytes). The nucleated white blood cells consist of three major subclasses: granulocytes, lymphocytes and monocytes, which can be further categorized as eosinophil, basophil or neutrophil granulocytes, T-lymphocytes, B-lymphocytes and ►natural killer cells (NK-cells). These cells are all derived from a common ancestor, the ►pluripotent progenitor cell in the bone marrow. In the bone marrow, different lineages are derived from this pluripotent progenitor. Precursor cells proceed through specific maturation steps before they, as mature circulating cells, leave the bone marrow in order to circulate in the bloodstream. Fig. 1 shows a simplified schematic representation of these processes. The pluripotent progenitor cell is shown in black in the middle, cells which are normally found only in the bone marrow (or thymus) are in blue, cells normally circulating in the blood are in red and cells found in tissues are in green.

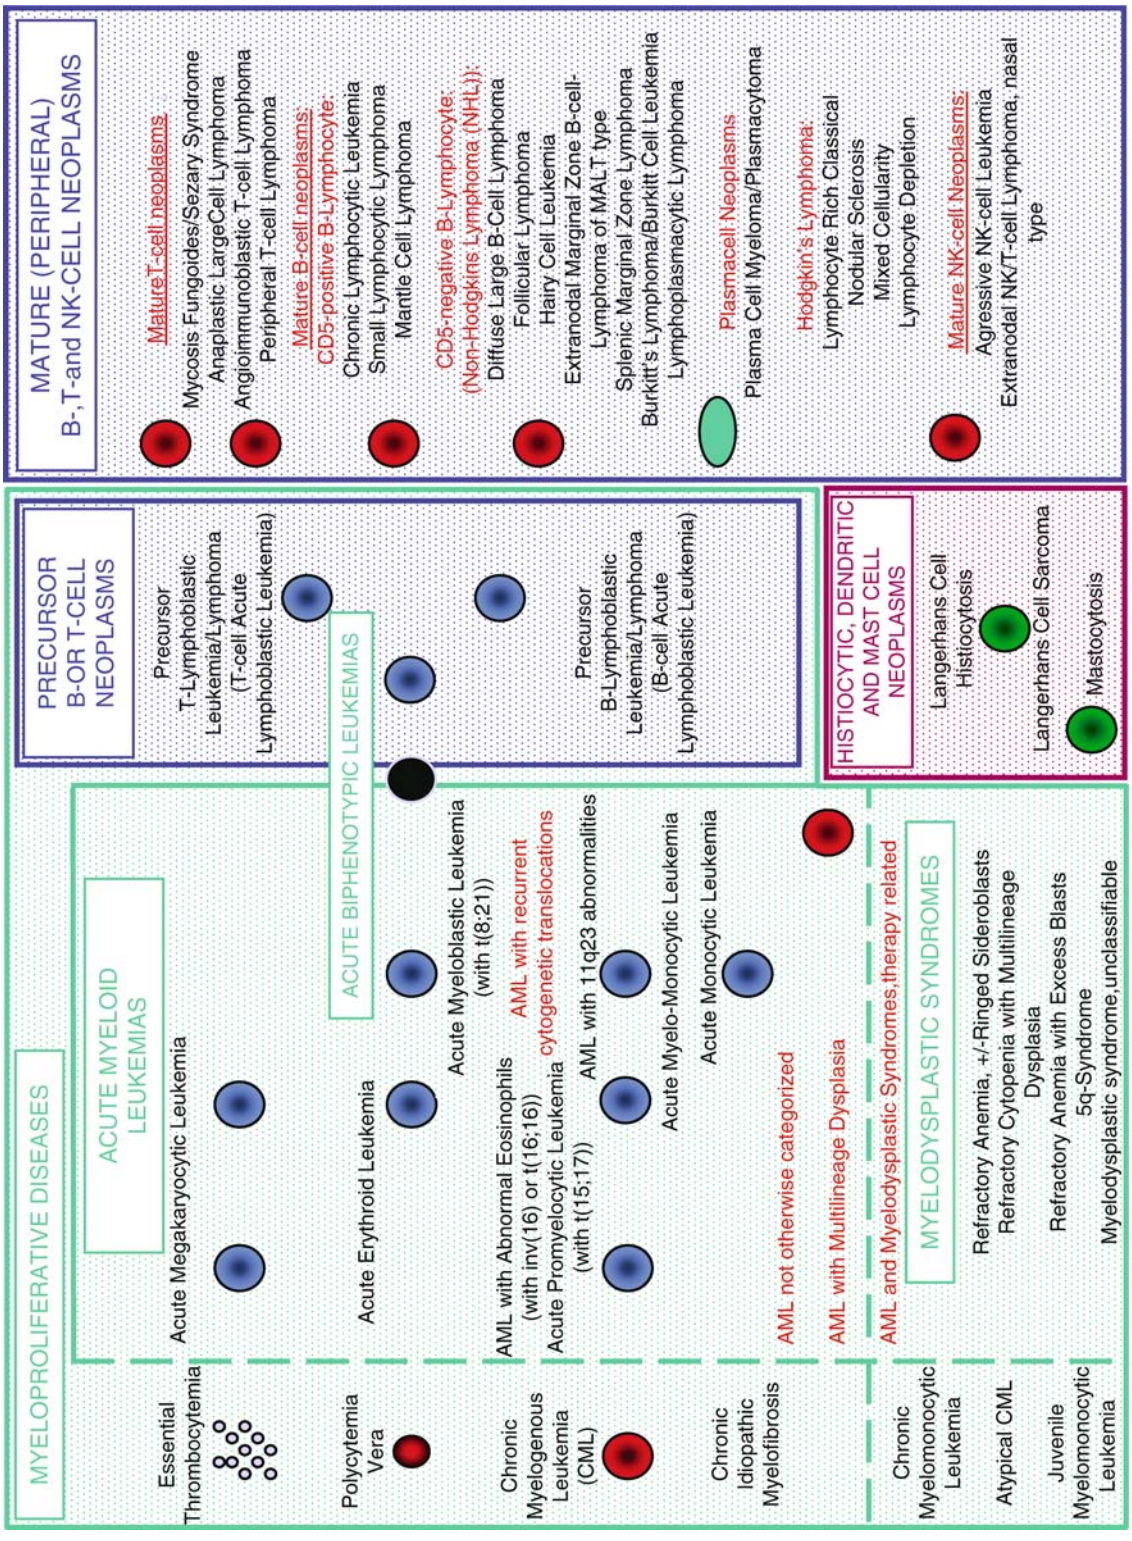
Two major lineages can be defined: The myeloid lineage (shown in green on the left side) and the lymphoid lineage (shown in blue on the right side). Platelets, erythrocytes, granulocytes, monocytes and ►dendritic cells are derived from the myeloid lineage. T- and B-lymphocytes, plasma cells and NK-cells are derived from the lymphoid lineage. The lineages, and the maturation steps involved, can be recognized using morphologic, cytochemical and immunophenotypic features. Similarly, hematologic malignancies are categorized according to such features.

The WHO Classification

The World Health Organization (WHO) has published a unified classification of neoplastic diseases of the hematopoietic and lymphoid tissues. In relation to the development of hematopoietic cells, the two major WHO classes can be viewed as disease "domains", based on the cell types primarily affected in each class and specific subclasses. The principles of this classification are shown in Fig. 2. The domains of the myeloid neoplasms are on the left side, rare histiocytic, dendritic or mast cell neoplasms are at the bottom and the domains of lymphoid neoplasms are on the right side. The WHO classification adopts the REAL (Revised European American Lymphoma) classification of lymphoid neoplasms, whereas the classification of myeloid neoplasms



Hematological Malignancies, Leukemias and Lymphomas. Figure 1 Hamatopoiesis.



Hematological Malignancies, Leukemias and Lymphomas. Figure 2 Leukemic Diseases.

has been revised in several categories compared to the FAB (French American British) classification.

Each of these two major classes consists of subclasses which subsequently categorize the specific disease entities, the most common of which are shown in Fig. 2. Myeloid neoplasms (Fig. 2, left side) consist of three major subclasses: chronic myeloproliferative disorders, ►myelodysplastic syndromes and acute myeloblastic leukemias, but also include more rare myeloid disorders with both proliferative and dysplastic features and disorders of histiocytes, mast (►Mastocytosis) cells and dendritic cells. Lymphoid neoplasms consist of two major subclasses, precursor and mature neoplasms, with specific disease entities of each subclass defined according to the involved cell type, that is, B-, T- or NK-cells. (Fig. 2, right side). Neoplasms of B-cell origin are exceedingly more common than disorders arising in T- and NK-cells (►Malignant lymphoma).

Major Myeloid Subclasses within the WHO Classification

Chronic Myeloproliferative Disorders (MPD's) are disorders of effective hematopoiesis initially presenting with increased levels of one or more of the circulating myeloid cell types: erythrocytes, platelets and granulocytes. On the basis of specific genetic events they can be subdivided into ►Philadelphia chromosome positive disorders, carrying the t(9;22) (►BCR-ABL1) hallmark of Chronic Myeloid Leukemia (►CML), and ►Philadelphia chromosome negative MPD's (Philadelphia chromosome negative myeloproliferative disorders), described as essential thrombocytemia, polycytemia vera and chronic idiopathic myelofibrosis in the WHO classification. The Philadelphia chromosome negative MPD's are better classified according to the presence or absence of activating mutations in the JAK2 protein kinase (►JAK2 mutations). Also recognized within the subclass of chronic MPD's, are rare disorders as chronic neutropilic leukemia, chronic eosinophilic leukemia and unclassifiable myeloproliferative diseases. The "domain" of MPD's is larger than the peripheral blood, since all of these disorders have the potential to transform into acute leukemia (►Blast crisis), including leukemias with a lymphoid phenotype. Furthermore, a small but distinct class of myeloproliferative diseases also show dysplastic features. Therefore the WHO classification has defined a class of myelodysplastic/myeloproliferative diseases, shown in the lower left corner of Fig. 2. This class includes chronic myelomonocytic leukemia, atypical chronic myelogenous leukemia and juvenile myelomonocytic leukemia.

The ►*myelodysplastic syndromes* (MDS) are diseases of ineffective hematopoiesis, resulting in decreased levels of one or more of the circulating myeloid cell types. As the myeloproliferative diseases, the myelodysplastic syndromes can also transform but only to acute myeloid leukemias, suggesting that the "domains" of these diseases may be somewhat smaller than that of myeloproliferative disorders. The class includes refractory anemia (with or without ringed sideroblasts), refractory cytopenia with multilineage dysplasia, refractory anemia with excess blasts, 5q-syndrome (MDS: 5q-syndrome) and unclassifiable myelodysplastic syndromes.

The acute myeloid leukemias (AML) (Acute myeloblastic leukemia) can be divided into sublasses (as shown in red in Fig. 2): AML's with recurrent cytogenetic ►translocations (►Chromosomal aberrations including ►acute promyelocytic leukemia, AML with multilineage dysplasia (with or without preceeding myelodysplastic syndrome), therapy-related AML and myelodysplastic syndromes and AML not otherwise categorized. Conversion from myelodysplastic syndrome to ouvert AML is defined by a blast count exceeding 20% of the cells in the bone marrow. Finally acute biphenotypic leukemias are included among myeloid neoplasms in the WHO classification.

Major Lymphoid Subclasses within the WHO Classification

The lymphoid precursor neoplasms are the acute lymphoblastic leukemias (ALL) of either B- or T-lineage origin, but also include the presentation of these diseases as lymphoblastic lymphomas.

The Mature T and NK-cell neoplasms include mycosis fungoides (and the leukemic variant of this lymphoma; ►Sezary syndrome), ►anaplastic large T-cell lymphoma angioimmunblastic T-cell lymphoma, peripheral T-cell lymphoma not otherwise specified (NOS) and a number of more rare diseases. NK-cell neoplasms are rare, but include both lymphoma and leukemia subtypes (Fig. 2, bottom right).

The mature B-cell neoplasms are historically and based on histology divided into of ►Hodgkin disease and ►Non-Hodgkin Lymphoma (NHL). ►Hodgkin disease is further subclassified as either nodular lymphocyte predominant Hodgkin lymphoma or classical Hodgkin lymphoma with the four specific subtypes: nodular sclerosis, lymphocyte-rich, mixed cellularity and lymphocyte depletion. The non-Hodgkin lymphomas are subclassified according to morphology, immune phenotype, rearrangement of the immunoglobulin genes and recurrent ►chromosomal aberrations. ►Chronic lymphocytic leukemia/small lymphocytic leukemia and ►mantle cell lymphoma are characterized by obligatory expression of ►CD5 in the cell membrane. The most common NHL is ►diffuse large B-cell lymphoma, which is not a single uniform entity

as demonstrated by gene expression profiling and molecular genetics (►Bcl-6 translocations in B-cell tumors), but may contain several related disease entities with variable clinical course. The most common small cell lymphoma is ►follicular lymphoma, characterized by the t(14;18) recurrent translocation resulting in rearrangement of ►Bcl-2. Several other small cell lymphoproliferative syndromes, often referred to as ►indolent lymphomas, exists including extranodal ►marginal zone ►B-cell lymphoma of ►MALT (mucosa associated lymphoid tissue) type, splenic marginal zone lymphoma and lymphoplasmacytic lymphoma (with the clinical syndrome of ►Waldenström macroglobulinemia). ►Burkitt lymphoma is a very aggressive disease characterized by the rearrangement of the ►MYC oncogene exists plus a number of rarer conditions and variants. The non-Hodgkin lymphomas have a very heterogenous clinical course and biology, from highly aggressive but potentially curable diseases such as diffuse large cell lymphoma and Burkitt lymphoma to indolent but incurable diseases as CLL and follicular lymphoma. Even these seemingly indolent diseases may over time acquire additional molecular changes, resulting in transformation to large cell lymphomas (Richters syndrome).

The plasma cell neoplasms are dominated by ►multiple myeloma and related variants as monoclonal gammopathy of unknown significance to localized plasmacytoma or disseminated plasma cell leukemia.

Diagnosis

The complexity of the hematopoietic system (Fig. 1) is reflected by the existence of a wide spectrum of distinct tumors, with numerous variants (Figs. 1 and 2). Optimal treatment of a given condition is dependent on exact classification of the disease. It is not sufficient to rely solely on morphology, cytochemistry and immunophenotype, since some specific conditions, which require specific treatments, can only be identified based on cytogenetics (►Chromosomal aberrations) or even more sensitive molecular methods as fluorescent in-situ hybridization (►FISH), polymerase chain reaction (►PCR) or DNA-sequencing of specific genes. The classification of hematological malignancies described here is based on these features, but also recognizes the clinical course of specific entities, such as the establishment of MDS- or therapy-related AML's as diseases with particularly poor prognoses compared to AML's with recurrent cytogenetic translocations. The continued elucidation of molecular mechanisms underlying hematological malignancies and the application of new technologies, such as ►microarray (cDNA) technology ►differential display or ►microRNA analysis, in this research will establish new entities and create a need for further revisions of the dynamic classification scheme in the near future.

Treatment

Biological risk prediction and targeted therapy, using antibodies alone, or in combination with chemotherapy or as intelligent probes carrying a radionucelotide to the very center of the tumor (►Radioimmunotherapy), are now being applied for the treatment of hematopoietic neoplasms. The indications for ►immunotherapy using ►allogeneic ►bone marrow transplantation are steadily expanding. A multitude of new designed drugs are under systematic development (►Drug design).

Hematopoiesis

Definition

Is the formation of blood cellular components. All of the cellular components of the blood are derived from haematopoietic stem cells.

►Acute Myeloid Leukemia

Hematopoietic Niche

Definition

Specific ►microenvironment to support the maintenance of multipotent stem cell activity of hematopoietic

stem cells. In bone marrow, osteoblasts are considered to provide major niche for the stem cells.

►Rap1 and Sipa-1

Hematopoietic Progenitors

Definition

Stem cells capable of differentiating into all cell types of the various blood lineages.

►AAV

Hematopoietic Stem Cell

Definition

HSC; A rare cell comprising <0.01% of normal bone marrow. It is normally quiescent in the osteoblast stem cell niche of the marrow but upon cell-cycle activation undergoes asymmetric self-division generating additional stem cells (self-renewal) and committed progenitors of multiple lineages (pluripotentiality). It is a target for oncogenic transformation in leukemia.

►NUP98-HOXA9 Fusion
►Stem Cell Telomeres

Hematopoietic Stem Cell Transplants

Definition

HSCT; A procedure also referred to as bone marrow transplantation, to deliver bone marrow stem cells to a patient, which for example suffers from cancer. The transplanted cells can originate from another individual (allogeneic) or from the same individual, which are transplanted back after removal (autologous) to stimulate blood cell production. An allogeneic transplant can be matched or mismatched for HLA self-antigens.

Hematopoietic System

Definition

The network of tissues, located principally in the bone marrow, that functions throughout life to replenish and replace the different cellular components of the blood.

►Chemokine Receptor CXCR4

Hematoporphyrin Derivative

Definition

HPD; Hematoporphyrin is a photosensitizer consisting of porphyrin derivatives. It is used in photodynamic therapy and fluorescence diagnosis due to its photochemical and fluorescent properties.

►Photodynamic Therapy

Hematoxylin and Eosin

Definition

Most used staining method in histology that uses a basic dye (hematoxylin) that stains basophilic structures such as nucleic acids in blue and an acid dye (eosin) that stains acidophilic structure such as proteins in red. Also known as H&E stain.

►Hurthle Cell Adenoma and Carcinoma

Hematuria

Definition

Excretion of blood in urine.

►Chemoprotectants

Heme

Definition
Is the prosthetic group of hemoglobin, myohemoglobin, cytochromes, and metalloproteins. It is composed of a heteocyclic organic ring with a central iron atom and formed in mitochondria. It is responsible for the red color of the blood (erythrocytes) and mediates the binding of oxygen.

►Photodynamic Therapy

Heme-Oxygenase 1

Definition
An inducible enzyme with potent anti-inflammatory and anti-cancer activities.

►Inflammation

Hemichannel

Definition
Is used to designate what is essentially a half gap junction channel; this is referred to as a "connexon" if composed of connexins, and a "pannexon" if composed of pannexins.

►Pannexins

Hemihypertrophy

Definition
Congenital muscular or osseous hypertrophy of one side of the face or body.

►Nephroblastoma

Hemizygous

Definition
Having only one copy of a gene as opposed to the two normally seen in a diploid genome.

►Allele

Hemizygous Deletion

Definition
In a diploid organism, loss of one ►allele or portion of an allele from the genome.

Hemochromatosis

Definition
A hereditary condition associated with iron overload. Because of increased reactive and nitrogen oxide species in the liver, there is a high risk of liver cancer in people with uncontrolled hemochromatosis.

►Inflammation
►Liver Cancer, Molecular Biology

Hemoglobin

Definition
Is a 64.5 kDa protein with heme as the oxygen-binding prosthetic group. It is responsible for binding and transport of oxygen by erythrocytes from the lung to the peripheral organs and tissues of the body.

►Photodynamic Therapy

Hemoglobinopathy

Definition
Refers to a range of genetically inherited disorders of red blood cell hemoglobin and includes sickle cell disease and the thalassemias.

►Adult Stem Cells

Hemosiderin

Definition
Is an insoluble amalgam of degraded ferritin plus ferric hydroxide. As ferritin becomes satiated with iron, it is transformed into hemosiderin. Excessive accumulation of hemosiderin is associated with macrophage cell death.

►Asbestos
►Macrophages

Henle–Koch Postulates

►Koch's Postulates

Hensin (Rabbit)

►Deleted in Malignant Brain Tumours 1

Heparan Sulfate

Definition
HS; is a linear sulphated polysaccharide found as part of proteoglycans on the cell surface or extracellular matrix, in all animal tissues. HS consists of alternating hexuronate and glucosamine units. The hexuronate can be either d-glucuronate (GlcA) or l-iduronate (IdoA). The amine of the glucosamine is usually acetylated (GlcNAc) or sulfated ($GlcNSO_3$), but it may also be unsubstituted. Within *N*-sulfated domains of HS, 2-hydroxyl groups of GlcA and IdoA, and 6-hydroxyl groups of $GlcNSO_3$ may be sulfated. Sometimes there are also 3-*O*-sulfate groups present on $GlcNSO_3$ units. There is evidence for a temporally and spatially controlled expression of HS epitopes within different organs and tissues.

Heparan Sulfate Proteoglycans

Definition
Consist of a core protein to which chains of the negatively charged glycosaminoglycan, heparan sulfate, are attached. The combination of various classes of core proteins and highly polymorphic heparan sulfate chains creates a superfamily of macromolecules that are widely distributed in mammalian tissues. Among their many activities, heparan sulfate proteoglycans are able to influence cell growth and differentiation by interacting with various proteins such as growth factors.

►Lactoferricin Antiangiogeneis Inhibitor

Heparanase

Israel Vlodavsky
Cancer and Vascular Biology Research Centre
Rappaport Faculty of Medicine, Technion, Haifa, Israel

Definition
Heparanase is a mammalian enzyme (endo-β-glucuronidase) degrading heparan sulfate (HS), a ubiquitous strongly anionic linear polysaccharide associated with the cell surface and ►extracellular matrix (ECM) of a wide range of cells of vertebrate and invertebrate tissues. The enzyme cleaves glycosidic bonds in HS with a hydrolase mechanism and is thus distinct from bacterial eliminases, called heparinases and heparitinase. The heparanase enzyme facilitates cell migration and egress from blood vessels and hence plays a role in tumor ►metastasis, ►angiogenesis, ►inflammation

and autoimmunity. Heparanase activity has been identified in a variety of human tumors (i.e., melanoma, carcinoma of the breast, liver, colon, prostate and pancreas; myeloid leukemia) and certain normal cells (i.e., cytotrophoblasts, platelets, neutrophils, activated T-lymphcytes). HS chains (Mr ~30,000) are cleaved by heparanase at only a few sites, resulting in HS fragments of still appreciable size (Mr ~5,000). Thus, the enzyme recognizes a particular and quite rare HS structure. A 2-O sulfate group on hexuronic acid residue located two monosaccharide units away from the cleavage site appears essential for substrate recognition by heparanase (Fig. 1). Heparanase activity (pH optimum in solution ~6.0) has been demonstrated in both lysosomal and endosomal cellular compartments and in the cell membrane. In human neutrophils the enzyme is localized in tertiary granules.

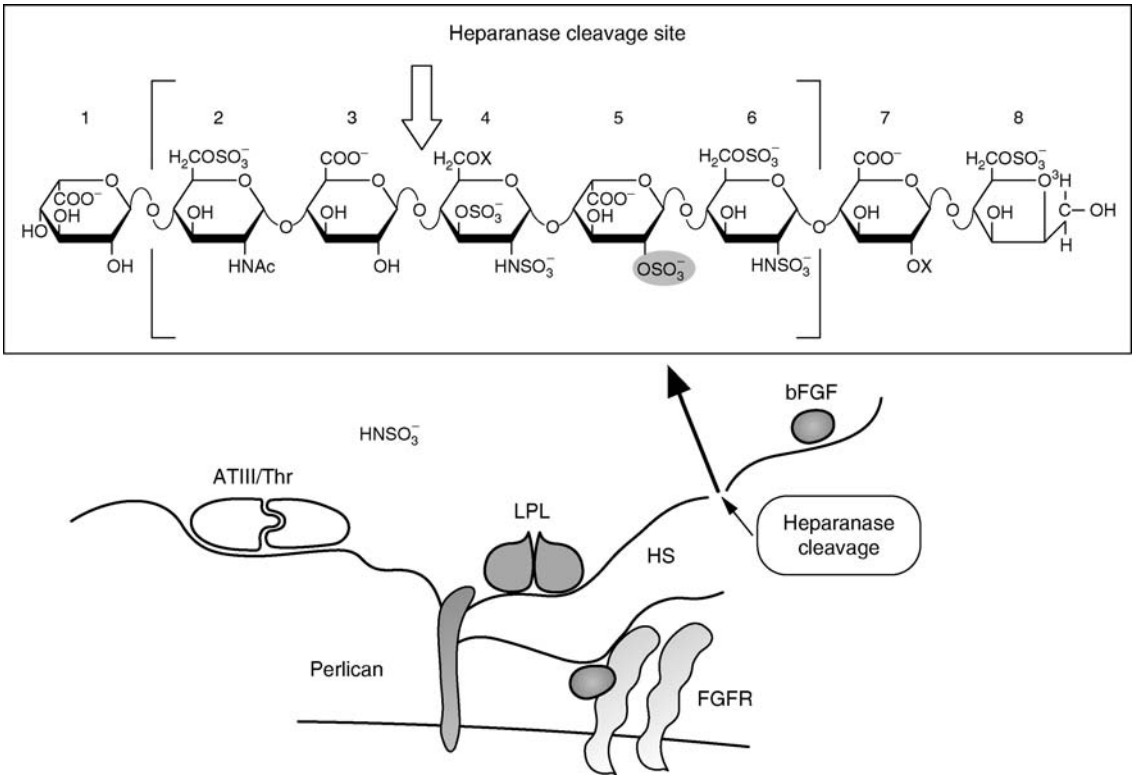
Characteristics

Heparan Sulfate Proteoglycans (HSPGs)

The basic HSPG structure consists of a protein core to which several linear heparan sulfate (HS) glycosaminoglycan (GAG) chains are covalently O-linked. The HS chains are typically composed of repeating hexuronic (L-iduronic or D-glucuronic acid) and D-glucosamine disaccharide units that are substituted to a varying extent with N- and O-linked sulfate moieties and N-linked acetyl groups (Fig. 1). The HS chains generally consist of clusters of sulfated disaccharide units separated by low or non-sulfated regions. Studies of the involvement of extracellular matrix (ECM) molecules in cell attachment, growth and differentiation revealed a central role of HSPGs in embryonic morphogenesis, angiogenesis, metastasis, neurite outgrowth and tissue repair. The HS chains, unique in their ability to bind a multitude of proteins, ensure that a wide variety of effector molecules (i.e., heparin-binding growth factors, chemokines, lipoproteins, enzymes) (Fig. 1) cling to the cell surface and ECM and thereby exert localized cellular effects. Moreover, transmembrane (syndecan) and membrane anchored (glypican) HSPGs have a co-receptor role in which the proteoglycan, in concert with other cell surface molecules, comprises a functional receptor complex that binds the ligand and mediates its action.

Molecular Properties

Cloning and expression of a single human heparanase cDNA sequence was achieved using amino acid sequences derived from heparanase enzymes purified from human platelets, placenta, hepatoma cells and



Heparanase. Figure 1 Scheme of heparan sulfate and the heparanase cleavage site (*top*), and of a basement membrane HSPG (perlecan) (*bottom*). Cleavage is associated with release of HS-bound growth factors and enzymes.

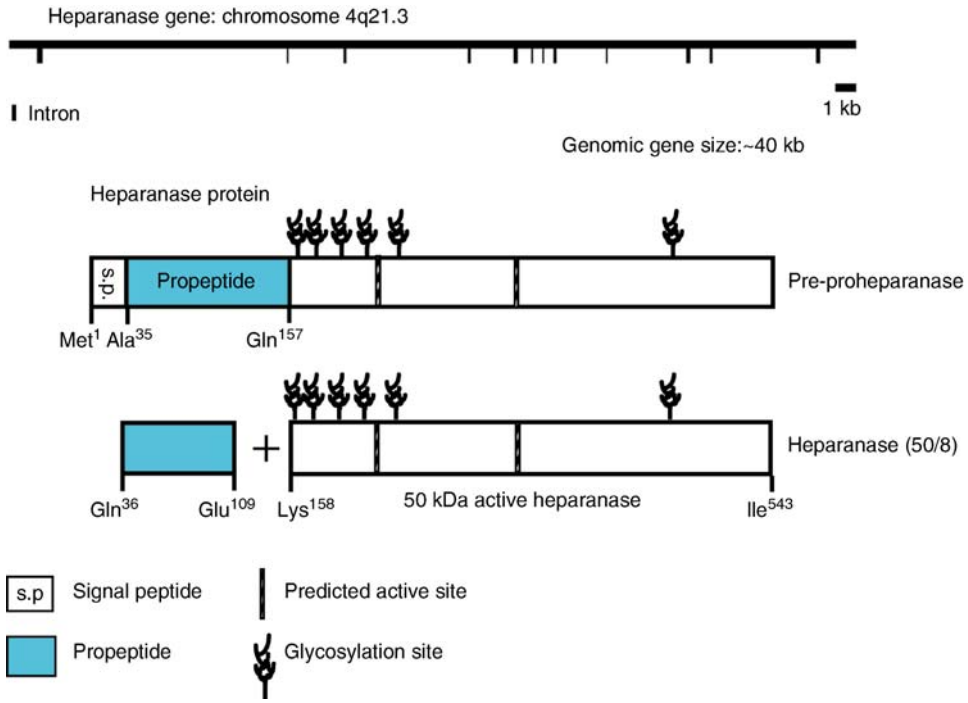
transformed embryonic fibroblasts. The heparanase cDNA contains an open reading frame of 1629 bp, which encodes for a 61.2 kD latent polypeptide of 543 amino acids (Fig. 2). This pro-enzyme is post translationally cleaved into 8 and 50 kDa subunits that non-covalently associate to form the active heparanase (Fig. 2). Heterodimer formation is essential for heparanase activity. Site-directed mutagenesis revealed that similar to other glycosyl hydrolases, heparanase has a common catalytic mechanism that involves two conserved acidic residues, a putative proton donor at Glu^{225} and a nucleophile at Glu^{343} (Fig. 2). The sequence also contains a putative N-terminal signal peptide sequence (Met1 to Ala35) and a candidate transmembrane region (Pro515 to Ile534; Fig. 2). Alignment of the human, mouse and rat heparanase amino acid sequences, corresponding to the 50 kD human mature enzyme (Lys158 to Ile543), demonstrated 80.0%, 79.7% and 92.7% identity between the human and mouse, human and rat, and mouse and rat heparanases, respectively. A 58–60% homology was found between these enzymes and the chicken heparanase. The fact that highly homologous cDNA sequences were derived from different species and types of normal and malignant cells is consistent with the notion that one dominant endoglucuronidase is expressed by all mammalian cells. Thus, unlike the large number of proteases that can solubilize polypeptides in the ECM, it appears that only one heparanase is used by cells to degrade the heparan sulfate side chains of HSPGs. The genomic locus that encodes heparanase spans ~40 kb. It is composed of 12 exons separated by 11 introns and is localized on human chromosome 4q21.3.

Preferential Expression in Human Tumors

Expression of the heparanase mRNA and protein in normal tissues is restricted to the placenta, activated immune cells, platelets and keratinocytes. Heparanase is preferentially expressed at early stages of carcinoma progression. Immunohistochemistry, *in situ* hybridization, RT-PCR and real time-PCR analyses revealed that heparanase is up regulated in essentially all human tumors examined. These include carcinomas of the colon, thyroid, liver, pancreas, lung, bladder, cervix, breast, gastric, prostate, head and neck, salivary gland, nazopharyngs, as well as leukemia, lymphoma and multiple myeloma. Patients exhibiting high levels of heparanase mRNA and/or protein had a significantly shorter postoperative survival time than patients whose tumors contained relatively low levels of heparanase. There is also a correlation between heparanase expression levels and tumor vascularity in cancer patients, indicating a significant role in tumor angiogenesis.

Involvement in Tumor Metastasis

A critical event in the process of cancer invasion and metastasis is degradation of various ECM constituents including collagen, laminin, fibronectin and HSPGs. The ability of HSPGs to interact with various ECM macromolecules and with different attachment sites on plasma membranes suggests a key role for this proteoglycan in



Heparanase. Figure 2 Scheme of the human heparanase gene and protein.

the self-assembly and insolubility of ECM components, as well as in cell adhesion and locomotion. Cleavage of HS may therefore result in disassembly of the subendothelial ECM and hence play an important role in fundamental biological phenomena involving cell migration and ranging from pregnancy, morphogenesis and development to inflammation, angiogenesis and cancer metastasis. Expression of HS degrading heparanase correlates with the metastatic potential of tumor cells. Moreover, elevated levels of heparanase were detected in sera of metastatic tumor-bearing animals and cancer patients, in tumor specimens and in the urine of patients with aggressive metastatic disease. A direct role of heparanase in tumor metastasis was provided by the increased lung, liver and bone colonization of melanoma, lymphoma, myeloma and prostate carcinoma following transfection and over-expression of the heparanase gene. A marked decrease in the metastatic potential of cells expressing high levels of endogenous heparanase was noted in response to administration of anti-heparanase siRNA, indicating that heparanase is causally involved in cancer progression.

Involvement in Tumor Angiogenesis

Angiogenesis represents a coordinated multicellular process that requires the functional activity of a wide variety of molecules including growth factors, ECM components, adhesion receptors and matrix-degrading enzymes. HSPGs and HSPG-degrading enzymes have been implicated in a number of angiogenesis-related cellular events including cell invasion, migration, adhesion, differentiation and proliferation. The heparin affinity of fibroblast growth factors (FGFs) and other heparin-binding growth factors appears to be the basis for their storage in ►basement membrane (BM) and ECM, where they are bound to HS and can be released in an active form by HS degrading enzymes. The released angiogenic factors may then stimulate endothelial cell proliferation and migration associated with neovascularization.

An important early step in the angiogenic cascade is degradation of the subendothelial capillary BM by proliferating endothelial cells and formation of vascular sprouts. Heparanase, degrading the polysaccharide scaffold of BM, markedly contributes to the invasive ability of endothelial cells and their migration through the ECM toward the angiogenic stimulus. Apart from direct involvement in BM invasion by endothelial cells, the heparanase enzyme elicits an indirect angiogenic response by releasing HS-bound angiogenic growth factors from ECM and BM (Fig. 1) and by generating HS degradation fragments that stabilize and promote the mitogenic and angiogenic activity of heparin-binding growth factors (i.e., bFGF, ►VEGF). In fact, recombinant mammalian heparanase, as well as heparanase secreted by platelets, tumor cells and inflammatory cells, release FGF as a complex with HS fragments. This yields a highly active form of FGF that readily interacts with high affinity receptors on the surface of endothelial cells and thus elicits an angiogenic response. The molecular size of the HS chain required for optimal stimulation of FGF receptor binding, dimerization and signaling is similar to that of HS fragments released by heparanase. A profound angiogenic response is elicited in vivo by lymphoma cells overexpressing the heparanase gene and embedded in a reconstituted BM (Matrigel). It appears that cooperative interaction between heparanases from tumor, inflammation and endothelial sources play an important role in the angiogenic cascade. Apart of the well studied catalytic feature of the enzyme, heparanase was noted to exert biological functions apparently independent of its enzymatic activity. Non enzymatic functions of heparanase include enhanced cell adhesion and induction of p38 and Akt phosphorylation. Moreover, enzymatically active and inactive heparanase were noted to induce VEGF expression, thus providing, among other mechanisms, a molecular basis for the potent angiogenic capacity of heparanase. The anti-cancerous potential of heparanase inhibitors is, therefore, not restricted solely to suppression of the invasive metastatic phenotype, but also to suppression of tumor angiogenesis.

Clinical Relevance

Heparanase inhibiting molecules (e.g., non-anticoagulant species of heparin, polysulfated polysaccharides, polyanionic molecules) markedly reduce (>90%) the incidence of lung colonization induced by various tumor cells, in correlation with their anti-heparanase activity. The occurrence of a single heparanase species and its ability to promote both tumor angiogenesis and metastasis, the most critical steps in tumor progression, make it a promising target for cancer therapy. The heparanase inhibiting pentasaccharide, phosphomannopentaose sulfate (PI-88) is being tested in cancer patients as it reduces the vascularity, primary tumor growth and metastasis of mammary adenocarcinoma in rats. A recently developed ELISA method indicates that determination of heparanase levels in body fluids (e.g., plasma, urine, saliva, pleural effusuions) may have a prognostic value in detection of cancer and response to treatment.

Heparanase Inhibitors

Jian Ding
State Key Laboratory of Drug Research, Shanghai Institute of Materia Medica, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai, P. R. China

Definition

Heparanase inhibitors are a group of compounds inhibiting/decreasing heparanase enzymatic activity, which abolish degradation of heparanase on heparan sulfate (HS) of extracellular matrix (ECM) and thus subsequential cascade.

Characteristics

►Heparanase, a single functional HS-degrading endoglycosidase, is a mammalian endo-β-*D*-glucuronidase cleaving HS chains at a limited number of sites. The enzyme is synthesized as a latent 65-kDa precursor that undergoes subsequent proteolytic cleavage, yielding 8-kDa and 50-kDa subunits. These subunits heterodimerize to form a highly active enzyme. The enzyme is thought to participate in the cleavage of HS chains from HS-containing proteoglycans (HSPGs), leading to ECM remodeling that facilitates the cell invasiveness and ►angiogenesis associated with ►cancer metastasis. The development of ►heparanase inhibitors for the treatment of highly malignant tumors is therefore of considerable interest.

In view of its enzymatic characteristics, much effort has devoted in drug development targeting the substrate as mimetics based on the high-affinity interaction between the enzyme and its substrate. These include heparin, chemical derivatives of heparin, nonanticoagulant heparin, and other polyanionic molecules such as sulfated phosphomannopentaose (PI-88), oligomannurarate sulfate (JG3), laminaran sulfate, and suramin. Others targeting heparanase itself includes small molecules, peptides, and neutralizing antibodies. In addition, effort also has been made on several fronts to inhibit heparanase gene expression.

Inhibitors Targeting the Heparanase Substrate

Heparin, Chemically Modified Derivative and Nonanticoagulant Heparin

As an analog of the natural substrate of heparanase, heparin is commonly considered to be a potent inhibitor of heparanase. This activity is attributed, in part, to the high affinity heparin–enzyme interaction and the limited degradation of heparin. Heparin thus serves as an alternative enzyme substrate. Early reports showed that heparin and some of its derivatives, as well as other sulfated polysaccharides inhibiting tumor cell heparanase, also inhibited experimental metastasis in animal models. Other related compounds lacking heparanase-inhibiting activity failed to exert an antimetastatic effect. No significant differences in tumor inhibition were found between the currently used unfractionated heparins and low molecular weight heparins (LMWH). Regardless of the mode of action, heparin and LMWH were reported to exert a beneficial effect in cancer patients. The use of heparin as an antimetastatic agent is, however, limited due to its potent anticoagulant activity. This drawback has stimulated research on the potential use of modified, nonanticoagulant species of heparin and HS in cancer therapy.

Glycol-split *N*-acetyl heparin, which shows dramatically increased heparanase-inhibiting activity compared with unmodified heparin, is a valuable compound. Notably, glycol-splitting causes substantial loss of the anticoagulant activity of heparin due to the complete removal of heparin affinity for antithrombin. The main reason for such an effect is the cleavage of C-2–C-3 bonds of the GlcA residue of the pentasaccharidic sequence, which is essential for binding to antithrombin. Encouragingly, glycol-split *N*-acetyl heparins also exhibit marked decreases in the ability to release basic fibroblast growth factor (bFGF) from the ECM. Mitogenic activity in the ECM is thus inhibited.

Work on heparanase inhibition by glycol-split heparin is mostly recent. The data from this nonanticoagulant heparin species applying on animals gave us clues that it is possible to separate the antimetastatic and anticoagulant activities of heparin. We thus predict that nonanticoagulant heparin species may have clinical potential, because they can be given in doses higher than those used for heparin, thereby exploiting fully the antimetastatic component of heparin species. Together, the combination of potent heparanase inhibition, the lack of anticoagulant activity, and the low release of ECM-bound bFGF, promises that *N*-acetylated glycol-split heparins will be highly effective and specific antiangiogenic and antimetastatic agents.

Sulfated Phosphomannopentaose

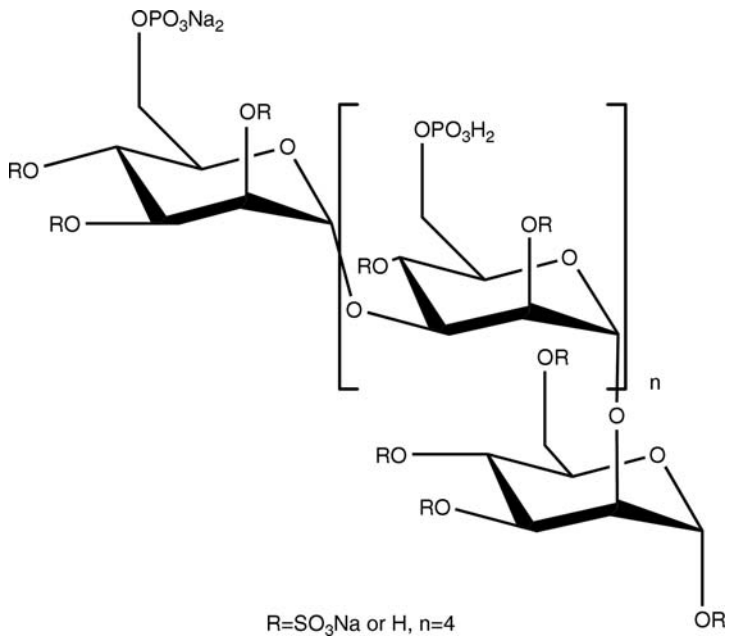
Heparanase enzyme activity also can be efficiently inhibited by shorter but more extensively sulfated oligosaccharides. The use of such small molecules may overcome intractable side effects caused by

administration of larger inhibitors. Researchers have therefore sought small saccharides potently inhibiting heparanase activity but without side effects. The first such molecule, PI-88, showed good safety and tolerability in Phase I trials and the Food and Drug Administration has now cleared PI-88 for a Phase III clinical trial.

PI-88, a highly sulfated phosphosulfomannan (Fig. 1), is a hemisynthesized product obtained by sulfation of a saccharide from the yeast *Pichia holstii*. PI-88 is a mixture of chemically sulfated oligosaccharides, ranging from disaccharides to hexasaccharides, with the majority (60%) being pentasaccharides. PI-88 exerts its biological effects by blocking the enzymatic activity of heparanase and by interfering with the action of HS-binding angiogenic growth factors such as aFGF, bFGF, and VEGF. In an animal model, PI-88 was shown to inhibit the primary tumor growth of the highly invasive rat mammary adenocarcinoma 13762 MAT by ~50%, to inhibit metastasis to the draining popliteal lymph node by ~40%, and to reduce the vascularity of tumors by ~30%. All these effects are highly significant. Acute hematogenous metastasis assays also demonstrated that PI-88 was a potent (>90%) inhibitor of blood-borne metastasis. The data from a completed Phase II clinical trial showed that PI-88 was especially well-suited to postoperative use. In particular, PI-88 was effective in postoperative liver cancer patients in whom tumor burdens were low. PI-88 is one of a new class of multi-targeted cancer drugs that have an antiangiogenesis effect. A particular concern with PI-88 systemic treatment is drug interference with a relatively broad range of protein–HS interactions. An interpretation of drug specificity is thus difficult.

Oligomannurarate Sulfate-JG3

The success of PI-88 inspired a surge in the development of additional oligosaccharide-based innovative heparanase inhibitors, using substrates mimicking GAG as prototypes. Oligomannurarate sulfate, a new, hemisynthesized, structurally novel, sulfated oligosaccharide derived from marine oligomannurarate blocks (Fig. 2), showed promising potential substrate-based heparanase inhibitor. JG3 is a highly sulfated oligosaccharide with molecules ranging in size from tetrasaccharides to decasaccharides. JG3 significantly inhibited tumor angiogenesis and metastasis both in vitro and in vivo. As a nondegradable substrate mimetic, JG3 specifically binds to the KKDC and QPLK domains of heparanase, with high affinity, and significantly inhibited heparanase activity (the IC_{50} was 6.55 ng/ml). The JG3–heparanase interaction was competitively inhibited by LMWH but not by other GAGs. In addition, JG3 abolished heparanase-driven invasion, inhibited the release of HS-sequestered bFGF from the ECM, and repressed subsequent angiogenesis. Moreover, JG3 inactivated bFGF-induced FGFR and ERK1/2 phosphorylation, and blocked bFGF-triggered angiogenic events by directly binding to bFGF. Thus, JG3 appears to inhibit both major heparanase activities by simultaneously acting as both a substrate mimetic and a competitive inhibitor of heparan sulfate. In vivo, the B16F10 ►melanoma lung metastasis model, orthotopic xenografts of human breast carcinoma MDA-MB-435, and ►hepatocellular carcinoma BEL-7402 in athymic mice, have been used to evaluate the effects of JG3 on tumor growth, angiogenesis and metastasis. JG3



Heparanase Inhibitors. Figure 1 Phosphomannopentaose (PI-88).

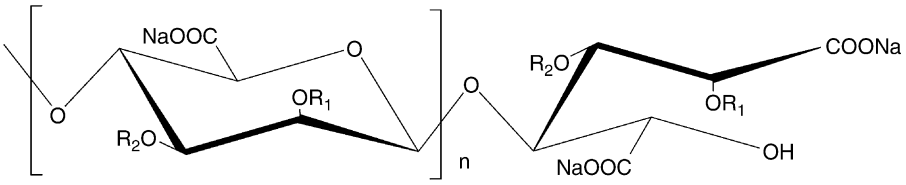
dramatically decreased the numbers of B16F10 metastases, with an inhibition rate of 82.2%. Also, JG3 suppressed MDA-MB-435 tumor growth by 37.6%, abated tumor metastasis by 88.3%, and inhibited tumor-related angiogenesis. In addition, JG3 inhibited hepatocellular carcinoma BEL-7402 primary tumor growth by 44.2%. Encouragingly, unlike other polyanionic compounds, JG3 showed very low toxicity, probably due to its weak anticoagulant activity (~13-fold less than that of heparin, and nearly threefold less than that of PI-88). These data all suggest that JG3 is potentially valuable as an ►anticancer agent.

Suramin

Suramin (Fig. 3) is a polysulfonated naphthyl urea, inhibiting heparanase with an IC_{50} of 48 μM. Suramin inhibited B16 melanoma cell invasion (IC_{50} = 10 μM) through reconstituted basement membrane, but had no effects on melanoma cell growth. Suramin has not been widely used because it has significant toxic effects in humans, including neurotoxicity, renal toxicity, adrenal insufficiency, and anticoagulant-mediated blood dyscrasias. In efforts to avoid these side effects, analogs of suramin have been synthesized and are undergoing evaluation. Compounds NF 227, NF 145, and NF 171 are three such analogs, all of which possess heparanase inhibitory activities more potent than that of suramin (the IC_{50} values were ~20–30 μM). These compounds effectively inhibited heparanase-mediated angiogenesis in an animal model.

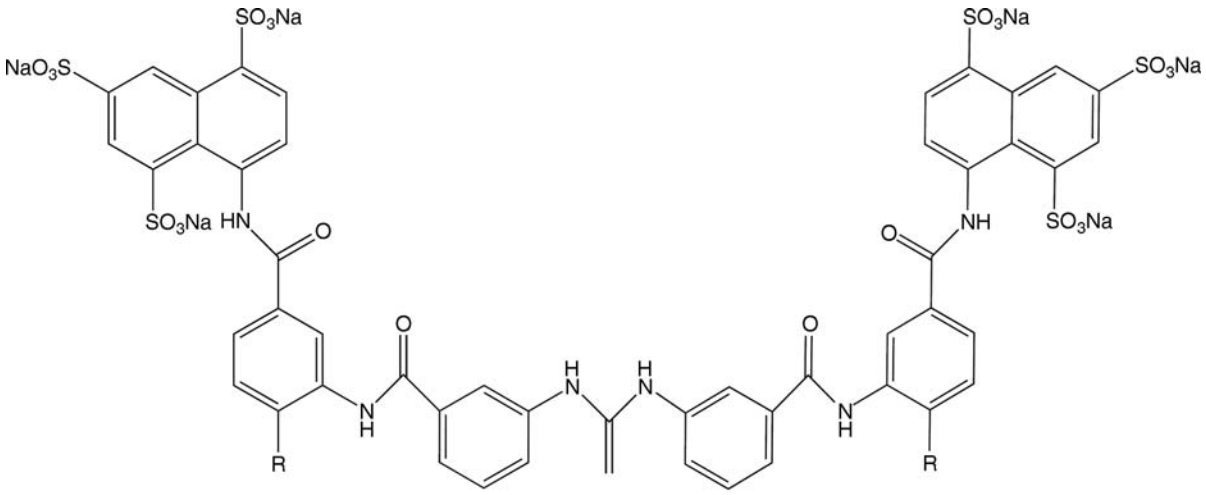
Noncarbohydrate Substrate Mimetic Polymers

Synthetic, linear, noncarbohydrate polyanionic polymers have also been studied as heparin mimetics. The materials were initially tested for inhibition of heparanase-mediated degradation of HS in the subendothelial ECM. One series of polymers, synthesized by polymerization of phenol-based monomers, showed high inhibitory effects on heparanase activity. Of these, RG-13577, polymerized from 4-hydroxyphenoxy monomers, has a molecular weight of ~5,800, and showed almost complete inhibition of heparanase activity at 2.5 μg/ml.



R_1=SO_3Na, R_2=SO_3Na or H, n = 3–9

Heparanase Inhibitors. Figure 2 Oligomannurarate sulfate (JG3).



R=Me

Heparanase Inhibitors. Figure 3 Suramin.

Another group of polymers, derived from *N*-acryl amino acid monomers bearing charged functional groups, range from ~3,000 to 6,000 Da in size, and also showed potent inhibition of heparanase. Polymers with hydroxyl groups, when sulfonated, showed ~70–80% inhibition of heparanase activity even at 1 μg/ml. This activity is comparable to that of heparin.

Inhibitors Targeting Heparanase

Small Molecules

Besides the efficacy of heparanase substrate mimetics, development of small-molecular weight compounds directly inhibiting heparanase activity is still required. Several heparanase inhibitors have been discovered among microbial metabolites or have been obtained by organic synthesis. This group of compounds does not contain any sulfate moieties and the group members have the clearly defined chemical structures. Compounds showing high potency against heparanase in vitro and in animal models, which would be developed as therapeutic leads.

A class of inhibitors, exemplified by 1*H*-isoindole-5-carboxylic acid, was reported. The structure activity relationship study of this class compound led to 2-[4-propylamino-5-[5-(4-chloro)phenyl-benzoxazol-2-yl] phenyl]-2,3-dihydro-1,3-dioxo-1H-isoindole-5-carboxylic acid (Fig. 4), which displayed potent heparanase inhibitory activity (IC_{50} = 0.2 μM) and a much improved antiangiogenic effect (IC_{50} = 1 μM) when compared to other derivates.

Other valuable small molecules are furanyl-1, 3-thiazol-2-yl-acetic acids and derivatives developed as potent heparanase and angiogenesis inhibitors. Although they showed promising in vitro potency against heparanase, this series of compounds suffered drawbacks such as synthetic difficulties and poor DMPK properties. On its structure basis, the changed chemical structure (benzoxazol-5-yl-acetic acids) showed much more activity and potency on DMPK. The most powerful inhibitor in this class (Fig. 5) showed antiheparanase activity with an IC_{50} of 0.4 μM and antiangiogenesis with an IC_{50} of 1 μM. More importantly, the material attained a plasma concentration ca. tenfold above its IC_{50} value for heparanase inhibition.

Novel 1-[4-*H*-benzoimidazol-2-yl]-phenyl]-3-[4-(1*H*-benzoimidazol- 2-yl)-phenyl]-ureas were recently described as potent inhibitors of heparanase. Among these compounds, 1,3-bis-[4-(1*H*-benzoimidazol-2-yl)-phenyl]-urea (Fig. 6) had high heparanase inhibitory activity (IC_{50} = 0.075 μM) in vitro and was effective in a B16 experimental metastasis model.

Two other types of small inhibitory molecules are those in the RK-682 series and the KI-105 series. Compound RK-682 was isolated from a *Streptomyces* species and showed anti-heparanase activity (IC_{50} = 17 μM). The derivative 4-Bn-RK-682, showed better selectivity for heparanase than did RK-682. Compound KI-105 was synthesized to mimic the anionic groups of HS using nitro and benzoic acid moieties.

Peptides Competing with the Heparin/HS Binding Domains of Heparanase

It has been reported that a peptide with the KKDC motif of the 50 kDa heparanase subunit region (Lys158–Asn171) physically associated with both heparin and HS, and inhibited heparanase enzymatic activity in a dose-dependent manner.

Antiheparanase Antibodies

Very limited work has been performed in this area. In one study, a rabbit antibody against recombinant heparanase demonstrated dose-dependent inhibition of heparanase activity. The antibody inhibited ovarian carcinoma cell invasion at a concentration of 0.67 μM.

Conclusions and Perspectives

As the predominant enzyme in tumor cells, heparanase represents an attractive target for the development of novel anticancer agents. Most research on heparanase inhibitors remains, however, at the in vitro or early preclinical stages. Currently, all heparanase inhibitors raise specificity concerns, because they may cross-react with other biological molecules including heparin-binding proteins or even tyrosine kinases. The phenotypes of animals with heparanase gene knockouts should provide great insights into the roles of heparanase in the complex in vivo environment. Studies on enzyme kinetics will help to obtain complete information on heparanase biochemistry. The determination of heparanase crystal structure will tremendously benefit rational drug design, leading to the development of more specific and more potent inhibitors. Also, researchers continue to focus on further defining heparanase substrate specificity, exploring both catalytic and noncatalytic enzyme activities. This work, in combination with enzyme crystal structure determination, allows us to hope that a more "rational" approach to the development of effective and highly specific heparanase inhibitors will soon be possible. We predict that future data will further reinforce the idea that heparanase represents a tractable and highly attractive target for novel types of anticancer agents.

Definition

►Epithelioid hemangioendothelioma (EH) is a neoplasm of vascular origin involving soft tissue and visceral organs such as liver, spleen, bone, brain, meninges, breast, heart, head and neck, soft tissue, stomach, and lymph nodes (Table 1).

Characteristics

The term EH was first recognized as soft tissue vascular tumors of endothelial origin with clinical course between benign ►hemangioma and ►angiosarcoma. The incidence of EH is less than 0.1 per 100,000 population. Hepatic EH (HEH) affects more commonly adult females and is characterized by an ►epithelioid or ►histiocytoid morphology and a growth pattern with evidence of endothelial histogenesis. Two different types of HEH have been described so far, the nodular type in the early stage of HEH; and the diffuse type that reflects the advanced stage of the disease with coalescence of the lesions which are associated with hepatic vascular invasion (Fig. 1a). The clinical manifestation of HEH is heterogeneous varying from cases with no symptoms to hepatic failure. In the symptomatic patients, the most common clinical manifestations include right upper quadrant pain, ►hepatomegaly, and weight loss. Weakness, ►anorexia, ►epigastric mass, ►ascites, nausea/vomiting, ►jaundice, and fatigue are the other common presenting manifestations. The majority of cases have a multifocal tumor involving both liver lobes. The right lobe is affected more than the left lobe in both multifocal and unifocal presentations. Lung, regional lymph nodes, ►peritoneum, bone, spleen, and diaphragm are the most common sites of extrahepatic involvement at the time of diagnosis. ►Pleura, ►mediastinum, ►retroperitoneum, ►myocardium, ►pericardium, brain, cervical lymph nodes, ►common bile duct, pancreas, and uterus are the other reported sites with HEH ►metastases.

Etiology

The definitive etiology of HEH is unclear. Some possible etiologic factors include oral contraceptives, vinyl chloride, ►asbestosis, thorotrast, major trauma to the liver, viral hepatitis, ►primary biliary cirrhosis, and alcohol consume. In contrast to many other types of primary liver tumors, HEH does not arise upon a background of chronic liver disease.

Diagnosis

Due to the rarity of the tumor, only strong suspicion can help to perform necessary evaluations and establish an appropriate diagnosis.

