Preface To The First Edition

Cancer, although a dreadful disease, is at the same time a fascinating biological phenotype. Around 1980, cancer was first attributed to malfunctioning genes and, subsequently, cancer research has become a major area of scientific research supporting the foundations of modern biology to a great extent. To unravel the human genome sequence was one of those extraordinary tasks, which has largely been fuelled by cancer research, and many of the fascinating insights into the genetic circuits that regulate developmental processes have also emerged from research on cancer. Diverse biological disciplines such as cytogenetics, virology, cell biology, classical and molecular genetics, epidemiology, biochemistry, together with the clinical sciences, have closed ranks in their search of how cancer develops and to find remedies to stop the abnormal growth that is characteristic of cancerous cells. In the attempt to establish how, why and when cancer occurs, a plethora of genetic pathways and regulatory circuits have been discovered that are necessary to maintain general cellular functions such as proliferation, differentiation and migration. Alterations of this fine-tuned network of cascades and interactions, due to endogenous failure or to exogenous challenges by environmental factors, may disable any member of such regulatory pathways. This could, for example, induce the death of the affected cell, may mark it for cancerous development or may immediately provide it with a growth advantage within a particular tissue.

Recent developments have seen the merger of basic and clinical science. Of the former, particularly genetics has provided instrumental and analytical tools with which to assess the role of environmental factors in cancer, to refine and enable diagnosis prior to the development of symptoms and to evaluate the prognosis of patients. Hopefully, even better strategies for causal therapy will become available in the future. Merging the basic and clinical science disciplines towards the common goal of fighting cancer, calls for a comprehensive reference source to serve both as a tool to close the language gap between clinical and basic science investigators and as an information platform for the student and the informed layperson alike. Obviously this was an extremely ambitious goal, and the immense progress in the field cannot always be portrayed in line with the latest developments. The aim of the Encyclopedia is to provide the reader with an entrance point to a particular topic. It should be of value to both basic and clinical scientists working in the field of cancer research. Additionally both students and lecturers in the life sciences should benefit highly from this database. I therefore hope that this Encyclopedia will become an essential complement to existing science resources.

The attempts to identify the mechanisms underlying cancer development and progression have produced a wealth of facts, and no single individual is capable of addressing the immense breadth of the field with undisputed authority. Hence, the ‘Encyclopedic Reference of Cancer’ is the work of many authors, all of whom are experts in their fields and reputable members of the international scientific community. Each author contributed a large number of keyword definitions and in-depth essays and in so doing it was possible to cover the broad field of cancer-related topics within a single publication. Obviously this approach entails a form of presentation, in which the author has the freedom to set priorities and to promote an individual point of view. This is most obvious when it comes to nomenclature, particularly that of genes and proteins. Although the editorial intention was to apply the nomenclature of the Human Genome Organisation (HUGO), the more vigorous execution of this attempt has been left to future endeavours.

In the early phase of planning the Encyclopedia, exploratory contacts to potential authors produced an overwhelmingly positive response. The subsequent contact with almost 300 contributory authors was a marvellous experience, and I am extremely grateful for their excellent and constructive cooperation. An important element in the preparation of the Encyclopedia has been the competent secretarial assistance of Hiltrud Wilbertz of the Springer-Verlag and of Ingrid Cederlund and Cornelia Kirchner of the DKFZ. With great attention to detail they helped to keep track of the technical aspects in the preparation of the manuscript. It was a pleasure to work with the Springer crew, including Dr. Rolf Lange as the Editorial Director (Medicine) and Dr. Thomas Mager, Senior Editor for Encyclopedias and Dictionaries. In particular I wish to thank Dr. Walter Reuss, who untiringly has mastered all aspects and problems associated with the management of the numerous manuscripts that were received from authors of the international scientific community. It has been satisfying and at times comforting to see how he made illustration files come alive. Thanks also to Dr. Claudia Lange who, being herself a knowledgeable cell biologist, has worked as the scientific editor. Her commitment and interest have substantially improved this Encyclopedia.

As a final word, I would like to stress that although substantial efforts have been made to compose factually correct and well understandable presentations, there may be places where a definition is incomplete or a phrase in an essay is flawed. All contributors to this Encyclopedia will be extremely happy to receive possible corrections, or revisions, in order for them to be included in any future editions of the 'Encyclopedic Reference of Cancer'.

Heidelberg, September 2001
MANFRED SCHWAB

Preface To The Second Edition

Given the overwhelming success of the First Edition of the Cancer Encyclopedia, which appeared in 2001, and the amazing development in the different fields of cancer research, it has been decided to publish a second fully revised and expanded edition, following the principle concept of the first edition that has proven so successful.

Recent developments are seeing a dynamic merging of basic and clinical science, with translational research increasingly becoming a new paradigm in cancer research. The merging of different basic and clinical science disciplines towards the common goal of fighting against cancer has long ago called for the establishment of a comprehensive reference source both as a tool to close the language gap between clinical and basic science investigators and as a platform of information for advanced students and informed laymen alike. It is intended to be a resource for all interested in information beyond their specific own expertise.

While the First Edition had featured contributions from approximately 300 scientists/clinicians in one Volume, the Second Edition includes more than 1000 contributors in 4 Volumes with an A–Z format of more than 7000 entries. It provides definitions of common acronyms and short definitions of both related terms and processes in the form of keyword entries. A major information source are detailed essays that provide comprehensive information on syndromes, genes and molecules, and processes and methods. Each essay is well-structured, with extensive cross-referencing between entries. Essays represent original contributions by the corresponding authors, all distinguished scientists in their own field, Editorial input has been carefully restricted to formal aspects.

A panel of Field Editors, each an eminent international expert for the corresponding field, has served to ensure the presentation of timely and authoritative Encyclopedia entries. These new traits are likely to meet the expectance that a wide community has towards a cancer reference works.

An important element in the preparation of the Encyclopedia has been the competent support by the Springer crew, Dr. Michaela Bilic, Saskia Ellis and, lately, Jana Simniok. I am extremely grateful for their excellent and pleasant cooperation.

The Cancer Encyclopedia, Second Edition, will be accessible both in print and online versions. Clinicians, research scientists and advanced students will find this an amazing resource and a highly informative reference to cancer.

►ADAM Molecules

A-Scan Ultrasonography

Definition

Ophthalmologic ultrasound that provides single-dimension information on the ultrasonic echogenicity of the ocular tissues providing information regarding axial length, size of intraocular structures (such as tumor height), and homogeneity of individual tissues within the eye.

►Uveal Melanoma

AAA^+

Definition

Superfamily of proteins characterized by a segment of ~220 aminoacids (the AAA domain) containing several conserved motifs including those necessary for ATP binding and hydrolysis.

►APAF-1 Signaling

AAMP

Marie E. Beckner
Department of Pathology, University of Pittsburgh School of Medicine, Pittsburgh, PA, USA

Definition

AAMP stands for angio-associated migratory cell protein and its gene is found on chromosome 2q35. ►HUGO nomenclature symbol is AAMP. AAMP has been conserved in evolution, is distributed intracellularly in many cells and also extracellularly on vascular cells, shares an ►epitope with motility-related proteins (►alpha-actinin and a fast twitch skeletal muscle protein) and contains potential heparin binding and thrombin cleavage sites. Antibody and antisense studies have indicated compartment (intracellular or extracellular) specific roles for AAMP in angiogenesis, cell-cell and cell-matrix interactions, and cell migration.

Characteristics

The cDNA derived from mRNA encoding AAMP was originally cloned from a human melanoma cell library (A2058) in a search for migration-related proteins. AAMP has been found in the cytoplasm of many

nucleated cells, in an extracellular mesh-like network on monolayers of endothelial and vascular-associated smooth muscle cells, and on the apical membranes of endometrial glandular cells. AAMP expression when normalized for tissue source has shown the highest levels of distribution in the esophagus (7.17% of tissue clones) (http://smd.stanford.edu/cgi-bin/source/sourceImage?File = Hs.83347). Local homologies discovered initially to human immunodeficiency viral proteins led to identification of two immunoglobulin-like ►domains in AAMP. In addition to melanoma, expression of AAMP has been observed in a variety of malignant cells, including poorly differentiated colon adenocarcinoma within lymphatics, gastric adenocarcinoma, Jurkat lymphoma, gastrointestinal stromal tumors with mutated ►*c-kit*, breast cancer cell lines and ductal adenocarcinoma *in situ* with necrosis, and brain tumor cells.

Co-culture of astrocytes with endothelial cells (without physical contact) led to increased amounts of extracellular AAMP associated with the endothelial cells. Stimulation of T lymphocytes and monocytes by a ►phorbol ester led to greatly increased AAMP expression, 1.6 kb message and 52 kDa protein. Hypoxia increased expression of the *AAMP* gene in a breast carcinoma cell line.

AAMP has demonstrated compartment-specific effects on endothelial cell migration. Affinity-purified antibodies, that interacted with the extracellular form of AAMP on non-permeabilized endothelial cells, inhibited cell migration and endothelial tube formation. However, anti-sense oligonucleotides, that decreased total AAMP expression, paradoxically increased cell migration, presumably via loss of intracellular AAMP.

The structure of AAMP was initially characterized as having two immunoglobulin-like domains and six ►WD repeats. Now eight WD repeats have been identified in AAMP, UniProt KB/Swiss-Prot Q13685. AAMP has been conserved in evolution. Comparisons of reference sequences for human AAMP (433 aa) with related forms in mouse (434 aa), rat (471 aa), chicken (419 aa), frog (438 aa), and zebrafish (408 aa) have shown 99.5, 98.9, 86.7, 76.5, and 69.0% identity, respectively (UniGene, NCBI, NIH). An acid box (short contiguous run of glutamic or aspartic acid residues) has been identified in the amino terminal regions of several AAMP homologs. They are comprised of seven glutamic acids in human, eight glutamic acids in mouse and rat, and six aspartic acid residues in the zebrafish forms of AAMP.

AAMP contains a strongly immunoreactive ESESES epitope at its ►amino terminal end that has been used to generate an anti-peptide antibody. Under normal reducing conditions, the epitope is immunoreactive for AAMP only in lysates of human brain and activated T lymphocytes. AAMP (52 kDa) shares this epitope with non-skeletal alpha-actinin (100 kDa) and an unidentified fast twitch skeletal muscle fiber protein (23 kDa), as demonstrated with anti-RRLRRMESESES (anti-P189) and related anti-peptide antibodies. The ESESES epitope is linear in AAMP but is discontinuous or conformational (formed by ►secondary structure) in alpha-actinin. The fast twitch skeletal muscle fiber protein with immunoreactivity for anti-P189 was found in the periodic bands (Z discs).

An alternatively spliced, slightly longer form of AAMP (452 aa) includes coding sequence upstream from MESESES. The immediate upstream sequence, RRLRR, potentially functions as a heparin binding site. In addition to an alternative initiating methionine, the upstream human coding sequence differs by only two of seventeen codons when compared to an even longer form of AAMP in rat. The coding sequence of AAMP in rat includes the sequence GRFRRMESESES that corresponds to RRLRRMESESES in the alternative form of human AAMP. In peptide studies, the bipolar RRLRRMESESES sequence was strongly self-aggregating, sensitive to thrombin digestion, and displayed binding to heparin and cells as either an immobilized, single peptide or as an aggregated peptide, without affecting cell viability or adhesion to collagen. Peptide sequencing verified the presence of RLRR in recombinant AAMP translated in *Escherichia coli* following thrombin digestion that cleaved the first R. Although anti-P189 (RRLRRMESESES) did not demonstrate reactivity with the RRLRR epitope in tissue that displayed reactivity with ESESES, the lack of reactivity for RRLRR could have been due to interference by strongly adherent ►glycosaminoglycans.

Thus initial studies of AAMP's distribution and structure are supportive of a role for this protein in cell migration and angiogenesis.

►APC Gene in Familial Adenomatous Polyposis

AAV

Dirk Grimm
University of Heidelberg, Cluster of Excellence Cell Networks, BIOQUANT, Heidelberg

Definition

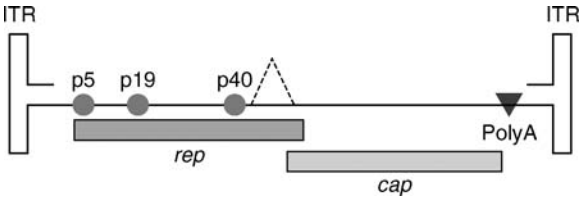
Adeno-associated viruses (AAV) are small DNA-containing viruses that belong to the family of *Parvoviridae*. Thus far, 11 ►serotypes of adeno-associated viruses (AAV-1 to AAV-11) have been cloned from humans and primates, and multiple further isolates were identified in various other species, including birds, bovines, mice, rats and goats. According to current knowledge, none of these naturally occurring viruses are pathogenic in humans. AAV type 2 (AAV-2) has been studied for over 40 years and is the best characterized AAV isolate, hence its frequent referral as the AAV prototype. All AAV serotypes are currently being developed and evaluated as gene transfer ►vectors for the human ►gene therapy of various inherited or acquired diseases, including different types of cancer.

Characteristics

As typical members of the ►Parvovirus family, AAV are characterized by non-enveloped, icosahedral capsids of about 18–24 nm in diameter. These capsids carry linear single-stranded DNA genomes of ~4.6–4.8 kb. The genomes of all known AAV serotypes have been cloned and sequenced. With the exception of AAV-4 and -5, which are distinct (>30%) from the other serotypes at both the nucleotide and amino acid level, all human and primate AAV genomes are related and highly homologous (>80%). Accordingly, their genomic structure and organization are also very similar.

AAV Genome Structure

As an example, the organization of the 4,681 nucleotide AAV-2 prototype genome is described (Fig. 1). The AAV-2 genome consists of two large ►open reading frames (orf), one at the left end encoding the non-structural proteins (replication, *rep* orf), and one at the right end encoding the structural proteins (capsid, *cap* orf). In addition, a single intron sequence is found in the center of the genome, where the *rep* and *cap* orfs overlap. The AAV-2 *rep* gene encodes four closely related proteins (Rep proteins) with partially shared amino acid sequences. On the basis of their molecular weights, these proteins were designated Rep78, Rep68, Rep52 and Rep40. Unspliced and spliced transcripts originating from a ►promoter located at map unit 5 (p5) are translated into the two large Rep proteins, Rep78 and Rep68. Rep52 and Rep40 are expressed from similarly spliced mRNAs that initiate from a second promoter, p19. The third AAV-2 promoter, p40, controls transcription of the *cap* gene. Translation of differentially spliced *cap* mRNAs results in expression of the three proteins that form the AAV-2 capsid, VP1, VP2 and VP3 (in a 1:1:10 ratio). The two viral genes are flanked by short (AAV-2: 145 nucleotides) inverted terminal repeats (ITR), palindromic sequences that are able to fold into T-shaped stem loop structures. The ITRs are necessary and sufficient for replication and encapsidation of the viral genome during a productive infection of cells. Moreover, they are important for integration and rescue of the AAV DNA into, or from, the genome of latently infected cells, respectively. Thereby, the ITRs serve as minimal *cis*-acting sequences during the two different AAV life cycles (see also below).



AAV. Figure 1 Structure of the AAV-2 genome. The 4,681 nucleotide single-stranded genome is depicted as a solid line; by convention, AAV genomes are drawn in 3′-5′ orientation. Shown are the locations of the *rep* and *cap* orfs and the single intron (caret), as well as the position of the three promoters (p5, p19, p40) and the polyA signal, which is used for polyadenylation of all AAV-2 transcripts. Further depicted at the ends of the genome are the palindromic inverted terminal repeat (ITR) sequences in their hairpin configuration.

AAV Life Cycles

AAV serotypes belong to the Parvovirus genus Dependovirus, indicative of their dependence on an unrelated helpervirus to undergo a productive infection of cells. In fact, AAV genomes can only express their genes, replicate and become encapsidated if the cell is simultaneously co-infected by one of these helperviruses. The typical helpervirus for AAV-2 is human ►Adenovirus type 2 or 5, but many other human viruses can also provide full or partial helper functions, including Herpes simplex virus, Vaccinia virus and Cytomegalovirus.

In the case of Adenovirus, one of the major helper functions is to stimulate AAV gene expression, by *trans*-activating the AAV-2 promoters. Additional help for the AAV life cycle is mediated at the post-transcriptional level, where adenoviral proteins and RNAs help to facilitate the cytoplasmic transport of AAV-2 mRNAs. Concurrently, adenoviral functions help to stabilize replicated AAV-2 genomic DNA later in the AAV infection. Notably, once expressed in the infected cell, AAV-2 Rep proteins subsequently further regulate and coordinate gene expression from the AAV promoters. They also play important roles for AAV DNA replication, as well as for packaging of viral genomes into empty new capsids (assembled from AAV-2 VP proteins). To mediate these diverse functions, Rep proteins bind to the AAV-2 ITRs and to sequences located in the AAV-2 promoters. They also interact with various cellular proteins, e.g. the TATA-box binding protein ►(TBP), as well as with each other and the AAV-2 VP proteins. The final step in a productive AAV-2 infection is the helpervirus-mediated lysis of the infected cell. This results in cell death and release of both new AAV-2 and helpervirus particles.

In contrast to this productive (or lytic) phase, AAV-2 can establish latency in the absence of any helpervirus. Rather than replicating, the AAV-2 DNA then integrates into the target cell genome, where it stably persists as a so-called provirus. Important to point out, wildtype AAV-2 integration is not random, as is the case for retroviruses (►Retroviral Insertional Mutagenesis) and other integrating viruses. Instead, it is targeted to a specific region on the long arm of human chromosome 19 (19q13.3-ter). The large Rep proteins (albeit only weakly expressed in the absence of a helpervirus) mediate this site-specific integration through binding to the AAV-2 ITRs, as well as to homologous sequences (AAVS1) located in chromosome 19. However, if a latently AAV-infected cell is later super-infected with a helpervirus, AAV-2 gene expression is induced and the AAV-2 genome is rescued from its integrated state. From this point on, a typical productive AAV-2 infection will occur. Thus, the helpervirus can act as an efficient switch between the two different phases that characterize the AAV-2 life cycle, lytic and latent.

Clinical Relevance

In theory, due to its inherent anti-tumor properties (see below), wildtype AAV-2 (and probably other serotypes alike) could be used as a therapeutic agent for the treatment of human cancers. However, more widely studied and applied are ►recombinant vectors derived from wildtype AAVs. Typically, these vectors are generated by replacing the two viral genes (*rep* and *cap*) with a foreign ►gene expression cassette, encoding RNAs or proteins that mediate an anti-tumor effect (if used for cancer therapy). The general clinical relevance of wildtype and recombinant AAVs is briefly discussed below; for more depth, the reader is referred to recent excellent reviews on the use of AAV for the treatment of human disease (see References below).

Are Wildtype AAVs Pathogenic in Humans?

According to the bulk data available, wildtype AAV serotypes are believed to be non-pathogenic in humans. In fact, despite estimates that up to 80% of adults are ►seropositive for AAV-2, no human disease has ever been causally linked to infection with the wildtype virus. This is even more remarkable considering that AAV-2 can infect a large variety of cells from diverse organs and tissues. Yet, although without gross pathological consequences for the cell, a latent AAV-2 infection can induce subtle changes in the cell ►phenotype. Examples are an increased ability to respond to stress factors, or a perturbation of the cell cycle, resulting in retarded cell growth. Most probably, these various effects are mediated by the large AAV-2 Rep proteins, even at the low expression levels typical for the latent stage.

Is There a Natural Connection Between AAV Infection and Cancer?

One frequently reported observation is that AAV-2-infected cells exhibit an increased resistance to ►oncogene- or tumorvirus-induced transformation. It is moreover known that AAV-2 infection can inhibit the proliferation of cultured cells derived from human cancers, e.g. ►melanomas. Cumulatively, these data strongly suggest that wildtype AAV-2 is not only non-pathogenic, but in fact has oncosuppressive properties. Moreover, certain human cancer cell lines become more sensitive to gamma irradiation (►Ionizing Radiation Therapy) and chemotherapeutic drugs (►Chemotherapy of Cancer, Progress and Perspectives) upon experimental infection with wildtype AAV-2, as compared to non-infected controls. From a clinical point of view, these findings are of particular interest, since a major limitation of cancer chemotherapies is increasing resistance of transformed cells towards the drugs used. The observations of AAV-2-mediated cell sensitization therefore suggest that wildtype AAV might help to improve cancer chemotherapy, when applied in combination with conventional drugs.

What are Recombinant AAV Vectors?

Recombinant AAV (rAAV) vectors are derivatives of wildtype AAV which lack the *rep* and *cap* genes, and instead carry a foreign gene expression cassette inserted between the two viral ITRs. By definition, AAV vectors are thus “gutless” or “gutted” (i.e., devoid of any viral genes). The generation of rAAV vectors is technically feasible and simple, due to the wide availability of molecular clones of the various wildtype viruses. These clones are easily modified using standard molecular

laboratory techniques. Particularly beneficial is that wildtype and recombinant AAV are very small as compared to all other viruses developed as vectors, which aids in their experimental manipulation. Except for the replacement of the wildtype genes with a recombinant DNA, AAV vectors are identical in structure and organization to wildtype viruses and thus also function alike. In fact, AAV vectors will infect the target cell via the same molecular and cellular pathways as the wildtype virus. Ultimately, this will lead to expression of the encapsidated recombinant gene in the cell and thus to the intended therapeutic effect. As gene transfer vehicles, AAV vectors hold enormous promise for therapeutic intervention for a multitude of human acquired or innate genetic diseases, including cancer.

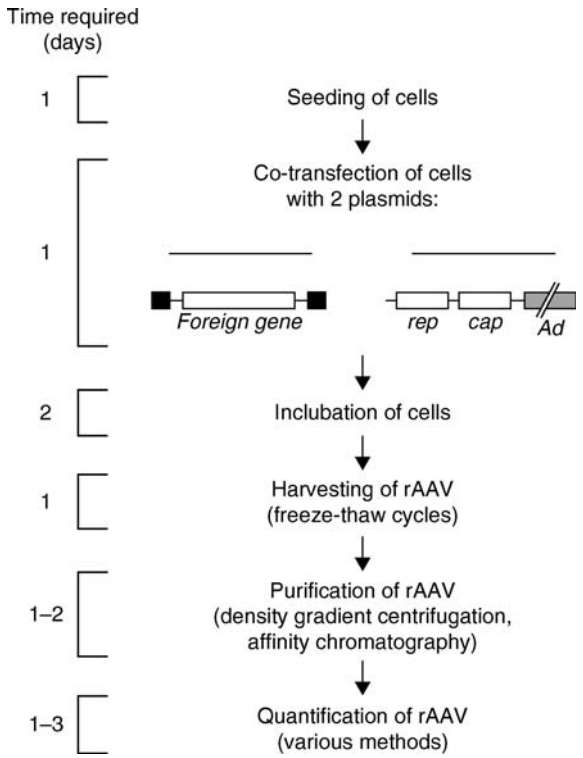
Is AAV Unique as a Human Gene Therapy Vector?

AAV vectors possess a multitude of advantages over all other virus-derived gene transfer vectors currently in (pre-)clinical development. One asset already mentioned is the lack of pathogenicity of the wildtype virus, which is in stark contrast e.g. to Adenovirus, another commonly used virus for gene therapy. Consequently, the production and handling of AAV vectors requires the lowest biosafety levels (S1, i.e., causing minimal risks for humans and the environment). The safety of AAV vectors is further increased by their "gutted" nature, precluding the expression of viral gene products which could cause cellular immune responses in the treated patient (a frequent adverse reaction to adenoviral vectors). A third unique asset, and a further difference to other viral vectors, is the availability of a wide spectrum of human, mammalian and non-mammalian natural serotypes. These isolates typically differ in their ►tropism, i.e., the range of cells and tissues they can infect. Fortunately, it is technically very simple to generate recombinant AAV vectors which carry the same expression cassette, but differ in the viral capsid. This process is called "pseudotyping" and allows for the targeted delivery of a given recombinant DNA to virtually any desired cell or tissue, provided it can be infected by a known wildtype AAV (or a mutant thereof, see below). A plethora of reports have already demonstrated the power of this approach, to use AAV vectors for therapeutic and specific gene transfer to all clinically relevant target organs, including liver, muscle, lung, eye and brain. Last but not least, AAV vectors also differ from all other viral vectors by their capability to mediate persistent and long-term gene expression, both in actively dividing and in quiescent (i.e., non-dividing) cells, and most importantly, without integrating into the host chromosome. Instead, the vector forms stable but extra-chromosomal DNA molecules, which are not capable of perturbing chromosome structures and thus do not pose a mutational risk. This is clinically most pertinent, as many gene therapy applications will require stable gene expression, ideally for the life-span of the patient. The only other viral vectors able to mediate long-term gene expression (and in non-dividing cells) are derived from retroviruses or lentiviruses (HIV). However, these vectors are associated with drastically higher concerns about biosafety, due to the inherent pathogenic nature of the parental wildtype virus, as well as due to their propensity for integration into the human genome. The latter can readily result in insertional mutagenesis, i.e., activation of endogenous oncogenes, or vice versa, inactivation of ►tumor suppressor genes. In both cases, the result is malignant transformation of the infected cell. This potentially serious adverse event from the use of retroviral vectors has indeed been observed in a recent clinical study, where multiple children developed leukemias, and some even died. Likewise, adenoviral vectors and the associated immune response have been blamed for the death of a patient in an early gene therapy trial in 1999. In striking contrast, thus far, none of the over 30 clinical trials using AAV vectors has yielded any evidence for a tumorigenic or lethal potential of this particular vector system.

What are Recent Advances in AAV Vector Technology?

In the early years, AAV vectors have been criticized for their small size (preventing packaging and therapeutic transfer of recombinant DNA >5kb in length), their relatively slow transduction kinetics (resulting from the single-stranded DNA genome and its need for conversion into a transcriptionally active DNA duplex), and their restricted cell and tissue tropism (based on the sole availability of the AAV-2 capsid in the early phase of AAV vector development). Nonetheless, even with those presumed limitations, AAV-2 vectors have been tested successfully in various large animal models and in human patients, addressing diverse diseases such as cystic fibrosis or hemophilia B. Most importantly, all three initial limitations of the AAV vector system have now been overcome, leading to the rapid expansion of AAV-based human gene therapy, especially for cancer treatment. First of all, the issue of limited packaging capacity has been solved with the creation of "split" AAV vectors which exploit the virus' natural propensity for ►concatamerization. In an infected cell, rAAV genomes frequently recombine with each other, resulting in large "head-to-tail" concatamers (i.e., multiple copies of an rAAV genome in the same orientation). This can be exploited experimentally, by splitting a large recombinant DNA (e.g., a gene and its promoter) into two halves, each of which is then delivered by a separate rAAV vector. This strategy effectively doubles the packaging limit of AAV vectors to up to 10 kb, which is sufficient even for large DNAs such as the factor VIII gene (encoding a blood clotting factor missing or defect in hemophilia A patients). Secondly, the inherently slow transduction kinetics of AAV

have been overcome with the development of self-complementary or double-stranded vectors. In these, two copies of a foreign gene expression cassette are cloned and packaged in an inverted format, only separated by a minimal version of an AAV ITR. In the transduced cell, these two inverted copies then rapidly anneal with each other without the need for conversion into a duplex AAV DNA molecule. This results in an extremely rapid onset as well as maximum efficacy of gene expression, both far superior to what is obtained with conventional single-stranded AAV vectors, or most other viral vector systems. Thirdly, the limited host range of AAV-2 was readily overcome with the engineering of the over 100 alternative naturally occurring AAV serotypes as vectors. This approach has not only substantially broadened the range of cells and tissues that can now be infected with AAV vectors, but it has also alleviated concerns over the prevalence of neutralizing antibodies against the AAV-2 prototype in the human population. In fact, a wealth of studies have shown that AAV vectors derived from non-type-2 serotypes are functional in many tissues that are refractory to AAV-2 infection, and most importantly, transduction readily occurred in the (experimentally induced) presence of anti-AAV-2 antibodies, mimicking the situation in most humans. Moreover, very recent work demonstrated the feasibility to create synthetic AAV capsids which are further unique from the AAV-2 prototype, as well as from any of the naturally occurring isolates. Multiple strategies are currently being pursued, including the random mutagenesis of the AAV(-2) *cap* gene, the insertion of peptide pools into exposed regions of the AAV-2 capsid (hoping the peptides will mediate re-targeting to unknown cellular receptors), or the creation of libraries of "shuffled" viruses, in which capsid genes from several parental viruses are mixed and recombined. Most importantly, all of these new approaches and designs remain fully compatible with already established AAV vector technology, allowing for their rapid and straightforward pre-clinical evaluation. In fact, current AAV vector production methodologies are highly advanced and permit the generation of high titer stocks (>1 × 10^{14} recombinant particles per batch) in a very short amount of time (~10 days) (Fig. 2). As a result, AAV vectors have entered clinical evaluation and are currently being studied in about 30 ongoing trials in human patients.



AAV. Figure 2 Streamlined protocol for rAAV production. Cultured cells are transfected with two plasmids: The vector plasmid containing the foreign gene to be packaged into the viral particles, flanked by the AAV-2 ITRs, and the helper plasmid carrying the AAV-2 *rep* and *cap* genes to supply the Rep and VP proteins, respectively. In addition, the helper contains all adenoviral (Ad) genes which encode proteins with supportive function for AAV vector production, but it does not yield Adenovirus after transfection. Helpervirus infection is thus superfluous, and the resulting AAV-2 vectors are free of contaminating Adenovirus. Following a 2-day incubation of the transfected cells, the rAAV particles are harvested, purified and quantified. Note that there are numerous modifications to this basic protocol, e.g., in the number of plasmids (1–3, depending on the arrangement of AAV and adenoviral sequences).

What are Clinically Relevant rAAV Applications in Cancer Treatment?

The sum of assets described above – safety, versatility, efficacy, specificity – makes AAV an ideal vector for multiple and diverse therapeutic applications in humans. With particular respect to cancer, the use of AAV vectors is still in its infancy, but increasing pre-clinical data suggest that this vector system holds enormous potential also for this specific application. Thus far, the approaches can be divided into strategies that either target the tumor cell directly or that modify host mechanisms. In more detail, AAV vectors have been employed in the following major categories: Anti-angiogenesis, ►immunotherapy, tumor suppressors, suicide gene therapy, drug resistance, repair strategies, and, last but not least, purging of tumor cells. For many of those categories, a currently emerging therapeutic modality which is also still in its infancy is RNA interference or RNAi (►RNA interference and Cancer). This term describes the natural phenomenon of gene silencing mediated by short double-stranded RNAs.

The latter can be expressed from AAV vectors and thus be used to effectively and specifically suppress, for instance, expression of cellular or virally-encoded oncogenes. RNAi will likely become a valuable and crucial aspect of AAV-based cancer therapy in the near future, and will complement or perhaps even replace many of the currently existing strategies.

Anti-Angiogenesis

The efficacy of ►angiogenesis inhibitors to undermine tumor ►neovascularization and to block cancer progression as well as formation of metastases (►metastasis) has been established in many animal models. However, this cancer therapy requires that the inhibitors are chronically administered as recombinant proteins, which is usually associated with severe problems. Therefore, AAV vectors with their unique ability to mediate sustained gene expression should prove particularly useful for this type of tumor therapy. Especially promising will be the future combination with synthetic AAV capsids that have been evolved to target the vasculature. Thus far, mostly AAV-2-based vectors have been used to deliver and express various anti-angiogenesis factors in small animals, typically mice. A first important example is angiostatin, which has been expressed from AAV-2 in multiple mouse models of human cancers, including gliomas (►Glioblastoma Multiforme) and liver cancers (►Liver Cancer, Molecular Biology]. In all reported cases, this led to suppression of in vivo tumor growth and to substantial improvements in tumor-free survival rates. Similarly impressive are results with the related anti-angiogenic peptide ►endostatin, whose expression from AAV-2 vectors inhibited the establishment or growth of various human cancers in mice, including liver, ovarian (►Ovarian Cancer), pancreatic (►Pancreas Cancer, Clinical Oncology) and colorectal (►Colon Cancer) tumors. Even better results have been obtained with the co-expression of both angiostatin and endostatin from a single or from two separate AAV vectors, exemplifying the potential for synergistic effects from combinatorial AAV therapies. Other examples for anti-angiogenic AAV therapies already evaluated include the expression of a truncated form of the ►vascular endothelial growth factor receptor (renal tumors), or of tissue inhibitors of ►matrix metalloproteases.

Immunotherapy

Failure of the immune system to recognize cancer antigens can substantially contribute to tumor manifestation and progression. Although tumors can illicit strong immune responses in the early stages, this effect is frequently lost in later phases, eventually allowing for aggressive and metastatic tumor growth. Gene transfer protocols involving AAV (or other viral) vectors have thus been developed which aim to potentiate the patient's antitumor responses, by either targeting the tumor cells directly, or by transducing host-derived immune effector cells. Examples for already reported tumor cell-directed therapies include AAV-mediated delivery of ►interferon genes to ex vivo cultured cancer cells, or via intra-tumoral injection (gliomas). Likewise, AAV-2 has been used to express tumor necrosis factor-related ►apoptosis-inducing ligand (►TRAIL) in colorectal, lung and liver tumor models, resulting in significantly inhibited tumor growth and, in some cases, even in regression. Targeting cells of the host immune system, on the other hand, is a promising alternative approach and could eventually be developed into a vaccination therapy. Already, AAV-2 vectors have been used to deliver dominant tumor epitopes to antigen-presenting cells, such as CD40 ligand which was expressed in B-cells from ►chronic lymphocytic leukemia (CLL) patients, leading to specific proliferation of ►HLA Class I-matched allogeneic T-cells. Another potential vaccine could be AAV vectors expressing an HPV16 (►Human Papillomaviruses) E7 CTL (cytotoxic T-cell) epitope/heat shock fusion protein, based on reports that infected mice became immunized against E7-expressing tumor cells. Last but not least, encouraging studies have identified ►dendritic cells (DC), the most potent antigen-presenting cells, as an attractive target for AAV-based cancer immunotherapies. For instance, DCs transduced with AAV vectors encoding HPV16 E6 or E7 genes caused a stark CTL response against cervical cancer cell lines, while in another study, DCs transduced with CD80-expressing AAVs induced high levels of CD8+ T-cells. Together, these findings suggest that AAV can be used to trigger strong anti-tumor CTL responses, and that AAV-based immunotherapy has substantial clinical potential for cancer treatment.

Tumor Suppressors

Highly attractive targets for AAV-mediated cancer therapy are oncogenes and tumor suppressor genes, respectively, whose expression is frequently dysregulated in malignant human cancers. An important example for a tumor suppressor involved in cellular checkpoint control is p53 (►p53 Protein, Biological and Clinical Aspects), which normally prevents passage of cells with DNA damage through the cell cycle. Consequently, expression of p53 from AAV vectors was consistently found to block the growth of cancer cells in vitro and in vivo, and to mediate apoptosis and cytotoxicity. Similar results were obtained after expression of the fragile histidine triad tumor suppressor (►FHIT), which delayed the growth of human pancreatic tumor ►xenografts and extended long-term animal survival. In a third example, delivery of the gene encoding the monocyte chemoattractant protein MCP-1 from AAV vectors suppressed expression of the HPV E6 and E7 proteins in cervical cancer cell lines, as well as in tumors derived from these cells.

Suicide Gene Therapy

This approach is based on the idea to bio-activate a pro-drug within tumor cells to a toxic species, triggered by the tumor-directed delivery of the activating enzyme from AAV vectors. The best studied example for this category is the Herpes simplex virus-encoded enzyme thymidine kinase (*tk*) in combination with gancyclovir. This system has already been used successfully from AAV vectors to inhibit tumor growth in a variety of human xenograft models, including liver cancer, gliomas and ►oral squamous carcinomas. Notably, the specificity of this approach can be enhanced by the use of tissue- and/or tumor-specific promoters, such as those only active in liver or melanoma cells. Moreover, the overall efficacy of the AAV/*tk* vectors was shown to increase following treatment of transduced cells with irradiation or topoisomerase inhibitors, both known to enhance AAV infection (in addition to their direct effects on cells).

Drug Resistance

Development of multiple drug resistance (MDR) is a major issue with cancer chemotherapies and is often associated with over-expression of the ►P-glycoprotein (an ATPase that pumps chemotherapeutic drugs out of the cancer cell). One recently reported, highly effective approach to reverse the MDR phenotype is to use double-stranded AAV vectors to express anti-P-glycoprotein short hairpin RNAs (effectors of RNAi). In human ►breast cancer and oral cancer cells, this led to a substantial sensitization to chemotherapy, suggesting a high potential to overcome the MDR obstacle with this approach. Another application is expression of the MDR1 gene from AAV vectors in ►hematopoietic progenitors. This should confer myeloprotection in patients undergoing high-dose chemotherapy for advanced tumors, and thus prevent myelosuppresssive effects (►Myelosuppression) from the chemotherapeutic regimen, such as infection or hemorrhaging. However, this strategy has not been fully explored in animal models yet.