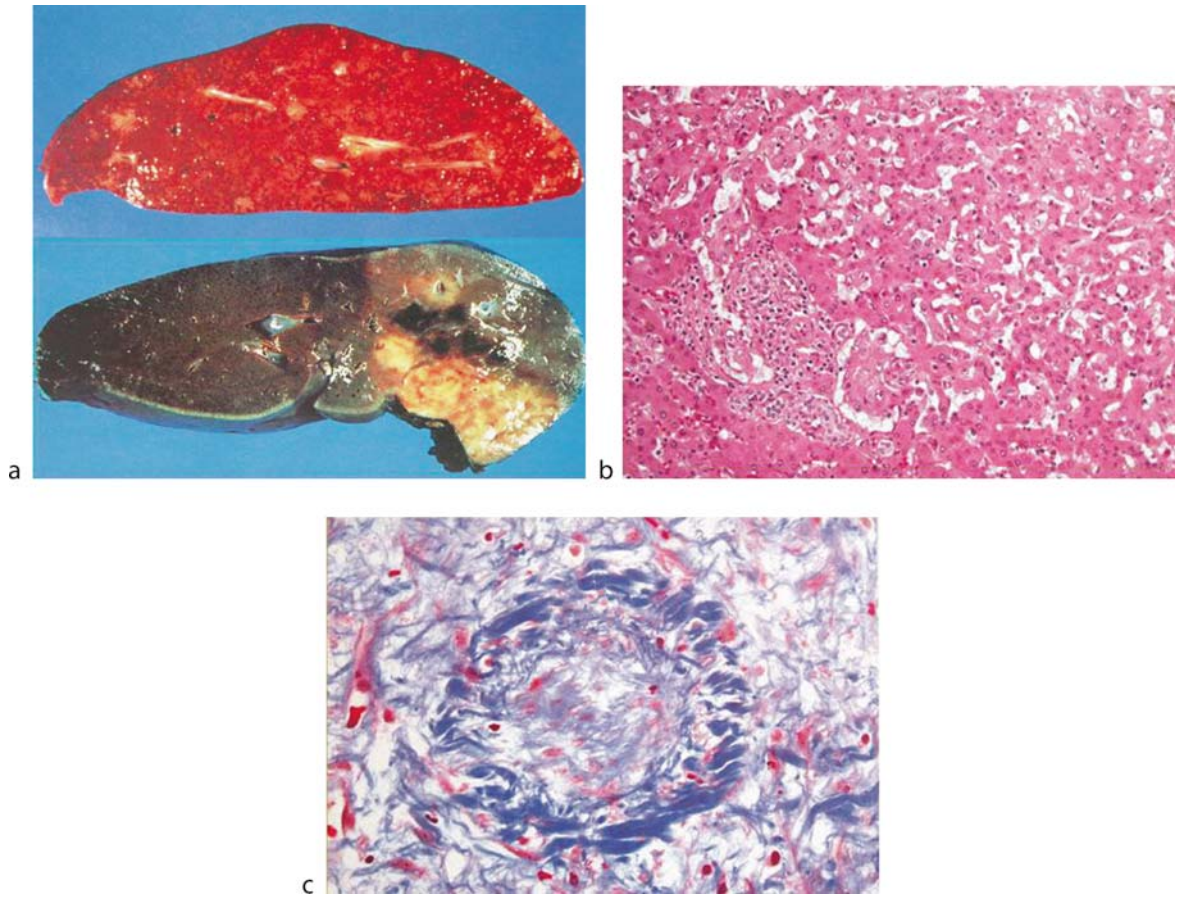
Laboratory. The majority of the cases have abnormal liver laboratory parameters such as elevated alkaline phosphatase, aspartate aminotransferase (AST), alanine aminotransferase (ALT), γ-glutamyl transpeptidase (GGT) and bilirubin. ►Tumor markers are mostly within normal range and only suitable to rule out other primary or metastatic tumors.

Imaging. Imaging studies include ultrasonography, computed tomography (CT) scan, magnetic resonance imaging (MRI), ►scintigraphy, and angiography. On ultrasonography the most common finding is ►hypoechoic lesions. On CT scan, ►low-density pattern is the most common abnormal feature. Moreover, the majority of cases show contrast enhancement in CT images. Two major manifestations of HEH in CT images are multiple, nodular lesions, and/or large masses which can be the result of coalescence of smaller nodules. The nodular type is relatively nonspecific, whereas the diffuse type is very suggestive. On MRI, HEH is usually hypointense on T1-weighted and hyperintense on T2-weighted images (►T1- and T2-weighted images) (►hypointense, ►hyperintense). One of the characteristic feature of the HEH is the target shape of the lesions which could be due to the presence of a central sclerotic zone and a peripheral region of cellular proliferation (Fig. 2). On scintigraphic

Hepatic Epithelioid Hemangioendothelioma. Table 1 Comparison of epithelioid hemangioendothelioma in different sites

Organ	Age	Gender	Distribution	Angiocentricity	Mortality (%)
Soft tissue	2nd–9th Dec.	m~f	Solitary, rarely multifocal	50% Arise from vessel	13
Bone	1st–8th Dec.; peak 2nd/3rd Dec.	m>>f	50% Multifocal	?	?
Lung	Median 40y	f>m	>50% Multifocal	Intravascular; spread common	65
Liver	2nd–9th Dec.	f>m	>50% Multifocal	Intravascular; spread common	35

The majority of primary epithelioid hemangioendothelioma arises from soft tissue, bone, lung, and liver. The worst outcome is seen in the lung and hepatic tumors. There is a difference in age and gender distribution of EH in various sites [1].



Hepatic Epithelioid Hemangioendothelioma. Figure 1 Hepatic epithelioid ►hemangioendothelioma. (a) Macroscopy: Multifocal growth pattern of nodules and coalescence of them to form confluent masses specifically in the periphery with extension to and retraction of liver capsule. (b) Hematoxylin–eosin stain: The tumor cells form intracytoplasmic lumina containing erythrocytes. (c) Tissue stain for factor VIII-related antigen: In addition to the intracytoplasmic lumens, the pleomorphic cells of tumor are immunoreactive for factor VIII related Ag in this tissue section.

imaging, ►low uptake is the major finding, which can be useful for the follow-up of patients under therapy. Angiographic findings are nonspecific ranging from hypo- to hyperperfusion. It is noteworthy that imaging studies can only lead to a strong suspicion regarding the presence of HEH and its pattern.

Histopathology. Definitive diagnosis requires a histopathological examination. Often, a laparoscopic wedge or core biopsy is sufficient to depict architectural features of the HEH such as the intravascular characteristics. The diagnosis is mostly confirmed with ►immunohistochemical (Immunohistochemistry) evidence of endothelial differentiation (Fig. 1b and c).

Differential Diagnosis. More than two thirds of HEH cases may be initially misdiagnosed. The most common misdiagnoses are ►cholangiocarcinoma, angiosarcoma, ►hepatocellular carcinoma (HCC), ►metastatic carcinoma (►Metastasis), and sclerosing hemangioma.

Hepatic Epithelioid Hemangioendothelioma. Figure 2 MRI sections of HEH T2-weighted hyperintense lesions and central necrosis showing a target appearance.

Some important features for differential diagnosis include the infiltrative growth pattern with preservation of the hepatic acinar (►Hepatic acinus) landmarks such as portal areas, the characteristic vascular invasion with tufting of portal vein branches and terminal hepatic venules, the identification of epithelioid tumor cells especially with intracytoplasmic lumina, and the delay of staining for epithelial differentiation markers.

Therapy

There is no generally accepted strategy for the treatment of HEH due to its heterogeneous dignity and variable clinical outcome. Theoretically, ►liver resection is the first choice for curative treatment of HEH, but in the majority of the cases an oncological resection is impossible due to multicentricity of the lesions or anatomical difficulties. ►Liver transplantation is generally the most common treatment modality. According to the Pychlmayr classification of hepatic malignancies, HEH is placed among the favorable indications for liver transplantation. Life expectancy of the patients with HEH is potentially good. Long-term disease-free survival after liver transplantation is reported in patients with disseminated disease at the time of diagnosis; conversely some patients with disease confined to the liver developed rapid recurrence and metastases following liver transplantation. The experience with other therapeutic modalities such as systemic or regional chemotherapy, ►transarterial chemoembolization (►Chemotherapy), and ►radiotherapy (►Chemoradiotherapy) is limited and variable, therefore, generally these treatments are of limited value especially as the first line therapy. Considering only follow-up without any treatment as a management option is controversial. There are some cases with long-term survival or even complete spontaneous tumor regression without receiving any treatment but until now, it is impossible to reliably identify HEH patients with a nonaggressive tumor and to consider them for a "wait and see" strategy. The mode of hepatic involvement and presence or absence of extrahepatic involvement are the main factors in the decision of the treatment modality.

When less than one lobe is involved and there is no extrahepatic involvement, liver resection could be done as the first choice in treatment of HEH. The therapeutic strategy in the presence of extrahepatic involvement is especially controversial. When extrahepatic involvement exists, independent of performing liver resection or not, ►adjuvant chemotherapy (►Adjuvant chemoendocrine therapy) may be considered. In the case of massive involvement of the liver, liver transplantation is the best therapeutic choice. Extrahepatic involvement by itself does not exclude liver transplantation. Although chemotherapy in this situation is questionable, it may control the growth of the extrahepatic tumor. It is noteworthy that the clinical course of HEH is variable, ranging from a favorable disease with prolonged survival, even without therapy, to a rapidly progressive disease with a grave outcome. Therefore, the decision of the treatment strategy has to be tailored for each case, and the individual rate of progression, severity of signs and symptoms, and response to other treatment modalities may be important determinants for decision making.

Clinical Outcome

Three main causes for tumor recurrence and treatment failure after liver transplantation are error in the pretransplant evaluation, enhanced tumor growth under immunosuppressive therapy, and lack of effective anticancer therapy following surgery. The 5-year survival in different reports varies from 45 to 70%. Generally, the surgical therapies such as liver resection or transplantation have the best survival rates and chemoradiotherapy or no treatment lead to the worst clinical outcome. The presence of tumor necrosis may be associated with poor outcome, while typical indicators of biologic aggression such as ►nuclear atypia, capsule penetration, and number of ►mitosis are found to be unrelated to clinical outcome. The unpredictable natural course and prognosis of HEH makes it difficult to give a correlation between the morphological grading or clinical staging and outcome.

Hepatic Ethanol Metabolism

Iain H. McKillop, Laura W. Schrum
Department of Biology, The University of North Carolina at Charlotte, Charlotte, NC, USA

Definition

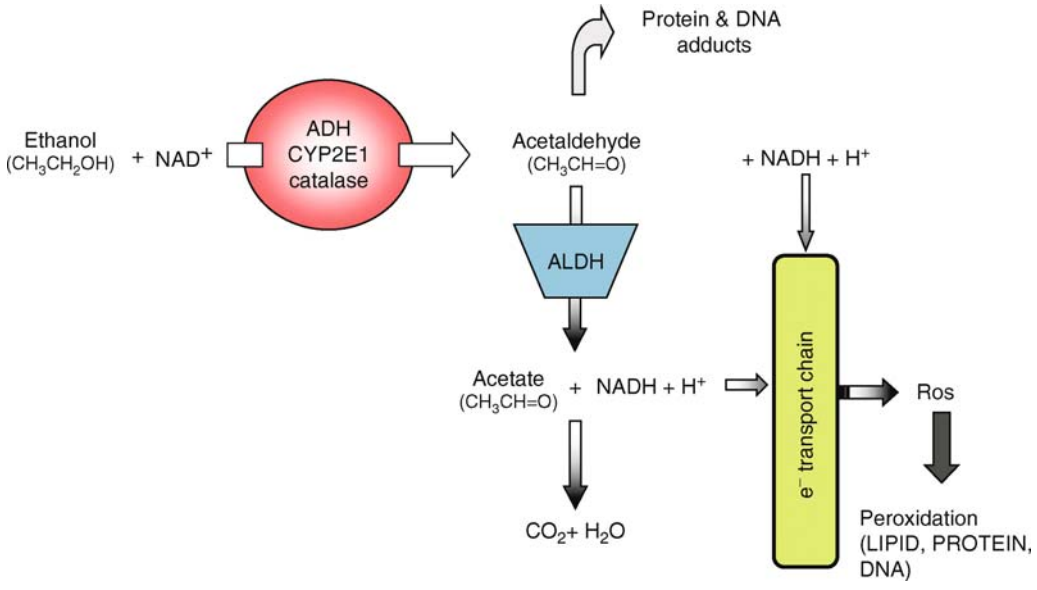
The majority of ►ethanol metabolism occurs in the ►liver following the ingestion of alcoholic beverages.

The enzymatic reactions involved in ethanol metabolism can in turn lead to a variety of deleterious effects on cells both within the liver and at the systemic level which has led to chronic ethanol consumption being identified as a major risk factor in the development of ►liver cancer and a significant risk factor for the development of non-hepatic tumors.

Characteristics

The liver demonstrates a "dual circulation" vasculature in which oxygenated blood is delivered *via* the hepatic artery and deoxygenated blood, containing substances that have been absorbed from the gastro-intestinal tract, via the hepatic portal vein. Following ingestion ethanol is rapidly absorbed and enters the hepatic portal vein where it is delivered to the functional subunits of the liver termed the hepatic lobules. As blood flows through the hepatic vasculature (sinusoids) specialized epithelial cells, termed ►hepatocytes, that line the vasculature process materials absorbed in the GI tract to maintain normal physiological homeostasis. In addition to performing essential physiological functions such as protein, lipid and carbohydrate metabolism, bile production and regulation of vitamin A storage the liver also plays a central role in drug and hormone metabolism.

Following ethanol consumption metabolism occurs in the hepatocyte via three main enzymatic pathways; ►alcohol dehydrogenase (ADH), ►cytochrome p450 2 E1 (CYP2E1) and catalase. The metabolism of ethanol is a two step process, the first involves the conversion of ethanol to ►acetaldehyde (via ADH, CYP2E1 or catalase) and the second requires the conversion of acetaldehyde to acetate by the ►aldehyde dehydrogenase (ALDH) enzyme (Fig. 1). In both instances, these reactions lead to the production of the reduced form of nicotinamide dinucleotide (►NADH). These metabolic pathways for ethanol directly contribute to many of the deleterious effects of ethanol intake on normal hepatic and systemic physiology. While the metabolism of acetaldehyde by ALDH is an efficient metabolic pathway, acetaldehyde is a highly reactive species that, if allowed to accumulate, can cause significant protein damage and formation of ►adducts to DNA and ►DNA damage. In addition to the damaging effects of acetaldehyde/NADH, once formed, must be recycled to the oxidized NAD+ form by the electron transport chain in the mitochondria of hepatocytes. This process requires increased oxygen demand and can in turn lead to the production of reactive oxygen species (►ROS) and increase cellular ►oxidative stress that can cause ►oxidative DNA damage and protein/lipid peroxidation. In the instance of moderate ethanol consumption the ADH–ALDH system is sufficient to metabolize ethanol. However, following chronic, excessive ethanol intake the CYP2E1 enzyme becomes induced leading to increased acetaldehyde/NADH production and further elevating ROS synthesis and hepatic oxidative stress (Fig. 1). Although ethanol metabolism is localized primarily in the hepatocytes, the nonparenchymal cells of the liver including ►hepatic stellate cells (HSCs) and ►Kupffer cells (KCs) have also been shown to express ethanol metabolizing genes. Human HSCs express both ADH and ALDH, and CYP2E1 expression has been observed



Hepatic Ethanol Metabolism. Figure 1 Hepatic ethanol metabolism as it pertains to potential mechanisms of liver damage. Ethanol is metabolized by a two-step process to acetaldehyde that, in turn, is metabolized by acetaldehyde dehydrogenase (ALDH) to acetate.

in both HSCs and KCs, therefore further contributing to the detrimental effects of ethanol metabolism in the liver. Depending on the level and period of ethanol consumption normal hepatic function becomes increasingly compromised with complications ranging from moderate steatosis (fatty liver) to acute alcoholic hepatitis and eventually the development of fibrosis and cirrhosis. In addition, epidemiological data indicates that chronic ethanol consumption acts synergistically to accelerate the progression of ►HCC in patients exposed to other common risk factors including exposure to ►aflatoxins and ►hepatitis virus associated HCC.

The damage caused to the liver through acetaldehyde adduct formation and/or ROS generation/oxidative stress is thought to be a major risk factor for ethanol related liver cancer development. Greater than 80% of all primary tumors diagnosed in the liver arise as a result of hepatocyte cell transformation (►hepatocellular carcinoma; HCC). Unlike other common malignancies HCC occurs most commonly in the absence of familial patterns and largely within the realms of known risk factors. Chronic ethanol consumption, metabolism and the cellular and genetic damage associated with these events thus represent a significant risk factor for hepatic damage, cell transformation and the development of HCC. In addition to the direct effects of ethanol metabolism on the hepatocyte integrity, such as impaired microtubule polymerization, several other direct and indirect factors can combine to augment the effects of ethanol consumption in the liver and the body as a whole. Glutathione (►GSH) is an antioxidant important in reducing the oxidative stress caused by the synthesis and release of ROS. In the mitochondria, GSH is the only source of hydrogen peroxide metabolism and becomes significantly depleted following chronic ethanol ingestion due, at least in part, to decreased GSH transport into the mitochondria. While these detrimental effects on hepatocyte function directly increase the probability of cell transformation, increasing evidence suggests that the sequential nature of tumor formation and/or other systemic effects may play an increasing role in the effects of ethanol during the development and progression of HCC.

Ethanol abuse accounts for the majority of liver fibrosis and cirrhosis cases in the western world; however, even though the clinical progression is well-described, the ►molecular pathology is less well understood. Current models propose that alcoholic liver disease is initiated by an inflammatory response due to the activation of KCs as well as the infiltration of leukocytes including macrophages, neutrophils and lymphocytes. The activation of these inflammatory cells has been shown to be due to elevated gut-derived endotoxin plasma levels. Ethanol alters gut permeability to macromolecules, decreases gut motility and increases growth of Gram-negative bacteria in the intestinal microflora which ultimately leads to the introduction of endotoxin into the portal microcirculation. The activation and recruitment of inflammatory cells lead to the production of several profibrogenic cytokines. These cytokines likely induce and perpetuate the activation of HSCs leading to increased deposition of extracellular matrix (ECM) like type I collagen. The HSCs themselves can also exacerbate the inflammatory response through the secretion of chemoattractants and adhesion molecules necessary for leukocyte adhesion and infiltration.

The presence and activation of KCs, other infiltrating inflammatory cells and damaged hepatocytes, lead to increased ROS resulting in the activation of quiescent HSCs. The quiescent HSCs reside in the perisinusoidal space of Disse, and one of their primary functions in the healthy liver is the storage and homeostasis of vitamin A, namely retinol, retinal and retinoic acid. Upon a fibrogenic stimulus, including ethanol, the HSC transdifferentiates from a quiescent, vitamin A storing cell to that of an activated myofibroblast-like cell which proliferates, migrates to the site of injury and is responsible for the excessive accumulation of ECM. This continued deposition of ECM leads to scarring of the liver and ultimately liver dysfunction. Reduced levels of serum and hepatic vitamin A have been reported in persons with alcoholic liver disease (►ALD). Ethanol exposure to HSCs inhibits retinoic acid production and intracellular retinol levels. Possible mechanisms which interfere with retinoid metabolism in the cell may include reduced vitamin A uptake and enhanced degradation of vitamin A.

In addition to oxidative damage incurred directly by the hepatocyte, liver damage also affects cell membrane integrity due to ethanol metabolism via a nonoxidative pathway leading to the generation of fatty acid ethyl esters (FAEE). Fatty acid ethyl esters accumulate in the cell plasma membrane as well as in the mitochondrial membrane leading to organelle dysfunction. Accumulation of FAEE, particularly linolenic acid ethyl ester (LAEE) has been reported to activate signaling pathways important in regulating collagen expression which may further contribute to ethanol-induced fibrosis and subsequently HCC progression.

In addition to the effects of ethanol and ethanol metabolism on hepatocytes and other cell populations other factors must also be considered as to how ethanol can affect tumorigenesis. For example, the high incidence of cigarette smoking in ethanol dependent patients, regional differences in dietary intake, the type of beverage consumed and the socio-economic status and relative balance of diet in ethanol dependent patients can all affect the incidence and rate of hepatic tumor development and progression. Similarly, the induction of CYP2E1 (following chronic ethanol intake) has also been demonstrated to play a significant role in pro-carcinogen and ►carcinogen metabolism, many of which are present in cigarette smoke and alcoholic beverages.

Since oxidative stress has been linked to the development of ALD, the use of antioxidants as possible therapeutic strategies has been explored. The addition of antioxidants such as vitamin E, superoxide dismutase, GSH precursors such as *S*-adenosyl-L-methionine (SAMe) and the green tea extract, (–)-epigallocatechin-3-gallate (EGCG), have been shown to prevent or ameliorate ethanol-induced liver injury in a variety of animal models of ALD and HCC. However, the use of antioxidants should be approached with caution due to the possible toxic properties of antioxidants under certain conditions. Similarly, the use of "over the counter" antioxidants raises the possibility of drug–drug interactions and altered endogenous and exogenous agent metabolism caused by antioxidant intake, many of which are currently poorly studied and reported.

Definition

The term hepatitis B x antigen, or HBxAg, refers to the gene product of hepatitis B virus (HBV) that contributes importantly to virus replication, the pathogenesis of chronic liver disease, and to the development of HCC.

Characteristics

There are an estimated 350 million people worldwide who are chronically infected with HBV and often replicate virus for many years or decades. These people are at high risk for the development of chronic hepatitis, which may progress onto cirrhosis (end stage liver disease) and then HCC. Although the pathogenesis of infection is immune mediated, this is characterized most often by responses that trigger hepatocellular damage and destruction but do not clear virus.

An important characteristic of ►chronic liver disease (CLD) is that ►liver cell regeneration provides opportunities for integration of virus DNA into the replication forks of cellular DNA. It turns out that the region encoding HBxAg is the most frequently integrated region of HBV DNA into the host genome. This region often encodes HBxAg, which is a ►*trans*-activating protein that alters the expression of cellular genes in many chromosomes throughout the host genome. This is quite an accomplishment for a small protein of only 17 kDa, and is achieved by constitutively activating a number of signal transduction pathways in the cytoplasm (such as JAK/STAT [►signal transducers and activators of transcription in oncogenesis], ►NF-κB, ►AP-1, AP-2, ►ras, src, PI3K/Akt [►PI3K signaling; ►Akt signal transduction pathways in oncogenesis] and β-catenin [►Wnt signaling], among others) and by binding to transcription factors in the nucleus (such as Oct-1, CREB, ATF-2, b-zip, TBP, and other basal transcription factors) or sequestering them in the cytoplasm (e.g., p53). HBxAg also alters gene expression at the post-transcriptional level by blocking the activity of the ►proteasome, which normally degrades proteins, and by altering the integrity of translation. Some of these pathways have been shown to be operative in the mechanism(s) whereby HBxAg promotes cell growth in culture dishes and anchorage independent growth in soft agar (a property often associated with cancer cells). The findings that HBxAg is capable of conferring tumorigenicity upon nonmalignant liver cells, and that the sustained over-expression of HBxAg in transgenic mice gives rise to HCC, further underscores the centrality of HBxAg expression to the development of HCC.

It is likely that inadequate immune responses permit the persistence of infected hepatocytes during chronic infection. However, there is increasing evidence that HBxAg inhibits a number of ►apoptotic pathways (►apoptosis signaling) (e.g., Fas and tumor necrosis factor alpha (TNFα), both of which trigger programmed cell death) during chronic infection, thereby promoting the persistence of infected cells during CLD. HBxAg is also promotes ►fibrogenesis, in that it promotes the expression of extracellular matrix proteins such as ►fibronectin, promotes the cross-linking of collagen, and potentiates ►TGFβ1 signaling, in part, by inhibiting expression of the TGFβ1 binding partner, α-2-macroglobulin. In this context, it is not surprising to find a strong direct correlation between intrahepatic HBxAg expression and CLD. This relationship would protect virus infected cells from immune destruction, but these same features also promote carcinogenesis, since tumor cells are also resistant to apoptosis and demonstrate constitutively active signaling pathways that had been previously altered in preneoplastic tissue by HBxAg.

There are few natural effectors of HBxAg that are known to be responsible for these profound biological changes that ultimately result in cancer. HBxAg appears to stimulate ►insulin-like growth factor 2 (IGF2), which promotes hepatocellular growth, activates wild type β-catenin (and its effector, c-*myc*), *trans*-activates several unique "oncogenes," and promotes ►angiogenesis. HBxAg also binds to and inactivates the ►tumor suppressors, ►p53 and ►PTEN, down-regulates expression of the natural cell cycle inhibitor, ►$p21^{WAF1/SDI1/CIP1}$, and promotes phosphorylation (inactivation) of the Rb tumor suppressor protein (►retinoblastoma protein), suggesting the molecular basis upon which HBxAg stimulates unchecked cell growth. HBxAg also binds to and inactivates a novel ►senescence factor, $p55^{sen}$, suggesting that HBxAg contributes to carcinogenesis, in part, by overcoming cellular senescence. The observation that HBxAg also down-regulates ►E-cadherin expression, the latter of which is involved in cell adhesion, provides at least part of the explanation as to how HBxAg stimulates cell motility (metastasis) in carcinogenesis.

►Oxidative stress is a common feature of CLD, resulting in the activation of HBxAg in CLD and HCC. Over-expression of HBV envelope associated polypeptides, cytokine signaling, and cell mediated immunity against HBV infected cells, all promote the development

of oxidative stress. This was associated with decreased intrahepatic levels of superoxide dismutase (Cu/Zn), which normally protects cells from ►reactive oxygen species. These conditions stimulate HBxAg, which compromises transcription coupled DNA repair and ►nucleotide excision repair, resulting in increased chromosomal alterations (genetic instability) and micronuclei formation (where metaphase plates separate prior to complete DNA replication). In addition, HBxAg is associated with the outer mitochondrial membrane, where it binds to the voltage dependent anion channel (VDAC3), resulting in decreased mitochrondrial membrane potential and the further development of oxidative stress. In this way, oxidative stress augments HBxAg function in propagating chronic infection and in stepwise hepatocarcinogenesis.

Synonyms

HCV

Definition

►Hepatitis C virus (HCV) belongs to the flaviviridae family (Hepaciviruses genus) and is a pathogenic human RNA virus, which causes chronic liver disease and hepatocellular carcinoma (►liver cancer, molecular biology) (HCC).

Characteristics

The size of this enveloped virus is ~60 nm. Its nucleocapsid contains a single-stranded RNA genome of ~9.6 kb genome (Fig. 1) of plus(+) strand polarity that carries a single open reading frame. At least six major genotypes (1–6) with up to three subtypes (a to c) exist, which differ not only in their nucleic acid sequence but also in their pathophysiological properties. All structural and non-structural viral proteins are processed from a polyprotein precursor of 3,010–3,033 amino acids in the cytoplasm or endoplasmic reticulum of the infected cell.

Untranslated Regions

The 5′- and 3′-untranslated regions (UTR) are highly conserved within the different genotypes. The 341–344 nucleotides 5′-UTR (Fig. 1) forms extensive stem-loop structures, which are important in translation initiation. It also harbors an internal ribosomal entry site. The 3′-UTR is composed of a poorly conserved variable region (28–42 nucleotides), a variable polypyrimidine stretch and conserved 98 nucleotides at the 3′ end (x region). Both UTRs seem to be crucial for regulation of HCV translation and possibly also for controlling HCV replication, and are therefore candidate targets for experimental antiviral strategies.

Structural Proteins

The core protein C (21 kD) polymerizes to an icosaedric capsid and binds RNA to form the nucleocapsid. The envelope proteins E1 (31 kD) and E2 (70 kD) form heterodimers whose formation is mediated by the chaperon calnexin. These dimers are embedded in a host-derived lipid bilayer. Within the E2 sequence there are two hot spots of mutations (hypervariable regions, HVR1 and HVR2). Mutations occurring during HCV infections are due to a selection driven by the host immune system and account for the regular existence of a variety of ►quasispecies. The E2 protein is produced as two precursors, E2/NS2 and E2/p7 that differ in their C-terminus. The hydrophobic p7 is probably important for membrane anchoring of E2. The function of p7 or E2/p7 during the HCV life cycle is not known. All structural protein processing is performed by cellular signal peptidases.

Non-structural Proteins

The non-structural protein NS2 (23 kD) is released from the polyprotein precursor both by host signal peptidases at the C-terminus of p7 and by a NS2/3 proteinase at the NS2-NS3 junction. NS3 (68 kD) has

Aminoacids	Protein	Function
1–191	C	Core

1712–1972	NS4B	?
1973–2420	NS5A	Interferon-α-resistance
2421–3010	NS5B	RNA polymerase

Hepatitis C Virus. Figure 1 Genomic organization and designation of HCV RNA, and amino acid positions and function of HCV proteins.

three different functions: It is part of the NS2/3 proteinase, its N-terminal third contains a serine proteinase and at the C-terminus a RNA-dependent NTPase/helicase was discovered. Together with NS4A (6 kD) as a stable complexed cofactor, the N-terminal NS3 serine proteinase catalyses the cleavage between NS3-NS4A, followed by cleavage between NS5A-NS5B, NS4A-NS4B and NS4B-NS5A. The NS3 helicase can unwind double-stranded (ds)RNA, dsDNA and RNA/DNA heteroduplex molecules. For this purpose any NTP or dNTP is used as source of energy. NS4B is a 26 kD membrane associated protein of unknown function. NS5A (56–58 kD) represents two cytoplasmatic proteins, p56 and p58, which are both phosporylated at serine residues. This process may be essential for the viral replication cycle, but the biological functions of these proteins are not understood. There is some evidence that NS5A mediates interferon-alpha resistance of HCV. The NS5B (65 kD) protein is responsible for HCV RNA replication; it represents an RNA-dependent RNA-polymerase that is not found in humans and may therefore be another attractive target for antiviral strategies. The RNA minus(−) strand is transcribed in the host cytoplasm into a plus(+) strand RNA. This serves as a template to produce new minus(−) strands for packaging into the envelope. Both steps are accomplished by the NS5B protein.

Cellular and Molecular Regulation

Although the HCV genome does not harbor acutely transforming oncogenes, the HCV core as well as the NS3 gene are candidate genes whose products may mediate malignant hepatocyte transformation.

Oncogene complementation assays using HCV core and H-►ras or c-►myc oncogenes showed that HCV core cooperates with these oncogenes and transforms primary rat embryo fibroblasts to the tumorgenic phenotype. Focus formation, soft agar growth and tumor development was also shown in nude mice using Rat-1 fibroblasts. Also in this model a loss of contact inhibition, morphological changes and anchorage- and serum-independent growth occurred when HCV core and v-H-ras were cooperatively expressed. The most striking evidence of an oncogenic potential of HCV comes from an HCV core-transgenic mouse model, in which hepatic tumors arose in up to 30% of animals of two different strains. Interestingly, all tumors occurred in male animals. However, other mice transgenic for HCV core or C-terminally truncated (amino acid 384–715) HCV core failed to develop histological or biochemical signs of liver disease.

The postulated underlying molecular mechanisms of HCV core-induced hepatocyte transformation are manifold. They comprise sequestration of LZIP in the cytoplasm leading to a loss of CRE-dependent

transcription and regulation of cell proliferation and subsequently to morphological transformation of NIH 3T3 cells. Other mechanisms may be interference with ►apoptosis or ►transactivation of cellular c-fos, c-myc, p53 or β-interferon promoters.

Stable expression of the 5′-portion of the NS3 gene was able to induce focus formation and soft agar growth in NIH 3T3 cells. Only recently it was demonstrated that internal cleavage of the NS3 protein occurs at cleavage sites FCH(1395)//S(1396)KK and IPT(1428)//S(1429) GD within the HCV RNA helicase domain in presence of NS4A. These findings were confirmed in two different isolates of HCV of genotype 1b. The 5′-portion of NS3 was more oncogenic than the full-length NS3 protein.

Clinical Relevance

An estimated 2% of the world's population is chronically infected with HCV. It accounts for 20% of acute and 70% of chronic hepatitis cases. HCV is mainly transmitted by blood. Since screening and treatment of blood products for HCV has been routinely performed, post-transfusion hepatitis has become extremely rare. Intravenous drug addiction is today a major way of HCV transmission. Acute hepatitis is often clinically inapparent, and in chronic hepatitis symptoms occur mainly in later stages of disease. A high chronicity rate of up to 75% of acute infection and its silent course account for the pathogenic potential of this virus, which includes extrahepatic manifestations. Twenty percent of chronically infected patients develop ►liver cirrhosis and 2–5% per year will progress to hepatocellular carcinoma (HCC).

Therapy for HCV infection comprises the combined use of 3–6 MU of α-interferon administered subcutaneously three times a week and 800–1200 mg of the nucleoside analog ►ribavirin p.o daily for 6–12 months dependent on the genotype and viral load. Roughly 40–45% of previously untreated or relapse patients benefit from the treatment, i.e. eliminate HCV and normalize liver enzymes. In addition, this treatment is capable of improving histological signs of liver damage. Its effect on HCC prevention can not clearly be judged at present.

Recent therapeutic innovations comprise ►pegylated interferons that allow single weekly dosing due to slow effector release from subcutaneous depots and a decrease of systemic side effects. Sustained response rates up to 70 % can be reached. A synthetic consensus interferon-alpha showed promising effects in monotherapeutic use in a preliminary trial and is presently being evaluated in combination with ribavirin. Major future achievements are expected from the development of inhibitors of HCV protease, helicase or RNA-dependent RNA polymerase, which may improve effectivity of antiviral treatment similarly to the situation in HIV infection, but are not yet available for clinical use. Therapeutic nucleic acids such as antisense oligodeoxynucleotides, RNAs or ribozymes may be another experimental concept for the treatment of HCV infection in the future.

[2]Universitäts-Kinderspital beider Basel (UKBB), Basel, Switzerland

Definition

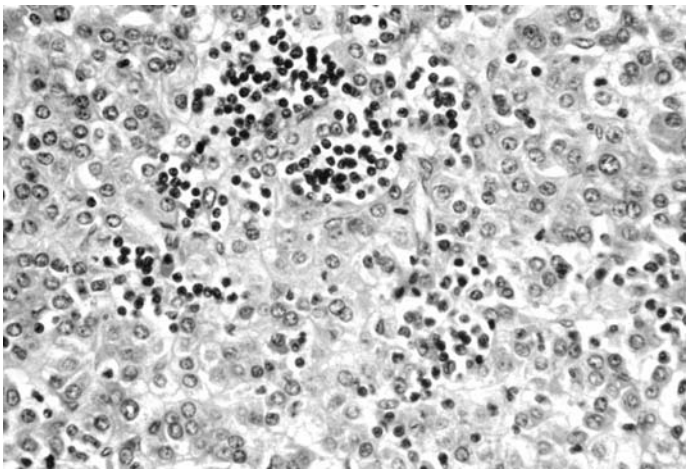
Heptoblastoma is a childhood malignant embryonal liver tumor consisting of immature epithelial cells with or without additional mesenchymal component.

Characteristics

Hepatoblastomas are the most frequent malignant liver tumors of childhood. Their annual incidence is 0.5–1 cases per million children under 15 years of age in Western countries. The affected children are most frequently between 6 months and 3 years old. Hepatoblastoma has also been detected in utero by prenatal ultrasound examination. Since liver tumors lack early clinical symptoms, hepatoblastoma patients often present with locally extended tumors at diagnosis. However, distant metatases usually occur very late in the disease progression. The patients frequently have highly elevated ►α-fetoprotein levels. In these cases this ►oncofetal antigen can be useful as a sensitive diagnostic marker and also as a marker for the monitoring of treatment response.

Pathological Classification

Hepatoblastomas always consist of immature epithelial liver cells resembling fetal or embryonal liver cells. Approximately one third of the cases contain additional mesenchymal components and are then termed "mixed" hepatoblastomas. According to Weinberg and Finegold (1983) the epithelial component is further classified into



Hepatoblastoma. Figure 1 Histopathology of an epithelial hepatoblastoma showing foci of hematopoietic cells.

well differentiated "fetal," less differentiated "embryonal" and undifferentiated "small cell anaplastic" categories. The latter is rare, as are "macrotrabecular" or "teratoid" variants. Small cell anaplastic as well as macrotrabecular variants indicate a bad prognosis. A histopathological hallmark of hepatoblastomas, in particular of the fetal differentiated cases, is the occurrence of hematopoietic foci mainly consisting of erythropoietic or thrombopoietic progenitor cells mimicking fetal hematopoiesis in the liver (Fig. 1).

Staging

In the last 30 years the treatment modalities and outcome of hepatoblastoma patients has significantly improved. It turned out that hepatoblastomas are responsive to chemotherapy. Today, most hepatoblastoma patients are enrolled in multicenter studies and receive a stage and risk adapted multimodal therapy. Different staging systems are used including the American and German four-graded postoperative staging system, the Japanese TNM classification and the European SIOP PreTreatment Extent of Disease (PRETEXT) grouping system. The patients are stratified into standard and high risk patients, the latter often presenting with extended, multifocal or metastatic disease.

Therapy and Outsome

In current protocols most patients receive a ►neoadjuvant chemotherapy with ►cisplatin and ►doxorubicin, in some studies combined with ifosphamid, 5-fluorouracil or carboplatin. The combination carboplatin and etoposide has also been effective. The overall survival after chemotherapy and resection is 70–80%. Unfortunately, approximately one quarter of the patients still die from the disease, so that predictive factors are important to early recognize these high risk patients and to offer them an intensified therapy. High risk patients have been treated with prolonged preoperative chemotherapy (SIOP, USA) or with mega-therapy (Germany).

Predictive Factors

Several histological, clinical as well as serological factors have been evaluated for their predictive value. In particular, the extension of the tumor in the liver, multifocality, vascular invasion and the presence of metastases have been of predictive importance in most studies. The decline of alpha-fetoprotein levels under chemotherapy predicts the clinical response. In contrast, the impact of distinct histological features such as mixed versus epithelial, or fetal versus embryonal differentiation and chromosome ►ploidy of the tumors is still under discussion and the data is controversial.

The etiology of hepatoblastomas is unknown. Environmental factors do not seem to play a major role in the pathogenesis of hepatoblastomas. Preterm infants may have an elevated risk for the development of hepatoblastomas. Although most hepatoblastomas occur sporadically, familial cases have been described. The incidence is highly elevated in families with ►adenomatous polyposis coli (FAP [►APC Gene in Familial Adenomatous Polyposis]) and ►Beckwith-Wiedemann Syndrome.

Genetic and Molecular Characteristics

Cytogenetic analyses have revealed several recurrent numerical aberrations as well as structural alterations. Most frequently trisomies of chromosomes 1, 2, 8 and 20 have been described as well as a recurrent translocation t(1;4)(q12;q34) in ~15% of hepatoblastomas. Approximately 50% of cases show gain of material of chromosome 2q. A few cases have an ►amplification of material from chromosomal band 2q24, indicating the location of a hepatoblastoma related oncogene. ►Microsatellite analyses have uncovered

frequent allelic losses of chromosomal regions of chromosome arms 1p and 11p. The losses of chromosomal region 11p15.5 are always of maternal origin indicating the existence of one or more imprinted hepatoblastoma associated gene(s) expressed from the maternal ►allele.

Studies on the mutational status of the ►TP53 gene resulted in conflicting data. Whereas TP53 mutations were described in a small Japanese tumor collection, these were absent in other studies. Similarly, somatic missense mutations were described in one study but not confirmed by others. The activation of the ►WNT signaling pathway by activating mutations in the ►β-catenin gene is a frequent event in hepatoblastomas. Approximately 50% of the hepatoblastomas save point mutations or deletions of exon 3 encoding the protein degradation targeting site of the β-catenin protein, resulting in a destruction of N-terminal phosphorylation sites that are necessary for protein degradation. This leads to the accumulation of a mutated protein, which transfers oncogenetic signals to the nucleus and increases transcription of specific target genes of the ►TCF/LEF family of transcriptions factors such as ►cyclin D1 and ►c-myc. Similar mutations have been described in other tumor entities including colorectal cancer. However, hepatoblastoma represents the malignant tumor with the highest incidence for β-catenin mutations.

Cellular Characteristics

Hepatoblastoma cells resemble liver progenitor cells during embryonic and fetal development suggesting that hepatoblastomas are derived from such progenitors. Hepatoblastoma cells are still dependent on growth factors and use specific growth factor signaling systems. The important fetal mitogen, insulin-like growth factor-II, has been demonstrated to be highly over-expressed in hepatoblastomas. The encoding ►IGF2 gene maps to chromosome 11p15.5, a region frequently altered in hepatoblastomas and related embryonal tumors. They also produce several hematopoietic ►cytokines such as ►interleukin-1, ►stem cell factor, ►erythropoietin and ►thrombopoietin that induce hematopoietic foci in hepatoblastomas. Hepatoblastoma cells over-express the receptor ►Met for hepatocyte growth factor (HGF; ►scatter factor) and proliferate in response to HGF in vitro. Concentrations needed for this effect are usually found in the serum of patients after liver surgery. This may explain why hepatoblastomas often show rapid regrowth after partial resection. Therefore it is now common sense that the tumors should undergo primary resection, only when they can be removed without residual tumor cells.

Liver cancer; Hepatoma; Hepatic carcinoma; Hepatitis B Virus x Antigen Associated Hepatocellular Carcinoma; Primary liver cancer; Primary hepatic carcinoma; Liver cell carcinoma

Definition

Hepatocellular carcinoma (HCC) is a primary cancer that arises from hepatocytes, the major cell type of the liver. Most cases of HCC are secondary to either hepatitis virus (usually type B or C) infection or cirrhosis.

Characteristics

Epidemiology

HCC is the fifth most common cancer in men and the eighth most common cancer in women worldwide. An estimated more than half a million new cases are diagnosed annually, while there are major geographical differences in incidence. The annual incidence rates in Eastern Asia and sub-Saharan Africa exceed 15/10,000 inhabitants, while the figures are intermediate (between 5/10,000 and 15/10,000) in the Mediterranean Basin and Southern Europe, and very low (<5/10,000) in Northern Europe and North America. In high-risk countries, HCC can develop before the age of 20 years, whereas in low-risk countries, HCC is rare before the age of 50 years. The incidence of HCC is increasing in several developed countries and the increase will likely continue for some decades. This trend is related to the

increasing incidence of ►hepatitis B virus (HBV) and ►hepatitis C virus (HCV) infections in those areas. In selected areas of some developing countries, the incidence of HCC has decreased, possibly as a result of the introduction of the HBV vaccine. The incidence of HCC worldwide varies according to the prevalence of HBV and HCV infections.

There are gender differences in the incidence of HCC, with a male predominance ranging between 2:1 and 4:1.

Risk Factors

In more than 80% of patients with HCC, it has developed as a consequence of chronic liver disease, usually (but not always) in association with cirrhosis. Exceptions include chronic HBV infection and certain types of HCC in sub-Saharan Africa, where aggressive and massive tumors can develop before the onset of cirrhosis. The major causes of cirrhosis, and hence HCC, are HBV, HCV, and alcohol, but less prevalent conditions such as hemochromatosis, primary biliary cirrhosis, nonalcoholic steatohepatitis, and Wilson disease have been also associated with the development of HCC. The attributable risk estimates (proportion of a disease due to a specific factor) for the combined effects of HBV and HCV infections account for well over 80% of HCC cases worldwide. The risk among those with cirrhosis increases in parallel with the impairment of liver function and is higher in males, patients older than 50 years, and subjects with increased ►alpha-fetoprotein (AFP) concentration.

►Aflatoxin has also been implicated as a factor in the etiology of HCC in parts of the world where this mycotoxin (a toxin produced by a fungus) occurs in high levels in food.

Diagnosis

Groups of subjects at higher risk for HCC can be identified. The major risk factors for HCC are chronic HBV infection, chronic HCV infection when associated with advanced fibrosis or cirrhosis, and cirrhosis regardless of cause. The surveillance tools are AFP concentration and liver ultrasonography (US). Other tumor markers such as lectin-bound AFP and ►des-gamma-carboxy prothrombin (DCP) have been proposed to surpass the efficacy of AFP, but their clinical efficacy is yet to be unequivocally proven. In patients with a high suspicion of HCC, dynamic enhanced computed tomography (CT) or magnetic resonance imaging (MRI) are generally used as confirmatory tools for diagnosis. A consensus statement from the European Association for the Study of the Liver (EASL) has been formulated to standardize diagnostic approaches in patients with HCC as below. Since nodules less than 10 mm in size were considered not feasible to be confidently diagnosed, close observation was recommended. For nodules between 10 and 20 mm in size, positive result of the biopsy was needed to establish the diagnosis, while for those larger than 20 mm a specific radiologic profile observed by two imaging techniques was considered to make the diagnosis if the patient was known to present with underlying cirrhosis.

Prognosis

The natural history of HCC depends on the stage of the tumor and the severity of associated liver disease at the time of diagnosis. For example, a patient with a 1 cm tumor with no cirrhosis has a >50% chance of surviving 3 years, even without treatment. In contrast, a patient with multiple tumors involving both lobes of the liver with decompensated cirrhosis is unlikely to survive more than 6 months, even with treatment.

AFP levels have been shown to be prognostically important, with the median survival of AFP-negative patients significantly longer than that of AFP-positive patients. Other prognostic variables include performance status (measure of general wellbeing), liver functions, and the presence or absence of cirrhosis and its severity in relation to the ►Child-Pugh classification.

Prognostic Staging System

A clinical staging system provides guidance for patient assessment and appropriate therapy. It is useful for the decision to treat certain patients aggressively while avoiding the overtreatment of other patients who would not tolerate therapy or whose life expectancy rules out any chance of success. Clinical staging is also an essential tool for comparison between groups in therapeutic trials and between different studies.

The current classifications most commonly used for HCC are the ►Okuda staging system, the ►Child-Pugh staging system, tumor node metastasis (TNM) staging, and Cancer of the Liver Italian Program (CLIP) score (Table 1). Among these, the CLIP score is currently the most commonly used integrated staging score, for both tumor and liver disease stages.

The Japan Integrated Staging (JIS) system, a new system that is based on a combination of the Child-Pugh system and the Liver Cancer Study Group of Japan (LCSGJ) system – the LCSGJ system is also concordant with TNM classification for HCC by the International Hepato-Pancreato-Biliary Association and the International Union Against Cancer (UICC) – has recently been proposed in Japan (Table 2). The stratification ability of the JIS scoring system is much better than that of the CLIP scoring system. The JIS scoring system also performed better than the CLIP scoring system in selecting the best prognostic patient group.

Treatment

There is no worldwide agreement on a common treatment strategy for patients with HCC, and several proposals have been published (Fig. 1).

Hepatocellular Carcinoma. Table 1 Definitions of the CLIP score

Variables	Score		
	0	1	2
Child-Turcotte-Pugh stage	A	B	C

T4		Fulfilling zero factors	
Stage I		T1 N0 M0	
Stage II		T2 N0 M0	
Stage III		T3 N0 M0	

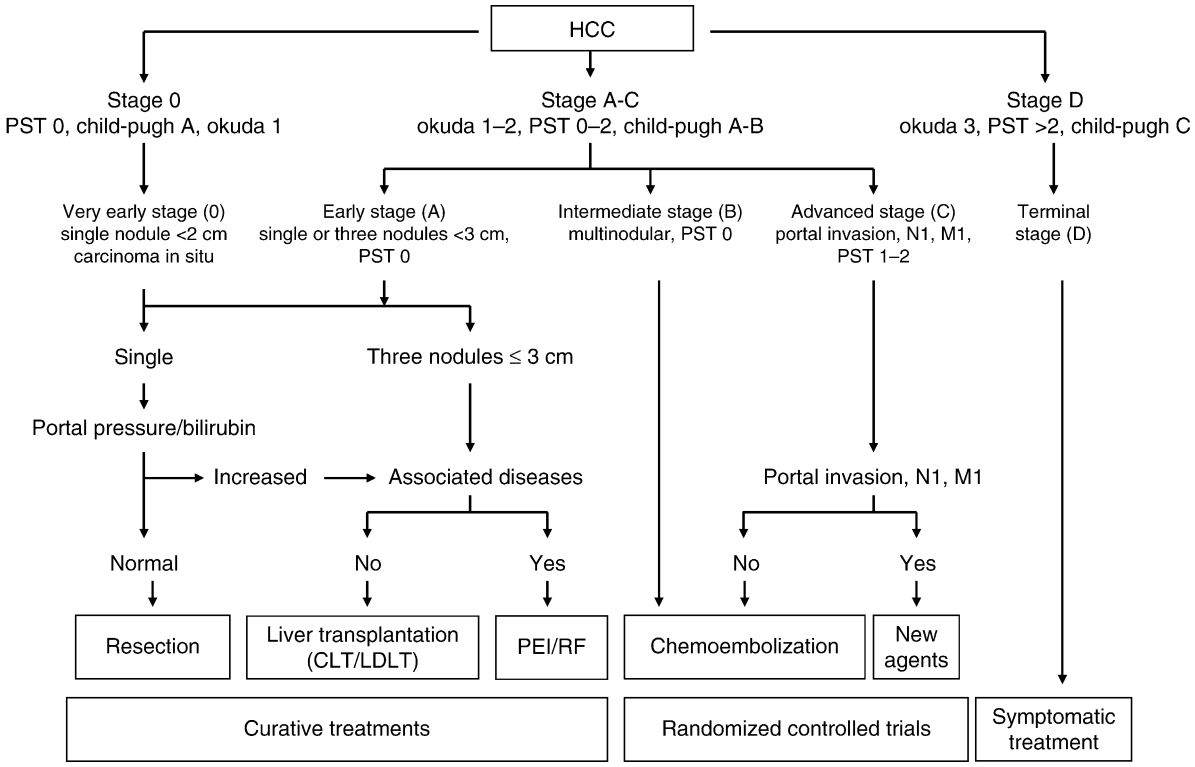
The three major curative therapies –surgical resection, liver transplantation, and percutaneous treatments – compete as first-line treatment options for single small HCC in patients with liver function.

Surgical resection yields good results in candidates who have single tumors and excellent liver functional reserve. Five-year survival in well-selected patients with substantial HCC is around 50%, reaching a 70% rate in those with normal bilirubin concentration who do not have portal hypertension. The main problem of surgical resection as compared with liver transplantation is the high recurrence rate that may exceed 50% at 3 years and 70% at 5 years.

Transplantation is the first choice for patients with small multinodular tumors (three nodules ≤3 cm) or those with advanced liver dysfunction. These are patients with single HCC ≤5 cm or up to three nodules ≤3 cm (the Milan criteria), who in major Liver and Transplantation Units achieve 70% survival at 5 years with a recurrence rate below 15%.

Percutaneous treatment is a therapeutic option that has become quite widely-used during the last decade. Destruction or ablation of tumor cells can be achieved by the injection of chemical substances (e.g., ethanol, acetic acid, and boiling saline) or by the insertion of a probe that modifies local tumor temperature (e.g., radiofrequency ablation, microwave, laser, and cryotherapy). This procedure can be done percutaneously with minimal invasiveness or during laparoscopy, and it's currently considered the best option for patients with early HCC who are not candidates for surgery.

Transcatheter arterial chemoembolization (TACE) is usually performed in the treatment of intermediate-advanced stages of HCC. TACE is the delivery of high concentrations of chemotherapeutic agents directly to the HCC tumors via the hepatic artery, which provides the tumor with most of its blood supply. Embolizing agents such as cellulose, microspheres, lipiodol, and gelatin form particles (Gelform) are used to deliver intra-arterial chemotherapy (e.g., doxorubicin,



Hepatocellular Carcinoma. Figure 1 Barcelona Clinic Liver Cancer (BCLC) staging and treatment algorithm. PST, performance status test; CLT, cadaveric liver transplantation; LDLT, live donor liver transplantation; PEI, percutaneous ethanol injection; RF, radiofrequency ablation.

epirubicin, ►mitomycin, or ►cisplatin) to the tumor via the hepatic artery. In general, patients with portal vein thrombosis, encephalopathy, or biliary obstruction are not candidates for TACE. Objective response, as reflected by intratumoral necrosis and reduced tumor burden on dynamic CT or MRI, is associated with delayed tumor progression, and as a whole, results in an improvement of survival. According to the prospective cohort study by the Liver Cancer Study Group of Japan, the survival rate of over 8,000 patients with unresectable (inoperable) HCC treated by TACE were 82% at 1 year, 47% at 3 years and 26% at 5 years.

Systemic chemotherapy has no effect (<10% objective responses) and is frequently associated with toxicity and hence is usually not recommended.

Radiation therapy has some effect, but the impact on survival is still unknown.

Prevention

Vaccination against HBV at birth has decreased the incidence of HCC in areas with high prevalence of this viral agent. Unfortunately, there are no similar means of preventing hepatitis C, alcoholic liver disease, or nonalcoholic steatohepatitis. Therapy for the underlying liver disease to prevent progression to cirrhosis may be the best approach for prevention of HCC. Antiviral treatment for chronic hepatitis decreases the proportion of patients developing cirrhosis and this should reduce the long-term incidence of HCC. When cirrhosis is already established, there is no evidence supporting a preventive effect of drugs such as interferon.

Definition

Hepatocytes and cholangiocytes are the most common types of liver epithelial cell, and their malignant transformation can lead to hepatocellular carcinoma (HCC) and cholangiocellular carcinoma (CCC), respectively.

Characteristics

Etiology

Oncogenic and Environmental Factors

The radioactive contrast medium thorotrast was used to detect arterial injury during World War II. This medium can become trapped in the reticulo-endothelial system of exposed individuals, and can release weak γ-rays over a prolonged period of time. As a result, HCC, angiosarcomas, and CCC can develop ≥10 years after exposure. For this reason, the clinical use of thorotrast was recently prohibited.

Aflatoxin B1, which is found in the fungus *Aspergillus flavus*, acts as an oncogenic factor of HCC. In 1979, the World Health Organization (WHO) reported the prevalence of HCC to be 13 cases per 100,000 individuals among the Mozambique population. Estimate uptake volume of aflatoxin was 222.4 ng/kg in adult which was most amount of consumption in the Africa.

Anabolic steroids are also hepatocarcinogenic substances, and have been closely linked to both HCC and liver cell adenoma; this association was first reported in 1971 in a patient with Fanconi anemia who was treated with oxymetholone.

Recently, oral contraceptives that contain synthetic estrogen and progestogen have been linked to an increased risk of HCC in a large cohort study in Europe; the relative risk was found to be 503 times greater for liver cell adenoma and 20 times greater for HCC after >8 years of administration.

High-Risk Non-viral Liver Diseases

Patients with Budd–Chiari syndrome, hemochromatosis, glycogen-storage disease, and α-antitrypsin deficiency represent high-risk groups for HCC.

Viral Hepatitis-Induced HCC

The most important factor influencing hepatocarcinogenesis is continuous infection with the hepatitis B virus (HBV) or the hepatitis C virus (HCV). In a clinical setting, continuous infection with HCV can induce chronic hepatitis concomitant with necroinflammation and disruption of the repair systems of the liver; this can lead to hepatic injury and further interference with the repair system for DNA damage, eventually resulting in hepatic fibrosis, liver cirrhosis, and, finally, HCC. HBV infection can lead to the same hepatocarcinogenic process, although an additional mechanism allows HBV integration to occur without chronic hepatitis and liver cirrhosis.

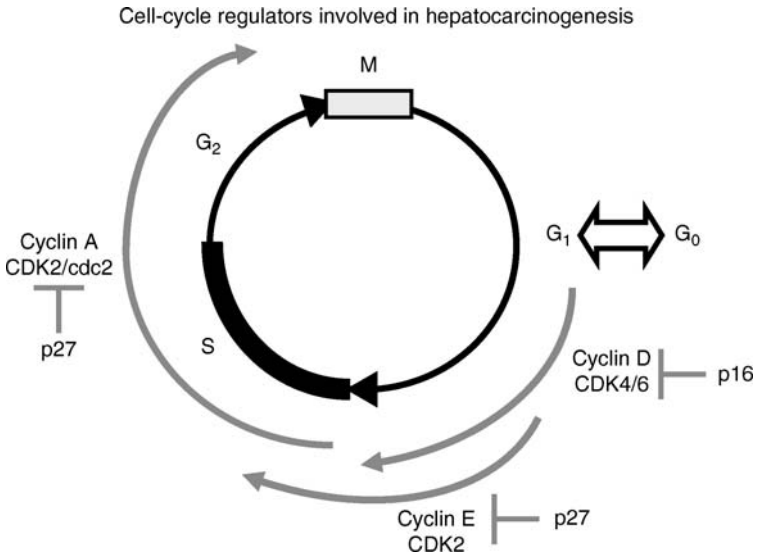
Traditionally, south-east Asian countries, particularly Korea, China, and Japan, have shown high infection rates for both HBV and HCV. Moreover, the incidence of HCC has been relatively high throughout Asia. An increased incidence of HCV among HCC cases was more recently reported in Japan, with prevalence rates of ∼75% compared with 17% for HBV infection. The maternal transmission of HBV has now been limited by a national HBV vaccination program, which is causing the prevalence to decrease. However, the prevalence of HCV is continuing to increase throughout Asia, and especially in Japan, because of its high incidence in past blood transfusions.

Alcohol intake, obesity, male gender, and old age are all recognized progression factors for HCC in chronic cases of HBV and HCV infection.

Molecular Aspects of Hepatocarcinogenesis (Fig. 1)

The mechanism of hepatocarcinogenesis is not yet completely understood; however, advances in molecular biology methods have revealed many altered genes in human HCC. A loss of heterozygosity (LOH) at chromosome arms 1p, 1q, 4q, 6q, 8p, 9p, 13q, 16p, 16q, and 17p has been found in HCC with a frequency of >20%, and chromosome arms 6q, 9p, 13q, 16p, and 17p LOH have been linked to inactivation of the tumor-suppressor insulin-like growth factor 2 receptor (IGF2R), p16, retinoblastoma (RB1), axin 1, and p53.

The genetic changes involved in hepatocarcinogenesis can be divided into at least five pathways: the p53 pathway, which is involved in the response to DNA damage or genomic instability; the p16/p27/RB1 pathway, which is involved in cell-cycle control; the transforming growth factor-β (TGF-β) pathway, which is involved in growth inhibition and apoptosis of hepatocytes; the Wnt/β-catenin/APC pathway, which is involved in intercellular interactions; and the E-cadherin/integrin and extracellular signal-regulated kinase kinase (MEK)/extracellular signal-regulated kinase (ERK) signaling pathways, which are involved in cancer cell migration and metastasis.



Hepatocellular Carcinoma – Etiology, Risk Factors and Prevention. Figure 1 Possible mechanisms of hepatocarcinogenesis. Cell-cycle regulators involved in hepatocarcinogenesis.

Among the different signaling pathways involved in hepatocarcinogenesis, deregulation of the cell-cycle machinery is thought to be closely involved in the progression of HCC. Cell-cycle progression in mammalian cells is mainly governed by cyclin A, cyclin D, and cyclin E, along with cyclin-dependent kinase 2 (CDK2) and CDK4. The kinase activities of these proteins are negatively regulated by the CDK inhibitors (CDKIs) p16 and p27. RB1, which is phosphorylated by CDKs and activates the E2F family of transcription factors, is mutated in ~15% of HCCs. The cyclin D1 gene, which is involved in the G1 progression and G1/S transition phases of the cell cycle, has been shown to be amplified in 10–20% of HCCs. By contrast, both p16 and p27 are frequently inactivated in HCCs. P16 is inactivated in ~50% of HCCs, mainly due to the *de novo* methylation of the DNA-promoter region. Somatic mutation of the p16 gene has also been described in some cases of HCC. Recently, p16 DNA methylation was identified in preneoplastic liver tissues of individuals with chronic hepatitis virus infections. P27 is a member of the KIP family of CDKIs, and its expression is reduced in 40–60% of HCCs. Decreased p27 expression is closely associated with poor prognoses of individuals with HCCs, indicating that it is an adverse prognostic factor. In some cases of HCC, increased cell proliferation has been noted despite relatively high levels of p27 expression, suggesting the inactivation of p27 by sequestration into cyclin D1–CDK4-containing complexes.

Although many genes appear to be altered in HCC, the frequencies of individual mutations are low, and the patterns of genetic alteration differ among patients. Connections between different pathways might thus be plausible mechanisms underlying hepatocarcinogenesis.

Diagnosis

Serum alpha-fetoprotein (AFP) and des-γ-carboxy prothrombin, which is also known as protein induced by vitamin K antagonist (PIVKA II), are useful serological markers of HCC. Although AFP exists in normal human tissues (both fetal and adult), serum levels are sensitive to the presence of HCC. The overall diagnostic accuracy of AFP is ~80%. By contrast, PIVKA II is only present in HCC tissues, so its specificity is relatively high, and its overall diagnostic accuracy is ~55%. The simultaneous measurement of AFP and PIVKA II could therefore be useful for the detection of HCC. However, as elevated AFP levels can be the result of liver cirrhosis, it is important to determine whether they are caused by active liver cirrhosis or by HCC that has arisen from liver cirrhosis. The elevation of serum AFP reflected as regeneration of hepatocytes.

The levels of carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 (CA19-9) are also often elevated in the serum of patients with HCC. However, the specificities of these markers are lower than those of AFP and PIVKAII.

Total imaging is important for detecting small HCCs. The majority of HCCs arise from chronic hepatitis and liver cirrhosis; periodical checking using ultrasound scanning and computed tomography (CT) is therefore crucial to detect the early stages of HCCs.

Recent advances in the use of imaging tools, such as CT scanning with contrast medium and magnetic resonance imaging (MRI), have enabled the precise detection of HCCs. Accuracy levels have reached >90% using enhanced CT and MRI techniques, and the current limit of detection for HCCs is ~10 mm diameter.

HCCS can develop from small nodules into large nodules when given access to an arterial blood supply rather than a portal blood supply. Small HCCs with poor arterial blood supplies are difficult to distinguish from adenomatous hyperplasia, large regenerative nodules, or angiomyolipoma. Direct tumor biopsy guided by ultrasound with a fine needle is therefore useful for making a final diagnosis in such cases.

Treatment

There are several treatment modalities for HCC. Surgical treatment is divided into two categories: hepatic resection and liver transplantation. The former is based upon the hepatic functional reserve, tumor location, and tumor numbers, and includes many procedures ranging from partial resection to extended right or left hepatic lobectomy. The latter is based on the tumor size and tumor numbers alone. The Milan criteria (that is, the presence of one nodule <5 cm in size or three nodules <3 cm in size, with no vascular involvement or extrahepatic metastasis) is applied worldwide to HCCs for both deceased and live donor liver transplantation. The current 5-year-survival rate for HCCs that meet the Milan criteria is >80%, compared with <30% for those that do not meet the criteria.

Medical treatment includes ethanol injection, microwave coagulation, and radiofrequency ablation (RFA) by ultrasound guidance. Recently, RFA has become popular for the treatment of HCC, because it offers complete necrosis, and is relatively safe and easy to perform. The 5-year-survival rate after RFA is >80%; however, the recurrence of nodules in non-treated lobes in cases of multicentric carcinogenesis is relatively common, especially in HBV-positive and HCV-positive HCCs. In addition, the differential diagnosis of intrahepatic metastasis and multicentric nodules can be difficult, although the rate of local recurrence is lower after RFA. Several reports have described a genetic approach for detecting multicentric and intrahepatic metastatic nodules, although this technique remains controversial. Only small nodules with an arterial blood supply are diagnosed as intrahepatic metastatic nodules during the early stages of HCC, because multicentric nodules still possess a portal blood supply at this time.

Transcatheter arterial embolization (TAE) has been developed as a technique for the treatment of advanced HCCs with high-volume arterial blood supplies. The blood supply to the normal liver is 25% arterial and 75% portal. By contrast, advanced HCC tissues have an arterial blood supply of 99%. The intensive embolization of a segment with advanced HCC can lead to 99% ischemic change in HCC tissues and 25% ischemic damage in non-cancerous tissues. Consequently, a major ischemic effect occurs in the HCC tissues with only a minor ischemic effect in the liver tissues. A meta-analysis and cohort study indicated that TAE combined with an anti-cancer agent containing lipiodol was an effective tool for the treatment of advanced HCC. An additional cohort study of 8,510 cases of advanced HCC reported 3-year and 5-year survival rates of 47 and 26%, respectively. These data were taken from the Japanese Liver Cancer Study Group during the past 10 years.

Recently, good results have been produced using chemotherapy along with an interferon injection. Advanced HCCs with portal vein tumor thrombi that were treated with intra-arterial continuous infusion of 5-fluorouracil (5-FU) via a reservoir, along with a daily subcutaneous injection of interferon alpha, showed a 45% response rate. Cisplatin (CDDP) is another eagerly anticipated new drug for use in chemotherapy against advanced HCC.

Prognosis and Prevention

The prognosis of HCC is dependent upon the tumor development and associated hepatic functional reserve. Several prognostic schemes have been developed for HCC, including the CLIP score from Italy, the Barcelona Clinic of Liver Cancer (BCLC) system from Spain, and the Japanese Integrated System (JIS) and modified JIS.

The natural course of HCC is usually studied over time; however, data from this type of study are not yet available for recently developed methods. The ultimate treatment modality for HCC without recurrence is liver transplantation, yet the problem of how to manage subsequent recurrent HCV infection persists. Rapid progression towards liver cirrhosis is also a major problem throughout the world.

The prevention of HCC has become an important medical issue. A program for the eradication of HCV by Peg interferon with ribavirin has been applied worldwide, with a current success rate of 50–60%. Patients who have undergone a virological response due to treatment with Peg interferon and ribavirin have shown no potential for subsequent hepatocarcinogenesis. Biochemical responder as normal transaminase with reappearance of HCV after combination therapy is also reduced the potential of hepatocarcinogenesis.

This preventative procedure has also been applied for HBV using lamivudine, adefovir, and entecavir. However, this approach has failed to eradicate HBV, and has only succeeded in reducing the HBV DNA titer. This reduction of HBV DNA and normal transaminase suggests the inhibition of hepatocarcinogenesis. Another chemoprevention material is not available until now in clinical.

Definition

The proto-oncogene HER-2/neu (ERBB2) is located on chromosome band 17q21.1 and encodes a transmembrane ►receptor tyrosine kinase. The name for the HER-2 protein is derived from "Human Epidermal growth factor Receptor" as it features substantial homology with the ►epidermal growth factor receptor (EGFR).

Characteristics

The HER-2/neu (p185neu) protein belongs to a family of closely related growth factor receptors including.

- HER-1 (ERBB1), EGFR
- HER-2 (ERBB2)
- HER-3 (ERBB3)
- HER-4 (ERBB4)

HER-2/neu gene ►amplification and protein overexpression have been identified in 10 to 34% of breast cancers, and patients whose breast cancers contain HER-2/neu aberrations have a poor prognosis. The prognostic impact of HER-2/neu amplification was initially most convincing in patients with axillary

lymph node metastases. By contrast, a prognostic role was less compelling in patients with localized (lymph node negative) breast cancer. Various studies came to different conclusions regarding a link between HER-2/neu gene or protein abnormalities and survival in lymph node negative patients. Reviews of these non-correlating studies have focused on the immunohistochemical methods used to identify over-expression of the HER-2/neu protein. Technical inconsistencies in the detection of HER-2/neu protein by ►immunohistochemistry have included both the differing sensitivities and specificities of the commercially manufactured anti-HER-2/neu antibodies and the several antigen retrieval techniques used in formalin-fixed paraffin embedded tissues. Also, the lack of a standardized interpretation protocol results in significant inter-observer variability. Notably, fluorescence in situ hybridization technique (►FISH) evaluations have consistently demonstrated a relationship between HER-2/neu gene amplification and breast cancer recurrence and disease-related death in both lymph node-negative and -positive cases (Figs. 1 and 2)

►ELISA-based measurements of HER-2/neu protein in breast cancer cytosols also correlate with disease outcome. Serum-based HER-2/neu evaluation can also be accomplished using the ELISA method, although consensus as to the clinical utility of this technique has not been achieved. Southern- and slot-blotting methods are less effective since the DNA of tumor cells extracted from the primary carcinoma sample are diluted by DNAs from benign breast tissue and inflammatory cells. More recent studies support an association between HER-2/neu gene amplification or protein over-expression with poor clinical outcome in gastrointestinal, pulmonary and genitourinary neoplasms.

Clinical efficacy of the drug, ►trastuzumab (Herceptin™), has stimulated significant expansion of HER-2/neu testing in the management of breast cancer. Tratsuzumab is a humanized monoclonal antibody administered intravenously that is particularly effective when combined with cytotoxic agents (either ►taxotere or ►Adriamycin plus Cytoxan). A 27% response rate with these treatment approaches has been described for patients with advanced metastatic breast cancer refractory to conventional treatment. In 1998, the US FDA approved the use of ►tyratsuzumab for the treatment of metastatic HER-2/neu positive breast cancer (IHC 2+ or 3+). In 2006, the US FDA also approved trastuzumab in combination with cytotoxic chemotherapy for the adjuvant treatment of lymph node positive primary breast cancer. On going clinical trials of trasuzumab plus cytotoxic therapy have, to date, failed to achieve significant results for patients with prostate, lung, ovarian and pancreatic cancers. The various products available for HER-2/neu testing are shown in the Table 1.

In addition to its role in predicting prognosis and response to trastuzumab therapy, HER-2/neu testing in breast cancer has also been used to select other treatment options including the use of the dual kinase oral HER1/HER2 inhibitor, ►lapatinib. Although the ability of HER-2/neu status to predict response to anti-estrogen therapy has not achieved consensus, the enhanced response of HER-2/neu positive tumors to chemotherapy regimens containing anthracyclines is generally well-accepted in clinical oncology practice. However, cardiotoxicity is the major side-effect of trastuzumab and this has limited the use of trastuzumab in combination with anthracylines especially in the metastatic disease setting.

Definition

Herceptin is a recombinant humanized monoclonal antibody that selectively binds with high affinity to an extracellular domain of the HER-2 receptor ►tyrosine kinase, and is approved by the United States Food and Drug Administration for therapeutic use in patients with early-stage and metastatic breast cancers that overexpress the HER-2 protein.

Characteristics

Approximately 20–30% of human breast cancers overexpress the ►HER-2/neu receptor tyrosine ►kinase protein. These cancers are extremely aggressive with an increased tendency to ►metastasize, decreased time to disease progression, and reduced overall survival. In 1998, the United States Food and Drug Administration approved Herceptin, a monoclonal antibody targeted against an extracellular portion of HER-2, for clinical use in metastatic breast cancers that show ►amplification of the *her-2* oncogene and overexpress the HER-2 protein. Recent studies also demonstrated that Herceptin-based treatment prevents recurrence of approximately half of all early-stage localized breast cancers that overexpress HER-2.

Clinical Activity

As a single agent Herceptin has a response rate of 12–34% in metastatic breast cancer, depending on the method used for assessing HER-2 status in the cancer cells and the number of prior therapies. These rates are significantly improved to about 60% when combined with chemotherapeutic agents of the ►taxane class. The duration of response is one year or less, indicating that resistance develops rapidly. The main side effect associated with Herceptin-based therapy is ►cardiotoxicity.

In the ►adjuvant setting, Herceptin shows significant benefit in early stage HER-2-overexpressing breast cancer. Randomized phase III clinical trials showed that addition of Herceptin to postoperative chemotherapy (either in sequence or in combination) reduces the risk of recurrence by half. However, ~15% of women still develop metastatic disease despite receiving Herceptin-based adjuvant therapy.

Mechanisms of Activity

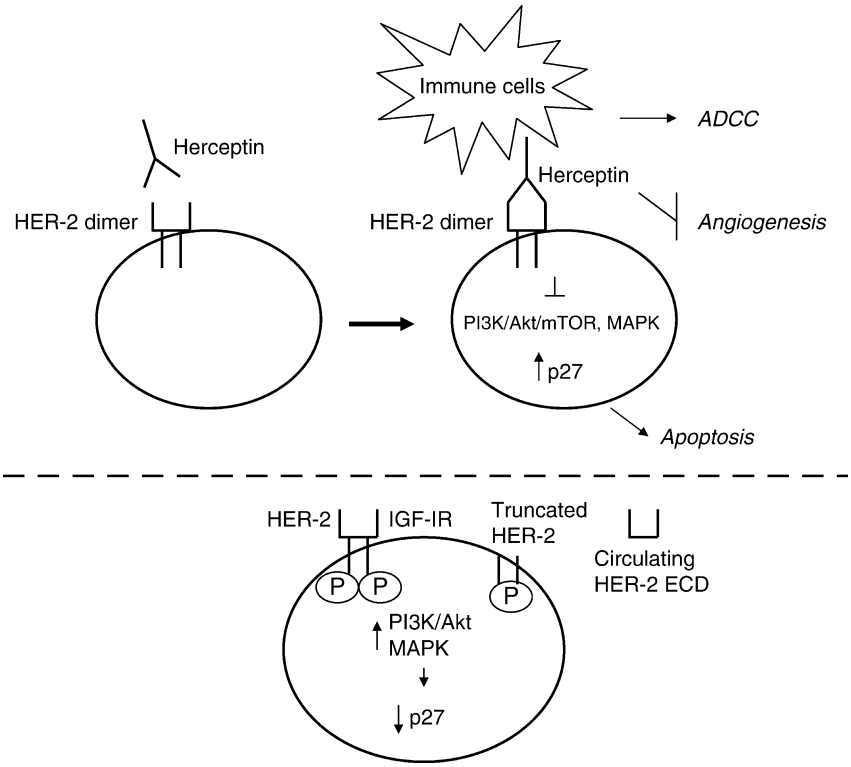
Molecular Level

Herceptin physically binds to the HER-2 receptor, and inhibits downstream signaling through the ►phosphatidylinositol-3-kinase (PI3K) and ►mitogen-activated protein kinase (MAPK) pathways (Fig. 1). This induces expression of the ►cyclin-dependent kinase (cdk) inhibitor p27kip1 and increases association of p27kip1 with cdk2, promoting G0/G1 cell cycle arrest and blocking cellular proliferation. In addition, Herceptin disrupts association between HER-2 and the non-receptor tyrosine kinase ►Src, thus, reducing Src activity such that the ►phosphatase PTEN is dephosphorylated and translocated to the plasma membrane where it is activated. Signaling from the PI3K downstream effectors ►Akt and ►mTOR are then inhibited, resulting in reduced proliferation and enhanced ►apoptosis.

Cellular Level

In vivo studies show that Herceptin activates an immune process called ►antibody-dependent cellular cytotoxicity (ADCC), which results in the lysis of cells to which Herceptin is bound. Mice deficient for immune cells mediating this process are less responsive to Herceptin, and patients treated with Herceptin show a higher infiltration of ►leukocytes and ADCC activity.

In addition, cellular survival is abrogated by Herceptin due to inhibition of ►angiogenesis, which is achieved by both reduced expression of pro-angiogenic



Herceptin. Figure 1 Herceptin: Mechanisms of Action. (Upper portion) Herceptin binds to the extracellular domain of the HER-2 protein, which is in a homodimer or heterodimer with another receptor. Upon binding, several molecular mechanisms become activated. Immune cells recognize the antibody-bound cells and initiate a process called antibody-dependent cellular cytotoxicity (ADCC), which results in lysis of the cells to which Herceptin is bound. Herceptin also decreases expression of factors that induce formation of blood vessels, a process called angiogenesis, and increases expression of anti-angiogenic factors. In addition, signaling from the downstream pathways including PI3K/Akt/mTOR and MAPK is inhibited leading to a block in proliferation and increased cell death, or apoptosis. (Bottom portion) Resistance to Herceptin is an important clinical problem. Preclinical studies show a unique interaction between HER-2 and the insulin-like growth factor-I receptor (IGF-IR) in resistant cells with cross talk occurring from IGF-IR to HER-2 resulting in heightened signaling and reduced p27kip1 levels. Other studies have shown increased Akt signaling due to other unknown mechanisms, which may include loss of the Akt negative regulator PTEN phosphatase. Truncated forms of HER-2 have also been discovered such that the cytoplasmic and transmembrane domains remain bound to the cell membrane with constitutive kinase activity, and the extracellular domain (ECD) is released and can be detected circulating in serum.

growth factors and increased expression of anti-angiogenic factors, resulting in decreased ►endothelial cell migration and formation. Combination of Herceptin with chemotherapeutic agents may actually rely upon this ability of Herceptin to block angiogenesis, as tumor vasculature and circulation of anti-neoplastic therapies may become normalized.

Mechanisms of Resistance

The majority of metastatic breast cancer patients who initially respond to Herceptin begin to demonstrate disease progression again within one year. Even in the adjuvant setting, where trastuzumab improves survival rates in patients with early-stage breast cancer, ~15% of patients eventually develop metastatic disease. Preclinical studies have provided some information regarding potential molecular mechanisms contributing to trastuzumab resistance, although further work is required to achieve an improved response rate in the HER-2-overexpressing population, and to identify novel agents that will benefit patients whose cancers are refractory to trastuzumab.

Insulin-like Growth Factor-I Signaling

Increased signaling from the ►insulin-like growth factor-I (IGF-I) receptor (IGF-IR) is associated with Herceptin resistance. Increased signaling may occur through two different mechanisms. Overexpression of

total IGF-IR levels resulted in resistance in two cell culture models. In addition, a unique physical interaction between IGF-IR and HER-2 resulting in increased IGF-IR signaling and receptor ►cross talk to HER-2 was observed in a separate model of Herceptin resistance developed subsequent to chronic drug exposure. Herceptin sensitivity was restored in this model when IGF-IR was inhibited. Further in vivo studies will determine whether this mechanism of resistance translates to patients and whether in fact IGF-I signaling is an appropriate target for drug development in Herceptin-resistant cancers.

Akt Signaling

Activation of the HER-2 tyrosine kinase secondary to protein overexpression results in increased signaling from the PI3K/Akt/mTOR pathway. Constitutive PI3K/Akt/mTOR signaling is observed in some Herceptin-resistant cells, perhaps due to deficient expression of the Akt negative regulator, the PTEN phosphatase. Although the mechanism by which Akt signaling may be heightened in Herceptin-resistant cancers remains unclear, this pathway is being developed as a putative novel target in this patient population.

Extracellular Domain and Truncated Forms of HER-2

The full-length HER-2 protein is cleaved into two fragments in some cancer cells, a 95 kDa truncated receptor that remains bound to the membrane with constitutive kinase activity, and a 110 kDa fragment consisting of the ►extracellular domain (ECD), which can be found circulating in cell culture media or in patient sera. Herceptin may bind the ECD, decreasing interaction between intact membrane HER-2 receptors and Herceptin, and thus reducing response. In addition, the truncated 95 kDa receptor lacks the ECD and thus cannot bind Herceptin. Hence, in cases where circulating HER-2 ECD levels are elevated, resistance to Herceptin may develop. A decline in ECD levels after exposure to Herceptin has in fact been correlated with response to treatment, suggesting that changes in ECD levels over time may serve as a biological predictor for response to Herceptin.

The mechanism by which the full length receptor becomes cleaved in some cases and not in others is unknown. Cleavage may occur due to the activity of ►matrix metalloproteinases (MMPs), as MMP inhibitors prevent ECD shedding. Alternatively, or in addition, recent evidence suggests that truncated forms of HER-2 may be a result of alternative initiation of translation using different start codons in the *her-2* gene. Understanding the mechanism of cleavage and the value of circulating ECD in predicting Herceptin response is an important focus of ongoing clinical investigation.

New Directions

The use of Herceptin has now expanded into the adjuvant setting to significantly benefit patients with early-stage, localized HER-2-overexpressing breast cancer. In the metastatic setting, Herceptin is being tested in combination with various other targeted agents to improve response rates and duration and limit cytotoxic effects. Lapatinib, a dual inhibitor of both the ►epidermal growth factor receptor (EGFR) and HER-2 tyrosine kinases, is being tested in patients whose breast cancer has progressed on trastuzumab, and appears to be a promising agent in this setting and in trastuzumab-naive patients. In addition, studies are examining the efficacy of targeting the IGF-I and Akt/mTOR signaling pathways in patients whose cancers are refractory to trastuzumab. Identification of novel therapeutic targets will guide the development of more effective treatments and trastuzumab-based combinations for the HER-2-overexpressing population of breast cancer patients.

Synonyms

HAUSP de-ubiquitinase

Definition

The cysteine protease ►de-ubiquitinase (DUB) Herpesvirus-Associated Ubiquitin-Specific Protease (HAUSP) has been fairly well characterized in recent years and has emerged as an important component of the ►p53-►Mdm2 signaling pathway.

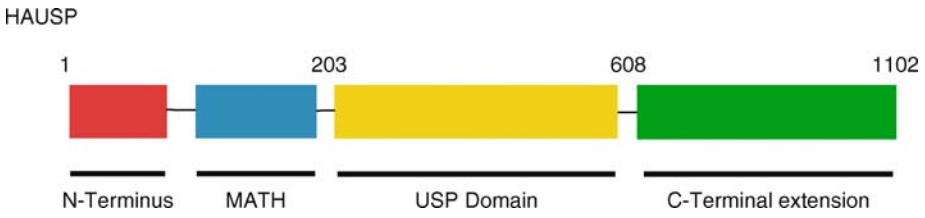
Characteristics

De-ubiquitinases are specific protease enzymes that catalyze the removal of ubiquitin from substrates by cleaving the isopeptide bond between ubiquitin and substrate. The de-ubiquitination enzyme family (DUBs) fall within two classes of proteases: the metalloproteases and cysteine proteases, though most DUBs fall within the latter. Further classification subdivides the cysteine proteases into four sub-classes: ubiquitin C-terminal hydrolases (►UCH), ubiquitin-specific proteases (►USP), ►Machado-Joseph disease proteases (MJD), and Otubain proteases (OTU). The MJD and OTU subclasses were more recently identified through a bioinformatics approach. The UCH human subclass consists of four proteins that are thought to function mainly for the recycling of ubiquitin or for the processing of newly synthesized ubiquitin that forms as either a polyubiquitin chain precursor or fused to ribosome precursors. The largest and best characterized sub-category is by far the USP family, with proteins having diverse cellular functions from oncogenesis to transcriptional regulation. USPs contain a well conserved catalytic site consisting of a Cysteine-Histidine motif that is critical for its enzymatic activity. However, aside from this core region, USPs are quite diverse in both their size and additional domains, a point that may be important for their range of functions and substrate specificities.

One particular cysteine protease DUB, the Herpesvirus-Associated Ubiquitin-Specific Protease (HAUSP), has been fairly well characterized in recent years and has emerged as an important component of the p53-Mdm2 signaling pathway. HAUSP was first identified as a 135 kD cellular factor that associated with the Herpesvirus regulatory protein Vmw110. It contains 1,102 amino acids and can be loosely divided into three functional domains: an N-terminal domain consisting of a meprin and TRAF homology motif (MATH), the core cysteine-histidine catalytic domain, and a C-terminal region (Fig. 1). HAUSP functions as a specific de-ubiquitinase for several substrates by removing ubiquitin monomers from them causing diverse functional consequences. De-ubiquitination of the mammalian proteins p53, Mdm2, and MdmX causes ►protein stabilization and significant effects to the p53-Mdm2 signaling pathway as detailed below. HAUSP-mediated de-ubiquitination of the transcription factor FOXO4 causes transcriptional repression in response to oxidative stress. HAUSP also has direct interactions with several viral proteins including the herpesvirus (HSV-1) ICP0 and Epstein-Barr Virus (EBV) EBNA1. In the case of the HSV-1 protein ICP0, a shared reciprocation occurs with HAUSP where ICP0 can also ubiquitinate HAUSP. However, the most well characterized functions of HAUSP to date are within the p53-Mdm2 pathway and indicate the growing complexity of the physiologic functions of HAUSP.

p53-Mdm2 Pathway

Regulation of the p53-Mdm2 pathway is of utmost importance for the development, formation, and progression of tumors. The tumor suppressive properties of the sequence-specific transcription factor p53 is underscored by the fact that it is frequently mutated in over 50% of all human tumors. The ability of p53 to quickly respond to cellular stress such as DNA



Herpesvirus-Associated Ubiquitin-Specific Protease De-ubiquitinase. Figure 1 Schematic representation of the HAUSP protein structure. HAUSP can be sub-divided into three main functional domains: the N-Terminus, which includes the meprin and TRAF-like homology motif (MATH), the core Cysteine-Histidine catalytic motif, and the C-terminal region.

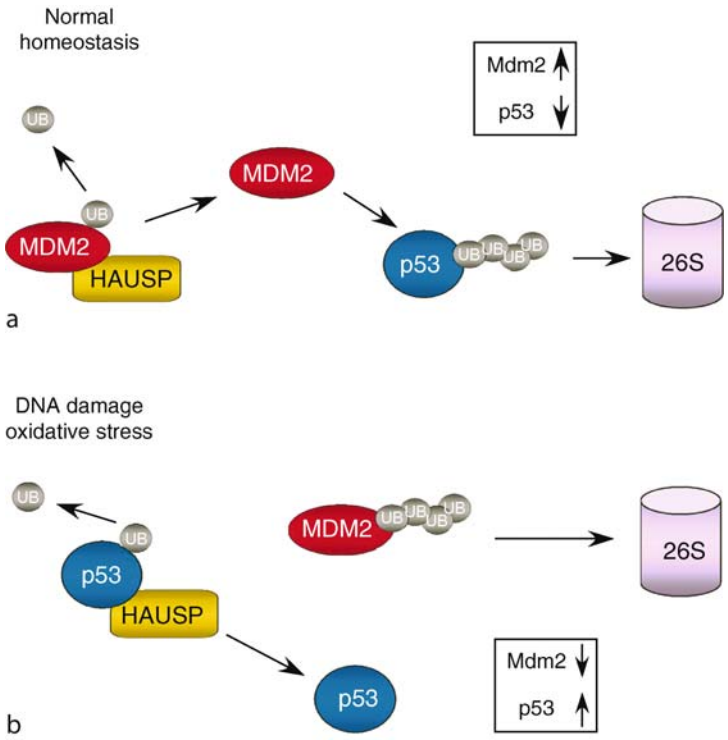
damage, oxidative stress, and aberrant ►oncogene expression occurs in part due to the multitude of mechanisms that exist to quickly stabilize and activate p53 to a level sufficient for it to activate genes involved in cell growth arrest and apoptosis. Without this pathway, the cell loses the tumor suppressive "brake" and increases the probability that cell growth will occur in an unregulated and chaotic fashion. p53 regulation is therefore a critical step in cellular homeostasis. The predominant negative regulator of p53 is the ►E3 ubiquitin ligase, ►Mdm2. This E3 ligase specifically ubiquitinates p53 and promotes ►proteasome-mediated degradation through the catalysis of ubiquitin chains on the substrate via isopeptide linkages. Mdm2 therefore ensures the correct spatial and temporal induction of p53 protein levels to prevent expression of this potent transcription factor when it is not needed. p53 and Mdm2 also exist in a negative feedback loop with each other, whereby p53 acts as a specific transcription factor for the *mdm2* gene and promotes its induction. When p53 is activated and protein levels are high, Mdm2 is induced, which in turn drives the reduction of p53. The balance of protein levels for p53 and Mdm2 is therefore a critical step in maintaining proper p53 expression and function.

HAUSP was first shown to function within this pathway when it was discovered that it could specifically interact with p53. HAUSP acts as a specific de-ubiquitinase for p53 in a dose-dependent manner by removing ubiquitin moieties and stabilizing the protein. It can also antagonize Mdm2-mediated ►ubiquitination of p53 and rescue the protein from degradation. Ubiquitination of p53 by Mdm2 and the subsequent degradation by the 26S proteosome is a critical regulatory mechanism for maintaining p53 at low protein levels during times of cellular homeostasis. By antagonizing this function, however, HAUSP serves as an important positive regulator of p53 and may be important for its function during times of cellular stress. Having a way for reversing protein degradation provides the cell with a mechanism for quick stabilization of p53 when needed. HAUSP provides this mechanism by blocking the degradation of p53 and allowing the protein to quickly accumulate.

In addition to p53, HAUSP can also de-ubiquitinate and stabilize Mdm2 protein. Mdm2 has inherent auto-ubiquitination capability, and as such ubiquitinates itself creating an unstable protein with a half-life of approximately 30 min. HAUSP can specifically de-ubiquitinate Mdm2 and block the self-ubiquitination. This stabilization effect in turn leads to more Mdm2 that is able to ubiquitinate and degrade p53, a finding that is contrary to the direct effects HAUSP has on p53. The mechanism underlying these seemingly different results seems to depend on the levels of HAUSP protein and suggests that HAUSP interacts with both proteins in a selective or guided manner. Complete ablation of the HAUSP gene using a somatic knockout approach in the colorectal cancer cell line HCT116 has a profound stabilizing effect on p53 and destabilizing effect on Mdm2. However, when the gene product is reduced marginally by transient siRNA in several different cell types, p53 reduction is also seen. The ability of HAUSP to de-ubiquitinate both proteins suggests an intrinsic "switch," whereby HAUSP is selectively triggered to de-ubiquitinate one substrate or the other. A provocative possibility is that HAUSP is DNA damage responsive and may switch substrate specificity upon receiving various stress signals. It has been shown that treatment with the ►radiomimetic drug ►neocarzinostatin (NCS) blocks the interaction between HAUSP and Mdm2. In addition, crystal structures have shown that the Mdm2-HAUSP complex has a higher binding affinity and makes more extensive interactions than the p53-HAUSP complex. The data to-date suggest a provocative model where HAUSP provides an important and delicate balance of proteins within the p53-Mdm2 pathway (Fig. 2). Under normal, unstressed conditions, the preferential interaction is the HAUSP-Mdm2 complex, where HAUSP can maintain sufficient levels of Mdm2 protein to keep p53 ubiquitinated and degraded. However, during times of cellular stress, the interaction between HAUSP and Mdm2 is blocked, possibly due to post-translational modification such as phosphorylation. The release of the HAUSP-Mdm2 complex creates a pool of free HAUSP monomers that can then interact with p53 to de-ubiquitinate and stabilize the protein. Free Mdm2 protein is then subject to auto-ubiquitination and degradation. The negative feedback loop of these 2 proteins will then drive higher Mdm2 expression and the subsequent downregulation of p53 when sufficient time has allowed for the cell to either repair the DNA damage or initiate an apoptotic response. The oscillating responses of p53 and Mdm2 protein levels together with the instability of these proteins through the ubiquitin-proteosome pathway indicate the important need of HAUSP in balancing these proteins for appropriate p53 responses to quickly occur.

Implications in Cancer Therapy

The reasoning for intense study of the p53-Mdm2 pathway and proteins that have functional impact on the pathway is clear when considering the large ►chemotherapy potential it could have for various cancer treatments. The p53 gene is frequently mutated in over 50% of all human tumors, and in addition, a subset of tumors retains a functional p53 gene and requires these tumor cells to circumvent this pathway. These tumors are prime candidates for chemotherapeutics that would induce p53 expression and subject the cells to an abundance of stabilized and activated p53 protein. Drug



Herpesvirus-Associated Ubiquitin-Specific Protease De-ubiquitinase. Figure 2 Model for the function of HAUSP in the p53-Mdm2 pathway. HAUSP preferentially interacts with Mdm2 during times of cellular homeostasis, which stabilizes Mdm2 through deubiquitination and results in Mdm2-mediated ubiquitination and degradation of p53. During times of cellular stress when p53 is needed, the HAUSP-Mdm2 interaction in blocked, resulting in Mdm2 destabilization and subsequent p53 stabilization through the direct interaction with HAUSP.

design has focused on blocking the interaction between p53 and its predominant negative regulator Mdm2 as a mechanism for stabilizing the protein. Indeed, moderate success has been seen with a small molecule inhibitor of Mdm2, Nutlin 3A, in a variety of cancer cell lines. Treatment with this drug significantly blocks the p53-Mdm2 interaction and yields a robust p53 response by stabilizing the protein. Still, other approaches of drug design in this pathway may need to be considered for two reasons. First, E3 RING ubiquitin ligases are not classical enzymes in that they only mediate the transfer of activated ubiquitin from an ►E2-conjugating enzyme to the substrate. Classical targeting of enzymes with small molecule inhibitors generally requires the presence of specific amino acids within the catalytic site of the protein that use energy for a defined enzymatic cascade. The ►RING domain of E3 ubiquitin ligases only mediates the transfer of ubiquitin and as such provides a poor target for drug inhibition. Second, the mechanism of action for Nutlin 3A is to block the protein-protein interaction of p53 and Mdm2. However, the precise binding site for p53 on Mdm2 is ill defined and it remains possible that the proteins are capable of making more than one interaction. This would require an inhibitor that could block multiple binding sites to efficiently and effectively inhibit the p53-Mdm2 interaction. An alternative approach of drug design for stabilizing and activating p53 in this setting would be to target the inactivation of HAUSP. It is clear that removing HAUSP completely causes a profound stabilization and activation of p53 protein. HAUSP also has a classic enzymatic motif that can be targeted for inhibition by small molecule inhibitors. An inhibitor of HAUSP would only have to target its specific de-ubiquitinase activity and not the protein-protein interactions occurring between p53-HAUSP and p53-Mdm2. Inhibition of its activity would create an environment where Mdm2 was severely unstable allowing for the accumulation and activation of p53.

The de-ubiquitinase HAUSP has emerged as an important regulator of the p53-Mdm2 signaling pathway. The process of de-ubiquitination has global consequences within the cell and the ability to reverse the ubiquitin-proteosome pathway has important implications for the quick regulation of protein levels. Further studies of HAUSP will elucidate regulatory mechanisms for the protein itself as well as develop further understanding of how it selectively chooses particular substrates.

Hexavalent Chromium

John Pierce Wise, Sr.
Department of Applied Medical Sciences, Maine Center for Toxicology and Environmental Health, University of Southern Maine, Portland, ME, USA

Synonyms

Chromate; Cr(VI); Chromium(VI); Cr^{6+}

Definition

Chromium is a metallic element with oxidation states ranging from +2 to +6. Hexavalent chromium rarely occurs naturally, but is produced from anthropogenic sources. Chromium in the hexavalent state occurs naturally only in the rare mineral crocoite ($PbCrO_4$).

Characteristics

Numerous regulatory agencies worldwide have concluded that all ►hexavalent chromium compounds should be considered carcinogenic among exposed populations although strong evidence has been presented that water-insoluble (also known as particulate) hexavalent chromium compounds are the more potent carcinogens.

Uses and Sources

The metallurgical, refractory and chemical industries are the major users and producers of hexavalent chromium. The compounds are used for chrome plating, the manufacture of dyes and pigments, leather tanning and wood preserving. Smaller amounts are used in rust and corrosion inhibitors, drilling muds, textiles and toner for copying machines. Hexavalent chromium compounds are brightly colored particularly with reds, yellows and oranges and are commonly seen in paints, dyes and inks of those colors.

Hexavalent chromium enters the environment mostly through human activities, particularly as chemical industry waste. It is emitted as mists and particulate matter during manufacture and use of metal chromates. Waste streams from electroplating, leather tanning and textile industries as well as those that make dyes and pigments can discharge hexavalent chromium into waters. The levels of hexavalent chromium in soil come mainly from disposal of commercial products containing chromium, chromium waste from industry and coal ash from electric utilities.

Epidemiology

Hexavalent chromium was first associated with human ►cancer more than one hundred years ago (in 1890) when a case report described an adenocarcinoma in the nasal turbinate bone of a Scottish chrome pigment worker. Since that report, numerous studies of the ►epidemiology of cancer showed that occupational exposure to hexavalent chromium can cause an 18–80 fold increased risk of cancer of the respiratory system, particularly bronchogenic and nasal cancers. These reports were primarily retrospective mortality studies of workers in factories involved in chromate production, chrome pigment production and chrome plating from countries around the world including the United States, United Kingdom, Germany, Norway and Japan. Further epidemiological work has considered other industries such as stainless steel welding, ferrochromium alloy production and leather tanning, but the results have been inconclusive due in part to mixed exposures. Tumors in organs other than the respiratory system have not generally been reported though sporadic reports have been made of stomach and immune-related cancers. This lack of evidence has led to the conclusion that hexavalent chromium is only carcinogenic at sites of contact, but few studies have focused on tumors at other sites and so such a conclusion may be premature.

Human pathology studies support the hypothesis that the water insoluble hexavalent chromium compounds are the more carcinogenic species. Specifically, they show that hexavalent chromium accumulates and persists at bifurcations in the bronchiole tubes where models show that insoluble particles impact and deposit (soluble compounds would likely dissolve in the mucosal lining and be distributed throughout the lung). Hexavalent chromium-induced tumors occur at these bronchial bifurcation sites.

Animal Studies

Animal studies have supported the findings of epidemiology studies and show that hexavalent chromium compounds are carcinogenic in animal assays producing the following tumor types: intramuscular injection site tumors in rats and mice and intrapleural and intrabronchial implantation site tumors in rats. Only hexavalent chromium compounds were found to be carcinogenic in animal studies. Trivalent chromium compounds were not carcinogenic in animals, and so it has been concluded that only hexavalent chromium should be classified as a human carcinogen. In addition, in general only the particulate hexavalent chromium compounds induced tumors in experimental animals.

Animal studies also show that hexavalent chromium compounds are genotoxic (i.e. damage DNA). Specifically, these studies show that hexavalent chromium compounds induce chromosomal aberrations, sister chromatid exchanges (SCEs), mutations, DNA strand breaks and DNA-protein crosslinks.

Cell Culture Studies

Cell culture studies also support the conclusion that hexavalent chromium compounds are carcinogenic. These studies show that hexavalent chromium compounds can transform normal cells into tumor forming cells (i.e. induce neoplastic transformation), though again this effect was specific to the water insoluble compounds, and both water insoluble and soluble compounds can change the morphology of cells. Extensive cell culture work also shows that hexavalent chromium compounds are highly genotoxic inducing DNA damage in cells from numerous species. The

damage includes a variety of DNA lesions including ►aneuploidy, chromosomal aberrations, ►centrosome amplification, SCEs, DNA double strand breaks, mutations, DNA single strand breaks, ►adducts to DNA, DNA-protein cross-links and DNA-DNA cross-links.

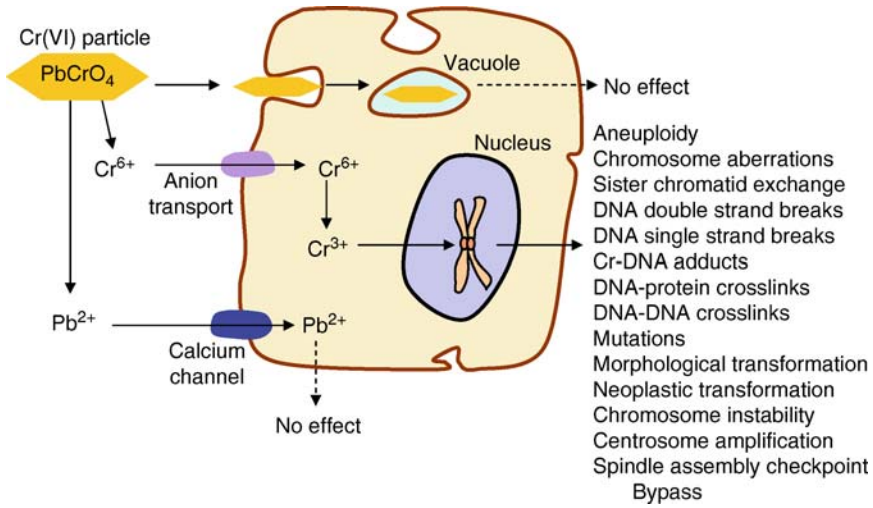
Role of Valence State, Uptake and Metabolism

Hexavalent chromium compounds are carcinogenic and trivalent chromium compounds are not considered to be carcinogenic. The explanation for this difference is related to their modes of uptake. Hexavalent chromium compounds are rapidly and well-absorbed by cells though a facilitated diffusion process involving an anion transport protein. By contrast, trivalent chromium compounds are slowly and poorly absorbed by simple diffusion. This diffusion is further slowed and reduced because trivalent chromium binds to many molecules in the extracellular environment.

Once inside the cell, it is clear that hexavalent chromium itself does not cause damage directly. Instead, it is almost immediately reduced inside the cell to trivalent chromium. *In vitro* studies using naked DNA show that hexavalent chromium cannot bind to or damage DNA itself, but that adding a reducing system does induce breaks and chromium binding to DNA. These studies also show that trivalent chromium can damage and bind to DNA. The reduction of hexavalent chromium to trivalent chromium involves a number of intermediate species. These include pentavalent chromium, tetravalent chromium and reactive oxygen species. *In vitro* studies show that each of these species can interact with and damage DNA. Thus, one or some combination of these species is the ultimate carcinogen. It is still unclear which species are the most important as methods to detect them within biological systems are limited by sensitivity and specificity. Current technology (e.g. electron paramagnetic resonance or spin trapping) can only detect these species at very high doses and data do suggest that the metabolism of hexavalent chromium may be different at lower concentrations. Moreover, pentavalent chromium is generally active in assays that measure reactive oxygen species (e.g. dye activation methods), and thus, one cannot distinguish between the various species in cells.

Role of Solubility

Epidemiological, whole animal and cell culture studies indicate that water solubility plays a key role in ►carcinogenesis caused by hexavalent chromium with water-insoluble compounds the most potent form as discussed above. The potency of the particulate form appears to be related to its ability to impact at bronchial bifurcation sites and continually dissolve over time releasing hexavalent chromium ions that can be taken into cells. Hexavalent chromium particles can clearly enter cells but do not seem to have an effect and the particles do not dissolve inside the cell. Instead, the water-insoluble particles partially dissolve in the extracellular environment. This dissolution releases both a hexavalent chromium anion and a cation (e.g. lead, barium, zinc etc.). The cations do enter cells, but again do not appear to reach high enough levels to induce biological effects. Instead, at this time, all of the toxicological effects of the water-insoluble compounds seem to result from the transport of hexavalent chromium into the cell and its subsequent reduction to trivalent chromium. This mechanism is illustrated in Fig. 1. Future research may reveal a



Hexavalent Chromium. Figure 1 Mechanistic model of particulate hexavalent chromium genotoxicity. This figure is a schematic diagram showing the hypothesized mechanism for particulate chromate carcinogenicity.

yet undiscovered effect of the internalized particles or cation.

Mechanism of Carcinogenicity

The mechanism of carcinogenicity is uncertain and poorly understood with several potential steps emerging. Lung cancers are characterized by aneuploidy (an abnormal number of chromosomes), particularly with a triploid or tetraploid chromosome complement. Recent data indicate that chronic exposures to the water-insoluble hexavalent chromium compounds induce this type of aneuploidy that is caused by centrosome amplification and bypass of the spindle assembly checkpoint. The centrosome amplification and spindle assembly checkpoint bypass may result from hexavalent chromium-induced DNA double strand breaks leading to a prolonged G2/M phase cell cycle arrest or alternatively direct effects on genes involved in centrosome duplication and the spindle assembly checkpoint or both.

A second mechanism is that chromium can bind to both DNA bases and the phosphodiester backbone potentially through coordinate covalent binding or electrostatic/ionic interactions or induce oxidative damage to the bases. These lesions may then result in base substitution mutations, which if unrepaired could lead to carcinogenesis if these mutations occur in key genes such as proto-oncogene or tumor suppressor genes.

A third mechanism involves hexavalent chromium-induced DNA double strand breaks. These breaks may be caused directly by either pentavalent chromium or reactive oxygen species produced by the intracellular reduction of hexavalent chromium or be caused indirectly by chromium-induced adducts to DNA or crosslinks resulting in collapse of replication forks. These double strand breaks then may lead to chromosome aberrations, and chromosome instability described above or may indirectly cause mutations through their repair.

Synonyms

Histone H2AX phosphorylated at serine 139

Definition

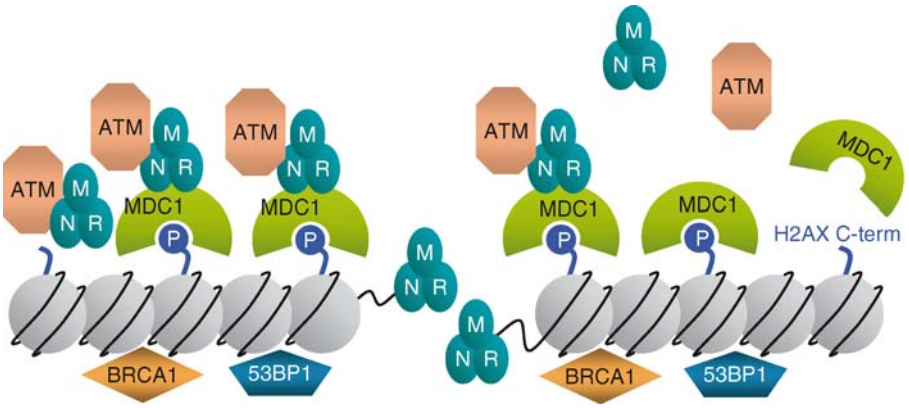
H2AX is one of the histone proteins that is systematically found and ubiquitously distributed throughout the genome. DNA double-strand breaks (DSBs) induce rapid phosphorylation of H2AX (142 amino acids) at serine 139, a highly conserved serine residue located in the C-terminus.

Characteristics

In eukaryotes, DNA is highly condensed and packaged into chromatin within the nuclei. This condensed chromatin forms a structural barrier for DNA processing during ►DNA repair, replication, transcription, and recombination. A fundamental subunit of the chromosome is the nucleosome, which is composed of 146 bp of DNA wrapped in two complete turns around an octamer of the core histones H2A, H2B, H3, and H4, and there are varying lengths of linker DNA connecting these subunits. The core histone octamer forms a 100-kDa protein complex. Histone H2A has been conserved throughout eukaryotic evolution. There are three H2A subfamilies: H2A1-H2A2, H2AZ, and H2AX. Histone variants are non-allelic isoforms that replace major histones within the nucleosome. In a normal human fibroblast, H2AX usually composes about 10% of the H2A histone complement, and the cell contains about 6 × 10^6 molecules of H2AX per cell. H2AX is ubiquitously distributed and expressed throughout the genome. H2AX contains a C-terminal region longer than those seen in the bulk H2A species. The phosphorylated form of histone H2AX, *i.e.* γH2AX, which is phosphorylated at serine 139 within the conserved C-terminal region, has attracted considerable attention. The detection of γH2AX has been estimated by Western blotting, flow cytometry, and imunocytochemistry. Various physical, chemical, and biological factors induced the phosphorylation of H2AX.

Mechanisms

The γH2AX is detectable within 3 min after ionizing radiation (IR), and the amount of γH2AX increases until a plateau is reached 10–30 min after IR. A proposed model could explain how H2AX phosphorylation is regulated and how various DNA repair proteins are recruited to γH2AX-containing chromatin. First, unrepaired DSBs are recognized directly by various proteins, including the MRE11 (meiotic recombination 11)/RAD50/NBS1 (►Nijmegen breakage syndrome 1; NBN; nibrin) (MRN) complex (Fig. 1). The MRN complex then recruits ►ATM (ataxia telangiectasia mutated) to the free DNA ends by mechanisms that include a direct interaction between ATM and the NBS1 C-terminus. ATM thus becomes activated and phosphorylates various target proteins at the site of the DNA damage, including H2AX molecules that are located proximal to the lesion. Next, MDC1 (mediator of DNA damage checkpoint 1) recognizes the phosphorylated H2AX proximal to the lesion *via* its tandem BRCT domain, and in so doing helps to counter γH2AX dephosphorylation by PP2A (protein phosphatase 2A) and possibly by other phosphatases. Concomitantly, MDC1 acts as a mediator/adaptor protein, thus providing a "landing-platform" for more molecules of the MRN complex to bind. Interactions between ATM and MRN and/or between ATM and MDC1 could then bring about the recruitment of further activated ATM molecules to the chromatin regions flanking the lesion: DNA-PKcs (DNA-dependent protein kinase catalytic subunit) and its interaction partner Ku (Ku70 and Ku80) might also be recruited by analogous mechanisms. This further PIKK (phosphatidylinositol 3-kinase-related protein kinase) recruitment then in turn leads to the phosphorylation of additional H2AX molecules that are located more distal to the initiating lesion. A positive feedback loop thus emerges, "fuelled" by MDC1 and its ability to associate with γH2AX; concomitantly protecting γH2AX from dephosphorylation and mediating the recruitment of the MRN complex, active ATM and associated proteins to the chromatin flanking the DNA lesion. As a consequence, γH2AX "spreads" further and further away from the initial break, and a visible γH2AX "focus" starts to form in the nucleus. Thus, many



γH2AX. Figure 1 H2AX phosphorylation.

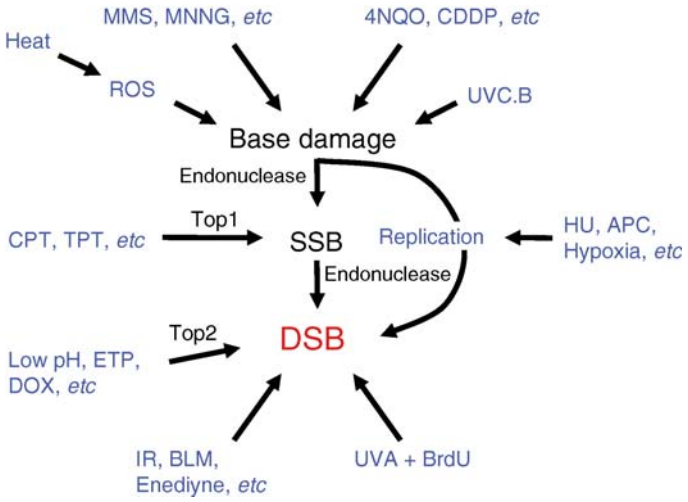
components of the DNA damage response, including ATM, ►BRCA1 (breast cancer 1), 53BP1 (►p53 binding protein 1), MDC1, RAD51, and the MRN complex, form IR-induced foci that co-localize with γH2AX foci. These nuclear micro-domains are thought to contain hundreds to thousands of molecules that accumulate in the vicinity of a DSB.

Among the variety of possible DNA-damage events, DSBs are the most lethal events. Previously, DSBs in cellular DNA have been quantified by pulse-field gel electrophoresis (PFGE) assays, neutral single cell gel electrophoresis (the comet assay), and the DNA elution assay. Since these methods all indicated that the efficiency of DSB detection was very low, the lower limit of DSB detection had been about 100 DSBs per cell nucleus. Because of the rapid induction and amplification of γH2AX, and the 1:1 correspondence between the number of γH2AX foci and the number of DSBs, γH2AX recognizing antibodies have become a gold standard to detect the presence of DSBs.

γH2AX foci were detected, not only after exposure to IR, a ultraviolet light (UV) A-laser microbeam in the presence of bromodeoxyuridine (BrdU) and heavy charged-particles, but also after exposure to classical DSB-inducing agents such as bleomycin (BLM), tirapazamine, etoposide (ETP) and doxorubicin (DOX) (Fig. 2). BLM and tirapazamine produce DSBs *via* production of free radicals. ETP and DOX are thought to induce DSBs by preventing Top2 (DNA topoisomerase II)-mediated DNA religation, because Top2 rewinds the superhelix by cutting DNA double strands and religating them. Low pH also induces the formation of γH2AX foci and DSBs by preventing Top2-mediated DNA relegation.