Repair Strategies

►Telomerase (the enzyme maintaining and stabilizing the integrity of telomeres, i.e., chromosome ends) is an example for a therapeutically relevant target for repair strategies. Its activity is often elevated in tumor cells, and it was shown that delivery of telomerase antisense molecules [Antisense DNA Therapy] via AAV vectors (in this particular case hybrids with adenoviral vectors) can reduce tumor cell proliferation, as well as induce apoptosis.

Purging of Tumor Cells from Autologous Transplants

Autologous grafts (►Graft Acceptance and Rejection), e.g. peripheral blood progenitor cells, are used for treatment of many solid human cancers. However, they can be contaminated with tumor cells that give rise to relapse after ►myeloablative megatherapy and graft transplantation. There is recent evidence that following infection of such contaminated grafts with recombinant AAV-2, the contaminating tumor cells are preferentially infected, while the hematopoietic progenitors are spared. Indeed, infection of sarcoma cells with AAV/tk vectors (see above) extended the survival of transplanted mice (over non-treated controls), while the same vector was unable to transduce and kill human peripheral blood progenitors. However, it remains to be proven that this strategy can indeed be applied to selectively purge tumor cells from autologous transplants.

RNAi

RNA-mediated silencing of gene expression (RNAi) will clearly become a major part of anti-tumor therapies in the future, as proof-of-concept for the efficacy of this approach is already overwhelming. In combination with AAV, there have only been a few reports thus far, but this field will certainly expand. One described application is to use AAV vectors to deliver short hairpin RNAs against the *hec1* gene, which is highly expressed in mitotic cells where it represents a vital component of the ►kinetochore outer plate. Transduction of glioma cells with anti-*hec1* AAV vectors resulted in selective cell death, while mitotically inactive control cells were unaffected. Likewise, infected xenografts showed lower densities and were highly fibrotic, as a result of AAV treatment. It can generally be predicted that virtually any over-expressed gene that contributes to transformation can be an AAV/RNAi target, including virally-encoded (see above, e.g., HPV E6/7) or cellular oncogenes.

Future Applications

With the current state-of-the-art technology, the AAV vector system is already one of the most powerful and promising toolkits for development as anti-tumor bioreagents. In the future, the versatility of this system will further increase with the discovery and creation of new natural or synthetic capsids, respectively. Likewise, the field will benefit from the engineering of novel tumor- and tissue-specific gene expression cassettes, and from the design of safer and more effective therapeutic sequences, e.g., for the induction of anti-cancer RNAi. A very important approach will be to merge the different strategies into combinatorial therapies, e.g., by mixing immunotherapies with RNAi vectors, or suicide gene expression with repair approaches. Examples for such multimodality cancer therapies with AAV vectors have already been reported, and their numbers will increase in the future. Last but not least, it will also be crucial to combine AAV (or other viral) vectors with further anti-cancer effectors, such as new classes of compounds including proteasome (►Proteasomal Inhibitors) and histone deacetylase (►Histone Deacetylases) inhibitors.

ABC Drug-Transporters

Definition

Synonym ABC Transporter, ABC (ATP-Binding Cassette) Superfamily. The adenosine-triphosphate (ATP) binding cassette (ABC) transporters form the largest family of transmembrane proteins that use ATP-derived energy to transport various substances over cell membranes. Primary-active transporters, driven by energy released from ATP by inherent ATPase activity, that export substrates from the cell against a chemical gradient, Based on the arrangement of the nucleotide binding domain and the topology of its transmembrane domains, human ABC-transporters are classified into seven distinct families (ABC-A to ABC-G), including ABCB1 (P-glycoprotein), ABCC1 (MRP1), ABCC2 (cMOAT; MRP2), ABCC4 (MRP4), and ABCG2 (ABCP; MXR; BCRP). Structural characteristics based on their ►Walker motif (ATP binding domain) and their nucleotide-binding folds across the membrane are responsible for their classification into this superfamily. Their localization pattern over the body suggests that they have an important role in the prevention of absorption as well as the excretion of potentially toxic metabolites and xenobiotics, both on a systemic and a cellular level. ABC drug-transporters (may) show substrate-overlap. Examples of mammalian ABC transporters include ►P-glycoprotein, MRP (►multidrug resistance protein), ►cystic fibrosis transmembrane conductance regulator (CFTR) and the transporter associated with antigen processing (TAP).

ABC (ATP-Binding Cassette) Superfamily

Definition

ABC (ATP-binding cassette) superfamily contains both uptake and efflux transport systems. These proteins bind ATP and hydrolyze it to energize transport of molecules outside or inside the cells.

ABC Transporter

Definition

ABC transporters are a superfamily of prokaryotic and eukaryotic proteins. They are usually involved in membrane transport and share a homologous nucleotide-binding domain, ABC (ATP-binding cassette). In addition to the ABC domain, ABC transporters contain or interact with hydrophobic domains containing multiple transmembrane segments. Examples of mammalian ABC transporters include P-glycoprotein, MRP (multidrug-resistance protein), cystic fibrosis transmembrane conductance regulator (CFTR) and the transporter associated with antigen processing (TAP).

ABC Transporter Proteins

Definition

ABC transporter proteins are a superfamily of proteins responsible for transporting a broad range compounds across membranes in cells. Structural characteristics based on their Walker domains (ATP binding domain) and their nucleotide-binding folds across the membrane are responsible for their classification into this superfamily.

Synonyms

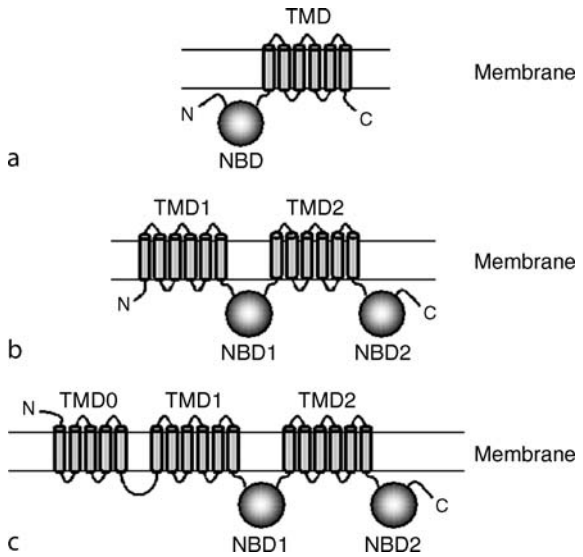
Multidrug resistance transporters; Traffic ATPases; Permeases (for import systems)

Definition

ABC (ATP-binding cassette)-transporters are membrane-embedded proteins with a characteristic ABC domain that utilize the energy from ATP hydrolysis for the transport of their substrates across a cellular membrane.

Characteristics

The superfamily of ABC-transporters comprises one of the most abundant protein families in nature. These transporters are believed to date back in evolutionary time more than 3 billion years and are distributed in all three kingdoms of living organisms, *archaea*, *eubacteria*, and *eukaryotes*. ABC-transporters have to be distinguished from ABC-proteins. Both types of proteins are defined by the presence of a highly conserved ~215 amino acids consensus sequence designated as ABC domain or nucleotide-binding domain (NBD). The domain contains two short peptide motifs, a glycine-rich Walker A and a hydrophobic Walker B motif, both involved in ATP binding and commonly present in all nucleotide-binding proteins. A third consensus sequence is named ABC signature and is unique in ABC domains. ABC-containing proteins couple the phosphate bond energy of ATP hydrolysis to many cellular processes and are not necessarily restricted to transport functions. However, the proper meaning of the term ABC-transporter is satisfied when the ABC-protein is in addition associated with a hydrophobic, integral transmembrane domain (TMD) forming a translocation path. TMDs are usually composed of at least six transmembrane (TM) α-helices. They are believed to determine the specificity for the substrate molecules transported by the ABC-transporter. The minimal structural requirement for a biological active ABC-transporter seems to be two TMDs and two NBDs $[TMD\text{-}NBD]_2$ (Fig. 1). In full-size transporters, this structural arrangement may be formed by a single polypeptide chain and in multi-protein complexes by more than one polypeptide chain. In *prokaryota*, ABC transport systems are often half-size transporters having only one TMD fused to one NBD [TMD-NBD]. Half-size transporters probably dimerize to form a full-size transporter $[TMD\text{-}NBD]_2$ to mediate mainly the influx of essential compounds such as sugars, vitamins, and metal ions into the cell. Eukaryotic ABC-transporters commonly function as exporters mediating the efflux of compounds from the cytosol to the extracellular space or to the inside of intracellular membrane-bound compartments, i.e., endoplasmic reticulum, mitochondria, peroxisomes, or vacuoles. The range of physiologically transported compounds includes lipids and sterols, ions, diverse small molecules, oligo- and polypeptides.



ABC-Transporters. Figure 1 Schematic representation of the predicted domain arrangement of (a) half-size transporters having only one TMD fused to one NBD [TMD-NBD], e.g., ABCG2 (BCRP); and (b,c) full-size transporters $[TMD\text{-}NBD]_2$, whereby (b) shows the predicted structure of ABCB1 (MDR1), and (c) the structure of ABCC1 (MRP1) containing an additional TMD (TMD0) of unknown function. Half-size transporters probably dimerize to form a biological active ABC-transporter. These three ABC-transporters are the most important drug extrusion pumps in multidrug-resistant cancers. TMD, transmembrane domain consisting of six α-helices; NBT, nucleotide-binding domain. It should be noted that the orientation of ABCG2 is reverse to that of ABCB1 and ABCC1.

Human ABC-Transporters

In humans, 48 ABC-transporters distributed to seven subfamilies have been identified (Table 1). Although the number of human ABC-transporters is much smaller than found in bacteria, many of them are of clinical significance. Currently, 18 human genes encoding ABC-transporters have been associated with genetic diseases. Even though the majority of the members of the human ABC-transporter family are active transporters, there are some exceptions in which the energy of ATP hydrolysis is utilized to control alternative biological processes. Thus, ABCC7 (CFTR), well known as mutated in patients suffering on ►cystic

fibrosis, appears as a chloride ion channel; ABCC8 (SUR1) and ABCC9 (SUR2) are both regulatory subunits of the regulatory sulfonylurea receptor (SUR). Other members of the ABC-transporter family couple ATP binding and hydrolysis to the control of translation or ►DNA repair. Although the active transporters have dedicated functions involving the transport of specific substrates, the complex physiological network of ABC-transporters may also have an important role in host detoxification and protection against xenobiotics. This general function is revealed by their tissue distribution. ABC-transporters are highly expressed in important pharmacological barriers, such as the epithelium that contributes to the blood–brain barrier (BBB), the brush border membrane of intestinal cells, the biliary canalicular membrane of hepatocytes, or the lumenal membrane in proximal tubules of the kidney. Anyway, this xenobiotics pump function is the basis for the pivotal role of ABC-transporters in ►multidrug resistance (MDR) of cancer.

ABC-Transporters and Multidrug Resistance of Cancer

MDR is defined as the simultaneous resistance of a tumor against a variety of antineoplastic agents with different chemical structure and mode of action. Thus, MDR is a major obstacle in clinical management of cancer by ►chemotherapy. Although various mechanisms have been identified to mediate a multidrug-resistant phenotype to malignant diseases, the enhanced drug extrusion activity of the ABC-transporter ABCB1 or ►P-glycoprotein (MDR1; PGY1) was the first mechanism that was demonstrated to be the reason for MDR. The substrates of ABCB1 include first and foremost natural product-derived anticancer drugs, such as ►anthracyclines, ►epipodophyllotoxins, ►taxans, and ►vinca alkaloids, but not clinically important drugs like platinum-containing compounds or ►antimetabolites. Besides ABCB1, in particular, ABCC1 (MRP1) and ABCG2 (BCRP) were found to be associated with a multidrug-resistant phenotype, but also alternative ABC-transporters can pump drugs from the inside to the outside of a cancer cell, e.g., ABCC2 (MRP2) is a platinum drug transporter. ABCB1, ABCC1, and ABCG2 have partial overlapping but not identical substrates.

ABC-Transporters as Anticancer Drug Targets

Following the identification of ABCB1 as a pivotal MDR-mediating factor, tremendous efforts were undertaken to identify ABCB1-interacting agents that inhibit its pump activity and, therewith, reverse the MDR phenotype. Such drugs are commonly designated as chemosensitizers or MDR modulators. Although many compounds, e.g., ►verapamil and ►ciclosporin derivatives, were identified as ABCB1 inhibitors or inhibitors of alternative MDR-mediating ABC-transporters, so far all of them failed in clinical trials.

ABVD

Anas Younes
Department of Lymphoma and Myeloma, M.D. Anderson Cancer Center, Houston, TX, USA

Definition

Doxorubicin, bleomycin, vinblastine, and dacarbazine combination chemotherapy used for the treatment of patients with Hodgkin lymphoma.

Characteristics

ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) is the most widely used regimen for the treatment of early and advanced stage Hodgkin lymphoma (HL). Treatment of patients with early stage classical HL evolved over the last three decades. Radiation therapy alone as the single treatment modality is no longer practiced. Today, the most widely used approach is combined modality therapy (chemotherapy plus involved field radiation therapy). In general, 2 (for favorable early stage) to 4 (for unfavorable early stage) cycles of ABVD plus 30 Gy of involved field radiation therapy is the most widely used standard of care approach. Using this approach, more than 90% of the patients are expected to be cured of their disease. Patients with bulky stage II disease, (especially with bulky mediastinal mass), or stage II with B-symptoms are usually treated similar to those with advanced stage HL with 6–8 cycles of ABVD followed by involved field radiation therapy to the bulky area.

Use of chemotherapy alone has recently been proposed for a selected group of patients with early stage classical HL. The rationale for this approach is to reduce radiation-induced morbidity and mortality, including second malignancies and cardiac complications. While this approach is appealing, it will need to be further examined after prolonged follow-up. For now, it seems appropriate to treat young female patients with non-bulky early stage classical HL (especially those with mediastinal or axillary adenopathy) with chemotherapy alone to reduce the risk for breast cancer. The risks and benefits of combined modality versus chemotherapy alone should be discussed with patients before making a final treatment recommendation. Based on several randomized studies comparing ABVD with other multi-drug regimens, ABVD became the most widely used combination regimen for the treatment of patients with advanced HL. Chemotherapy alone (6–8 cycles) is usually considered sufficient for treating patients with advanced stage classical HL. However, involved field radiation therapy is frequently added at the end of chemotherapy to areas of bulky disease. This combined modality approach has been recently compared with chemotherapy (MOPP/ABV) alone in a randomized trial in patients with advanced stage classical HL, and showed no survival advantage, especially in those who achieved complete remission after the completion of chemotherapy. Furthermore, meta-analysis review of fourteen clinical trials comparing chemotherapy with combined modality also showed no survival advantage for those receiving the combined modality approach.

Newer treatment programs such as Stanford V and BEACOPP have shown successful results, but remain less widely used compared with ABVD. Although BEACOPP has been shown to be superior to ABVD-like regimens in large-scale randomized trials, the superiority of Stanford V over standard ABVD has not yet been established. Because ABVD may cure only 50–65% of patients with poor risk advanced stage HL, more intensive programs such as BEACOPP may add benefit, despite the increased toxicity. Patients with good risk features have a high cure rate with ABVD, so the use of more intensive and more toxic regimens in this patient population should be used with caution, and preferably within a clinical trial. In fact, a recently published randomized study demonstrated that early intensification with autologous stem cell transplantation after four cycles of ABVD-like chemotherapy did not improve the outcome in patients with advanced stage HL compared with conventional chemotherapy, perhaps because many patients did not have poor risk features as identified by the international prognostic score for HL.

Accelerated Phase

Definition

Occurs between chronic phase and ►blast crisis. Characterized by 10–19% myeloblasts and >20% basophils in blood or bone marrow and cytogenetic evolution; also increasing splenomegaly, platelet count, or white blood cells if unresponsive to treatment.

►Nilotinib

ACD

Definition

Abbreviation for Appraisal Consultation Document.

►National Institute for Health and Clinical Excellence (NICE)

ACDC

►Adiponectin

Acetaldehyde

Definition

Highly reactive chemical compound (CH_3CHO) that forms following ethanol metabolism. Toxic, mutagenic and carcinogenic.

►Alcohol Consumption
►Hepatic Ethanol Metabolism

Acetaldehydehydrogenase

Definition

The enzyme which oxidizes ►acetaldehyde.

►Alcohol Consumption

Acetylation

Definition

The reversible, covalent attachment of an acetyl group to the lysine residue of proteins. Acetylation and deacetylation of histones play an important role in transcriptional regulation

►Histone Deacetylases

N-Acetylcysteine

Definition

A pharmacological agent used mainly as a mucolytic and in the management of ►paracetamol overdose and is available in different dosage forms for different indications: solution for inhalation – inhaled for mucolytic therapy or ingested for nephroprotective effect; i.v. injection – treatment of paracetamol overdose; or oral solution – various indications.

►Chemoprotectants

Acetylsalicylic Acid

Definition

ASA/aspirin; one of the most successful drugs in combating reactive species overload diseases, and the ►chemoprevention of cancers such as ►colon cancer.

►Inflammation

Acetyltransferase

Definition

An enzymic activity that catalyzes the transfer of an acetyl moiety from acetyl CoA to a specific amino acid on a substrate protein. CBP and p300 are lysine (K)-directed acetyltransferases.

►CBP/p300 Coactivators

N-Acetyltransferase

Definition

Is an acetyl-CoA requiring enzyme that catalyses the acetylation of ►xenobiotics that are aromatic amines or contain a hydrazine group. It participates in the ►detoxification of a plethora of hydrazine arylamine drugs and is also able to bioactivate several known carcinogens. (Vatsis KP, Weber WW, Bell DA et al (1995) Nomenclature for N-Acetyltransferases. Pharmacogenetics 5:1–17)

►Detoxification

ACF

Definition

Aberrant crypt foci; Putative precursors of colon cancer ►Preneoplastic lesions.

►Trefoil Factors
►Colon Cancer
►Conjugated Linolenic Acids

Acharan Sulfate (AS)

Definition

Is isolated from the giant African snail Achatina fulica, responsible for inhibitory effect of tumor growth. AS inhibits tumor growth by binding the ►nucleolin protein on the surface of cancer cells.

Achneiform Rash

Definition

Is a pustular rash with usual distribution over the face, scalp, and upper trunk.

►Erlotinib (Tarceva®)

Acid Rain

Definition

Is formed by absorption of acidic gases as SO_2 or NO_x by water droplets in clouds Precipitation then increases the acidity of the soil, and affects the chemical balance of surface water bodies.

►Xenobiotics

Acidosis

Definition

Is present in a tissue whenever the pH is below 7.0 (or the H^+-concentration is higher than 10–7 mol/L).

►Oxygenation of Tumors

Acinar Cells

Definition

Key cell in the exocrine pancreas. These are arranged around a central lumen and form the bulk of the pancreatic gland. They contain digestive enzymes usually found in the apical region of the cells.

Acites

Gerhild Becker
Department of Internal Medicine II (Gastroenterology, Hepatology, Endocrinology), University Hospital Freiburg, Freiburg, Germany

Definition

Ascites is derived from the Greek word ασκός (gr. sack, wineskin) and is defined as accumulation of protein rich fluid in the peritoneal cavity. It occurs mainly in ►cirrhosis of the liver, but also in heart failure, tuberculosis and malignancy. Malignant ascites occurs in association with a variety of neoplasms and is defined as the abnormal accumulation of fluid in the peritoneal cavity caused by cancer.

Characteristic

Malignant ascites accounts for around 10% of all cases of ascites and occurs in association with a variety of neoplasms. Malignant effusion is the escape of fluid from the blood or vessels into tissues or cavities, and is a common problem in patients with cancer. All types of cancer can metastasize to any of the body's serous cavities and result in malignant effusion. In the Western World the most common cause of malignant ascites is ►ovarian cancer. Other common primary sites are the pancreas, stomach and uterus, with breast, lung, and lymphoma representing the commonest extra-abdominal sites. Up to 20% of all patients with malignant ascites have cancer of unknown primary origin (►CUP). Except in breast and ovarian cancer, the presence of malignant ascites in patients with neoplastic disease frequently signalizes the terminal phase of cancer. The mean survival time for ovarian cancer is 30–35 weeks and for tumors of lymphatic origin 58–78 weeks, whereas for cancers of the gastrointestinal tract the mean survival is only 12–20 weeks. In patients with CUP the median survival shows a great variability ranging from 1 week to 3 months in different series.

Pathophysiology

Fluid accumulation in the peritoneal cavity is dependent on the amount of fluid generated and the rate at which it leaves the abdominal cavity. When fluid production exceeds its clearance, free transudate will accumulate. Under physiologic conditions, transudation of plasma through capillary membranes of the peritoneal serosa continuously produces free fluid to lubricate the serosal surfaces. This fluid production is under the influence of portal pressure, plasma oncotic pressure, sodium and water retention, hepatic lymph production, and microvascular permeability for macromolecules. Under physiologic conditions, at least two-thirds of the peritoneal fluid reabsorbs into open-ended lymphatic channels of the diaphragm and is propelled cephalad by the negative intrathoracic pressure. This fluid proceeds through mediastinal lymph channels into the right thoracic duct and empties into the right subclavian vein. The ability of the healthy subject to resorb fluid is much greater than the fluid generated, with the result that there is normally only a small volume of approx. 50 mL of fluid in the peritoneal cavity.

Ascites as an abnormal accumulation of fluid in the peritonal cavity can be induced by several causes. In principle, four types of causes can be identified. (i) Ascites due to raised hydrostatic pressure, caused by cirrhosis, congestive heart failure, inferior vena caval obstruction, or hepatic vein occlusion. (ii) Ascites due to decreased osmotic pressure, caused by protein depletion (e.g. nephrotic syndrome), reduced protein intake (malnutrition) or reduced protein production (cirrhosis of the liver). (iii) Ascites due to fluid production exceeding resorptive capacity, caused by infections or malignancies. (iv) Chylous ascites, caused by obstruction and leakage of the lymph channels draining the gut.

The pathophysiology of malignant ascites is multifactorial and is yet incompletely understood. Ascites may result from obstruction of lymphatic drainage by tumor cells that prevent absorption of intraperitoneal fluid and protein as often seen in lymphomas and breast cancer. Since the ascites of many patients with malignant ascites has a high protein content, alteration in vascular permeability has been implicated in the pathogenesis of ascites production. The tumor induces increasing production of peritoneal fluid due to increased microvascular permeability of tumor vasculature and the amount of ascites production correlates with the extent of neovascularization. Aside from mechanical obstruction and cytokines, the pathophysiology of malignant ascites also consists of hormonal mechanisms. Due to decreased removal of fluid as a consequence of obstructed lymphatics, the circulating blood volume is reduced and this activates the renin-angiotensin-aldosterone system, leading to sodium retention. Therefore, reduced sodium intake together with diuretics is often used to treat malignant ascites, but there is no consensus on effectiveness. Available trials considering diuretics often include different patients groups with varying dose regimens and there are no randomized controlled trials to asses the efficacy of diuretics in malignant ascites.

Diagnosis

In most cases, ascites can be diagnosed by careful physical examination and taking a detailed history. The main clinical symptoms of ascites include abdominal

distension, ankle edema, continuous abdominal discomfort or pain, nausea, vomiting, shortness of breath and decreased mobility. Greater quantities of ascites cause abdominal distension, bulging flanks that are dull to percussion, shifting dullness and a fluid wave. Ultrasound is able to detect free peritoneal fluid if its volume is greater than 100 mL. CT and MRI are also able to detect little quantities of ascites. Malignant diagnosis is indistinguishable by physical examination from ascites caused by non-malignant conditions. Ascites detected by ultrasound, CT or MRI in the presence of typical imaging features of a malignant tumor is strongly suggestive of a malignant ascites. Diagnosis is confirmed by positive cytology of malignant cells in the fluid. A positive cytology result has a specificity of nearly 100%, but it is not very sensitive with only about 60% of malignant aspirates being cytologically positive. Compared to ascites caused by cirrhosis, malignant ascites usually contains more white blood cells and a higher level of lactate dehydrogenase. Fibronectin, cholesterol, lactate dehydrogenase, sialic acid, proteases, and antiproteases have been studied with fibronectin performing best in differentiating between malignant and non-malignant acites in most series. However, at present there is no single test available to be used routinely to differentiate between malignant and non-malignant ascites. Tumor markers, especially ►CEA and CA-125 can be useful in diagnosing the primary tumor in malignant ascites, although they lack specificity. In case of doubt abdominal ►paracentesis with chemical and cytologic analysis of the ascitic fluid should be used. The cell count provides immediate information about possible bacterial infection. Samples with a predominance of a least 250 neutrophils per cubic millimeter of ascitic fluid are suggestive of infection. Gram stains and culture for bacterial, fungal, and acid fast organisms are mandatory. ►Spontaneous bacterial peritonitis is characterized by the spontaneous infection of ascitic fluid in the absence of an intra-abdominal source of infection and involves the translocation of bacteria from the intestinal lumen to the lymph nodes, with subsequent bacteremia and infection of ascitic fluid. Third-generation cephalosporins are the treatment of choice. Ascitic fluid amylase content helps to detect pancreatic ascites and gut perforation. 80% of all cases of ascites are caused by cirrhosis of the liver. The chief factor contributing to ascites in liver cirrhosis is ►portal hypertension. Patients with ascites caused by liver disease usually have a ►serum-ascites albumin concentration gradient (calculated by subtracking the albumin concentration of the ascitic fluid from the albumin concentration of a serum specimen obtained on the same day) ≥1.1 g/dL. If serum albumin: ascites albumin gradient is less than 1.1g/dL, portal hypertension can be safely ruled out.

Treatment

In general, practice of managing malignant ascites seems to be influenced by the evidence obtained in the context of non-malignant ascites, especially ascites caused by liver disease. Malignant ascites only accounts for approximately 10% of all cases of ascites whereas over 80% of cases are caused by chronic liver disease. So, most evidence in treatment of ascites is obtained in the context of liver disease. In ascites caused by liver cirrhosis the most important treatments are the restriction of dietary sodium intake and the use of oral diuretics because patients with liver cirrhosis retain sodium and water as a result of the renin-angiotensin-aldosterone pathway. In ascites due to liver disease there is good evidence for the efficacy of a combined therapy with the diuretics spironolactone and furosemide supported by several randomized controlled trials. Treatment options for the minority of patients who are resistant to standard therapy with diuretics are therapeutic paracentesis, ►peritoneovenous shunting, ►transjugular intrahepatic portosystemic shunt (TIPS), extracorporal ultrafiltration of ascetic fluid with reinfusion and liver transplantation. Of these, ►transjugular portosystemic stent shunts, extracorporal ultrafiltration and liver transplantation are specific to liver diseases, whereas abdominal paracentesis and peritoneovenous shunting are often used in managing malignant ascites. In contrast to the treatment of underlying cancer, there is no generally accepted gold standard for the management of malignant ascites so far.

There are two principle approaches in managing malignant ascites. The first attempts to treat the cancer as the underlying cause of the ascites. The main treatments are systemic or intraperitoneal chemotherapies, biological therapies like intraperitoneal α or β ►interferon, tumor necrosis factor TNF or administration of infectious agents in non pathogenic form like corynebacterium parvum or OK-432, a penicillin- and heat-treated powder of Su-strain streptococcus pyogenes A3 in peritoneal cavity. Octreotide, a somatostatin analogue known to decrease the secretion of fluid by the intestinal mucosa and to increase water and electrolyte reabsorption, was used successfully in some case reports of malignant ascites. Novel therapies are radiolabeled monoclonal antibodies and radiocolloids. In tumors associated with increased activity of ►vascular endothelial growth factor (VEGF) like ovarian, gastric, colon, pancreatic carcinomas and omental or hepatic metastatic malignancies, a new concept is to reduce the production of ascites by the inhibition of neovascularization. This is achieved via inhibition of vascular endothelial growth factor (VEGF) or inhibition of ►matrix metalloproteinases, which are a family of enzymes present within the normal healthy individuals, but produced in high

concentrations by a variety of tumors. However, these concepts are comparatively new and are based on experimental results or only partially investigated in Phase I trials and have not yet been evaluated in randomized controlled trials.

The second approach in managing malignant ascites is palliative and relies upon reducing the volume of fluid through a variety of approaches like paracentesis, diuretics, or peritoneovenous shunts. Paracentesis is indicated for those patients who have symptoms of increasing intra-abdominal pressure. Available data show good, although temporary relief of symptoms in most patients. Symptoms seem to be significantly relieved by drainage of up to 5 L of fluid. When removing up to 5 L, intravenous fluids seem to be not routinely required. If the patient is hypotensive, dehydrated or known to have severe renal impairment and paracentesis is still indicated, intravenous hydration should be considered. The only investigated therapy in malignant ascites is infusion of dextrose 5%. There is no evidence of concurrent albumin infusions in patients with malignant ascites. To avoid repeated paracenteses, a peritoneovenous shunting may be considered. Major complications like pulmonary edema, pulmonary emboli, infection or clinically relevant disseminated intravascular coagulation have to be expected in about 6% of patients. There are no randomized trials assessing the efficacy of diuretic therapy. The available data are controversial and there are no clear predictors to identify which patients would benefit. Therefore, the use of diuretics should be considered in all patients with malignant ascites, but has to be evaluated individually. Patients with malignant ascites due to massive hepatic metastasis seem to respond more likely to diuretics than patients with malignant ascites caused by peritoneal carcinomatosis or chylous ascites. Choice of diuretics is also not sufficiently evaluated. As available data suggest that the efficacy of diuretics in malignant ascites depends on plasma renin/aldosterone concentration, aldosterone antagonists like spironolactone should be used, either alone or in combination with a loop diuretic.

Aclarubicin

Definition

Is an anthracycline anticancer agent; Synonym aclacinomycin A.

►Adriamycin

Acquired Immunodeficiency Syndrome

Definition

AIDS; A life-threatening disease caused by he human immunodeficiency virus (►HIV) and characterized by breakdown of the body's immune defenses.

Acquired Mutation

Definition

A mutation (a genetic change) acquired by a somatic cell after conception.

►Gastrointestinal Stromal Tumor

Acromegaly

Definition

The name “acromegaly” comes from the Greek words for “extremities” (acro) and “great” (megaly), because one of the most common symptoms of this condition is abnormal growth of the hands and feet. A hormonal disorder that most commonly occurs in middle-aged men and women. The prevalence of acromegaly is approximately 4,676 cases per million population, and the incidence is 116.9 new cases per million per year. The symptoms of acromegaly can vary and they

develop gradually over time; therefore, a diagnosis of this condition may be difficult. Early detection is a goal in the management of acromegaly because the pathologic effects of increased growth hormone (GH) production are progressive.

ACRP30

►Adiponectin

ACTH

Definition

Adrencorticotropic Hormone.

►Corticotrophin

Actin

Definition

A protein that is found abundantly in all eukaryotic cells. The protein exists in monomeric (globular or Gactin) and polymeric forms (filamentous or F-actin). Filamentous actin bundles to form long fibers known as Actin Microfilaments or stress fibers. Actin is a globular structural protein that polymerizes in a helix to form an actin filament. Actin filaments determine the cell shape, stabilize the cell mechanically, enable cell movements, and participate in contraction of the cell during ►cytokinesis. Monomers of the protein actin polymerize to form long, thin fibers about 8 nm in a globular protein found in all cells. It is a major component in microfilaments and forms the contractile filaments in muscle cells.

►Huntingtin Interacting Protein 1 (HIP1)
►Micronucleus Assay
►Migration
►Tight Junction

Actin Cytoskeleton

The actin cytoskeleton is a dynamic structure of ►actin bundles and networks in the cytoplasm that provides a framework to maintain cell shape, protects the cell and enables cell locomotion. It also plays an important role in intra-cellular transport.

Actin Filament Severing

Definition

The breakage of noncovalent bonds between ►actin molecules within an actin filament.

►Geloslin

Actinic Keratosis

Definition

Scaly, erythematous patches found on the skin in sun-exposed areas. Radiation induced keratosis (hornification) of the skin. It represents a precancerous lesion also known as solar keratosis or senile keratosis. May undergo malignant progression to form squamous cell carcinoma.

►Epidermoid Carcinoma
►Squamous Cell Carcinoma
►Photodynamic Therapy

Actinomycin D

Definition

Synonym Dactinomycin. An antineoplastic antibiotic used for Nephroblastoma, Rhabdomyosarcoma, and trophoblastic disease in women.

►Placental Site Trophoblastic Tumor (PSTT)

Activated Fibroblasts

►Myofibroblasts

Activated Natural Killer Cells

Norimasa Ito, Herbert J. III Zeh, Michael T. Lotze
University of Pittsburgh, Departments of Surgery and Bioengineering, Pittsburgh, PA, USA

Synonyms

K cells; killer cells; K lymphocyte; large granular lymphocyte; lymphokine activated killer; LAK

Definition

White blood cells that kill tumor and virus-infected cells as part of the body's immune system (Unified Medical Language System). A type of white blood cell that contains granules with enzymes that can kill tumor cells or microbial cells (National Cancer Institute). A circulating cellular biosensor, regulating immunity through release of cytokines, maturation of dendritic cells, and recognition and lysis of stressed cells, allowing sampling of cellular contents for delivery to phagocytic cells (our definition).

Characteristics

Biology of NK Cells

►Natural Killer cells comprise 10–15% of circulating lymphocytes in normal adults and are also found in peripheral tissues, including the liver, peritoneal cavity, lymph nodes, and placenta. NK cells were first reported by Wunderlich, Herberman, and Sendo and others in the early 1970s. They were first discovered on the basis of their nonspecific killer activity, disturbing attempts to generate tumor-specific, ►MHC-restricted cytotoxic T lymphocytes (CTLs). NK cell belongs to the innate immune system, bridging ►adaptive immunity in concert with ►dendritic cells. NK cells play a major role in the host defense against tumors and infected cells. NK cells mediate cytolysis of cultured tumor cells, and when lymphokine activated (LAK activity), against freshly acquired tumor cells. "Natural killer" suggests the initial notion that they do not require activation in order to kill target cells. NK cells are large granular lymphocytes (LGL). The targets of NK cells are stressed cells expressing either "nonself" or "the self that changed in quality," prompting their recognition. NK cells, when activated, can recognize cells which fail to express cognate self MHC molecules and simultaneously express (stress-induced) ligands recognized by activating NK receptors. These ligands include MICA/MICB ULPBs, PVR, and Nectin-2 in humans or Rae-1 in mice. NK cytolytic activity is almost nonexistent at birth, increases until 15 years of age, and then gradually reduces through old age. Natural killer cells (NK cells) lack the ability to destroy tumor cells at the time of birth, acquiring cytolytic capacity following recognition. Given their ready acquisition from the peripheral blood, multiple studies have evaluated their activity in various clinical studies; for example, chronic mental stress, fatigue, and physical exertion suppress NK activity. Reduced NK activity may be related to increasing cancer risk. Patients deficient in NK cells prove to be highly susceptible to early phases of herpes virus infection. Many studies indicate that NK activity is reduced in patients with advanced cancer. Tumor infiltrating NK cells of pediatric cancer are significantly less in number than that observed in adult cancers, prompting the notion that this creates a major nosologic difference of adult and pediatric neoplasms.

Role of NK Cells in Human Cancer

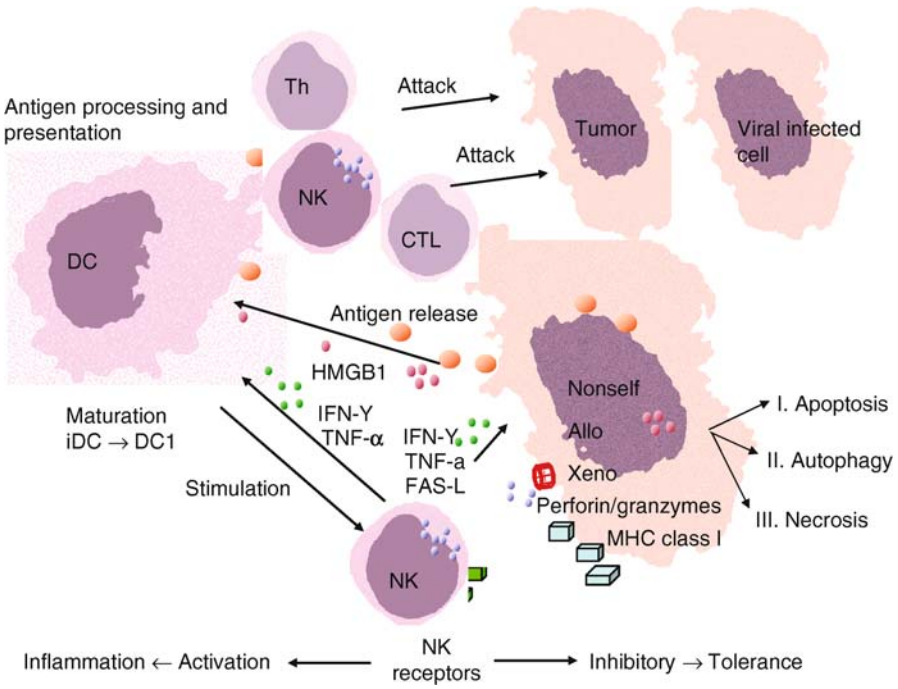
NK cells induce tumor cell death when NK cells recognize tumor cells with NK cell activating receptors. NK cells produce many cytokines including ►IFNs and ►TNF-α and suppress proliferation of tumor and cells and drive type 1 immunity. NK cells help dendritic cells to mature into DC1. NK cells have some suppressive roles against cancer. NK cells have inhibitory receptors. They become tolerant to tumor cells when inhibitory receptors are stimulated with their ligands (Fig. 1).