DNA lesions, other than DSBs, produced by mono-functional alkylating agents such as *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine (MNNG) and adozelesin, can also lead to γH2AX foci. The γH2AX foci induced by other alkylating agents such as methyl methanesulfonate (MMS) were depressed by DNA repair mechanisms containing Polβ (DNA polymerase β) activity. Since the majority of MMS-induced foci detected were present in PCNA (proliferating cell nuclear antigen) positive cells, these foci might be attributed to replication-mediated DSBs. DSBs are formed in response to single strand breaks (SSBs) being repaired *via* base ►excision repair (BER). This idea is supported by the fact that 4-nitro-quinoline-*N*-oxide (4NQO) and hydrogen peroxide, which produce primarily SSBs, can produce DSBs, and an increase in γH2AX foci is seen in response to this agent. The enediyne antibiotics calicheamicin γ1 and C-1027, which directly produce DSBs at a high frequency, efficiently induced H2AX phosphorylation. Exposure to DNA cross-linking agents such as cisplatin (CDDP) and actinomycin D also result in the production of phosphorylated H2AX. SSBs are induced by DNA cross-links *via* nucleotide excision repair (NER), and the induced SSBs can be converted to DSBs. CDDP induces DSBs and CDDP lethality is reduced by DSB repair mechanisms such as non-homologous end joining repair (NHEJ). Although actinomycin D action is usually considered to be unrelated to DNA damage and to cause an inhibition of RNA polymerase, actinomycin D has been shown to prevent the religation step of Top1 (DNA topoisomerase I) action. When an RNA polymerase molecule progresses through a transcription bubble, the generated topological stress must be released by the DNA nicking and closing activities of a Top1. The production of SSBs would be especially prevalent at transcriptionally active sites. When a replication fork collides with a covalently bound Top1 cleavage complex, the extension of the leading strand is terminated at the 5′-end of the template strand, which generates a DSB. Therefore, actinomycin D can induce the formation of γH2AX foci. Additional support for this idea is provided by the fact that the induction of γH2AX foci occurs only in S-phase cells with active replication fork progression after treatment with Top1 inhibitors such as camptothecin (CPT) and topotecan (TPT).

In response to replication stress induced by UVC, UVB, hydroxyurea (HU), aphidicolin (APC),



γH2AX. Figure 2 DSB formation.

adozelesin, MMS and hexavalent chromium (Cr(VI)), H2AX molecules are phosphorylated by ATR (ataxia telangiectasia and Rad3 related) and ATM through Top1 activities at multisteps. An alternative model suggests that the S phase-dependent DSBs could be generated from SSBs. The formation of DSBs induced by UVC, HU and APC was found by using PFGE and the alkaline comet assay.

DSBs are generated endogenously during regulated DNA transposition events in which H2AX has also been demonstrated to play a role. Such processes include meiotic recombination, V(D)J recombination, heavy chain class switching, apoptotic DNA fragmentation, senescence and dysfunctional telomeres. In addition, the background expression of γH2AX in S/G_2-phase cells could be a response to DSBs or stalled replication forks at damage sites introduced during normal DNA replication.

Hyperosmotic stress and heat stress have also been reported to induce the formation of γH2AX foci by PFGE and the comet assay. The number of existing DSBs is increased when DNA repair is inhibited under hyperosmotic conditions because transient DNA strand breaks are continuously created during transcription and replication, and then hyperosmotic stress induces ►apoptosis.

Heat stress induces ATM activation, and ATM is known to be activated by the presence of DSB lesions. Heat induces DSBs through a different pathway and not in the same manner as that seen in replication arrest in the presence of HU with ATR activation. The inhibition of base BER of base damage is induced by heat stress through the production of reactive oxygen species (ROS), and leads to an increase in the number of existing DSBs. Because DNA synthesis enzymes such as DNA Polβ are heat sensitive when compared with incision enzymes, theoretically providing a mechanism which could account for increased numbers of DNA breaks in heated cells. Therefore, there might be a mechanism to explain the possibility that heat indirectly induces nick formation through enzymatic repair processes. DSBs could then be generated when nicks form in close proximity to each other on opposite strands. The inhibition of ►poly(ADP)ribose polymerase, which is involved with BER and SSB repair, also induces γH2AX foci, providing support for the above hypothesis.

Although hypoxia did not induce apoptosis or any DNA damage detectable with the comet assay, phosphorylation of H2AX occurs with much slower kinetics in response to hypoxic stress. It is still necessary to clarify if hypoxia-induced γH2AX depends on the presence of well-known factors such as DSBs or replication arrest, or on the presence of still unknown factors.

Although there is a report that γH2AX foci formation results from disorganization of chromatin structure, this possibility has not been directly shown to occur. No γH2AX foci were detected after chromatin-modifying treatments (hypotonic conditions, or exposure to chloroquine or tricostatin A). Although γH2AX foci are also induced by replication arrest, it is well established that the formation of γH2AX foci depends on the formation of DSBs, and not just the presence of S-phase.

Clinical Aspects

Hereditary diseases affecting the cellular response to DSBs include ataxia telangiectasia (AT), Nijmegen breakage syndrome and ►Bloom syndrome. The hallmarks of these disorders are growth defects, immunodeficiency, hypogonadism, hypersensitivity to specific DNA damaging agents, chromosomal fragility, and cancer predisposition. Mouse models in which specific components of the DSB repair/signaling pathway are disrupted recapitulate most of the pleotropic features found in ►genomic instability syndromes.

H2AX-deficient mice resemble chromosomal instability disorders in that they show radiosensitivity, male specific infertility, small size, reduced levels of secondary immunoglobulin isotypes, and tumor susceptibility.

The histone H2AX gene, located 11 Mb telomeric to ATM at 11q23.3, is in a region commonly deleted or translocated in several human hematological malignancies and solid tumors. Heterozygous deletion of chromosome bands 11q22–q23 is detected at a particularly high frequency in some types of lymphoma/leukemia with rapid disease progression and poor survival. Since somatic disruption of ATM only accounts for a distinct subset of tumors involving alterations in 11q, other tumor suppressor genes in this chromosomal region are likely to play a pathogenic role. Given that H2AX deficient mice present all of the features of genomic instability syndromes and that the H2AX gene is located in close proximity to the ATM locus, it remains possible that the molecular basis for some AT-like patients that have been classified on the basis of physical mapping may reside in mutations in H2AX.

Hirschsprung Disease

Definition

HSCR; Is an inherited disease caused by absence of intramural ganglia of Meissner and Auerbach in the intestinal tract. The lack of these enteric ganglia leads to absence of innervation which results in intestinal obstruction. The disease can affect either only a part of the colon (most common) or the entire intestinal tract (very rare). HSCR usually occurs as an isolated case, however, HSCR can also be familial. Evidence suggests that the genetics of long-segment Hirschsprung disease and short-segment Hirschsprung disease is different. To date, more than ten genes (►*RET*, *GDNF*, *NTN*, *EDNRB*, *EDN3*, *SOX10*, *ECE1*, *PHOX2B*, *SMADIP1*, *HSCRM1*, and *HSCRM2*) have been identified to play some role in the pathogenesis of HSCR. The major susceptibility gene for HSCR is *RET*.

Histone

Definition
A group of simple alkaline proteins found in the chromosomes of eukaryotic cells.

►Histones

Histone Acetylation

Definition
Functional histone modification of the N-terminal tails at lysine residues by histone acetyltransferases. The source of the acetyl group in histone acetylation is acetyl-coenzyme A.

Histone Acetyltransferases

Definition
HATs; Family of proteins that acetylate conserved lysine amino acids on histone proteins by transferring an acetyl group from acetyl CoA to lysine to form ε-N-acetyl lysine. Lysine acetylation neutralizes the positive charge normally present, thus reducing affinity between histone and (negatively charged) DNA which renders DNA more accessible to transcription factors. Also, histone acetylation and other posttranslational modifications generate binding sites for specific protein-protein interaction domains.

►Lunasin

Histone Deacetylases

Olaf Witt
CCU Pediatric Oncology, German Cancer Research Center, Heidelberg, Germany

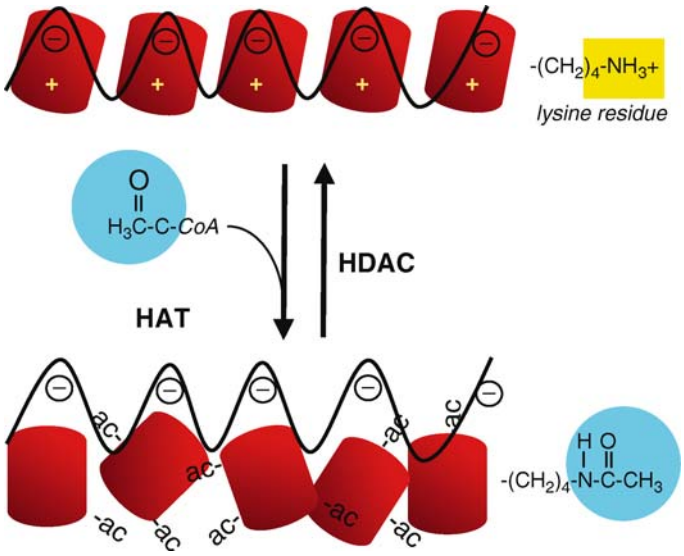
H

Synonyms
HDACs

Definition
►Histone deacetylases (HDACs) are a family of protein deacetylating enzymes that remove acetyl-groups from lysine residues of histone proteins and also non-histone proteins, such as transcription factors.

Characteristics
Functional Roles of Histone Deacetylases (HDACs)
HDACs regulate the acetylation status of histone and also non-histone proteins. They are ubiquitously expressed in all major tissues investigated. By controlling the acetylation level of histone proteins, HDACs are major players in the regulation of ►chromatin structure and transcriptional activities in the genome. Besides this role in the control of chromatin function, HDACs regulate posttranslational acetylation of transcription factors, cytoskeletal proteins and signal transduction molecules thereby modulating their cellular activities. Thus, two major functions of HDACs can be defined:

1. Regulation of chromatin structure and transcriptional activity. Together with histone acetyl transferases (►HATs), HDACs regulate the acetylation status of histone proteins. HATs transfer acetyl-groups from acetyl-CoA to ε-amino residues of lysines within histone proteins, resulting in a neutral charge of its amino acid residue. HDACs catalyse the opposite reaction and remove acetyl-groups from lysines, resulting in a positively charged, free amino-group (Fig. 1). The balance of these counteracting enzyme systems regulate the charge of histone proteins and their interaction with the negatively charged DNA. High activity of HDACs causes deacetylation of lysine residues, increase of positive charge of histone proteins, increase of histone-DNA-interaction and finally, a condensed chromatin structure (Fig. 1).



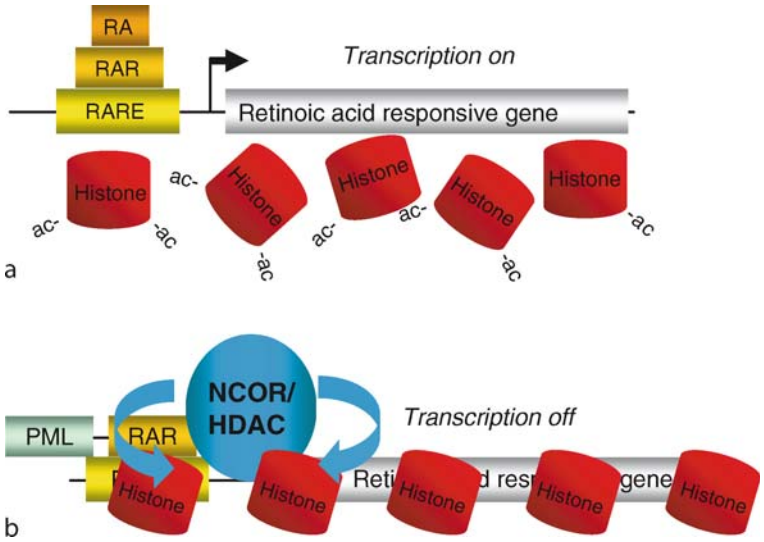
Histone Deacetylases. Figure 1 Histone acetyl transferases (HATs) and histone deacetylases (HDACs) control the level of histone acetylation. Histone proteins within nucleosomes are depicted as red cylinders interacting with the DNA (black line). The depicted chemical structures illustrate the underlying acetylation and deacetylation reaction in more detail. HATs transfer acetyl-groups (blue circle) from acetyl-Coenzyme A (CoA) to the ε-amino groups of lysine residues. This results in loss of positive charges of histone proteins, reduced binding with the negatively charged DNA and finally, an open chromatin structure (bottom panel). The opposite reaction is catalyzed by HDACs: removal of acetyl groups from lysine residues (blue circle, bottom panel) results in an increase in positive charges (yellow box, top panel) with subsequent increased interaction of histones with DNA leading to a condensed chromatin structure (top panel). Thus, HDAC activity favors a condensed, transcriptionally inactive chromatin structure. ac: acetyl-groups.

Therefore, deacetylated histones are found in silenced, transcriptional inactive chromatin regions and acetylated histones are found in transcriptional active chromatin regions. HDACs are recruited to specific chromatin sites as components of multi-protein ►repressor complexes. For example, HDAC1 and 2 are components of the Co-REST complex which inactivates the expression of neuronal genes in non-neuronal tissues. Other complexes which contain HDAC1 and 2 are the NURD and SIN3A repressor complexes. HDAC 3 is found within the NCOR/SMRT repressor complex.

2. HDACs are involved in the regulation of non-histone protein functions. In addition to the regulation of the acetylation status of histone proteins, HDACs deacetylate several non-histone proteins such as transcription factors, signal transduction proteins and cytoskeletal proteins thereby regulating their protein-stability, protein-protein interactions, cellular localization and DNA-binding activity. Among the growing list of non-histone proteins identified as substrates for HDACs are ►p53, ►E2F, GATA1, STAT3, TFIIE, TFIIF, HMGB1, ►HSP90, NF-kB, tubulin and importin. For example, the acetylation status of the oncosuppressor p53 regulates its stability, interaction with DNA and its transactivation activity.

HDACs and ►Cancer

Aberrant recruitment of HDACs to target genes with subsequent ►transcriptional silencing plays an important role in the malignant transformation of cells. In general, it is believed that aberrant recruitment of HDACs primarily affects silencing of genes involved in cell cycle control, ►apoptosis and differentiation. Recruited HDACs induce a compact chromatin structure and subsequent ►epigenetic inactivation of the involved genes by the mechanism depicted in Fig. 1. The best studied molecular model in this respect is ►acute promyelocytic leukemia (APL). In most APLs, ►the retinoic acid receptor-α (RAR) gene is fused to the PML gene through a translocation process involving chromosomes 15 and 17. Expression of the resulting fusion protein PML-RAR results in aberrant recruitment of HDACs to retinoic acid target genes (Fig. 2). This in turn leads to aberrant transcriptional silencing of retinoic acid regulated genes resulting in a differentiation block of myeloid precursor cells giving rise to leukemia (Fig. 2). This differentiation block can be overcome by high doses of retinoic acid and also by HDAC inhibitors. Other examples of aberrant recruitment of HDACs by deregulated transcription factor activities are ►AML1-ETO and TEL-AML1 in ►acute myeloid leukemias and ►BCL6 in ►B-cell lymphomas.



Histone Deacetylases. Figure 2 HDACs are involved in transcriptional silencing of retinoic acid responsive genes in acute promyelocytic leukemia (APL). (a) In normal myeloid precursor cells, retinoic acid (RA) binds to its retinoic receptor (RAR) which recognizes the retinoic acid response element (RARE) in the promoter of genes involved in myeloid differentiation. Thus, in the presence of retinoic acid, these retinoic acid responsive genes are actively transcribed. (b) In APL, the retinoic acid receptor (RAR) is fused to the promyelocytic leukemia (PML) protein (PML-RAR). PML-RAR also binds to the promoter, but has much lower affinity for retinoic acid and recruits HDAC containing repressor complexes (NCOR/HDAC) to retinoic acid responsive genes. Recruited HDAC activity in turn leads to histone deacetylation and chromatin condensation via the mechanism depicted in Fig.1. Subsequently, retinoic acid responsive genes become epigenetically silenced resulting in a differentiation block of myeloid precursor cells giving rise to leukemia.

H

HDAC Family Members

The first HDAC was affinity purified and cloned from cells using trapoxin, an inhibitor of HDAC activity, in 1996. Since then, 18 HDAC family members have been identified. The classification of the human HDAC family is based on their homology to the three yeast histone deacetylases Rpd3, Hda1, and Sir2. Hence, three major classes of human HDACs have been defined (Table 1). Whereas class I and II HDACs can be inhibited by HDAC-inhibitors such as trichostatin A, class III enzymes are resistant to these agents and also differ in their absolute dependency on NAD+ for their activity. HDAC11 appears to be a destinct family member and it has been suggested as a class IV enzyme (Table 1). As opposed to sirtuins, HDAC1–11 are currently referred to as "classical" HDACs by most authors. Class I HDACs are found almost exclusively in the nucleus, whereas class II HDACs are able to shuttle in and out of the nucleus in response to certain cellular signals.

Little is known about the regulation of the expression of HDAC genes themselves. SAGE analysis revealed that HDACs are widely expressed in almost all tissues investigated. No major differences were observed between the expression pattern in normal and malignant tissues at the mRNA level. However, significant variation in expression levels between individual HDAC family members was observed within a given tissue type. The enzymatic activity of HDACs can be regulated by posttranslational modifications such as phosphorylation.

Histone Deacetylases. Table 1 Classes of histone deacetylase enzymes

HDAC classes	HDAC family member
Class I yeast Rpd3 homologues	HDAC1
	HDAC2
	HDAC3
	HDAC8
Class II yeast Hpa1 homologues	HDAC4
	HDAC5
	HDAC6
	HDAC7
	HDAC9
	HDAC10
Class III (sirtuins) yeast Sir2 homologues	SIRT1–7
Class IV (?)	HDAC11

HDAC Inhibitors

Several compounds have been identified that inhibit the enzymatic activity of histone deacetylases. Exposure

of cancer cells to HDAC inhibitors results in inhibition of cell proliferation, induction of apoptosis, induction of differentiation, inhibition of ►invasion and ►migration, inhibition of clonogenic growth and also ►anti-angiogenic effects in a variety of cultured cancer cells. Based on ►microarray analysis, it has been estimated that approximately 2–10% of genes are modulated in their expression following exposure of cancer cells to HDAC inhibitors. Among the genes frequently altered in expression are the CDK inhibitors ►p21, p16 and p27, ►cyclin A and D, the actin-binding protein gelsolin, involved in morphologic and cytostructural changes and apoptotis modulating genes such as Fas and TRAIL receptors. Interestingly, it appears that non-transformed are less sensitive to HDAC inhibitors.

To date, several structurally divergent compounds with inhibitory activity against HDACs are known with an ongoing list of novel variants. HDAC inhibitors bind to the ►catalytic pocket of HDACs and chelate the zinc ion at its base, thereby inhibiting the enzymatic activity. Based on their chemical structure, HDAC inhibitors are grouped into four categories (Table 2): (i) short

Histone Deacetylases. Table 2 Structural classes of HDAC inhibitors

HDAC inhibitor class	Compounds	Concentration range	Example with chemical structure
Short chain fatty acids	►Valproic acid, butyric acid, phenyl butyric acid	mM	Valproic acid Hydroxamic acids	SAHA, TSA, CBHA, scriptaid, pyroxamide	nM-μM	SAHA 
Cyclic tetrapeptides	Apicidin, depsipeptide, trapoxin, CHAP, HC-toxin	nM-μM	Apicidin Benzamides	MS-275, Cl-994	μM	MS-275 
Histone Deacetylases. Table 3 Selection of clinical studies using HDAC inhibitors

Compound	Trial	Results	Toxicity
►Valproic acid	Phase II Acute myeloid leukemia, MDS	Partial and complete remissions in combination with retinoic acid; minor hematological improvements in extended Phase II study	Neurological toxicity
MS-275	Phase I/II Refractory solid tumors, leukemias and lymphomas	Long half life (39–80 h), once every 14 d best oral schedule	Nausea, vomiting, anorexia and fatigue dose-limiting toxicities
SAHA	Phase I/II Refractory solid tumors, leukemias and lymphomas	Good oral bioavailability, partial and complete responses in hematological and solid malignancies FDA approval for cutan out T-cell lymphoma	Dehydration, fatigue, diarrhoea, anorexia, thrombocytopenia, anemia
FK-228 (depsipeptide)	Phase I/II T-cell lymphoma (cutaneous), leukemias, solid tumors	Partial and complete responses in ►T-cell lymphomas	Bone marrow toxicity, cardiac arrhythmia, fatigue, nausea, vomiting

chain fatty acids,(ii) hydroxamic acids, (iii) cyclic tetrapeptides, and (iv) benzamides. Whereas short chain fatty acids require millimolar concentrations in order to exert anti-tumoral effects *in vitro*, the other classes of HDAC inhibitors act in the micro- to nanomolar range (Table 2). Hence, short chain fatty acids are considered to induce "off-target" effects besides HDAC inhibition, whereas hydroxamic acids, cyclic tetrapeptides and benzamides act in a more specific manner. The selectivity of HDAC inhibitors for targeting individual members of the HDAC family is largely unknown. Whereas TSA has been described as a pan HDAC inhibitor, other compounds have been shown to vary in their selectivity against individual HDAC family members up to 3 orders of magnitude.

In several animal models, anti-tumoral activities of HDAC inhibitors have been described. Hence, clinical trials using HDAC inhibitors as anti-cancer compounds have been initiated. So far, pilot studies have shown promising results with moderate toxicities. Currently, HDAC inhibitors are evaluated in several ►phase I and II clinical trials in patients with leukemias and solid tumors (Table 3).

Epigenetic Therapy

Besides HDAC inhibitors, DNA-methyltransferase (DNMT) inhibitors (i.e. 5-aza-deoxycytidine and 5-aza-cytidine) are being used as epigenetically active compounds in cancer therapy. Hence, the term "Epigenetic Therapy" of cancer has been introduced to indicate that HDAC and DNMT inhibitors target epigenetic regulatory mechanisms in cancer cells. Whereas, DNMT inhibitors are thought to act epigenetically in the strict sense by inducing DNA de ►methylation at ►CpG islands thereby activating genes silenced in cancer (i.e. ►tumor suppressor genes), it is currently not known, whether HDAC inhibitors act solely through epigenetic mechanisms (i.e. histone and chromatin modifications) or also by modulating the activity of transcription factors and other non-histone proteins. Both, DNA-methylation and histone acetylation are linked processes. For example, methylated CpG islands are bound by methyl-cytosine binding proteins (MeCP2) which in turn recruit HDACs to promoter sites to suppress transcription.

Histone Deacetylation

Definition

Is a process that removes the acetyl groups from lysine residues on histone proteins, resulting in net positive charge of histones. This increases the affinity of histones for the negatively charged DNA and blocks the access of transcription factors. Histone acetylation is associated with active gene transcription, whereas histone deacetylation is associated with transcriptional silencing.

Histone Demethylases

Definition
Group of enzymes that remove methyl groups from target proteins.

►Histone Modifications

Histone H4

Definition
Histone genes encoding five classes of histone protein are clustered on chromosomes 1 and 6. The H4 gene consists of a single exon flanked by histone gene-specific motifs. The H4 promoter sequence contains consensus binding sites for histone nuclear factor D (HiNF-D) and interferon regulatory factor 2. HiNF-D is a multicomponent protein containing cyclin A, CDC2 and an RB-related protein, which links H4 gene regulation directly to cell cycle control.

►BCL6 Translocations in B-cell Tumors

Histone H2AX Phosphorylated at Serine 139

►γH2AX

Histone Methylation

Definition
Functional histone modification of the N-terminal tails at lysine residues by ►histone methyltransferases. The enzymes catalyze the transfer of one to three methyl groups from s-adenosylmethionine to lysine.

►Class II Tumor Suppressor Genes

Histone Methyltransferase

Definition
An enzyme that mediates the methylation of lysine or arginine residues onto histones. This mark behaves as an index for chromatin, so that cellular memory and identity can be retained after mitosis.

►Methylation
►Histone Modification

Histone Modification

Matthew A. McBrian, Siavash K. Kurdistani
Department of Biological Chemistry, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

Definition
Histones are negatively charged proteins which assemble into a multi-subunit protein octamer complex around which the DNA of eukaryotic cells is wrapped. The ►posttranslational modification of histones, along with ►DNA methylation, has been commonly termed an ►epigenetic process, although the heritable nature of histone modifications has yet to be clearly demonstrated. Histones are aberrantly modified in cancers, leading to deregulated expression of ►tumor suppressors and ►oncogenes, events important in tumorigenesis and cancer progression. In addition, cellular levels of histone modifications are altered in cancer and are predictive of clinical outcome in a number of cancer types.

Characteristics
Histones and Chromatin
The DNA of eukaryotic cells associates with numerous different proteins to form ►chromatin, the physiologically relevant form of DNA. The most abundant proteins in chromatin are the histone proteins which are small, basic proteins that are highly conserved among eukaryotic organisms. There are four canonical histone proteins, H2A, H2B, H3 and H4 which interact with each other and DNA to form a ►nucleosome. Histones H2A and H2B interact with each other to form a heterodimer while two copies each of H3 and H4 interact to form a heterotetramer. The H3-H4 heterotetramer associates with two H2A-H2B heterodimers to assemble into a histone octamer with a roughly cylindrical core in which the N-terminal tails of each of the histones extends outwards in a relatively unstructured manner.

The intimate association of DNA with histones in the context of nucleosomes has significant functional consequences on DNA-templated processes, including DNA replication, DNA repair and transcription. The nucleosome presents an efficient barrier to these processes, thereby imposing the need for a dynamic chromatin structure. This principle is reflected partly in the heterogeneous distribution of nucleosomes and histone modifications throughout the human genome giving rise to the nucleosome rich, transcriptionally inactive ►heterochromatin and the relatively nucleosome depleted and transcriptionally active ►euchromatin structure.

Histone Modifications

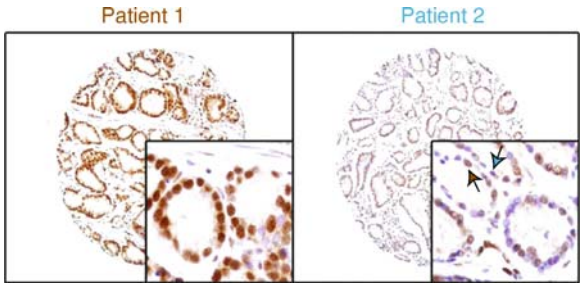
Chromatin structure is also affected by the covalent posttranslational modification of the histone proteins, particularly at their N-terminal tails. The modification of histones occurs at lysine, arginine and serine amino acid residues by the covalent attachment of chemical moieties including – but not limited to – acetyl, methyl, and phosphoryl groups. In general, acetylation of lysine residues is associated with an open chromatin conformation that allows for active gene transcription. Methylation of lysines and arginines tends to be more ambiguous in its effects on chromatin structure and transcription, with the specific functional output depending on the particular amino acid residue that is methylated.

Large families of enzymes, collectively termed ►histone-modifying enzymes, catalyze the modification of histones. ►Histone acetyltransferases (HATs) utilize acetyl-CoA to attach acetyl groups to lysine residues while ►histone deacetylases (HDACs) remove this mark. Methylation of lysine and arginine residues is catalyzed by a family of ►histone methyltransferases (HMTs) using S-adenosyl methionine (SAM) as a substrate. Methyl groups are removed from histones by a family of ►histone demethylases (HDMs). Examples from each class of histone-modifying enzymes have been found to be altered in cancer. ►Translocation of the HAT ►p300 has been found in ►certain hematological malignancies while inactivating mutations of a closely related HAT, ►CBP, is associated with the onset of Rubenstein-Taybi syndrome which predisposes to cancer. Elevated levels of the HMT SMYD3 occur in colorectal and ►hepatocellular carcinomas due to an increase in the number of repeats of an ►E2F transcription factor binding site while another HMT, MLL, is found translocated in various forms of leukemia. A number of HDACs and HDMs are also found mis-expressed in multiple cancer types, including GASC1, a gene originally identified as being amplified in oesophageal squamous carcinomas and which was only later shown to possess demethylase activity. Changes in levels of expression for the histone-modifying enzymes seem to be a common feature of cancer and may explain why expression patterns of select groups of histone-modifying enzymes can be used to distinguish cancer cells from normal cells and also have the ability to specify cancer type.

►Histone modifying enzymes are targeted to specific gene promoters by sequence-specific transcription factors or through specialized domains such as the ►bromodomain and ►chromodomain that recognize and bind to existing histone modifications. In this way, histone modifications are regulated at the level of individual genes which contributes to regulation of gene expression at these genes. In cancer, the aberrant recruitment of histone modifying enzymes establishes altered patterns of histone modifications at specific genes including oncogenes and tumor suppressors. For example, the cyclin E gene – which has an important role in the G_1 to S phase transition – is normally silenced by the deacetylation of lysine residues catalyzed by HDAC1. HDAC1 is recruited to this locus by the ►retinoblastoma (Rb) tumor suppressor protein. Mutations in Rb are common in cancer and can result in aberrant recruitment of HDAC1 to genes such as cyclin E that are involved in cell cycling with subsequent changes in the levels of gene expression. Similarly, an altered pattern of lysine methylation at the ►CDKN2A locus – which encodes the p16INK4A and p14ARF tumor suppressors – is found concurrent with silencing of this gene. The upregulation of oncogenes by epigenetic means is less well-documented than the silencing of tumor suppressors, but examples have been noted. For instance, the MLL HMT is translocated in certain leukemias, leading to the upregulation of the developmentally important Hox genes, a step that may be necessary for leukemic transformation. Other than gene promoters, lower levels of acetylation of lysine 16 and methylation of lysine 20 on histone H4 have been found at DNA repetitive elements in hematological malignancies and colorectal adenocarcinomas.

Histone Modifications and Cancer Prognosis

Differences in levels of histone modifications at the DNA repetitive elements, and at individual genes, have not proven to be predictive of clinical outcome. However, in addition to alterations at specific gene promoters, histone modifications also show large-scale deregulations in cancer. When examined at the level of individual nuclei (i.e. cellular level), cells within a tumor tissue display dissimilar levels of histone modifications, where cells have relatively high or low levels, revealing an epigenetic heterogeneity at the cellular level within cancers (Fig. 1). This cellular epigenetic heterogeneity exists not only within individual tumors, but also between patients who have varying levels of cells with relatively high or low cellular levels of histone modifications. In fact, patterns of cellular levels of various histone modifications can be used to



Histone Modification. Figure 1 Cancer tissues exhibit cellular epigenetic heterogeneity. ►Immunohistochemical (IHC) analysis of histone modifications in malignant prostate glandular epithelial cells from tumors of similar ►grade and ►stage reveals heterogeneity in cellular levels of specific modifications. In a given patient's tissue, some cells have higher levels of certain histone modifications (brown nuclei indicated by the *brown arrow*) than other cells (blue nuclei indicated by the *blue arrow*). Increased prevalence of cells with low levels of histone modifications (i.e., cells with blue nuclei) indicates poorer prognosis. In the case shown here, patient 2 has increased number of cells with low levels of histone acetylation at histone H3 (lysine 18) and therefore poorer prognosis compared to patient 1.

group patients into separate classes that exhibit significantly different clinical outcomes. Generally, patients with increased prevalence of cells with lower levels of histone modifications have poorer outcome. Although the biological significance and the underlying molecular mechanism of the cell-to-cell variability in histone modifications is poorly understood, the clinical data suggest that cellular levels of modification may serve as a valuable ►biomarker in the near future.

Epigenetic Therapy: HDAC Inhibitors

The reversible nature of histone modifications has raised the possibility that changes in gene expression due to altered patterns of modifications can be effectively treated. An altered pattern of histone acetylation as a result of mis-targeting of HDACs is a common phenomenon seen in hematological malignancies. This type of epigenetic aberration has received much attention due to the discovery of a group of natural and synthetic molecules known to inhibit HDACs, termed ►HDAC inhibitors (HDACi). These molecules have been shown to inhibit HDACs by occluding access of the substrate to the active site of the enzyme. HDACi are currently utilized in chemotherapeutic regimens and can be grouped into several classes based on their molecular structure. Some HDACi inhibit specific classes of HDACs (which are grouped into three different classes based on regions of homology) while others are known to inhibit all three classes. However, the specificity of a given HDACi for a specific HDAC is poorly defined and continues to be a topic of investigation.

The treatment of transformed cells with HDACi promotes differentiation of tumor cells and leads to growth arrest and ►apoptosis in both cultured cell lines and animal models. HDACi exert their function selectively on cancer cells which display a tenfold higher level of sensitivity to these drugs than do their non-transformed counterparts. The use of HDACi in cancer treatment relies on the ability of these molecules to affect the gene expression program, silencing the expression of oncogenes while promoting the re-expression of silenced tumor suppressors. Perhaps surprisingly, the use of HDACi affects the expression of only a small subset of the genome, with some genes being upregulated and some being downregulated. While the exact mechanism of HDACi has not been elucidated, it is thought that they work in part by affecting chromatin structure. This has been shown to occur at tumor suppressor genes, such as the ►$p21^{WAF1}$ gene where treatment with HDACi has been shown to increase levels of acetylation on both histones H3 and H4. In addition to increasing acetylation the $p21^{WAF1}$ locus demonstrated a more open chromatin conformation upon treatment with HDACi. This observation has raised the idea that HDACi may also work by inducing changes in chromatin structure leading to ►genomic or chromosomal instability. Increased genomic instability may activate the cell cycle checkpoint, leading to cell cycle arrest.

Histone Modifying Enzymes

Definition

Group of enzymes that collectively catalyze the posttranslational modifications of histone proteins.

►Histone Modification

Histone Proteins

Definition
Small, basic DNA-binding proteins of eukaryotes. Together, histones and DNA form chromatin.

►Epigenetic Therapy

Histones

Definition
DNA-binding proteins that form the basic subunit of chromatin in eukaryotes, the nucleosome. A nucleosome consists of eight core histone proteins (two of each H2A, H2B, H3, H4) forming the central histone octamer and a stretch of DNA wrapped around it. The interaction of histone proteins with the DNA occurs through side chains containing the basic amino acids lysine and arginine, which are subject to reversible acetylation. Other posttranslational modifications of histone side chains are methylation, phosphorylation and ubiquitination.

►Histone Deacetylases
►Histone Modification

Histopathological

Definition
Human tissues embedded in paraffin and sectioned as a part of the diagnostic process reveal cellular differences that can be used to classify different grades of cancer.

►Pathology

HIV

Definition
The human immunodeficiency virus (HIV) is the causative agent of the acquired immune deficiency syndrome (AIDS). HIV is a ►retrovirus of the lentivirus family that selectively infects macrophages and CD4 T cells, leading to their slow depletion, which eventually results in immunodeficiency. There are two major strains of the virus, HIV-1 and HIV-2, of which HIV-1 causes most disease worldwide, HIV-2 is endemic to West Africa but is spreading.

►TAT Protein of HIV

HLA

Definition
The acronym for Human Leukocyte Antigen, is the genetic designation for the human ►MHC. Individual loci are designated by uppercase letters, as in HLA-A, and alleles are designated by numbers.

►Sjögren Syndrome

HLA Class I

Natalia Aptsiauri,
Franciso Ruiz-Cabello Osuna
Hospital Universitario Virgen de las Nieves, Granada, Spain

Definition
The major histocompatibility complex (►MHC) is a system of genes encoding molecules expressed on the cell surface that are required for ►antigen presentation to the immune system. In humans, this system is called ►Human Leukocyte Antigen or HLA genes, since it was discovered through antigenic differences among white blood cells from different individuals in the search for polymorphic antigens to match for transplantation. HLA class I molecules are of key importance in the cell-mediated anti-tumor immune response against viral infections and transformed cells by presenting peptide antigens to ►cytotoxic T lymphocytes.

Characteristics
The classical HLA class I and class II molecules (HLA-ABC and HLA-DR, DP, DQ, respectively) are cell-surface glycoproteins closely related in structure and function. HLA class I molecules consist of two poly-

peptide chains, a heavy chain of 340 amino acids encoded in chromosome 6, and a light non-polymorphic chain, β2-microglobulin (β2-m), encoded on chromosome 15. The class I and the class II molecules have a distinct distribution among cells with a functional role in the immune response. MHC class I molecules are expressed on the surface of nearly all nucleated cells with various levels of expression. MHC class II molecules are expressed on ►antigen-presenting cells (APC). Structurally, HLA molecules are cell surface-bound glycoproteins that contain four immunoglobulin-like domains. The two external domains form a peptide-binding groove consisting of two parallel α-helix amino acid chains on an eight β-pleated polypeptide sheet.

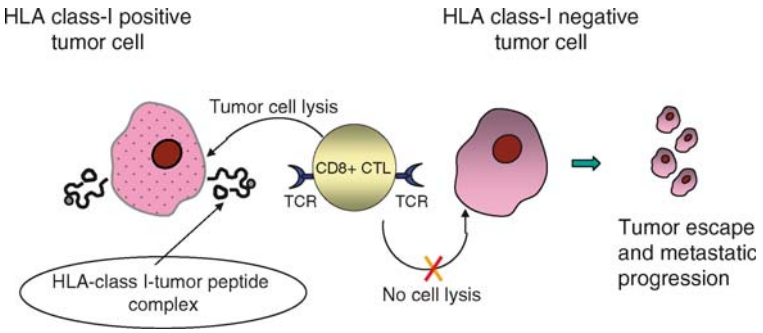
Bioactivity

HLA class I molecules bind peptide fragments derived from proteolytically degraded proteins that are endogenously synthesized by a cell. The processing of antigens is accomplished by a complex series of intracytoplasmic events involving antigen-processing machinery (APM). Processed foreign or self-antigen in a complex with HLA class I or II molecules is recognized by a specific TCR on the surface of T cells. The major function of HLA class I molecules is to alert T cells to the presence of intracellular extraneous peptides derived from intracellular pathogens (viruses, some bacteria) and tumor cells. HLA class I molecules can also interact with natural killer cells (►NK cells) via inhibitory ►receptors or activating ligands to prevent NK-mediated cell lysis. Two classes of HLA molecules are specialized to present antigens of different origin. HLA class I molecules present endogenously synthesized antigens (e.g., tumor associated antigens) to CD8+ CTLs (Fig. 1), whereas HLA class II molecules present exogenously derived proteins (e.g., bacterial products) to CD4+ helper cytotoxic T lymphocytes. Among the different reasons for a poor immunogenicity of tumor cells, the most frequent one is the loss of the expression of HLA class I molecules, which prevents the presentation of tumor antigen peptides to T cells (Fig. 1).

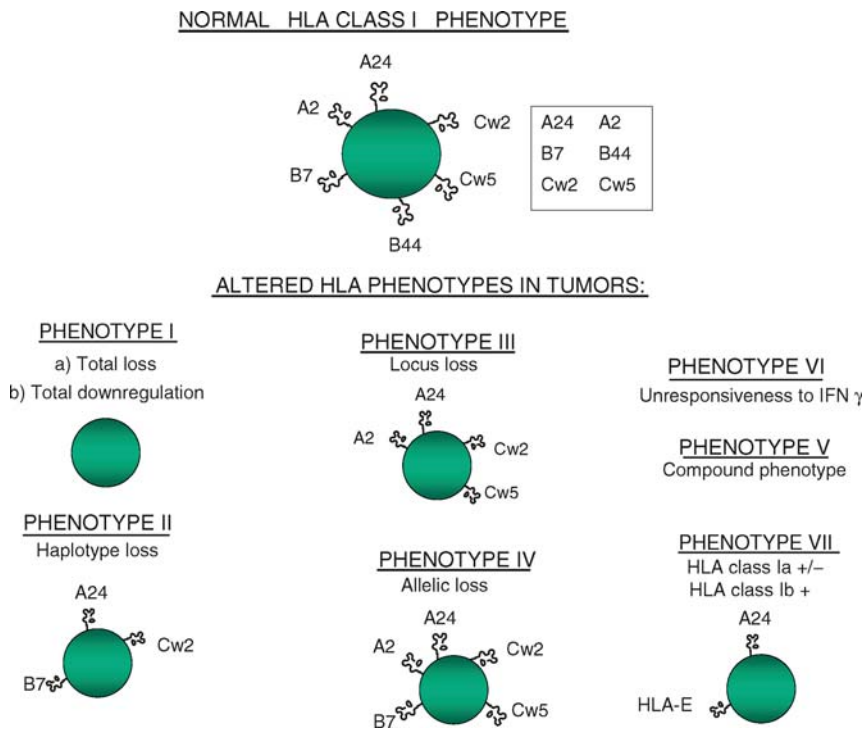
Altered HLA Class I Phenotypes in Tumors

The data obtained over the past 15 years lead us to classify altered HLA class I tumor phenotypes into seven groups (Phenotypes I to VII) (Fig. 2):

- *Phenotype I*: (a) total HLA class I loss, which is associated with structural defects in the β2-microglobulin gene. These defects have been identified in ►melanoma, colon carcinomas (►colon cancer) and other types of malignancy, and range from single base mutations to partial gene deletion. (b) Total HLA class I downregulation, when the class I molecules are not absent but the level of their expression is significantly reduced. It may be caused by defects in the regulation of transcriptional activity of HLA class I heavy chain genes, a dysfunction of the components of the antigen processing and presentation pathway, or some epigenetic (►epigenetics) events such as hypermethylation of cis-acting regulatory elements of the HLA ►promoter.
- *Phenotype II*: HLA ►haplotype loss. The loss of an HLA haplotype associated with the loss of a full chromosome 6 (LOH, loss of heterozygocity) or deletion of a large genomic region has been shown practically in all types of tumor analyzed to date. Chromosomal non-disjunction or mitotic recombination has been proposed to underlie this phenotype.
- *Phenotype III*: HLA ►locus loss. The loss of class I locus expression of HLA-A or HLA-B has been documented in many types of tumor, with HLA-B loss being the most frequent type. The mechanisms of locus downregulation may be transcriptional and can frequently be reversed by ►interferon-gamma (IFN-gamma).
- *Phenotype IV*: HLA allelic loss. It is difficult to define the precise frequency of tumors that show the loss of



HLA Class I. Figure 1 Schematic representation of the HLA class I–mediated interaction between cytotoxic T lymphocytes (CTL) and tumor cell. Tumor cell presents a "peptide/HLA class I" complex to CD8+ CTL via TCR (T-cell receptor). Binding of this complex to TCR initiates a chain of reactions leading to proliferation of CTLs and tumor cell lysis. Tumor cells with lost HLA class I escape T-cell lysis and proliferate leading to cancer progression.



HLA Class I. Figure 2 Altered HLA class I phenotypes in tumors.

only one HLA ►allele because of the limited availability of allele-specific antibodies. The molecular mechanisms underlying the selective allele loss might result from point mutations, partial deletions of HLA class I genes, or splicing defects.

- *Phenotype V*: compound phenotype. It involves multiple events and may be the result of immunoselection during tumor development.
- *Phenotype VI*: Unresponsiveness to IFN-gamma due to various defects in IFN receptor activation or signal transduction.
- *Phenotype VII*: expression of non-classical HLA class I molecules, such as HLA-E, in tumor deficient for classical HLA class I molecules (HLA-A, B, C).

All of these phenotypes can be found in various types of tumor, regardless of the tissue origin or of the carcinogen inducing the tumor. However, there are differences in the distribution of the phenotypes and the combinations of molecular mechanisms leading to each phenotype vary (Table 1).

HLA Class I. Table 1 Frequency of HLA class I expression defects in various types of tumor detected by immunohistological examination using anti-HLA class I specific antibodies

Tumor type	Total
Breast	88
Cervix	63
Colon	81
Larynx	79
Melanoma	69
Pancreas	39
Prostate	85

The results are expressed as percentage of alterations of HLA, including total or partial losses.

Functional Significance of HLA Class I Loss: Implications for Immune Evasion

Tumor cells often express new antigens because of multiple genetic alterations that are associated with malignant transformation. These antigens are recognized by T cells in association with HLA class I molecules, and the activated T cells consequently eliminate tumor cells. The process that involves the recognition and destruction of cancer cells by numerous immune effector cells and molecules is known as immunosurveillance. Nevertheless, cancer cells escape from immunosurveillance through the outgrowth of poorly immunogenic tumor cell variants, which emerge due to growth advantages created by a combination of features in tumor cells and factors in the tumor environment. Therefore, cancer progression may be considered as a result of a balance between tumor immunosurveillance and tumor escape. Several mechanisms have been discovered that enable malignant

H

tumors to evade immune surveillance. Loss of antigens, costimulatory signals and/or adhesion molecules (►cell adhesion molecules), expression of immuno suppressive factors like ►Fas ligand and deficiencies in the signal transduction pathway of CD8+ cytotoxic T cells (CTL) have all been reported. HLA class I downregulation is one of the major tumor ►escape mechanisms, and it represents a significant challenge for a successful application of cancer ►immunotherapy.

A key contributor to the appearance of HLA class I-negative tumor clones is T-cell immunoselection. Cells that are highly immunogenic and express high levels of HLA class I are eliminated by CTLs, while cancer cells with no HLA class I expression proliferate and result into a metastatic colonization (Fig. 1). On the other hand, malignant cells with total HLA class I loss are susceptible to NK cell lysis because of inactivation of inhibitory receptors on NK cells. Another immunoselection route is provided by the partial loss of HLA class I antigens that allows tumor cells to escape both CTL and NK attack. Thus, tumor evolution may involve multiple steps, thereby generating heterogeneity of HLA expression even within an individual cancer. For instance, the metastatic capacity (►metastasis) of different tumor clones measured in spontaneous metastasis assays has been correlated with high MHC class I expression and low NK sensitivity in some tumor models.

A normal expression of HLA class I molecules on the tumor cell surface is crucial for a successful outcome of peptide-based cancer therapy (►peptide vaccines for cancer), since cytotoxic T cells can only recognize tumor-derived peptides in a complex with self-MHC class I molecules. Peptide-based immunotherapy is an established approach of cancer treatment, with the aim of boosting anti-tumor T-cell reactivity by stimulation with tumor specific peptides. However, the overall clinical outcome of this type of treatment is poor. In many cases the failure of this therapy and the progression of the cancer are associated with total loss of HLA class I tumor expression.

When the mechanism underlying total HLA class I loss is at a transcriptional level, the expression of surface HLA class I antigens can be reversed by cytokine treatment and T-cell based therapy can be successfully applied. Evidence for immunoselection of tumors that have lost the expression of several HLA molecules under selective pressure to escape T-cell cytotoxicity was recently demonstrated in patients who had undergone immunotherapy. In patients with structural HLA loss, the defects are irreversible and peptide-based vaccines will be of limited value. It is, therefore, important to develop strategies to classify altered HLA phenotypes and identify the molecular mechanisms underlying these alterations.

HMG-CoA Reductase

Definition

3-Hydroxy-3-methyl-glutaryl-CoA reductase (HMGR) is the first enzyme of the HMG-CoA reductase pathway,

the metabolic pathway that produces cholesterol and various other biomolecules. HMG-CoA reductase inhibitors are a group of prescription drugs used to lower cholesterol, a white waxy substance that can stick to the inside of blood vessels, resulting in clogged arteries, heart disease, and strokes. These medicines work by slowing down the body's ability to make cholesterol. Drugs in this class include atorvastatin (brand name Lipitor), fluvastatin (Lescol), lovastatin (Mevacor), pravastatin (Pravachol), and simvastatin (Zocor). Collectively, they are known as ►statins.

HMG-I/Y

►Cannabinoids and Cancer

HMGA1

Definition

High mobility group A1 protein, a distinct member of the HMG protein family. HMGA1 is a small basic protein that binds to AT-rich regions of DNA and functions mainly as a specific cofactor for gene activation. HMGA1 by itself has no intrinsic transcriptional activity; rather, it can transactivate promoters through mechanisms that facilitate the assembly and stability of stereospecific DNA–protein complexes that drive gene transcription. Stabilization of transcription factor-DNA interactions by HMGA1 plays a critical role in gene regulation. In particular gene contexts, HMGA1 acts to stabilize transcription factor-DNA and protein–protein interactions through a combination of its own binding to a proximal minor groove AT-rich sequence and through direct interaction with an adjacent transcription factor through one of its additional AT-hook motifs or through direct effects on the conformation of multisubunit proteins.

►Insulin Receptor

HMGA2

Definition

High Mobility Group A2 is a member of the HMGA subfamily of high mobility group (HMG) proteins. HMG proteins are abundant, non-histone chromosomal proteins. The HMGA subfamily is composed of four members: HMGA1a/b/c which are proteins encoded by alternatively spliced mRNAs of the *HMGA1* gene, and the HMGA2 protein, which is derived from a different gene, located at human chromosome region 12q15. HMGA2 contains three DNA-binding domains (AT-hooks) followed by an acidic carboxyterminal tail and functions as an architectural transcription factor: it has no intrinsic transcriptional activation/repression capacity, however, it bends DNA in such a way that other transcription factors can bind more easily to promoters and/or enhancers of their target genes.

Hodgkin Disease

Umberto Tirelli
National Cancer Institute, Aviano, Italy

Definition

Hodgkin disease (HD) is unique among the neoplasms derived from lymphoid tissues, i.e., malignant lymphomas. In fact, many characteristics of HD are controversial, in particular the epidemiological, virological, genetic, histopathological, immunological, and biological findings. It is now clear that HD is not a single disease with variants, but rather a group of at least two diseases, namely nodular lymphocyte predominant Hodgkin disease (nLPHD), and classic Hodgkin disease (cHD).

Characteristics

While nLPHD is a B-cell neoplasm, it is not clear whether the B-cell-derived displastic cells, i.e., the L-H or popcorn cells are monoclonal or polyclonal. Moreover, it is not clear whether nLPHD should be treated in as it shows slow or no progression at all. In contrast, cHD contains four histotypes, i.e., NSHD (nodular sclerosis HD), MCHD (mixed cellularity HD), LDHD (lymphocyte depletion HD), and cLRHD (lymphocyte-rich HD) that require treatment because otherwise they are fatal.

Immunological and molecular biological studies of cHD at the single cell level suggest that HRS (Hodgkin and Reed–Sternberg) cells in most cases are monoclonal derivatives of late germinal center B-cells, but in few cases are derivatives of cytotoxic T-cells and although less likely of NK-cells. The major event in the pathogenesis of B-cell related cHD is the blockage of apoptotic pathway. Epstein–Barr virus (►EBV) might be involved in the postulated dysfunction of the apoptotic pathway, leading to the genesis of classic HRS cells.

The essential elements for diagnosis of HD are the following:

- Lymphomegaly, single or multiple, not painful, often monostational and with variable dimensions over time
- Frequent presence of one or two systemic symptoms (fever, night sweat, loss of weight)
- Presence of the Reed–Sternberg cell in the lymphonodal biopsy

The most characteristical clinical presentation of HD is a young adult, showing an asymptomatical lymph node swelling. The enlarged lymph gland, which is usually not tender, occurs most widely in the neck, often in the sopraclavicolar fossa but it may also be discovered in the mid- or right neck or in the axilla. Another common presentation of the illness is the discovery of an anterior mediastinal mass on the routine chest radiographic examination.

Treatment of patients with HD has been one of the most significant successes in twentieth century clinical medicine. This was once uniformly a fatal disease, now is curable in approximately 75% of patients at many major medical centers worldwide. The management of these patients, however, is often difficult and requires particular attention to details of the staging and

treatment program. This is a necessary procedure in order to obtain good results by keeping the potential serious toxicities and morbidities of the therapy to a minimum. Most of the serious side effects of the therapy of HD are not evident for at least 5–20 years or more after treatment is completed. These might be described as problem of success, since they require many years of survival, free of HD recurrence to be recognized. As they have become evident, treatment programs have been modified in an effort to reduce their incidence and severity to a minimum. Therefore, the management of patients with HD continues to evolve. Treatment recommendations however, may differ somewhat among physicians and investigators with great experience in the treatment of HD.

A therapeutic program for a patient with HD should not be initiated without definitive diagnosis by an experienced hematopathologist. Appropriate diagnostic studies and stage determination should be made before start of a therapy. Almost all patients benefit from consultation with both an experienced medical oncologist or hemathologist and a radiation oncologist to jointly plan a treatment program, although not all patients require both modalities, chemotherapy and radiation therapy, in their initial management. Generally, the standard recommended treatment for patients with HD depends on the stage of the disease. There are special clinical situations and settings in which the standard approach must be modified, for example, in patients with HIV infection. Briefly, patients with stage IA and IIA supradiaphrammatic may be managed with full dose extend field radiation without chemotherapy. Those patients with bulky disease request management with combined chemo- and radiation therapy modality. Patients with stage IA and IIA infradiaphrammatic may be cured with radiation therapy alone. Patients with stages I and IIB are usually treated with chemotherapy alone or with a combined modality approach, i.e., chemotherapy and radiation therapy. Patients with stage IIIA may be treated with a combined modality approach, while those in stage IIIB are generally treated using chemotherapy alone as in a those with stage IV. ABVD (adriamycin, bleomycin, vinblastine, and dacarbazine) is the most effective single chemotherapy regimen in HD.

There are a lot of clinical problems that require the intervention of experienced medical oncologists. In particular, pulmonary infiltrates, epidural cord compression, herpes zooster, and postsplenectomy sepsis. Moreover, there are clinical problems after therapy including complications and late effects of the therapy, either from radiation therapy or from chemotherapy, e.g., sterility, second-tumors, coronary heart, lung, and artery diseases from radiation therapy, etc. Recently, in order to avoid these serious long-term side effects, treatment centers try to use a combined chemo- and radiation therapy approach with a short but intensive chemotherapy regimen in combination with limited field, low-dose radiation therapy. This approach could be successful, in order to maintain the high rate of cures decreasing the potential serious side effects in the follow-up. Finally those patients who relapsed or become resistant may be salvaged by high dose chemotherapy with stem cell support. This approach has been shown to cure some of the patients who otherwise would have died from HD.

Synonyms

Hodgkin lymphoma

Definition

Hodgkin disease is a form of cancer – a type of ►malignant lymphoma. It is a malignancy of ►Reed-Sternberg cells and variants (Hodgkin cells, collectively). It occurs in about 3–4 per 100,000 population, and represents approximately 25% of all cases of ►lymphoma.

Characteristics

Pathology

Hodgkin disease is identified by the recognition of Reed-Sternberg cells and variants (collectively called Hodgkin cells) in the appropriate milieu, which usually consists of varying numbers of small lymphocytes, histiocytes, eosinophils, and plasma cells. Typically, the cellular milieu consists of greater than 99% of the reactive non-neoplastic elements, with the Hodgkin cells representing a rare dispersed population within involved tissues (and therefore difficult to study, except by single-cell dissection). Hodgkin disease can be separated histologically into classical type and nodular lymphocyte predominance type. The classical type is generally subdivided into nodular sclerosis, lymphocyte-rich, mixed cellularity, and lymphocyte

depletion subtypes, also based on their histologic appearance. Cases of nodular sclerosis are characterized by the presence of thick fibrous bands that traverse the affected lymph node and a variant of Hodgkin cell, the lacunar cell, which shows artifactual retraction of the cytoplasm in formalin-fixed sections. Cases of the lymphocyte-rich subtype have a marked predominance of small lymphocytes and have few identifiable Reed-Sternberg cells, while cases of lymphocyte depletion have a relative paucity of small lymphocyte and often show diffuse fibrosis. The mixed cellularity subtype lacks thick fibrous bands and has an intermediate number of Hodgkin cells. The Reed-Sternberg cells of classical Hodgkin disease are unique polyploid or multinucleated cells, with large inclusion-like nucleoli, while variants consist of similar mononucleated cells with large nucleoli. In nodular lymphocyte predominance, a nodular pattern is often seen in the absence of broad fibrous bands, and there is a predominance of small lymphocytes. The Hodgkin cells in the nodular lymphocyte predominance type are known as ►L&H cells, and have multilobated nuclei with less prominent nucleoli than the cells in classical Hodgkin disease. Classical Hodgkin cells have a characteristic immunohistochemical profile, being ►$CD30^+$, ►CD15 (X carbohydrate hapten)$^+$, ►CD20 (B lineage marker)$^{+/-}$ and ►CD45 (leukocyte common antigen)$^-$, while the L&H cells in the nodular lymphocyte predominance subtype are generally $CD30^-$, $CD15^-$, $CD20^+$, and $CD45^+$. CD30 is a member of the ►tumor necrosis factor receptor superfamily and is a late activation marker of lymphoid cells. The reactive lymphocytes are usually helper T cells in classical Hodgkin diseases. In nodular lymphocyte predominance, B cells make up the predominant cell type in the nodules; however, the L&H cells are usually surrounded by a collar of ►$CD57^+$ ►helper T cells.

Basic

Studies of the variable-region genes of the immunoglobulin receptors have demonstrated that the vast majority of cases of Hodgkin cells are derived from ►germinal center B cells. In nodular lymphocyte predominance Hodgkin disease, the precursor cells are usually mutating germinal-center B cells, and the pattern of suggests that the cells have been selected for expression of functional immunoglobulin receptors. In classical Hodgkin disease, the Reed-Sternberg cells are heavily somatically mutated, but ongoing mutations are not identified; in fact, some of the mutations identified result in stop codons that would ordinarily lead to elimination of the cell in the germinal center through apoptosis. This suggests that the Reed-Sternberg cells of classical Hodgkin disease are preapoptotic, crippled, germinal center B cells. There is some data to suggest that escape from apoptosis may arise through deregulation of ►NFκB, possibly due to mutations in the ►IκBα molecule that is the natural inhibitor of NFκB, ►amplification of the ►REL gene, overexpression of the tumor necrosis factor receptor–associated factor 1(►TRAF-1) 1 molecule, or stimulation of the CD30 or CD40 expressed on Hodgkin cells. Escape from ►apoptosis may also result in some cases from inactivation of the ►CD95 death receptor pathway, possibly by mutations in the CD95 gene or by expression of $cFLIP_L$. In rare cases, Hodgkin cells may be derived from T cells. Hodgkin cells produce a variety of cytokines, including tumor necrosis factor, interleukins 1–10 and 13, lymphotoxin-alpha, tumor necrosis factor, transforming growth factor-beta, interferon-gamma, granulocyte-macrophage colony-stimulating factor, macrophage colony-stimulating factor, and ►TARC chemokine. Since Hodgkin cells produce both interleukin-13 and its receptor, this may provide an ►autocrine proliferation stimulus. These cytokines probably account for the abundant cellular milieu as well as some of the unusual clinical findings, such as systemic symptoms. For example, the secretion of TARC may be the main reason for the predominance of T-helper cells in involved tissues. Although high levels of ►p53 protein have been identified in Hodgkin disease, only a minority of case has detectable mutations of the p53 gene. About 40% of cases of the classical form of Hodgkin disease are associated with the ►Epstein-Barr virus. In these cases, monotypic episomes of the Epstein-Barr virus can be identified in the Hodgkin cells; these cells have a latency pattern II. Epstein-Barr virus-associated cases are particularly found in younger patients and with mixed cellularity and lymphocyte depletion subtypes, particularly in economically disadvantaged populations. There are few cytogenetic studies of Hodgkin disease, because Hodgkin cells are rare in involved tissues, they are difficult to grow in culture, and few bona fide cell lines exist. Most reported karyotypes are extremely complex, with frequent polyploidy; no characteristic abnormalities have been consistently identified. Single cell studies have demonstrated the absence of the t(14;18) that is the hallmark of ►follicular lymphoma.

Clinical

Patients with Hodgkin disease usually present with an enlarged lymph node. Patients with the nodular sclerosis subtype have a predilection for disease above the diaphragm, particularly mediastinal node involvement. Patients with lymphocyte depletion often present with abdominal nodal involvement, while patients with nodular lymphocyte predominance often present with isolated disease in the upper neck. Some patients may also have systemic, or "B," symptoms – weight loss >10% during the previous six months, documented fever, and night sweats. There is a slight male

predominance and a bimodal age distribution in Western populations, with peaks of incidence in young adulthood and old age. Among economically disadvantaged populations, the first peak of incidence occurs earlier in childhood, particularly for males. There is a relatively low incidence of Hodgkin disease among Asian populations. Hodgkin disease usually starts at a single site and progresses in an orderly manner through the lymphatic system to local lymph nodes before disseminating hematogenously to distant sites, particularly the bone marrow, spleen, or liver. Hodgkin disease is typically staged from I to IV. Stage I represents involvement of a single lymph node structure, stage II is involvement of two or more lymph node regions on the same side of the diaphragm, stage III is involvement of lymph node regions or structures on both sides of the diaphragm, and stage IV is involvement of extranodal sites. Prognosis is directly related to stage. Hodgkin disease is typically treated by multidrug chemotherapy and/or radiotherapy, with an overall 5-year survival of greater than 80%. Patients who relapse usually do so within the first three years after treatment, and have a significantly worse prognosis. High-dose chemotherapy with ►autologous bone marrow transplantation or peripheral blood stem-cell transplantation has become a standard therapy for patients who fail conventional chemotherapy regimens. Novel immunotherapies have been proposed, including treatment with interleukin-2, bi-specific antibodies, immunotoxins, and radioimmunoconjugates. Patients with the nodular lymphocyte predominance subtype may behave differently than the classical forms of Hodgkin disease, with a better overall survival, but a greater number of recurrences, which are independent of time after treatment.

H

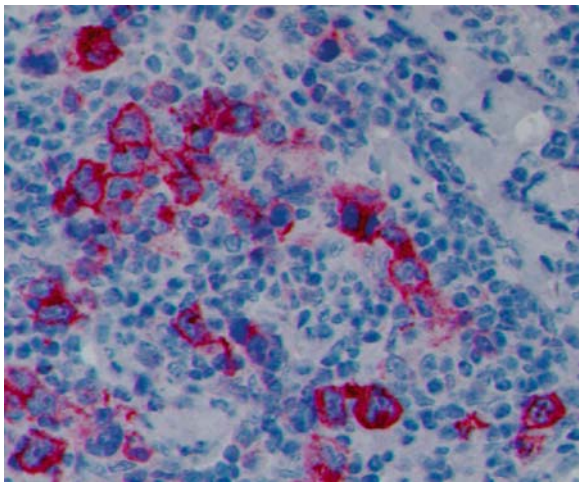
Definition

Hodgkin and Reed/Sternberg (HRS) cells are large cells with a peculiar morphology and immunophenotype that does not resemble any other normal cell in the body. The cells are called Hodgkin cells when they are mononucleated and Reed/Sternberg cells when they are multinucleated. HRS cells in nearly all instances derive from B lymphocytes, but in rare cases they originate from T cells. HRS cells are the hallmark cells of Hodgkin lymphoma, in which they represent the tumor cell clone.

Characteristics

Associated Pathologies

The first cases of Hodgkin lymphoma (HL) were described by Thomas Hodgkin in 1832. A peculiar type of cells that is a hallmark of HL was first characterized in detail about 100 years ago by Dorothy Reed and Carl Sternberg. These cells are called Hodgkin cells when they are mononucleated and Reed/Sternberg cells when they are bi- or multinucleated. HRS cells are large cells ten times or more of the size of small lymphocytes with prominent nucleoli. Reed/Sternberg cells most likely derive from Hodgkin cells by endomitosis, i.e., nuclear division without cell division. In HL, the HRS cells usually represent less than 1% of cells in the tumor tissue (Fig. 1). They are surrounded by a mixture of various types of cells, including T cells, B cells, plasma cells, macrophages, eosinophils, and others. In about 40% of cases of HL in the Western world, the HRS cells are latently infected by the ►Epstein–Barr virus (EBV). HL is one of the most frequent malignant lymphomas in the Western world, with an incidence of about 2.5–3 new cases per 100,000 people per year. Nowadays, about 90% of the patients can be cured by chemo- and/or radiation therapy. Based on differences in the histological picture and the cellular



Hodgkin and Reed/Sternberg Cell. Figure 1 HRS cells in Hodgkin lymphoma tissue. CD30 immunostaining (red) of a HL lymph node tissue section with CD30-positive HRS cells. Nuclei of the cells are stained in blue with haemalaun.

composition of the lymphoma, HL is subdivided in four types of classical HL (nodular sclerosis, mixed cellularity, lymphocyte depletion, and lymphocyte-rich classical) and lymphocyte-predominant HL. This latter type represents about 5% of cases. In lymphocyte-predominant HL, the tumor cells have a distinct morphology and immunophenotype and are normally not multinucleated. These cells are not called HRS cells but lymphocytic and histiocytic ►(L&H) cells.

It is very difficult to grow HRS cells in culture, and only a few cell lines could be established from HL biopsies. Nevertheless, these cell lines are valuable models for the functional analysis of HRS cells. The cell lines still available and considered as HRS cell-derived include the B cell lineage lines L428, L1236, KMH2, L591 (the latter is the only EBV-positive line) and the T cell lineage HL lines HDLM2 and L540.

Although HRS cells are the pathognomonic cells in HL, HRS or HRS-like cells are also occasionally observed in other lymphomas. These include some ►diffuse large B cell lymphomas and ►B cell chronic lymphocytic leukemia (B-CLL). In B-CLL, the HRS-like cells can either be clonally related to the B-CLL lymphoma clone, or they can represent an independent cell clone. HRS cells are also regularly found in an infectious disease, i.e., ►infectious mononucleosis. This disease is caused by EBV and can occur if the primary infection of an individual by EBV does not occur in young children (when it is usually asymptomatic) but is delayed into adolescence or adulthood. In infectious mononucleosis many B cells are infected by EBV and can expand to large clones. Some of the EBV-infected B cells for unknown reasons acquire the morphology and to some extend the immunophenotype of HRS cells.

As HRS cells have most extensively been analyzed in HL, the following discussion of HRS cells refers to HRS cells in HL.

Cellular Origin

As the HRS cells usually represent only a small fraction of the cells in the HL tissue and as they have an unusual immunophenotype that does not resemble any normal hematopoietic cell type (see later) the cellular origin of these cells was unclear for a long time. However, about 10 years ago, the molecular analysis of isolated HRS cells revealed that these cells derive from B lymphocytes in nearly all cases. HRS cells carry rearranged immunoglobulin (Ig) genes which is specific for B cells. These rearranged Ig genes carry with few exceptions a high load of somatic mutations. The acquisition of such mutations through the process of ►somatic hypermutation takes place in antigen-activated B cells in the course of T cell-dependent immune responses in specific histological structures of lymph nodes and other lymphoid organs – the ►germinal centres. Therefore, it is very likely that HRS cells derive from such mature germinal centre B cells. Curiously, HRS cells frequently carry destructive somatic mutations that prevent expression of a functional B cell antigen receptor. As normal germinal centre B cells acquiring such mutations undergo ►apoptosis, HRS cells may represent transformed preapoptotic germinal centre B cells. The detection of rearranged T cell receptor genes in a few cases of HL indicates that in rare instances (less than 2% of cases), HRS cells may also derive from T cells.

Immunophenotype

HRS cells show an unusual immunophenotype with coexpression of markers of distinct hematopoietic cell lineages. B cell antigens (e.g., CD19, CD20) or T cell antigens (e.g., CD3, CD4) are detectable on variable proportions of HRS cells in about 10–20% of cases. Several markers of dendritic cells are regularly expressed (e.g., thymus and activation regulated chemokine (TARC), fascin, and restin), but also markers of myeloid cells are found (CD15). As HRS cells are in nearly all cases derived from B cells, it is evident that many of these markers are aberrantly expressed by HRS cells. It also became clear that HRS cells lost expression of most typical B cell markers. For the diagnosis of HL, it is important that HRS cells in all cases of classical HL express CD30, an activation marker and member of the tumor necrosis factor receptor family.

Cell Differentiation and Function

HRS cells can be considered as hyperactivated cells, as a multitude of signaling pathways is chronically

activated in these cells. HRS cells show constitutive activity of the transcription factor NFκB, which regulates the expression of many genes, including important antiapoptotic factors. Indeed, inhibition of NFκB in HRS cell lines induced apoptosis of the cells. Also the PI3 kinase/AKT signaling pathway and the activator protein 1 (AP-1) are active in HRS cells and contribute to cell survival and/or proliferation. Remarkable is Notch-1 activity in HRS cells, as this transcription factor is normally active only in T cells and suppresses expression of B cell-specific genes. Thus, the deregulated activity of Notch-1 in HRS cells may contribute to the downregulation of B cell genes, as discussed earlier. In HL tissues, many cytokines are produced by HRS cells and surrounding cells. On this basis, it is perhaps not surprising that HRS cells have an active Jak/STAT pathway, as many cytokines signal through this pathway. There appears to be even an autocrine interleukin stimulation in HRS cells, as they express interleukin 13 and the interleukin 13 receptor. Three of the STAT transcription factors have been identified as constitutively active in HRS cells, STAT3, 5 and 6. Another important family of signaling molecules is receptor tyrosine kinases. In several cancers, specific members of this family show deregulated activity that contributes to pathogenesis. In HL, multiple receptor tyrosine kinases are expressed and active, which is in its extent unique among human tumors.

Transforming Mechanisms of HRS Cells

As mentioned earlier, in about 40% of cases of HL in the Western world, HRS cells are infected by EBV. In some instances (e.g., in childhood cases in Central America) the association can be even up to 90%. In EBV-positive cases, three latent viral proteins are expressed, the EBV nuclear antigen EBNA1, and the latent membrane proteins LMP1 and LMP2A. EBNA1 is essential for the replication of the viral genome in proliferating cells. Interestingly, LMP1 and LMP2A functionally mimic two main survival signals for germinal centre B cells, i.e., CD40 signaling and B cell receptor signaling. In this way, EBV can rescue the HRS cell precursors from apoptosis and contributes to the malignant transformation.

HRS cells usually show multiple numerical and structural chromosomal abnormalities. Some of these are shared by all HRS cells, while others are found only in fractions of cells of a tumor clone, indicating a significant genomic instability. Due to the multitude of genomic aberrations, it has been difficult to identify events causally involved in the transformation of HRS cells. However, some genomic imbalances occur recurrent and are therefore candidates for pathogenetic events. These include, for example, amplification of the genomic region including the *c-Rel* gene, a member of the NFκB family. HRS cells frequently also harbor translocations involving the immunoglobulin loci, but the partner genes involved in these translocations have not yet been identified.

Isolated HRS cells were also analyzed for mutations in proto-oncogenes and tumor suppressor genes. Mutations in the tumor suppressor genes *p53* and *CD95* were found in less than 10% of cases investigated. Inactivating mutations in a main inhibitor of the NFκB transcription factor, IκBα, are present in about 20% of cases. Rare cases may also carry mutations in IκBε, another inhibitor of NFκB. Mutations in these NFκB inhibitors contribute to the constitutive activity of this factor, which has an important role as an antiapoptotic factor in HRS cells (see earlier). Mutations were recently also found in the *SOCS1* gene, which is an inhibitor of STAT transcription factors. Thus, these mutations likely contribute to the constitutive activity of STATs in HRS cells.

In summary, the transforming events involved in the generation of the malignant HRS cells in classical HL have only partly been revealed, and it appears so far that multiple different combinations of genetic aberrations can cause the pathogenesis of HL.

Hollow Fiber Assay

Irene V. Bijnsdorp, Godefridus J. Peters
Department of Medical Oncology, VU University Medical Center, Amsterdam, The Netherlands

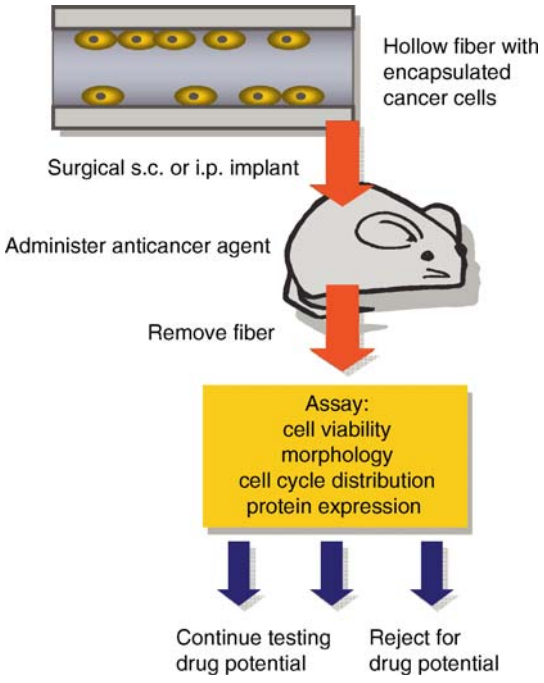
Definition

The hollow fiber assay (►HFA) is a fast in vivo assay to determine the cytotoxic effect of drugs, as well as their pharmacodynamic (►Pharmacodynamics) effects on human tumor cell lines grown in hollow fibers that are implanted subcutaneously or intraperitoneally in mice or rats.

Characteristics

Various in vivo models exist to asses the efficacy of potential anticancer agents, including subcutaneously implanted ►xenografts, ►orthotopic models, and the HFA. The HFA has been optimized at the National Cancer Institute (►NCI) and is a unique in vivo model for ►drug discovery. It permits the simultaneous evaluation of the efficacy of anticancer agents against multiple tumor cell lines in two physiological compartments of one animal. In this assay, semipermeable biocompatible fibers are used, which can be filled with cancer cells. These cancer cells can be derived from different tissue origins and can have different cellular characteristics. The fibers are made of polyvinylidene fluoride (PVDF) and have an internal diameter of 0.5–1 mm and are 2 cm long. The fiber has a molecular weight exclusion of 500,000 Da. Therefore soluble bioactive agents (e.g., proteins, such as growth factors produced by tumor cells or host) can bypass the fiber, but tumor cell to host cell contact is not possible. The fibers are mostly implanted in mice, but it is also possible to implant the fibers in rats and other animals for ►preclinical testing of anticancer agents. One mouse can support the growth of up to six cancer cell lines, and therefore enables to test more than one cell line simultaneously in one animal. The fibers can be transplanted in both immunocompromized and in immunocompetent mouse strains, since the immune cells of the host can not infiltrate into the hollow fiber and therefore can not activate an immune response or impede the growth of the tumor cells. The fiber can be implanted either intraperitoneally (►i.p.) or subcutaneously (►s.c.), therefore differences of intravenous (►i.v.), oral, i.p., and s.c. administration of drugs can aid in assessing the effects of hepatic pass through, thus providing information for dose estimations and administration routes for more extensive in vivo testing of both cytotoxic and antiangiogenic ►chemotherapy. After treatment, active cell proliferation and cellular characteristics, including ►cell cycle distribution, ►DNA damage induction, cell death induction (►Apoptosis), protein expression levels and cell morphology can easily be studied (Fig. 1). Besides this, in vivo pharmacokinetic (►Pharmacokinetics) parameters, including drug transport, pH and pO_2 can be analyzed.

The NCI currently uses a panel of 12 tumor cell lines for routine hollow fiber screening of anticancer drug activities. It is used as the initial in vivo assessment to determine potential activity of agents that have reproducible activity in the in vitro anticancer drug screen. The HFA prioritizes compounds for secondary ►xenograft screening and helps to reduce the large number of active compounds generated by the in vitro ►NCI 60 cell line screen that were forming a bottleneck for entry into secondary xenograft testing. The NCI HFA requires 24 mice for testing of one compound against a panel of 12 cancer cell lines in contrast to the NCI xenograft model, where three xenograft models are used to test one agent with each xenograft model, which requires about 50 mice. The use of the HFA in early ►preclinical drug screens fits excellently with the philosophy of replacement, refinement and reduction (3Rs) of animals in research, controlling the use of laboratory animals.



Hollow Fiber Assay. Figure 1 Schematic overview of the HFA procedure for preclinical testing the anticancer activity of a compound using cancer cell lines transplanted subcutaneously (s.c.) or intraperitoneally (i.p.) in mice. Method is described according to NCI guidelines, http://dtp.nci.nih.gov/branches/btb/hfa.html.

Since the development of the HFA for ►drug screening, other groups have used this assay to independently demonstrate drug activity. Compound efficacy has been demonstrated using the HFA, using both primary human tumor cells and characterized tumor cell lines. Although the NCI uses the HFA successfully to quantitatively define anticancer activity, the role of this in vivo assay could be extended. The HFA has already been adapted for evaluation of antiviral agents and it may also be adapted to use it in other medical fields.

The in vivo HFA has demonstrated a good predictivity of xenograft activity. Anticancer activity in xenograft models is defined by a reduction in relative tumor volume. In the HFA the activity is defined as a reduction of the number of viable cells, measured with an ►MTT assay. Any compound found to be active in xenograft models is often also active in the HFA.

A xenograft model does not easily permit elucidation of the mechanism of action of a compound in a tumor. Retrieval of tumor cells from xenograft models for pharmacodynamic analysis is complicated by host cell contamination. Cells grown in a hollow fiber can easily be harvested for mechanistic studies as a single cell suspension without contamination of host cells. When the HFA is used for preclinical pharmacodynamic investigations, compounds may progress to the clinic much faster. On the other hand, more information is required on tumor cell–stroma interaction. The development of such a model using the HFA is a new challenge in its application.

The HFA has several advantages over standard animal efficacy models. First, the assay has demonstrated the ability to provide quantitative indices of drug efficacy with minimum expenditures of time (procedure takes less than 2 weeks) and materials (e.g., test compounds). It is not limited by the high costs that are associated with large-scale animal testing using xenograft tumor models. Second, conducting studies in animal models requires substantial amounts of time and resources for the testing procedure. Even when it is possible to conduct such studies, it is possible that the experimental agents will exhibit only minimal antitumor activity. Thus, the HFA will prevent to test inactive compounds in a xenograft model. Third, cancer treatments that appear promising in tissue culture are often less effective in solid tumors. This can be partially because of the proliferative and microenvironmental heterogeneity that develops in these tumors during their growth in a ►three-dimensional structure; cells in a hollow fiber also grow in a three-dimensional structure. Fourth, this procedure of testing takes the pharmacokinetic behavior of the drug into account, as well as potential biotransformation. Fifth, the HFA is excellently suited to perform initial in vivo experiments to study combinations, because the compounds will have a dynamic in vivo interaction. Sixth, the HFA prevents that the mouse suffers from the tumor induced cachexia.

The HFA was not developed to replace the classic xenograft model. Complex interactions which occur when the transplanted tumor cells are growing in and interacting with the host's tissue can not be analyzed. Cells can not metastasize to secondary organs of the animal, since the fiber prevents cellular ►migration. Although ►angiogenesis in the tumor will not be induced when these fibers are used, neovascularization occurs to supply the fiber with nutrients. This is possibly induced by growth factors that are released by the tumor cells in the fiber. The hollow fiber can be used perfectly as a preliminary tool to asses the capacity of a compound to reach tumor cells growing in two distinct physiologic compartments (s.c. or i.p.) and to asses whether the drug can reach pharmacologically active concentrations in the tumor cells. Using modern ►bioluminescent techniques, it will be possible to perform dynamic growth of the cells in the fibers.

Methodology

The HFA procedure is as follows (Fig. 1): tumor cells are harvested at the desired cell density from a log phase growing in vitro culture. The cell suspension is flushed into the hollow fibers, which are subsequently heat-sealed so that the cells can not escape from the fiber. The density is dependent on the cell line and may vary from 1 to 100×10^5 cells/fiber. Prior to transplantation into the host, fibers are placed into tissue culture medium and incubated at 37°C in 5% CO_2 atmosphere for 24–48 h. On the day of implantation, samples of each tumor cell line preparation can be quantified for viable cell mass by a stable endpoint MTT assay. Mice can then be treated with anticancer agents starting few days after fiber implantation and for a maximum of 2 weeks. Following treatment, the fibers are collected from the host and subjected to the stable endpoint MTT assay. The percent net growth for each cell line is calculated and compared to the percent net growth in the vehicle treated controls. Furthermore, at the treatment endpoint, various other cellular analyses can be performed.

Homeobox

Definition

A short usually highly conserved DNA sequence found within genes that are involved in the regulation of development (morphogenesis) of animals, fungi and plants. Genes that have a homeobox are called homeobox genes and form the homeobox gene family.

►Nucleoporin

Homeobox Genes

Stacey Stein, Cory Abate-Shen
Center for Advanced Biotechnology and Medicine, UMDMJ – Robert Wood Johnson Medical School, Piscataway, NJ, USA

Definition

Homeobox genes are a class of developmental regulatory genes that encode homeoproteins. Homeoproteins function as transcription factors to regulate downstream targets, turning on (activating) or turning off (repressing) other genes that in turn regulate developmental processes. Aberrant expression of homeobox genes has been implicated as causal factors in leukemia and solid tumors.

Characteristics

Homeobox genes are often referred to as master control genes. They are active during embryonic development and regulate important processes such as ►morphogenesis and cellular ►differentiation. They were first identified in Drosophila as the homeotic cluster (HOM-C) genes and were later found to have homologs in many species. They are now known to be highly evolutionarily conserved and are present in animals, plants and fungi.

Homeobox genes share a common sequence motif (the homeobox), which is 180 nucleotides in length and encodes a 60 amino acid region (the homeodomain). The homeodomain mediates DNA binding to sites containing a ►TAAT sequence that are found in the transcriptional regulatory elements of target genes. Upon DNA binding, homeoproteins are thought to act as transcription factors to regulate downstream targets.

There are two major subclasses of vertebrate homeobox genes:

- The clustered genes, or HOX genes
- The non-clustered genes

The non-clustered genes are sub-divided into many subfamilies, which are classified on the basis of sequence similarities within their homeobox regions. The HOX family of homeobox genes, as well as most other families of homeobox genes, is thought to control cellular proliferation and differentiation during development. The HOX genes are expressed beginning in ►gastrulation and are involved in patterning the body axis from the branchial arches to the tail.

What is most notable about HOX genes is their positioning on four chromosome clusters. Not only are the sequences of the individual genes highly conserved across species, the order of the genes on the chromosomes is conserved as well. Moreover, the physical order of the genes on the chromosome correlates with their spatial and temporal expression patterns along the anteroposterior axis of the embryo.

Many studies have reported a link between deregulated homeobox gene expression and abnormal cellular proliferation, which implicates homeobox genes not only as development regulators, but also as potential protooncogenes and tumor suppressor genes. The downstream targets of homeobox genes are postulated to include extracellular matrix proteins, adhesion molecules and growth factors. Because these target genes are likely to be important for tumorigenesis as well as development, their misexpression may upset the delicate balance of cell proliferation, differentiation and apoptosis, thereby contributing to carcinogenesis.

Hox Genes and Leukemia

In addition to their functions during development, homeobox genes also play important roles in adult tissues. For instance, the HOX genes are expressed in specific patterns during lineage determination in ►hematopoiesis. HOX genes have been demonstrated to be important for normal blood cell formation; in addition, abnormal expression of HOX and other homeobox genes contributes to the development of leukemia and lymphoma.

A common mechanism by which abnormal gene expression contributes to leukemia is through translocation of two chromosomal regions, which may

produce fusion proteins with novel properties or impaired activities. For example, in human acute myeloid leukemia (AML) a translocation between chromosomes 7 and 11 fuses the nucleophorine gene NUP98 in frame with HOXA9. It is thought that the resulting chimeric protein is no longer able to interact with HOXA9 target genes. Another example of a homeobox translocation in leukemia is the fusion of PBX1 homeobox gene and the E2A gene. Normally, PBX1 forms transcriptionally active protein complexes with HOX proteins; its fusion with E2A alters such interactions, which is thought to direct homeoproteins to different targets, thereby inducing leukemogenesis.

Like PBX, other divergent homeoproteins interact with specific HOX proteins to potentiate or modulate their effects, and their genes are potential targets for deregulation in carcinoma. For example, it now appears that the MEIS1 homeobox gene is co-activated with HOXA9 in human myeloid leukemia. In addition, translocation of the MLL gene is a common event having been found to be fused to more than 25 other genes in leukemia. While MLL is not a homeobox gene, it is homologous to a Drosophila protein that is an important regulator of HOM-C genes. The leukemogenic MLL fusion proteins are thought to disrupt HOX gene expression in hematopoietic progenitor cells, thereby contributing to myeloid or lymphoid acute leukemias.

Homeobox Genes and Solid Tumors

A common feature of HOX gene expression in certain adult organs, such as kidney, lungs and colon, are the significant differences in expression pattern between normal and cancer tissue. For example, in the kidney HOXC11 is present in tumors but not in normal tissue. Conversely, HOXB5 and HOXB9 are normally expressed in the kidney but expression is often lost in tumors. Other HOX genes, such as HOXD4, are expressed in both normal kidney and in kidney tumors, although they express a different-sized transcript in the tumors versus the normal tissue. In each of these cases the significance of these differential gene expression patterns remains undetermined.

Similar observations have been made in the colon. Misexpression of some HOX genes (HOXA9, HOXB7 and HOXD11) is found in primary colon cancer and metastatic lesions originating from colorectal tumors. In addition, HOXB6, HOXB8, HOXC8 and HOXC9 are misexpressed at specific stages of colon cancer progression. And, while HOXB7 and HOXD4 are both expressed in normal and neoplastic colon, the size of the transcripts differ. Again, the significance of these observations for disease initiation or progression is unclear.

CDX1 and CDX2 homeobox genes are expressed in normal colon, while their expression is reduced in colon tumors. Interestingly, there appears to be an inverse correlation between the levels of protein expression and the severity of the dysplasia. This correlation, in conjunction with other data, suggests that expression of CDX1 and CDX2 is important for maintaining normal colon differentiation and that their loss of expression may promote a cancer phenotype. These observations have been supported by mutant mouse models in which loss of CDX genes results in colon tumors.

Misexpression of certain homeobox genes has also been implicated in prostate cancer. For example, the GBX2 homeobox gene is overexpressed in several metastatic prostate cell lines, suggesting a possible role in cancer progression. Conversely, loss of function of the NKX3.1 homeobox genes has been implicated in prostate cancer initiation. Notably, NKX3.1 maps to a hotspot that is frequently deleted in many prostate cancer samples, and mutant mice lacking NKX3.1 display prostatic epithelial dysplasia. Like, the CDX genes, these mutant mouse models provide excellent support for a functional role of these homeobox genes in cancer.

At this point much of the data is rather circumstantial and based on altered expression patterns. Nonetheless, the available evidence suggests that homeobox genes may provide an important link in understanding the delicate balance of development, cell-cycle control and cancer. The specific molecular events that occur between the misexpression of homeobox genes and the progression to cancer remains a topic of active investigation.

Homing Peptides and Vascular Zip Codes

Erkki Ruoslahti
Vascular Mapping Center, Burnham Institute for Medical Research at University of California, Santa Barbara, CA, USA

Definition

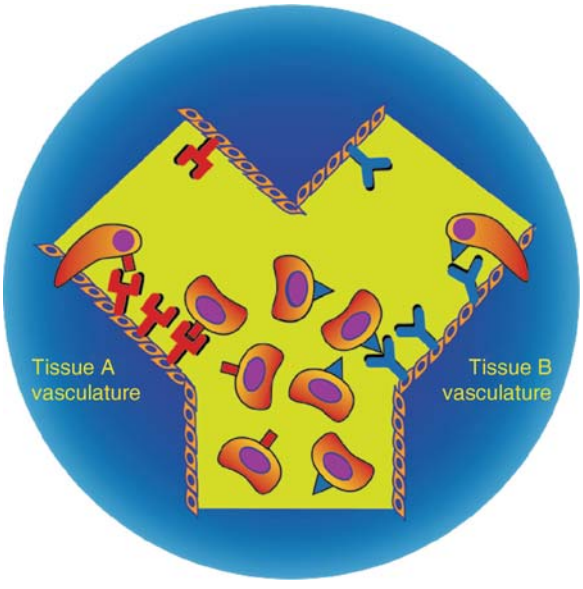
Vascular Zip Codes refers to tissue- and disease-specific molecular differences in vessels.

Characteristics

Peptide libraries displayed on phage can be screened *in vivo* to derive peptides capable of homing to selected target tissues through the circulation. The resultant peptides bind to endothelial (and possibly pericyte) surface proteins that are selectively expressed in the vasculature of individual tissues (Fig. 1). Homing peptides have been obtained for the vasculature in a large number of individual normal tissues that reveal a previously unsuspected degree of endothelial specialization. Screening for tumor homing has produced a collection of peptides that home to tumor vasculature. Atherosclerotic lesions have also been targeted in this manner.

The vessels of some normal organs have been known to express specific marker molecules, but *in vivo* phage has revealed an unprecedented degree of diversification in endothelia. The tissues for which vascular homing peptides have been described in the literature include brain, kidney, lung, heart, skin, pancreas, retina, intestine, muscle, uterus, prostate, fat tissue, and the adrenal gland. Success with so many tissues indicates that many, perhaps all, organs modify the endothelium of the vasculature, and that it is justified to refer to this heterogeneity as "vascular zip codes."

The vasculature of tumors is also specialized. Tumors depend on ►angiogenesis to grow and undergo ►metastasis. The actively growing tumor vessels are biochemically and structurally different from normal resting blood vessels. Integrins αvβ3, αvβ3, and α5β1as well as receptors for various vascular endothelial growth factors, are examples of molecules expressed at elevated levels in tumor blood vessels. Significantly, each of these receptors plays a critical role in angiogenesis. Other markers of tumor vasculature include an alternatively



Homing Peptides and Vascular Zip Codes.
Figure 1 Homing peptides direct phage binding to specific sites in the vasculature.

spliced form of fibronectin, endosialin, certain aminopeptidases, an anthrax toxin receptor, and intracellular proteins aberrantly expressed at the cell surface (nucleolin, annexin A1). Melanoma-associated proteoglycan NG2 is a marker of pericytes in tumor vessels.

Phage library screening *in vivo* has resulted in the identification of several peptide motifs that selectively direct phage into tumors. One of these motifs contains the sequence RGD (arginine-glycine-aspartic acid) embedded in a peptide motif previously shown to bind selectively to αv integrins. A number of additional tumor-homing peptides and receptors for some of them have been identified. Examples include peptides that recognize aminopeptidase N, cell surface nucleolin and clotted plasma proteins in tumor vessels. Homing peptides have also been used to show that the blood vessels of pre-malignant lesions differ from those of the corresponding normal tissue and from the vessels of fully developed tumors in that tissue. Further, lymphatic vessels in tumors differ molecularly from the lymphatics of normal tissues.

Biological Significance

Vascular zip code molecules are functionally important in the vessels that express them. A prime example is various angiogenesis markers, many of which are involved in the angiogenesis process. One known function of zip code molecules in the vessels of normal tissues is to serve cell trafficking. Tumor cells appear to make use of such molecules in homing to preferred sites of metastasis.

Clinical Significance

Coupling of drugs, ►apoptosis-inducing peptides, protein therapeutics, or imaging agents to tumor-homing peptides enhances the activity of these compounds in mice and lowers their toxicity. The homing peptides are also useful for the targeting of nanoparticles and potentially also cells to tumors. Delivery strategies similar to the tumor targeting should be applicable to targeting of pathological conditions other than tumors.

Homologous Recombination Repair

John Thacker
Medical Research Council, Radiation and Genome Stability Unit, Harwell, Oxfordshire, UK

Definition

Homologous recombination repair is a DNA repair process that includes the invasion of an undamaged DNA molecule by a damaged molecule of identical or very similar sequence. Resynthesis of the damaged region is accomplished using the undamaged molecule as a template.

Characteristics

Homologous recombination repair has been found in all organisms examined from bacteria to man. It has an important role in repairing DNA damage with high fidelity by correcting damage with the use of information copied from an homologous undamaged molecule. Sister chromatids (duplicated chromosomes following DNA replication) or the paternal and maternal copies of chromosomes provide the required homology (sequence identity or near-identity over a few hundred DNA base pairs). In somatic cells, if the homologues have some sequence differences the copying process may alter the sequence of the damaged chromosome to the same as that of the undamaged chromosome, potentially revealing mutations (►loss of heterozygosity). Additionally, recombination between repeat sequences may lead to high frequencies of sequence variation as seen in certain ►minisatellite sequences. In germ cells, homologous recombination is vital for the reassortment of chromosomes during meiosis to create genetic diversity in organisms.

Cellular Regulation

The proteins that mediate homologous recombination repair have functions and often structures that have been conserved in evolution. These proteins have to seek out homologous regions of chromosomes, exchange DNA strands, copy sequence from the undamaged strand and finally resolve the DNA structures arising from exchange. This complex series of events is best understood in bacteria but recently many of the components and functions of homologous recombination repair have been identified in mammalian cells. Evidence suggests that DNA double-strand breaks commonly trigger repair by homologous recombination; these breaks may be caused by the interaction of DNA with chemical radicals, produced as a consequence of cellular metabolism, or by external damaging agents such as ionizing radiations. Meiotic recombination is also driven by DNA double-strand breaks, but these are formed enzymatically at specific sites in DNA.

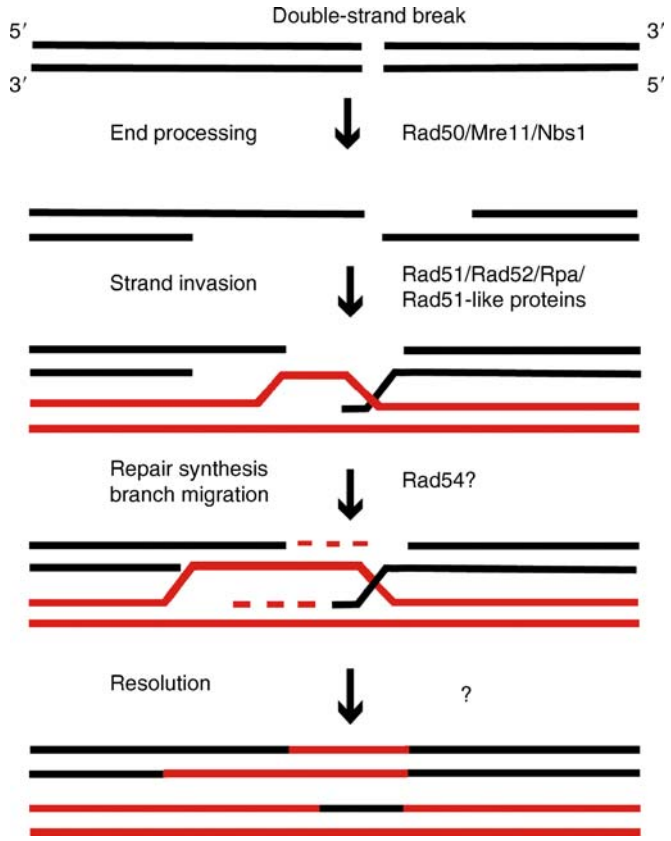
In bacteria, the ►RecA protein is central to homologous recombination through its ability to search for homologous regions of DNA and promote strand exchange. RecA forms a polymer on DNA to give a nucleoprotein filament, acting as a DNA-dependent ATPase. Filament formation occurs very rapidly on single-stranded DNA; in purified solutions the rate can approach 1,000 RecA monomers assembled per minute. RecA will also polymerize on double-stranded DNA but needs a short single-stranded gap to start the process, potentially targeting the protein to sites needing repair. On binding RecA and in the presence of homologous double-stranded DNA, strand exchange occurs to form junctions between the two DNA molecules. A number of other proteins are involved in the early stages of homologous recombination repair in bacteria; to generate the single-stranded DNA required for RecA-mediated strand exchange different proteins (RecBCD, RecJ, RecQ, or RecE) may be used depending on the initial state of the DNA. For example, during bacterial conjugation the RecBCD protein will unwind DNA from a break and cut the unwound DNA at a specific sequence-recognition site,

forming a long 3′ single-stranded region suitable for invading homologous double-stranded DNA. Other proteins assist in the loading of RecA onto single-stranded DNA and/or strand-invasion activities (RecF, RecO, RecR and single-stranded DNA binding protein). During recombination the junctions formed at sites of exchange migrate along the DNA molecules to complete gap repair, and finally the junctions must be cut to free the participating DNA molecules. Again some of these functions are supplied by different proteins, in this case either RuvABC or RecG, indicating the presence of more than one pathway for homologous recombination.

While much of the mechanistic detail of homologous recombination repair has been described in bacteria, it is clear that the principles of this mechanism have been retained by all organisms. RecA-like proteins have been found in eukaryotes; in particular the ►Rad51 protein from the yeast *Saccharomyces cerevisiae* (Rad51p) has both structural and functional similarities to RecA. Rad51p leads to the formation of nucleoprotein filaments on DNA and the promotion of homologous pairing and strand exchange reactions in vitro. However, in addition to Rad51p there are three other ►RecA/Rad51-like proteins in yeast; Rad55p, Rad57p and Dmc1p. Biochemical studies suggest that these RecA/Rad51-like proteins do not have redundant functions but rather have distinct roles to play in the early stages of repair. The Dmc1 protein functions exclusively in meiosis, with loss of its function leading to sterility, while the other RecA-like proteins operate in both mitosis and meiosis. Rad55p and Rad57p exist as a dimer and appear to act as a cofactor for the assembly of Rad51p onto single-stranded DNA. A three-protein complex (►Rad50p/►Mre11p/Xrs2p) has been found that promotes the early stages of homologous recombination but is also involved in a number of other repair and DNA maintenance functions; the Mre11 protein in particular has nuclease activities that may process double-strand breaks to form single-stranded regions associated with strand invasion. Other yeast recombination proteins, such as ►Rad52p and ►Rad54p, interact with Rad51p and promote Rad51-mediated strand exchange. Rad52p interacts with single-stranded DNA binding protein (Rpa) and facilitates the loading of Rad51p onto single-stranded DNA lacking secondary structure. Rad54p is structurally related to a family of putative DNA helicases but its precise function is unknown.

Rad51 also occurs in human cells. Despite millions of years of evolutionary divergence, the human protein is remarkably similar in structure and function to the yeast Rad51 protein. Additionally, six further RecA/Rad51-like proteins have recently been identified in humans. Two of these, Xrcc2 and Xrcc3, were found through their ability to complement the sensitivity of certain mammalian cell mutants to DNA-damaging agents. The remainder, including a protein closely similar to the yeast Dmc1, were found by searching for RecA/Rad51-like proteins in the human protein sequence databases. These proteins are presently the subject of intensive study but there is already evidence that some may function like the yeast Rad55 and Rad57 proteins in forming dimers that help Rad51 to function efficiently. The increase in the numbers of RecA/Rad51-like proteins in higher organisms also suggests that certain specialized functions may have evolved to deal with specific types of DNA damage or with tissue-specific recombination events. The yeast Rad50 and Mre11 proteins are also conserved in mammalian cells, but a structural homologue of the yeast Xrs2 protein has not been found in humans. Instead the Nbs1 (►Nijmegen breakage syndrome) protein (also known as p95 or nibrin), defective in the radiosensitive and cancer-prone human disorder Nijmegen breakage syndrome, appears to be a functional analogue of Xrs2. The features of Nbs1-deficient cells are very similar to those of ataxia-telangiectasia cells, and recently the human Mre11 protein has been shown to be mutated in individuals with an ataxia-telangiectasia-like disorder. Proteins similar to the yeast Rad52 and Rad54 have also been found in humans, and in the case of Rad54 it has been shown that the human protein is able to function in place of the yeast protein. The Rad52 protein is not so well conserved in structure between yeast and humans, although it is possible that another Rad52-like protein remains to be discovered in humans. In biochemical experiments, however, the human Rad52 protein has been shown to stimulate Rad51-mediated DNA-strand transfer reactions, probably at an early stage of Rad51 filament formation. Proteins involved in the later stages of recombination repair have yet to be identified in yeast or mammalian cells. The interactions of these proteins in the early stages of repair of a DNA double-strand break by homologous recombination are illustrated in the Fig. 1.

To study the effects of loss of recombination genes in mammals, several of the genes have been disrupted in mice (“knockout mice”). Surprisingly, disruption of Rad51 in mice is lethal for embryonic development and cells could not be cultured from tissue derived from the knockout animal. This finding suggests that the mammalian Rad51 gene has an important role in essential aspects of DNA metabolism or in development. It also suggests that the other Rad51-like genes cannot replace the function of Rad51 itself. Disruption of some of the Rad51-like genes in mice also leads to embryonic lethality, showing that these similarly have important functions in the organism. In contrast, knocking-out other recombination genes in mice is not necessarily lethal. Disruption of the meiosis-specific Dmc1 gene, as well as similar knockout



Homologous Recombination Repair. Figure 1 A model for the repair of a DNA double-strand break by homologous recombination in human cells. The main steps are noted to the left, and the proteins involved (where known) to the right. The Rad51-like proteins include Xrcc2 and Xrcc3. The broken DNA molecule (black) is processed to give long 3′ single stranded regions; these invade an undamaged homologous molecule (red). The branched-out undamaged strand acts as a template to repair the break. Repair synthesis is accompanied by branch migration. Resolution involves cutting the junctions between the two molecules; here it is shown without crossing-over, potentially leading to gene conversion where the homologous molecules differ in sequence.

experiments with the mouse Rad52 and Rad54 genes, yielded viable progeny. With the possible exception of the Rad52 knockout mouse, each has severe defects in aspects of mitotic and/or meiotic processes, consistent with roles in homologous recombination repair.

The potential importance of homologous recombination repair genes in genetic stability and in development has been highlighted by several recent discoveries. Firstly, it has been found that the human Rad51 protein interacts physically with the tumor-suppressor protein p53, which has a central role in the control of the cell cycle and apoptosis. Additionally, Rad51 knockout embryos survived longer in a p53-deficient background, suggesting at least part of the growth problems experienced by Rad51 knockouts arises from unrepaired damage triggering ►cell-cycle checkpoints leading to growth arrest. Equally important, Rad51 interacts with the breast cancer-susceptibility gene products ►Brca1 and ►Brca2. Disruption of the Brca1 or Brca2 genes in mice gives embryonic lethality and shows a similar elevation of chromosomal aberrations as that found in Rad51-disrupted cells. The link between the Brca proteins and homologous recombination repair has been extended by showing that Brca1 and Brca2-deficient cells have a large reduction in ability to repair double-strand breaks in homologous substrates integrated into the genome. Brca1 is phosphorylated in response to DNA damage and this event is dependent on the protein kinase mutated in the cancer-prone disorder ataxia-telangiectasia (Atm). Atm may act as a sensor of DNA damage, especially double-strand breaks, and there is evidence supporting a model in which Brca1 phosphorylation triggers the activity of Rad51 and Brca2 to initiate homologous recombination repair. However, Brca1 also associates with the human Rad50 protein and has a role in the ►transcription-coupled repair pathway, so its action is likely to be broader than this model suggests.

The role of recombination proteins in influencing development in multicellular organisms has been illustrated by recent findings in the fruit fly, Drosophila melanogaster. Mutations in the spindle class of genes lead to patterning defects in the oocyte and embryo, apparently due to mis-localization and/or failure to accumulate normal levels of oocyte signaling molecules. The cloning and sequencing of these genes showed that they are homologues of RAD51 or RAD54. Mutation in these genes leads to the accumulation of DNA damage, which triggers a meiotic recombination checkpoint that down-regulates some of the genes essential for embryonic development. Interestingly, oocytes that are mutant for both spindle-class genes and the Drosophila homologue of ATM (mei-41) can bypass this meiotic arrest and show normal developmental patterning, suggesting that loss of ability to signal damage fails to trigger this checkpoint. The downside of this checkpoint loss is that DNA damage may be carried through into later cell divisions, resulting in genomic instability.

The mechanisms of homologous recombination repair are still being investigated, but it is clear that this repair pathway is of considerable significance in all organisms. Other pathways can repair certain types of DNA damage; for example, in mammalian cells, ►non-homologous end joining is an alternative way to repair DNA double-strand breaks. However, simple end joining of broken DNA is prone to loss of sequence (DNA deletion) at the damage site, while homologous recombination repair can rejoin breaks with high fidelity. In bacteria it is clear that a major role of homologous recombination repair is to sort out problems arising during DNA replication, in particular where a replication fork stalls due to damage in its path. In yeast and mammals there is also evidence that homologous recombination proteins are particularly active during DNA replication. Additionally, certain types of DNA damage such as ►DNA interstrand cross-links formed by agents such as mitomycin-C may be resolved only by the homologous recombination repair pathway. In support of this idea, cell lines lacking homologous recombination repair genes are very sensitive to mitomycin-C and other DNA cross-linking agents.

Clinical Relevance

Loss of homologous recombination repair leads to unrepaired damage in the genome, which in turn can give rise to genomic instability. Both Mre11 and Nbs1 have been found to be associated with rare human disorders with complex phenotypes, including radiation sensitivity and cancer-proneness (ataxia-telangiectasia and Nijmegen breakage syndrome, respectively). The association of homologous recombination repair proteins with p53 and the Brca proteins also suggests that this repair pathway has potentially important connections with predisposition to cancer. The links are strongest with breast cancer, through the Brca proteins and possibly the Atm protein. Additionally, loss of one of the human Rad51-like proteins (Rad51L1) has been associated with uterine leiomyomas.

Hormonal Carcinogenesis

Sushanta K. Banerjee
Cancer Research Unit, Research Division, VA Medical Center, Kansas City, MO
Division of Hematology and Oncology, School of Medicine, Kansas University of Medical Center, Kansas City, KS, USA

Definition

The process by which a normal cell is transformed into a cancer cell is called "Carcinogenesis". When the carcinogenic event is either potentiated or promoted by hormones (i.e., natural or synthetic) (►diethylstilbestrol, estradiol) is considered as "Hormonal Carcinogenesis" (►Estrogenic hormone and cancer) (►Hormones and Cancer).

Characteristics

There are three major classes of hormones based upon their chemical structures. These are (i) peptide/protein hormones (e.g., leptin, angiotensin II, interleukins, ACTH, gastrin and others), (ii) amino acid or fatty acid-derived hormones (e.g., epinephrine, acetylcholine, prostaglandins and others, and (iii) steroid hormones (e.g., estrogen, progesterone, testosterone and others). Each hormone has its unique features and plays specific role under normal physiological conditions. Normally, it requires very minute amounts to exert its biological function through its receptor or other signaling pathways. However, excess or alter form of a hormone or its receptor sometimes exhibits carcinogenic behavior and distort the regulated state of the cells, which ultimately activate the carcinogenic switch or growth of the tumor or aggressive properties of a tumor or all the above events. The ideal example of carcinogenic hormone is natural or synthetic estrogens such as 17β-estradiol (E2) and diethylstilbestrol (DES). In animal system (i.e., mice, rats and hamsters), these two estrogenic compounds induces tumors in various estrogen-depended organs or tissues and the incidence rate is 100%. Moreover, a strong links between estrogens and the development cancer in human have been evident over 300 years ago that showed a protective effect of pregnancy on the development of breast cancer and also underscored that the higher rates of breast cancer among catholic nuns. This finding was reconfirmed by several epidemiological studies that showed a single full-term pregnancy reduces the risk of development of breast cancer by 50% or more. Subsequent births, especially at an early age, further reduce the risk. Moreover, breast cancer risk in the presence of estrogen can be determined by several factors including early menarche, late menopause and obesity in postmenopausal women.

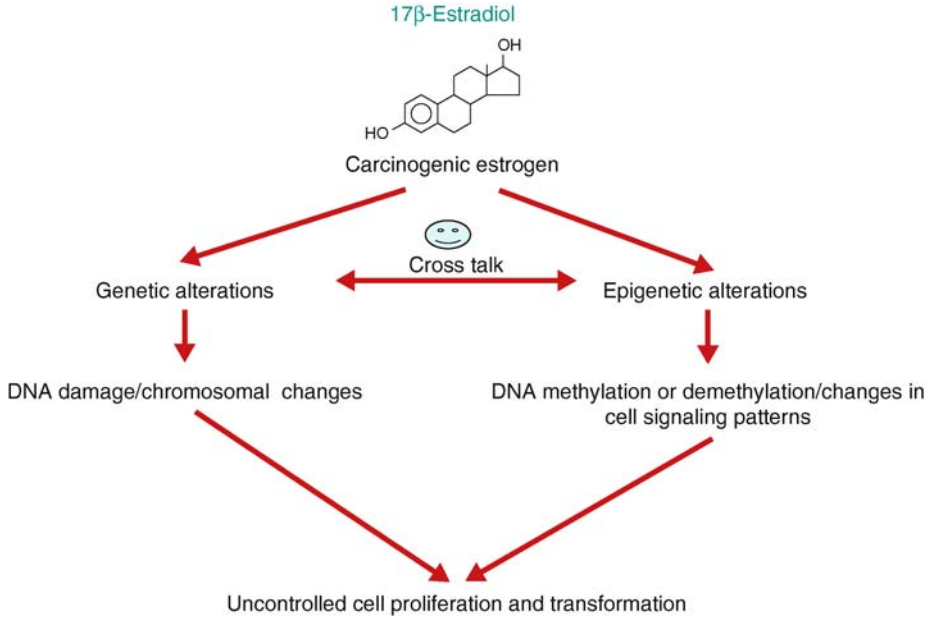
Several cancers have been found to relate with the status of carcinogenic hormones in the body. For instance, breast or prostate cancer development may depend on the supply of estrogen or androgen, respectively, or their cognate receptors in the tumor cells. Therefore, the removal of the source glands (ovary, testis or pituitary) or targeting the receptors by antagonists (i.e., tamoxifen) of the hormones is used to prevent the growth of these tumors.

Mechanisms

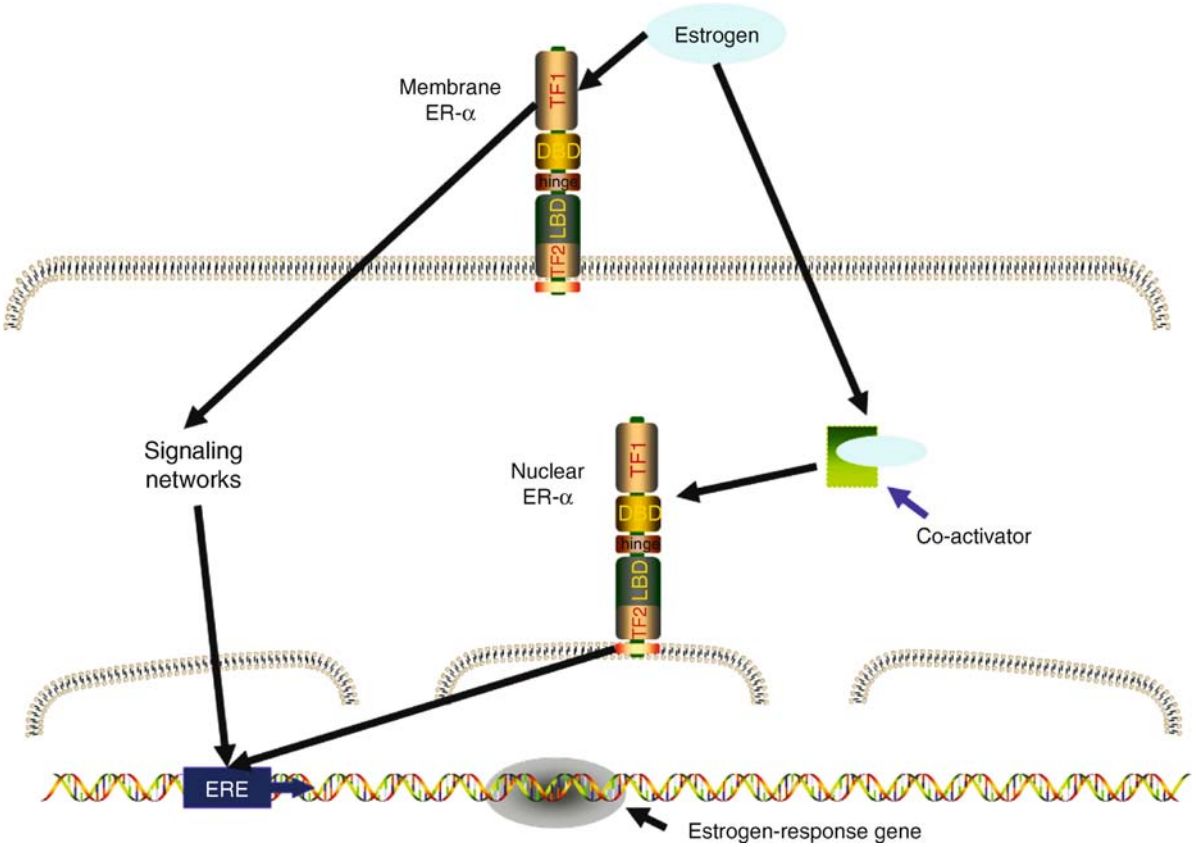
Cancer is a mixed tissue of abnormal cells, and the etiology of this disease remains uncertain. After decades of studies it has been apparent that cancer begins with multiple genetic and epigenetic insults that included mutations of regulatory genes, activation of oncogenes or inactivation of tumor suppressor genes. These molecular insults facilitate the cells to grow abnormally, gain motile behavior and other features needed to grow the cancer cells and invade to distant parts of the body. These fatal abnormalities are probably built up in the normal cells through endogenous or exogenous carcinogens.