Markers of NK Cells

NK cells express CD16 (FcγRIII), CD56, ►CD57, CD94, or CD158a. They do not express ►T-cell receptor (TCR) or the pan T cell marker ►CD3 or surface immunoglobulins (Ig) B cell receptor (►CD20). NK cells recognize specific polysaccharide on target cells with NK receptor (CD161; NKR-P1) and expression of MHC class I molecules.

NK Cell Receptors

There are two main types of receptors for MHC class I on NK cells including the KIR (killer cell immunoglobulin-like receptors, one of the immunoglobulin superfamily) and NKG2 receptor (CD94, type C lectin family). In both, there are activating and suppressing forms that accelerate or suppress NK activity. Two explanations for NK-cell self-tolerance have been proposed: first, NK cells from MHC-class-I-deficient hosts have a lower activation potential, owing to decreased activating-receptor expression and/or



Activated Natural Killer Cells. Figure 1 Role of NK cells in tumor immunity. NK cells play multiple roles in tumor immunity. They recognize stressed cells or those failing to express cognate Class I major histocompability molecules, both lysing targets and serving as a source of cytokines important in initiation and perpetuation of the inflammatory response is carried out by them. They serve as helper cells, promoting immune interaction with both T and dendritic cells, critically being required for initiation of the TH1 response. Their absence may also be important in limiting autoimmunity as revealed by their critical absence in the NOD mouse strain, susceptible to autoimmune diabetes. When lysing cells, normal cells capable of undergoing apoptotic or autophagic00128 death, Types I and II death, do so. Many virally infected or transformed cells fail to undergo such death because of block of these pathways, and when lysed, undergo necrotic cell death causing DC maturation and promoting recruitment of additional inflammatory cells. In the absence of viral or bacterial pathogen signals, such chronic necrotic cell death is associated with inhibition of immune effectors and promotion of a wound repair phenotype with angiogenesis and stromagenesis, characteristic of many tumors.

function; or second, NK cells are kept self-tolerant by interactions between non-MHC-dependent receptor–ligand pairs CD94: NKG2, a C-type lectin family receptor, is conserved in both rodents and primates and identifies nonclassical (also nonpolymorphic) MHC I molecules including HLA E. Though indirect, this is a means to survey the levels of classical (polymorphic) HLA molecules. Expression of HLA E at the cell surface is dependent upon the presence of classical MHC class I leader peptides. Ly49 is a relatively ancient, C-type lectin family receptor. Humans have only one pseudogenic Ly49; the receptor for classical MHC I molecules. KIRs belong to a multigene family of more recently evolved Ig-like extracellular domain receptors. They are present in nonrodent primates and are the primary receptors for both classical MHC I (HLA A, HLA B, HLA C) and nonclassical HLA G in primates. KIRs are specific for certain HLA subtypes. ILT or LIR (leucocyte inhibitory receptors) are recently discovered members of the Ig receptor family. ►Carcinoembryonic antigen related cell adhesion molecule 1 (►CEACAM1 Adhesion Molecule) is an inhibitory receptor and its ligands are CEACAM1 itself and CEACAM5, known as CEA. Sialic acid binding immunoglobulin-like lectins (SIGLECs) have a V-set immunoglobulin domain, which binds sialic acid, and varying numbers of C2-set immunoglobulin domains. IRp60, KLRG1, and LAIR1 are other inhibitory receptors recently discovered (Table 1).

NK Cell and Cytokines

NK cells are capable of producing many cytokines including IFN-γ (►Interferon-*f* γ), IFN-α, IFN-β, and TNF-α. They suppress proliferation of tumor and virally infected cells and regulate immune responses. IFN-γ (Interferon-*f* γ) increases NK activity as a positive feedback mechanism. NK cytolytic activity is increased by IFN-α, IFN-β, and IFN-γ (Interferon-*f* γ) (produced by T and NK cells), IL-2\(produced by T cells), IL-10, IL-12, and IL-15 (produced by B cell, monocyte/macrophage, or dendritic cells). NK cytolytic activity is inhibited by IL-4 (►Interleukin-4). IL-15 induces

NK cell proliferation. IL-12 induces IFN-γ (Interferon-*f* γ) production by NK cells. IFN-α, IFN-β, IFN-γ (Interferon-*f* γ), and TNF-α produced by NK cells activate monocyte/macrophage, vascular endothelial cells, neutrophils, and induce a local inflammation response.

Cytotoxicity of NK Cells against Tumor or Infected Cells

NK cells release ►perforin from intracellular granules when they bind to target cells, along with granules containing serine proteases known as ►granzymes. Perforin attaches to the membrane inducing an autophagic (►Autophagy) repair process, inducing uptake of vesicles containing granzymes and associated molecules that can target cells for lysis, with perforin allowing escape through pore formation once intracellular. Granzyme induce apoptosis to the target cells utilizing various intracellular pathways. NK cells also induce ►apoptosis to target cells by expressing apoptosis inducing molecules such as FAS ligands or ►TRAIL on the cell surface. The distinction between apoptosis and ►necrosis is important in cancer immunology – necrotic cells release danger/damage associated molecular pattern molecules (DAMPs) such as high-mobility group box 1 (HMGB1) protein, whereas apoptosis leads to retention of HMGB1 within the cells or apoptotic nuclei.

NK Cells and Cancer Immunotherapy

Their rapid cytolytic action and broad target range suggest that NK cells may be promising candidates for cancer cell therapy. The clinical application of ex vivo manipulated cells, including NK cells, is referred to as ►adoptive immunotherapy (AIT). The first clinical AIT trial exploited autologous ex vivo expanded and interleukin 2 (IL-2) stimulated ►lymphokine activated killer (LAK). Although this approach produced nearly 15–20% partial and complete responses in initial trials, subsequent studies showed that a similar antitumor effect could be achieved with administration of high dose IL-2 alone. Purification and enrichment of NK cells on a clinical scale may improve therapeutic outcomes. Alternatively, stimulation of LAK cells with IL-15 or IL-21 instead of IL-2 might increase efficacy.

Myeloid ►dendritic cells (mDCs) support the tumoricidal activity of NK cells, while cytokine-preactivated NK cells activate DCs and induce their maturation and cytokine production. NK–DC interactions promote the subsequent induction of tumor-specific responses of CD4+ and CD8+ T cells, allowing NK cells to act as nominal "helper" cells in the development of the desirable type-1 responses to cancer. NK–DC interaction provides a strong rationale for the combined use of NK cells and DCs in the immunotherapy of patients with cancer. Clinical trials that are being

implemented at present should allow evaluation of the immunological and clinical efficacy of combined NK–DC therapy of melanoma and other cancers.

Acute Lymphoblastic Leukemia

Ching-Hon Pui
St. Jude Children's Research Hospital, Memphis, TN, USA

Synonyms

Acute lymphoblastic leukemia; ALL

Definition

Acute lymphoblastic leukemia (ALL) is a malignant disease that arises from several cooperative genetic mutations in a single B or T-lymphoid progenitor, leading to altered blast cell proliferation, survival, and maturation, and eventually to the lethal accumulation of leukemic cells. Although cases can be subclassified further according to the stages of T or B-cell maturation, these distinctions are not therapeutically useful, except for the recognition of a mature B-cell, B-cell precursor, or T-cell stage.

Characteristics

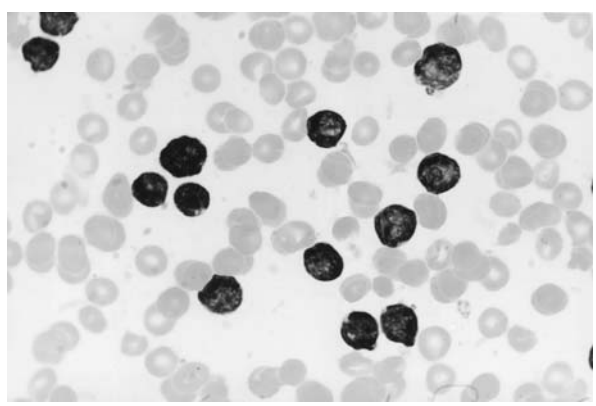
ALL accounts for about 12% of all childhood and adult leukemias diagnosed in developed countries and for 60% of those diagnosed in persons younger than 20 years. It is the most common cancer in children (25% of all cases) and has a peak incidence in patients between the ages of 2 and 5 years, with a second, smaller peak in the elderly.

The factors predisposing children and adults to ALL remain largely unknown. Fewer than 5% cases are associated with inherited genetic syndromes defined by chromosomal instability and defective DNA repair. Ionizing radiation and mutagenic chemicals have been implicated in some cases of ALL, but their contributions appear negligible. Nonetheless, evidence collected over the past two decades has revealed that ALL is essentially a disease of acquired genetic abnormalities. Specific genetic abnormalities are found in the leukemic cells of approximately 75% of patients with ALL to date, and in all likelihood, will be identified in all cases with the improved genetic techniques. These include chromosomal translocations and chromosomal gains or losses, resulting in ►hyperdiploidy or ►hypodiploidy, respectively. Chromosomal translocations often activate transcription factor genes, which in many cases control cell differentiation, are developmentally regulated, and frequently encode proteins at the tops of critical transcriptional cascades. These "master" oncogenic transcription factors, which can exert either positive or negative control over downstream responder genes, are aberrantly expressed in leukemic cells as a single gene product or as a unique fusion protein combining elements from two different transcription factors. Recently, activating mutations of ►*NOTCH1*, a gene encoding a transmembrane receptor that regulates normal T-cell development, and mutations of ►*PAX5*, a gene essential for B-lineage commitment and maintenance, have been identified to be most frequent cooperative mutations in T-cell and B-cell precursor ALL, respectively.

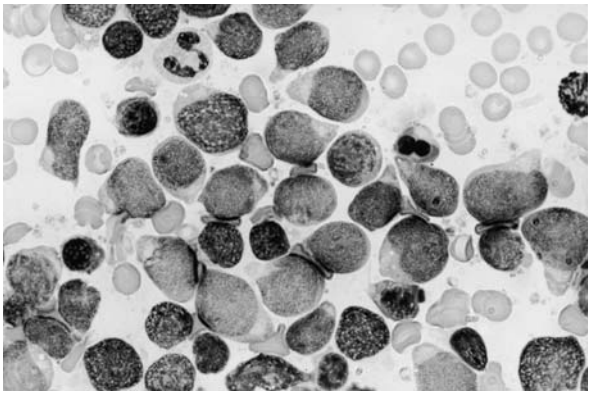
Although most leukemias begin in the bone marrow and spread to other parts of the body, some may arise in an ►extramedullary site, such as the thymus or intestine, and subsequently invade the bone marrow. The presenting features of ALL generally reflect the degree of bone marrow failure and the extent of extramedullary spread. Common signs and symptoms are

- Fever
- Fatigue and lethargy
- Dyspnea, angina, and dizziness (older patients mainly)
- Limp, bone pain, or refusal to walk (young children)
- Pallor and bleeding in the skin or mouth cavity
- Enlarged liver, spleen, and lymph nodes (more pronounced in children)
- Anemia, low neutrophil count, and low platelet count
- Metabolic abnormalities (e.g., high serum uric acid and phosphorus levels)

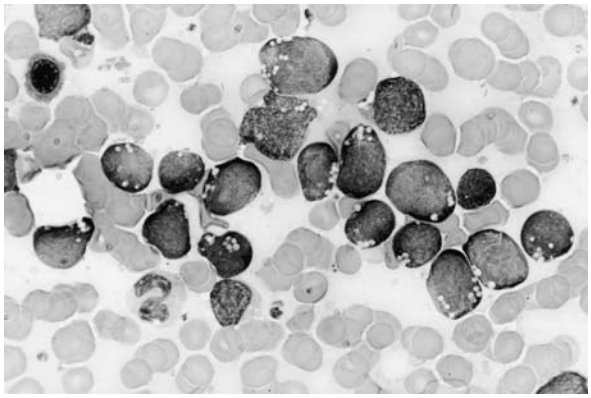
The diagnosis of ALL is based on a morphologic examination of bone marrow cells (Figs. 1–3) and immunophenotype of cells from the same sample.



Acute Lymphoblastic Leukemia. Figure 1 Small regular blasts with scanty cytoplasm, homogeneous nuclear chromatin, and inconspicuous nucleoli.



Acute Lymphoblastic Leukemia. Figure 2 Admixture of large blasts with moderate amounts of cytoplasm and smaller blasts. Such cases may be mistaken for acute myeloid leukemia, emphasizing the importance of immunophenotyping and genotyping to corroborate the differential diagnosis.



Acute Lymphoblastic Leukemia. Figure 3 Mature B-cell ALL blasts characterized by intensely basophilic cytoplasm, regular cellular features, prominent nucleoli, and cytoplasmic vacuolation.

Karyotyping, fluorescence in situ hybridization (FISH), and molecular genetic analysis by RT-PCR (reverse transcriptase-polymerase chain reaction) are now routinely performed by many centers to identify subtypes of ALL with prognostic and therapeutic significance, for example:

- *BCR-ABL* fusion gene due to the t(9;22), or ►Philadelphia chromosome – 25% of adult cases and 3–4% of childhood cases (dismal prognosis)
- ►*TEL-AML1* fusion gene due to a cryptic t(12;21) – 22% of childhood cases (favorable prognosis)
- Hyperdiploidy (more than 50 chromosomes per cell) – 25% of childhood cases (favorable prognosis)
- Hypodiploidy (fewer than 45 chromosomes per cell) – 1% of childhood cases and 2% of adult cases (unfavorable prognosis)

Contemporary risk-directed treatment can cure 80% or more of children and up to 40% of adults with ALL. Cases are generally classified as standard or high risk in adults and as low, standard, and high risk in children. Factors used to determine the relapse hazard include the presenting leukocyte count, age at diagnosis, gender, immunophenotype, ►karyotype, molecular genetic abnormalities, initial response to therapy, and the amount of "minimal residual leukemia" upon achieving a complete ►remission.

Multidrug remission induction regimens almost always include a glucocorticoid (prednisone, prednisolone, or dexamethasone), vincristine, and at least a third agent (L-asparaginase or anthracycline), administered for 4–6 weeks. Some treatments rely on additional agents to increase the level of cell kill, thereby reducing the likelihood of the development of drug resistance and subsequent relapse. However, several studies suggest that intensive remission induction therapy may not be necessary for low or standard-risk patients, provided that they receive postinduction intensification therapy. Remission induction rates now range from 97 to 99% in children and from 78 to 93% in adults. Complete clinical remission is traditionally defined as restoration of normal blood cell formation with a blast cell fraction of less than 5% by light microscopic examination of the bone marrow. With this definition, some patients in complete remission may harbor as many as 1×10^{10} leukemic cells in their body. With sensitive and specific methods developed to measure minimal residual disease, it is now recognized that most patients actually have less than 0.01% of residual leukemia after 4–6 weeks of remission induction therapy, and they have excellent treatment outcome. By contrast, patients with 1% or more leukemic cells after remission induction treatment have a poor prognosis and may be candidates for hematopoietic stem cell transplantation. To improve treatment outcome, most protocols specify an intensification (or consolidation) phase in which several effective antileukemic drugs are administered in high doses soon after the patients attain a complete remission. Reinduction treatment, essentially a repetition of the initial induction therapy administered during the first few months of remission, has become an integral component of successful ALL treatment protocol.

Regardless of the intensity of induction, consolidation or reinduction therapy, all children require 2–3 years of continuation treatment, usually methotrexate and mercaptopurine, with pulses of vincristine and dexamethasone for low-risk cases, and multiagent intensive chemotherapy for standard and high-risk cases. The need for continuation therapy in adults is less clear, although in most cases it is discontinued after 2–2½ years of complete remission. The central nervous system can be a ►sanctuary site for leukemic cells, requiring intensive,

intrathecally administered chemotherapy that begins early during the remission induction phase, extending through the consolidation phase and into the continuation phase. Once considered standard treatment, cranial irradiation is now reserved for less than 10% of patients who are at very high risk of relapse in the central nervous system.

For selected high-risk cases, such as patients with Philadelphia chromosome-positive ALL, and those who require extended therapy to attain initial complete remission, hematopoietic stem-cell transplantation is currently the treatment of choice. In light of the development of new therapeutics, the indications for transplantation should be continuously evaluated. For example, therapy with imatinib mesylate (Gleevec; Novartis) or second-generation tyrosine kinase inhibitors has improved the duration of remission of patients with Philadelphia chromosome-positive ALL, but whether this therapy will increase the cure rate remains to be determined. Finally, the optimal clinical management of patients with ALL requires careful attention to methods for the prevention or treatment of metabolic and infectious complications, which may otherwise be fatal.

Acute Megakaryoblastic Leukemia

Jean-Pierre Bourquin[1], Shai Izraeli[2]
[1]Pediatric Oncology, University Children's Hospital Zurich, Zurich, Switzerland
[2]Pediatric Hemato-Oncology, Sheba Medical Center and Tel Aviv University, Ramat Gan, Israel

Synonyms

Acute Myeloid Leukemia; Subtype AML-M7 according to the French-American-British (FAB) Classification; Myeloid Leukemia of Down Syndrome (DS-ML); WHO classification: Acute Megakaryoblastic Leukemia (M7)

Definition

Acute Megakaryoblastic Leukemia (AMKL) is defined as a malignant ►clonal proliferation of immature hematopoietic cells of the megakaryocytic lineage. AMKL is a subtype of Acute Myeloid Leukemia (AML). The biologic features of AMKL are heterogeneous and ongoing characterization of the disease pathogenesis is likely to lead to a novel clinically meaningful classification of the disease.

Characteristics

Epidemiology

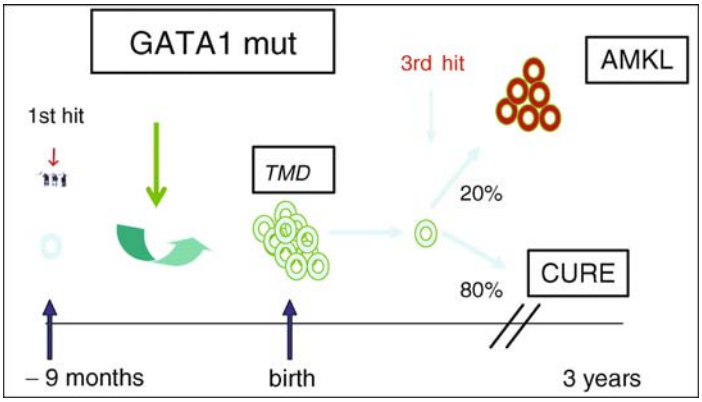
AMKL is diagnosed in 7–10% of infants and children with AML without Down syndrome (DS). In most pediatric cases the disease occurs de novo and subgroups can be identified based on cytogenetic features or biological features as described later. In contrast, AMKL is rare in adults, occurring in 1–2% of all AML cases and is frequently associated with antecedent hematological disorder such as myelodysplastic syndrome.

Children with DS have a markedly increased risk to developing AMKL and represent up to 10 % of children with AML. A large proportion of Children with DS (estimated 10%) are born with a unique transient form of AMKL, often called transient myeloproliferative disorder (TMD) or transient abnormal myelopoiesis (TAM). This congenital leukemia resolves spontaneously in most of the patients. Up to 20% of those patients will relapse with a full blown AMKL by the age of 4 years. Thus the leukemia of DS represents a unique clinical entity of multistep leukemogenesis (Fig. 1).

Clinical and pathologic features

Typical features at diagnosis include hepato-splenomegaly, anemia, thrombocytopenia and myelofibrosis. The fibrosis is probably caused by soluble factors (such as TGF-β) secreted from the malignant megakaryoblasts. Infants with DS may exhibit marked liver failure that sometimes may be life threatening. The liver failure is secondary to liver fibrosis caused by the infiltration of leukemic cells.

►Flow cytometry is the preferred method for ►immunophenotypic characterization of AMKL, although in some cases the diagnosis can only be made from bone marrow or liver biopsies due to extensive myelofibrosis. Typically, the leukemic blasts express at least one megakaryoblastic antigen [CD41(GPIIb)/CD42b(GPIbalpha) or CD61]. Coexpression of the T-lineage marker CD7 is frequently observed, suggesting pathogenic mechanism that could lead to aberrant regulation of lymphoid genes. Expression of erythroid markers (e.g. glycophorin A) and of CD36 (thrombospondine receptor) characterize the AMKL of DS. Because AMKL blasts may display low expression levels of the pan-hematopoietic CD45 antigen, the distinction from metastatic solid tumours may be challenging.



Acute Megakaryoblastic Leukemia. Figure 1 Multistep evolution of AMKL in Down Syndrome. Mutation in GATA1 is acquired during fetal liver hematopoiesis in cells carrying a germline trisomy 21 results in congenital clonal megakaryoblastic proliferation (TMD). In almost all patients TMD resolves spontaneously leading to cure. However in about 20% of the patients additional postnatal acquired mutations in residual cells from the resolved TMD results in the development of full blown acute megakaryocytic leukemia (AMKL) during early childhood.

Cytogenetic and Biological Features

Increasing evidence suggest that distinct subtypes of AMKL can be identified based on genetic and molecular characteristics. Recurrent cytogenetic abnormalities are specifically associated with AMKL and at least in part convey a prognostic significance.

The megakaryoblastic disorders associated with DS (both AMKL and TMD) are characterized by the presence of an acquired mutation in the ►transcription factor GATA1. The mutations occur in exon 2 or in the beginning of exon 3 and uniformly results in the production of a short GATA1 protein (GATA1s) that lacks the amino-terminal of the full length GATA1. GATA1 is a major regulator of normal megakaryopiesis. GATA1s blocks terminal differentiation and enhances proliferation of immature fetal megakaryoblasts. The mutations occur during ►fetal liver hematopoiesis. The initiation of the leukemia during fetal liver hematopoiesis explains the frequent liver dysfunction observed in DS newborns with TMD. Strikingly, GATA1 is located on chromosome X and is mutated only in AMKL with trisomy 21. The precise mechanism by which trisomy 21 promotes the survival of cells with acquired mutation in GATA1 is presently unknown. One hypothesis suggests that genes on chromosome 21 code proteins that enhance fetal megakaryopoiesis. This developmental pressure of megakaryopoiesis coupled with differentiation arresting mutation in GATA1 cause clonal accumulation of megakaryoblasts diagnosed at birth as TMD. GATA1 mutation is necessary and probably sufficient for the development TMD, but additional mutations are required for the occurrence of full blown AMKL in DS patients. Why TMD spontaneously resolves and which mutations cause further evolution to AMKL is largely unknown.

There are several biological subgroups among patients with AMKL that do not have DS. The most frequent recurrent chromosomal aberration detected in non-DS AMKL is the translocation t(1;22), which typically occurs in infants and very young children that present with hepatosplenomegaly and pronounced myelofibrosis. This translocation fuses RBM15/OTT1, an RNA export factor to MKL1/MAL1, a cofactor of the transcription factor SRF (Serum Response Factor). Less commonly fusion translocations between the MLL gene and different partners, often AF10, have been reported in AMKL. Interestingly, a second translocation involving AF10, the translocation t(10;11) which results in the fusion of CALM (clathrin-assembly protein-like lymphoid myeloid) with AF10 was reported in several cases. This translocation was also identified in other AML subtypes and in cases of T-cell ALL. In a mouse model, infection of bone marrow cells with a retroviral vector to express CALM-AF10 results in a transplantable AML, demonstrating that this fusion gene represents a fundamental leukemogenic event.

By ►gene expression profiling, at least two distinct classes of non-DS AMKL could be discriminated based on their molecular phenotype. Approximately one third of the cases display an erythroid expression pattern coupled with expression of CD36 and higher expression levels of the transcription factor GATA1 in absence of detectable mutations. Interestingly this gene expression signature is reminiscent to the increased expression of erythroid markers detected in AMKL from DS patients, which are characterized by increased expression levels of mutated GATA1s. The second subtype of non-DS AMKL samples include all cases with recurrent translocation t(1;22). Interestingly, samples that share similar expression profiles with the samples positive for the translocation t(1;22) are characterized by increased expression levels of another SRF cofactor, HOP,

suggesting that similar regulatory pathways may be involved. This second class is associated with higher levels of expression of the surface antigen CD44, which was associated with worse outcome in other type of malignancies and coexpressed on the leukemia initiating cells from patients with AML. It is currently not possible to determine if the distinction of these two classes by expression profiling has a prognostic significance due to the small numbers of patients that were treated on different therapeutic protocols. A prospective study using selected genes from the AMKL signature will be required to determine if this information could be used as prognostic marker to guide selection of treatment intensity.

Prognosis and Treatment

Treatment results from several international study groups, including the European AML-BFM study group and UK-MRC cooperative groups, and the north american SJCRH and CCG cooperative groups show a marked difference in treatment outcome between DS and non-DS AMKL. Reduction of treatment intensity for patients with DS resulted in a marked decrease in treatment related mortality and an excellent treatment outcome (91% event free survival at 5 years in the AML-BFM 98 study), strongly suggesting a distinct leukemia biology between DS and non-DS AMKL patients. AMKL blasts from patients with DS are extremely sensitive to the chemotherapy drug Cytosine Arabinoside (ARA-C), probably due to a decrease in its cellular degradation caused by an enzyme regulated by GATA1.

The results for patients with AMKL excluding patients with DS are still poor, despite of intensification of AML treatment regimens. The 5–year event free survival (EFS) reported for the most recent treatment regimen correspond to results obtained for other AML subtypes, with EFS of 42% reported for the AML-BFM93/98 trials and of 47% reported by the UK-MRC 10 and 12 trials. Further research is necessary to identify new treatment modalities and biomarkers to guide treatment intensification, including the indication for bone marrow transplantation for patients at highest risk of relapse. Recent data in mouse models suggest that targeted therapy with antibodies directed against the surface marker CD44 may be a future therapeutic.

Definition

Acute myeloid leukemia (AML) is part of a group of hematological malignancies (►hematological malignancies) in the bone marrow involving cells committed to the ►myeloid line of cellular development. It is defined by the malignant transformation of a bone marrow-derived, self-renewing stem cell or progenitor (►stem cells and cancer) which demonstrates a decreased rate of self-destruction and aberrant ►differentiation. Uncontrolled growth of such cells, named blasts, is the result of ►clonal proliferation. Blasts accumulate in the bone marrow and other organs. As a result, mature cells of ►hematopoiesis are suppressed. For the leukemia to be called acute, the bone marrow must include greater than 20% leukemic blasts.

Characteristics

Classification

The first comprehensive morphologic-histochemical classification system for AML was developed by the French-American-British (FAB) Cooperative Group. This classification system categorizes AML into eight major subtypes (M0 to M7) based on morphology and

immunohistochemical detection of lineage markers. This classification of AML was recently revised under the auspices of the World Health Organization (WHO) (see list 1). While elements of the older FAB classification were preserved, the WHO classification incorporates and interrelates morphology, cytogenetics, molecular genetics, immunologic markers, and clinical features in an attempt to define categories that are biologically homogeneous and that have prognostic and therapeutic relevance.

The most significant difference between the WHO and FAB classifications is that the minimum blast percentage for the diagnosis of AML is at least 20% blasts in the blood or bone marrow (the FAB scheme required the blast percentage to be at least 30%). What was known as "refractory anemia with excess blasts in transformation" (RAEB-t) of myelodysplastic syndromes (►MDS), is now included within the broader category of "AML with multilineage dysplasia" as "AML with multilineage dysplasia following a MDS."

List 1 – WHO classification of AML (the older FAB classifications are given in parentheses where appropriate):

- AML with characteristic genetic abnormalities
  - AML with t(8;21)(q22;q22); (AML/ETO)
  - AML with inv(16)(p13q22) or t(16;16)(p13; q22); (CBFβ/MYH11)
  - Acute promyelocytic leukemia (AML with t(15;17)(q22;q12); (PML/RARα) and variants)
  - AML with 11q23 (MLL) abnormalities
- AML with multilineage dysplasia
  - AML with prior MDS
  - AML without prior MDS
- AML and MDS, therapy-related
  - Alkylating agent-related AML and MDS
  - Topoisomerase II inhibitor-related AML
- AML not otherwise categorized
  - Acute myeloblastic leukemia, minimally differentiated (FAB M0)
  - Acute myeloblastic leukemia without maturation (FAB M1)
  - Acute myeloblastic leukemia with maturation (FAB M2)
  - Acute myelomonocytic leukemia (AMML) (FAB M4)
  - Acute monoblastic leukemia and acute monocytic leukemia (FAB M5a and M5b)
  - Acute erythroid leukemias (FAB M6a and M6b)
  - Acute megakaryoblastic leukemia (FAB M7)
  - AML/transient myeloproliferative disorder in Down syndrome
  - Acute basophilic leukemia
  - Acute panmyelosis with myelofibrosis
  - Myeloid sarcoma
- Acute leukemias of ambiguous lineage

Epidemiology

AML is infrequent but highly malignant, responsible for a large number of cancer-related deaths. AML accounts for approximately 25% of all leukemias in adults in industrialized countries and, thus, is the most frequent form of leukemia. Worldwide, the incidence of AML is highest in the United States, Australia, and Western Europe.

The age-adjusted incidence rate of AML in the United States in the years 1975–2003 has been relatively stable at approximately 3.4 per 100,000 persons (=2.5 per 100,000 when age-adjusted to the world standard population). The American Cancer Society estimates that 11,930 individuals will be diagnosed with AML in 2006 in the United States. Patients that are newly diagnosed with AML have a median age of 65 years. From 2000 to 2003, the U.S. incidence rate in people under the age of 65 was only 1.8 per 100,000, while the incidence rate in people aged 65 or over was 17 per 100,000 (Fig. 1). AML is thus primarily a disease of later adulthood with an age-dependent mortality of 2.7 to nearly 18 per 100,000. The incidence of AML varies to a small degree depending on gender and race. AML in adults is slightly more prevalent in males in most countries. In the US in 2000, AML was more common in Whites with 3.8 per 100,000 than in Blacks (3.2 per 100,000).

	Anthracyclines
	Taxanes

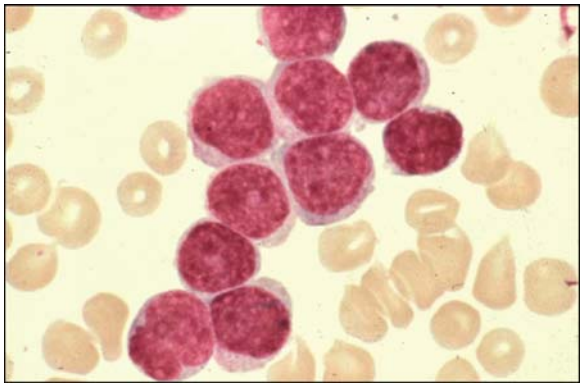
Etiology

The development of AML has been associated with several risk factors summarized in Table 1.

Generally, only a small number of observed cases can be traced back to known risk factors. These include age, antecedent hematological disease, genetic disorders as well as exposures to radiation, chemical or other hazardous substances (e.g., benzene), and previous chemotherapy (e.g., treatment with ►alkylating agents). Leukemogenesis, like ►carcinogenesis is a multistep process that requires the susceptibility of a hematopoietic progenitor cell to inductive agents at multiple stages. The different subtypes of AML may have distinct causal mechanisms, suggesting a functional link between a particular molecular abnormality or mutation and the causal agent. Most cases of AML arise without objectifiable leukemogenic exposure.

Signs and Symptoms of AML

AML can cause different uncharacteristic signs and symptoms such as weight loss, unusual fatigue, and fever. Many patients feel a loss of well-being. Most symptoms can be traced back to bone marrow insufficiency: Anemia, immunodeficiency caused by neutropenia, and thrombocytopenia. Diagnostic procedures and types of specimen necessary to reach the diagnosis of AML are the following:



Acute Myeloid Leukemia. Figure 2 Myeloid blasts in peripheral blood detected by light microscopy.

- Blood cell counts and microscopic blood cell examination (Fig. 2)
- Bone marrow aspiration and biopsy
- Routine microscopic exam of bone marrow
- Flow cytometry
- Immunocytochemistry
- Cytogenetics
- Molecular genetic studies

The peripheral blood count may reveal a decreased white blood cell count (leukopenia) as well as leukocytosis (increased white blood cell count). Leukemia cells do not protect against infection and may cause congestion of blood vessels (leukostasis). Thrombocytopenia, a decrease of platelets, can lead to excessive bruising, ►petechiae, and bleeding. When leukemia cells spread outside the bone marrow, it is called extramedullary manifestation. Small pigmented spots that look like common rashes may indicate skin involvement. A tumor-like collection of AML cells is called chloroma or granulocytic sarcoma. AML sometimes causes enlargement of the liver and spleen.

Prognostic Factors

AML is a curable disease; the chance of cure for a specific patient depends on a number of prognostic factors. Some of the strongest prognostic information can be obtained by ►cytogenetic analysis. Normal cytogenetics indicates average-risk AML. Cytogenetic abnormalities that suggest a good prognosis include translocations t(8;21) and t(15;17), as well as inv(16). Patients with AML that is characterized by deletions of the long arms or monosomies of chromosomes 5 or 7; by translocations or inversions of chromosome 3, t(6;9), t(9;22); or by abnormalities of chromosome 11q23 have particularly poor prognoses.

Further adverse prognostic factors include central nervous system involvement with leukemia, elevated

white blood cell count (>100,000/mm^3), treatment-induced AML, and a history of MDS. Leukemias in which cells express the progenitor cell antigen CD34 and/or the P-glycoprotein (MDR1 gene product) have an inferior outcome. Due to a higher relapse rate, patients with AML associated with an internal tandem duplication of the FLT3 gene (FLT3/ITD mutation) have a poorer outcome.

Beyond these disease-specific factors, patient-specific parameters like comorbidities and frailty have a strong impact on the course of the disease and treatment tolerability, as reflected by the age-dependent surge in mortality.

Therapy

Therapeutic approaches can be differentiated as curative (aimed at long-term cure) or palliative (principally aimed at achieving best quality of life) (►palliative therapy).

Curative intensive chemotherapeutic treatment (►chemotherapy of cancer, progress and perspectives) for AML is considered the standard procedure, usually divided in two phases, induction and consolidation (post-remission) therapy. It is traditionally based on two substances, cytarabine (cytosine arabinoside) and anthracycline. The objective of a curative treatment approach is to rapidly eliminate the cancer cells with induction chemotherapy, called remission. Complete remission occurs in 60–80% of patients. More than 15% of adults with AML (about 25% of those who attain complete remission) can be expected to survive 3 or more years and may be cured. Remission rates in adult AML are inversely related to age, with an expected remission rate of >65% for those younger than 60 years. Duration of remission may be shorter in older patients. Increased morbidity and mortality during induction appear to be directly related to age. This is associated with several factors including the ability to tolerate intensive treatment approaches. Without treatment, the average life expectancy is about 3 months. Complications during treatment include relapse of the disease, severe infections, or life-threatening bleeding. During this time, supportive care consists of patient isolation to prevent infection, antibiotics to treat infections, and transfusion of blood products. After remission is achieved, further treatment is known as consolidation and is necessary in order to achieve a permanent cure. Consolidation may consist of either further chemotherapy or a bone marrow, or stem cell transplantation. The aforementioned treatments are appropriate for all subtypes of AML except for one type of AML known as ►acute promyelocytic leukemia (APL).

Newer treatments, especially for those patients not tolerating intensive chemotherapy, include monoclonal antibodies, demethylating agents, and experimental drugs given in clinical trials. Thus, while the diagnosis of AML in itself does not represent a therapeutic mandate for intensive chemotherapy in all cases, the latter is the only curative approach to treatment. Decisions whether to treat patients with intensive chemotherapy, new agents, or solely best ►supportive care should be based on a sum of patient factors (including age, previous history of MDS, ►comorbidity, frailty, and patients' preferences), in addition to the blast count and the above-described prognostic factors. Careful consideration of these factors is especially relevant in older, multimorbid patients with AML.

Definition

Acute promyelocytic leukemia (APL) is a distinct subtype of ►acute myeloid leukemia (AML) characterized by the expansion of leukemic cells blocked at the promyelocytic stage of myelopoiesis. According to the French–American–British (FAB) classification of acute leukemia, APL corresponds to the M3 and M3-variant subtypes, and according to World Health Organization classification (2001) it corresponds to the subtype: AML associated with translocations involving chromosomes 15 and 17 [t(15;17)] and variants. APL accounts for 5–10% of adult AML patients in Caucasian populations and for 20–30% among patients with Latino ancestry. Invariably, APL leukemic cells harbor ►chromosomal translocations involving the *retinoic acid receptor α* (*RARα*) gene on chromosome 17 (Table 1), which may be fused to one of five possible partner genes: *promyelocytic leukemia* (*PML*), *promyelocytic leukemia zinc finger* (*PLZF*), *nucleophosmin* (*NPM*), *nuclear mitotic apparatus* (*NuMA*), and *signal transducer and activator of transcription 5B* (*STAT5b*). This leads to the generation of fusion genes encoding distinct fusion proteins. The sensitivity of APL to the differentiating action of all-trans retinoic acid (ATRA) is differentially mediated by the various fusion proteins (see Molecular Characterization).