Estrogens have been used for last several decades to explore the molecular mechanisms of hormonal carcinogenesis by several investigators. These studies found chronic exposure of estrogens involve interplay and cross-talk between genotoxic and epigenetic changes that eventually lead to an uncontrolled cell proliferation and cellular transformation (Fig. 1). The genetic alterations are accomplished by estrogens through the formation of DNA adducts and chromosomal abnormalities including chromosome breaks, aneuploidy and telomeric association, while epigenetic alterations are potentiated through DNA methylation/demethylation or through the alterations in cell signaling molecules such as WISP-2/CCN5 and others. These epigenetic changes through the molecular cross-talk may precede genetic changes in normal or premalignant cells and foster the accumulation of additional genetic and epigenetic hits.

How estrogens induce genetic and epigenetic abuses in some cells? Despite decades of investigations, an absolute answer of this question is elusive. Because estrogen-induced carcinogenesis can be blocked by estrogen antagonists (i.e., Tamoxifen or ICI 182,780) or estrogen withdrawal, the estrogen receptors (nuclear or cytoplasmic) may be involved in estrogen-induced carcinogenic switch (Fig. 2). The normal physiological effects of estrogen are usually mediated through two classical estrogen receptors, estrogen receptor-alpha (ER-α) and estrogen receptor-beta (ER-β). These receptors are encoded by two separate genes though they have some common domains and have similar binding affinity with the ligands. Nevertheless, these two receptors play redundant roles in estrogen signaling. In cells where both



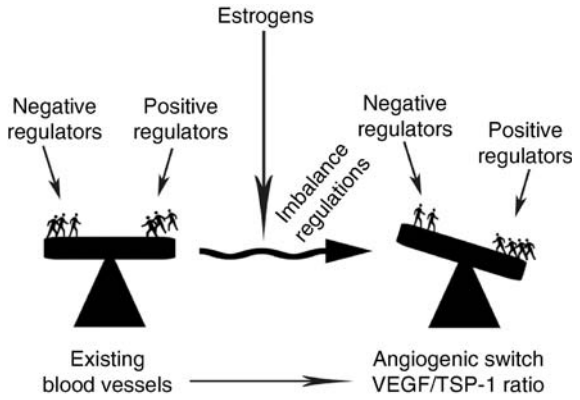
Hormonal Carcinogenesis. Figure 1 Putative Pathways involved in hormonal carcinogenesis. Carcinogenic estrogens-induced neoplastic transformation is mediated through genetic and epigenetic abuses in the target tissues or cells. Presumably genetic and epigenetic changes by carcinogenic hormones are interdependent and cross-talk or side-talk with each other to enhance uncontrolled proliferation and genomic instability which are the hallmarks of carcinogenic switch.



Hormonal Carcinogenesis. Figure 2 The role of nuclear and cytoplasmic receptors in hormonal carcinogenesis. The endogenous or exogenous estrogen binds with either cytoplasmic estrogen receptor or nuclear receptor and subsequently activates estrogen-response genes associated with cellular proliferation and transformation events.

receptors are expressed, the estrogen responsiveness is determined by the ER-α: ER-β ratio. The studies shown that isoforms of ER-β heterodimerize and inhibit the activity of ER-α, which suggest a modulatory role of ER-β. In hormonal carcinogenesis, participations of these two receptors are considered to be crucial. However, some investigators believe that non-receptor pathways are also involved in hormonal carcinogenesis. Like estrogens, other hormones which are having carcinogenic potential exhibit identical effect on the cells for the induction of transformation.

The formation of new blood vessels surrounding the tumors from preexisting blood vessel, which is also known as tumor angiogenesis, is the hallmark of cancers. It is necessary for increased nutrient and oxygen supply to the tumor cells. This process is controlled by several positive and negative angiogenic factors including vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF) and transforming growth factor-alpha (TGF-α), TGD-β, thrombospondin-1 (TSP-1) and statin (►Antiangiogenesis). Some of these angiogenic factors such as PDGF and TGFs are proteins/peptide hormones. Normally, angiogenesis is a highly controlled



Hormonal Carcinogenesis. Figure 3 Angiogenic switch during hormonal carcinogenesis. Estrogen plays dual roles in tumor angiogenic switch. It activates positive regulator of angiogenesis and simultaneously silenced the expression of negative regulator.

process. Uncontrolled and persistent changes in angiogenic process are occurred at different stages of tumor progression. This phenomenon is occurred by imbalance expression of positive and negative angiogenic

regulators. Multiple studies have shown that tumor angiogenic switch can be regulated by steroid hormones including estrogen and progesterone. These hormones modulate both positive and negative angiogenic regulators for angiogenic switch (Fig. 3).

Hormone-Responsive Element

Definition

A specific *cis*-regulatory DNA sequence for a certain hormone that acts by binding to a receptor. This hormone–receptor complex can act as a transcription factor by binding to the hormone responsive element.

Hormones

Rekha Mehta, Jayadev Raju
Toxicology Research Division, Bureau of Chemical Safety, Food Directorate, HPFB, Health Canada, Ottawa, ONT, Canada

Definition

Hormones are complex chemical messengers that bind with high affinity to specific cellular receptors to activate single or multiple ►signal transduction pathway(s) leading to growth, ►differentiation, embryogenesis or other biological processes. More than one hormone may work in concert to fulfill a physiological function. Hormones, through their capacity to influence cell growth and differentiation, may further modify the response of the body to carcinogens, the biological behavior of established tumors, and overall ►cancer risk. Hormones, therefore, play an important role in both the genesis and treatment of cancer.

Characteristics

Hormone-dependent malignancy has been most extensively studied in steroid hormone responsive organs. The steroid hormones, androgens, estrogens (►Estradiol; estrogenic hormones and cancer) and progestins (►Progestins and cancer), are implicated as key regulators in the development and the cancer process in the breast (►Breast cancer), prostate (►Prostate cancer, clinical oncology), ovary (►Ovarian cancer) and endometrium (►Endometrial cancer). More recently, however, hormonal influences in cancer are also becoming apparent in steroid hormone independent organs such as the colon. Likewise, non-steroid hormones participate, directly or indirectly, as modifiers of cancer, not only in endocrine system responsive organs, but also at other sites.

Mechanisms

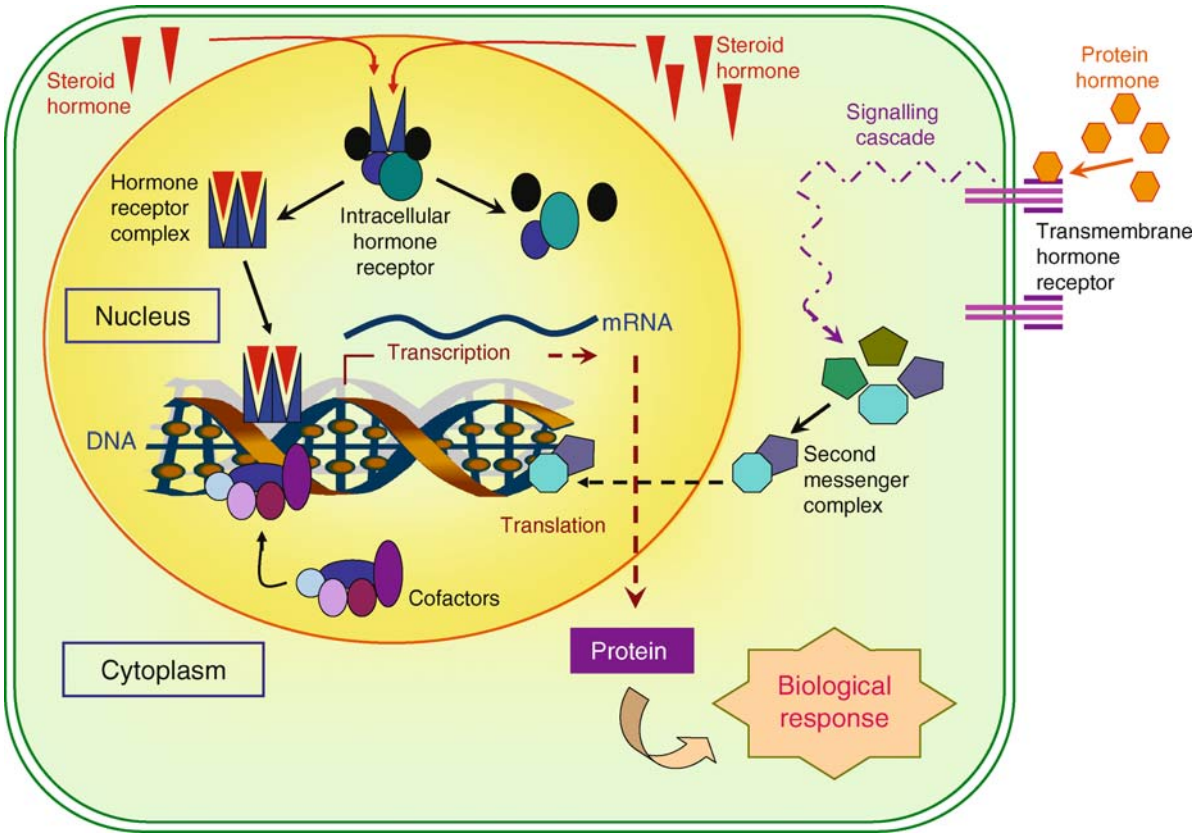
The precise mechanisms of hormonal influences on cancer are being elucidated. In the context of the multistage theory of ►carcinogenesis (►Multistep development), it has been generally recognized that the principal effects of a given hormone are during the ►cancer promotion stage, occurring predominantly in tissues where normal cellular growth and function are regulated by the specific hormone. Single or multiple hormones may interact to modify carcinogenesis. The tumor promoting effects of hormone(s) may be a result of indirect interaction of the hormone with the genome, culminating in epigenetic (►Epigenetics) consequences. Recent evidence, however, implicates hormonal modulation during the ►cancer initiation stage as well by direct interaction of certain hormonal metabolites with the genetic material.

The Receptor Concept

A receptor-mediated mechanism for hormone action during normal physiological functions is now widely accepted (Fig. 1). Hormones play a role as ligands that interact with specific receptors: the protein type binds to trans-membrane receptors, while the steroidal type binds to intracellular receptors. In the case of a protein hormone, a cascade of receptor-ligand mediated cytoplasmic responses is triggered leading to activation of post-receptor secondary messengers. On the other hand, a steroid hormone on entry into the cell forms cytoplasmic – receptor complexes that bind to DNA as a dimer. In both cases, recruitment of other co-factors ultimately regulate the activities of the cell's general transcription apparatus assembled at the gene's promoter. The mRNA produced is eventually translated into proteins which elicit and achieve a complex array of cellular responses such as alterations in growth and differentiation of the target tissue.

An interplay of a variety of factors can interfere with the normal development and function of the ►hormone receptors in target tissues, culminating in pathological conditions such as cancers. Thus, hormone receptors may be activated non-specifically by hormone-like endogenous metabolites or xenobiotic (►Xenobiotics) ligands found as dietary constituents (e.g. ►phytoestrogens), environmental pollutants, or food contaminating chemical or veterinary drug residues. Inherited genetic polymorphisms or mutations in hormone receptors and/or hormone metabolizing enzymes may further affect normal hormonal function.

In the case of steroid hormones, estrogens function as growth promoters through the nuclear receptors, estrogen receptor-α (ER-α) (►Estrogen receptor) or ER-β by signal transduction-mediated increase in cellular proliferation, decrease in ►apoptosis and regulation of growth factor production. ER-α and ER-β are products of two different genes, and ER-α may predominate in breast tumors. Likewise, androgen action on physiological processes such as cellular differentiation, secretory function, metabolism, morphology, proliferation and survival, is exerted in target tissues via binding to another nuclear receptor transcription factor, the ►androgen receptor (AR). Testosterone, produced mainly in the testis, is able to directly bind to and activate the AR. However, the androgens produced in the adrenal glands, androstenedione and dehydroepiandrosterone, are converted to testosterone in peripheral tissues prior to their interaction with the AR. Similarly, in the prostate, testosterone is first metabolized to a more potent ligand dihydrotestosterone, before its interaction with the AR. The effects of progestins as



Hormones. Figure 1 Schematic presentation of two types of receptor mediated hormonal action. Hormone binding to a trans-membrane or an intracellular receptor activates a cascade of events which eventually regulate the cell's transcription and translation machinery to elicit a complex array of functional responses by the cell.

well are mediated through two isoforms of progesterone receptor in a tissue-specific manner.

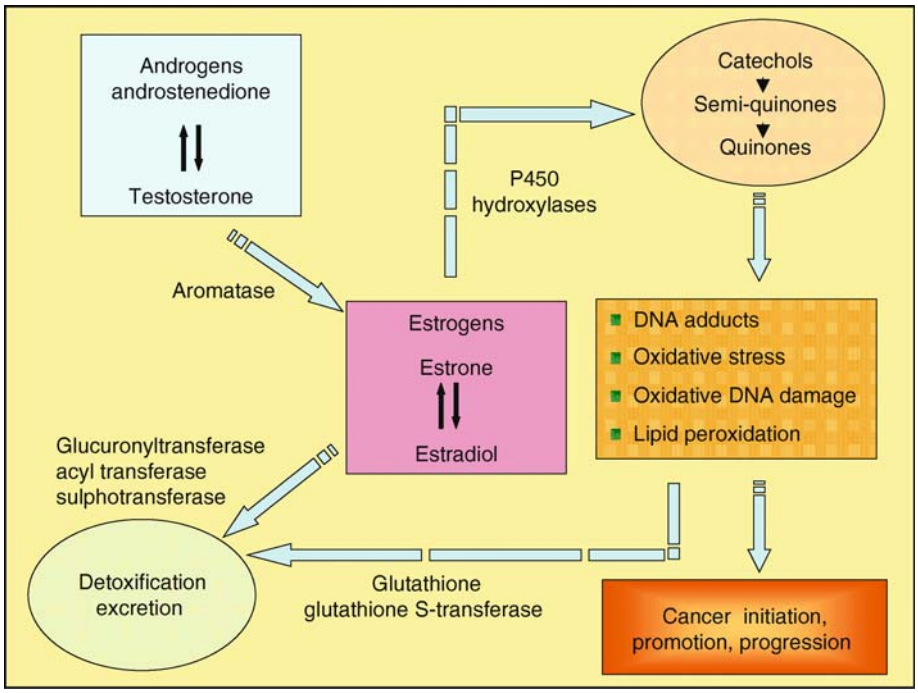
Prolactin exhibits dual characteristics of a circulating hormone and a ►cytokine, both of which utilize receptor-mediated mechanisms. In its role as a cytokine, prolactin is secreted and regulated in extrapituitary sites where its binding to cytokine superfamily receptors not only can promote cell proliferation and survival, but also increase cell motility, suppress apoptosis, upregulate BRCA1 (►Breast cancer genes BRCA1/BRCA2), induce both ER-positive and ER-negative tumors, increase tumor growth rates (►Prolactin and cancer), support tumor vascularization and enhance tumor metastases.

Insulin and ►insulin-like growth factors (IGF-I) likewise act through a receptor (►Insulin receptor) -mediated mechanism to regulate energy metabolism. The bioactivity of IGF-I is increased through its enhanced synthesis and by a decrease in several of its binding proteins (IGFBP; IGFBP-1 and -2). Insulin and IGF-I both stimulate ►anabolism based on the amount of available energy and the necessary substrates such as amino acids. The anabolic signals by insulin or IGF-I can promote tumor development by inhibiting apoptosis, and by stimulating cell proliferation. Furthermore, both insulin and IGF-I stimulate the synthesis of sex steroids, and inhibit the synthesis of sex hormone-binding globulin, a binding protein that regulates the bioavailability of circulating sex steroids to tissues. Receptor-mediated mechanisms also intercede the action of thyroid hormone, and the gastrointestinal hormones gastrin, cholecystokinin, neurotensin and ►gastrin-releasing peptide.

Hence, the receptor concept provides one common mechanism whereby a steroid or a non-steroid hormone may potentially mediate or modulate cancer under the conditions that an aberration in its receptor-mediated signal transduction system favors an enhancement or prevention of neoplasia.

Endogenous Metabolic Activation of Steroids

A second mechanism of action implicated in hormonal modification of carcinogenesis involves endogenous metabolism of the steroid hormones, estrogen and androgens by tissue-specific enzymes (Fig. 2). A similar mechanism for non-steroid hormones has not been described so far. Estrogen is biotransformed by several ►cytochrome P450 isoforms and various peroxidases



Hormones. Figure 2 Metabolic activation of steroid hormones. Aromatase-mediated metabolism of androgens to estrogens, and further oxidative metabolism of estrogens lead to genotoxic effects that may contribute to cancer induction.

to produce estrogenic metabolites that may be protective through their antioxidant properties or growth and ►angiogenesis inhibitory activities. On the contrary, the more reactive quinone metabolites of estrogen may directly form ►adducts with DNA and/or cause oxidative damage to lipids and DNA (►Oxidative DNA damage) through redox cycling processes that produce ►reactive oxygen species (ROS). Increased production of ROS may further alter regulation of gene expression through effects on transcription factor function. The androgens testosterone, androstenedione and dehydroepiandrosterone may act as additional cancer modifiers *in situ* in their respective target organs when they are metabolized first to estrogens by aromatase, another cytochrome P-450 enzyme, followed by their metabolic activation to quinones.

Epidemiology and Animal Studies

Steroid Hormones

Breast cancer risk is associated with prolonged exposure to predominantly estrogens. Thus, increased *in utero* exposure to estrogens, early onset of ►menarche, late ►menopause, hormone replacement therapy and postmenopausal obesity enhance breast cancer incidence. Androgens, through their metabolism to estradiol by the aromatase enzyme expressed in epithelial cells of both normal and neoplastic breast, act synergistically with estrogens to directly stimulate tumor growth and increase breast cancer risk in postmenopausal women. Androgens are further implicated as a causative factor in prostate cancer induction, though with limited epidemiological evidence (►Epidemiology of cancer). Human plasma levels of androgens do not always correlate with prostate cancer susceptibility. Animal studies, however, support a strong tumor promoting role for androgens acting via androgen receptor-mediated mechanisms, and following a tumor-initiating stimulus. Exposure of the fetus to higher androgen concentrations is a potential ►risk factor for prostate cancer in later life. However, as in the breast, malignant changes to the prostate gland depend upon both androgenic and estrogenic responses that are accomplished through aromatase mediated conversion of testosterone to estradiol and via estrogen receptors found in both human and rat prostate. Similar synergistic links between androgens and estrogens have been reported in uterine cancer in experimental animals, and clinically, in ovarian and endometrial cancers.

Estrogen receptors are likewise expressed in several ►gastrointestinal cancers such as those of the esophagus, gallbladder, stomach and colon (►Colon cancer). Estrogens may further interact with additional growth factors and polyamines to modulate growth and progression (►Cancer progression) of colorectal tumors. However, the epidemiological evidence for a role for estrogens in colorectal cancers is currently inconsistent.

Loss or down-regulation of progesterone receptor observed in ovarian carcinoma, and antiproliferative

and apoptotic effects of progesterone in the ovary, suggest that progestins protect against ovarian cancer. On the contrary, synthetic progestins, globally used as contraceptive agents, are implicated as tumor promoters or ►cocarcinogens in rodent liver, pituitary and mammary gland.

Prolactin

The neuroendocrine hormone prolactin may play a role in several types of cancers in reproductive and non-reproductive tissues. Its possible role in breast cancer has been widely considered because of its physiological action in the stimulation of mammary gland development and differentiation during puberty, pregnancy, and lactation. While experimental data support a relationship between increased prolactin levels and breast cancer, epidemiological data is discrepant.

Insulin

Physiologically, the growth hormone insulin-like growth factor-I (IGF-I)-axis is an important modulator of growth and development, as well as a regulator of a wide range of biological functions. Their potent mitogenic and anti-apoptotic effects, for example, play a critical role in the development of the breast, and in regulation of rapidly renewing epithelial cell populations such as those in the colon. In cancer patients, increased insulin production is commonly observed during cancer development. Some types of tumors produce constituents that stimulate insulin secretion by the pancreas, while other more aggressive tumor types produce insulin ectopically. Global variations in cancer incidence rates provide evidence for diet and associated factors such as nutritional energy balance, macronutrient composition of the diet, physical activity and body size (►Obesity and cancer risk) as among the most important lifestyle factors that influence cancer risk (►Nutritional status and cancer). Recent studies further suggest that these dietary and related factors may influence the risk of cancers of the colon, pancreas, endometrium, breast, ovary and prostate by affecting the levels of circulating serum insulin and increasing the bioavailability of IGF-I. IGF-I has been positively associated with the risk of colorectal cancer in human studies. *In vitro,* IGF-I elicits mitogenic and anti-apoptotic actions on colorectal cancer cells.

Gastrointestinal Hormones

The gastrointestinal hormones (►GI hormones), gastrin, cholecystokinin, neurotensin and gastrin-releasing peptide (►Gut peptides), are localized mainly in the pancreas and in the mucosa of the gastrointestinal tract from the stomach to the rectum. Certain gastric (►Gastric cancer), pancreatic (►Pancreas cancer, basic and clinical parameters) and colorectal cancers possess specific G-protein-coupled receptors through which the gastrointestinal hormones stimulate cancer cell growth. Gastrointestinal hormone receptors have also been noted in breast, lung and prostate cancers where they may modify neoplastic growth and aggressive behavior of the lesions.

Thyroid Hormones

An association between thyroid hormones and cancer has been considered extensively with conflicting results. In experimental models, perturbations in thyroid hormones affect estrogen and prolactin secretion, and cause pathological alterations in the ovary, endometrium and breast that are consistent with precancer. However, clinical evidence for the role of thyroid hormones in cancers in these organs is not definitive due to difficulties in differentiating thyroid hormone-induced cellular alterations from neoplasia-induced cellular atypia.

Hormonal Management of Cancer

Recognition of the role of estrogens in the stimulation of breast tumor growth has led to the development of several therapeutic endocrine agents. In premenopausal women ►gonadotrophin-releasing hormone (GnRH) agonists suppress ovarian oestrogen synthesis and reduce estradiol close to postmenopausal levels. Inhibition of aromatase, the terminal step in estrogen biosynthesis, provides another way of treating hormone-dependent breast cancer in older patients. Currently available ►aromatase inhibitors are effective in the management of hormone-dependent breast cancer in post-menopausal women failing antiestrogen or tamoxifen therapy (►Tamoxifen) in locally advanced or metastatic disease. GnRH agonists used in combination with an aromatase inhibitor suppress estrogen levels even further. Similarly, hormone therapy for prostate cancer has evolved from the use of estrogens to GnRH agonists. Recently, investigational GnRH antagonists have been discovered that cause the inhibition of luteinizing hormone production, eventually leading to a suppression of testosterone and dihydrotestosterone on which continued growth of prostate cancer cells is dependant. Steroid hormone receptors are another well established therapeutic target in cancer, and drug development has continued to focus on agents that either block steroid hormone production or bind to and modulate their receptors. The implication of insulin and IGF-I as additional factors in cancer modulation may further advance development of newer cancer prevention drugs that restore sensitivity to insulin and reduce hyperinsulinemia.

HOX

Definition

The HOX homeodomain (HD) proteins are DNA-binding transcription factors that are key regulators of development and hematopoiesis. In vertebrates, there are 39 *HOX* genes that are organized into four chromosomal clusters (*HOXA*, *B*, *C* and *D*), which can be classified into 13 paralogous groups based on their extensive sequence homology within the HD and their relative chromosomal locations within a cluster. *HOX* genes are expressed at various stages during hematopoietic development. Perturbation of orderly HOX gene activation and inactivation results in hematological abnormalities. Increased expression of HOXA and B genes has been documented in human acute myeloid malignancies.

►NUP98-HOXA9 Fusion

HOXA5 gene

Definition

Is part of the A cluster of *HOX* genes on chromosome 7 and encodes a DNA-binding transcription factor that may regulate gene expression, morphogenesis, and differentiation. ►Methylation of this gene may result in the loss of its expression and, since the encoded protein up-regulates the tumor suppressor p53, this protein may play an important role in tumorigenesis.

►Pleiotrophin

Definition

hSNF5/INI1 is a member of the highly conserved ►SWI/SNF complex, involved in the ATP-dependent ►chromatin remodeling. hSNF5/INI1 acts as a ►tumor suppressor gene.

Characteristics

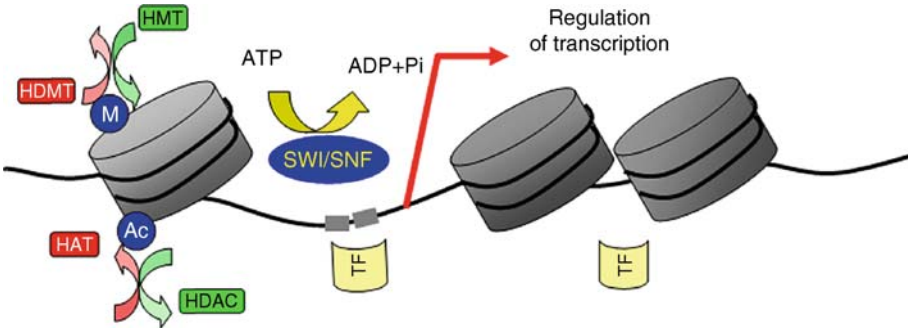
The Chromatin Remodeling and the SWI/SNF Complex

In the nucleus of eukaryotic cells, DNA is wrapped around histones, constituting a dense histone–DNA complex referred to as nucleosomes. The closed conformation of DNA in nucleosomes precludes the binding of transcription factors to their target promoters. By regulating the compaction degree of nucleosomes, cells can allow interactions between promoters and transcription factors. This regulation relies on two main mechanisms: (i) stable covalent modifications of histones, including actelyation, methylation, ubiquitination, etc. (ii) ATP-hydrolysis-dependent chromatin remodeling, capable to affect the spatial organization of the chromatin and the stability of nucleosomes in a dynamic way. The SWI/SNF complex, first described in *Saccharomyces cerevisia*, is the prototype of ATP-dependent chromatin remodeling complex. Approximately 5% of the genome is affected by the SWI/SNF-dependent regulation of the transcription, either by induction or by repression (Fig. 1).

The SWI/SNF complexes are conserved throughout the evolution. In humans, chromatography has lead to identify two fractions of SWI/SNF complexes, PBAF or SWI/SNF-B, characterized by the presence of polybromo protein, and BAF or SWI/SNF-A, which may be the actual homolog of yeast SWI/SNF. The BAF complexes are variably composed of approximately ten subunits, in a cell-type-specific manner. However, all BAF complexes contain one of the two ySnf2 human homologs, hBRM or hBRG1 (Fig. 2). Either of them brings the ATPase activity of the complex. In vitro, hBRG1 and hBRM are sufficient to induce a chromatin remodeling. Nevertheless, the addition of other members of the core complex increases the efficiency of the remodeling. Furthermore, the integrity of the entire complex seems to be indispensable in vivo. Among the BAF proteins, at least three are ubiquitously expressed, demonstrating a critical role in the function of the complex: BAF155, BAF 170 and BAF47. Altogether, these indispensable subunits constitute the core complex of SWI/SNF. The latter, BAF47, maintains the stability of the whole complex in yeasts but might not play such a role in mammals. Since its interaction with the HIV1 integrase IN was its first role identified, it has been called "INI1."

hSNF5/INI1 Gene and Protein Structures

In human, hSNF5/INI1 gene is located in 22q11.2. It is composed of nine exons and spreads over ~50 kb (Fig. 3a). An alternative splicing in exon 2 produces two



hSNF5/INI1/SMARCB1 Tumor Suppressor Gene. Figure 1 Chromatin remodeling and regulation of transcription. The chromatin is wrapped around histones. Acetyl or methyl radicals are added or removed by histone acetyltransferases (HAT) or histone deacetylases (HDAC) and histone methyl transferases (HMT) and histone demethylases (HDMT) respectively. ATP hydrolysis (ATP = ADP + Pi) also participates to a direct chromatin remodeling through the ATPase activity of remodeling complexes such as SWI/SNF, regulating the accessibility of the chromatin to transcriptions factors (TF).

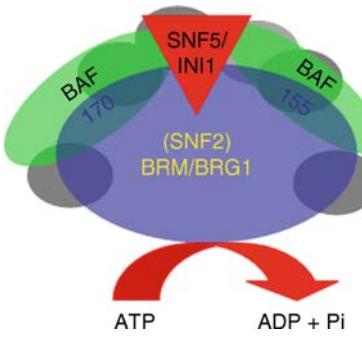
different transcripts of 1155 and 1128 nucleotides. hSNF5 protein has strong homologies with other SWI/SNF proteins in various species (yeast Snf5, *Drosophila* dSNR1, *Caenorhabditis elegans* CeSnf5). The homology domain encompasses 193 amino acids and two highly conserved repeated sequences, Rpt1 and Rpt2 (Fig. 3b). This repeated domain brings a nuclear export signal, consistent with the subcellular localization of the protein. Rpt1 directly interacts with several partners, such as HIV IN, c-MYC, hBRM or ALL1. A coiled-coil domain at the C-terminal extremity plays a role in the binding to interaction partners.

Biological Roles of *hSNF5/INI1*

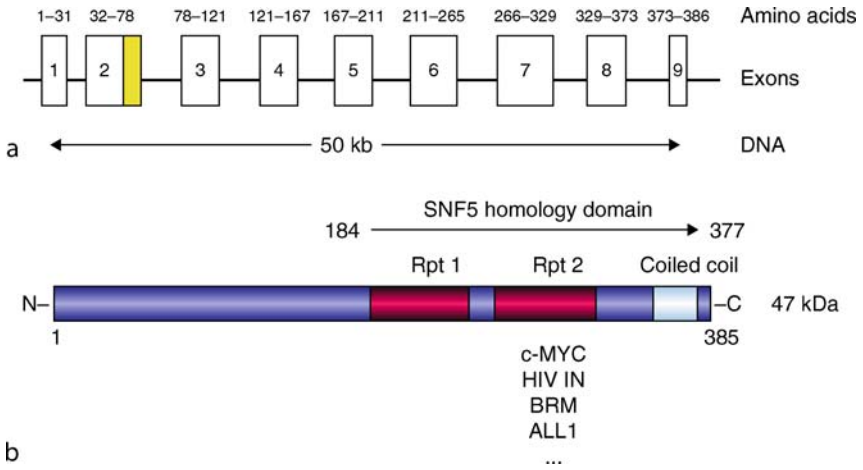
Studies of Snf5 inactivation in cell and mouse models have brought numerous insights on Snf5 biological functions. First, there are some strong evidences of Snf5 being involved in cell survival. Indeed, complete inactivation of Snf5 leads to early embryonic lethality and decreases cell survival in vitro. In MEFs, loss of Snf5 also impairs the cell cycle progression and, consistently, alters the expression of various Rb-E2f-responsive genes. Furthermore, the defect of Snf5 enhances sensitivity to DNA damage and subsequent apoptosis through a p53-dependent manner. These paradoxical roles in survival and apoptosis might be time-, cell-type- and stress-dependent. However, the most relevant observation is that conditional inactivation of Snf5 leads to the development of a tumor in 100% of the mice. Moreover, the short median delay of 11 weeks before tumor development is rarely observed with the inactivation of a single gene, and indicates a tremendously potent tumor suppressor role for SNF5.

To which extent the tumor suppressor function of SNF5 depends on SWI/SNF remains unclear. However, reexpression of hSNF5/INI1 in rhabdoid cells has demonstrated its critical role in the control of the ►G1–S transition. This effect could rely either on a repressive effect upon ►Cyclin D1 expression, or on a strong induction of ►p16/INK4a. Interestingly, a functional RB protein is required for INI1-dependent cycle control, whereas INI1 is dispensable for normal RB-mediated growth arrest (Fig. 4). Hence, INI1 definitely acts upstream RB.

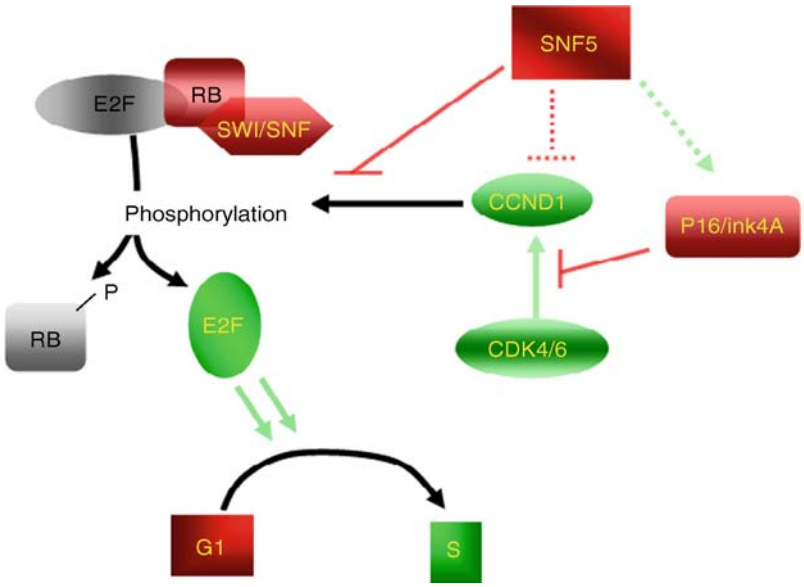
However, the control of the G1–S transition may not fully explain the antioncogenic role of hSNF5/INI. Indeed, missense mutations do not affect the replication checkpoint, but might rather lead to polyploidy by promoting chromosomal instability and compromising the mitotic checkpoint. Furthermore, there has been evidence for the involvement of hSNF5/INI1 in



hSNF5/INI1/SMARCB1 Tumor Suppressor Gene. Figure 2 The SWI/SNF complex. SWI/SNF complexes are composed of up to 12 proteins. Alternatively hBRM or hBRG1 carries the ATPase activity. The other proteins of the core complex are BAF155, BAF170, and BAF47.



hSNF5/INI1/SMARCB1 Tumor Suppressor Gene. Figure 3 *hSNF5/INI1* gene and protein structure. Interacting proteins are indicated in front of the Rpt2 domain. a. Structure of the gene: 9 exons encompassing ~50 kb. b. Structure of the protein with the highly conserved hemology domain.



hSNF5/INI1/SMARCB1 Tumor Suppressor Gene. Figure 4 hSNF5/INI1 and the G1–S transition. Arrows in green and red indicate respectively a positive and negative regulation. Dot lines indicate not fully consensual links. SWI/SNF has a physical interaction with RB and directly coregulates E2F1 transcription. hSNF5/INI1 on its own represses the G1 to S transition. This effect can be due either to *CCND1* downregulation or to *p16/INK4a* over expression. hSNF5/INI1 acts upstream RB.

dynamic regulation of the cytoskeleton. The restoration of the hSNF5/INI1 gene in rhabdoid cells alters the expression of Rho-family genes, likely to modulate the cytoskeleton, and obviously modifies the organization of actin stress fibers. hSNF5/INI1 might therefore play a role in cellular adhesion and migration properties.

Finally, taking into consideration the critical role of chromatin remodeling in the activation of cell-type-specific genetic programs, the role of hSNF5/INI1 in driving cell differentiation has also been investigated. INI1-dependent differentiating effect has been observed in hepatocytes. Conversely, reexpression of hSNF5/INI1 in rhabdoid cell lines drives distinct differentiation phenotypes according to the cell anatomic origin. A critical impairment of INI1-dependent differentiation programs may account for the highly undifferentiated phenotype of hSNF5/INI1-deficient tumors.

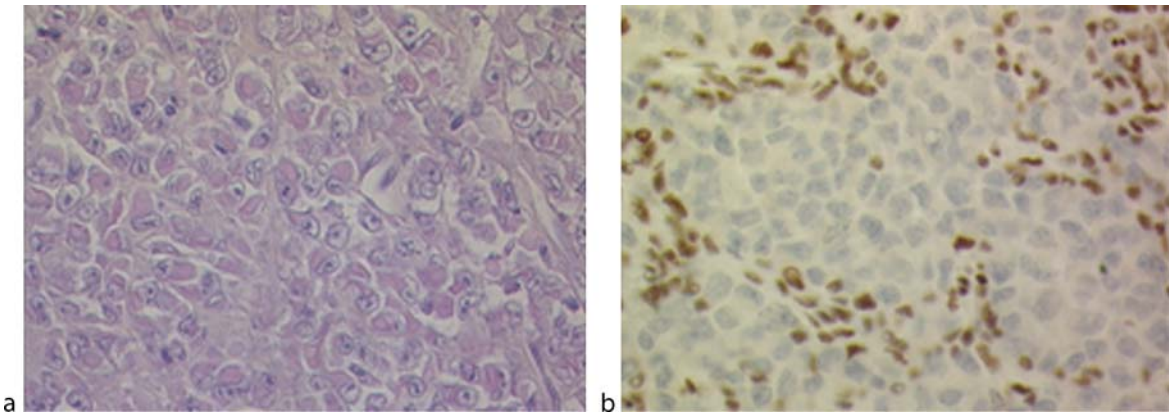
Genetic Alterations of *hSNF5/INI1* in Human Malignancies

Deletions encompassing the hSNF5/INI1 locus are encountered in many tumor types, including ►rhabdoid tumors (RTs), ►proximal epitheliod sarcomas (PES), meningiomas, schwannomas. Biological effects of hemizygous INI1 deletions are questionable, since loss of one allele results only in a 15–20% reduction in total *INI1* mRNA levels due to transcriptional compensation by the remaining allele. Hence, "two-hit" events only are likely to drive transformation. Strikingly, biallelic inactivation is encountered in about 80% of rhabdoid tumors. Karyotypic analyses in RTs usually show no or few other alterations than deletions or translocations of 22q11. Altogether, this indicates a very strong association between hSNF5/INI1 extinction and RTs. Both homozygous deletions and hemizygous deletions with point mutations are encountered.

In RTs cell lines, mitotic recombinations of chromosome 22q and nondisjunction/duplication, lead to partial or complete uniparental disomy. This mechanism may account for most homozygous changes and result in the total or partial loss of one chromosome associated with the duplication of the remaining chromosome carrying the deleted or mutated allele. The association of a point mutation with a whole gene deletion is less frequently encountered, but seems to be preponderant in ►brain tumors. Point mutations, consisting in nucleotides replacement, deletion or insertion and leading to truncating nonsense codons, are spread all over the nine exons with no obvious hotspot. Missense mutations are much rarely reported.

Studies using immunohistochemistry with anti-SMARCB1 antibody have confirmed the total loss of protein expression in a high proportion of RTs as a direct consequence of the genetic alterations. Whether hSNF5/INI1 inactivation is specific for RT or could be involved in miscellaneous other tumors remains not fully consensual (see next section).

Congenital multifocal rhabdoid tumors and familial cases strongly supported the existence of constitutional mutations in a predisposing syndrome. Indeed, about 40



hSNF5/INI1/SMARCB1 Tumor Suppressor Gene. Figure 5 pathological aspects of *hSNF5/INI*-deficient ►rhabdoid tumor. (a) "Rhabdoid" cells: discohesive polygonal or round cells with abundant cytoplasm, juxtanuclear globular eosinophilic cytoplasmic inclusion, large nucleus with one prominent nucleolus. (b) negative staining of rhabdoid cells with anti-hSNF5/INI1 antibody, resulting from a complete loss of the protein and the biallelic inactivation of *hSNF5/INI1* gene. Positive staining is retained in normal stromal cells.

germline mutations have been reported so far, associated to the development of a tumor during early childhood in almost all patients. Hence, the penetrance is very high, though not full. Nucleotides or whole gene deletions, point mutations and splice site changes have all been observed at the constitutional level.

Pathological and Clinical Aspects of hSNF5/INI-Deficient Tumors

RTs were initially described as highly aggressive variants of Wilm tumors occurring in infants (►Nephroblastoma). "Rhabdoid" cells were defined by key morphologic histological and immunophenotypical features: polygonal or round shape with abundant cytoplasm, juxtanuclear globular eosinophilic cytoplasmic inclusion, large nucleus with one prominent nucleolus (Fig. 5a), coexpression of vimentin and epithelial markers such as epithelial membrane antigen and/or cytokeratins. Such features were then observed in other pediatric malignancies, in brain (Atypical Teratoid/Rhabdoid Tumors) (Brain tumors) and miscellaneous soft-tissues. Presently, the cell origin of RTs remains unknown. The actual incidence of RTs may still be underestimated since those rare tumors are frequently misdiagnosed. However, immunohistochemistry with a monoclonal anti-hSNF5/INI1 antibody is very sensitive and highly specific for the detection of hSNF5/INI1 loss-of-function (Fig. 5b), and should now facilitate the diagnosis of most RTs.

hSNF5/INI1 biallelic genetic inactivation has also been reported in other types of ►childhood cancers such as central PNET (►Medulloblastoma, deleted in malignant brain tumors), choroid plexus carcinomas, and in a small subset of undifferentiated malignant tumors without evidence of "rhabdoid" morphological features. In adults interestingly, in which RTs are thought to be much rarer, hSNF5/INI1 complete defect has also been observed in some "proximal-type" of epithelioid sarcomas (►Proximal-type epithelioid sarcomas), and, marginally, in composite tumors with "rhabdoid" component. hSNF5/INI1 deficiency might therefore account for a wider spectrum of tumors. Nevertheless, it still remains unclear whether these different malignancies should be considered as phenotypical variants of a same biological entity. In accordance with this hypothesis, they usually share with typical RTs a highly aggressive clinical behavior.

Conclusion

There are increasing evidences of chromatin remodeling being a critical process in oncogenesis. hSNF5/INI1 offers a convincing example as a tremendously potent tumor suppressor gene. In humans, hSNF5/INI1 inactivation is strongly associated with rhabdoid tumors, but may not be as restricted to these children malignancies as previously thought. Identification of hSNF5/INI1 involvement in human cancers has given helpful diagnostic tools, based on molecular screening and specific anti-hSNF5/INI1 immunohistochemistry. Better knowledge on hSNF5/INI1 roles in oncogenesis should lead to more efficient targeted therapies, and improve the dramatically poor prognosis of hSNF5/INI1-deficient tumors.

HSP

Definition

Heat shock protein. HSP89α, HSP90β; the HSP89α and HSP90β genes are composed of 11 and 12 exons, respectively. The regulation of HSP gene expression in eukaryotes is mediated by the conserved heat shock transcription factor (HSF). HSF acts through heat shock elements (HSEs) composed of three contiguous inverted repeats of a 5 bp sequence, nGAAnnTTCn; upon heat stress, HSF binds to HSEs as a trimer.

Heat shock protein 90

Definition

Hsp90, the 90-kDa heat shock protein, is a ►molecular chaperone that regulates the degradation, folding and/or transport of a diverse set of critical cellular regulatory proteins. Most Hsp90 clients, i.e. those proteins that require its "chaperoning" activity for appropriate function, participate in some aspect of signal transduction including a wide variety of protein kinases, hormone receptors, and transcription factors. Moreover, Hsp90 can stabilize mutated proteins allowing them to maintain normal function despite genetic abnormalities. This ability to buffer genetic changes and serve as a capacitor of phenotypic variation has implicated Hsp90 in evolutionary and oncogenic processes.

Characteristics

Hsp90 is an ATP-dependent molecular chaperone and is one of the most highly expressed proteins in eukaryotic cells. There are two major isoforms of Hsp90, the major form Hsp90α and the minor form Hsp90β. The two hsp90 genes differ primarily in their non-coding and regulatory regions. Both the α and β proteins consist of four basic structural domains. The N-terminal domain is the site of ATP binding and is essential for its chaperone function. Inhibitory agents, at least those developed to date, specifically target this site preventing ATP binding and consequently Hsp90 function. The N-terminal domain is connected to the middle domain by a small highly charged linker region that is thought to be the site for co-chaperone binding. The larger middle domain contains the site for client protein binding and the C-terminal domain provides the dimerization site, which is essential for Hsp90 activity. The Hsp90 proteins function as homodimers of α/α and β/β. Whereas there does appear to be functional differences between the isoforms with β being associated with development, there is also considerable overlap.

Although the majority of Hsp90 is located in the cytoplasm, this molecular chaperone can also be found in the nucleus, albeit at considerably lower levels, where it has been associated with the regulation of gene expression and the ►DNA damage response to radiation. In addition, Hsp90 is located on the cell surface where it plays a role in antigen processing and the immune response. Finally, recent studies have shown that Hsp90 can be secreted into the extracellular space. Although the specific function has not been clearly defined, in this location Hsp90 has been suggested to play a role in blood clotting, cell migration and tumor metastatic processes.

Mechanism

Hsp90 chaperone function is mediated by an ATP-dependent cycling between two conformations, which regulates its interactions with specific co-chaperones

and co-factors and drives the loading and off loading of client proteins. The Hsp90 dimer typically exists in a multi-protein chaperone complex that includes the co-chaperones Hsp70 (70-kDa heat-shock protein) and Hsp40 (40-kDa heat-shock protein), the adaptor protein HOP (hsp co-chaperone organizing protein) and the cofactor p23. In addition, there are specific immunophilins and other co-chaperones that regulate substrate binding. For example, the co-chaperone ►Cdc37 is involved in Hsp90-mediated stabilization of protein kinases. A client protein initially binds to the Hsp70/Hsp40 complex, which links via HOP to an ADP-bound Hsp90. Exchanging ADP with ATP alters Hsp90 confirmation such that HOP and Hsp70/Hsp40 are released and p23 and other co-chaperones such as Cdc37 are recruited to the complex. In the ATP-bound confirmation and associated with these co-chaperones Hsp90 folds and stabilizes a client protein maintaining it in a responsive conformation. Although the specific processes have not been completely defined, in the absence of the appropriate stimulus or ligand binding to the client protein, Hsp90 through its ATPase activity cycles back to its ADP-bound conformation recruiting the initial set of co-chaperones, which ultimately leads to client protein degradation. Considerable insight into the mechanism of Hsp90 chaperone activity has been generated through the use of the inhibitor ►geldanamycin. This benzoquinone ansamycin binds to the nucleotide binding site of Hsp90 resulting in a conformation that resembles the ADP-bound conformation. The inability of Hsp90 to cycle to its ATP-bound conformation then maintains the chaperone complex in a state that favors client protein degradation. Studies to date indicate that in cells treated with geldanamycin or one of its analogs the half lives of the Hsp90 client proteins are uniformly and significantly reduced.

Clinical Aspects

As a Single Modality

Hsp90 has received considerable attention as a potential target for cancer therapy. Because of an increased understanding of the mechanisms and molecules that mediate malignant transformation, recent strategies in cancer therapy have begun to focus on a target-based approach. The putative advantages of this strategy include tumor selectivity sparing normal cells and the availability of markers indicative of tumor susceptibility. Most attempts to apply target based therapy have entailed the use of agents that target a single molecule. For tumors in which their phenotype is driven by a single oncogenic molecule, such as the targeting of Bcr-Abl by ►STI571 in chronic myelogenous leukemia and ►Her2/neu by ►Herceptin is certain breast tumors, this approach has demonstrated clinical activity. However, most tumors, especially solid neoplasms, contain multiple genetic abnormalities and are subject to a high degree of genomic instability. The result is that their malignancy/survival is driven by variety of molecules existing in a number of different survival pathways. Under these circumstances, targeting a single molecule is likely to be of limited consequence. As an alternative to targeting a single molecule, inhibiting Hsp90 provides a multi-target approach to cancer treatment. Hsp90 client proteins include a large number kinases, receptors and transcription factors that have been implicated in transformation and maintenance of the malignant phenotype. Examples of such proteins dependent on Hsp90 include ErbB2 (►Her2/Neu), Src, ►Akt, ►c-Raf-1, cyclin dependent kinases Cdk4 and Cdk6, HIF1-α, estrogen and androgen receptors and hTERT. Thus, Hsp90 inhibition provides a means of simultaneously targeting multiple proteins critical to a malignant cell. In addition, Hsp90 can stabilize mutant proteins (e.g. ►p53) allowing for at least some functional activity. Given the level of genomic abnormalities and instability of tumor cells, the ability to buffer against such genetic variation suggests another avenue through which Hsp90 contributes to tumor cell survival.

In laboratory studies exposure of tumor cells to Hsp90 inhibitors such as geldanamycin and its analogs 17-allylaminogeldanamycin (17-AAG) and 17-(dimethylaminoethylamino)-17-demethoxygeldanamycin (17-DMAG) results in the combinatorial decrease in its client proteins mentioned above as well as additional client proteins, although there is some cell type specificity. With respect to a potential cancer therapy, inhibition of Hsp90 induces tumor cell death or significantly slows their proliferation in a number of in vitro and in vivo experimental systems, although the critical target or targets (i.e., client proteins) for the most part have not been defined. An additional characteristic that supports the application of Hsp90 inhibitors in cancer treatment is their relative selectivity for tumor cells over normal cells. The molecular basis for this selectivity has not been clearly defined. However, Hsp90 is typically expressed at higher levels in tumor cells than normal cells suggesting that tumors may be more dependent on its chaperoning activity. Regardless of the specific mechanisms involved, the ability of Hsp90 inhibitors to preferentially kill tumor cells over normal has led to the ongoing evaluation of 17AAG and 17DMAG in clinical trials as single modality agents.

In Combination with Radiotherapy

Hsp90 has also been identified as a determinant of tumor cell ►radiosensitivity. Among Hsp90 clients are included a number of proteins (e.g. Raf-1, Akt and ErbB2/Her2/Neu) that have been associated with protection against radiation-induced cell death; a reduction in their individual activities has been shown to result in radiosensitization in some, but not all tumor cell lines. Tumor cell radiosensitivity is regulated by a wide variety of signaling

molecules with their specific contributions often determined by cell type. Because Hsp90 inhibitors induce the simultaneous loss of a number of these molecules that can potentially affect radiosensitivity, the use of these agents allows for implementing a multi-target approach to ►radiosensitization. The putative advantages of such a multi-target strategy are increases in the degree and probability of radiosensitization. Indeed, inhibitors of Hsp90 such as geldanamycin, 17AAG, 17DMAG and radicicol have been shown to significantly enhance the radiosensitivity of a number of tumor cell lines derived from a variety of histologies. As for Hsp90 inhibitor treatment alone, the inhibitors have little to no effect on the radiosensitivity of normal cells evaluated in vitro. This lack of normal cell radiosensitization occurs despite a similar reduction in client proteins suggesting that it is not the difference between Hsp90 per se in tumor and normal cells, but the actions of its client proteins.

Mechanistic studies of the tumor cell radiosensitization induced by 17DMAG have implicated Hsp90 in two components of the DNA damage response – DNA double strand break repair and ►cell cycle checkpoint activation. The inhibition of double strand break repair could be traced to the loss of ErbB2 (Her2/neu) in 17DMAG treated cells and the consequent reduction in ErbB1 (EGFR) activity, which leads to a reduction in the ErbB1 interaction with DNA-PKcs and the subsequent attenuation of ►DNA-PK activation after irradiation. The abrogation of cell cycle checkpoint activation by 17DMAG was associated with a reduction in radiation-induced activation of ►ATM, which was the result of a reduced interaction between ►NBS1 and ATM. Whereas most studies regarding Hsp90 as a target for cancer treatment have focused on its cytoplasmic activities, these radiation studies indicate that this chaperone has a critical role within the nucleus. The contribution of Hsp90 to double strand break repair and cell cycle checkpoint activation in tumor cells suggests that its inhibition may also be of benefit in combination with chemotherapeutic agents that kill tumor cells through DNA damage.

HSV-TK/Ganciclovir Mediated Toxicity

Donna Shewach
Department of Pharmacology, University of Michigan Medical School, Ann Arbor, MI, USA

Synonyms

Suicide gene therapy; Gene directed enzyme-prodrug therapy; GDEPT

Definition

A form of ►suicide gene therapy in which the cDNA for a viral enzyme, the herpes simplex virus thymidine kinase (HSV-TK), is transferred to tumor cells followed by treatment with the antiviral drug ganciclovir (GCV). Expression of HSV-TK enables cells to phosphorylate GCV to a monophosphate derivative. Cellular enzymes convert the monophosphate to GCV triphosphate, which elicits toxicity through incorporation into DNA.

Characteristics

HSV-TK/GCV mediated killing of tumor cells, and indeed suicide gene therapy in general, has been developed as a mechanism to improve the selectivity of cancer chemotherapy. Since traditional antitumor drugs target rapidly dividing tissues, such as tumor cells, they also can destroy normal dividing host tissue

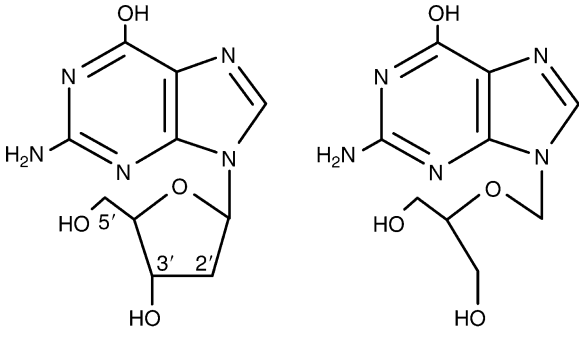
such as cells in the bone marrow, gastrointestinal tract, or hair follicles. Normal tissue toxicity is the major impediment to traditional chemotherapy. With HSV-TK/GCV therapy, a foreign gene (encoding HSV-TK) which can activate a normally innocuous ►prodrug (GCV) to a toxic product is transferred selectively to the tumor. When the patient is treated with the prodrug, only the tumor cells expressing the foreign gene will be affected (thus the designation of "suicide" gene therapy); since normal host tissues cannot activate the prodrug, they are spared from toxicity.

Toxicity to HSV-TK-Expressing Cells

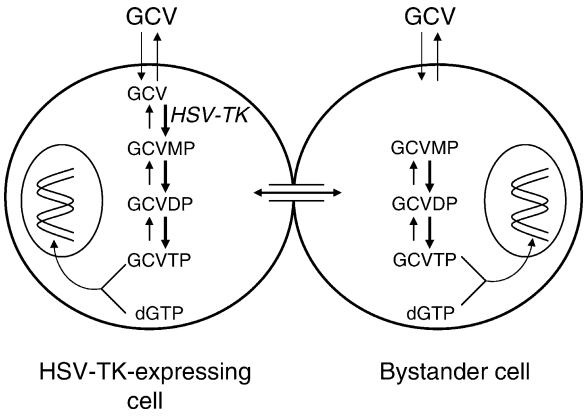
GCV is an acyclic analog of 2′-deoxyguanosine that requires phosphorylation for biologic activity (Fig. 1). It was originally discovered as an antiherpesvirus agent, and it is used clinically in the treatment of cytomegalovirus infection. When herpes simplex virus infects human cells, a number of proteins are expressed from the viral genome to facilitate virus replication and spread. One of these proteins, HSV-TK, contrasts with mammalian thymidine kinase in that it can phosphorylate purine as well as pyrimidine nucleoside substrates and their analogs. GCV serves as a substrate for HSV-TK with a Km value of ~50 μM, but it is not an efficient substrate for any of the mammalian nucleoside kinases thus accounting for its selectivity in herpesvirus-infected cells. Following subsequent phosphorylation by mammalian kinases to its triphosphate metabolite, the drug is incorporated into the viral DNA leading to cessation of replication. Based on this mechanism of selectivity, it was proposed that tumor cells genetically engineered to express HSV-TK would be killed when treated with GCV. Proof of this principle was first shown in murine sarcoma cells, and since then numerous reports have demonstrated similar results in many different cell types.

At the triphosphate level, GCV can compete with the endogenous 2′-deoxyguanosine 5′-triphosphate (dGTP) for incorporation into DNA by mammalian DNA polymerases. Since GCV has the equivalent of both the 5′ and 3′ hydroxyls of deoxyguanosine, it can be incorporated into DNA and allow further extension of the DNA strand (internucleotide addition). In contrast, the structurally related ►acyclovir lacks the equivalent of a 3′ hydroxyl group, and thus is an obligate DNA chain terminator. GCV and its metabolites do not interfere with RNA or protein synthesis. The incorporation of GCV monophosphate into DNA is the primary lesion that results in cell death. For some cell types, GCV induces cell death through ►apoptosis (Fig. 2).

Compared to other substrates for HSV-TK, such as acyclovir, GCV is significantly more toxic and more mutagenic to cells that express HSV-TK. The action of acyclovir is primarily ►cytostatic, whereas GCV induces cell killing at low, clinically achievable concentrations. Although GCV triphosphate accumulates in cells to a relatively low level of 10–20 μM, this is sufficient to produce several logs of cell death. This high toxicity may be attributable to the avid incorporation and lengthy retention of GCV into DNA. GCV triphosphate and its incorporation into the nascent DNA strand do not produce strong inhibition of DNA synthesis, so cells incorporate high levels of this drug, complete DNA replication and go on to divide. Daughter cells become irreversibly blocked when they enter S-phase, suggesting that GCV monophosphate cannot serve as a template for DNA replication. A



HSV-TK/Ganciclovir Mediated Toxicity. Figure 1 Structure of GCV.



HSV-TK/Ganciclovir Mediated Toxicity. Figure 2 Mechanism of Cytotoxicity for GCV in HSV-TK-Expressing Cells and Bystander Cells. GCV is selectively phosphorylated to the monophosphate in HSV-TK expressing cells. Further phosphorylation can be accomplished by cellular enzymes. GCV triphosphate competes with the endogenous dGTP for incorporation into DNA, leading to cell death. GCV at the mono-, di- or triphosphate level can be transferred directly to bystander (non-HSV-TK-expressing) cells via GJIC channels, resulting in its incorporation into DNA of bystander cells with subsequent cytotoxicity.

strong G2/M block has also been observed in some cell types after GCV treatment. The cell cycle position in which cells become blocked may depend on the concentration of GCV.

Toxicity to Non-HSV-TK-Expressing Cells (►Bystander Effect)

With current gene transfer technologies, only a small percentage of tumor cells will express the foreign gene. For this approach to be successful in cancer treatment in patients, there must be a mechanism by which cells that do not express the ►transgene (bystander cells) can be killed. It was noted early on that when only a fraction of the cell population expressed HSV-TK, treatment with GCV resulted in killing of both the HSV-TK-expressing and HSV-TK-nonexpressing bystander cells. The strong cell killing ability of GCV in HSV-TK-expressing and neighboring bystander cells has resulted in complete regressions of experimental tumors in animals, spurring clinical interest in this approach.

In suicide gene therapy, bystander cell killing generally occurs through the transfer of a toxic metabolite, produced in the transgene-expressing cell, to bystander cells. The bystander cell killing with HSV-TK/GCV was an unexpected finding since the toxic metabolite, GCV triphosphate, is negatively charged and therefore would not readily pass through cell membranes to kill bystander cells. However, GCV mono-, di- and triphosphate accumulate in bystander cells when co-cultured with HSV-TK-expressing cells and GCV. The primary mechanism that appears to account for transfer of GCV phosphates is ►gap junctional intercellular communication (GJIC). GJIC allows the direct exchange of small molecules (<1,000 D) between neighboring cells. With a molecular weight ranging from ~350–510 D, GCV mono-, di- or triphosphate could potentially be transferred between cells through gap junctions. Tumor cell lines show varying levels of GJIC activity, in which some are totally devoid of GJIC whereas others show nearly 100% communication between cells, yet transfer of GCV phosphates can occur even between low GJIC-expressing cells. Increasing the GJIC activity of tumor cells increases the transfer of toxic GCV metabolites to bystander cells thus enhancing bystander cell killing, however this lower the amount of GCV phosphates in the HSV-TK-expressing cells with a concomitant reduction in cell killing.

Characteristics in Vivo

Experimental Tumors in Animals

Human tumor xenografts that stably express HSV-TK exhibit strong tumor growth delay and complete regressions after treatment with GCV. However, this is an idealized system in which all cells can activate GCV, whereas engineering an existing tumor to express HSV-TK is an inefficient process even when mediated by a viral vector (retrovirus, adenovirus, herpes simplex virus, adeno-associated virus, lentivirus) to transfer the cDNA for the transgene. Although viral ►transduction of tumors *in vivo* represents the best of our current gene transfer approaches, the percentage of cells that express the transgene is typically less than 10%. Nevertheless, *in vivo* transduction of tumors in animals has produced excellent tumor growth delay with some complete regressions, suggesting an impressive bystander effect *in vivo*. These successful animal studies fueled in large part the clinical interest in HSV-TK/GCV, and to date it is one of the most commonly used gene therapy approaches in cancer treatment.

Mechanism of the Bystander Effect in Vivo

With demonstration of transfer of phosphorylated GCV between HSV-TK-expressing and non-expressing cells *in vitro* as an important component of the bystander effect, it was expected that a similar mechanism would explain the bystander effect noted *in vivo*. While this may explain a portion of the bystander cell killing in experimental tumors, there is ample evidence implicating an immune component as well. Tumors in immune-competent animals usually exhibit more regressions than the same tumor in immune-deficient animals, and following tumor regression immune-competent animals reject the same tumor upon rechallenge. Further evidence of the involvement of the immune system is shown by the ability of GCV treatment to regress two separate tumors in an animal when only one expresses HSV-TK. It has been postulated that the dying tumor cells expressing HSV-TK are immunogenic, mediating the antitumor response. The assistance of the immune system *in vivo* in promoting tumor regression is a powerful addition to the HSV-TK/GCV approach.

Clinical Relevance

Since the initial reports of tumor regression in animals treated with HSV-TK/GCV, many clinical trials utilizing this approach have been initiated. Based on reports of brain tumor regressions in experimental tumors in animals, glioblastoma was targeted initially for HSV-TK/GCV treatment in clinical trials. Other trials have focused on treatment of ovarian cancer and prostate cancer with HSV-TK/GCV. Recently HSV-TK/GCV has been evaluated in the treatment of graft vs. host disease in allogeneic bone marrow transplant recipients. These trials have employed primarily retrovirus or adenovirus vectors to transduce tumor cells to express HSV-TK, and the results have shown that these vectors are safe to use in humans.

While HSV-TK/GCV has been well tolerated in patients, Phase I/II clinical trials have not demonstrated strong antitumor activity with this approach. There are

several possible reasons that the results have not been more dramatic. First, most patients in these trials had been previously treated with surgery, chemotherapy and/or radiation therapy, so these trials were treating tumors that were already resistant to initial therapy and therefore less likely to respond to the gene therapy. Second, despite the administration of high numbers of virus particles and multiple administrations of the vector in some trials, it is likely that less than 1% of the cells in the tumors expressed HSV-TK, and thus tumor eradication relied almost entirely on the bystander effect. Recently, promising results have been reported in clinical trials in men with prostate cancer, in which the combination of HSV-TK/GCV with another suicide gene therapy, cytosine deaminase to activate 5-flucytosine to the anticancer drug 5-fluorouracil, produced evidence of tumor control. Considering that cancer is usually treated with more than one drug, it is reasonable to expect that the optimal use of HSV-TK/GCV will be in combination with other agents and modalities.

Improving Cancer Therapy with HSV-TK/GCV

In view of the low efficiency of gene transfer for current methodologies, the major limitation to the therapeutic efficacy of HSV-TK/GCV is the inability to express the transgene in a larger percentage of the tumor. Improved vector delivery systems are needed to enhance tumor transduction. Replication competent adenovirus vectors may increase transduction somewhat, although they have only transient expression. Newer approaches include nonviral methods, such as nanoparticles, to deliver the transgene. Structural modifications to HSV-TK that improve affinity for GCV have been shown to be efficacious in preclinical models and are undergoing clinical study, and this approach will be most useful in combination with superior transduction methods.

One aspect of this treatment that has not received much attention is optimizing the administration of GCV. The current dosing regimen is based on that used for treating patients with herpes virus infections. Given that most current gene transfer approaches produce only transient expression of HSV-TK, increasing dose intensity to match the duration of expression of the transgene may improve therapy. ►Pharmacodynamic studies are needed to determine the optimal dose and schedule that will maximize the activation of GCV in tumors expressing HSV-TK.

With the current low efficiency of gene transfer regardless of the vector used, methods to improve bystander cell killing could make a major impact. Preclinical models have shown that increasing GJIC through gene transfer of cDNAs for ►connexins can improve bystander killing. However, to increase bystander killing by this mechanism requires connexin expression in a large percentage of both the bystander and HSV-TK-expressing cells, and thus with the low level of gene transfer by current methodologies this may not impact tumor therapy significantly. Recent reports demonstrate that the addition of inhibitors of ►ribonucleotide reductase, such as hydroxyurea or gemcitabine, to HSV-TK/GCV regimens can synergistically increase bystander cell killing both *in vitro* and *in vivo* in animal models. This appears to work through increasing the GCV triphosphate:dGTP value resulting in greater GCV incorporation into DNA. Pharmacologic modulation to increase bystander cell killing would be expected to make a more dramatic improvement in efficacy than methods requiring gene transfer, and merit testing in clinical trials.

Suicide gene therapy in cancer treatment is still in its infancy. Although the excellent responses in preclinical models have not been realized yet in clinical studies, promising evidence of efficacy is emerging, particularly in the treatment of prostate cancer. In addition, new technologies and approaches that enhance response in preclinical systems may have clinical impact. Improving gene transfer, optimizing drug administration regimens, increasing bystander cell killing through pharmacologic means, and combining HSV-TK/GCV with other therapies may translate to greater clinical efficacy with this novel approach to cancer treatment.

Definition

The family Herpesviridae is comprised of viruses characterized by a distinct morphology. Virion particles are enveloped and have a diameter of ~200 nm. The icosahedral capsid contains a double stranded linear DNA molecule with a molecular weight of 80–150 million daltons.

Characteristics

According to their biologic and molecular properties, ►herpesviruses are classified in three subfamilies (alphaherpesvirinae, betaherpesvirinae, gammaherpesvirinae). Humans are the natural host for eight herpesviruses: herpes simplex 1 (HSV-1), herpes simplex 2 (HSV-2), varicella zoster virus (VZV), human cytomegalovirus (HCMV), ►Epstein Barr virus (EBV), human herpesvirus 6 (HHV-6), human herpesvirus 7 (HHV-7) and human herpesvirus 8 (HHV-8), also known as ►Kaposi sarcoma associated herpesvirus.

All herpesviruses have the important biologic characteristic of establishing life-long latent infections within specific cells of the host after primary infection. Latent virus may occasionally reactivate and produce recurrent infections. Both animal and human herpesviruses have been implicated in the etiology of animal or human neoplasms. The human herpesviruses with oncogenic potential include EBV and HHV-8. In addition, a potential oncogenic role has been suggested also for HHV-6, but no firm association has been established.

HHV-6 is a betaherpesvirinae encoding ~100 genes and has a selective tropism for T-lymphocytes and macrophages. Viral strains can differ in biological properties such as pathogenic potential, in vitro cell tropism, reactivity with monoclonal antibodies, and are consequently divided in two variants: HHV-6A and HHV-6B. Infection with HHV-6, usually acquired in early infancy, is highly prevalent in humans. The virus

causes Exanthem Subitum, a benign childhood disease, but primary infection can remain asymptomatic or result in febrile episodes without relevant symptoms. As a result of primary infection the virus establishes latent infection and resides silently in T-lymphocytes and in macrophages. In fact, small amounts of viral DNA are commonly detected in peripheral blood mononuclear cells of healthy adults, in the absence of viral replication. Occasionally, the virus may reactivate, especially in immunocompromised individuals (HIV-infected, transplant recipients). HHV-6 reactivation has been linked to disease especially in bone marrow transplant recipients. HHV-6 is present also in salivary glands and may be shed with saliva.

Clinical Aspects

A possible role of HHV-6 in human oncogenesis has been suggested since its original isolation from patients with B- and T- cell lymphoproliferative diseases. Subsequently, HHV-6 DNA sequences have been detected in a variable number of non-Hodgkin lymphomas, in sporadic cases of leukemia, angioimmunoblastic lymphoadenopathy, cerebral lymphoma and also in neuroglial tumors, oral carcinoma, cervical carcinoma. However, an etiological role of the virus in these cases is not likely, whereby only a small number of cells are infected by HHV-6, even in the case of clonal lymphoproliferations. The stronger potential association is with ►Hodgkin disease. Viral sequences are present in about 30% of cases and viral antigens can be detected in Reed-Sternberg cells, which appear to be the neoplastic element in this non-clonal lymphoproliferative disease. Furthermore, HHV-6 can reactivate EBV and enhance its gene expression. This synergistic interaction could be significant in the development of EBV-associated oncogenesis. However, the ubiquitous nature of the virus, the persistance of latent infection in virtually all healthy adults and the ability to integrate in the host cell chromosomal DNA complicate the interpretation of viral footprint in neoplastic lesions. HHV-6 is detected in some neoplastic lesions of the uterine cervix and virus infection enhances the tumorigenic potential of human papillomavirus. However, current evidence suggests that a role of HHV-6 in cervical oncogenesis is unlikely.

The tumorigenic role of HHV-6 is supported by in vitro studies that show a transforming potential on murine and human cells. Three different fragments of viral DNA immortalize primary cells or morphologically transform continuous cell lines. These cells injected in nude mice develop tumors. The protein encoded by the viral gene DR7, encoded by one of the transforming fragments, has the ability of transactivating heterologous promoters and binds to the antioncogene p53, altering its ability to regulate genes important in growth control.

In conclusion, the etiologic role of HHV-6 in human neoplasias is still undefined. The observation that only a small proportion of cells shows footprints of viral infection, even in neoplasias with a clonal origin, suggests the possibility that the virus might simply be a passenger in the tumor tissues. On the other hand, the detection of viral sequences in lymphoproliferative diseases and the in vitro transforming potential of selected fragments of viral DNA support the hypothesis that the virus might be involved in the oncogenetic process, at least in a fraction of cases.

Synonyms

Human papillomavirus; HPV; Human wart virus

Definition

Human papillomaviruses (HPV) are members of a heterogenous group of viruses; to date, there are more than 100 different viruses (HPV 1, 2, etc.) identified by DNA sequence analysis (genotypes). Papillomaviruses of a number of animal species have been found (e.g., bovine papillomavirus, canine oral papillomavirus). With very few exceptions, papillomaviruses infect only their natural hosts.

Characteristics

Virus Particle

Human papillomavirus consists of an icosahedral virus capsid (without a lipid-containing envelope) of 55 nm in diameter that is built up of 360 copies of the major structural protein (L1) and 12 copies of the minor capsid protein (L2). Enclosed in the protein shell is one molecule of a circular double-stranded DNA of about 8,000 bp, which constitutes ~20% of the virus particle by weight. In addition to the genes L1 and L2 coding for the structural proteins, the genome contains also 6–8 "early" genes. These code for "nonstructural" proteins required for the regulation of viral gene expression (E2), for DNA replication (E1, E2, E6, E7), and virus maturation (E4). Transcription of the entire genome proceeds in one direction, i.e., only one strand contains the coding information. The major promoters are located in a 1 kb region ("upstream regulatory region"; URR), which contains the origin of replication.

Virus Replication

Papillomaviruses infect basal cells of stratified epithelia. Binding to and uptake into target cells appears to be mediated by a specific receptor(s), although the precise mechanism is not known. Low levels of DNA replication occur within basal cells, which appears to be necessary for persistence of papillomavirus infection. In suprabasal cells, vegetative DNA replication is initiated. By the aid of the viral proteins E6 and E7, the cells of the stratum spinosum that have entered the program of epithelial differentiation reinitiate the S-phase of the cell cycle. This switch provides the virus with the cellular machinery that is required for its own DNA replication. The E7 protein was found to bind to the hypophosphorylated form of the retinoblastoma (►Retinoblastoma protein, cellular biochemistry) protein (pRB), a critical molecule in the control of the G1/S boundary during the cell cycle. As a consequence, transcription factors of the E2F family are released from a complex with pRB and trigger expression of genes that are necessary for DNA replication and cell division, such as Myb and cyclin A and cyclin E. There is evidence that E7 can also override cell cycle control at the G2/M checkpoint via interaction with and functional inactivation of inhibitors of cyclin-dependent kinases (p21Waf1/Cip1 and ►p27). Additional effects of the E7 have been described that may lead to cell proliferation, such as binding to members of the ►AP-1 transcription factor family.

The papillomavirus protein E6 binds to the product of the tumor suppressor gene p53, leading to its ►ubiquitination and rapid degradation. This gene, which by deletion or mutation is involved in more than 50% of human cancers, is crucial for cell cycle control, like the members of the RB family. Activated in response to stress (e.g., by DNA damage), the p53 protein leads to cell cycle arrest and eventually to ►apoptosis. It is assumed that one of the functions of the E6 protein is to counteract the side effect of E7-dependent hyperproliferation, i.e., p53-induced apoptosis. Additional cellular proteins were found to be targeted by E6, e.g., ►telomerase, ERC-55 (a putative calcium binding protein), paxillin (a cytoskeleton protein), and the interferon regulatory factor-3 (IRF-3). The consequences of such interactions are still unknown, but in the latter instance it is tempting to speculate that the E6 protein interferes with activation of interferon (as an antiviral principle) as the transcriptional activity of IRF-3 is inhibited after binding. The interaction between the E6 and E7 and cellular proteins was most intensively studied in case of the HPV type 16, which is the prototype of a cancer-associated papillomavirus. It is

unclear, however, whether the role of the E6 and E7 proteins in virus replication are comparable between different HPV types. The interaction of these proteins with cellular proteins could not be demonstrated for certain HPV types.

Although it was observed that papillomavirus particles bind to a variety of different cells in culture, there is no evidence for persistence or replication of papillomaviruses other than in skin or mucosa. The conditions of differentiating epithelia are very difficult to reconstitute in cell culture, thus the propagation of papillomaviruses in experimental systems was impossible until recently. By the aid of ►organotypic cultures established from human keratinocytes, the functions of papilloma virus genes can be studied. This system, however, is still insufficient to generate papillomavirus progeny on a preparative scale. Thus the molecular analysis of papillomavirus mostly depends on the molecular cloning of the DNA of the viral genome. Recent progress has been made by characterization of virus-like particles (VLP) that are generated by expression of the major structural protein L1 (with or without L2) in recombinant vectors (e.g. baculovirus or yeast). VLP were also used to study early steps of the virus life cycle.

Pathogenesis of Papillomavirus Infection

Papillomaviruses are mostly transmitted by direct skin contact (e.g., during sexual intercourse), but also infection via contaminated objects has been reported. Replication of HPV induces benign proliferations (skin warts, genital warts, laryngeal papillomas) within the affected skin or mucosa. Depending upon the site of infection and the condition of the patient (e.g., age), such lesions often regress spontaneously. Malignant progression of HPV-induced lesions is uncommon and depends upon the site of infection and on the HPV type. Despite the plethora of HPV types, there is a striking association of certain types to particular disease (e.g., HPV 1–4 in skin warts, HPV 6 and HPV 11 in genital warts and laryngeal papillomas).

Papillomavirus infection of the genital tract is very common. It is detected in women and in males at high frequency (in 5–50% of women depending on age and sexual behavior). Those infections remain frequently subclinical and are diagnosed only by detection of viral DNA in cervical swabs. Clinical manifestations of genital papillomavirus infections are genital warts (condylomata acuminata) or intraepithelial neoplasias of the uterine cervix (CIN), vulva (VIN), penis (PIN), or the perianal region (AIN). CIN is considered a precursor to cervical cancer. However, the risk for malignant progression varies greatly (1–30%) depending upon the degree of severity defined as CIN I-III, which have been recently reclassified as low grade (CIN I) and high grade (CIN II + III). The second important parameter is the presence of particular HPV types. Thus papillomaviruses infecting the genital tract are classified as low-risk types (e.g., HPV 6, 11) and high-risk types (e.g., HPV16, 18, 31, 45).

Bioactivity

The role of certain (high-risk) HPV types in the development of anogenital cancers, most notably tumors of the uterine cervix, has been demonstrated by a large number of epidemiological studies and experimental observations.

1. Viral DNA of 14 different HPV types (most frequently HPV 16, followed by HPV 18, 45, 31) was found in more than 99% of large numbers of cervical cancer biopsies analyzed in worldwide studies. Also, cells established from cervical cancer and kept in culture for many years as cell lines, such as the HeLa line, contain HPV genomes; virus-specific mRNA and some proteins can be detected in cell lines and in biopsies, although fewer samples have been analyzed for gene expression.
2. An infectious etiology of cervical cancer has been suspected for many decades; recently the risk factors for cervical cancer and infection by high-risk HPV types (e.g., number of sexual partners) were shown to be identical.
3. Follow-up studies demonstrated that there is no development of high-grade CIN (the end-point of the follow-up) without the persistence of high-risk HPV.
4. CIN-like changes can be induced experimentally in organotypic cultures of human keratinocytes and in the epithelia of ►transgenic mice expressing the E6 and E7 proteins.
5. Cells of rodent and human origin can be transformed in culture by the expression of the E6 and E7 genes. Following inoculation, such cells grow as malignant tumors in small laboratory animals. The E6 and E7 proteins are required not only during the initial steps of transformation but also for the maintenance of the transformed state of the cell. Suppression of gene expression (by as yet undefined host factors or by introduction of an E6/E7-specific ►antisense nucleic acid) leads to reduction of proliferation or even to loss of the malignant phenotype. The constant expression of the E6 and E7 proteins within the infected epithelium favors the accumulation of mutations in the cellular genome leading to the activation of oncogenes or inactivation of negatively regulating factors and ultimately to the development of cancer.

Despite the causative role of papillomaviruses, it is obvious that only a minority of infected women (1–5%, depending upon geographic region) develop cervical

cancer, which with few exceptions occurs at least two to three decades after primary infection. Cervical cancer is several-fold more prevalent in developing countries than in affluent societies, whereas the prevalence of HPV infection is comparable across societies. Hence it is likely that other influences such as personal hygiene and sexual infections (e.g., chlamydia) may act as cofactors. Besides the recently developed HPV-specific prophylactic vaccines the regular attendance in cervical cancer screening programs (not available in poor resource countries) that are based on the detection of abnormal cells obtained from cervical swabs (►Papanicolaou test) is the most effective protection against the disease. Other widely used cofactors such as smoking or use of oral contraceptives seem to be of minor influence.

HPV may play a role in the development of other cancer types as well (e.g., some cancers of the respiratory tract) but the evidence is less complete. Non-melanoma skin cancer is another candidate for being associated with papillomavirus infection, but the types that may be involved (e.g., HPV 20) are as yet only scarcely characterized.

Clinical Relevance

Papillomavirus infections, at least in their initial stages, are usually unrecognized by the immune system. In terms of expression of cytokines and the presence of immune cells, there is no difference between a wart and normal skin. However, based on animal experiments and by studying the natural history of papillomavirus infections, it was concluded that the immune system plays an important role both in preventing papillomavirus infections and in eliminating the clinical manifestations of infections (regression of warts). For instance, patients suffering from immunosuppression (e.g., by receiving immunosuppressive drugs after renal transplantation) have an increased prevalence of HPV-associated disease. It is not clear which event triggers HPV-specific immune responses during the natural courses of infection and why eventually such immune responses are ineffective (cervical cancer occurs in immunological normal women).

Human T-cell Leukemia Virus

Jay A. Levy, Edward L. Murphy
University of California, School of Medicine, San Francisco, CA, USA

Synonym

Human T-lymphotropic virus (HTLV)

Definition

The human T-lymphotropic virus (HTLV), also known as human T-cell leukemia virus, was first identified in the early 1980s and is associated with adult T cell leukemia (ATL) and HTLV-associated myelopathy/tropical spastic paraparesis (HAM/TSP), a neurologic condition. Two related but distinct types of HTLV exist; HTLV-I and HTLV-II. HTLV-I is somewhat more common worldwide and is the only type associated with ATL. Both HTLV-I and HTLV-II have been linked to HAM/TSP (►T-cell leukemia/lymphoma 1 (TCL1)).

Characteristics

►Retroviruses are 100 nm, lipid-enveloped RNA viruses. HTLV is a deltaretrovirus with a 9 kb genome.

The genome consists of two identical RNA molecules located within the virus capsid. The viral genes include the *gag* (core region), *pol* (polymerase), *env* (the envelope) and certain other genetic regions that produce proteins associated with transformation or pathogenesis (e.g., X region). The X region encodes the viral proteins Tax and Rex that are involved in up-regulating virus expression. Both HTLV-I and II infect CD4+ lymphocytes; however, HTLV-II appears to preferentially infect CD8+ T cells. Although lymphocyte subsets are not altered to the same extent as in HIV infection, certain studies have demonstrated that HTLV-II, and to a lesser degree HTLV-I, are associated with an increased incidence of pneumonia, bronchitis and urinary tract infections. These conditions may reflect an immunodeficiency resulting from direct infection of CD8+ lymphocytes, the induction of CD4+ CD25+ T regulatory cells that suppress the immune response, or from inflammatory responses to HTLV-II in these organ systems.

HTLVs are spread by blood, genital secretions and by mother to child transmission often via maternal milk. This transmission appears to be primarily by cell to cell contact since low progeny production occurs with very little virus release from the infected cell. In this regard, HTLV particles are not generally observed in biopsies from ATL or TSP patients in vivo but the virus can be induced to replicate in cell culture. Instead, the HTLV-I provirus is propagated by lymphocyte division, resulting in oligoclonal infection with the occasional emergence of monoclonal proliferation. This latter event can result in frank leukemia.

Currently around 20 million individuals are infected worldwide with HTLV-I. This virus is most prevalent in southwestern Japan, the Caribbean, parts of South America and in central Africa. HTLV-II is endemic among Indian tribes in North, Central and South America and in central African pygmies. Within the last 30–50 years a low level epidemic of HTLV-II has affected injection drug users and their sexual partners in the United States and Europe.

Leukemia

Clinical Presentation

ATL occurs in 2–4%of HTLV-I-infected persons and takes up to 30 years to develop. Infection in childhood is thought to predispose to the development of adult T cell leukemia (ATL), since the mothers of ATL cases are more likely to be HTLV-I seropositive than the mothers of healthy HTLV-I carriers. ATL can be distinguished from other human T cell leukemias by its occurrence predominantly in adulthood with an acute course, the morphologic properties of the leukemic cells (indented and lobulated nuclei), the generalized lymphadenopathy with an absence of mediastinal lymph node involvement, frequent lytic changes in the bone associated with hypercalcemia and in some cases infiltration of the skin. Chemotherapy can reduce the tumor mass but long-term survival has not been achieved. Hypercalcemia can be managed by standard protocols. There have been case reports of hairy cell leukemia, large granular cell leukemia and CD8+ cutaneous lymphomas occurring in HTLV-II infected persons, with the latter found particularly in whose with concomitant HIV infection. However in contrast to HTLV-I, an etiological role for HTLV-II in hematologic malignancy has not been shown in epidemiologic studies.

Pathology

HTLV, by infecting CD4+ helper T cells, establishes a chronic infection that over time develops into leukemia. The glucose transporter 1 (GLUT-1) protein is most likely the receptor for HTLV-1 and is expressed on the surface of many different cells. This finding can explain the ability of HTLV to infect a wide variety of human cells. The mechanism for cell transformation is not fully explained but appears to be related to expression of the X region viral proteins particularly Tax. This transcriptional transactivator protein enhances the activity of cellular transcription factors and activates various promoters including NFkB. Tax can also block the activity of the tumor suppressor protein p53 and inhibit apoptosis. These effects result in immortalization of cells in culture and eventual tumor development. Some investigators believe that the production of the lymphocyte growth factor interleukin-2 (IL-2) drives the CD4+ lymphocytes to proliferate, particularly since there is an up-regulation of IL-2 production and expression of the IL-2 receptor on the infected cell surface. The leukemic cells, once proliferating, spread through the body and can induce a variety of syndromes including bone lesions due to osteoclastic activity. Hypercalcemia is frequently found in patients with acute ATL in association with an increased number of osteoclasts possibly induced through cytokine effects on hematopoietic precursor cells. ATL differs from cutaneous T cell leukemia by the absence of leukemic cell infiltration of the epidermis despite presence of tumor cells in the dermis and subcutaneous tissue. Moreover, the bone marrow and lungs are usually not involved in ATL. ATL treatment includes IFN-α and zidovudine, as well as inhibitors of NFkB activity, but the median survival with ATL is about a year even with therapy.

Neurologic Disease

Clinical Presentation

Cases of tropical spastic paraparesis (TSP) have occurred in the Caribbean (e.g., Jamaica, Dominican Republic, Martinique, Trinidad) in Latin America, Africa and India. In Japan, a similar disease, called HTLV-associated myelopathy (HAM), is frequently diagnosed in HTLV-I endemic areas. This neurologic

disease occurs in up to two percent of infected individuals, most commonly between ages 35 and 45; it is observed more often in females than in males. This finding can reflect either sexually acquired infection or a female predilection for the immunologic basis for its pathology. A neurologic syndrome identical to TSP/HAM is found in HTLV-II infected persons, although the occurrence of neurologic disease may be less common than with HTLV-I. When first observed, TSP may suggest transverse myelopathy or multiple sclerosis. TSP can occur rapidly (within 3–4 months after blood-borne HTLV-I infection) but generally also takes several years to develop in infected people. Symptoms include bilateral weakness of the legs, back pain, and loss of vibration sensation in the feet. Bladder and bowel dysfunction is common. Mental capacity is usually normal and examination of the cerebral spinal fluid does not usually reveal abnormal findings, although tests for HTLV antibody and provirus are often positive.

Pathology

Because of the very high titer of antibody to HTLV-I and the presence of lymphocytes within the central nervous system, TSP has been considered to result from an autoimmune-like response of the host. The neuropathology can be caused by inflammation of nerve roots from HTLV-1 infected cells infiltrating the spinal cord, or by direct infection of glial cells by HTLV-1. Cellular and cytokine-mediated inflammatory responses directed at HTLV-I initiate the damage to neural tissue, followed by gliosis in advanced cases. Treatment with corticosteroids has shown some improvement but generally TSP has a slow unremitting course.

Huntingtin Interacting Protein 1 (HIP1)

Theodora S. Ross
Department of Internal Medicine, University of Michigan, Ann Arbor, MI, USA

Definition

►HIP1 is the first example of an endocytic adapter protein that is altered in many human cancers. HIP1 represents a novel type of oncoprotein that hijacks ►endocytosis to increase signaling from multiple receptors in parallel to transform normal cells into cancer cells.

Characteristics

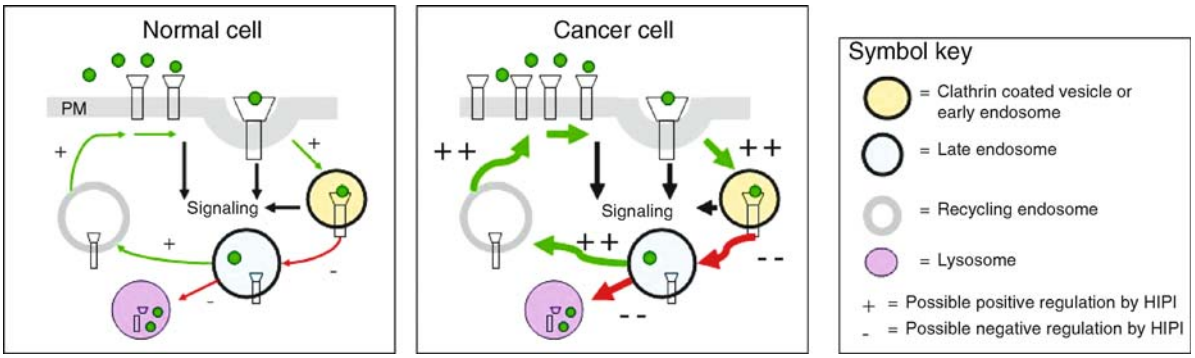
HIP1.

HIP1 is a 116 kDa cytosolic protein that was originally identified to interact with huntingtin, the protein whose gene is mutated in Huntington disease. HIP1 and its only known mammalian relative, HIP1-related (►HIP1r), contain ►clathrin-binding domains and carboxyl terminal ►actin-binding TALIN homology domains. HIP1 and HIP1r also contain amino terminal epsin/AP180 N-terminal homology (E/►ANTH) domains. These domains bind specific inositol lipids and have been shown to be important in epsin- and AP180-mediated modulation of the growth factor receptor uptake phase of clathrin mediated endocytosis.

HIP1's Original Link to Cancer. HIP1 was cloned independently after it was identified it as part of a t(5;7) ►chromosomal translocation in a patient with myeloid leukemia. The t(5;7) breakpoint encoded a fusion protein between HIP1 and PDGFßR, designated HIP1/PDGßR. The HIP1/PDGFßR fusion protein oligomerizes, has constitutive kinase activity, and transforms hematopoietic cells to IL-3-independent growth. Mutation analysis of HIP1/PDGßR indicated that constitutive kinase activity was not sufficient for transformation. Rather, transformation required HIP1 functions aside from the ability to oligomerize with the fusion protein. The fact that HIP1 sequences independent of the oligomerizing domain(s) were necessary for transformation was the first indication that over-expression of HIP1 alone may contribute to tumorigenesis through novel mechanisms. HIP1 is a specific marker for a variety of other cancer types and is associated with a negative prognosis (►Autoimmunity and prognosis) in prostate cancer.

How Might Hip1 and Hip1r Use Clathrin-Mediated Trafficking to Promote Cancer? Both structural (lipid-, clathrin-, and actin-binding domains) and functional data suggest that HIP1 and HIP1r are involved in membrane trafficking. One simple possibility of how HIP proteins use clathrin-mediated membrane to promote the survival of cells is that altered expression of HIP1 and HIP1r could alter growth factor receptor density and signaling, affecting cellular proliferation, survival, and differentiation (Fig. 1). Over-expression of HIP1 and HIP1r inhibits ligand stimulated degradation of growth factor receptors, leading to elevated receptor levels.

Targeted Mutations of Murine Hip1 and Hip1r. To understand the normal function of HIP1/HIP1r and how these proteins may interact with cancer pathways, phenotypes that result from mutant Hip1 and Hip1r alleles in gene targeted mice have been examined. Based on these studies, it is clear that deficiency of either HIP1 or HIP1r alone does not severely affect embryonic or early adult development. However, HIP1 (but not HIP1r) is required for maintenance of adult spinal, testicular, and hematopoietic tissues. Combined HIP1r and HIP1 deficiency accelerates (earlier onset and increased severity) spinal defects and leads to dwarfism and premature death. Remarkably, transgenic ubiquitous expression of the human HIP1 protein in the double Hip1/Hip1r mutant mice corrects these defects. This transgenic rescue is important since it indicates that studying the role of mouse HIP1 or human HIP1 in the mouse will yield valuable insights into the role of the human HIP1 protein family in human diseases such as cancer. The findings from these studies, particularly the rescue experiments, underscore the power of using



Huntingtin Interacting Protein 1 (HIP1). Figure 1 Altered membrane trafficking and cellular transformation. The left-hand panel displays the steps in membrane receptor uptake, recycling, and degradation. The middle panel displays how increased uptake, decreased degradation, or increased recycling could lead to increased signal transduction and tumor-cell proliferation and survival.

mouse genetics to study human disease. That is, the conclusions derived from these studies are especially rigorous compared to studies that use cultured cells or cell lines because mouse experiments are performed under physiological conditions *in vivo* .

Hip1 and Hip1r have Restricted Patterns of Expression and are not House-Keeping Genes. Since testicular degeneration is observed in *Hip1* mutant mice and HIP1 is specifically expressed in post-meiotic spermatids, the cells that exhibit increased apoptosis in the Hip1 knockout testis, it is likely that HIP1 expression is cell-intrinsically required for the survival of progenitors at a specific stage of spermatogenesis. Single and double knockout mice present with abnormalities only in early adulthood, emphasizing that HIP1 family members are not housekeeping genes that are widely expressed or widely required for the survival of most cells. Both HIP1 and HIP1r are expressed in restricted patterns in many different tissues. Even within tissues affected by Hip1-deficiency, HIP1 and HIP1r appear to regulate the survival or proliferation of only certain cell types within these tissues. Therefore, transient inhibition of HIP1 or HIP1r as a cancer therapy could potentially be well-tolerated.

HIP1 and Solid Tumors. Using monoclonal antibodies against human HIP1, it has been found that benign colon and prostate epithelia do not express detectable HIP1, yet malignant colon and prostate epithelia usually do. Examination of patients with prostate cancer indicates that HIP1 expression in prostate tumors is associated with cancer progression and a poor prognosis (►Autoimmunity and prognosis). These data raise the intriguing question of whether over-expression of HIP1 or mutated HIP1 in other tissues might promote tumorigenesis. HIP1 participates in numerous pathways (PtdIns signaling, clathrin trafficking, actin dynamics), and future use of human HIP1 transgenic mice and cellular transformation assays to determine whether dysfunction of all, or only a subset, of these pathways contributes to tumorigenesis will be important. A separate, but equally important question is whether HIP1 is necessary for cancer initiation or progression. In fact, the prostate cancer-prone TRAMP mice that are deficient for HIP1 are resistant to prostate cancer progression but not initiation.

Humoral Response to HIP1 Overexpression. The observation that HIP1 expression is necessary for the full tumor phenotype in TRAMP mice and that HIP1 expression is elevated in mouse and human prostate cancers raised the question of whether aberrant HIP1 expression could be monitored in the serum. As one would expect of a cytoplasmic protein, HIP1 itself was difficult to detect in serum. However, anti-HIP1 antibodies in the serum of mice and humans with lymphoid, brain and prostate cancer are detectable. This is not unprecedented, as ►autoantibodies to other solid tumor antigens as well as leukemia antigens have been detected in patient sera. Additionally, antibodies to HIP1r have been found in patients with colon cancer. In addition to use of this test in humans, this newly-developed test specifically detects HIP1 changes in sera from TRAMP mice and p53 deficient mice with prostate cancer and lymphoid cancers, respectively. Given the fact that some cancer-bearing mice as well as humans with prostate cancer and lymphoma develop antibodies to HIP1, it will be important to expand these findings to larger cohorts of patients with different types of tumors at different stages of the disease.

Over-expression of HIP1 is Sufficient to Transform Fibroblasts. Since abnormalities in proliferation are hallmarks of cancerous cells and HIP1 is over-expressed in tumor cells, HIP1 over-expression may be directly oncogenic. To begin to test this, full-length HIP1-overexpressing 3T3 cell lines have been constructed and assayed for anchorage-independent growth in soft agar and for their ability to form tumors in nude mice. In both assays, HIP1-overexpressing cells were transformed, while control cells were not. An important

clue as to how HIP1 may achieve these transforming effects came from the finding that EGFR (►epidermal growth factor receptor ligands) levels are elevated in the HIP1 transformed cells and inhibition of the EGFR (►epidermal growth factor receptor ligands) tyrosine kinase with the specific small molecule inhibitor, CI-1033 (Pfizer), inhibited HIP1-mediated transformation. These data suggest that HIP1 over-expression transforms fibroblasts by increasing signaling by receptor tyrosine kinases. A mutant form of HIP1 in which the lipid binding-ANTH domain was deleted was unable to transform cells. HIP1 transforming activity should be next tested *in vivo* and in additional cell types (epithelial and hematopoietic cells) by transgenically expressing high levels of human HIP1 or mutants of human HIP1 in different murine tissues.

Future

How abnormalities in the trafficking of membranes and their components lead to cancer initiation and evolution is a major question to answer as a result of HIP1's looming role in cancer. HIP1 represents a novel type of oncogene that we believe transforms cells by dysregulating membrane trafficking and by upregulating signaling through multiple pathways. Although the link between endocytosis and cellular signaling has been well established, the link between clathrin-mediated membrane trafficking and cancer has only been referred to as an interesting possibility due to anecdotal leukemic alterations or as it relates to monoubiquitination and degradation targeting of growth factor receptors by the E3 ligase, Cbl. It had not been experimentally verified in humans prior to the discovery of HIP1 abnormalities in a variety of cancer types.

The aim of future research will be to not only gain a deeper understanding of HIP1, but also to expand work beyond the HIP1 pathway to determine if other proteins involved in membrane trafficking are linked to tumorigenesis. By combining *in vitro* cell culture and *in vivo* (mouse and human) work, the paradigm of trafficking and tumorigenesis will move to a new level. It is anticipated that changes in trafficking will not only upregulate signaling for relevant pathways (such as the EGFR (epidermal growth factor receptor ligands) tyrosine kinase) that promote survival and proliferation, but that these changes in membrane dynamics will also influence yet to be discovered transcriptional regulators through novel mechanisms.

Future research should also expand the analysis of the HIP1 antibody response. Testing this further with immunization of mice with HIP1 antigens as well as testing more patients for antibody levels is necessary. The need for serum biomarkers for clinical cancer care is great. By analyzing the humoral response to abnormal HIP1 in controlled animal models, as well as screening less controlled but direct human serum samples from patients with pathologic or clinically linked data (Brca mutation (►BRCA1/BRCA2 Germline Mutations and Breast Cancer Risk), p53 loss, Androgen Receptor, Estrogen Receptor, Progesterone Receptor, Her2/neu, survival, relapses and time to relapses), use of a humoral response to HIP1 may or may not be deemed be a useful screening tool.

The antigen that is expressed in cancer samples could be a mutated or a posttranslationally altered form of HIP1/HIP1r. A good example is the t(5;7) chromosomal translocation that results in the expression of HIP1/PDGFβR in CMML. Analysis of the HIP1 and HIP1r genes in primary human breast, lymphoid, brain and prostate cancer samples using Southern blot and sequence analysis will answer this. If cancers frequently harbor mutant forms of HIP1 or HIP1r, then this information will guide investigators in their design the HIP1 antigens, which should then be used to detect serum humoral response.

In addition to altered clathrin-mediated membrane trafficking in cancer there are other interesting cancer-related pathways that have not yet been investigated for links to HIP1 abnormalities and that may be functionally important. For example, mutations in the BRCA1 and BRCA2 genes are the main causes of hereditary breast and ovarian cancers. BRCA1 mutant tumors are distinct from BRCA2 mutant and sporadic tumors in that they are Estrogen Receptor negative, Progesterone Receptor negative, Her2/neu negative, and have upregulated EGFR (epidermal growth factor receptor ligands). Could BRCA1 deficiency lead to mutations at the HIP1 locus that affect the levels of EGFR (epidermal growth factor receptor ligands)? Could inhibition of HIP1 be a way to target BRCA1 mutant tumors? By screening humans with these mutations for anti-HIP1 antibodies an investigation of these interesting questions may yield novel mechanistic insights into human cancers.

Significance

HIP1 proteins are clearly important to normal and neoplastic physiology. Ongoing work is focused on understanding mechanisms of transformation by HIP1 and its mutants and why deficiency of both HIP1 and HIP1r leads to premature degenerative phenotypes in adult mice. With this work, ways to monitor and modulate the HIP1 family to alleviate neoplastic and degenerative diseases in patients can be easily imagined. Longer term goals are to expand the idea that abnormalities in the movement of cell membranes and their components can cause cancer and that modulating membrane trafficking will lead to effective cancer therapies. Continuous use of mouse models and patient materials to experimentally pursue these future goals is needed. By discovering a role for disrupted membrane trafficking in cancer and by working toward a better

understanding of how this dysregulation contributes to tumorigenesis, establishment of a new field of study that integrates cancer biology, clinical oncology, and basic molecular biology will be achieved.

Hurthle Cell

Definition

Oncocytic cell arising from the follicular epithelium and characterized by an eosinophilic granular cytoplasm and a vesicular nucleus with a large nucleolus. Named after Karl Hurthle German histologist born 1860-died 1945. This is a misnomer since Askanazy was the first to describe these cells.

►Hurthle Cell Carcinoma

Hurthle Cell Adenoma and Carcinoma

Ronald A. Ghossein
Department of Pathology, Memorial Sloan-Kettering Cancer Center, New York, NY, USA

Synonyms

Follicular carcinoma, oncocytic variant; Follicular adenoma, oncocytic variant

Definition

►Hurthle cell adenomas and carcinomas are respectively benign and malignant epithelial tumors arising from the follicular epithelium of the thyroid gland, containing at least 75% of ►oncocytes and lacking the characteristic nuclear features of papillary thyroid carcinoma (i.e. irregular clear nuclei with grooves, overlapping and pseudo-inclusions). The oncocytes in Hurthle cell adenomas and carcinomas are characterized by an eosinophilic granular cytoplasm on ►hematoxylin and eosin sections with a vesicular nucleus and a large centrally located nucleolus. The oncocytic nature of the cytoplasm is due in the vast majority of the cases to its high content in mitochondria.

Characteristics

Clinical and Histopathologic Characteristics. Hurthle cell carcinomas is a rare tumor accounting for only 3–4% of the ~33,550 newly and yearly diagnosed thyroid malignancies in the United States. The median age at diagnosis for Hurthle cell carcinomas is ~61 years and the female to male ratio is 2:1 while it is 8:1 for Hurthle cell adenomas. The exact incidence of Hurthle cell adenoma is unknown but probably much higher than the incidence of its malignant counterpart. Most patients with Hurthle cell adenoma and carcinoma present with a painless thyroid mass. Patients with carcinoma tend to present at an older age and usually have larger tumors than adenoma patients. Rarely patients with Hurthle cell carcinoma present with distant metastases usually to lung and bone. Hurthle cell carcinomas should be separated from Hurthle cell adenoma on the basis of presence or absence of invasion of the tumor capsule (capsular invasion) as well as presence or absence of vascular invasion. The latter is defined as invasion of a vessel within or beyond the tumor capsule in the surrounding thyroid or extrathyroid tissue. Hurthle cell adenoma and carcinoma cannot be separated on the basis of growth pattern whether follicular (i.e. making glands) or solid. The size of the tumor cell and its nuclear-cytoplasmic ratio cannot also be used to diagnose malignancy. Therefore, the differentiation between benign and malignant Hurthle cell tumors is impossible in smears from fine needle aspiration since it is not possible to assess capsular or vascular invasion in cytology specimens. The diagnosis of malignancy can be a very difficult exercise in tissue sections, especially after fine needle aspiration. In addition to causing infarction, the needle biopsy can lead to artefactual irregularities of the tumor capsule rendering the evaluation of capsular and vascular invasion very difficult. Hurthle cell carcinomas should also be differentiated from the ►tall cell variant of papillary carcinoma and ►papillary carcinoma, oncocytic variant. These two entities share with Hurthle cell carcinoma the presence of an oncocytic cytoplasm but differ from it by displaying the nuclear features of papillary carcinoma (i.e. irregular clear

nuclei with grooves, pseudo-inclusions and nucleoli apposed to the nuclear membrane). Hurthle cell carcinoma are divided into minimally invasive and widely invasive tumors The minimally invasive carcinoma, also termed encapsulated, is totally surrounded by a fibrous capsule and displays capsular invasion and/or foci of vascular invasion. It is unusual for these foci of invasion to be detected grossly. In contrast, widely invasive Hurthle cell carcinoma are defined by extensive areas of invasion at both the macroscopic and microscopic level and the capsule remnant is often difficult to identify. This classification correlates very well with outcome, such that minimally invasive tumors have an overall excellent prognosis, whereas widely invasive tumors have a much poorer outcome with a 55% mortality rate according to one series. However, there are cases of encapsulated minimally invasive follicular carcinoma that recur and metastasize. Identifying these cases at the time of diagnosis is crucial because a minimally invasive tumor will be treated by lobectomy alone followed by observation in some centers. This approach will risk undertreating those few minimally invasive tumors with poor outcome. At variance with the minimalist surgical approach, many surgeons will perform a total ►thyroidectomy followed by radioactive iodine therapy on any minimally invasive Hurthle cell carcinoma, most likely overtreating a large number of cases. In view of the limitations of the above subcalssification, many authors have attempted to revise this classification. Indeed, some researchers will exclude from the minimally invasive category any tumor with vascular invasion, even if microscopic while we will exclude from the minimally invasive group any tumor with ≥4 foci of microscopic vascular invasion since the latter has a significant recurrence rate. Within widely invasive Hurthle cell carcinoma, adverse predictors of survival are extrathyroidal extension, nodal metastasis, positive margin, and a solid growth pattern. On multivariate analysis, extrathyroidal extension and nodal metastases are independent predictors of outcome within widely invasive Hurthle cell carcinoma, present in 59 and 21% of cases respectively.

Immunohistochemistry. Hurthle cell tumors are typically positive for the thyroid markers thyroid transcription factor 1 (►TTF-1) and ►thyroglobulin. In carcinomas with a solid growth pattern, thyroglobulin positivity can be very focal. Various cell cycle proteins have been used to differentiated between benign and malignant Hurthle cell tumors and stratify patients with Hurthle cell carcinoma. Only Ki67 was found to be significantly elevated in widely invasive Hurthle cell carcinoma in comparison to Hurthle cell adenoma and minimally invasive Hurthle cell carcinoma. But this marker is not an independent prognostic marker since it correlates very well with the extent of vascular invasion and the presence of extra-thyroid extension.

Genetics. Hurthle cell tumor frequently show chromosomal DNA imbalance. Somatic mutations have been identified in the mitochondrial DNA of Hurthle cell carcinoma. These findings have no clinical use in these tumors.

Imaging. It is important to note that the follow up imaging of Hurthle cell carcinomas include radioactive iodine scans and positron emission tomography (PET). Hurthle cell adenomas can also be positive by both modalities. This is important to know since PET performed for non-thyroid malignancies (like melanoma) can lead to the discovery of Hurthle cell tumors whether benign or malignant. These are referred to as PET incidentalomas. The presence of PET incidentalomas should lead to a thyroid nodule work up.

Treatment. All authors agree that non-minimally invasive Hurthle cell carcinoma should be treated by total thyroidectomy followed by radioactive iodine administration. For minimally invasive carcinomas, there is disagreement between authors. While some recommending full therapy for these patients (similar to widely invasive tumors), we believe minimally invasive tumors should be treated by ►thyroid lobectomy alone as long as they display no more than two foci of capsular and or vascular invasion. All authors agree that lobectomy is sufficient for the treatment of Hurthle cell adenoma.

Current and Past Controversies

Hurthle cell tumors have generated a large number of controversies since their original description. One controversy regards the cell type. While most physicians, especially in North America go by the term Hurthle cell, it is a misnomer. It is ►Askanazy and not Hurthle who provided the description of these follicular oncocytic cells. A much more debated issue is whether Hurthle cell carcinoma is a distinct tumor entity. Some authors believe this tumor should be separated from conventional non-oncocytic follicular carcinoma. Indeed, compared to non-oncocytic follicular carcinoma, Hurthle cell malignancies generally take up less radioactive iodine, have a higher frequency of extrathyroid extension, local recurrence and nodal metastases. Hurthle cell carcinoma are overall more aggressive tumors. Since many of the differences are not evident when patients are stratified by extent of invasion, other authors believe Hurthle cell carcinoma are simply a morphologic variant of follicular carcinoma. This is the official position emanating from the last world health organization classification of endocrine tumors. Another controversy arose in the 1970's when some authors suggested that all Hurthle cell tumors are malignant. This view is no longer accepted and all current thyroid pathologists believe it is possible to

differentiate benign from malignant Hurthle cell tumors on histologic grounds. As mentioned above, there is still controversy as to what constitutes a minimally invasive tumor and there is still a debate regarding the optimal therapy for minimally invasive Hurthle cell carcinomas.

Hyaluronan Synthases

Natalie Thomas
Department of Biochemistry and Molecular Biology, Monash University, Melbourne, VIC, Australia

Synonyms

Hyaluronic acid synthases; HAS; Hyaluronic acid; HA

Definition

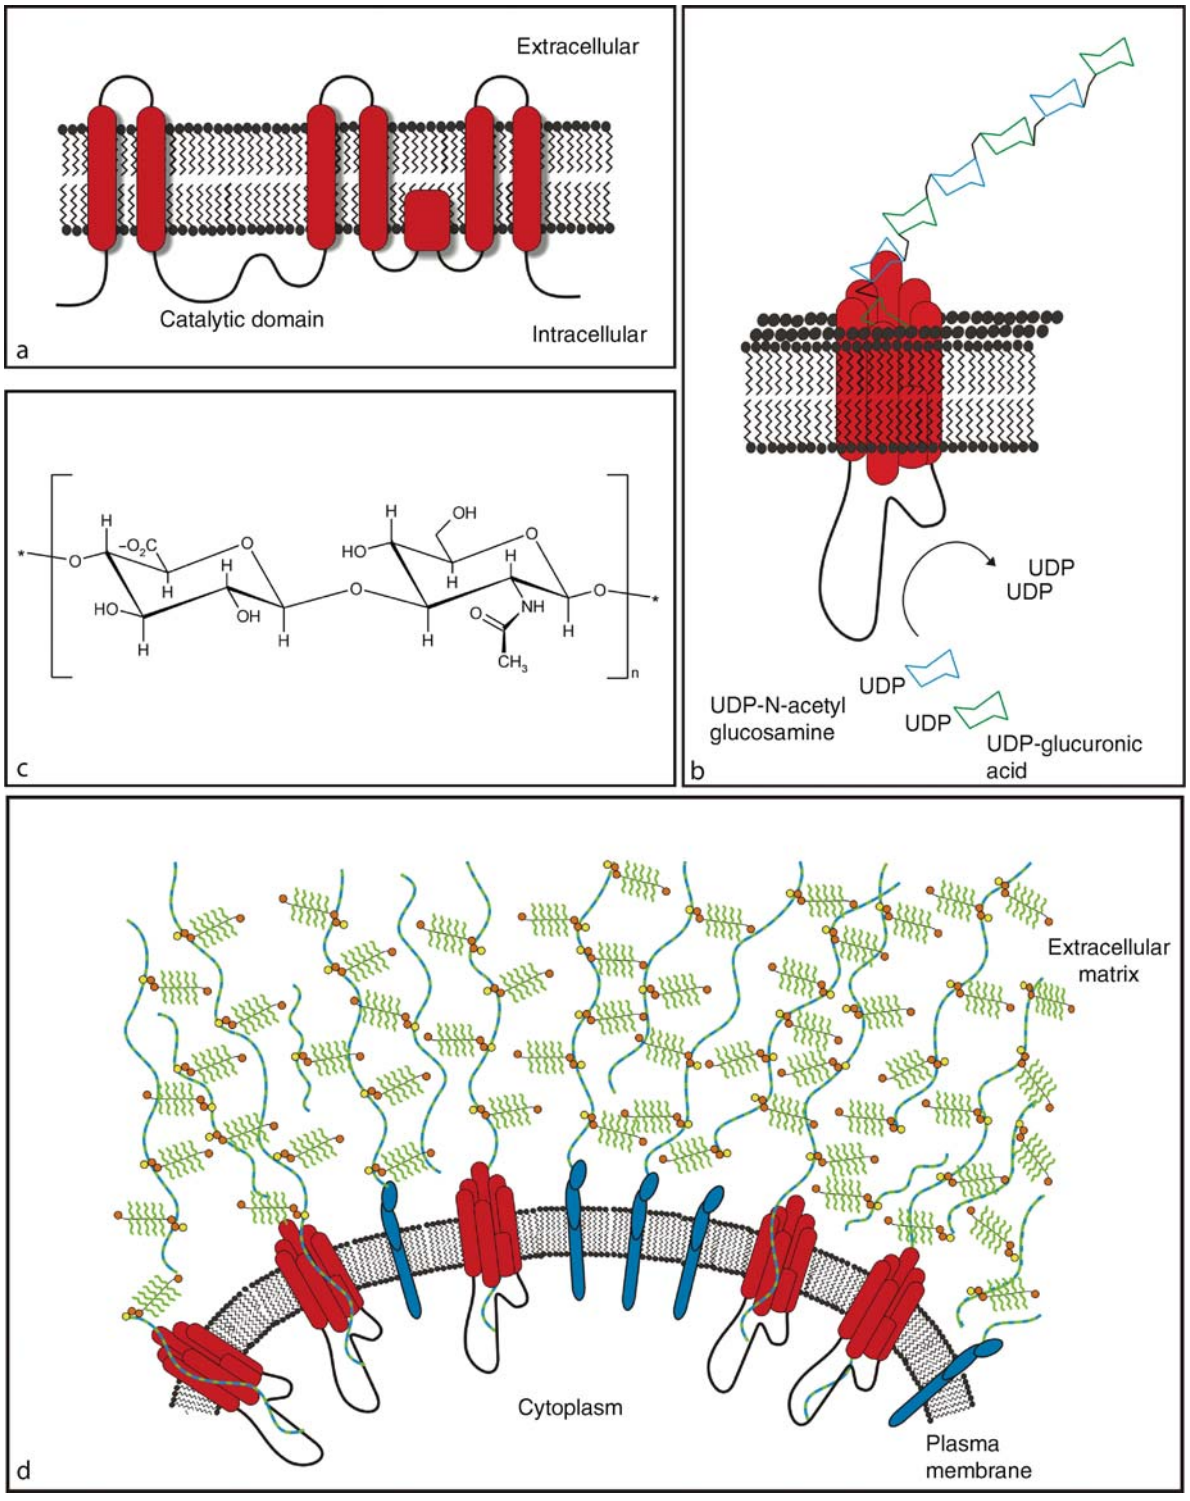
Hyaluronan synthases (HAS) are multi-isoform transmembrane proteins which catalyse the synthesis of the high molecular weight carbohydrate, ►hyaluronan (HA). High expression of hyaluronan synthases in a neoplasm or associated peritumoral ►stroma is often a poor prognostic indicator in cancer. Hyaluronan is a ubiquitous component of the ►extracellular matrix where it has various roles in matrix hydration, promotion of cellular growth and proliferation, induction of malignant transformation, and invasion and metastasis.