Characteristics

Clinical and Laboratorial Presentation

The symptoms of APL are similar to those of other subtypes of AML such as weight loss, fatigue, weakness, pallor, fever, and bleeding. These symptoms manifest acutely and are accompanied by petechiae, bruising, oral bleeding, or epistaxis as well as symptoms and signs related to specific bacterial infections. Patients with APL are particularly susceptible to disseminated intravascular coagulation (DIC) and extensive bleeding is common at onset. The most common sites of clinically overt extramedullary leukemic infiltration include superficial lymphonodes, liver, and spleen. The leukocyte counts are usually lower than those observed in other AML subtypes and the differential counts reveal a variable percentage of blasts in the majority of patients. In most cases, anemia and thrombocytopenia are present at diagnosis. Abnormal promyelocytes constitute more than 20% of marrow-nucleated cells or more than 20% of leukocytes in peripheral blood. Leukemic blasts are morphologically characterized by the presence of distinctive large cytoplasmic granules, frequent multiple Auer rods, and a folded nucleus. The hypogranular variant (M3-variant) is characterized by the expansion of blasts containing large number of small granules that may be difficult to distinguish by light microscopy, and may be wrongly classified as monoblasts. However, both in the classical and variant M3 subtypes the cells are strongly positive for myeloperoxidase staining. A more rare hyperbasophilic variant has been described.

The diagnosis is usually suspected upon the morphological examination of bone marrow and peripheral blood smears. The immunophenotypic profile suggestive of APL is composed by heterogenous intensity of expression of the CD13 surface marker associated with a homogenous expression of CD33; HLA-DR is negative in the majority of cases, and the expression of CD15 and CD34 is mutually exclusive and usually dim. The genetic confirmation of gene rearrangements involving the RARα locus is mandatory and can be done by classical cytogenetics, FISH, or RT-PCR. The

Acute Promyelocytic Leukemia. Table 1 Molecular genetics of acute promyelocytic leukemia

Translocation	Fusion proteins		Response to RA
t(15;17)	PML–RARα	RARα–PML	Good
t(11;17)	PLZF–RARα	RARα–PLZF	Poor
t(5;17)	NPM–RARα	RARα–NPM	Good
t(11;17)	NuMA–RARα	RARα–NuMA?	Good
t(17;17)	STAT5b–RARα	RARα–STAT5b?	Poor?

pattern of immunofluorescence staining using an anti-PML antibody is also useful for a rapid diagnosis of APL. In APL cells a nuclear microspeckled pattern is observed in contrast to other subtypes of AML in which larger and less numerous dots (nuclear bodies) are evident.

DIC occurs in 75% of M3 patients accompanied by secondary fibrinolysis. The cause of coagulopathy is complex, resulting from a combination of tissue factors and cancer procoagulant-induced activation of the coagulation, exaggerated fibrinolysis due predominantly to enhanced expression of annexin II on APL blasts, and blast cell production of cytokines. Laboratory evidence of DIC (prolonged prothrombine time and partial thromboplastin time, decreased fibrinogen and increased fibrin degradation products) should be examined in all APL patients.

Molecular Characterization

APL has been well characterized at the molecular level and has become one of the most compelling examples of aberrant transcriptional regulation in cancer pathogenesis. Due to reciprocal translocations, the *RARα* gene on chromosome 17 is fused to one of five distinct partner genes (for brevity, hereafter referred as *X* genes; Table 1). In the vast majority of cases, *RARα* fuses to the *PML* gene (originally named *myl*) on chromosome 15. In a few cases *RARα* fuses to the *PLZF* gene, to the *NPM* gene, to the *NuMA* gene, or to the *STAT 5B* gene located on chromosomes 11, 5, 11, or 17, respectively. The various translocations result in the generation of *X–RARα* and *RARα–X* fusion genes and the coexpression of their chimeric products in the leukemic blasts. The characterization of the genetic events of APL, and the availability of techniques such as FISH and RT-PCR, render it possible to confirm the diagnosis at the molecular level and to monitor minimal residual disease. RARα is a member of the superfamily of nuclear receptors, which acts as a retinoic acid (RA)-dependent transcriptional activator in its heterodimeric form with retinoid-X-receptors (RXR). In the absence of RA, RAR/RXR heterodimers can repress transcription through histone deacetylation by recruiting nuclear receptor corepressors (SMRT), Sin3A, or Sin3B, which in turn, form complexes with histone deacetylases (HDAC) resulting in nucleosome assembly and transcription repression. PML–RARα represses transcription not only through HDAC, but also via interactions with DNA methyltransferases (DNMTs) leading to hypermethylation at target promoters. The epigenetic changes induced by PML–RARα are stable and maintained throughout cell divisions. ATRA causes the disassociation of the corepressor complex and the recruitment of transcriptional coactivators to the RAR/RXR complex. This is thought to result in terminal differentiation and growth arrest of various types of cells, including normal myeloid hematopoietic cells. The X–RARα fusion proteins function as aberrant transcriptional repressors, at least in part, through their ability to form repressive complexes with corepressors such as NCoR and HDACs. PLZF–RARα can also form, via its PLZF moiety, corepressor complexes that are less sensitive to RA than the PML–RARα corepressor complexes, thus justifying the poorer response to RA-treatment observed in these patients (see also Therapeutics). The X–RARα oncoproteins retain most of the functional domains of their parental proteins and can heterodimerize with X proteins, thus potentially acting as double-dominant-negative oncogenic products on both X and RAR/RXR regulated pathways.

Recently, it has been demonstrated that APL blasts present a marked defect in TGF-β signaling including Smad2/3 phosphorylation and nuclear translocation, which is similar to that in Pml null primary cells. Remarkably, RA-treatment, which induces PML–RARα degradation, resensitizes the cells to TGF-β. It is plausible that PML–RARα may inhibit TGF-β signaling through direct inhibition of the interaction between Smad3 and the cytoplasmic form of PML (cPML).

Modeling APL in Mice

The transgenic approach in mice has been used successfully in modeling APL and in generating faithful mouse models harboring various APL fusion genes. In vivo, transgenic mice (TM) harboring X–RARα oncoproteins develop leukemia after a long latency suggesting that the fusion proteins are necessary, but not sufficient to cause full-blown APL. In the PML–RARα TM model, mice develop a form of leukemia that closely resembles human APL, presenting blasts with promyelocytic features that are sensitive to the differentiating action of RA. A similar phenotype was observed in NuMA–RARα TM, in which leukemia was also preceded by a period of latency, but displayed a higher penetrance. On the contrary, the leukemia developed by the PLZF–RARα TM lacked the distinctive differentiation block at the promyelocytic stage, morphologically resembling more a chronic myeloid leukemia (CML) type of disease, while NPM–RARα TM developed myelomonocytic leukemia. This analysis demonstrated that the X–RARα fusion protein plays a critical role in determining leukemic phenotype as well. Moreover, it is the X moiety of the X–RARα product to determine sensitivity to ATRA, since leukemia in PML–RARα, but not in the PLZF–RARα TM, is responsive to ATRA treatment. Modeling APL in TM contributed to the understanding of the important role of the reciprocal RARα–X fusion proteins. RARα–PML

and RARα–PLZF TM do not develop overt leukemia. However, the coexpression of RARα–PML with PML–RARα increases the penetrance and the onset of leukemia development in double mutants. Strikingly, in the PLZF–RARα TM model, the coexpression of RARα–PLZF with PLZF–RARα metamorphoses the "CML-like" leukemia in PLZF–RARα TM to a leukemia with classical APL features. In addition, RARα–PLZF renders the leukemic blasts even more unresponsive to the differentiating activity of RA. At the transcriptional level, RARα–PLZF acts as an aberrant transcription factor that can interfere with the repressive ability of PLZF. Therefore, RARα–X and X–RARα fusion products act in combination to dictate the distinctive phenotypic characteristics of each APL subtype disease. Modeling of APL in the mouse is thus allowing a better comprehension of the molecular mechanisms underlying the pathogenesis of APL as well as the development of novel therapeutic strategies.

Therapeutics

The exquisite sensitivity of APL blasts to the differentiating action of RA makes APL a paradigm for therapeutic approaches utilizing differentiating agents. This therapeutic approach conceptually differs from the treatments involving drug and/or irradiation therapies, because instead of eradicating the neoplastic cells by killing them, it reprograms these cells to differentiate normally. The utilization of ATRA in APL patient management has reduced early death from DIC-related complications and dramatically improved the prognosis. However, treatment with ATRA alone in APL patients induces disease remission transiently and relapse is inevitable if remission is not consolidated with chemotherapy. Most contemporary therapy protocols incorporate an anthracycline (e.g., dauno or idarubicin) with ATRA during induction, followed by consolidation therapy with ATRA, anthracyclines and cytarabine, followed by maintenance therapy. Leukocyte and platelet counts at diagnosis are frequently used as risk factors for relapse: patients presenting with more than 10,000 leukocytes/μl have high risk in contrast with those with less than 10,000/μl and platelet counts higher than 40,000/μl. In the majority of cases, relapse is accompanied by RA resistance. Unlike t(15;17)/PML–RARα APL, t(11;17)/PLZF–RARα leukemias show a distinctly worse prognosis with poor response to chemotherapy and little or no response to treatment with RA, thus defining a new APL syndrome.

Up to 50% of patients treated with ATRA alone develop an "ATRA syndrome" characterized by a rapid rise in circulating polymorphonuclear leucocytes and associated with weight gain, fever, occasional renal failure, and cardiopulmonary failure, which may be life threatening in some patients. The combination of ATRA and chemotherapy in the induction and consolidation treatment phases has been proven to be an effective strategy to prevent "ATRA syndrome" and achieve long-term disease-free survival.

Arsenic trioxide (As_2O_3), a chemical used in Chinese medicine, is also extremely effective in the treatment of APL. About 90% of APL patients treated with As_2O_3 alone achieve complete remission, especially in relapsed patients who are resistant to RA and/or conventional chemotherapy. RA triggers blast differentiation while As_2O_3 induces both apoptosis and partial differentiation of the leukemic blasts. Utilizing PML–RARα and PLZF–RARα transgenic mouse models of APL, it has been demonstrated that the association of RA and As_2O_3 is effective in the former but not in the latter.

Considering the importance of HDAC-mediated transcriptional repression in APL pathogenesis, the utilization of histone deacetylase inhibitors (HDACIs) such as suberanilohydroxamic acid (SAHA) or sodium phenylbutyrate (SPB) in combination with RA may represent a promising experimental therapeutic approach. Preclinical studies in transgenic mouse models of APL suggest that in fact HDACIs work as growth inhibitors and inducers of apoptosis, and that these effects are potentiated by RA.

TACE; Tumor necrosis factor-alpha converting enzyme; CD156b antigen

Definition

ADAM17 is a zinc-dependent ►metalloprotease belonging to the ►ADAM (A disintegrin and metalloproteinase) family of type I transmembrane proteins. ADAM17 is involved in the ectodomain shedding of a wide variety of membrane-bound ligands and cytokines that are implicated in diverse biological processes including growth and ►inflammation.

Characteristics

Structure

The 50 kb ADAM17 gene, which is located at chromosome 2p25, consists of 19 exons and encodes an 824 amino acid protein. ADAM17 is synthesized as an inactive precursor protein consisting of five domains: the

pro-, metalloprotease, cysteine-rich, transmembrane and cytoplasmic domains. Prior to ADAM17 maturation, a conserved cysteine residue within the pro-domain interacts with the active site zinc atom maintaining the enzyme biologically inert. The active site of the metalloprotease domain contains a histidine consensus sequence (HExxHxxGxxH) that coordinates zinc atoms and water required for the enzymatic processing of ADAM17 substrates. Removal of the pro-domain occurs through a ►furin cleavage site (RVKR), by an unidentified furin or proprotein convertase, enabling the active site zinc to interact with the required histidine residues and to generate the active protease.

While the structural and functional aspects of the pro- and metalloprotease domains have been studied extensively and are well defined, the precise functions of the remaining ADAM17 domains are still somewhat obscure. The cysteine-rich domain consists of two subdomains: the disintegrin and EGF-like domains. A role in cellular ►adhesion has been proposed for the disintegrin domain. In support of this hypothesis, ADAM17 has been shown to interact with at least one ►integrin (α5β1) and modulate cell migration as a result of this interaction. It has also been demonstrated that the cysteine-rich domain is indispensable for the ectodomain shedding of select ADAM17 substrates and thus, might function in substrate recognition through the recruitment of accessory proteins or direct contact with the substrates themselves. The transmembrane domain tethers mature ADAM17 in the cell membrane where it exerts most of its physiological functions. Finally, the cytoplasmic domain comprises several ►Src homology 2 (SH2) and 3 (SH3) domain binding sites as well as phosphorylation sites, and is likely involved in regulatory ►signal transduction pathways.

Expression and Regulation

ADAM17 mRNA is ubiquitously expressed in most adult tissues, albeit at lower levels than those observed in fetal tissues at various stages of development. The ADAM17 zymogen is synthesized in the rough endoplasmic reticulum and is processed in the late Golgi compartment to produce the mature protease lacking the inhibitory pro-domain. This maturation step seems to entail a constitutive process as the majority of cellular ADAM17 exists in its mature form. The greater part of ADAM17 protein is localized in the perinuclear area while the remaining fraction resides at the cell surface, as expected. Notably, it appears that the membrane-bound ADAM17 population is exclusively in the processed form. This surface pool of ADAM17 is relatively stable with a half-life of ~8 h.

The mechanism by which ADAM17 function is regulated is not entirely clear, however, two methods by which the protease can be activated have been described. The first method involves the activation of ADAM17 by growth factors, such as the ►fibroblast growth factor (FGF) and the ►platelet-derived growth factor (PDGF). ADAM17-mediated ligand shedding can also be induced by non-physiological stimuli such as phorbol esters (►Phorbol myristate acetate). Treatment of cells with phorbol esters, such as ►PMA, results in increased ligand shedding without affecting the quantity or localization of endogenous ADAM17 in the cell. There is conflicting evidence with respect to the mechanism by which this stimulation occurs. One study demonstrated that PMA exerts its effects by activating the ►extracellular signal-regulated kinase (ERK) signaling pathway, which results in the phosphorylation of ADAM17 at Thr735 in its cytoplasmic tail, while another group showed that the cytoplasmic tail of ADAM17 is not required for PMA-induced ligand shedding. Although there is no evidence that phorbol esters regulate ADAM17 activity *in vivo*, the ►ERK signaling pathway has also been implicated in growth factor stimulated ADAM17 activation. For this reason, the ERK signaling pathway will likely be the focus of future studies aimed at delineating the mechanisms involved in the positive regulation of ADAM17 activity.

In addition to stimulating ADAM17-mediated ligand cleavage, the treatment of cells with PMA also triggers the establishment of a negative feedback mechanism. Following an increase in ADAM17 activity and ligand shedding, the protease itself is internalized and degraded in response to prolonged treatment with PMA. This negative regulatory mechanism is probably in place to prevent over-stimulation of ligand-activated signaling pathways. In attempt to identify potential regulators of ADAM17 activity, two ADAM17 binding partners were uncovered by yeast two-hybrid screens: synapse associated protein 97 (SAP97) and protein tyrosine phosphatase PTPH1. Overexpression of either molecule results in decreased ligand shedding implicating them in the negative regulation of ADAM17 activity. Whether either of these two proteins regulates ADAM17 activity *in vivo* remains to be seen. The only known endogenous inhibitor of ADAM17 is the tissue metalloprotease inhibitor, TIMP3. The mechanism by which TIMP3 expression results in reduced ADAM17 activity is unknown.

Biological Function

ADAM17 was initially identified as the secretase responsible for the cleavage of tumor necrosis factor-alpha (TNFα), a pro-inflammatory cytokine. The generation of transgenic mice expressing ADAM17 lacking the zinc-binding sequence in its metalloprotease domain ($ADAM17^{\Delta Zn/\Delta Zn}$) allowed for the identification of a multitude of additional ADAM17 substrates. The vast majority of the $ADAM17^{\Delta Zn/\Delta Zn}$ mice die at birth as a result of severe deficiencies in skin, muscle, lung and

neuronal system development that cannot be entirely attributed to loss of TNFα shedding. This indicates the existence of other biologically relevant ADAM17 substrates. Interestingly, the few animals that do survive display a phenotype that is comparable to that of ►transforming growth factor alpha (TGFα) or ►epidermal growth factor receptor (EGFR) knockout mice. This includes the failure of eyelids to fuse as well as defects in skin and hair follicle development. Upon further investigation it was confirmed that ►TGFα, an ►EGFR ligand, is in fact an ADAM17 substrate. Moreover, ADAM17 appears to be the major convertase of several ►EGFR ligands which are involved in a variety of cellular processes including cellular proliferation, survival, migration, and differentiation. The bulk of ADAM17 substrates, including the EGFR ligands, are involved in cell development and differentiation. Other examples include the neurogenic signaling molecule ►Notch, the neurotrophin receptor TrkA, and the EGFR-family receptor HER4. The remaining substrates can be classified as those involved in cellular immunity and regulation of immunogenic responses, like TNFα. These substrates include the TNF receptors (TNF-RI and TNF-RII), the chemokine fractalkine, and the leukocyte adhesion molecule L-selectin to name a few. While many ADAM17 substrates have been identified to date, there is no obvious sequence or structural homology between their cleavage sites. How ADAM17 achieves substrate specificity is a key question that remains to be answered. Nonetheless, it is evident that ADAM17 substrates play an important role in a broad range of fundamental cellular processes.

Clinical Relevance

Due to its involvement in TNFα processing, ADAM17 is considered to be a central mediator in human inflammatory diseases such as rheumatoid arthritis. Direct inhibition of TNFα or ADAM17 in arthritis-affected cartilage has been shown to reduce inflammation. For these reasons ADAM17-based therapies, such as zinc-chelating sulfonamide hydroxamates, are in use for the treatment of such diseases.

In addition to its role in inflammatory diseases, ADAM17 is becoming increasingly implicated in the development and progression of cancer as a result of its role in the processing of EGFR ligands. The upregulation of EGFR expression and signaling is a common feature in human cancer. Unfortunately, ►EGFR inhibitors have rendered disappointing results in ►clinical trials and there is an apparent resistance of several cancer cell lines to these agents. Importantly, ADAM17 is also overexpressed in several neoplastic tissues including ►breast carcinomas, ►colon carcinomas, pancreatic ductal adenocarcinomas, and ►ovarian carcinomas. There is also a positive correlation between ADAM17 expression and the aggressiveness of the malignancy. Thus ADAM17 is most highly expressed in advanced tumors, suggesting that ADAM17 and its substrates play a role in tumor progression.

In accordance with these observations, there is a growing amount of evidence supporting the use of anti-ADAM17 drugs in the treatment of cancer. Several studies have shown that inhibition of ADAM17 activity using a variety of approaches is sufficient to inhibit EGFR ligand release and to prevent the proliferation, migration, and survival of squamous cell, ►kidney cancer, ►bladder cancer and ►breast cancer cell lines *in vitro*. It was recently demonstrated that ►siRNA-mediated silencing of ADAM17 inhibits the release of soluble TGFα in highly malignant ►renal carcinoma cells, thereby abolishing their ability to form tumors in nude mice. This was the first *in vivo* evidence that ADAM17-mediated ligand cleavage is a pivotal step in the establishment of the TGFα/EGFR autocrine ►(Autocrine signaling) growth stimulatory loop and thus in tumorigenesis. Another study revealed that targeting ADAM17, using a ►small molecule inhibitor, prevents ►heregulin cleavage and hence ►HER3 activation in non-small cell lung cancer cells. Not only did this inhibition abolish tumor growth *in vivo* but it also enhanced the sensitivity of the cancer cells to gefitinib, an anti-EGFR based therapy. This result suggests that the concomitant inhibition of ADAM17 and EGFR should improve patient responsiveness to such agents and increase survival. Thus targeting ADAM17 is a promising new alternative to traditional EGFR-based therapies in the treatment of human cancer.

Summary

ADAM17 was originally characterized for its role in TNFα processing and the regulation of inflammatory responses. It has since been demonstrated that ADAM17 is also a physiological convertase of a wide variety of signaling molecules implicated in the development and progression of cancer. The importance of ADAM17 in these oncogenic pathways is highlighted by the finding that silencing of ADAM17 is sufficient to abolish tumor formation *in vivo*. These results validate ADAM17 as a rational therapeutic target and endorse the use of ADAM17 inhibitors in the treatment of human cancer.

Definition

A disintegrin and metalloprotease (ADAM) molecules share a common domain structure: a propeptide (prodomain), a metalloproteinase domain, a disintegrin domain, a cysteine-rich region, an epidermal growth factor (EGF)-like domain, a transmembrane region, and a cytoplasmatic domain (Fig. 1). Several ADAMs exist in both membrane-bound and secreted isoforms; the functional significance of this, in most cases, is still unclear. A subset of the presently known ADAM molecules shows catalytic activity. To date, at least 40 ADAMs have been identified in a variety of species. A large proportion (13 ADAMs) is exclusively expressed in the male reproductive system, and only a minority can be found throughout all tissues.

Characteristics

ADAM molecules, with their unique potential to combine ►adhesion, ►proteolysis, and signaling, are involved in a variety of cellular functions. Some have been shown to play an important role in diverse biological processes such as fertilization, myogenesis, cell signaling, inflammatory response, and cell–cell/cell–matrix interactions. However, the respective key function has remained elusive for most ADAMs.

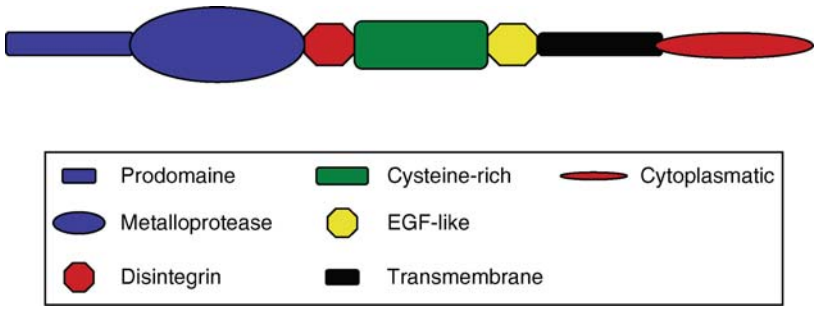
Dysregulation of ADAM molecules has been shown in various diseases. However, there is a growing amount of reports about the role of ADAM molecules in malignant tumors.

Metalloprotease Function

To regulate biological activity, in normal as well as in malignant cells a wide variety of proteins are synthesized as inactive precursors that are subsequently converted to their mature active forms by ADAM molecules.

A well-studied member of the ADAM molecules is ADAM17/►TACE, which was originally described as being responsible for the proteolytic cleavage of the soluble form of ►TNF-α. Subsequent studies have shown that ADAM17/TACE is also involved in the shedding of other biologically active proteins, including growth factors (erbB4/HER-4 and ►transforming growth factor (TGF)-α), surface molecules (L-selectin), and interleukin (IL) receptors (IL-R; IL-1R type II and IL-6R; Fig. 2).

TACE cleavage function in the activation of EGF receptor (EGFR) and EGFR signaling systems, which regulate the proliferation and motility of ►squamous cell carcinoma cells in vitro. The key role of the EGFR/EGFR ligand system for cancer development is well-known. In this context, the transactivation of EGFR via ADAM17/TACE is of special interest. ADAM



ADAM Molecules. Figure 1 Domain structure of ADAMs. The ADAMs consist of a propeptide domain, a metalloprotease domain, a disintegrin domain, a cysteine-rich region, a EGF-like, a transmembrane domain, and a cytoplasmatic domain.

metalloproteases such as ADAM9 and ADAM17/TACE regulate G protein-coupled receptor induced cell proliferation and survival.

Aberrant expression of a proteolytic active ADAM17/TACE has been reported in pancreas ►cancer cells. The increasing prevalence of ADAM17/TACE expression with higher pancreatic intraepithelial neoplasia (PanIN) grade as precursor lesions underlines the role of this molecule in ductal pancreatic adenocarcinoma development. Gene silencing experiments showed a critical role of ADAM17/TACE in the invasion process of pancreatic cancer cells. The aberrant expression of proteolytically active ADAM17/TACE may result in an uncontrolled turnover of activated target molecules, such as TNF-α, TGF-α, and MUC1 (►mucius).

Silencing of ADAM17 in human renal carcinoma cell lines corrects critical features associated with cancer cells, including growth autonomy, tumor inflammation, and tissue invasion. In addition, these cells fail to form in vivo tumors in the absence of ADAM17. It has also been shown that ADAM17/TACE is overexpressed in mammary cancer and other cancer types (Table 1).

ADAM12, which is upregulated, for example, in breast and gastric cancer (Table 1), is expressed in two splice forms, the transmembrane ADAM12-L and the soluble ADAM12-S. In a mouse breast cancer model, ADAM12 decreased tumor cell apoptosis and increased stromal cell apoptosis. The shedding of heparin-binding EGF by ADAM12 was shown to

ADAM29	Chronic lymphocytic leukemia

promote human ►glioblastoma. In addition, in liver cancers, ADAM12 and ADAM9 expression is associated with tumor aggressiveness and progression. ADAM9 is also described to shed heparin-binding EGF. Overexpression of cytoplasmatic ADAM9 in pancreatic cancer is associated with poor differentiation and shortened survival.

It is of particular interest for cancer development that ADAM molecules reported to shed cell-associated adhesion molecules such as L-selectin, MUC1, and glycoprotein (Gb) 1bα.

In general, the metalloprotease protease function might be involved in various processes of cancer cells and be relevant to promote cell migration and invasion.

Adhesion Function

ADAM molecules are potential ligands for ►integrins due to the presence of binding sites within the disintegrin domain. Only one ADAM (ADAM15) contains the ►RGD integrin-binding motif and it can therefore interact not only with the αvβ3 integrin but also with the αvβ5. Additional ADAM–integrin interactions have been reported: a large number of ADAMs (1, 2, 3, 9, 12, and 15) with α9β1; ADAM9 with α6β1 and αvβ5; and ADAM28 with α4β1. Considering the recently published data on the interaction of ADAM17/TACE with the α5β1 integrin in ►HeLa cells, it is also conceivable that ADAM17/TACE may influence the migration and invasion in other cancer types.

We are beginning to gather insights into ADAM–integrin and ADAM–►extracellular matrix (ECM) interactions. The interplay with integrins and ECM compounds might promote ADAM function in malignant cells. Thus, cell binding to ADAM12 via beta3 integrin results in the formation of focal adhesions. Furthermore, it was shown that the cystein-rich domain of ADAM12 supports tumor cell adhesion through syndecan.

ADAM23 with its inactive metalloprotease domain is exclusively involved in cell-adhesion. It was demonstrated that the interaction between the disintegrin-loop of ADAM23 and the αvβ3 integrin promotes the adhesion of ►neuroblastoma and ►astrocytoma cells. In contrast to the described overexpression or de novo expression in various cancer types, downregulation of ADAMs might also promote cancer development. Thus, ADAM23 gene silencing in breast cancer by promoter ►hypermethylation may result in abnormal cell–cell interactions favoring cell migration.

Signaling Function

Beside the involvement of ADAM molecules in the EGFR transactivation, only few data about the signaling function of ADAM molecules are known. It is intriguing that interactions between integrins and/or ECM- and ADAM-binding domains may induce outside–in signaling. ADAM inside–out signaling pathways might regulate shedding and/or adhesion function of the molecules. However, many ADAM cytoplasmatic domains contain binding motives for the Src homology region 3 (SH3 Domain) of various intracellular proteins. Tyrosine residues could be substrates for tyrosine kinases or could act as ligands for phosphotyrosine-binding domains, when phosphorylated. A number of binding partners have been identified for the cytoplasmatic domains of various ADAM molecules. Interaction of the cytoplasmatic domain of ADAM9 and 15 with endophilin and SH3PX1are reported. ADAM12 and ADAM15 are associated with ►Src protein-tyrosine kinases. However, the shedding of the L1 adhesion molecules in breast cancer cells might involve a Scr protein-tyrosine kinase. Furthermore, mitotic arrest-deficient-2 (►MAD2) was found as binding partner of ADAM17/TACE and ADAM15; MAD2β is linked to ADAM9. To date, the physiological role of this interactions as well as the implication in malignancies is speculative.

Other Functions

Within the ADAM molecules, ADAM11 might play a special role in malignancies. ADAM11 represents a candidate tumor suppressor gene for human breast cancer. This is based on its location within a minimal region of chromosome 17q21 previously defined by tumor deletion mapping.

Taken together, there are rapidly increasing data supporting a critical implication of ADAM molecules in malignancies. But there are still more questions than answers on the function of ADAMs in human cancer and cancer development.

Adaptive Immunity

Definition

Adaptive immune responses occur when the host comes into contact with immunogenic molecules or organisms. These stimulate the expansion of the antigenspecific lymphocytes, antibody secreting B cells and T cells of the cytotoxic and helper phenotypes, which recognize cells expressing foreign antigens. B cells and T cells are the effector cells of the adaptive immune response. They bear antigen specific receptors of great diversity that are generated by random rearrangement of gene segments and other mechanisms. This results in a vast array of antigen-specific receptors clonally distributed on T and B cells, which clonally expand on contact with antigen. As the immunogen is cleared these clonal populations shrink but leave behind longlived populations of memory cells that are easily recalled on subsequent exposure to the same immunogen. Unlike the innate immune response, adaptive responses are not immediate, requiring 3–5 days for clonal expansion and differentiation of effector lymphocytes. The adaptive immune system allows for a strong immune response as well as immunological memory, where a tumor antigen is "remembered." The adaptive immune response is antigen-specific and requires the recognition of tumor antigens during a process called antigen presentation. Antigen specificity allows for the generation of responses that are tailored to cancer cells and the ability to mount these tailored responses is maintained in the body by "memory cells." Cells of the adaptive immune system are B- and T-lymphocytes. Adaptive humoral responses are mediated by tumor specific antibodies.

►Adducts to DNA

Adducts to DNA

Helmut Bartsch
Division of Toxicology and Cancer Risk Factors, German Cancer Research Center (DKFZ), Heidelberg, Germany

Synonyms

DNA-bound carcinogens

Definition

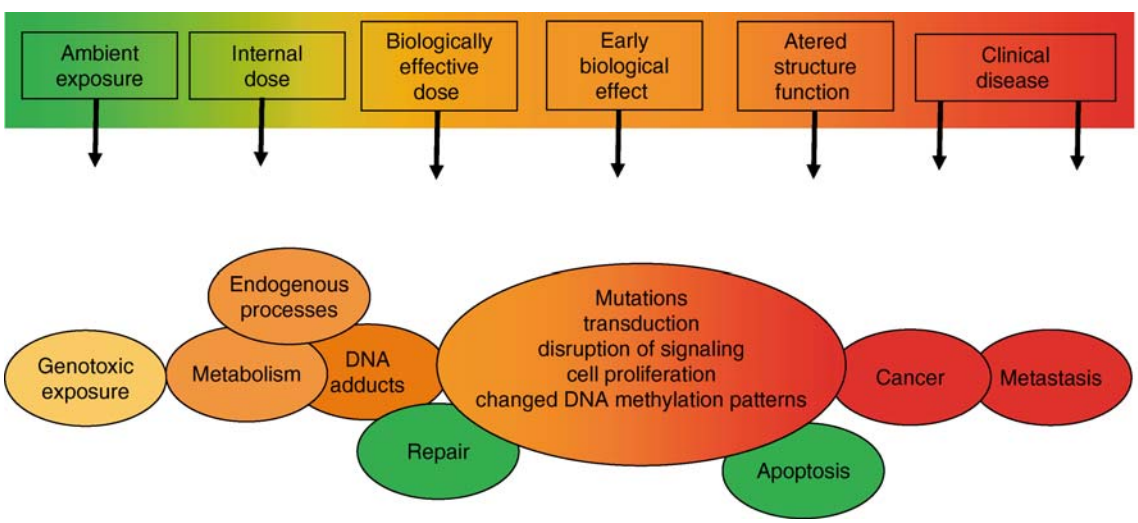
DNA-adducts reflect the amount of a ►xenobiotic that covalently reacts with nucleic acid bases at the target site (biologically effective dose) or in surrogate tissues (►surrogate markers). DNA adducts are mechanistically more relevant to ►carcinogenesis than the internal dose of a carcinogen, since they take into account interindividual differences in metabolism and of DNA repair capacity (Fig. 1). Several hundred DNA adducts, many with miscoding properties, are known to be produced by some 20 classes of carcinogens and through endogenous oxidative processes. DNA adducts are used in human ►biomonitoring as dosimeters of early biological effects and predictors of cancer risk. These ►biomarkers also provide tools for studying disease pathogenesis, etiology and for verifying preventive measures in human cancer.

Characteristics

Rationale for Using DNA Adducts as Biomarkers for Exposure and Adverse Effects

Evidence for the biological significance of DNA adducts in carcinogenesis is supported by the following:

- Over 80% of identified or suspected human carcinogens react often after metabolic activation with nucleic acids and proteins to form macromolecular adducts
- Carcinogen-DNA adducts represent the initiating events leading to mutations in ►oncogenes and ►tumor suppressor genes, and to ►carcinogenesis
- The carcinogenic potency of a large number of carcinogens is proportional to the extent they bind to rodent liver DNA
- Humans with inherited or acquired defects in ►DNA repair have an elevated risk of developing cancer



Adducts to DNA. Figure 1 Paradigm for the multistage process of ►carcinogenesis with DNA adducts as initiating lesions. They are used mostly as biomarkers for the biologically effective dose both of exogenous carcinogens and of DNA-reactive agents produced by endogenous processes, such as chronic oxidative stress. Over the past 40 years emphasis has been placed on the development of accurate and sensitive methods for the detection and quantitation of DNA adducts.

Biological effect markers are defined as indicators of irreversible genetic damage that result from genotoxic interactions at the target site. As DNA adducts do not often cause completely irreversible lesions, because the DNA undergoes repair (which may not be complete), they are not in the strict sense biological effect markers. However, as carcinogen dosage is linked to cancer outcome, and permanent mutations can be caused by DNA adducts, they are associated with cancer risk. This has been shown for many carcinogens and their DNA adducts, when critical toxico-kinetic parameters are taken into account. These include the steady state adduct concentration, the amount of the miscoding adduct compared to others of lesser biological relevance, the adduct half-life after carcinogen exposure has stopped, the organ, cell and gene selectivity of the adduct (Fig. 2).

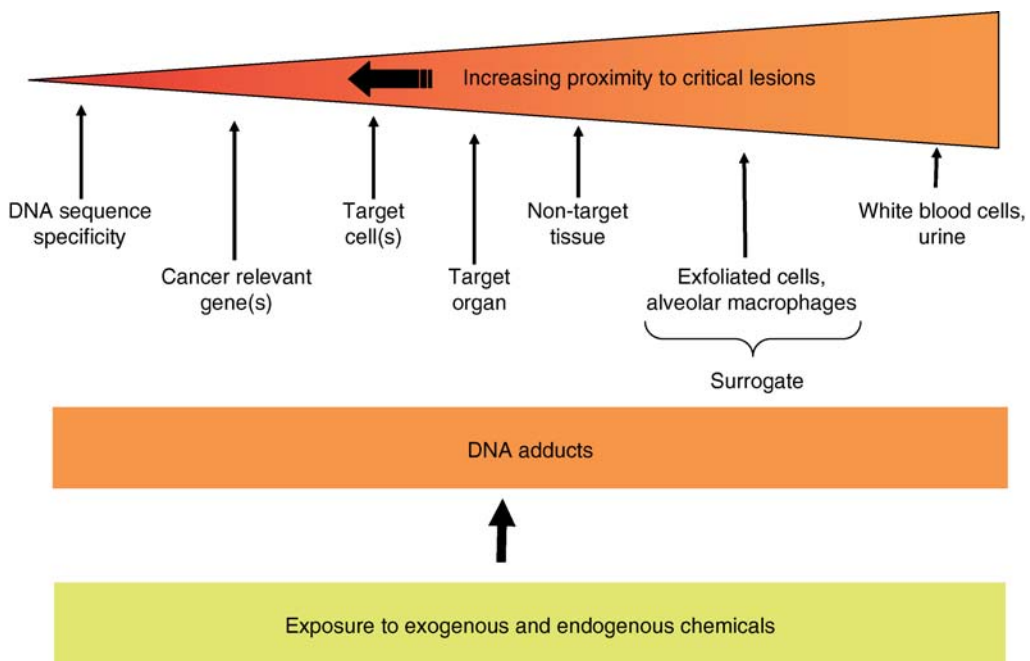
Advantages and Disadvantages of DNA Adducts Compared to Other Biomarkers

For human biomonitoring both DNA and protein adducts can be used for exposure assessment as long as the response in target organs *versus* surrogate tissue is shown to be proportional. The latter has to be determined individually for each carcinogen. The advantage of certain protein adduct measurements is that they often reflect cumulative past exposure (of several months), while the majority of DNA adducts is rapidly repaired or lost after exposure has ceased. However, a small portion of DNA adducts either with slow repair and/or subpopulations of non-dividing cells can survive for several months or even years.