Characteristics

Hyaluronan Synthases and Hyaluronan

Hyaluronan synthases (►HAS1, ►HA2, ►HAS3) are integral plasma membrane proteins that utilize UDP-glucuronic acid and UDP-N-acetyl glucosamine substrates to alternately add monosaccharide units to a growing chain of hyaluronan. Three isoenzymes (designated *HAS1*, *HAS2*, and *HAS3*) are localized to separate chromosomes and exhibit varying enzymatic properties despite having relatively high amino acid sequence homology. Each isoform however, is topologically and structurally similar with predicted clusters of transmembrane domains seen at either end of the protein which vary from 1 to 2 in number at the amino terminal and from 4 to 6 at the carboxyl terminus. A large cytosolic region separates the transmembrane domains of the amino- and carboxyl termini and contains the active sites and substrate binding residues to fulfill HA synthetic capacity. All isoforms catalyse the polymerisation of the ►UDP-monosaccharides at the internal face of the plasma membrane, where catalysis occurs within the large cytoplasmic domain which constitutes approximately half of the overall protein. The growing *HA* chain is extruded through the plasma membrane into the ►extracellular matrix (ECM) or onto the ►pericellular surface where it can remain bound to *HAS* or associates with cellular *HA* receptors to form a ►glycocalyx. The expansion of the *HA* chain into the extracellular matrix allows the size constraints that would normally be imposed by cellular dimensions to be overcome, and thus permits unrestrained polymer growth. Upon release of *HA* into the extracellular milieu, it is retained within the matrix via interaction with ►proteoglycans and receptor proteins which typically contain a *HA*-binding structural motif (Fig. 1).

Hyaluronan (►HA) exhibits a diverse range of physiological functions despite its simple and unadorned structure of repeating disaccharide units of N-acetyl glucosamine and glucuronic acid. The disaccharide building blocks are linked by glycosidic bonds (in which a single oxygen atom links the two sugar units) into a macromolecule which typically contains 2,000–25,000 disaccharides and ranges in molecular weight between 10^5 and 10^7 Da. It is highly negatively charged due to the prevalence of carboxyl groups contributed from the glucuronic acid moiety. Within an aqueous environment, the hyaluronan becomes heavily hydrated primarily due to the formation of large solvation cavities which are a result of electrostatic repulsion between intra-hyaluronan anionic groups. Hyaluronan adopts a random coil structure in solution where molecules entangle to form a viscous, gel-like meshwork that can contract in response to external pressure, but will relax and expand when released as a result of charge repulsion. In this way a *HA*-rich extracellular matrix is malleable, elastic and flexible,



Hyaluronan Synthases. Figure 1 Hyaluronan and hyaluronan synthases. (a) The HA synthase is predicted to be a multipass transmembrane protein with a large cytoplasmic domain, which holds key substrate binding and catalytic residues. (b) HA is extruded through the plasma membrane following polymerisation of UDP-glucuronic acid and UDP-N-Acetyl Glucosamine. (c) HA is composed of repeating units of glucuronic acid and N-acetyl glucosamine linked by glycosidic bonds. (d) HA chains can associate with HA Synthases (*red*), cell surface receptors such as CD44 and RHAMM (*blue*), and interact with other matrix components including proteoglycans (*green*), forming a structured, malleable and hydrated pericellular and extracellular matrix.

and provides an ideal medium for growth, expansion and cushioning of tissues.

The broad range of physiological activities of *HA* are typically dependent on molecular weight and concentration as these impact on the physical and mechanical properties, viscosity, hydration, matrix forming capacity and the interactions between *HA* and cellular receptors. Therefore as each of the *HAS* isoenzymes differ in catalytic rate and molecular weight of the synthetic products, the differential regulation and control of HAS expression are important determinants in HA function. HAS1 characteristically drives the synthesis of high molecular weight *HA* (ranging from 2×10^5 to $\sim 2 \times 10^6$ Da), however exhibits a relatively low catalytic rate suggesting a role in maintenance of a basal level of cellular HA. HAS2 produces higher molecular weight HA and is more catalytically active; increased expression of this isoenzyme is observed in many developmental and repair process involving tissue expansion and growth. ►HAS3 is most active and synthesizes lower molecular weight HA (10^5 to 10^6 Da) that has been associated with providing HA for release into the ►pericellular matrix, or for interaction with cell surface receptors.

The molecular weight of native HA can be degraded through cleavage mediated by ►hyaluronidase enzymes; there are six hyaluronidases that exhibit varying cellular locations and properties, of which Hyal-1 and Hyal-2 hyaluronidases are the predominant forms responsible for HA catabolism in somatic tissues. Hyal-2 is anchored to the plasma membrane and can cleave HA to 20 kDa fragments, enabling it to be internalized for lysosomal degradation into disaccharides in a process mediated by Hyal-1. The concurrent activity of *HAS* and hyaluronidase enzymes results in significant polydispersity of HA within the extracellular matrix. Whilst originally though to be an inert, space-filling macromolecule, the diverse sizes of HA molecules can bind to specific cell surface receptors such as ►CD44 and ►RHAMM (Receptor for Hyaluronan Mediated Motility) to induce transduction of various size-dependent cell signals, thereby highlighting the importance of action of HA synthetic and degradative enzymes.

Hyaluronan Synthases and Hyaluronan in Cancer

The extracellular environment within and surrounding a tumor mass can have a profound effect on tumorigenesis, progression and invasion. This is perhaps most evident in metastasis where cell migration and invasion must be mediated by manipulation and breakdown of the extracellular matrix; inevitably alteration and disruption of the matrix composition is characteristic of cancer initiation and progression. Increased HAS expression and deposition of HA in comparison to that in normal and benign tissue is one such morphological change in matrix composition that is commonly observed in many malignancies. The correlation between high levels of hyaluronan and tumor aggressiveness and invasiveness is long established and in many malignancies, elevated intra-tumoral HA is associated with poor prognosis and low survival rates. Elevated intra-tumoral HA can be resultant of higher expression levels of HAS within the tumor cells, and/or through the HA synthesized by stromal cells that surround a tumor. There is a dynamic interplay between stromal and malignant tissue, where paracrine signaling by tumor cells can induce upregulation of expression of HAS in stromal cells such as fibroblasts or smooth muscle cells. Paracrine stimulation of HAS activity can be attributed to tumor release of growth factors such as ►TGF-β, ►FGF and ►PDGF, or by inflammatory cytokines such as ►TNF-α.

These observations have established a clear link between HAS, HA and tumorigenesis; the mechanisms by which HA production augments the malignant process have begun to be elucidated by manipulation of expression levels of the *HAS* enzymes, and disruption of the endogenous interactions that occur between HA and tumor cells via receptors such as CD44 and RHAMM.

H

Proliferation and Tumor Growth

Increases in ►pericellular HA are observed in proliferating and migrating cells during normal physiological processes such as morphogenesis, growth and wound healing, so it is not surprising that elevated hyaluronan also correlates to pathologies like cancer that are defined by rapid and inappropriate cell division and motility. Structurally, increased synthesis and deposition of HA results in hydration and expansion of the tissue volume creating less dense connective tissue that differs significantly from the architecture of the extracellular matrices associated with non-diseased cells and normal tissue. This flexibility and malleability of HA-rich matrices provides a medium that can readily surround rapidly dividing cells concomitantly accommodating changes in shape that occur during mitosis. Extracellular matrices rich in HA can also promote proliferation through the facilitation of diffusion of nutrients, growth factors and cytokines to a tumor, and creation of a concentrated reservoir of various growth effectors.

Expression of the hyaluronan synthases fluctuate within the cell cycle progression, with maximal activity occurring during mitosis where HA facilitates partial cell rounding and detachment. The interaction of HA and the centrosomally localized RHAMM receptor results in stabilization of the mitotic spindle during mitosis. Cell division is inhibited when the pericellular HA matrix that forms immediately prior to mitosis is disrupted, thereby demonstrating the multifaceted roles that both HA and HAS play in cell cycle regulation and cellular proliferation.

Experimentally induced overexpression of each HAS isoenzyme enhances the growth kinetics of a wide range of tumor cell lines; conversely, the

disruption of interactions of HA with ►CD44 or ►RHAMM induces cell cycle arrest or apoptosis, suggesting that the role of HA in a tumor is structurally permissive but also has more complex roles in the initiation of cell signaling cascades promoting proliferation. Very high overexpression of HAS isoenzymes and high concentrations of high molecular weight HA can conversely inhibit tumor growth, indicating that there is a tightly controlled active regulation of HAS expression during the development of malignancy. The increased expression of hyaluronidase in many malignancies is suggestive of a cooperative balance between increased HA synthesis and degradation in tumors, where an imbalance in expression may lead to growth inhibition. Controlled regulation of HAS and hyaluronidase expression is evident in induction of angiogenesis. When diffusion of nutrients within a high molecular weight HA rich matrix is no longer sufficient for growth and proliferation, the HA can be degraded to low molecular weight products which stimulate endothelial cell proliferation, migration and tumor vascularization.

Production of HA can also contribute to the acquisition of an anti-apoptotic phenotype in cancer thereby promoting tumorigenesis. Normal cell survival requires anchorage to the substratum; cancer cells can avert this requirement and grow independently in a manner dependent on binding of native HA to CD44. This interaction can facilitate cell survival by promoting the activation of the ►PI3K signaling/►AKT pathway and stimulating phosphorylation of pro-survival effectors, ►FAK and BAD. Hyaluronan binding to CD44 is also required for complex assembly of a number of factors critical for signaling in the ►HER-2/neu pathway; when this signaling pathway dysfunctions there is a direct correlation with malignancy development in a number of solid tumors. RHAMM-HA interaction similarly initiates signaling cascades directing phosphorylation of BAD, and appears implicated in aberrant mitosis through disruption of RHAMM binding to microtubules leading to chromosomal misaggregation.

Invasion and Metastasis

Hyaluronan synthase expression and production of hyaluronan can augment the invasion and metastasis of tumor cells in several ways:

- By creation of hydrated, expanded matrix pathways which are compatible with cell migration and facilitate tissue penetration
- Promotion of anchorage independent growth
- Stimulation of cell locomotion and migration mediated by HA interaction with CD44 and RHAMM: CD44 has the capacity to interact with cytoskeletal proteins such as ►actin and ankyrin. The activation of CD44 induced by HA binding can initiate signaling cascades involving ►Src kinases and Ras/Rho GTPases that lead to cytoskeletal rearrangement, membrane ruffling and migration. Cellular locomotion also requires turnover of focal adhesions (cell substratum adhesions); this process appears to require RHAMM-mediated activation of Src kinase and transient phosphorylation of focal adhesion kinase dependent on HA-RHAMM interaction
- HA-CD44 interaction stimulates the expression of ►matrix metalloproteinases (MMPs): MMPs are required for proteolytic degradation of the extracellular matrix; this occurs when cells invade normal tissue and penetrate through the basement membrane into the surrounding vasculature. Association of *HA* and CD44 can promote expression of MMP-9 and MMP-2 and memprane-type1-matrix metalloproteinase (MT1-MMP). MT1-MMP additionally mediates the proteolytic cleavage of CD44 from the cell surface and the detachment from underlying hyaluronan during cell locomotion. Shedding of CD44 promotes CD44 expression and the continual receptor cycling allows continued adherence and detachment from the matrix as a tumor cell migrates
- *Induction of* ►epithelial-mesenchymal transition *(EMT)*: The acquisition of an invasive and metastatic phenotype in carcinomas is akin to EMT seen in embryogenesis. Increased HAS expression and production of high molecular weight HA can be sufficient to induce stimulation of ErbB and PI3K signaling/Akt pathways and EMT. Elevated *HA* production can interfere with formation of intercellular and matrix adhesions increasing cellular autonomy, and inducing anchorage independent growth, MMP expression and cytoskeletal rearrangement which are typical characteristics of mesenchymal tissue

Multidrug Resistance

Multidrug ►resistance hinders the administration of an effective chemotherapy regime. Acquisition of resistance can be from mutation of drug binding sites, enzymatic deactivation or decreased permeability of drug entry, however is most commonly associated with increased drug efflux by ATP-binding pumps such as MDR (multi-drug resistance) proteins. Overproduction of hyaluronan promotes multidrug resistance, observed when upregulation of HA synthesis renders drug sensitive cancer cells resistant. Administration of hyaluronidase as an adjunct to chemotherapy regimes increases the sensitivity of tumors to various therapeutic agents by reducing barriers to drug penetration, and degrading the HA-rich matrix which typically facilitates cytokine diffusion. Hyaluronan synthesis also stimulates the expression of MDR1 and acquisition of drug resistance via HA-CD44 mediated activation of the ErbB2 signaling complex; this leads to downstream activation of PI3 Kinase signaling which subsequently stimulates both HAS and MDR1 expression. Hyaluronan additionally stimulates MDR1 in an unknown mechanism independent of PI3 Kinase activation.

Hyaluronic Acid

Definition

HA; High molecular weight sugar consisting of multimers of three repeats of a basic disaccharide repeat (glucuronic acid and N-acetyl glucosamine joined in β1Π 3). The hexamers are joined in β1Π 4 formation between N-acetyl glucosamine and glucuronic acid. HA is present in high concentration in extracellular spaces and promotes cell migration in embryogenesis and neoplastic transformation. The aminoterminal region of CD44 can bind to HA.

Definition

HAases are endoglycosidases that degrade hyaluronic acid (HA). HA is a non-sulfated glycosaminoglycan. Exhaustive digestion of HA with HAase generates tetrasaccharides, whereas, limited digestion generates HA fragments, some of which induce angiogenesis.

Characteristics

Six HAase genes are present in the human genome and these occur in two linked triplates. HYAL-1, -2 and -3 genes are clustered in the chromosome 3p21.3 locus, whereas, HYAL-4, HYAL-P1 and PH20 (encodes testicular HAase) reside in the chromosome 7q31.3 locus [1, 2]. Based on their pH activity profiles, HAases are divided into two categories. HYAL-1, -2 and -3 are considered acidic HAases because they are active at acidic pH. For example, HYAL-1 has a pH optimum around 4.0–4.2 and the enzyme is inactive above pH 5.0. It is normally expressed in serum and urine. On the contrary, PH20 or the testicular HAase is a neutral HAase as it is active at pH 7.0 (pH activity profile 3.0–9.0) and is involved in ovum fertilization.

Among the six mammalian HAases, HYAL-1 is the major tumor-derived HAase and is expressed by a variety of tumor cells. HYAL-1 was initially purified from the urine of patients with high-grade bladder cancer and was shown to be expressed in bladder epithelial cells, prostate tumors and in head and neck squamous cell carcinoma cells.

HAase Expression in Cancer

(►Cancer, ►biomarkers) Using a modified HAase ELISA-like assay (referred to in this review as the HAase test) Lokeshwar et al. found that HAase levels are elevated in prostate cancer tissues, when compared to normal prostate and benign prostatic hyperplasia tissues. HAase levels were also shown to be elevated in high-grade bladder tumor tissues, in the urine of patients with high-grade bladder cancer and also in the urine of patients with Wilms tumor. These studies have established a link between HAase and the tumor invasive/metastatic phenotype. In addition to genito-urinary tumors, HAase levels are elevated in head and neck squamous cell carcinoma, breast tumors, metastatic tumors and glioma cells.

For example, in head and neck squamous cell carcinomas the expression of HYAL-1 protein and mRNA is elevated, along with the expression of PH20 mRNA. In breast cancer, the less invasive cells appear to express HA-synthase (HAS)-3 and HYAL-3, whereas, highly invasive cells express HAS-2 and HYAL-2. However, how and why the HA production by HAS-2 and HA degradation by HYAL-2 promote tumor cell invasion, but HA production by HAS-3 and HA degradation by HYAL-3 associates with low-invasive phenotype is unclear. It is noteworthy that in these studies, the expression of HAS and HYAL isoforms was studied only at the transcript level by real time RT-PCR. Given that functionally inactive splice variants of HYAL-1 and HYAL-3 are previously reported [3], the expression

of HYAL genes at the mRNA level may not translate into HAase activity produced by breast cancer or any other cell type. Similar observations regarding HYAL-2 and HYAL-3 mRNA expression were reported for endometrial carcinoma.

Contrary to the findings regarding elevated expression of one or more HAases in tumors, based on real time RT-PCR studies Bertrand et al. reported that HYAL-2 expression correlates with lymphoma diagnosis, but the expression actually decreases in high-grade lymphomas, when compared to low-grade lymphomas.

Taken together, HAase expression appears to be elevated in many carcinomas and the expression correlates with tumor invasiveness. However, in some carcinomas Haase expression may inversely correlate with tumor grade.

HAase Functions in Cancer

HAase a Tumor Promoter. The angiogenic (3–25 disaccharide units) (Angiogenesis) HA fragments have been shown to stimulate endothelial cell proliferation, adhesion and capillary formation. Such angiogenic HA fragments are found in the urine of patients with high-grade bladder cancer, in the tissue extracts of high-grade prostate tumors, and in the saliva of patients with head and neck squamous cell carcinoma, suggesting that the HA-HAase system is active in high-grade invasive tumors.

cDNA transfection studies have shown that HYAL-1 is involved in tumor growth, infiltration and angiogenesis [4]. Lokeshwar et al. showed that blocking HYAL-1 expression in bladder and prostate cancer cells decreases tumor cell proliferation due to cell cycle arrest in the G2-M phase and decreases their invasive activity. In xenografts, inhibition of HYAL-1 expression results in decreased tumor growth. Furthermore, while HYAL-1 expressing tumors infiltrate muscle, blood vessels and lymphatics, tumors lacking HYAL-1 expression resemble benign neoplasms and have a significantly low microvessel vessel density and smaller capillaries [4, 5]. Interestingly, HA production by the tumor stroma correlates with HYAL-1 levels in tumor cells, suggesting crosstalk between the tumor and the tumor-associated stroma [4, 5]. Such crosstalk between HA and HYAL-1, with respect to tumor growth and angiogenesis, was recently confirmed by Simpson who tested tumor growth and angiogenesis following the expression of HAS-2 and HYAL-1, either individually or together, in a non-invasive prostate cancer cell line. While HAS-2 or HYAL-1, when expressed individually in a prostate cancer cell line caused increased tumor growth and angiogenesis, their co-expression had a synergistic effect on this increase. In addition, HYAL-1 expression in prostate cancer cells induces both lymph node and lung metastasis in orthotopic tumor models.

HAase a Tumor Suppressor. In some epithelial carcinomas, the 3p21.3 locus is deleted, and although, the tumor suppressor gene (►Tumor suppression) in this locus is not a HYAL gene (i.e., HYAL-1, -2, or -3), it was previously suggested that HYAL-1 is a tumor suppressor [5]. In support of HAase being a tumor suppressor, Jacobson et al. reported that while HAS-2 expression in a rat colon carcinoma line promoted tumor growth, the over-expression of HYAL-1, at levels (220–360 mu/10^6 cells) that are not found in tumor tissues and tumor cells, inhibited tumor growth and generated necrotic tumors. Furthermore, Shuster et al. showed that administration of super high concentrations of bovine testicular HAase (300 units) caused a ~50% regression in breast tumor xenografts. However, Lokeshwar et al. recently showed that while HYAL-1 levels that are expressed in tumor tissues and cells promote tumor growth, invasion and angiogenesis, HAase levels exceeding 100 mU/10^6 cells), i.e., at levels that are not naturally expressed by tumor cells, significantly reduce tumor incidence and growth due to induction of apoptosis [5]. Therefore, the function of HAase as a tumor promoter or a suppressor is a concentration-dependent phenomenon, but in tumor tissues, the tumor cell-derived HAase acts mainly as a tumor promoter.

Regulation of HAase Activity

Except for HYAL-2, the promoter region of other HAases has not been cloned, and therefore, very little is known about the regulation of HAases at the genomic level. Alternative mRNA splicing is another mechanism by which HAase activity is regulated. For example, in some tumor cells internal splicing within the 5′ untranslated region in exon 1 correlates with HYAL-1 protein levels and HAase activity. HYAL-1 protein is not detected in tumor cells which express a HYAL-1 transcript that retains the 5′ untranslated region. However, it is unclear how and why the 5′-untranslated region in the HYAL-1 mRNA prevents translation. Lokeshwar et al. have reported several alternatively spliced variants of HYAL-1 and HYAL-3 transcripts. All of these variants are enzymatically inactive [3]. Recent data on one of the HYAL-1 variants, HYAL1-v1, shows that the expression of HYAL1-v1 is higher in normal bladder tissues than in bladder tumor tissues. Furthermore, HYAL1-v1 expression reduces HAase activity secreted by bladder cancer cells because of a complex formation between HYAL-1 and HYAL1-v1. HYAL-1-v1 expression induces apoptosis in bladder cancer cells and reduces tumor growth, infiltration and angiogenesis. This suggests that a critical balance between the levels of HYAL-1 and HYAL-1 variants may regulate HYAL-1 function in cancer.

Clinical Importance of HAase

HAase as a Diagnostic and Prognostic Indicator. The diagnostic and prognostic potential of HAase, either

alone or together with HA has been extensively explored in cancer of the prostate and bladder. For example, the HA-HAase test, which measures urinary HA and HAase levels, has 91.2% sensitivity, 84.4% specificity and 88.3% to detect bladder cancer, regardless of the tumor grade and stage. More importantly, the HA-HAase test appears to detect bladder cancer recurrence even before the tumor becomes clinically detectable. Thus, a false positive HA-HAase test (i.e., test positive but no tumor is detected) carries a tenfold risk of developing bladder cancer within 5 months. In a side-by-side comparison, the HA-HAase test was also superior to a variety of FDA-approved bladder tumor markers. In addition to urinary HAase levels, measurement of HYAL-1 mRNA levels in exfoliated cells found in urine also appears to be a marker for bladder cancer. For example, Eissa et al. found that HYAL-1 mRNA expression determined by RT-PCR has >90% accuracy in detecting bladder cancer. Furthermore, HYAL-1 mRNA levels measured in exfoliated cells are elevated in patients with invasive and poorly differentiated carcinoma. These studies show that HAase is a highly accurate marker for detecting high-grade bladder cancer, and when it is combined with HA, it detects both low-grade and high-grade bladder cancer with ~90% accuracy.

The prognostic potential of HYAL-1 has been explored in prostate cancer. By performing immunohistochemistry on radical prostatectomy specimens, on whom there was a minimum 5-year follow-up, Posey et al. and Ekici et al. found that HYAL-1 staining in radical prostatectomy tissues is an independent predictor of prostate cancer progression (local recurrence or distant metastasis). Furthermore, HA-HYAL-1 staining has an 87% accuracy in predicting disease progression. It is noteworthy that in prostate cancer specimens, while HYAL-1 is exclusively expressed by tumor cells, HA expression mainly results from the tumor-associated stroma.

In a limited number of studies, HAase expression has also been studied in other carcinomas. For example, there is some evidence that HYAL-1 may be a marker for head and neck squamous cell carcinomas, as salivary HAase levels are elevated in head and neck cancer patients. PH20 mRNA levels are elevated in primary and lymph node metastatic lesions of laryngeal carcinoma when compared to normal laryngeal tissues. In contrast to the observations in many carcinomas, increased HYAL-2 expression inversely correlates with invasion in B-cell lymphomas and may serve as a prognostic indicator (►Chemotherapy of cancer; Progression and perspectives).

HAase and Cancer Therapeutics. Testicular HAase has been added in cancer chemotherapy regimens to improve drug penetration. Tumor cells growing in three-dimensional multicellular masses, such as spheroids *in vitro* and solid tumors *in vivo* acquire resistance to chemotherapeutic drugs (i.e., multicellular resistance). But this acquired chemoresistance can be abolished by the addition of testicular HAase. In limited clinical studies, HAase has been used to enhance the efficacy of vinblastin in the treatment of malignant melanoma and Kaposi's sarcoma, boron neutron therapy of glioma, intravesical mitomycin treatment for bladder cancer and chemotherapy involving cisplatin and vindesine in the treatment of head and neck squamous cell carcinoma. It is noteworthy that the HAase concentrations (1×10^5–2×10^5 IU) used in these clinical studies far exceed the amount of HAase present in tumor tissues, and therefore, it is unlikely that at these concentrations the infused HAase will act as a tumor promoter.

Summary

HAase appears to be an important molecular determinant of tumor growth, infiltration and angiogenesis. At concentrations that are present in tumor tissues, HAase acts as a tumor promoter. HAases either alone, or together with HA are potentially accurate diagnostic and prognostic indicators for cancer detection and tumor metastasis. We are only beginning to understand the complex role that this enzyme plays in cancer. Nonetheless, it is already proving to be a useful target for developing novel cancer therapeutics and diagnostics.

Hydrogen Peroxide

Miguel Lopez-Lazaro
Department of Pharmacology, Faculty of Pharmacy, University of Seville, Seville, Spain

Synonyms

Dihydrogen dioxide; Hydrogen dioxide

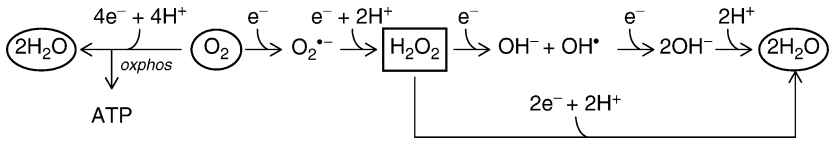
Definition

Hydrogen peroxide (H_2O_2) is a ►reactive oxygen species (ROS) generated from molecular oxygen (O_2). Although the controlled cellular production of H_2O_2 plays an important physiological role, high cellular levels of H_2O_2 can produce carcinogenic effects and induce cell death.

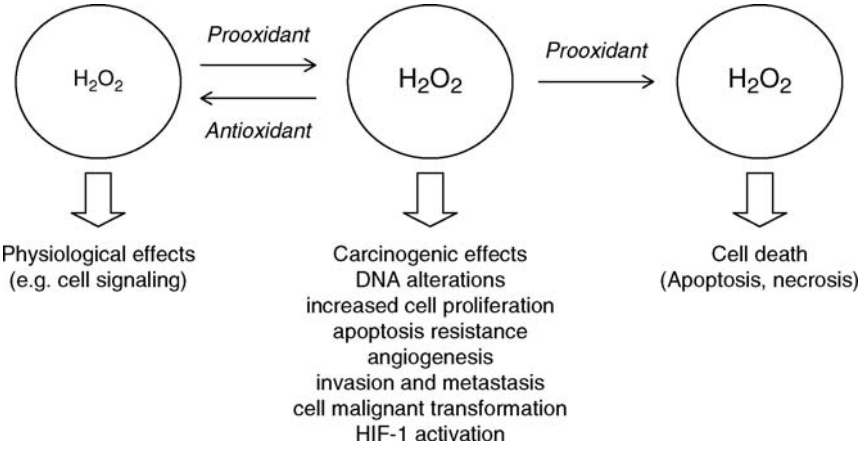
Characteristics

H_2O_2 is a pale-blue liquid first isolated in 1818 by Louis Jacques Thénard. H_2O_2 has industrial and domestic uses (e.g. paper bleaching, chemical synthesis, laundry detergents, antiseptic for wound cleaning, etc.) and it is manufactured today through an autoxidation reaction using O_2 from the air. Cells of aerobic organisms also generate H_2O_2 from O_2. Most of the energy (ATP) that aerobic cells need to live is obtained through a process called ►oxidative phosphorylation (oxphos). In this process, ATP generation is coupled with a reaction in which O_2 is reduced [►reduction/oxidation] to water (H_2O) by a mitochondrial protein complex called cytochrome oxidase. In this reaction, four electrons and four protons are added to O_2 to form two molecules of H_2O. But when a molecule of O_2 gains only one electron to form superoxide anion ($O_2^{\bullet-}$), this highly reactive oxygen species tends to gain three more electrons and four protons to form H_2O; this process involves several reactions and results in the production of other ROS such as H_2O_2 (Fig. 1).

ROS are generated in multiple compartments within the cell (e.g. mitochondria, cytosol, plasma membrane, peroxisomes, endoplasmic reticulum, etc.) and by numerous enzymes (e.g. cytochrome oxidases, NADPH oxidases, cyclooxygenases, cytochromes *P*450, xanthine oxidase, etc.). ROS can be eliminated by endogenous antioxidant systems. For instance, glutathione and thioredoxin systems decrease the cellular levels of H_2O_2 by catalyzing a reaction in which H_2O_2 is reduced to H_2O. Likewise, the enzyme catalase eliminates H_2O_2 by transforming two molecules of H_2O_2 into two molecules of H_2O and one molecule of O_2. Antioxidant agents can reduce the cellular levels of ROS by preventing their generation or by favoring their elimination. For instance, some polyphenols (e.g. ►flavonoids) can prevent the generation



Hydrogen Peroxide. Figure 1 Aerobic cells generally use O_2 to generate energy (ATP) through a process called oxidative phosphorylation (oxphos), but they can also use O_2 to generate reactive oxygen species such as hydrogen peroxide (H_2O_2).



Hydrogen Peroxide. Figure 2 While the controlled generation of H_2O_2 has an important physiological role, a sustained increase in the cellular levels of H_2O_2 can produce carcinogenic effects, and an excessive increase in the levels of H_2O_2 can induce cell death. Antioxidant agents can reduce the cellular levels of H_2O_2 and prevent the carcinogenic effects induced by H_2O_2; these agents may therefore exert a cancer-preventive activity. Prooxidant agents can increase the cellular levels of H_2O_2 and may induce carcinogenic effects. A sufficient increase in the cellular levels of H_2O_2 induced by prooxidant agents may trigger cell death and be therapeutically useful.

of H_2O_2 by scavenging $O_2^{\bullet-}$; and selenium compounds can favor the elimination of H_2O_2 by providing selenium atoms, which are essential components of the H_2O_2-detoxifying enzyme glutathione peroxidase. Prooxidant agents, on the contrary, can increase the cellular levels of ROS by increasing their generation or by reducing their elimination. For instance, arsenic can increase ROS generation by activating the enzyme NADPH oxidase, and buthionine sulfoximine (an inhibitor of γ-glutamylcysteine synthetase, the rate-limiting enzyme of glutathione synthesis) can reduce ROS elimination by decreasing glutathione-mediated H_2O_2 decomposition.

The controlled generation of ROS plays an important role in the physiological control of cell function. For instance, cells under hypoxic conditions generate H_2O_2 and use it to activate hypoxia-inducible factor 1 (HIF-1) [►hypoxia and tumor physiology], a transcription factor that codes for many proteins that help cells adapt to low oxygen levels. An uncontrolled or excessive cellular production of H_2O_2, however, can produce carcinogenic effects and cell death (Fig. 2).

Carcinogenic Effects

Cancer cells from different tissues have been observed to produce high amounts of H_2O_2. High cellular levels of H_2O_2 have been associated with DNA alterations, including DNA damage, mutations, and genetic instability. For instance, transition metals such as iron or copper can react with H_2O_2 to produce hydroxyl radical ($OH^{\bullet}$) via the Fenton reaction; $OH^{\bullet}$ is a highly reactive species known to produce ►oxidative DNA damage. The production of DNA alterations by H_2O_2 may play an important role in ►carcinogenesis, as cancer is considered to be a genetic disease caused by DNA alterations.

Cell proliferation, ►apoptosis resistance, ►angiogenesis, invasion and ►metastasis are key events of the carcinogenesis process. It is well known that, in order for cancer to develop, tumor cells must proliferate. Accumulating data have shown that H_2O_2 stimulates cell proliferation; in fact, the cell proliferation induced by different stimuli can be decreased by H_2O_2-detoxifying enzymes (e.g. catalase). Under

physiological conditions, cells with irreparable damages usually commit suicide by triggering a programmed process called apoptosis. Since tumor cells have important damages in many of their components, the formation of a cancer requires that tumor cells develop apoptosis resistance. Interestingly, it has been found that non-cytotoxic concentrations of H_2O_2 can produce apoptosis resistance in cancer cells. Angiogenesis – the generation of new blood vessels – is also necessary for the formation of a solid tumor; without vascular growth, the tumor mass is restricted to within a tissue-diffusion distance of approximately 0.2 mm. Recent results support that H_2O_2 has an important function in angiogenesis. For instance, angiopoietin-1 plays an important role in angiogenesis and it has been found that its angiogenic effect is mediated by H_2O_2. It is recognized that the metastatic spread of primary tumors accounts for approximately 90% of all cancer deaths. The process by which cells from a localized tumor invade adjacent tissues and metastasize to distant organs is therefore the most clinically relevant processes involved in carcinogenesis. H_2O_2 has been found to modulate the activity of several processes (e.g. cell ►motility, migration, adhesion) and molecules (e.g. ►MET, ►matrix metalloproteinases) involved in tumor invasion and metastasis. Indeed, studies carried out in animal models have revealed that the targeted delivery of catalase can inhibit tumor metastasis.

Although the transcription factor HIF-1 plays an important role in the physiological control of cell function, HIF-1 overexpression is commonly observed in most human cancers and has been associated with increased patient mortality in several cancer types. HIF-1 increases the transcription of a variety of genes that code for proteins involved in processes intimately related to cancer, including apoptosis resistance, angiogenesis or invasion and metastasis. H_2O_2 can both activate HIF-1 and mediate the activation of HIF-1 caused by different stimuli; in fact, the presence of enzymes that reduce the cellular levels of H_2O_2 prevents the activation of HIF-1 caused by different triggers (e.g. hypoxia, TNF-alpha). The key role of H_2O_2 in carcinogenesis is also supported by experimental data that have demonstrated that H_2O_2 can cause and mediate cell malignant transformation. For instance, it has been reported that the expression of Nox1 (a homologue of gp91phox, the catalytic moiety of the $O_2^{\bullet-}$-generating NADPH oxidase of phagocytes) in normal NIH3T3 fibroblasts resulted in cells with malignant characteristics that produced tumors in athymic mice. These transformed cells showed a 10-fold increase in H_2O_2 levels. When catalase was overproduced in these transformed cells, H_2O_2 concentration decreased, and the cells reverted to a normal appearance, the growth rate normalized, and cells no longer produced tumors in athymic mice.

Clinical Relevance

Despite some important advances in cancer therapy, the number of cancer deaths has not decreased in the last three decades. New strategies to control this disease are required. It is recognized that cancer chemoprevention (the use of chemicals to prevent, stop or reverse the process of carcinogenesis) is an essential approach to controlling cancer. Since H_2O_2 seems to have an important role in carcinogenesis, a chemical capable of preventing or decreasing excessive cellular levels of H_2O_2 might be useful in cancer chemoprevention.

Some complementary and alternative medicine practitioners have used H_2O_2 and other "hyperoxygenation" therapies for the treatment of cancer. In 1993, the American Cancer Society studied the available literature and found no evidence that treatment with H_2O_2 and other "hyperoxygenation" therapies was safe or resulted in objective benefit in the treatment of cancer. Today it is accepted that the direct administration of H_2O_2 is not an appropriate strategy for the treatment of cancer, as H_2O_2 can produce toxicity by oxidizing macromolecules such as DNA, proteins or lipids. Indeed, as discussed above and represented in Fig. 2, a large body of research strongly supports that H_2O_2 can produce carcinogenic effects. However, an increasing number of reports indicate that a sufficient increase in the cellular levels of H_2O_2 may be an effective therapeutic strategy. For instance, it is recognized that many anticancer drugs currently used in the clinic produce their antitumor activity by inducing apoptosis in cancer cells, and H_2O_2 is an effective inductor of apoptosis in cancer cells. In addition, some studies have shown that specific concentrations of H_2O_2 can kill cancer but not normal cells; it has been proposed that the increased levels of H_2O_2 found in tumor cells may account for their increased susceptibility to H_2O_2. This selectivity for cancer cells is in accordance with animal experiments that have shown that the use of H_2O_2-generating systems can deliver H_2O_2 to sites of malignancy and produce anticancer effects with little toxicity to the host. The therapeutic potential of H_2O_2 is also supported by the fact that the anticancer activity of several drugs commonly used in the clinic (e.g. paclitaxel [►taxol], arsenic trioxide) is mediated, at least in part, by an increase in the cellular levels of H_2O_2. Recent data have also shown that high concentrations of vitamin C (only achievable through the i.v. route) can produce selective killing of cancer cells through a H_2O_2-dependent mechanism. Therefore, although the direct administration of H_2O_2 does not seem an appropriate anticancer approach, any strategy capable of increasing the levels of H_2O_2 in cancer cells might be therapeutically useful.

Accumulating evidence suggests that the modulation of the cellular levels of H_2O_2 may be an important

approach for the development of cancer chemopreventive and therapeutic strategies. Chemicals with antioxidant properties may reduce the cellular levels of this oxidant and produce cancer chemopreventive effects; indeed, most cancer chemopreventive agents have antioxidant properties. Chemicals with prooxidant properties may induce a sufficient increase in the cellular levels of H_2O_2 and produce cell death in cancer cells; these drugs may produce a chemotherapeutic effect. Many chemicals (e.g. vitamin C, vitamin E, β-carotene, ►curcumin, ►sulforaphane, ►epigallocatechin, etc) induce either an antioxidant or prooxidant effect mostly depending on the concentration at which they reach the cells. Low concentrations of these agents would therefore produce chemopreventive effects, while high concentrations would produce chemotherapeutic effects. However, these agents may produce carcinogenic effects when used at concentrations that increase the cellular levels of H_2O_2, but not sufficiently to induce cell death (Fig. 2). Antioxidant/prooxidant drugs may act as cancer preventive, therapeutic or carcinogenic agents mostly depending on their dose and route of administration.

Hydrophilic

Definition

Literally means water loving. These are drugs that much prefer to dissolve in water than in fat.

►ADMET Screen

Hydroquinone

Definition

Product of two-electron reduction of quinone ($C_6H_4(OH)_2$).

►Mitomycin C

Hydroxyapatite

Definition

Hydroxyapatite crystals constitute the major and essential component of normal bone and teeth. Hydroxyapatite crystals represent the mineral matrix of bone and teeth and give rigidity to bones and teeth. The chemical formula of basic hydroxyapatite is $Ca_{10}(PO_4)_2OH_6$ and these crystals can be physiologically substituted with magnesium, fluor, or carbonate.

►Zoledronic Acid
►Bisphosphonates

Hydroxybutyrate Dehydrogenase

►Serum Biomarkers

5-HydroxyIndoleacetic Acid (5-HIAA)

Definition

A breakdown product of serotonin that is eliminated in the urine. Urinary levels of 5-HIIA are used as a diagnostic and monitoring tool in carcinoid tumors.

►Neuroendocrine Carcinoma

Hydroxyl Group

Definition
Functional group consisting in an atom of oxygen joined to a hydrogen atom by a single bond.

►Bisphosphonates

Hydroxylapatite

Definition
Synonym ►hydroxyapatite $Ca_5(PO_4)_3(OH)$.

14-Hydroxyldaunorubicin

►Adriamycin

4-Hydroxynonenal

Definition
An unsaturated hydroxyalkenal that is generated by the breakdown of arachidonic acid during stress in cells.

►Glutathione Conjugate Transporter RLIP76

13-Hydroxyoctadecadienoic Acid (13-HODE)

Definition
A primarily growth stimulatory signaling molecule resulting from the metabolism of LA by 15-lipoxygenase-1 in cancer cells.

►Melatonin

2-Hydroxyoleic Acid

Definition
Synonym α-hydroxyoleic acid and 2-hydroxy-9-cis-octadecenoic acid. Synthetic derivative of oleic acid with anticancer activity against a wide variety of cancer types, oral administration and negligible side effects.

►Membrane-Lipid Therapy

7-Hydroxystaurosporine

►UCN-01 Anticancer Drug

7-Hydroxystaurosporine, NSC 638850

Definition
►UCN-01 Anticancer drug

Hydroxysteroid Dehydrogenases

►Reductases

Hyperalgesia

Definition
Type of pain that is frequently associated to cancer chemotherapy or cancer itself. Hyperalgesia is an increased sensitivity and lowered threshold to a stimulus – such as burn of the skin – that is normally painful. Allodynia is caused by a stimulus – such as touch, pressure and warmth – that does not normally provoke pain.

►Cannabinoids and Cancer
►Allodynia

Hypercalcemia

Definition
An excess of calcium in the blood (normal range: 9–10.5 mg/dL or 2.2–2.6 mmol/L). Can be due to excessive skeletal calcium release, increased intestinal calcium absorption, or decreased renal calcium excretion. Symptoms of hypercalcemia include fatigue, vomiting, depression, confusion, anorexia. Severe hypercalcemia (range above 15–16 mg/dl) may lead to coma and cardiac arrest.

►Vitamin D
►Bone Loss, Cancer Mediated

Hyperchlorhydria

Definition
Is the increased gastric acid secretion.

►Gastrinoma

Hyperdiploidy

Definition
Having a chromosome number that is more than the normal diploid number.

►Acute Lymphoblastic Leukemia

Hypergastrinemia

Definition
Is increased serum gastrin.

►Gastrinoma

Hyperglycemia

Definition
Is a condition of elevated glucose levels in the bloodstream. It is a hallmark of metabolic syndrome and diabetes.

►Adiponectin

Hypericin

Constance L. L. Saw, Paul W. S. Heng
Department of Pharmacy, National University of Singapore, Singapore, Singapore

Synonyms
Hypericum extract; Hypericum red

Definition
Hypericin is a natural ►photosensitizer present in the plant, *Hypericum perforatum*, commonly known as St John's wort. It belongs to the class of phenanthroperylenequinones and napthodianthrone, has a molecular weight of 504.45. St John's wort has been used for centuries to treat mental disorders and nerve pain.

In ancient times, herbalists wrote about its use as a sedative and a treatment for malaria, as well as a balm for wounds, burns, and insect bites.

Today, St John's wort is used by some for depression, anxiety, and/or sleep disorders. Hypericin is used in photodynamic diagnosis (►PDD) and photodynamic therapy (►PDT) for diagnosis and treatment of cancers.

Characteristics
Physical Properties
Hypericin yields red fluorescence when excited with a specific wavelength of light by lasers such as 442 nm (He-Cd), 488 nm (Ar), or 543 nm (He–Ne), and light by xenon-arc lamp with a band-pass filter of 380–450 nm or 375–400 nm. It has a high extinction coefficient near 600 nm. The two main maximum absorption and ►photoactivation peaks of hypericin occur near 550 and 600 nm. The two fluorescence peaks of hypericin are near 600 and 650 nm. Hypericin has very low water solubility. The aggregated hypericin is not fluorescent. It generates a high quantum yield of singlet oxygen and superoxides.

H

Clinical Applications

PDD of Cancers

The initial presentations of bladder cancer in 70–80% of the cases are superficial and limited to the urothelial lining of the bladder mucosa and submucosa. Visual differentiation between normal tissue and transitional cell carcinoma is relatively easy but not for carcinoma in situ or nonmalignant diseases such as cystitis due to radiotherapy, chemical or bacterial origins. They are often invisible to the naked eye. ►Fluorescence cystoscopy is a form of PDD of cancer and has significantly improved the diagnosis and early detection of cancer. In bladder cancer detection, hypericin has several advantages over conventional photosensitizer, ►5-aminolevulinic acid (►5-ALA, a prodrug) (Table 1). A human clinical trial had found that the use of hypericin showed higher sensitivity (82%) than just white-light cystoscopy (62%). This report justifies the use of hypericin-PDD for bladder cancer in clinical settings. Hypericin was also shown to accumulate in patients with stomach cancer, and detected stomach cancer with 85% specificity.

►PDT of Cancers

►Basal cell carcinoma and ►squamous cell carcinoma are the most common cancers among the Caucasians. The effect of hypericin-PDT had been investigated in these skin cancers. It was found that 1 mg or more of hypericin was acceptable as an alternative treatment for basal cell carcinoma with clinical remission achieved in 2 out of 11 patients. One out of eight patients with squamous cell carcinoma achieved clinical remission without sign of recurrence observed after 5 months of treatment with 1.5–3 mg of hypericin. Mild to transient erythema and edema at the tumor lesions were observed when the cancers were treated with hypericin and there appeared to be a correlation between the degree of tumor reduction and occurrence of erythema and edema at the tumor lesions. As this is the first reported clinical trial on the use of hypericin-PDT in the reported skin cancers, the PDT treatment protocol and dosage were transposed from results with animal models and the trial was restricted to 4–6 weeks because of ethical reasons. Thus, long-term remission rates are needed to further evaluate the clinical usefulness of hypericin with additional trials.

Another hypericin-PDT use in cancer treatment was for local application of hypericin in a patient with recurrent malignant mesothelioma. The patient had previously been treated with radiotherapy, chemoimmunotherapy and subsequently PDT using hematoporphyrin derivatives (Photosan III). Topical hypericin was applied to the patient and a month later, the combination of hypericin and Photosan III was applied. It was found that complete remission was achieved histologically with a light dose at 90 J/cm^2 together with PDT using combined systemic Photosan III and topical application of hypericin.

Preclinical Investigations

The chemical groups reported to cause the photodynamic activities of hypericin are semiquinone, singlet oxygen, and superoxide anion radicals. Light triggers the photosensitization (photoactivation) of hypericin for photodynamic reactions. Hypericin-PDT effect is a function of drug, light, and oxygen present. There are three PDT effects of the photosensitizers on biological systems. Firstly, it can damage the vasculature, causing thrombosis and blood flow stasis. Secondly, PDT kills tumor cells via generation of free radicals that damage mitochondria, plasma membrane, and other organelles, hence inducing apoptosis or necrosis of the tumor. Thirdly, PDT modulates the immune system against cancer cells. Successful cancer treatment is usually a result of the combination of all these effects. With the appropriate use of light and adjuvant therapy such as heat or ►antiangiogenesis agents, better therapeutic outcomes can be expected. Table 2 shows the reported methods to improve the efficiency of hypericin for PDD and PDT in preclinical investigations. As

Hypericin. Table 1 Comparison of 5-ALA and hypericin for detecting human superficial bladder carcinoma

Characteristics	5-ALA	Hypericin
Form	Prodrug, need to be converted to the active form	Active form
Sensitivity	75–100%	82–94%
Specificity	Very low specificity, 43–68.5% (with many false-positives)	High, 91–98.5%
Stability	Easily photobleached during process	Greater stability, no significant photobleaching
Permeability across biological membrane	Charged molecule – difficult to cross biomembranes	Hydrophobic – good permeability

Hypericin. Table 2 Methods for enhancement of hypericin-PDD/PDT efficacy

Concept	Methods
Chemical modifications	Improve physicochemical properties of hypericin. Analogs with better water solubility, absorption and fluorescence properties, and singlet oxygen quantum yield
Physical methods	Optimize light conditions (fractionated light dose), oxygen perfusion, hyperthermia
Pharmaceutical formulations	Prepare liposomes, nanoparticles, topical applications
Combination with adjuvant therapy	Add oxygen carrier, antiangiogenesis agents, drugs that are able to synergize with hypericin for cancer treatment

administration of hypericin to patients remains a challenging task due to its poor aqueous solubility and lipophilic nature, the most popular approach is by a formulation approach to enhance the efficacy of hypericin-PDT. There is a trend to develop formulations of hypericin without plasma proteins. Despite the use of cutting-edge technology approaches, such as preparing transferrin-mediated targeted delivery liposomes and nanoparticles of hypericin, such preparations did not always confer the desired enhanced treatment effects. It appeared that the use of an adjunct with hypericin, especially those prepared without using plasma proteins, was more successful in enhancing the delivery of hypericin with both in vivo and in vitro systems.

Using a pharmaceutical solvent and penetration enhancer, *N*-methyl pyrrolidone, delivery of hypericin was shown to be better than the conventional formulation of hypericin with albumin. Using chick chorioallantoic membrane implanted with human bladder cancer cells, *N*-methyl pyrrolidone was demonstrated to be an excellent alternative to plasma proteins as adjuvant with hypericin. The improved *N*-methyl pyrrolidone–hypericin formulation enabled more efficient delivery and uptake of hypericin at the target site. This will not only allow a lower drug dose to be used potentially but will also significantly reduce patients' waiting time.

The exact mechanism for the tumor selectivity uptake of hypericin has not been fully understood. The uptake/transport/delivery of hypericin is dependent on several competing or interrelated factors, which include the type of incubation medium (with or without serum proteins), cell type, delivery system, and biological testing method. It is likely that both active and passive transport mechanisms contribute to the overall uptake of hypericin but passive diffusion is likely to be the more dominant mechanism.

Apart from its photosensitizing properties, hypericin was found to be a ►protein kinase C inhibitor. It was also reported to involve in the modulation of immune system such as expression of cytokines. Hypericin-PDT triggered the expression of angiogenic factors, ►matrix metalloproteinases, and various signaling pathways. The rapid advancement in genetic research had shown that the effects of hypericin-PDT could be independent of the status of ►*p53*, the tumor suppressor gene. Many reports have attributed the failure of conventional chemotherapy and radiotherapy to the mutated ►*p53*, due to apoptosis failure caused by the nonfunctional p53. Therefore, hypericin-PDT provides an alternative pathway in treating cancers.

In the absence of light, toxicity of hypericin was found to be very low. Apart from its potent photosensitizing properties that are light-dependent, hypericin shows unique activities even in the dark. In complete darkness, hypericin has cytostatic activities that were able to prolong the survival of mice with high-grade squamous carcinoma tumors. This is attributed to hypericin inhibiting several key steps of the angiogenesis.

Many different types of cancers including leukemia, glioblastoma, and childhood rhabdomyosarcoma have been treated with hypericin-PDT and in vitro results were promising in many of the cases. Continual effort in basic and translational research will lead to a better understanding of the contributing factors responsible for effective hypericin-PDT applications.

Hyperlipidemia

Definition
Refers to an elevation of lipids (fats) in the bloodstream.

►Cachexia

Hypermethylation

Definition
Increased ►methylation of cytosine residues in cytosine-guanine pairs in regulatory regions of DNA of specific genes or of global DNA within a cell or tissue.

►Fragile Histidine Triad
►Methylation-Controlled J Protein (MCJ)

Hyperplasia

Definition
Consists of an increase in the number of tissue cells, without changes in their volume. This alteration, generally secondary to prolonged growth stimuli, is reversible and does not evolve to malignancy.

►Preneoplastic lesions

Hyperplastic growth

Definition
Tissue overgrowths that still retain their normal characters and ability to differentiate.

Hypersensitivity

►Allergy

Hypersensitivity Reaction

Definition
A serious and sometimes life-threatening reaction to a drug or other chemical or venom.

►Paclitaxel

Hyperthermia

Ashley A. Manzoor, Mark W. Dewhirst
Department of Radiation Oncology, Duke University, Durham, NC, USA

Definition
Hyperthermia refers to the elevation of temperature above physiological levels, typically to values of 40–45°C.

Characteristics
Hyperthermia utilizes elevated tissue temperatures, typically between 40°C and 45°C, to alter the tumor and normal tissue environment. The goal of hyperthermia in cancer treatment is to create an environment that will aid in eradicating tumor while sparing normal tissue. Hyperthermia accomplishes this by causing direct cytotoxic effects and a variety of physiologic effects, including the alteration of blood flow and oxygenation status. Clinically, hyperthermia can work synergistically with both radiation and chemotherapy.

Cytotoxic Effects
Hyperthermia elicits cytotoxic effects in tissue through a variety of mechanisms, inducing both ►apoptosis and ►necrosis. Above 40°C, protein is a dominant molecular target, with protein denaturation exhibiting a similar heat of inactivation as thermal cell kill and damage (130–170 kcal/mole). Other cellular targets include the cytoskeleton, which controls many signal transduction pathways, cellular respiration enzymes, and DNA repair processes. These components of the cell are particularly heat sensitive and lead to increased cytotoxic effects.

Physiologic Effects
Hyperthermia also has an intricate relationship with tumor physiology, as the degree of physiologic response varies with temperature. An initial temperature increase to 41–41.5°C will result in elevated blood flow and increased vascular permeability.

Generally, muscle and skin perfusion increase by at least tenfold, while tumor perfusion increases only 1.5- to 2-fold. This difference in response between normal and cancerous tissue is one of the most exploited benefits of hyperthermia in cancer treatment. At these initial hyperthermia temperatures, edema may result from the increase in vascular permeability, and as higher temperatures are reached, vascular stasis and hemorrhage may develop. Additionally, higher temperatures may result in vascular damage, although typically these temperatures are neither utilized nor often achievable in the clinic.

With respect to normal tissue, thermal damage from hyperthermia exhibits varying degrees of severity depending on temperature and tissue type. Some normal tissues are more heat sensitive than others, yet the sensitivity is not easily predicted by classical cytotoxicity or radiotherapy principles. While these principles correlate proliferative potential with radiation or chemo-sensitivities, this is not predictive of thermal sensitivity. For example, the brain and testes both exhibit high thermal sensitivities, yet the brain has almost no proliferative potential and the testes are highly proliferating. Furthermore, in addition to showing no correlation between thermal sensitivity and proliferative potential, there is also no tissue-specificity. For instance, the spinal cord, peripheral nerves, and brain all demonstrate varying sensitivity to heat, yet these are all nervous tissue.

In addition to physiologic changes in blood flow and vascular permeability, ►tumor metabolism and oxygenation can also be altered substantially with hyperthermia. As mentioned earlier, certain enzymes may be highly heat sensitive. Along metabolic pathways, enzymes involved in aerobic tumor metabolism exhibit much greater heat sensitivity than those involved in anaerobic metabolism. This lends itself to a theory that hyperthermia treatment may cause reductions in tumor metabolism and respiration. Reported effects in support of this theory have been decreased ATP production and increased lactate concentration following hyperthermia.

Furthermore, alteration in tumor metabolism has additional downstream effects, particularly with respect to tumor oxygenation status. As a tumor shifts from aerobic to anaerobic metabolism following hyperthermia, the tumor may experience decreased oxygen consumption rates; this decrease in oxygen consumption may consequently lead to significant improvement in the tumor oxygenation status. Studies have shown oxygenation increases following hyperthermia in rodent and canine tumors, as well as human tumors. However, this oxygenation effect is most pronounced at temperatures between 41°C and 43°C, decreasing at higher temperatures where vascular damage occurs.

Immunological Effects