Since somatic genetic or cytogenetic effect markers are neither chemical- nor exposure-specific, only macromolecular adducts allow identification of the structure and thus the determination of the genotoxic exposure sources. Also, cytogenetic markers are more easily affected by lifestyle and environmental components (confounders) that often act as uncontrolled or uncontrollable variables in biomonitoring and molecular epidemiology studies. In addition, at equal levels of carcinogen exposure, DNA adduct levels are a measure for the host's capability of carcinogen metabolism and adduct repair and can be used to determine the overall effect of genetic polymorphisms on DNA damage and cancer susceptibility by a given carcinogen.

Cellular Defense: Repair of DNA Adducts

DNA repair (►repair of DNA) systems such as ►base and ►nucleotide excision repair, O^6-alkylguanine-DNA alkyltransferase and ►mismatch repair operate in human cells to remove adducted and oxidatively damaged DNA bases. Deficiency in nucleotide excision repair genes cause ►Xeroderma pigmentosum (XP) and a high-rate occurrence of skin cancers, as well as a high susceptibility to UV-light and ►polycyclic aromatic hydrocarbon-induced carcinogenesis. A defective mismatch repair system causes hereditary non-polyposis colorectal cancer (HNPCC).



Adducts to DNA. Figure 2 Measurement of carcinogen-DNA adducts in target tissue and cells or in surrogates. The predictive value of DNA adducts for disease risk increases with the proximity of measurements to critical lesions. Accordingly, from right to left, the specificity of this biomarker increases for predicting disease outcome.

Genetic defects in these DNA repair functions or inhibition of repair proteins may have dramatic consequences when DNA adducts, DNA mismatches and DNA loops are not repaired prior to cell replication and when damaged cells are not eliminated by apoptosis. Thus, characterization of germ-line and somatic mutations in DNA-repair genes can identify high-risk subjects who especially in the case of bi-allelic mutations suffer from functional defects of proteins that repair DNA-adducts leading to genetic instability and cancer.

Adduct Measurements in Disease Epidemiology

Cross-sectional and longitudinal studies in cancer epidemiology assess the relationship between carcinogen exposures and biomarker (adduct) levels. Adduct measurement exposed in humans allow the detection, quantification and structural elucidation of specific DNA damage. Findings from such studies include the detection of background exposures manifested in "unexposed" populations and a significant interindividual variation in adduct levels in persons with comparable exposure. The latter is in part due to genetic variation in carcinogen metabolism and DNA-repair processes. Positive correlations between the extent of occupational and environmental exposures, adduct levels and adverse effects, e.g. mutations in oncogenes and tumor suppressor genes have been observed. For example, large-scale studies on geographical variations of ►hepatocellular carcinoma and exposure to ►aflatoxins have used aflatoxin-bound albumin adducts, urinary aflatoxin B1-N7-guanine adducts, and mutational hotspots in the ►TP53 gene as biomarkers. They revealed more than an additive interaction between the hepatocarcinogen and hepatitis B virus (►hepatitis viruses) infection.

►Case-control studies in disease epidemiology allow the evaluation of the role of biomarkers as cancer risk factors and the exploration of underlying mechanisms, but such studies cannot establish causality between biomarker response and cancer causation. This is especially the case when the latency period (between exposure and cancer) is long. Here, adduct measurements are of greater relevance for cancer risk estimation when exposure has been continuous. An optimal study design that can establish causality is a nested case-control study that uses questionnaire data and biological sample collection prior to disease manifestation. Once diagnosis of cancer has been made, cases are matched to appropriate controls and their stored samples analyzed. The predictive value in terms of specificity and sensitivity of a DNA adduct biomarker in biological samples can thus be determined.

Association of DNA Adducts with Cancer Risk

Not all types of DNA adducts are associated with the same cancer risk. Using alkylating agents, aflatoxins and aromatic amines (that induced 50% tumor incidence) DNA adduct levels were compared in animal experiments. A 40- to 100-fold difference in the ability of DNA adducts to induce the same tumor incidence in target tissues was detected. Thus, it is difficult to predict the tumor induction potential of unknown DNA adducts. In the past, assays for DNA adduct determination provided mostly information on the total amount of adducts in bulk genomic DNA. However, new methods are capable of pinpointing adduct profiles in critical target genes (Fig. 2). Because of the multistage and complex nature of human carcinogenesis, carcinogen-DNA adducts *per se* cannot precisely and quantitatively predict an individual's cancer risk. At present risk estimation is limited to a group level.

Background DNA-adduct Levels: Sources, Variations and Cancer Risk Prediction

The major analytical challenge has been to detect levels of DNA adducts at a concentration of 0.1–1 adducts per 10^8 unmodified DNA bases using only low microgram amounts of DNA, and with high specificity and accuracy. Several methods are available including ^{32}P-postlabeling assays often in combination with immunopurification and liquid chromatography coupled to electrospray ionization-mass spectrometry. By using ultrasensitive detection methods background DNA adduct levels have been found in organs of unexposed humans and untreated animals. These are due to physiological lipid peroxidation (LPO) processes, whereby endproducts, such as 4-hydroxynonenal and malondialdehyde when formed in excess in the body, can react with DNA to yield background levels of a variety of exocyclic DNA adducts. These types of adducts generally increase with age, but are significantly increased in human subjects affected by risk cancer factors that induce chronic oxidative stress. These include chronic inflammatory processes and infections, nutritional imbalances, and metal storage disorders. In addition, oxidized DNA bases and LPO-derived DNA adducts occur more frequently in cells with impaired antioxidant defense. Exogenous carcinogens can also induce oxidative stress causing agent-specific DNA adducts and secondary oxidative DNA base damage. The biological relevance of both oxidative and LPO-derived DNA damage is supported by the fact that these adducts are miscoding lesions which are recognized by specific DNA-repair enzymes. There is a growing evidence that both types of DNA lesions, either derived from exogenous and endogenous agents, play a role in the initiation and progression of the multistage carcinogenesis process, as well as other chronic degenerative diseases. Current research addresses some open questions:

- What is the significance of endogenously formed DNA adducts in human cancer, particularly associated with chronic inflammatory conditions and also in relation to spontaneous tumors?

- Has the proportion of cancers that result from environmental agents been overestimated compared to those arising from endogenous DNA damaging processes?
- Can one protect humans against endogenously derived DNA damage and prevent chronic degenerative diseases by administration of chemopreventive (antioxidative) agents, using DNA-adduct measurements to verify their efficacy?
- Will LPO-derived DNA adducts serve as potential prognostic markers for assessing progression of chronic inflammatory cancer-prone diseases?

Contributions of DNA-adduct Measurements to Disease Etiology and Pathogenesis

New insights are gained since

- Adduct analysis permits identification of hitherto unknown exogenous and endogenous DNA-reactive agents and of carcinogenic components in complex exposures, thus increasing the power to establish causal relationships in molecular epidemiology.
- Highly exposed individuals can be more readily identified, and exposure to carcinogenic risk factors can be minimized or even avoided.
- Subgroups in the population (so called pharmacogenetic variants) that are, due to genetic polymorphism of xenobiotic-metabolizing and DNA-repair enzymes, more susceptible to carcinogens, are identifiable by a combination of genotyping and DNA-adduct measurements.
- Repeated applications of dosimetry methods for macromolecular adducts can evaluate the effectiveness of primary and secondary interventions, either by reduction of carcinogen exposure or through (chemo-)preventive strategies.
- Incorporation of DNA-adduct measurements (and of other critical endpoints involved in carcinogenesis) can reduce (i) the enormous uncertainties currently associated with high-to-low dose and species-to-species extrapolation and (ii) yield information on inter-individual risk assessment procedures.
- The role of specific carcinogen exposures may be retrospectively implicated in cancer etiology by analyzing decades after the period of exposure, mutational fingerprints in tumors that arise from exogenous and endogenous agents after their reaction with DNA. Specific mutational signatures, detected in the tumor suppressor gene TP53, were associated with distinct past carcinogen exposures (e.g. tobacco smoke, aflatoxin B_1, vinyl chloride, and UV-light) or inflammatory disease state (such as chronic inflammatory bowel diseases).
- Adducts and derived mutations should allow to study pathogenesis and preventive approaches of chronic degenerative diseases other than cancer (e.g. atherosclerosis, Alzheimer disease).

Adenine Nucleotides

Definition

Energy-carrying molecules composed of the purine base adenine, the sugar ribose, and one (AMP), two (ADP) or three (ATP) covalently-attached phosphate groups.

►Adenosine and Tumor Microenvironment

Adenocarcinoid

Definition

An appendiceal malignancy that contains both an epithelial neoplasm and a neuroendocrine (carcinoid) neoplasm simultaneously.

►Appendiceal Epithelial Neoplasms
►Carcinoid Tumors

Adenocarcinoma

Definition

A form of carcinoma that originates in glandular tissue. To be classified as adenocarcinoma, the cells do not necessarily need to be part of a gland, as long as they

have secretory properties. This form of carcinoma can occur in some higher mammals, including humans. The term adenocarcinoma is derived from "adeno" meaning "pertaining to a gland" and "carcinoma" which describes a cancer that has developed in the epithelial cells, i.e. cells that line the walls of various organs. This type accounts for about 40% of ►lung cancer. It is usually found in the outer part of the lung.

►Vanadium
►Bile Duct Neoplasms
►Appendiceal Epithelial Neoplasms

Adenomas

►Colorectal Premalignant Lesions

Adenomatous Polyposis Coli

Definition

Familial Adenomatous Polyposis; APC.

Adenomatous Polyps

►Colorectal Premalignant Lesions

Adenomucinosis (DPAM)

Definition

An appendiceal epithelial neoplasm that is noninvasive so that peritoneal surfaces are coated by increasing quantities of a mucinous neoplasm.

Adenosine and Tumor Microenvironment

Jonathan Blay
Department of Pharmacology, Dalhousie University, Halifax, NS, Canada

Synonyms

Adenosine; Adenine nucleoside; purine nucleoside; adenine-9-β-D-ribofuranoside

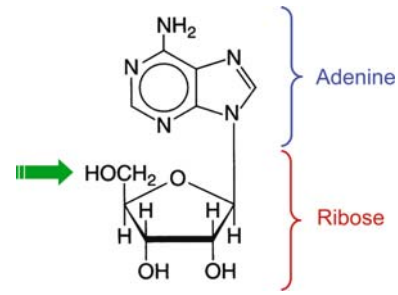
Definition

Adenosine is a small molecule that is released into tissue at high concentrations in response to a deficiency of oxygen, which occurs characteristically in solid tumors. Adenosine has multiple effects within the tumor, including controlling cancer cell growth, locally inhibiting the immune system, and increasing blood vessel formation.

Characteristics

Adenosine (adenine-9-β-D-ribofuranoside, Fig. 1) is a small organic molecule that plays an important part in general cellular biochemistry. Chemically, it is a purine nucleoside. Adenosine is abundant within all cells, predominantly in the form of ►adenine nucleotides (AMP, ADP and ATP) which participate widely in cellular energy metabolism and act as precursor molecules in many processes. However, adenosine itself can exist in a free form both inside and outside of cells, and extracellular adenosine is responsible for the regulation of many processes throughout the body.

Adenosine becomes particularly important when tissues become deprived of oxygen (a state known as



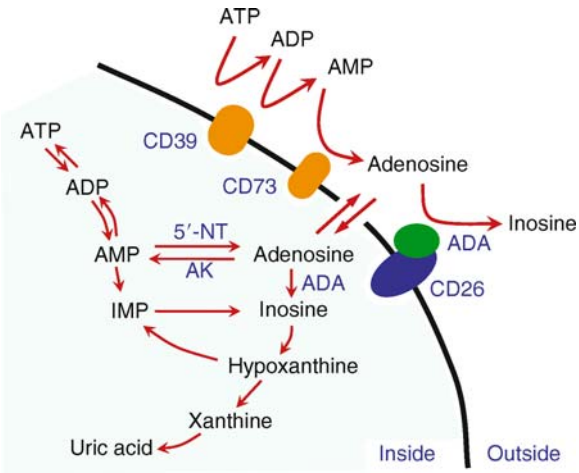
Adenosine and Tumor Microenvironment. Figure 1 The chemical structure of adenosine. Adenosine is composed of a purine base (adenine) linked through a glycosidic bond to a sugar (ribose). Successive phosphate groups may be added at the position indicated by the *arrow* to give AMP (adenosine monophosphate), ADP (adenosine diphosphate) and ATP (adenosine triphosphate).

►hypoxia). This can happen in certain pathological situations, including cancer. It may occur suddenly when blood flow is interrupted, as takes place in a stroke within the brain or during a heart attack. In solid tumors however, hypoxia is a chronic condition because the blood vessels that the cancer forms to nourish itself are not well made and are unable to supply the tissue with sufficient oxygen and other nutrients. For cells to be well oxygenated, they need to be within a distance of about 150 μm of a properly functioning blood vessel. Tumor vessels are typically far apart, are irregular in both size and orientation and can be so poorly regulated that the blood flow may periodically change direction. Cancer cells respond to these harsher conditions by changing their metabolism.

In hypoxic cancer tissues, the balance of energy metabolism in the cells becomes altered. Specific changes in the biochemical pathways of hypoxic cells dramatically change the fate of adenosine. Free adenosine is normally formed principally from adenine nucleotides by the enzyme 5′-nucleotidase inside the cell (some tissues have another pathway that also contributes), and adjacent to the exterior of the cell membrane by a series of proteins including ►CD39 and ►CD73, the latter of which also has 5′-nucleotidase activity (Fig. 2) In hypoxia, the 5′-nucleotidase pathways that lead to adenosine production from adenine nucleotides are activated, while the adenosine kinase enzyme which serves to convert adenosine to AMP is inhibited. These and other changes rapidly increase the concentrations of adenosine within and outside the cell. Since adenosine can pass freely into and out of the cell through various ►nucleoside transporters in the outer membrane, any excess adenosine in the cytoplasm escapes from the cell and further accumulates in the extracellular space. These sources of adenosine contribute to very high extracellular adenosine concentrations in hypoxic tissues.

In tumor tissue the average concentration of adenosine in the extracellular space is approximately 10 μM. Such high concentrations can be found in small tumor nodules of about 2–3 mm in diameter, so are likely to be present in the extracellular fluid of early cancers even before the ►angiogenic switch. Furthermore, because the level of hypoxia varies through the tumor depending upon the proximity of blood capillaries, local levels can be much higher. Finally, adenosine concentrations are highly regulated by ►ecto-enzymes such as adenosine deaminase (ADA) at the cell surface (Fig. 2), so that the ultimate effects of adenosine depend heavily on events at the cell surface.

In normal tissues, where the concentrations of adenosine are low (in the nanomolar range), the principle pathway through which adenosine is metabolized involves phosphorylation to AMP by adenosine kinase. At higher adenosine concentrations, as are present



Adenosine and Tumor Microenvironment. Figure 2 Adenosine production in and around the tumor cell. Adenosine is produced in the cell principally from AMP through the action of 5′-nucleotidase (5′-NT). This pathway is more active under hypoxic conditions, such as exist in solid tumors. Hypoxia also inhibits adenylate kinase (AK), which catalyzes the reverse reaction to convert adenosine to AMP. Outside the cell, adenosine is produced from ATP that is present in the extracellular fluid, by the sequential enzyme activities of CD39 and CD73. The major factor restraining the levels of adenosine that can be reached is the activity of the enzyme adenosine deaminase (ADA), which breaks adenosine down to inosine. This is present both within the cell, and as an enzyme outside of the cell (ecto-enzyme) that is held in place by an anchoring protein, CD26.

inside a tumor, the major route through which disposal of adenosine occurs is by deamination to ►inosine through ADA. ADA is found both within the cell and in the external milieu. The ADA that is present in the extracellular fluid does not remain free, but is largely captured by a 110-kDa binding protein present at the surface of many cells, particularly those of epithelial origin. This ►ADA-binding protein (ADAbp) is found embedded as a dimer in the outer membrane of many cancer cells, where it functions to hold ADA. There is also evidence that some ADA can bind directly to adenosine ►receptors of A_1 and A_{2B} subtypes. ADA held in this way is then able to modify adenosine concentrations immediately next to the cell surface (where the adenosine receptors are located).

One factor that complicates our understanding of how adenosine levels may be regulated within cancer tissue is the fact that adenosine has the capacity to regulate its own levels. This interesting complication arises because ADAbp (also known as CD26 or DPPIV) can be down-regulated at the cell surface by adenosine. That reduces the capacity of the cell to bind ADA at the cell surface and therefore the local rate

of degradation of adenosine. This will extend the half-life of adenosine and increase the persistence of its action. As a result, in the high concentration environment of a tumor, adenosine has the capacity to suppress its own breakdown and enhance its actions still further. (See also ►CD26/DPPIV in Cancer Progression and Spread.)

Although adenosine is a common molecule and has a relatively simple structure, it is able to regulate cellular behavior by interacting with specific receptors. The different types of adenosine receptors are outlined in Table 1 There are four known types, all of which are ►G-protein-coupled receptors with seven transmembrane segments in their structure, embedded in the outer membranes of responsive cells. Adenosine receptors may be found on any of the cell types within a tumor including the cancer cells, the supporting stromal cells, the endothelial cells within blood vessels, or inflammatory cells that are infiltrating the tumor. All four of the adenosine receptor subtypes have been shown to exist on cancer cells; indeed it is possible for a single cancer cell population to express all four forms of the receptor. However, adenosine receptor subtypes A_3 and A_{2B} are the most commonly observed in cancers. The adenosine concentrations that exist in tumors are sufficient to activate all four of the adenosine receptor subtypes.

There are four different types of adenosine receptor Table 1, which differ in their affinity for adenosine and the signalling pathways to which they are linked through G proteins. All of the receptor subtypes are able to act on adenylyl cyclase but may either increase or decrease the production of cAMP as shown. The receptors can also be coupled to phospholipase C (leading to calcium release and activation of protein kinase C), to phospholipase A_2 (causing generation of arachidonic acid and subsequent production of eicosanoid lipid mediators), to phosphatidyl inositol 3-kinase (PI3K, leading to increased activity of the phospholipase D pathway) or in certain cell types can cause the activation of potassium (K) channels.

Adenosine and Tumor Microenvironment. Table 1 The different types of cellular receptors for adenosine

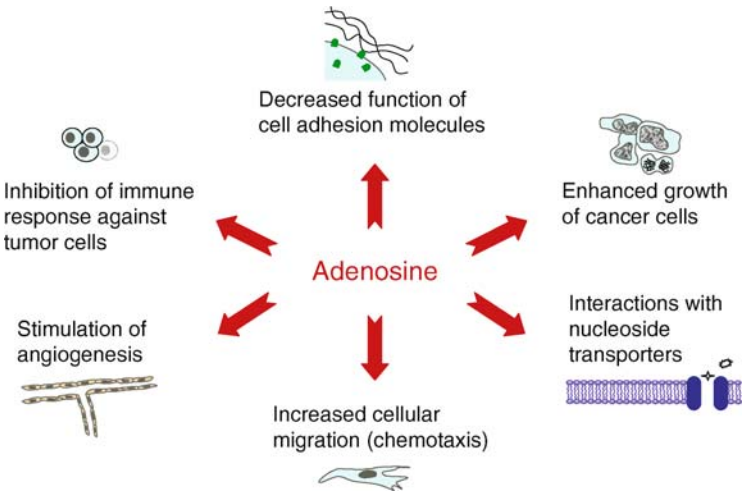
Receptor subtype	Affinity for adenosine	Major G_α protein (s)	Signalling pathways used by receptor
A_1	High	$G_{i/o}$	Adenylyl cyclase (↓ cAMP)
			Phospholipase C
			K^+ channels
A_{2A}	High	G_s	Adenylyl cyclase (↑ cAMP)
			Phospholipase C
A_{2B}	Low	G_s, $G_{q/11}$	Adenylyl cyclase (↑ cAMP)
			Phospholipase C
			Phospholipase A_2
			PI3K
A_3	Low	$G_{i/o}$, $G_{q/11}$	Adenylyl cyclase (↓ cAMP)
			Phospholipase C
			K_{ATP} Channels

The interaction of adenosine with its receptors on the different cell types in a tumor leads to a myriad of different cellular responses. Although it is at times difficult to extrapolate from the experimental approach to the disease itself, these are such as to generally favor the expansion and spread of the cancer (Fig. 3) There is evidence that synthetic agents which target individual receptor subtypes may have different actions to adenosine, sometimes not clearly directed through the adenosine receptor. When adenosine itself is studied at concentrations that are known to be present within the tumor extracellular fluid, it is typically shown to increase the growth of cancer cells. At very high concentrations of adenosine, cells may be triggered to undergo ►apoptosis, although some tumor cells are resistant to this action of adenosine.

In addition to effects on cancer cell growth and survival, adenosine acts on isolated cancer cell populations to increase cell motility, adhesion to the extracellular matrix, the expression of cell attachment proteins and receptors for molecules that can direct cell movement. The patchiness of hypoxia within tumor tissue leads to local areas of high adenosine concentrations that would be capable of influencing tumor cell behavior directionally in this way. While not yet proven, it is possible that within the context of the tumor itself, adenosine may have an influence on the distribution of cells within the tumor and perhaps their dissemination at the later stage of metastasis.

Adenosine receptors are also found on endothelial cells, which are the flattened cells that line blood vessels and which are the major cellular component of the newly-formed vasculature that is formed to supply the expanding cell population with nutrients. Adenosine is able to promote endothelial cell division and motility, and has been shown to enhance the formation of blood vessels (►angiogenesis) in experimental animal models. Adenosine may therefore have an ancillary role alongside other angiogenic factors such as ►VEGF in regulating the formation of the tumor microvascular network.

Probably the greatest potential role for adenosine in the context of cancer however, is as a local immunosuppressant within the tumor. It has long been known that the local tissue environment in cancer is capable of suppressing the immune response, and that this



Adenosine and Tumor Microenvironment. Figure 3 The multiple potential actions of adenosine within a tumor. This diagram summarizes the different ways in which adenosine might act to facilitate the survival and expansion of a malignant tumor. This figure is drawn based upon studies on individual tumor cell populations and other studies *in vivo* in which these responses have been observed.

is one of the factors that limits the capacity of our immune system to eliminate the cancer. Experimental studies have shown that a significant proportion of the immunosuppressive activity is mediated by soluble factors, that it increases in proportion to tissue bulk, and it is seen to decline substantially when the cancer tissue is removed from the animal or patient and dissociated into isolated cells. Adenosine is one of the possible factors responsible for this phenomenon of "metabolic suppression" of the anti-tumor immune response. The capacity for adenosine to act as an immunosuppressant is dramatically illustrated by a rare but well-known genetic disease involving a lack of ADA. In this disorder, levels of adenosine within lymphoid tissues rise and (through a combination of events involving both toxic metabolites and adenosine acting through its receptors) cause a severe immunodeficiency (well known because of the need to protect afflicted children from infection in "biobubble" tents).

Adenosine is capable of interfering with the immune response at different levels and by acting on different cell types. It works through cell-surface adenosine receptors (principally A_{2A} and A_3 subtypes) to suppress various functions of T lymphocytes, natural killer (NK) cells, polymorphonuclear granulocytes, and phagocytic cells such as tissue macrophages that play a key role in recognizing the targets for immunological attack. In the case of T lymphocytes and NK cells, whose infiltration and activity is of key importance to the fate of the tumor and prognosis of the patient, adenosine suppresses successive stages in the evolution and function of the cells. It inhibits proliferation of the cells, the expression of key molecules on the cell surface that are needed to allow full activation, the extent of interaction with the cancer cell, the release of toxic molecules involved in cell killing, and the overall capacity for killing of the cellular targets.

Given the extensive effects of adenosine on nearly all of the cell types present in tumors, it would be appealing to attempt to use drugs that interfere with adenosine pathways as a way of interfering with the growth of the cancer cells, blocking the formation of new blood vessels to nourish the tumor, or relieving the immunosuppression that is due to adenosine. The challenge here lies in the fact that this is a primitive regulatory network in evolutionary terms, and adenosine has a role in the regulation of most organ systems in the mammal. Adenosine receptors of the four subtypes are found on cells throughout the body. Drugs that would a block adenosine's action at its receptors (antagonists) or mimic its actions at a certain receptor subtype (selective agonists) run the risk of interfering with normal processes such as the control of blood flow or the transmission of nerve signals. Nevertheless, there is hope that careful targeting of certain receptors (particularly the A_3 subtype) in cancer may prove to be a useful intervention.

Adenosine Deaminase

Definition

An enzyme involved in the metabolism of deoxyadenosine to deoxyinosine. Congenital deficiency of this enzyme results in the clinical syndrome of severe combined immunodeficiency.

Adenovirus

Stefan Kochanek
Division of Gene Therapy, University of Ulm, Ulm, Germany

Definition

Adenoviruses were originally isolated as etiologic agents for upper respiratory infections. Their name is derived from the initial observation that primary cell explants from human adenoids were found to degenerate secondary to the infection by an, at the time, unknown virus. According to the current official taxonomy, there are four adenovirus genera (Mastadenovirus, Atadenovirus, Aviadenovirus and Siadenovirus), indicating that adenovirus is widely distributed in vertebrates. More than 50 human serotypes have been identified. The individual serotypes are distinguished by different parameters such as immunological properties, tumorigenicity, and DNA sequence. Some serotypes may cause more serious infectious diseases such as epidemic keratoconjunctivitis, gastroenteritis or hemorrhagic cystitis. The adenovirus particle is composed of an outer icosahedric protein capsid with an inner linear double-stranded DNA genome of approximately 36 kilobases (kb) size. There are eleven structural proteins, seven to form the capsid, among them hexon, penton base and fiber being the major constituents of the adenoviral capsid, and four that are packaged in the core. Internalization of the viral particle during infection requires the interaction of the fiber and the penton base with surface proteins (receptors) of the cell. Several virally encoded proteins are associated with the viral DNA.

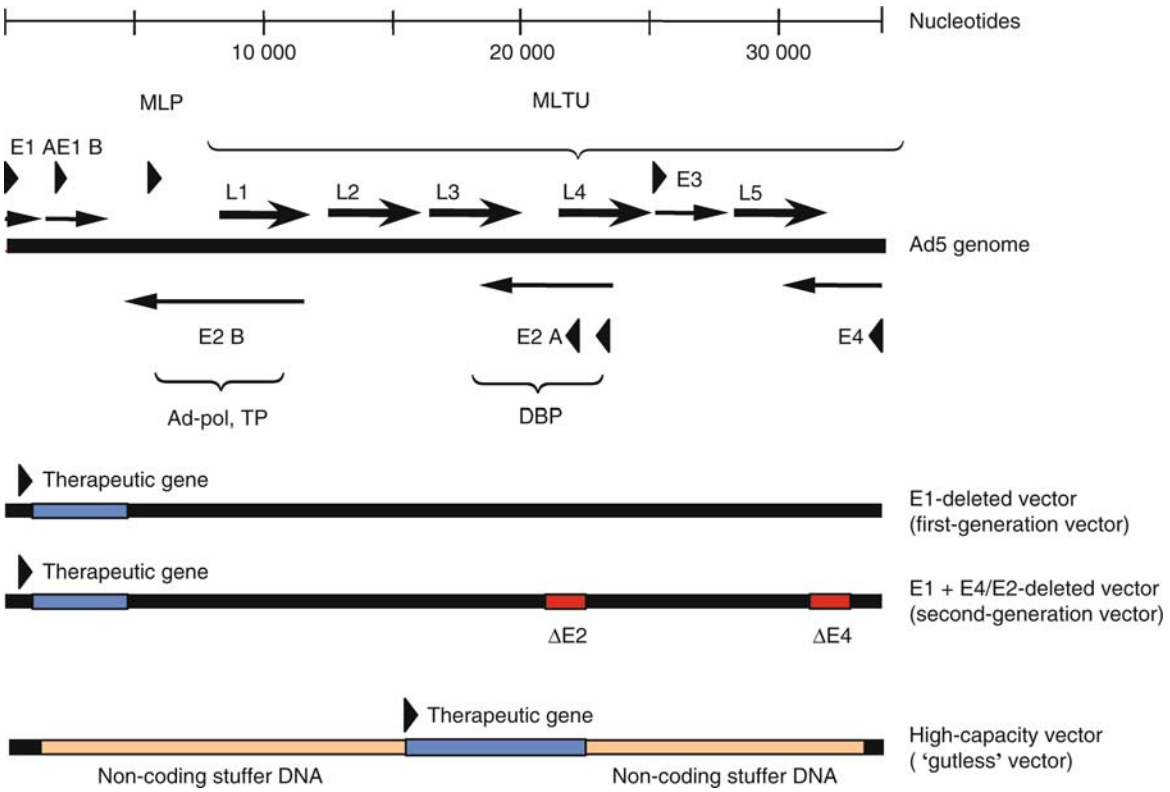
Adenovirus is being used as a gene carrier for ►gene therapy. Most adenoviral vectors (see below) are derived from the serotypes 2 and 5 (Ad2, Ad5) which are frequent causes for mild colds. During childhood most individuals will become immunized against different adenoviral serotypes by natural infection. Ad2 and Ad5 are not oncogenic in humans Adenoviruses have a good safety record based on vaccination studies that have been performed in military recruits two to three decades ago. As detailed below, during natural infection of permissive cells the adenoviral DNA is transcribed, replicated, and packaged into capsids within the nuclei of infected cells. Similar to other DNA viruses, two main phases can be distinguished during infection:

- An early phase that is characterized by the expression of the ►early virus genes E1, E2, E3, and E4
- A late phase after onset of viral replication in which the viral structural proteins are produced

Characteristics

Infection and Viral Transcription

A productive infectious cycle takes approximately 2–3 days and under optimal conditions more than 50,000 particles are produced in every infected cell. In the case of most human adenvirus serotypes the infection begins with the attachment of the virus particle to the cell surface via interaction of the tip of the capsid fiber protein with the membrane protein CAR (Coxsackie–Adenovirus receptor). As it is apparent from the name, CAR is also used by some coxsackie viruses as receptor for entry. Naturally, CAR plays an important role in the interaction of neighboring cells. The adenoviral particle is internalized by receptor-mediated endocytosis into clathrin-coated pits requiring a secondary interaction of the penton base with an αv-integrin. Following endocytosis the viral particle is sequentially disassembled, initally losing the fiber proteins, later most of the other viral structural proteins. Finally, the viral DNA is released as a DNA–protein complex through nuclear pores into the nucleus of the host cell. Shortly thereafter, transcriptional activation of the early genes E1A and E1B initiates a complex transcriptional program designed to first replicate the viral DNA and later to generate new infectious viral particles (Fig. 1). The activation of early and late transcription units follows a relatively well understood transcriptional pattern. The gene products of the E1A and E1B genes are involved in the activation of both viral and cellular genes. Under certain conditions, in particular if infection of a cell does not result in a productive but rather abortive infection (abortive infection = the infectious cycle is blocked at an early stage following infection of the host cell) together with the rare event of integration of the viral DNA into the chromosome, cellular transformation may be a consequence. The E2A and E2B gene products are involved in the replication of the viral genome and include the viral DNA polymerase (Ad-Pol), the terminal protein (TP), and the DNA-binding protein (DBP). The E3 and E4 gene products have diverse functions leading to transcriptional activation of other promoters, preferential export of viral RNAs out of the nucleus of infected cells and suppression of host defenses. With the begin of replication of the viral genome approximately 6 h after infection, late phase transcription units are activated. Most of the late phase proteins are capsid proteins or proteins that are involved in the organization and packaging of the viral genome inside the viral capsid. The most active promoter at this stage is the major late promoter (MLP) that directs the transcription of a large primary RNA transcript that covers more than two thirds of the viral genome. From this transcript five families (L1-L5) of structural proteins are generated by differential splicing and polyadenylation. During the course of an infection the metabolism



Adenovirus. Figure 1 Organization of the adenovirus genome and the different adenoviral vector types employed for gene transfer. Promoters are indicated by arrowheads, transcribed genes by arrows. The genes that are transcribed early during infection are the E1A, E1B, E2, E3, and E4 genes. The main gene products, generated late during infection, are transcribed from the Major Late Promoter (MLP), which directs a very long RNA message (MLTU = major late transcription unit). Different RNA species (L1-L5) that code for structural proteins are generated by alternative splicing and differential polyadenylation (for clarity not all adenoviral genes and gene products are indicated). First-generation adenoviral vectors are characterized by deletion of the E1 genes, second-generation adenoviral vectors by the additional deletion of the E2 and/or E4 genes. High-capacity adenoviral vectors have most of the viral genome removed and retain only the noncoding viral ends. In high-capacity adenoviral vectors, stuffer DNA is included in the vector genome for stability reasons.

of infected cells is redirected to support a predominant production and assembly of viral proteins.

Adenoviral Functions and Oncogenesis

Adenoviruses have played important roles as experimental tools in the discoveries of several fundamental principles in molecular biology, including RNA splicing and oncogenic transformation of cells. In fact, the 1993 Nobel Prize for Physiology or Medicine was awarded to Dr. Phillip Allen Sharp and Dr. Richard John Roberts for the discovery or RNA splicing and was based on their work with adenovirus RNA transcription. The induction of malignant tumors by injection of adenovirus type 12 in newborn hamsters was the first direct demonstration of a human virus causing malignant cellular transformation. This observation greatly stimulated the interest in using viruses as experimental systems in the study of the pathogenesis of cancer. While there is no epidemiological evidence for an involvement of adenoviruses in the pathogenesis of human cancers, several serotypes have been shown to cause tumors in rodents. Some serotypes, such as Ad12 or Ad18 are highly oncogenic in animals, others, for example Ad4 or Ad5 have a low oncogenic potential. Based on several complementing observations cellular transformation is mediated by the viral E1A and E1B genes: In most virus-transformed cells the viral E1 genes are consistently found integrated into the cellular genome where they are expressed. Transfection of cells with the E1A and E1B genes is necessary and sufficient for cell transformation, and viruses with mutations in the E1 genes are defective for transformation. Several RNAs are transcribed from the E1A genes, the main species in Ad5 being the 12S and the 13S RNAs coding for E1A proteins of 243 and 289 amino acids. To a large extent, the E1A proteins exert their transforming activity by interaction with cellular proteins that are involved in cell cycle regulation such as the tumor

suppressor pRB. While E1A alone is capable of immortalizing cells, cooperation with E1B functions is required to achieve a full transformation phenotype. Two main proteins are produced from the E1B gene by alternative splicing. The 21 kD E1B protein that has been shown to inhibit apoptosis, and the 55 kD E1B protein that interacts with the tumor suppressor protein p53. The expression of additional viral functions may contribute to E1 mediated tumorigenesis. For example, a 19 kD protein expressed from the E3 region can decrease MHC class I levels in transformed cells, and certain functions expressed from the E4 region can cooperate with the transforming activity of the E1B 55 kD protein.

Gene Therapy: First- and Second-Generation Adenoviral Vectors

First-generation adenoviral vectors do not replicate in human cells under normal conditions because the E1A and E1B genes are deleted from the vector genome (Fig. 1). These vectors are produced in complementing cell lines that express the E1A and E1B genes. First-generation vectors have been used for gene transfer in cultured cells, animals and even clinical trials in humans to express a large number of genes in different cell types and tissues. So far the results of experiments performed in animals and clinical studies in humans have been relatively disappointing. Several significant disadvantages of first-generation adenoviral vectors have been acknowledged:

- Because first-generation vectors still contain a nearly complete set of viral genes, toxicity and antiviral immune responses are frequently observed resulting in the clearance of transduced cells. Consequently, gene expression is only transient. Contributing factors for short-term gene expression include immune responses directed to the transgenic proteins expressed from the vector, if the organism is not tolerant to that protein.
- The upper DNA packaging limit for adenoviruses is about 38 kb. Because most viral genes are retained on the vector only about 7–8 kb of nonviral DNA can be incorporated into such vectors. However, in many conditions the therapeutic cDNAs are either large, additional elements have to be included to achieve regulated gene expression, or multiple genes need to be expressed to obtain a therapeutic effect. Thus, it is clear that the size constraints in first-generation adenoviral vectors may be a limiting factor for many potential applications. In order to further decrease expression of late viral proteins, adenoviral vectors with inactivation of the E2 and/or E4 functions in addition to the deletion of the E1 region have been generated. These vectors are produced in cell lines that complement both E1 and E2 and/or E4 functions. Currently it is controversial whether these second-generation adenoviral vectors have any significant advantages over first-generation vectors and lead to a longer duration of gene expression.

"Gutless" Adenoviral Vectors

In an attempt to address several of the problems observed with first-generation adenoviral vectors a novel adenoviral vector has been developed that will be useful for the functional analysis of genes in vivo and clinical studies. This vector has been variably called "high-capacity (HC)" adenoviral vector, "gutless", "gutted" or "helper-dependent (HD)" adenoviral vector. Because all viral genes are deleted from this vector the capacity for the uptake of foreign DNA is more than 30 kb. The current production system involves the use of an adenoviral helper virus and takes advantage of the Cre-loxP recombination system. In this production scheme a first-generation adenoviral vector carries two loxP-recognition sequences that flank the adenoviral packaging signal. The vector is produced in E1-complementing cells that express the Cre-recombinase of bacteriophage P1. After infection of these cells both by helper virus and vector the packaging signal of the helper virus is excised. Therefore, vector and only little helper virus is packaged. From several in vivo experiments performed in different animal species it is apparent that these new vectors have clear advantages compared to earlier versions of adenoviral vectors and are considerably improved in safety and expression profiles. Their increased capacity for foreign DNA allows gene transfer of several expression cassettes, large promoters and some genes in their natural genomic context, a significant advantage over first- and second-generation adenoviral vectors.

Replication-Competent Adenoviral Vectors for Cancer Gene Therapy

While the above mentioned adenoviral vectors have been widely used in preclinical and, with the exception of "gutless" adenoviral vectors, also in clinical studies to express a wide variety of transgenes including cytokines, p53 and thymidine kinase (TK), it would be desirable to achieve gene transfer into all or most neoplastic cells within a tumor. This is clearly not possible with current vector technology. Recently, a new concept has been proposed that is based on the use of an adenovirus that is both replication competent and tumor-restricted in its growth. This virus is based on an Ad5 mutant virus that has an inactivating deletion within the E1B gene and does not express the E1B 55 kD protein. Initially, it was thought that replication of the virus was dependent on the p53 status of the host cell and that the virus was able to grow only in cells deficient for function p53 expression. However, more recent results indicate that the growth of this virus is

independent of the p53 status cells and may depend on other cell cycle related factors. Although clinical studies so far have not been or only partially been successful, such a virus has been approved in 2005 in China for cancer therapy and is currently used in combination with chemotherapy and/or radiotherapy.

In addition, replication-competent adenovirus vector are being developed, in which expression of essential viral genes, in particular of E1A, is under control of a tumor-specific promoter. These vectors have been named CRADs (conditionally replicating adenoviruses).

Adenovirus Vectors for Genetic Vaccination

One of the most promising applications of adenovirus vectors is in the area of genetic vaccination. For many common diseases including AIDS or Malaria there are currently no vaccines available. Since adenovirus vectors have been found to induce strong cellular and humoral (antibody) immune responses against expressed genes, many preclinical studies have been performed with the aim of vaccine development. In these studies adenovirus vectors have been found to belong to the strongest inducers of antigen-specific immune responses against different antigens. Therefore, clinical studies have been initiated, in which adenovirus vectors, either alone or in combination with proteins or other vectors, are evaluated for their potential as a vaccine against different infectious diseases.

Adherens Junctions

Definition

Adherens junctions are intercellular junctional structures, most prominent in epithelial cells. In the adherens junction, the cell-cell adhesion is mediated by Ca^{2+}-dependent cell adhesion molecules, the cadherins; the cytoplasmic tail of these cadherins is indirectly linked to the ►actin cytoskeleton. Normally are located more basally than ►tight junctions.

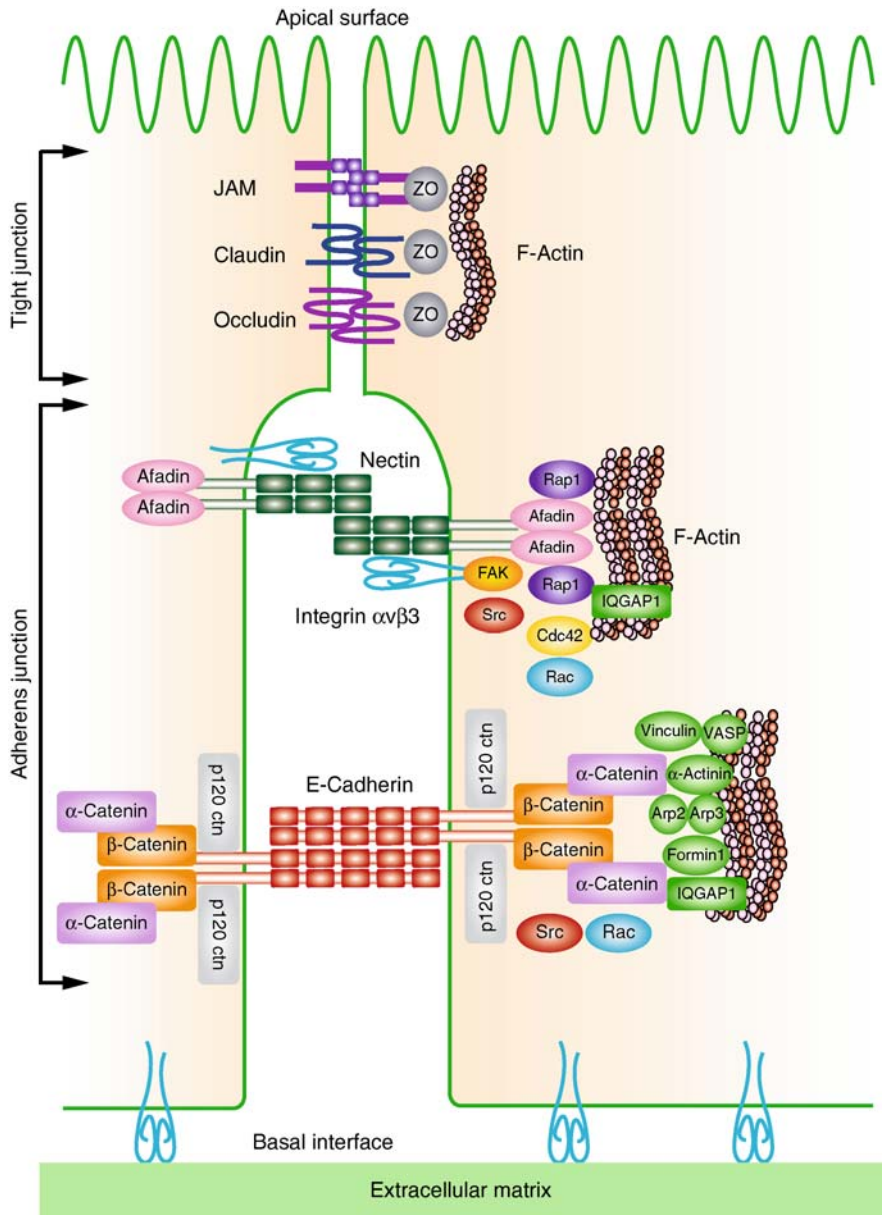
Zonula adherens; intermediate junction

Definition

Adherens junctions are specialized cell–cell attachments composed of transmembrane proteins and cytoplasmic proteins that anchor to the actin cytoskeleton (Fig. 1). Anchoring proteins are clustered with several actin-binding proteins in the cytoplasm adjacent to the junctional membranes. Adherens junctions form punctate or streak-like attachments in nonepithelial tissues, whereas they encircle the apical portion of adjacent epithelial cells below ►tight junctions. Adherens junctions have prototypic roles in stabilizing the epithelium, establishing apical–basal polarity of epithelial cells, and



Adherens Junctions. Figure 1 Epithelial cells joined by the apical adhesion complex. Adherens junctions are located below tight junctions near the apical end of the lateral cell interface in epithelial cells. Nectin and E-cadherin-based cell adhesions are connected via several cytoplasmic proteins into belts of actin filaments that underlie adherens junctions. Nectins are localized to adherens junctions via afadin, and they are associated with integrin αvβ3 in the extracellular space. Afadin binds to the tail of nectin *cis*-dimers as well as F-actin directly, interacting with Rap1. β-catenin binds to the tail of E-cadherin *cis*-dimers directly, and then α-catenin binds to β-catenin. The catenins can mediate interactions to F-actin through binding to several actin-binding proteins such as ZO proteins, afadin, vinculin, α-actinin, VASP, formin-1, and Arp2/3 complex. c-Src, Rac, Cdc42, and FAK play roles in regulating dynamic changes of the actin cytoskelton, facilitated by E-cadherin and nectin clustering.

facilitating cell–cell communication that regulates cell proliferation and movement. Since most human cancers are of epithelial origin, disruption of adherens junctions is one of the hallmarks of cancer cells exhibiting malignant transformation.

Characteristics

Adherens junctions are sites of mechanical attachment regulated by dynamic changes in the actin cytoskeleton, and they also serve as sites of cell–cell communication. Adherens junctions are abundant in many tissues that

are subjected to mechanical stress. In epithelial cells, adherens junctions coalesce into the mature zonula adherens. In cooperation with the zonula occludens (tight junctions), the zonula adherens defines apical–basal polarity by physically separating the membrane into apical and basolateral membrane domains. In addition, adherens junctions mediate nuclear ►signal transduction induced by cell contact. For example, molecules clustered at adherens junctions could mediate contact-dependent inhibition of cell proliferation and movement: the arrest of the cell cycle in G1 phase that occurs when cell density increases to confluence in culture. Thus, the coupling of cell contact and signaling at adherens junctions reflects structural and functional regulations involved in establishing multicellular organisms.

Cadherins and nectins are two major ►cell adhesion molecules in the extracellular space. Cadherins are a superfamily composed of classical cadherins, which are the main components of adherens junctions, and nonclassical cadherins, which include desmosomal cadherins and protocadherins. The classical cadherins share a motif of five cadherin repeats in the extracellular domain, and they are divided into several subtypes including epithelial ►(E) cadherin, placental (P) cadherin, neural (N) cadherin, and vascular endothelial (VE) cadherin. On the other hand, nectins are immunoglobulin-like adhesion molecules composed of four members.

Adherens junctions facilitate cell–cell adhesion through homophilic binding between cadherin molecules, as well as homophilic and heterophilic bindings between nectin molecules on adjacent cells. It remains controversial whether or not the extracellular domain of E-cadherin first binds to form *cis*-dimers on the surface of the same cells, and then promotes cell-cell contacts by forming *trans*-dimers in a Ca^{2+}-dependent manner. On the other hand, each member of nectins forms *cis*-dimers, and then promotes homophilic or heterophilic *trans*-dimer formation in a Ca^{2+}-independent manner. Heterophilic *trans*-interactions have been detected between nectin-2 and nectin-3, between nectin-1 and nectin-3, and between nectin-1 and nectin-4. Importantly, heterophilic *trans*-dimers form stronger cell–cell attachment than homophilic *trans*-dimers, which actually determines the type of cell–cell adhesion. Namely, cadherins exclusively promote adhesion between homotypic cells, whereas nectins have a dual role in promoting adhesion between homotypic cells and between heterotypic cells. Heterophilic engagement of nectins may thus play key roles in cell recognition and sorting *in vivo*.

The intracellular domain of cadherins is associated with a cytoplasmic complex consisting of α-catenin and β-catenin, and forms structural links to the actin cytoskeleton. α-catenin does not act as a stable link to filamentous actin (F-actin) but possibly acts as a molecular switch that regulates actin dynamics at adherens junctions. The catenins could also mediate interactions with F-actin via binding to proteins such as ►ZO protein-1, afadin, vinculin, and α-actinin. The intracellular domain of nectins directly binds to afadin that links nectins to the actin cytoskeleton. Localization of nectins to adherens junctions depends on the presence of afadin. Thus, the catenins and afadin cooperatively contribute to form adherens junctions that are strong yet easily remodeled.

Nectin-based cell–cell adhesions establish adherens junctions, both independently and cooperating with cadherin-based cell–cell adhesions. In Madin–Darby canine kidney (MDCK) cells in culture, nectins first form cell–cell adhesion and then recruit cadherins to the nectin-based cell–cell adhesion sites to establish adherens junctions. Nectins further promote formation of tight junctions in MDCK cells by recruiting JAM (junctional adhesion molecule)-A, claudin-1, and occludin. On the other hand, nectins and integrin αvβ3 are physically associated through their extracellular domains to cooperatively regulate cell movement, proliferation, adhesion, and polarization. Thus, nectins play roles in establishing apical junctional complex, as well as in communication between cell–cell and cell–matrix junctions.

Trans-interacting E-cadherin induces activation of Rac small ►G-protein, which stabilizes non*trans*-interacting E-cadherin on the cell surface by inhibiting endocytosis through the reorganization of the actin cytoskeleton. p120 catenin ($p120^{ctn}$) also plays a role for inhibiting endocytosis of E-cadherin. In contrast, E-cadherin undergoes endocytosis when adherens junctions are disrupted by the action of an extracellular signal, such as hepatocyte growth factor/►scatter factor. Activated c-Src enhances endocytosis of E-cadherin by inducing the tyrosine phosphorylation and ubiquitylation of the E-cadherin complex. On the other hand, *trans*-interaction of nectins activates Cdc42 and Rac, which promotes the formation of adherens junctions mediated by the ►IQGAP1-dependent actin cytoskeleton. In addition, afadin and activated ►Rap1 complex interacts with $p120^{ctn}$ to strengthen the binding between $p120^{ctn}$ and E-cadherin. Furthermore, the cell polarity proteins Par-3, Par-6, and aPKC that form a ternary complex could be implicated in the assembly of adherens junctions. They regulate the association of afadin with nectins in MDCK cells. These cell polarity proteins and afadin could play cooperative roles in the formation of adherens junctions and tight junctions although the mechanism is largely unknown. Thus, E-cadherin and nectin *trans*-interactions induce elaborate interactions between peripheral proteins to establish mature adherens junctions.

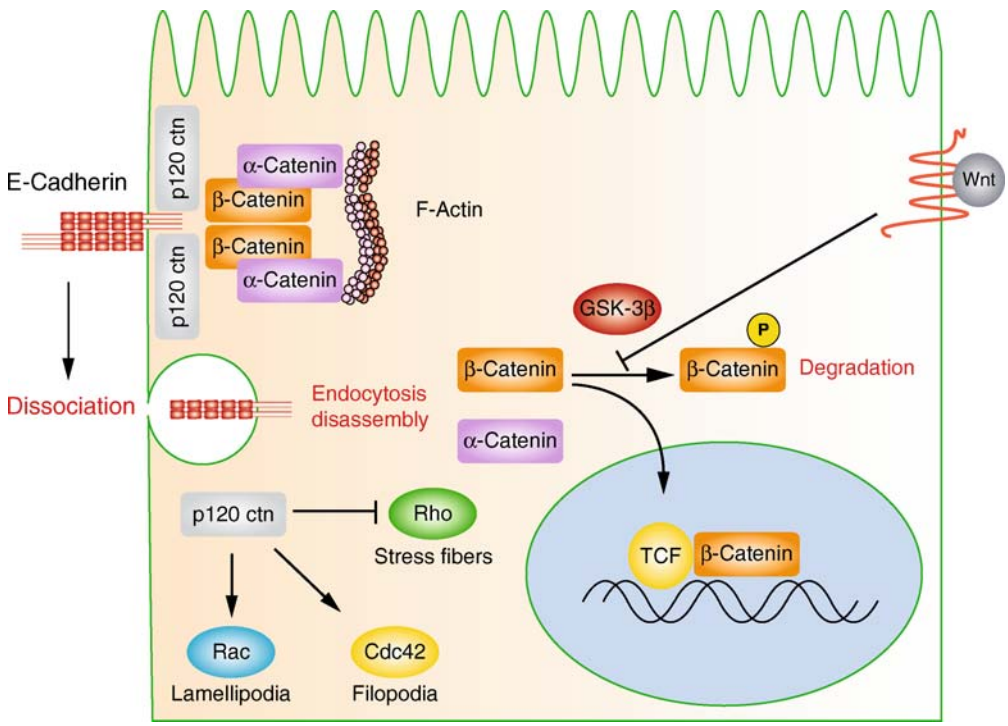
β-catenin is able to translocate to the nucleus, where it binds to lymphoid enhancer factor–T-cell factor (LEF/TCF) that regulates gene transcription. β-catenin is involved in several signaling pathways including the

wingless-type mammary virus integration-site family (►Wnt) ►signaling pathway. When Wnt proteins bind their receptors, they inactivate the serine/threonine kinase GSK3β that phosphorylates β-catenin and targets it for destruction in the proteosome. Mutations involving the serine/threonine residues of β-catenin that are phosphorylated by GSK3β can stabilize the β-catenin protein or increase its nuclear localization. Furthermore, tyrosine phosphorylation of β-catenin also disrupts the association between E-cadherin and β-catenin, allowing β-catenin to transduce signals to the nucleus.

Necl-5, a member of nectin-like cell adhesion molecules (Necls), originally identified as a poliovirus receptor, could mediate growth arrest that has been known as contact inhibition of cell proliferation and movement. Necl-5 is overexpressed in human colon carcinoma, as well as in NIH3T3 cells transformed by ►Ras activation. Necl-5 colocalizes with integrin αvβ3 and growth factor receptors at leading edges of migrating cells and regulates growth factor induced cell migration. When Necl-5 interacts *in trans* with nectin-3 at cell–cell contacts in NIH3T3 cells, Necl-5 undergoes downregulation from the cell surface, resulting in reduction of cell proliferation and movement. Thus, nectins and Necls have roles in mechanical cell–cell adhesion as well as cell–cell communication.

Implications in Cancer

Adherens junctions control epithelial cell polarity while other adhesion apparatus tends to inhibit cell migration, which is crucial for the differentiation and morphogenesis of many tissues. Loss of adherens junctions, as well as aberrant signaling involving the Wnt pathway, could contribute to carcinogenesis and ►metastasis by causing cell depolarization, loss of contact-dependent inhibition of proliferation, and increased ►motility and invasiveness (Fig. 2). Cancer cells that show migratory properties undergo ►epithelial to mesenchymal transition (EMT), with the induction of transcriptional repressor proteins, such as ►snail transcriptional factor, slug, and Twist, that downregulate E-cadherin gene expression. EMT is a basic mechanism that mediates disruption of epithelial polarity and disintegration of cancer cell nests.



Adherens Junctions. Figure 2 Signaling induced by loss of E-cadherin. Disruption of adherens junctions is caused by mutation or transcriptional repression of E-cadherin and growth-factor signaling. Dissociation of homophilic binding of E-cadherin promotes the endocytosis of E-cadherin and the disassembly of the catenins. $p120^{ctn}$ further promotes cell motility by activating Rac and Cdc42 to form lamellipodia and filopodia, and inhibits Rho activity that leads to stress-fiber formation. β-Catenin dissociated from the E-cadherin and catenin complex accumulated in the cytoplasm. Part of β-catenin translocates to the nucleus and binds to TCF to activate transcription of key genes required for survival of detached cells, while the other part of β-catenin is modified by phosphorylation and ubiquitination, leading to proteosome degradation. The Wnt pathway promotes β-catenin signaling by repressing the phosphorylation of β-catenin mediated by GSK-3β.

Reduced E-cadherin levels in cancer cells are accomplished by genetic events such as somatic mutation and reduced gene expression mediated by repressor proteins or by methylation of the promoter region of the E-cadherin gene. The genetic defects of E-cadherin have been found in human lobular breast carcinomas and scirrhus-type ►gastric cancers, both of which have highly metastatic potentials. Mutations of β-catenin also promote migration and ►invasion of cancer cells by the loss of interaction of adherens junctions with the actin cytoskelton.

Distributions of E-cadherin and β-catenin tend to change depending on sites of tumor remodeling. In epithelial structures in the centre of cancer, E-cadherin and β-catenin are mostly present in adherens junctions. However, solitary cells at the invasive front of cancer plates shows no signal for E-cadherin but often produce signals for nuclear β-catenin. Thus, decreased E-cadherin expression promotes the release of solitary cancer cells at the invasive front and increases the survival of cancer cells by stimulating β-catenin signaling.

Strategy for restoring adherens junctions, as well as cell–cell and cell–matrix communication may prevent cancer-cell invasiveness. Therapeutic targets might be molecules involved in pathways affecting the adhesive properties of E-cadherin and the assembly of the adherens-junction complex: c-Src and other tyrosine kinases, tyrosine phosphatases such as PTP-LAR, Rho, Rac, and Rap small G-proteins, transcriptional repressor proteins, and ►merlin and the ►ERM proteins. For example, c-Src regulates both disruption of adherens junctions and focal-adhesion turnover that are required for cancer cell motility. Twist is highly expressed in human cancers with reduced E-cadherin mRNA expression levels. In contrast, podoplanin promotes cancer cell invasion in the absence of EMT, suggesting cancer cells can also migrate as a mass, not necessarily as a single cell. Restoring E-cadherin-mediated cell adhesion could be means of preventing EMT in cancer and metastasis although EMT is not essentially required for cancer-cell invasion.

Adhesion

Dario Rusciano
Friedrich Miescher Institute, Basel, Switzerland

Definition

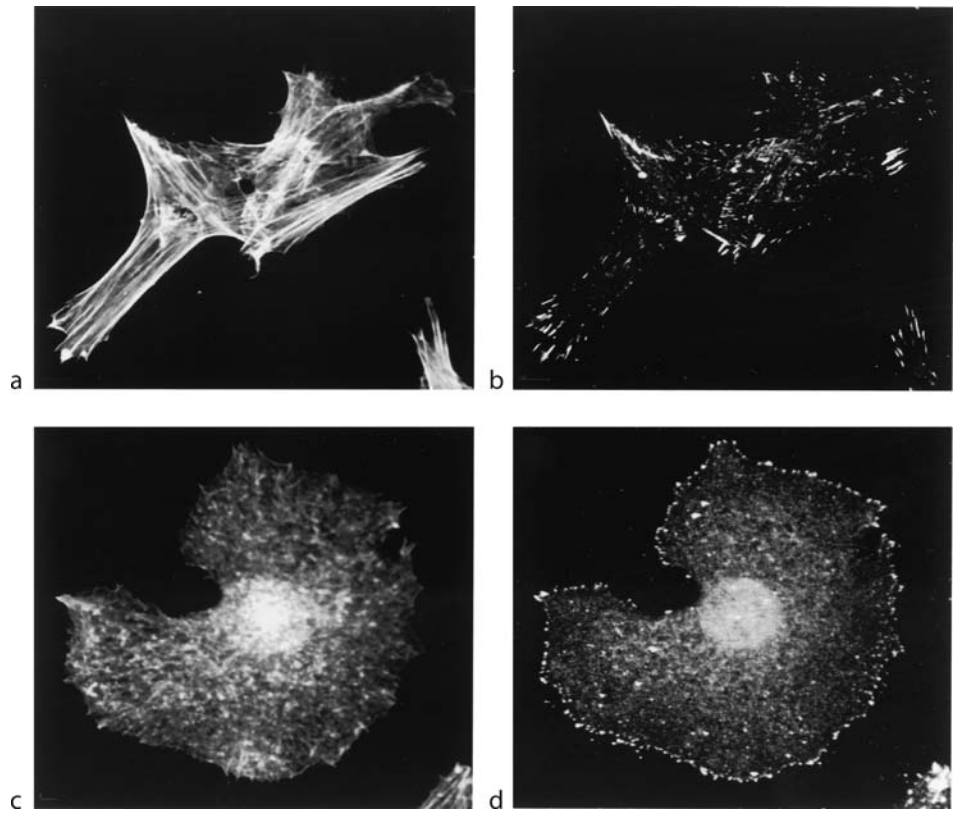
Cell adhesion is a dynamic process that results from specific interactions between cell surface molecules and their appropriate ligands. Adhesion can be found between adjacent cells (cell-cell adhesion) as well as between cells and the ►extracellular matrix (ECM) (cell-matrix adhesion). Besides keeping a multicellular organism together, cell adhesion is also a source of specific signals to adherent cells; their phenotype can thus be regulated by their adhesive interactions. In fact, most of the cell adhesion receptors were found to be involved in ►signal transduction. By interacting with growth factor receptors they are able to modulate their signaling efficiency. Therefore, gene expression, cytoskeletal dynamics and growth regulation all depend, at least partially, on cell adhesive interactions (Fig. 1).

Characteristics

Cell Adhesion Receptors

Cell adhesion molecules were grouped into distinct classes according to structural and/or functional homologies. The following receptors have been directly implicated in the malignant phenotype of tumor cells.

- Integrins represent a family cell surface ►glycoproteins that depend on divalent cations and are important in cell-ECM and cell-cell adhesion. The non-covalent association of an alpha and a beta subunit results in heterodimers that span the plasma membrane, enabling contacts with elements of the ►cytoskeleton and signal transducing intermediates.
- The immunoglobulin superfamily of adhesion receptors is mainly involved in cell-cell adhesion. Named after a 90–100 amino acid domain that is also present in Ig molecules, these kind of receptors can be expressed either as plasma membrane-spanning molecules. However, some of them are alternatively spliced and are anchored to the cell membrane by covalent linkage to phosphatidylinositol.
- ►Selectins represent a class of structurally related monomeric cell surface glycoproteins that bind specific carbohydrate ligands via their ►lectin-like domains. Since the ligands are expressed in a specific way by vascular endothelial cells, selectins are important in lymphocyte trafficking and homing of malignant tumor cells.
- Cell surface ►proteoglycans consist of ►glycosaminoglycans (GAG) attached to core proteins through



Adhesion. **Figure 1** Cell adhesion in normal (a, b) and cancer (c, d) cells. Normal mesenchymal cells show regular actin stress fibers (a: stained with phalloidin) and focal contacts (b: stained with anti-vinculin antibodies). In contrast, cancer cells (a highly motile melanoma cell is shown) often present with a completely disorganized actin cytoskeleton (c) and few focal contacts (d). Vinculin is typically arranged in patches at the periphery of the cell (d) (Confocal micrograph courtesy of Dr. Jörg Hagmann, FMI, Basel).

an O-glycosidic linkage. They can mediate cell-cell and cell-ECM adhesion.

- ►CD44 comprises a large family of proteins generated from one gene by alternative splicing. Variants of CD44 (CD44v) differ from the standard form (CD44s) by their implementation of ten variant exons in various combinations. Some variants have been causally related to the metastatic spread of some tumor cells. Among the ligands for CD44 are hyaluronic acid (HA), fibronectin and collagen, and chondroitin sulfate-modified proteins.
- ►Cadherins are surface glycoproteins involved in cell-cell interactions. They are involved in the formation of adherens-type functions between cells. Through their cytoplasmic tail they interact with catenins, which are important for the signal transducing ability of cadherins.
- ►Connexins are gap junction-forming proteins that oligomerize into specialized intercellular channels, connecting apposing plasma membranes. They allow the exchange of low molecular weight metabolites such as second messengers that are important in signal transduction (Table 1).

Adhesion and Cancer

The selective adhesion of one cell to another or to the surrounding ECM, is of paramount importance during embryonic development as well as for the maintenance of normal adult tissue structure and function. Severe perturbations of these interactions can be, at the same time, cause and consequence of malignant transformation and also play a fundamental role during malignant progression and metastatic dissemination (Fig. 1).

- Adhesion to the ECM through integrin receptors is important for anchorage dependent cell growth and cell survival. Normal cells that are detached from the ECM are locked in the G1 phase of the cell cycle (by loss of activity of the cyclinE/cdk2 complex) and undergo apoptosis (anoikis). Transformed cells, in which integrin signaling is altered, acquire the ability to grow in suspension and do not succumb to anoikis.
- Adhesion to neighboring cells, mediated by cell-cell adhesion molecules (e.g. N-CAM and C-CAM) and by gap-junctions, inhibits growth of normal cells (what is commonly known as "contact growth inhibition"). Loss of these contacts due to the

disrupted function of the relative adhesion molecules may result in uncontrolled proliferation.

- The differentiated state of mature cells (their "identity") is also maintained through specific adhesion to the ECM and adjacent cells: a loss of identity is thus a likely consequence if specific contacts are lost, finally resulting in the ambiguous phenotype of many tumor cells (Fig. 2).

Certain genes that code for cell adhesion molecules may therefore be considered as ►tumor suppressor genes or even ►metastasis suppressor genes since their loss or a functional mutation can strongly contribute to the acquisition of the malignant phenotype.

Adhesion in Metastasis

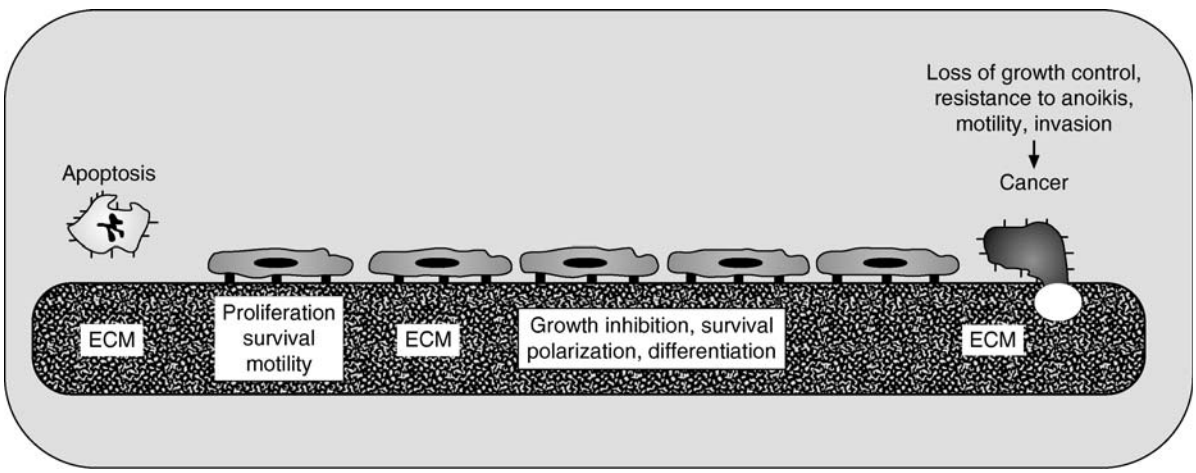
Adhesive interactions play a very critical role in the process of metastatic tumor dissemination, and the abnormal adhesiveness that is generally displayed by tumor cells appears to contribute to their metastatic behavior. Both positive and negative regulation of cell adhesion are required in the metastatic process, since metastatic cells must break away from the primary tumor, travel in the circulation where they can interact with blood cells and then adhere to cellular and extracellular matrix elements at specific secondary sites.

Adhesion within The Tumor Mass

The majority of normal adult cells are restricted by compartment boundaries that are usually conserved during the early stages of development of a tumor. Therefore, the detachment of malignant cells from the primary tumor is an essential step for the initiation of the metastatic cascade. During ►tumor progression changes on the cell surface that lead to a weakening of the cellular constraints, contribute to the release of such mutant cells

Adhesion. Table 1 Adhesion receptors

Family	Main members	Type of adhesion
Integrins	Characterized by the different α- and β-subunits	Cell-ECM cell-cell
IgG superfamily	ICAM-1, V-CAM, N-CAM, CD2 (LFA2), LFA3, CD4, CD8, MHC (class I and II)	Cell-ECM cell-cell
Cadherins	E, P, L	Cell-cell (adherens junction)
Selectins	E, P, N	Cell-cell
Connexins	26 (tumor suppressor) 32 (liver) 43 (glial cells)	Cell-cell (gap junctions)
Cell surface proteoglycans	Syndecan, glypican	Cell-ECM cell-cell
CD44	CD44s, CD44v	Cell-ECM cell-cell



Adhesion. Figure 2 Cell adhesion and maintenance of a normal differentiated phenotype: Detachment of a normal cell from the extracellular matrix (ECM) would normally lead to apoptosis. Normal cells that keep contact with the ECM are protected from apoptosis and may migrate and grow. Normal cells tend to be organized as sheets onto the ECM, which contributes to their polarization and differentiation. Extensive intercellular contacts among cells adhered onto the ECM lead to contact-mediated growth inhibition. Tumor cells do not undergo apoptosis when detached from the ECM and may grow, migrate and invade into the matrix, to enter the circulation and give rise to distant metastases.

from the primary tumor mass. Indeed, it was found that tumor cells separate more easily from solid tumors than normal cells from corresponding tissues.

- Cadherin expression has been shown to influence intercellular cohesion in direct correlation with invasive behavior. An increased cadherin expression in tumor lines, generally causes a tighter association of tumor cells. In vitro experiments have shown that cells which do not express cadherins or in which cadherins are functionally inhibited are more invasive than cells with normal cadherin activity. In cases where E-cadherin was involved, re-introduction of a wild type copy of the gene could revert the invasive phenotype. The loss of cadherin activity however, is not sufficient to make cells invasive. ►Invasion also requires other cellular activities, such as ►motility and protease production. In vivo, tumors expressing low levels of cadherins tend to be less differentiated and to exhibit higher invasive potential, although they are not necessarily more metastatic. In human cancer, a reduction in cadherin activity correlates with the infiltrative ability of tumor cells, a correlation that in many tumors is also retained in distant metastasis.
- A different type of cellular constraint is provided by gap junction communication. Gap junctions play an essential role in the integrated regulation of growth, differentiation and function of tissues and organs. The disruption of gap junction communication can cause irreversible damage to the integrity of the tissue and finally contribute to tumor promotion and malignant progression by favoring local cell isolation. There is experimental evidence that a loss of intercellular junction communication affects the metastatic potential of cell lines. Normal cells use gap junctions to control the growth of tumor cells. Once gap junctional communication is lost, the signaling mechanism responsible for the exertion of such growth control is also lost. Both quantitative and qualitative changes in gap junction protein (connexins) expression were found to be associated with tumor progression during multistage skin carcinogenesis in the mouse model system as well as with tumorigenesis in a rat bladder tumor cell line.

Malignant Tumor Cells in the Blood Stream: Adhesion to Blood Cells and Platelets

Blood-borne tumor cells undergo various homotypic and heterotypic interactions, the effect of which will also influence their metastatic behavior. Some of these interactions may be detrimental to circulating tumor cells such as tumor cell recognition by natural killer (NK) cells, or by tumor infiltrating lymphocytes (TIL). Others may provide, to a certain extent, a protective effect and/or contribute to metastatic spreading, such as interactions with platelets or, in certain cases, with leucocytes.

- De novo expression of the cell adhesion molecule ICAM-1 by melanomas might lead to heterotypic adhesion between melanoma cells and leukocytes bearing the relative receptor (LFA-1). Such interaction might thus enhance tumor cell adhesion to migratory and invasive leukocytes, thereby contributing to further dissemination of malignant tumor cells. In this regard, it has been suggested that site specificity of cancer metastasis might be, at least partially, a consequence of the formation of "multicellular metastatic units" (MSU) consisting of tumor cells, platelets and leukocytes. A subset of leukocytes within the "MSU" would be responsible for site-specific endothelium recognition, adhesion and stable attachment, thus serving as "carrier cells" targeting the metastatic "spheroids" to specific sites of secondary tumor foci formation.
- Several lines of evidence have provided strong support for the concept that tumor cell-platelet interaction significantly contributes to hematogenous metastasis. Two categories of molecules can trigger tumor cell induced platelet aggregation (TCIPA) and activation; soluble mediators and adhesion molecules. The latter are likely to be responsible for the initial contact between tumor cells and platelet cells, and might later stabilize the interaction. P-selectin and αIIbβ3 integrin on the platelet surface may bind Lex carbohydrate determinants and fibrin on the surface of tumor cells, thus triggering platelet activation. Sialylation appears to be a general requirement for TCIPA, and ►sialoglycoconjugates present on both tumor cells and platelets have been involved in tumor cell-platelet interactions. Mechanistically, platelets may contribute to metastasis by stabilizing tumor cell arrest in the vasculature, shielding tumor cells from physical damage, providing additional adhesion mechanisms to endothelial cells and subendothelial matrix, and serving as a potential source of growth factors. If tumor cell interaction with host platelets occurs while tumor cells are circulating, an organ-specific colonization ability of blood-borne tumor cells may be influenced. In fact, the resulting embolus will be more easily arrested in the vasculature of the first organ downstream from the primary tumor site. If this organ represents a favorable milieu for tumor growth, then interaction with platelets will enhance tumor metastasis at that site; if this is not the case, it may prevent tumor cells from reaching their preferred organ and thus cause a reduction of the metastatic potential. It seems, however, that in most cases platelets are involved only after tumor cells have arrested, and platelet activation may then stabilize the initial tumor cell arrest in the microvasculature.

Adhesion in the Target Organ

Circulating tumor cells, either as single cells or most likely as homotypic and/or heterotypic aggregates that have escaped killing by the host immune system and lysis by mechanical shear forces associated with passage in the blood stream, need now to arrest in the microvasculature and extravasate into the organ parenchyma. In fact, the survival time of tumor cells entering the circulation is very short, usually less than 60 min. Therefore those cells that can rapidly arrest and are able to get out the blood stream might have a selective advantage in giving rise to metastatic colonies.

Specific adhesion in the target organ has been proposed as a critical determinant of organ specific metastasis, and experimental data indicates that malignant tumor cells preferentially adhere to organ-specific adhesion molecules. Tumor cells, for instance, adhered more efficiently to disaggregated cells or to histologic sections prepared from their preferred site of metastasis than from other organs. These type of assays, however, do not accurately mimic the physiological situation in vivo, where the first contact of circulating tumor cells happens with the luminal surface of the vascular endothelium, and, after endothelial retraction, with the subendothelial ►basement membrane.

Adhesion to Endothelial Cells (EC)

The arrest of tumor cells in the capillary bed of secondary organs and their subsequent extravasation occur through interactions with the local microvascular endothelium and the subendothelial matrix.

- Biochemical heterogeneity of EC is related to both the heterogeneous microenvironment within tissues and the size of the vessel. Heterogeneity is seen in the differential expression of plasma membrane glycoproteins, cytoskeletal proteins and surface receptors in microvascular endothelium of different organs. Such heterogeneity of endothelium underscores the importance of using organ-specific capillary endothelium in studying the role of organ-specific tumor cell adhesion in metastasis.
- The specificity of the adhesive interactions that depends on the heterogeneity of microvascular EC and tumor cells, may favor, in a selective way, the initial adhesive events in preferred metastatic sites. As a consequence it may also facilitate metastatic dissemination to those organs, in a way that is similar to extravasation of lymphocytes from high endothelial venules of lymphoid tissues. Infact, lymphocyte "homing" represents the paradigm for organ-specific cell adhesion and it has been shown to follow specific interactions between surface "homing" receptors on lymphocytes with vascular "addressins" expressed on the high endothelial venule surface. In a similar way, tumor cells express various combinations of cell surface molecules that may serve as ligands for EC surface receptors, which are typically induced upon stimulation by mediators of inflammation. A local inflammatory response might thus facilitate circulating tumor cells adhesion and arrest. The relevance of this type of interaction in directing tumor metastasis has been recently demonstrated in vivo using strains of transgenic mice that constitutively express cell surface E-selectin either in all tissues or in the liver alone. Metastatic tumor cells that do not express the ligand, colonized mostly the lung. However, following the induction of ligand expression, tumor cell colonization was redirected to the liver with tremendous efficiency.

Adhesion to Extracellular Matrix Components

Mammalian organisms are composed by a series of tissue compartments separated from one another by two types of extracellular matrix (ECM): basement membranes and interstitial stroma. ECM consists of three general classes of macromolecules, including collagens, proteoglycans and non-collagenous glycoproteins (such as fibronectin, laminin, entactin and tenascin among others), which are expressed in a tissue-specific fashion.

Malignant cells arrested in the microcirculation sometimes do not migrate further into the organ parenchyma but grow locally in an expansive fashion until they rupture the vessel wall. In most cases however, the contact between tumor cells and the endothelium results in EC retraction with exposure of the underlying basement membrane, followed by invasion of tumor cells in the tissue.

The presence of specific adhesion receptors on the membrane of metastatic cells, and the peculiar composition of the extracellular matrix at a given site will influence tumor cell retention, motility and invasion, and growth at target organs.

- Electron microscopy observation on the formation of pulmonary metastasis has shown that tumor cells often adhere to regions of exposed basal lamina. The exposed subendothelial matrix is usually a better adhesive substrate for tumor cells than the endothelial cell surface.
- In order to move through the ECM, tumor cells must make firm contacts with matrix molecules, be able to break these adhesive contacts as they move on and respond to chemotactic molecules that direct their movement. Interactions with the ECM may fulfill all these scopes, through the signaling effect of several cytokines (growth factors, motility factors, enzymes and enzyme inhibitors) that are stored bound to ECM molecules, and released upon interaction with tumor cells. Moreover, ECM macromolecules themselves may also function as motility attractants, and have

been shown to stimulate both ►chemotaxis and ►haptotaxis. Haptotactic migration over insoluble matrix components may occur predominantly during the initial stages of metastatic invasion, while at later stages partially degraded matrix proteins, derived from proteolytic processing of the matrix, could be the major determinant of directed motility.

- Finally, it has to be considered that some ECM components may actually impede cell adhesion and thus might influence directional tumor cell motility by promoting the localized detachment of the trailing edge of migrating cells. ECM-associated chondroitin sulfate proteoglycans such as decorin, or the glycoprotein tenascin, have been suggested to modulate tumor cell adhesion and motility in this way.

Adhesion and Drug Resistance

The malignant phenotype of tumor cells depends, at least partially, on the weakening of cell-matrix and cell-cell interactions that occurs during tumor progression. However, late stage tumors maintain some level of intercellular adhesion, or even tend to reactivate certain adhesion mechanisms, indicating that modulation of cell adhesion is a dynamic process. Given the beneficial effect of cell adhesion on apoptosis resistance, an increased level of adhesion may facilitate survival of tumor emboli, and there is evidence that it can help tumor cells to evade the cytotoxic effects of anticancer therapy.

Adhesion Molecules

Definition

Are transmembrane cell adhesion proteins which extend across the cell surface ►membrane and typically have domains that extend into both the extracellular space and the intracellular space. The extracellular domain of a cell adhesion protein can bind to other molecules that might be either on the surface of an adjacent cell (cell-to-cell adhesion) or part of the ►extracellular matrix (cell-to-ECM adhesion).

Definition

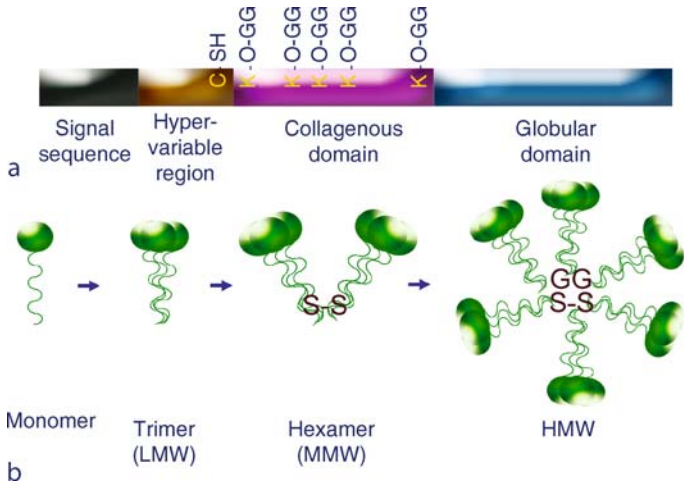
Adiponectin is a major ►adipokine secreted exclusively from adipocytes. This adipokine has been demonstrated to possess antidiabetic, antiatherogenic, antiinflammatory and, more recently, antitumorigenic properties.

Characteristics

Adiponectin was originally identified as an adipose-specific gene dysregulated in ►obesity. Human adiponectin gene is located on chromosome 3q27 and encodes a 244 amino acids polypeptide comprising of an NH_2-terminal secretory signal sequence, followed by a hypervariable region, a collagenous domain, and a COOH-terminal globular domain (Fig. 1a). Circulating concentrations of adiponectin range from 3 to 30 μg/ml, which accounts for about 0.05% of total human blood proteins. Endogenous adiponectin is predominantly present as several characteristic oligomeric complexes. The basic building block of the adiponectin complex is a trimer or low molecular weight (LMW) oligomer, which is formed via hydrophobic interactions within its globular domain. Two trimers self-associate to form a disulfide-linked hexamer or middle molecular weight (MMW) oligomer, which further assembles into a bouquet-like high molecular weight (HMW) multimeric complex that consists of 12–18 monomers (Fig. 1b). Posttranslational modifications, including disulfide bond formation at a conserved cysteine residue and glycosylations occurred on several hydroxylated lysine residues within the collagenous domain, are involved in the assembly and stabilization of the



Adiponectin. Figure 1 Schematic representation of the primary structure (a) and the oligomeric complexes of adiponectin (b). Adiponectin contains a NH_2-terminal signal sequence peptide and a hypervariable region, followed by a conserved collagenous domain and a COOH-terminal globular domain. A cysteine residue within the hypervariable region is involved in the disulfide bond formation. Several lysine residues located within the collagenous domain are hydroxylated and glycosylated. (b) Adiponectin exists as three oligomeric species, including the trimer (LMW), hexamer (MMW), and HMW. Disulfide bond formation and glycosylation are involved in its oligomeric formation. GG, glucosylα(1–2)galactosyl group; S−S, disulfide bonds.

oligomeric structures. Different oligomeric complexes of adiponectin activate distinct signaling pathways and possess different biological functions.

Two putative adiponectin receptors, termed AdipoR1 and AdipoR2, have recently been identified. AdipoR1 is highly expressed in skeletal muscle whereas AdipoR2 is most abundantly expressed in liver. Both receptors are integral membrane proteins containing seven transmembrane spanning domains. AdipoR1/R2 mediates the effect of adiponectin on activation of ►AMP-activated protein kinase (AMPK) and stimulation of glucose uptake and fatty acid oxidation. T-cadherin, which is highly expressed in endothelium and smooth muscle, has been identified as an adiponectin coreceptor with preference for hexameric and HMW adiponectin multimers. Both adiponectin analogues and adiponectin receptor agonists represent the potential therapeutic targets for obesity-linked diseases.

Adiponectin and Carcinogenesis

Although adiponectin is secreted exclusively from fat cells, the circulating adiponectin levels are paradoxically reduced in obese individuals and obesity-related pathological conditions, such as ►insulin resistance, type 2 diabetes, and atherosclerosis. Adiponectin has been proved to have insulin-sensitizing, antidiabetic, and antiatherogenic activities. In addition, growing evidence has demonstrated adiponectin to be a potent inhibitor of carcinogenesis. Numerous clinical studies have observed an inverse association between blood adiponectin concentrations and risks of several ►obesity-related cancers, such as ►prostate, ►breast, ►endometrial, ►gastric, and ►colorectal cancers.

Prostate Cancer

Obesity is associated with prostate cancer progression, increased tumor aggressiveness, and poor prognosis. Higher plasma adiponectin is associated with a marked reduction in risk of prostate cancer, independent of other risk factors. Additionally, blood adiponectin levels in those with high-grade prostate cancer are significantly lower than those in the low-grade and intermediate-grade groups, suggesting that plasma adiponectin levels are negatively associated with the histologic grade and disease stage of prostate cancer. Adiponectin has been shown to inhibit leptin- and/or ►insulin-like growth factor-1 (IGF-1)-stimulated DU145 androgen independent prostate cancer cell growth and dihydrotestosterone-stimulated growth of androgen-dependent LNCaP-FGC cells at subphysiological concentrations. In addition, adiponectin enhances the inhibitory effects of the cytotoxic chemotherapy agent, doxorubicin, on prostate cancer cell growth. These data suggest that adiponectin could play an important role in the pathogenesis of prostate cancer, and may be used as a drug target for therapeutic interventions.

Breast Cancer

Excess adiposity over the pre- and postmenopausal years is an independent risk factor for the development of breast cancer, and is associated with late-stage disease and poor prognosis. Clinical studies have shown that low plasma adiponectin levels are significantly associated with an increased risk for breast cancer in both pre- and postmenopausal women, particularly in a low estrogen environment. Moreover, tumors from women with low plasma adiponectin levels are more likely to show a biologically aggressive phenotype. In line with these clinical findings, experimental evidence supports the role of adiponectin as an inhibitory factor for breast cancer development. Adiponectin at physiological concentrations suppresses the proliferation and induces ►apoptosis in the ►estrogen receptor (ER)-negative human breast carcinoma MDA-MB-231 cells and the ER-positive human MCF7 breast cancer cells. It also inhibits insulin- and growth factors-stimulated cell growth in another ER-positive T47D human breast cancer cells. Furthermore, adiponectin replenishment therapy suppresses mammary tumorigenesis of MDA-MB-231 cells in nude mice.

Endometrial Cancer

Adiponectin is decreased in obesity, insulin resistance, type 2 diabetes, and polycystic ovary syndrome, all of which are well-established risk factors for endometrial cancer. Several case-control studies have demonstrated an inverse correlation between plasma levels of adiponectin and the risk of endometrial cancer, independent of other obesity-related risk factors as well as the major components of the IGF system. Moreover, a stronger inverse association is observed among obese women than among nonobese women. Further studies are needed to investigate whether adiponectin deficiency plays a causative role in the pathogenesis of endometrial cancer.

Gastric and Colorectal Cancer

Low plasma levels of adiponectin have been observed in patients with gastric cancer, especially in those with upper gastric cancer. Furthermore, plasma adiponectin levels tend to decrease as the tumor size, depth of invasion, and tumor stage increases. Additionally, the negative correlation is more significant in undifferentiated forms than in differentiated forms of gastric cancers. These data raise the possibility that adiponectin might play a potential role in the progression of gastric cancer, especially in the upper stomach.

Although colorectal carcinogenesis is related to abdominal obesity and insulin resistance, the associations between low adiponectin levels and colorectal cancer are not conclusive. Two independent studies have suggested that men with low plasma adiponectin levels have a higher risk of colorectal cancer,

whereas another report does not support this association. Moreover, adiponectin has been reported to have growth-promoting and proinflammatory actions on HT-29 colonic epithelial cancer cells.

Leukemia

Adiponectin inhibits cell proliferation and induces apoptosis in myelomonocytic cell lines. Decreased levels of plasma adiponectin have been found to be associated with ►childhood acute myeloblastic leukemia (AML), but not with ►acute lymphoblastic leukemia of B (ALL-B) or T (ALL-T) cells. Adiponectin levels are also reported to be inversely associated with ►chronic lymphocytic leukemia and myeloproliferative diseases. However, it is worthy to note that adiponectin concentrations can be modulated by various inflammatory cytokines and interferon therapy in these conditions. Thus, whether low adiponectin level is a causal factor of leukemia, or a secondary response to ►inflammation, needs to be further clarified.

Mechanisms

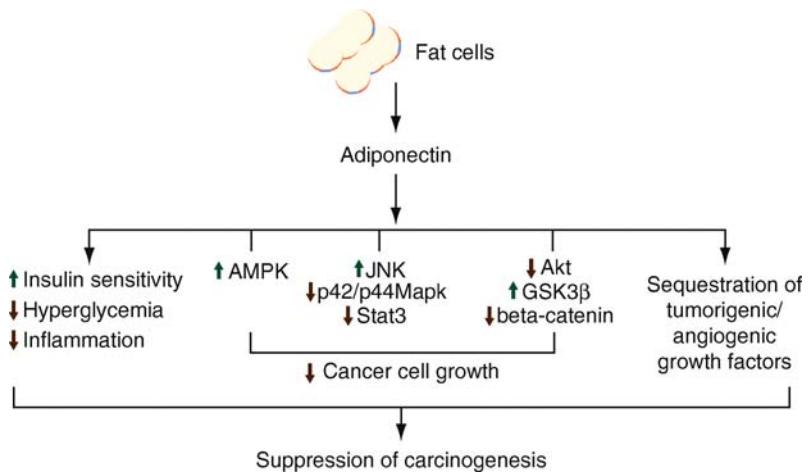
As summarized above, both clinical and experimental evidence support the role of adiponectin as a suppressor of tumorigenesis. Adiponectin has direct antiproliferative effects in a number of cancer cell lines. Although the underlying mechanisms remain poorly understood, adiponectin has been shown to modulate several intracellular signaling cascades involved in regulating cell proliferation and apoptosis (Fig. 2).

AMPK

The phosphorylation-dependent activation of ►AMPK is the major signal transduction pathway evoked by adiponectin. AMPK mediates the insulin-sensitizing effects of adiponectin in liver and muscle. It is also involved in the regulatory activities of adiponectin on endothelial cell functions and cardiac remodeling. AMPK is a negative regulator on cell growth. The upstream kinase LKB1 that activates AMPK is a ►tumor suppressor. ►Tuberous sclerosis complex 2 (TSC2), another tumor suppressor, is downstream of AMPK and a key player in regulation of the ►mammalian target of rapamycin (mTOR) pathway. Through inactivation of ►mTOR, AMPK negatively regulates protein synthesis and de novo fatty acid synthesis, two essential elements for rapid cancer cell growth. In addition, AMPK controls phosphorylation and activation of the ►P53 tumor suppressor and expression of the cell cycle inhibitor ►p21. These molecular events might represent the potential mechanisms through which adiponectin regulate carcinogenesis. Indeed, it has been reported that adiponectin at subphysiological concentrations can induce AMPK phosphorylation and reduce the cell growth in human breast cancer MCF-7 cells.

c-Jun N-Terminal Kinase (JNK) and Signal Transducer and Activator of Transcription 3 (STAT3)

Both ►JNK and STAT3 are the important regulators of cell proliferation, apoptosis, and differentiation in various physiological and pathophysiological conditions. Constitutive activation of STAT3 is crucial in malignant transformation and cancer progression. It has been reported that adiponectin stimulates the phosphorylation of JNK in prostate cancer DU145, PC-3, and LNCaP-FGC cells, as well as in hepatocellular carcinoma HepG2 cells. On the other hand, adiponectin inhibits constitutive activation of STAT3 in DU145 and HepG2 cells, suggesting that activation of JNK and inhibition of STAT3 may contribute to the suppressive effect of adiponectin on carcinogenesis. In addition, the inactivation of p42/p44



Adiponectin. Figure 2 Adiponectin elicits its antitumorigenic activities through multiple mechanisms.

MAP kinase has been implicated in the antiproliferative effects of adiponectin in human beast carcinoma MCF-7 and T47D cells.

Glycogen Synthase Kinase (GSK) 3β/β-Catenin Signaling Pathway

Hyperactivation of the canonical ►Wnt/β-catenin pathway is one of the most frequent signal abnormalities in many types of cancers. The central event in this pathway is the stabilization and nuclear translocation of β-catenin, where it binds to the transcription factor TCF/LEF and consequently activates a cluster of genes that ultimately establish the oncogenic phenotype. β-catenin is phosphorylated by GSK3β and then modified by ►polyubiquitination for ►proteasome-mediated degradation. Adiponectin could modulate the GSK3β/β-catenin pathway in human breast cancer cells. In MDA-MB-231 cells, prolonged treatment with adiponectin markedly reduces serum-induced phosphorylation of GSK3β, decreases intracellular accumulation and nuclear translocation of β-catenin, and suppresses ►cyclin D1 expression. These effects can be inhibited by inhibitors of GSK3β. These data suggest that the cross-talk between adipokines and the Wnt signaling pathway might represent a key mechanism underlying the development of obesity-related cancers.

Other Pathways

In addition to its direct suppressive effect on cancer cell proliferation, as an insulin-sensitizing hormone, adiponectin could ameliorate tumorigenesis indirectly by alleviating ►hyperglycemia and insulin resistance, the two established risk factors for many obesity-related cancers. Furthermore, adiponectin possesses antiinflammatory activity and can inhibit the production of a number of inflammatory factors involved in promoting tumorigenesis, such as IL6, IL8, TNFa, and MCP-1. There is also evidence supporting the anti ►angiogenesis activity of adiponectin. It inhibits tumor neovascularization in mice, through suppression of endothelial cell proliferation, migration, and tubular formation. Moreover, adiponectin can act as a decoy for several proangiogenesis growth factors, including basic fibroblast growth factor (bFGF), platelet-derived growth factor BB (PDGF-BB), and heparin-binding epidermal growth factor (HB-EGF). In this manner, adiponectin prevents these growth factors from activating their respective receptors and effectively impedes their tumor-promoting activities.

In summary, both experimental and clinical evidences support the suppressive role of adiponectin in tumorigenesis. In humans, adiponectin deficiency is closely associated with increased risks of several obesity-related cancers. Therefore, adiponectin and its agonists might represent a novel class of the anticancer agent for the treatment of these malignant tumors. Further studies are warranted to investigate the prospective associations between plasma adiponectin levels and the risk of several obesity-related cancers, and to elucidate the detailed molecular events underlying the antitumor activities of adiponectin.

Synonyms

Lipomatous tumors; Adipocytic tumors; Lipomas; Liposarcomas

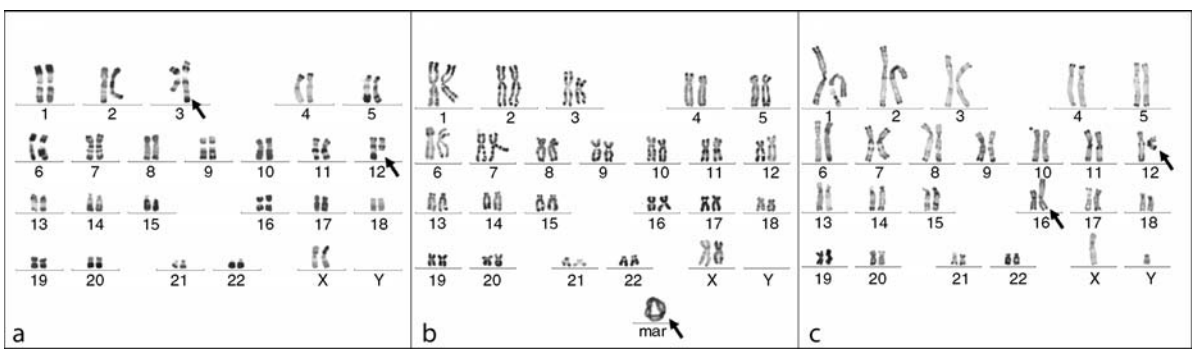
Definition

Adipose tumors (AT) are mesenchymal neoplasms that form the largest group of human tumors. They include benign tumors, such as the very common lipomas, as well as rare malignant tumors with various degrees of clinical aggressiveness. Histologically, AT consist of adipocytic cells showing different levels of differentiation, from mature adipocytes in benign lipomas up to undifferentiated lipoblastic cells in high-grade ►liposarcomas. The 2002 World Health Organization classification distinguishes seven entities of benign AT: lipoma, lipoblastoma/lipoblastomatosis, angiolipoma, myolipoma of soft tissue, chondroid lipoma, spindle cell/pleomorphic lipoma, and hibernoma. Malignant AT, also called liposarcomas, include three types: well differentiated liposarcoma/dedifferentiated liposarcoma, ►myxoid/round cell liposarcoma, and pleomorphic liposarcoma. Except for the ordinary superficial lipomas, differential diagnosis between benign and malignant AT and between AT and other kinds of tumors is sometimes difficult. Studies based on tumor karyotypes have identified chromosomal abnormalities specific to benign and malignant AT and recent advances in molecular cytogenetics improved AT diagnosis. It is now possible to directly detect the genic rearrangements resulting from chromosomal alterations on interphase nuclei such as those in formalin-fixed and paraffin embedded tumor tissue sections using fluorescence in situ hybridization (FISH) (►interphase cytogenetics) or polymerase chain reaction (PCR).

Characteristics

Benign Adipose Tumors

The most common benign AT are the so-called superficial "conventional lipomas." The other types of benign AT are rare and may be the cause of diagnostic difficulties because of their clinical or histological resemblance to malignant soft tissue tumors. In most cases benign AT do not require any treatment. Surgical removal may be necessary in case of functional or cosmetic impairment. ►Conventional lipomas are the most common soft-tissue neoplasm in adults. They occur mainly in the 5–7th decades of life and are generally located superficially in subcutaneous fat. They can also be situated deeply in muscles or on the surface of bones or rarely in visceral and other organ sites. Lipomas usually present as a small (<5 cm), well-circumscribed painless mass under the skin of the neck, shoulders, back, arms or thighs. However, almost all subcutaneous anatomical locations have been reported. Occasionally, lipomas can be painful if they grow large or press nearby nerves. Microscopically they are composed of mature adipocytes, which are usually indistinguishable from those observed in normal adipose tissue. Cytogenetic studies have shown that lipomas are characterized by clonal chromosomal aberrations in approximately two thirds of the cases. A majority of these aberrations involve the 12q13–15 region. Such rearrangements are often balanced ►chromosome translocations or inversions that frequently result in fusion of the *HMGA2* gene (12q15), with a variety of partners. The most frequent aberration is the translocation t(3;12)(q28;q15) that fuses *HMGA2* to ►*LPP* (3q28) (Fig. 1a). In lipomas, the *HMGA2* breakpoints are preferentially clustered in the large third intron of the gene. Extragenic breakpoints located 5′ or 3′ to *HMGA2* also have been described. Of note, *HMGA2* is rearranged not only in lipomas but also in several benign mesenchymal tissue tumors such as uterine leiomyomas, pulmonary chondroid hamartomas and chondromas. It has been proposed that the truncation of *HMGA2* might be the critical step in tumorigenicity by inducing derepression of the gene. The importance of the role of *HMGA2* in adipose proliferation has been shown in studies of *Hmga2*-null and heterozygous mice. These mice are resistant to diet-induced or genetic obesity because of the retarded proliferative capacity of preadipocytes. Moreover, several transgenic mouse



Adipose Tumors. Figure 1 Representative RHG-banded karyotypes from a case of lipoma (a), a case of well-differentiated liposarcoma (b) and a case of myxoïd liposarcoma (c). (a) Balanced translocation t(3;12). (b) Supernumerary ring chromosome. (c) Balanced translocation t(12;16). The arrows indicate the abnormal chromosomes.

models have demonstrated that the misexpression of *HMGA2* is sufficient to induce benign mesenchymal tumors such as lipomas. Among conventional lipomas without involvement of chromosome 12, the most frequent rearrangements are translocations involving 6p21–23 in the region of *HMGA1* (6p21), loss of 13q material with breakpoints in 13q12–14 and/or 13q22 and 8q anomalies. However, a variety of other chromosomal aberrations – most often simple structural rearrangements – can be observed in conventional lipomas. ►Spindle cell or pleomorphic lipomas are usually seen in the subcutaneous tissue of the neck and upper trunk of middle-aged men. They are composed of varying amounts of fat cells and bland CD34+ spindle cells present within a background of wiry collagen and myxoid ground substance. Only a few cases have been investigated cytogenetically. The main characteristic features are complete or partial losses of chromosomes 16 and 13. When located in an anatomical site other than neck and shoulders, spindle cell lipomas may be difficult to diagnose. ►Chondroid lipomas have a significant female predilection. Histologically, they consist of mature fat cells, with myxoid, chondroid, and hyalinized areas. Cells contain vacuoles resembling lipoblasts or chondroblasts and stain positively for S100 protein. The differential diagnosis includes myxoid liposarcomas (see below) or extraskeletal myxoid chondrosarcomas, and distinguishing these can be sometimes difficult. Only four cases of chondroid lipoma have been investigated cytogenetically and all showed translocation t(11;16)(q13;p13). ►Angiolipomas are subcutaneous lesions most commonly affecting male in the late teens or early twenties. The most frequent sites of involvement are the forearm, the trunk and the upper arm. Multiple lesions are seen in the majority of cases. The familial prevalence is estimated at 5%. Angiolipomas consist of mature adipocytes and small capillaries often containing fibrin thrombi. The pathogenesis of such lesions is unknown and no specific cytogenetic aberration has been reported to date. ►Hibernomas consist of brown fat and usually occur in young adults. The thigh is the most common location. Hibernomas are cytogenetically characterized by deletions of the long arm of chromosome 11. ►Lipoblastomas are made up of embryonal white fat and occur in the first 3 years of life more frequently in males. However lipoblastomas may occasionally affect older patients. Lipoblastomas most commonly manifest as asymptomatic, circumscribed masses in the superficial or subcutaneous soft tissue of the extremities although less frequent locations including mediastinum, retroperitoneum, trunk, neck and various organs have been reported. In contrast, the diffuse type (diffuse lipoblastomatosis) tends to infiltrate not only into the subcutis but also into the underlying muscle. These lesions are composed of an admixture of lipoblasts and mature adipocytes, organized into lobules separated by fibrous septa. The stroma is myxoid with a plexiform capillary network. Therefore, confusion with myxoid liposarcoma (see below) may occur. Cytogenetic investigations have shown that lipoblastomas are characterized by rearrangements of chromosome bands 8q11–13, with breakage of the *PLAG1* gene. ►Myolipomas of soft tissue are extremely rare benign lipomatous lesions occurring most often in adult females. These lesions are frequently located deeply in the abdominal cavity, retroperitoneum, and inguinal areas. Histologic analyses demonstrate a variable admixture of smooth muscle and mature adipose tissue.

Malignant Adipose Tumors

Liposarcomas are the most common type of soft-tissue sarcoma. They usually present as painless mass, the size of which can be larger than 20 cm. Once the diagnosis is suspected by clinical examination and imaging, complete staging and treatment performed by a experienced multidisciplinary team are required. Treatment usually involves a combination of surgery with preoperative or postoperative radiotherapy. Chemotherapy represents the mainstay of treatment for patients with metastatic disease and can be useful in some cases of localized-tumors. ►Well-differentiated liposarcomas (WDLPS) are the most common type of liposarcomas. They are defined as tumors of intermediate malignancy given their high rate of local recurrence and low rate of metastatic evolution. WDLPS occur almost exclusively in adults with a peak in the early seventh decade. They are frequently located in the deep soft tissues of the limbs, most often the thigh, or the retroperitoneum. WDLPS usually consists of mature fat with a variable number of spindled cells with large hyperchromatic and pleomorphic nuclei and monovacuolated or multivacuolated lipoblasts (immature fat cell). Histologically, WDLPS may be confused with lipomas, especially when lipomas are deep-seated or infiltrating the muscle, or show secondary changes in the form of fibrosis or liponecrosis (Fig. 1b). WDLPS may also be hard to distinguish from spindle cell/pleomorphic lipomas. ►Dedifferentiated liposarcomas (DDLPS) are biphasic neoplasms occurring in the same age group as WDLPS, with one component being a WDLPS and the other a non lipogenic sarcoma of variable histological grade. Dedifferentiation can be observed in primary or recurrent lesions. Distant metastases are observed in 20% of cases of DDLPS, worsening the prognosis in comparison to WDLPS. In case of heterologous differentiation DDLPS, are likely to be confused with a wide range of spindle cell or pleomorphic undifferentiated tumors including fibrosarcomas, malignant peripheral nerve sheath tumors (MPNST), leiomyosarcomas, rhabdomyosarcomas, chondrosarcomas and osteosarcomas. WDLPS and DDLPS share similar cytogenetic features:

they are both characterized by the presence of supernumerary ring or giant marker chromosomes (Fig. 1b). These supernumerary chromosomes contain amplified sequences from the 12q13–15 chromosomal region, including the *MDM2* and *CDK4* genes. The detection of *MDM2* and *CDK4* overexpression or ►amplification using methods such as immunohistochemistry (IHC), real-time PCR or FISH is now recognized to be reliable and useful for identifying WDLPS and DDLPS among benign or malignant tumors. The comparative genomic hybridization analyses on DNA micro-arrays (►array CGH) have been very useful in demonstrating that a susbset of tumors with 12q amplification that were formerly classified as malignant fibrous histiocytoma (MFH) were indeed DDLPS with an exclusive or highly prominent dedifferentiated component. Another characteristic feature of WDLPS/DDLPS supernumerary chromosomes containing 12q amplification is their absence of ►alpha-satellite centromeric sequences. Alpha-satellite negative chromosomes are generally acentric and unstable and are eliminated with successive mitoses. In contrast, WDLPS supernumerary chromosomes are stable and contain a functional centromere called a "►neocentromere." WDLPS is the only example of a tumor type in which the formation of a neocentromere is a recurrent and consistent pathognomonic feature. ►Myxoid liposarcomas and round cell liposarcomas (MRLPS) are the second most frequent subtype of liposarcomas. Histologically, MRLPS are composed of uniform non lipogenic mesenchymal cells with variable numbers of small signet-ring lipoblasts in a prominent myxoid stroma with a characteristic arborizing capillary network. These lesions occur in adults most frequently in the 4–5th decades of life, and are preferentially located in the deep soft tissues of the extremities, such as the medial thigh and popliteal regions. The prognosis is highly related to the proportion of round cells. Metastases occur in 25% of patients with a round cell component of less than 5% and 55% of patients with a round cell component of more than 25%. Cytogenetically, MRLPS are characterized by a specific t(12;16)(q13;p11) translocation which fuses exons 5, 7 or 8 of *FUS* with exon 2 of *DDIT3* (Fig. 1c). A t(12;22)(q13;q12) translocation which fuses exon 7 or exon 10 of *EWS* with exon 2 of *DDIT3* is present in about 5% of the cases (►see fusion genes). Of note, nine molecular variants of the *DDIT3-FUS* fusion transcript have been described, with no demonstrable prognostic effect. MRLPS shows significantly higher response rate to chemotherapy compared to other liposarcomas. ►Pleomorphic liposarcomas (PL) are the least common subtypes of liposarcomas, accounting for only 5–15% of all liposarcomas. PL are characterized by a relatively high malignant potential with metastases present in 30% of cases. PL affect adults older than 50 years of age with no gender predilection and are most frequently located on the lower extremities. They are composed of a variable number of pleomorphic lipoblasts in a background of a high grade pleomorphic sarcoma. The karyotype of PL is usually complex, showing multiple numerical and structural chromosomal alterations. No specific molecular anomaly has been identified so far.

Adjuvant Chemoendocrine Therapy

Lorenzo Gianni, Alberto Ravaioli, Valentina Arcangeli
Department of Oncology, Infermi Hospital, Rimini, Italy and Instituto Scientifico Romagnolo per lo studio e la cura dei Tumori, Meldola (FC), Italy

Synonyms

Adjuvant chemohormonal therapy; Post surgical systemic therapy; Adjuvant cytotoxic and hormonal therapy

Definition

Adjuvant chemoendocrine therapy is a combination of ►chemotherapy and hormonal treatments that may be

administered to patients after surgery for a nonmetastatic tumor with the goal of decreasing the risk of cancer recurrence.

Characteristics

Adjuvant chemoendocrine therapy is potentially useful for tumors which are responsive both to cytotoxic chemotherapy and to hormonal interventions. The growth of these types of tumors is boosted by hormones and usually it may be limited not only by blocking these hormones but also by chemotherapy. Adjuvant chemoendocrine therapy is a standard treatment for early ►breast cancer, while it is experimental in ►prostate cancer, and it is not generally an option in other tumors with possible endocrine responsiveness such as endometrial cancer or ovarian cancer.

Breast Cancer

Surgery generally remains the first step for treating early-stage breast cancer with the goal to remove any visible tumor. Radiotherapy is often offered to patients after surgery, particularly when ►conservative surgery has been performed, to reduce the risk of local recurrence. However, more than half the women with operable disease who receive only surgery, with or without radiotherapy, eventually will die from metastatic disease. This indicates that ►micrometastasis may be present at the time of initial clinical presentation. ►Adjuvant therapy is intended to eliminate potential breast cancer cells lingering in the body: it is an "insurance policy" that may be used even if there is no direct proof that cancer has spread. Together with mammography screening, adjuvant chemoendocrine therapy contributed to the reduction of breast cancer mortality, which has been registered in the past decade in western countries. Adjuvant systemic therapies for breast cancer currently include endocrine therapy, chemotherapy, new ►targeted therapy such as trastuzumab (►Herceptin), which may be differently combined on the basis of the characteristics of the patients and of the tumor.

Adjuvant Hormone Therapy

Breast cancer is generally considered as an endocrine responsive disease. However, sensitivity to hormonal therapy may be quite variable among breast cancer patients. Currently endocrine responsiveness is tested evaluating the presence of ►estrogen receptors (►ER) and progesterone receptors (►PR) with immunohistochemistry on breast tumor sections. Approximately 70% of breast cancers at diagnosis are ER and/or PR positive, with increasing ER positivity according to age. Diseases with strong ER and PR expression may be considered as endocrine responsive, while hormonal treatment will not be useful in tumors with no detectable ER and PR. Endocrine responsiveness may be uncertain for tumors with intermediate or low hormone receptor expression, lack of PR irrespective of ER expression, ►HER-2/neu overexpression, and high number of axillary metastatic lymph nodes.

Hormonal (antiestrogen) therapies either reduce the amount of oestrogen (►Estradiol) in the body or block oestrogen's effects. Different hormonal therapies are currently available and are usually given by pill or, less commonly, by injection: Tamoxifen and other selective estrogen receptor modulators, ►fulvestrant and the ►aromatase inhibitors (anastrozole, letrozole, and exemestane). Besides ►ovarian function suppression may be used for premenopausal patients.

Tamoxifen. Tamoxifen has been the mainstay of hormonal therapy in both early and advanced breast cancer patients for approximately three decades. After binding to the estrogen receptor, it competitively blocks estrogens from binding to tumor cells.

Clinical studies and ►metaanalyses have shown that tamoxifen is effective in all patients with expression of hormone receptors, independently by age or menopausal status and chemotherapy use. Five years of tamoxifen lead to a proportional reduction of the annual recurrence rate of about 40% and of the breast cancer mortality of 31%. Furthermore, local recurrence is decreased and the risk of contralateral breast cancer is reduced by 40–50%. Five years of tamoxifen are more effective than 2 years, while there is no evidence that longer duration would improve results.

The side effects of tamoxifen include a small increased risk of uterine cancer, an increased risk of blood clots, hot flashes, loss of libido, vaginal dryness, vaginal discharge or bleeding, and rarely ocular alterations.

Aromatase Inhibitors (►*AIs*). In contrast with tamoxifen, they act by inhibiting oestrogen synthesis and are effective only in postmenopausal women.

Clinical studies in early breast cancer have shown that AIs are more effective than tamoxifen and improve relapse-free survival when started upfront or after 2–3 years of treatment with tamoxifen rather than continuing tamoxifen. In addition, when used as extended therapy after 5 years of tamoxifen, AIs reduce the risk of recurrence and improve the survival in patients with positive axillary lymph nodes. AIs could be more effective in PR negative tumors and with HER-2/neu overexpression or ►amplification. AIs, in combination with ovarian ablation, are experimental in premenopausal patients.

AIs cause fewer hot flashes, less vaginal discharge, less vaginal bleeding, less endometrial cancer, and venous thromboembolism than tamoxifen; however, they may cause joint and muscle pain, osteoporosis, and an increased risk of bone fracture.

Ovarian Function Suppression. It is the oldest treatment for breast cancer, known from 1889, useful only for premenopausal women. In the past years, it could be induced with surgical oophorectomy or radiotherapy. Surgical oophorectomy causes an immediate and permanent drop in ovarian estrogens production; radiation induced ovarian ablation may be incomplete or delayed in some women, and biochemical verification of ovarian function cessation may be advisable. Injections of Luteinizing hormone-releasing hormone (►LH-RH) agonists are an effective therapeutic alternative with the advantage of reversibility of induced menopause. Chemotherapy may also induce temporary or definitive menopause and this side effect could explain in part the beneficial activity of chemotherapy in women with endocrine responsive disease. Age and type of chemotherapy may influence the likelihood of chemotherapy induced menopause.

In patients with endocrine responsive tumors, ovarian function suppression may be as effective as ►CMF combination chemotherapy; combined hormone therapy with ovarian ablation and tamoxifen may be superior to CMF in the same subset of patients.

Symptoms of menopausal estrogen deprivations are the most common side effects of ovarian function suppression.

Adjuvant Chemotherapy

Chemotherapy is the use of cytotoxic drugs to kill cancer cells. Chemotherapy may be given orally (by mouth) or intravenously (injected into a vein) and is usually given in cycles in an outpatient setting.

The results of different randomized ►clinical trials and metaanalyses have shown that combination adjuvant chemotherapy is more effective than single agent chemotherapy. Chemotherapy including anthracyclines is more effective than others such as CMF. Moreover, adding taxanes (►Paclitaxel or docetaxel) to ►adriamycin or other anthracyclines or the use of ►dose-dense chemotherapy may improve results. Efficacy of adjuvant chemotherapy is greater in younger than older women, but this observation needs to be interpreted on the basis of hormone receptor status of disease.

Adjuvant chemotherapy should start within 12 weeks from surgery; however, different subsets of patients, such as young women with negative hormone receptors could benefit from starting chemotherapy earlier.

Side effects of adjuvant chemotherapy can include fatigue, nausea and vomiting, lowered white blood cell count and a corresponding increased risk of infection, mouth sores, hair loss, and premature menopause. Most of these side effects go away once treatment is stopped and are not long-term. However, long-term effects may occur including heart damage, nerve damage, or secondary cancers.

Planning the Adjuvant Treatment: Adjuvant Chemoendocrine Therapy

If both adjuvant hormone therapy and chemotherapy are active for early breast cancer and have different toxicity profiles, it would seem reasonable to combine them in all patients to improve results. However, the problem is more complex than what it seems. Doctors should take into account many factors in order to tailor the therapy for each patient. Patient's age and general health, menopausal status, risk of breast cancer recurrence, likelihood of tumor response to different therapies and patient's preference are all important items. The main risk factors for the development of metastatic disease after surgery are the involvement of axillary lymph nodes, a poor histological grade, large tumor size, histological evidence of ►lymphovascular invasion, and age. In addition, tumor proliferation rate, the absence of oestrogen and progesterone receptor, and HER-2/neu overexpression or amplification also carries an adverse prognosis. The next important step for better choice of adjuvant therapy should be the evaluation of responsiveness of tumors to different adjuvant therapy. Endocrine responsiveness (see above) is the first target to be determined because it suggests if disease is likely to respond to hormone therapy. However, recent accumulating evidence seems to indicate that adjuvant chemotherapy, in general, and chemotherapy including anthracyclines and/or taxol and docetaxel could be more effective in patients with endocrine unresponsive disease or HER-2/neu overexpression or amplification; on the contrary, the benefit of chemotherapy seems smaller in patients with strong ER and PR expression. Finally, overexpression or amplification of HER-2/neu defines a subset of breast cancer patients who strongly benefit from immunotherapy with the monoclonal antibody trastuzumab. The evaluation of gene-profile expression of tumors could help to improve risk prediction and treatment outcomes, but its successful implementation in clinical practice will depend on the integration with existing clinicopathologic markers and validation on large clinical trials. These evaluations will guide the doctors to choose whether adjuvant treatment is needed and whether it should include only hormone therapy (and what kind of hormone therapy), only chemotherapy, or their combination. Hormone therapy should be offered to all patients with endocrine responsive disease for whom adjuvant treatment is indicated.

For decades, chemotherapy was considered the adjuvant treatment of choice for premenopausal patient, regardless of hormone receptor status. However, metaanalyses showed that, in receptor positive women younger than 50 years, the use of tamoxifen reduces the risk of recurrence and death regardless of the use of chemotherapy. In the same subset of patients, ovarian ablation with or without tamoxifen provides results

similar to CMF and represents an alternative to chemotherapy when the risk of recurrence is low or medium. Women with higher recurrence risk or uncertain endocrine responsiveness should receive a combination of endocrine therapy and chemotherapy. For patients younger than 35 years with endocrine responsive disease receiving chemotherapy, additional endocrine therapies should be considered.

In postmenopausal patients with clear endocrine responsiveness, adjuvant chemotherapy probably adds little benefit to adjuvant hormone therapy. Endocrine treatment should include an AI, either upfront or sequentially after tamoxifen. The concurrent use of AIs and tamoxifen is not useful and should be avoided. Two or three years of tamoxifen followed by 3 or 2 years of an AI, 5 years of an AI upfront, or 5 years of tamoxifen followed by an AI are all possible options. According to St. Gallen Consensus, chemotherapy should be added in patient with high-intermediate risk of recurrence, particularly when endocrine responsiveness is uncertain. We have only limited information from clinical studies about adjuvant treatment for older women. Data from one study suggest that older patients with receptor positive disease benefit even from a short tamoxifen therapy (1 year); in patients with endocrine unresponsive tumors clinical decision about offering them chemotherapy should strongly consider biological age and concurrent diseases; enrollment in clinical trials, if available, should be encouraged. Finally, when both tamoxifen and chemotherapy are to be used, current evidence suggests a sequential treatment: it is preferable to give chemotherapy first and to start tamoxifen after chemotherapy completion. Indeed concurrent tamoxifen seems to decrease effectiveness of chemotherapy and to increase the risk of thrombotic events. At present time it is not known if this modality should be extended to other hormonal treatments such as ovarian ablation and aromatase inhibitors.

Prostate Cancer

Prostate cancer is the most common cancer in European and American men. The growth of prostate cancer cells in most cases is due to ►androgens and these types of tumors may respond to hormonal therapy. The aim of hormonal therapy in prostate cancer is to lower androgen levels or to prevent their action on prostate cancer cells. Hormone interventions for prostate cancer include ►orchiectomy, LH-RH analogs, and antiandrogens and are currently used in advanced prostate cancer. Eventually metastatic prostate cancer develops endocrine refractoriness. Recently, taxotere has been approved for hormone refractory metastatic prostate cancer.

Treatment choices for early prostate cancer are based on clinical and histopathologic factors: clinical stage, tumor grade, and level of ►PSA. For patients undergoing radical surgery, if the resection margins are positive or if there is seminal vesicle or capsular invasion, adjuvant strategy options are radiotherapy or close surveillance until a detectable PSA develops. Adjuvant hormonal treatment is not the standard at this time. Some trials have explored if hormonal therapy after primary treatments (surgery or radiotherapy) is useful, but results are inconclusive and it seems that only patients with positive lymph nodes could have some benefit from these drugs. There are more randomized trials (and one ►metaanalysis) comparing radiotherapy alone versus radiotherapy and hormonal treatment (LH-RH analogs or orchiectomy): the survival seems to be better adding prolonged hormonal therapy to radiotherapy. Adjuvant chemoendocrine therapy is not standard in prostate cancer and is under evaluation in randomized clinical trials.

Adjuvant Effect

Definition

Describes the helper-effect of an (in most cases) immunostimulatory substance or compound. Well-known is the use of Freund adjuvant to enhance the effect of antigens in immunization strategies. If containing immunostimulatory mycobacterial subcomponents Freund adjuvant is referred to as complete Freund adjuvant. Enhances cell-mediated immunity and antibody production.

►Bacillus Calmette-Guérin

Adjuvant Therapy

Charles L. Vogel
Sylvester Cancer Center, School of Medicine, University of Miami, Plantation, FL, USA

Definition

Adjuvant therapy is an auxiliary therapy (e.g. ovarian ablation) administered concomitant with another therapy (e.g. surgery or radiation) in the treatment of primary ►breast cancer.

Characteristics

As defined in Webster's Deluxe Unabridged Dictionary adjuvant is:

- "An assistant"
- "In medicine, a substance added to a drug to aid in the operation of the principal ingredient" (e.g. Freund's adjuvant in immunotherapeutic research)

In clinical cancer research and treatment any therapy that in some way helps another modality is considered an "adjuvant." Most of the time cancer therapy is a multidisciplinary endeavor involving specialists from many treatment modalities. These specialists include (but are not limited to) medical oncologists, surgical oncologists and radiation oncologists. As more specific and targeted drug treatments become available, specialists in biologic and immunotherapeutic approaches will need to join the multidisciplinary team.

Cancer treatment for many tumor types involves some combination of surgery, cytotoxic chemotherapy and radiation therapy. In some hormonally-sensitive tumor types such as breast and prostatic cancer, hormonal manipulations may also be utilized. At present "adjuvant" therapies usually imply systemic therapies such as chemotherapy or hormonal therapies, with surgery and/or radiation therapy as the primary treatments. It is possible that as systemic therapies become more effective they may be the primary treatments, with surgery and radiation therapy then being used as "adjuvants."

It has been well established in animal tumor systems, that forms of chemotherapy unable to cure established metastatic cancer could lead to a cure in animals initially rendered disease-free by surgery. These seminal studies have been translated into the clinical setting. The concept of adjuvant therapy is based on the premise that even relatively early cancers may have already disseminated to distant sites by the time of diagnosis. With current diagnostic technologies it is seldom possible to detect systemic metastasis that are less than 1 cm in size. Since this would contain approximately one billion tumor cells, it is likely that many tumors may have already disseminated microscopically via the bloodstream leaving tumor foci of millions of tumor cells undetectable by current diagnostic imaging techniques. This premise underlies current theories attempting to explain why only 70% of women with early stage breast cancer (tumors between 1 and 2 cm with negative axillary lymph nodes) are cured by standard surgical techniques. Much research is being done in an effort to identify those 30% of women destined to relapse and ultimately die of metastatic breast cancer, so that aggressive chemotherapeutic "adjuvant" therapies can be directed toward that high risk subset, and thus sparing the cured 70% the toxic side effects of chemotherapy. Various attempts at prognostication including (but not limited to) the analysis of bone marrow cells for micrometastasis using immunocytochemistry or, more recently, polymerase chain reaction technologies still require validation in large-scale clinical trials.

As examples, reasonably well accepted adjuvant therapies include; the use of chemotherapy, hormonal therapy or both after primary surgery ± radiation therapy for stages I and II breast cancer; radiation therapy to the breast for women undergoing lumpectomy instead of mastectomy for early stage breast cancer; chemotherapy for primary colon cancer that has spread to regional lymph nodes; and radiation therapy after surgery for women with locally advanced cancers of the uterine cervix. In some cancers, such as small cell carcinoma of the lung, chemotherapy is generally considered to be the primary form of therapy thus making surgery and/or radiation therapy, when used, the "adjuvants." Similarly in certain forms of leukemia where chemotherapy is considered the standard form of treatment, the use of whole brain radiation to prevent central nervous system relapse has been used as another example of "adjuvant" therapy.

In summary, as of the year 2000 the term adjuvant therapy in clinical cancer therapy is usually applied to the use of systemic cytotoxic chemotherapy and or hormonal

therapy (for hormonally sensitive tumors). However, in reality the term adjuvant can be applied to any treatment modality applied (generally with curative intent) after whatever initial treatment modality is considered to be the standard primary therapeutic intervention.

ADMET

Definition

Is an abbreviation for Absorption, Distribution, Metabolism, Excretion and Toxicity.

►ADMET Screen

ADMET Screen

Christopher A. Lipinski
Scientific Advisor, Melior Discovery, Waterford, CT, USA

Definition

An ►ADMET Screen is the application of a group of experimental assays to measure characteristics of a drug candidate in order to predict the Absorption, ►Distribution, Metabolism, Excretion and ►Toxicity properties of that drug.

Characteristics

ADMET is an abbreviation for Absorption, Distribution, Metabolism, Excretion and Toxicity. The term ADMET is often loosely used to denote those properties required for an orally active drug that are apart from the inherent biological activity of the drug. In a stricter sense the term ADMET denotes the properties denoted by the abbreviation that are the focus of specialized knowledge in the fields of medicinal chemistry, drug metabolism, pharmaceutical sciences and toxicology. The five properties in ADMET can be determined experimentally and to some degree computationally. As of 2007 all these properties can to variable degree be experimentally measured in manual or automated, medium to high capacity experimental assays (screens). The term "ADMET Screen" often refers to a group of screens that measure these properties. The term "screen" is quite appropriate because these ADMET assays are often used in a screening sense to remove chemical compounds with severe ADMET flaws that will never become real orally active drugs. Compounds are screened to remove flawed compounds just like a metal screen (sieve) might be used to remove sand or gravel from a water supply.

Drugs (medicines) are chemicals. They broadly consist of two types. There are those drugs that are of small size, i.e. low molecular weight (MWT). Typically these are below 500 Da (►Daltons) (atomic mass units). Currently the average MWT of an FDA approved drug is 347. About 90% of these low MWT drugs are orally active, i.e. are given to the patient by mouth and swallowed. The term ADMET overwhelmingly refers to these compounds. Another type of drug consists of ►biologicals. Biologicals are large drug compounds e.g. vaccines, antibodies, proteins. These are not given by mouth. The properties of these latter compounds are so different from those of the small orally active compounds that there is little or no overlap in the ADMET properties and screens for the two groups. Broadly, the properties of biologicals tend to be very specific to the individual compound and broadly useful ADMET screens for biologicals mostly do not exist.

What is required for a useful small MWT orally active drug? Broadly, two types of effects are required. The chemical (drug) must have the desired biological effect and the chemical must possess a variety of other properties (the ADMET properties) that are known by historical experience to be required for an orally active drug. There is a misconception prevalent in academia that a medicine requires only the desired biological effect plus an avoidance of toxicity. This is completely wrong. In developing small orally active drugs, solving the ADMET problems is frequently more difficult than obtaining the desired biological activity.

►Intestinal absorption is the entry of the drug from the contents of the gastrointestinal (GI) tract into the tissue lining the GI tract. Little or no absorption occurs in the stomach. Generally absorption starts as soon as soluble drug passes out of the stomach into the duodenum which is the part of the GI tract joining the stomach to the first section of the small intestine. With few exceptions, absorption is finished by the time the drug passes into the large intestine. A generalization says that to be absorbed a drug must be soluble (dissolved) in the contents of the GI tract. Near neutral water at about pH 6.5 is a very simple mimic of the GI tract contents at the point in the duodenum where absorption starts. In actuality, the real duodenal tract contents are more complicated than water and contain biological detergents, i.e. bile acids that help dissolve

►lipophilic (literally fat loving -greasy) drugs. Because of this complexity a small number of lipophilic drugs are in reality more soluble and better absorbed than would be suggested by their solubility in aqueous medium. Nevertheless, drug solubility in water is an excellent predictor for drug absorption. Within limits better aqueous solubility correlates with better absorption. Measuring drug aqueous solubility in water buffered at pH 6.5 or 7 is universally used to assess the likelihood of absorption and highly efficient automated equipment to make this measurement is readily available. Problems of a chemical (potential drug) having low water solubility are today the single most important early discovery problem in the discovery and development of low MWT orally active drugs. Across the board about 30–40% of chemicals in a drug discovery program might be expected to have an aqueous solubility problem.

The vast majority of orally active drugs must move from being dissolved in the aqueous content of the GI tract and must move across the GI tissue wall and then dissolve into the blood on the other side of the GI tract to get to their eventual site of action. The process of passing across the GI wall is termed "►intestinal permeability." Simplifying greatly, the GI wall can be considered as a greasy barrier. Think of a porous material soaked with fat. Chemicals that are very water loving (►hydrophilic) dissolve easily in water but do not dissolve easily in fat. A specific example would be sucrose (table sugar). So to be absorbed a chemical must have an appropriate balance between being water soluble (hydrophilic) and fat soluble (lipophilic). If the chemical is too hydrophilic it will dissolve easily in the GI contents and in blood but will not cross the GI wall (often called the GI barrier). If the chemical is too lipophilic it could cross the GI barrier easily but because of poor solubility in the GI contents the amount that crosses into the blood is very low. Highly efficient automated experimental equipment exists and is widely used to identify compounds likely to have difficulty crossing the GI barrier. A very widely used assay is termed ►PAMPA (Parallel Artificial Membrane Permeability Assay). In PAMPA a measurement is made of the speed with which a chemical crosses a porous material like fritted glass or plastic soaked with a fat. Across the board about 10% of chemicals in a drug discovery program might be expected to have a permeability problem.

When a chemical is absorbed it moves along a concentration gradient from high concentration in the GI tract to low in the blood. The GI barrier contains biological pumps that may literally pump the chemical out of the GI wall back into the GI tract. The best studied of these pumps in humans is called ►p-glycoprotein (PGP) and is the same biological pump that makes cancer cells resistant to chronic chemotherapy. If this pumping occurs to a significant extent, absorption is hindered. To measure this process requires an assay mimicking the live cells of the GI wall. A very common assay to do this is called ►Caco-2. The assay involves growing cells originally obtained from a human colonic cancer cell line on a porous plate. The cells form a continuous sheet on the porous plate substrate. The upper surface resembles the inner (GI tract exposed) surface of the GI wall. This is termed the ►apical surface. The surface growing on the porous substrate is termed the ►basolateral surface. It is possible to measure the speed of the chemical crossing the live cell sheet which gives a rough measure of how fast the chemical will cross the GI wall. It is possible also to measure the rate of chemical crossing the cell layer from either direction; the normal absorption direction termed apical to basolateral (abbreviated A to B) and the reverse pumped out direction termed basolateral to apical (abbreviated B to A). A to B rate divided by B to A rate gives a measure of the probability that the pump will hinder passage of chemical across the GI wall. Ratios of A to B divided by B-A are termed ►efflux ratios. A value greater than 1 suggests the beginnings of a problem. Ratios greater than 10 suggest further studies to see how much of a problem actually exits in a whole animal experiment. High efflux rates can lead to poor absorption and to dose non linearity, i.e. as the chemical dose increases the amount of drug in blood initially low suddenly jumps as the capacity of the efflux pump is exceeded. This is a highly undesirable effect if it occurs in the clinical dose range.

Some chemicals enter into the GI wall but are chemically destroyed either at the inner GI tract surface or within the GI wall. The most common problem is chemical oxidation of the drug by an iron containing enzyme called in humans ►cytochrome P450 CYP-P450 3A4. This enzyme occurs both in the GI wall and especially in the liver. About 60% of drugs might to a variable extent be subject to this process. Accordingly, measuring this oxidation is important both to detect compounds that are rapidly oxidized and to minimize potential interactions with the many other drugs that are oxidized by this same enzyme. Assays for so called drug-drug interactions are very common in ADMET assays. High capacity assays are commonplace to detect interactions with CYP-P450 3A4 as well as four other important CYP's such as ►CYP P-450 2D6 (important in metabolism of CNS drugs), CYP P-450 2C9, CYP P-450 2C19 and CYP P-450 2A1.

Distribution is the term describing how a chemical distributes among various compartments in the body. Fifteen years ago it was thought that distribution was governed by a chemical's physicochemical properties, e.g. size, polarity, lipophilicity acidity or basicity. We now believe that most or all distribution processes are governed by ►biological transporters which move a chemical from one place in the body to another and that

physicochemical properties are simply a crude surrogate measure for whether a chemical interacts with a particular transporter. There are myriads of ►transporters in the body many/maybe most of which are incompletely or entirely uncharacterized. As a result distribution is the property in the ADMET suite that is currently most poorly understood and for which assays are poorest. In general, with few exceptions, it is not possible to predict a priori the tissue distribution or localization of a new chemical.

Metabolism is the term that describes the biological caused change in a compounds chemical structure that occurs to a chemical when it gets into the body. The general pattern is that chemistry occurs to make a chemical more polar and more hydrophilic and more water soluble so that it can be more easily excreted by the body through the kidneys or the liver. Across the board, about 80% of drugs undergo ►oxidative metabolism. Frequently this consists of replacing a carbon hydrogen bond in the chemical by a carbon oxygen bond or the breaking of a carbon nitrogen bond (N-dealkylation). The family of CYP's are the most common cause of this chemistry although there are a handful or more of other less common enzymes that do similar transformations. Assays for these types of oxidations are a part of every ADMET assay suite. Compounds can be incubated with components of a liver which contains many CYP's. Artificially formed cell structures called ►microsomes can be formed from chopped up liver and these ►microsomes can be simplistically thought of as miniature livers. A chemical/drug is warmed up with the microsomes and measurements are made to see if the structure of the starting chemical changes. Very often the results are reported in terms of half life, i.e. does the chemical stay unchanged for less than or more than a certain length of time under some standard set of assay conditions. The interaction of a chemical with CYP's can also be measured by incubating the chemical with cells containing a single CYP enzyme.

Metabolism for about 15% of drugs occurs by a process termed "►phase II metabolism." A very polar small biologically occurring molecule like a special type of acid containing sugar group, e.g. ►glucuronic acid or a ►sulfate group is chemically attached to the starting chemical. This process can occur directly on the starting chemical if it contains something to attach the polar piece or it can occur after the starting chemical is changed by a CYP oxidation. A soluble liver fraction termed ►S-9 is used in an incubation to measure this process.

About 5% of drugs are not metabolized. Ultimately this can be advantageous clinically but in the drug discovery process it is currently a disadvantage since learning how long a chemical survives unchanged in an animal requires animal testing and animal in-vivo testing is always more difficult than testing in a test tube (also termed in-vitro meaning literally in glass).

Metabolism is sometimes termed detoxification, however this is really a misnomer. It is true that metabolism can reduce or abolish biological activity (including toxicity) in a starting chemical but it can just as well lead to an equally active (or even more active) biologically active compound. The biological activity can be the desired effect or something unwanted (toxicity). It is possible to start with a biologically inactive compound and have it biologically converted to a biologically active compound. Such a compound is called a ►prodrug. This process is surprisingly common amounting to about 25% of older drugs. Today this happens much less often because metabolism is scientifically much better understood than even a decade ago and because a directly biological active drug is generally considered advantageous over a chemical that requires metabolism for biological activity.

Excretion is the process by which a chemical is removed from the body. Overwhelmingly this is by excretion through the kidney into the urine (►renal excretion) or by excretion by the liver by way of the gall bladder emptying into the intestine and ultimately into the feces (►hepatic excretion). There has been great progress in understanding both modes of excretion and assays exist for some of the major biological transporters that are important in both processes. The non expert reader will have difficulty understanding the science because the terminology (►transporter nomenclature) used to describe the various transporters is frankly a mess and is changing currently and the same transporter may be described in the literature by multiple names and some of the names themselves unfortunately can be misleading. Very minor methods of excretion exist such as excretion through the lung and sweat. A rough rule of thumb is that MWT governs whether a compound or more often its metabolite or conjugate is excreted through the kidney or liver. A MWT less than 300 suggests excretion through the kidney is more likely. As MWT increases above 400 excretion through the liver becomes more likely. Many drugs show excretion through both liver and kidney. This profile is considered an advantage because damaged excretion through either kidney or liver is common in sick people.

Toxicity is a term denoting unwanted biological activity. Currently, the target and thus the desired mechanism of action (on target activity) is known for over 95% of newer drugs. Knowing the target mechanism is extremely useful when something untoward (toxicity) happens during ►preclinical studies (before ►clinical studies start) or during clinical studies (while the compound is studied in humans). Very commonly the toxicity is off target, i.e. not related to the desired biological activity. This is a good finding because it means that

changing to a different chemical structure but with the same desired mechanism will solve the toxicity problem.

Based on history, about 50% of drugs will cause tumors in one or more tissues in male or female rats in lifetime carcinogenicity studies. These studies may or may not be relevant to cancer risk in human patients. A major relevant factor is whether the drug is inherently ►mutagenic (causing DNA chromosomal damage). It is very common to exclude chemicals from drug development if they contain any chemistry pieces (moieties) previously associated with mutagenic activity and to rigorously test for in-vitro mutagenic activity. Mutagenic assays like the many versions of the ►Ames assay are used. A compound is incubated with genetically crippled but still viable bacteria designed to be very sensitive to chromosomal damage. The dose used is one that is not toxic to normal bacteria. A positive finding of mutagenicity is killing of crippled bacteria at doses where normal bacteria are unaffected. In general it is common that tumor findings in a compound clean with respect to no suspect chemical features and no mutagenicity can be explained as being irrelevant to human risk. For example, long term tissue irritation or stimulation of a growth factor or formation of a metabolite in rodents but not in man or damage to a cell type not found in man can cause tumors in rodents but these causes are likely irrelevant to human risk.

Liver toxicity is extremely common in drug discovery hence a whole variety of assays for liver damage are commonly used. The goal in general is to improve the prediction of liver damage at an earlier time point in the discovery process with less use of resources and with smaller amounts of compound.

►Attrition (loss) of compounds in the entire drug discovery and development process is well understood in the pharmaceutical industry. Generalizing across all types of therapeutic areas: about one in four projects succeeds from first inspiration to choice of a compound to enter the clinic (pre-clinical phase); about in 10–12 projects succeeds in the clinical (human testing phase). This gives an overall success rate of 1 in 40 or 48. Genomically derived projects have particularly poor success rates of 1 in 50 or 100. Cancer and CNS are the two therapeutic areas with poorer clinical success rates of about 1 in 20.

In the current era there are three major causes of roughly similar importance in clinical attrition. These are (i) toxicity; (ii) lack of efficacy and (iii) commercial reasons. These three factors are interrelated and it is very common for there to be multiple causes of failure. For example, Pfizer the largest pharmaceutical company worldwide identified three causes of failure in that organizations attrition analysis of many hundreds of failed clinical candidates over a time period of more than a decade. In this authors opinion toxicity is the most complex attrition cause and therefore the most resistant to a fix. We can expect toxicity to persist as a major attrition cause for multiple decades into the future.

ADMET assays have been summarized so far from an experimental perspective. However, if one tests enough compounds it is, in theory, possible to develop a computer program to predict an assay outcome based just on the structure of the compound. Computational prediction of ADMET is an extremely active area of research and many computational prediction programs of variable quality already exist. For example, the Lipinski "►rule of five" is a very widely used algorithm (with 2,000 literature citations to date) that is used to predict the likelihood of poor oral absorption. The rule states that poor oral absorption is more likely if: the MWT is over 500; the lipophilicity as measured by logP is over 5; there are more than five hydrogen bond donors and there are more than ten hydrogen bond acceptors. There are actually only four rules. The five in the name comes from the number 5 appearing in the parameter cutoff values. The reader is referred to the many review articles on rules and filters and computational prediction of ADMET.

Common sense is needed with regard to predictions. There is a natural importance order in drug discovery and development. Most important is the clinical information. This trumps all. Next in importance is high quality experimental information. Prediction has its best value and impact when neither clinical nor experimental information is available.

Adoptive Immunotherapy

Chrystal U. Louis, Helen E. Heslop
Center for Cell and Gene Therapy, Baylor College of Medicine, Texas Children's Hospital, and The Methodist Hospital, Houston, TX, USA

Definition

Adoptive immunotherapy involves the passive transfer of cellular products designed to augment immunity against cancer or infections. To date, clinical trials have evaluated the efficacy of different cell populations including, but not limited to: unmanipulated leukocyte infusions from bone marrow donors, cytokine induced T cells, lymphokine activated killer cells, tumor infiltrating lymphocytes, ►NK cells and antigen specific T cells.

Characteristics

Unmanipulated T Cells

Adoptive immunotherapy with unmanipulated donor lymphocytes (DLI) has effectively treated patients with relapsed or residual disease after hematopoietic stem cell transplant (HSCT). DLI provides the host immune system an additional graft vs. leukemia (GVL) effect and has been most successful in patients with chronic myeloid leukemia who relapse post transplant (70–80% cytogenetic remission rate) or with ►Epstein Barr virus-associated lymphoproliferative disease (EBV-LPD) (up to 90%). Moderate success has been seen when DLI was used after relapse in other malignancies such as: ►acute myeloid leukemia (15–40%), low-grade lymphomas (~60%), and metastatic ►multiple myeloma (40–60%). However, less than 5% of patients with relapsed acute lymphoblastic leukemia (ALL) respond to DLI alone. While the etiology is unclear, this could be due to lack of antigenic expression, down-regulation of T cell recognition molecules, and/or overall tumor burden at the time of treatment.

Although treatment with DLI has led to remission in patients with disease after HSCT, unmanipulated cells also contain alloreactive T cells and can induce graft versus host disease (GVHD). The incidence of GVHD ranges from 55 to 90% and is associated with a 20% treatment-related mortality rate. Different methods to maintain the graft versus tumor (GVT) effect while decreasing the incidence of GVHD have been investigated. One strategy is to transduce donor T cells with a "suicide gene" like herpes simplex virus type 1 thymidine kinase that can be activated by ganciclovir if GVHD develops. An additional method to spare the GVT effect involves selectively depleting alloreactive cells in the T cell product prior to adoptive transfer.

Cytokine Induced Killer Cells

Cytokine induced killer cells (CIK) have been generated from both peripheral blood and cord blood mononuclear cells stimulated with anti-CD3, interferon-γ, and interlekin-2 (IL-2). CIK derived from peripheral blood cells have induced either partial responses or stable disease in patients with lymphoma after autologous HSCT. Pre-clinical studies using cord blood CIK have been promising by demonstrating cytotoxic responses when stimulated with either lymphoma or myeloid leukemia cell lines.

Lymphocyte Activated Killer Cells

Lymphocyte activated killer cells (LAK) were one of the first adoptive immunotherapy approaches used to treat patients with advanced-stage malignancies. These cells were generated by culturing peripheral blood mononuclear cells with IL-2; however, they provided no additional clinical benefit compared to administration of IL-2 alone in patients with renal cell carcinoma or melanoma.

Tumor Infiltrating Lymphocytes

Tumor infiltrating lymphocytes (TIL) are cells harvested from tumor sites and expanded *ex vivo* with IL-2. As the cells are being expanded, increased tumor specificity has been achieved by pulsing the cells with tumor-specific peptides or exposing the lymphocytes to a retrovirus encoding a tumor-specific T cell receptor (TCR). Although a major limitation is that patients must have pre- existing lymphocytes that can both respond to tumor and be expanded *ex-vivo*, one study has reported that transfer of these cells led to tumor regression in 50% of lymphodepleted patients with metastatic melanoma.

Antigen-Specific Cytotoxic T Lymphocytes

Ex vivo generation of cytotoxic T lymphocytes (CTL) provide another avenue for increasing the antitumor or antiviral specificity of adoptively transferred cells. Two major prerequisites for generating antigen-specific CTL are the identification of appropriate viral or tumor target antigens and the availability of suitable antigen-presenting cells (APC). Once identified, CTL lines can be generated by co-culturing T cells with APC that express the target antigen. These lines are then expanded by restimulation with the antigen of choice and the addition of cytokines such as IL-2.

Initial studies with antigen-specific CTL were undertaken in patients diagnosed with viral infections after HSCT. In Phase I studies, the prophylactic use of cytomegalovirus (CMV)-specific CTL after HCST decreased the percentage of CMV reactivation in a small cohort of patients. Our group has successfully used EBV-specific CTL not only for the prophylactic treatment of EBV-LPD, but also for the treatment of patients with EBV-LPD after HSCT and solid organ transplant. Furthermore, EBV-CTL have been used with moderate success to treat patients with type II latency EBV-associated malignancies like ►Hodgkin's lymphoma, ►non-Hodgkin's lymphoma and ►nasopharyngeal carcinoma. Patients with HIV have also been treated with CTL therapy. Autologous gag-specific CTL were reported to accumulate in lymph nodes and transiently reduce the levels of circulating infected $CD4^+$ T cells. More recently we have developed an approach where multivirus specific CTL can be generated *ex-vivo* and provide protective immunity against adenovirus, CMV and EBV in recipients.

These strategies are limited by the time required for CTL generation using current good manufacturing processing techniques. Rapid selection techniques such as tetramer selection and gamma-interferon capture are being evaluated, but the CTL product generated may have a more restricted specificity. An alternative approach is to use banked allogeneic CTL lines, but persistence of a mismatched product may be clinically suboptimal.

NK Cells

►Natural killer (NK) cells are effectors from the innate immune system, which also mediate antiviral and antitumor immunity. Recent studies have shown that haploidentical NK cells infused after lymphodepleting chemotherapy can have antitumor effects.

Enhancing the Function of Adoptively Transferred Cells

To increase treatment efficacy of adoptively transferred cells, investigators are lymphodepleting patients prior to adoptive cell transfer or genetic modifying cells to enhance effector function. Lymphodepletion, removal of the host's lymphocytes, prior to adoptive transfer should allow the infused cells to expand using the body's own homeostatic cytokines like IL-7 and IL-15. Data from the Rosenberg group has shown improved outcomes in patients with metastatic melanoma who were lymphodepleted prior to receiving melanoma specific T cells. Additionally, infused T or NK cells may be genetically modified with artificial receptors targeting tumor antigens or with molecules that may confer resistance to tumor evasion strategies.

Malignant adrenocortical tumor; Carcinoma of the adrenal cortex

Definition

Adrenocortical cancer (ACC) is a malignant tumor from the adrenal cortex. It is a rare tumor with a poor prognosis. The consequences of ACC are due to tumor growth and metastasis and also due to steroid oversecretion.

Characteristics

Epidemiology of Adrenocortical Cancer

ACC is a rare disease with an estimated incidence between 1 and 2 per million and per year in adults in North America and Europe.

Pathophysiology of Adrenocortical Cancer

Analysis of the pattern of X-chromosome inactivation in heterozygous female tissue has shown that ACC consists of monoclonal populations of cells. A large number of molecular techniques, such as comparative genomic hybridization (CGH) and microsatellite analysis, have identified alterations affecting various chromosomes and loci in ACC. Most of the changes observed concern losses on chromosomes 2, 11q and 17p, and gains on chromosomes 4 and 5. Studies using microsatellite markers have demonstrated a high percentage of loss of heterozygosity (LOH) or allelic imbalance at 11q13 (≥90%), 17p13 (≥85%), and 2p16 (92%) in ACC.

IGF-II (Insulin-Like Growth Factor II)

The insulin-like growth factors system is involved in the development of the adrenal cortex and its role has been largely documented in adrenocortical tumors. The ►*IGF-II* gene located at 11p15 encodes an important fetal growth factor, is maternally imprinted, and is therefore expressed only from the paternal allele. Genetic or epigenetic changes in the imprinted 11p15 region, resulting in increases in *IGF-II* expression, and mutations of the ►*p57kip2* gene have been implicated in Beckwith-Wiedemann syndrome. This overgrowth disorder is characterized by macrosomia, macroglossia, organomegaly and developmental abnormalities (in particular abdominal wall defects with exomphalos), embryonal tumors – such as Wilms' tumor – and ACC, neuroblastoma, and hepatoblastoma.

Many studies have demonstrated that *IGF-II* is strongly overexpressed in malignant adrenocortical tumors, with such overexpression observed in ~90% of ACC. Transcriptome analysis of adrenocortical tumors has demonstrated that *IGF-II* is the gene most overexpressed in ACC by comparison with benign adrenocortical adenomas or normal adrenal glands. The mechanisms underlying *IGF-II* overexpression are paternal isodisomy (loss of the maternal allele and duplication of the paternal allele) or, less frequently, loss of imprinting.

β-Catenin Activation in Adrenocortical Cancer

Genetic alterations of the Wnt signaling pathway were initially identified in familial *adenomatous polyposis coli* (►*APC*) and have been extended to a variety of cancers. Adrenocortical tumors have been observed in some case reports of patients with familial *APC*. Furthermore, familial *APC* patients, with germline mutations of the *APC* gene that lead to an activation of the Wnt signaling pathway, may develop ACTs. The Wnt signaling pathway is normally activated during embryonic development. β-catenin is a key component of this signaling pathway. Interestingly, gene profiling studies in various types of adrenocortical tumors have shown the frequent activation of Wnt signaling target genes. In both benign and malignant ACT, β-catenin accumulation can be observed. These alterations seem very frequent in ACC, consistent with an abnormal activation of the Wnt signaling pathway. This is explained in a subset of adrenocortical tumors by somatic mutations of the *β-catenin* gene altering the Glycogen synthase kinase 3-β (GSK3-β) phosphorylation site.

TP53

The tumor suppressor gene ►*TP53* is located at 17p13 and involved in the control of cell proliferation. Germline mutations in *TP53* are identified in 70% of families with Li-Fraumeni Syndrome (LFS). This syndrome displays dominant inheritance and confers susceptibility to breast carcinoma, soft tissue sarcoma, brain tumors, osteosarcoma, leukemia, and ACC. Germline mutations in *TP53* have been observed in 50–80% of children with apparently sporadic ACC in North America and Europe. The incidence of pediatric ACC is about ten times higher in Southern Brazil than

in the rest of the world, and a specific germline mutation has been identified in exon 10 of the *TP53* gene (R337H) in almost all cases. In sporadic ACC in adults, somatic mutations of *TP53* are found in only 25–35% of cases. LOH at 17p13 has been consistently demonstrated in ACC but not in adrenocortical adenomas. LOH at 17p13 was recently reported to occur in 85% of ACC.

Diagnosis and Treatment of Adrenocortical Cancer

Clinical and Hormonal Investigations

Symptoms leading to the diagnosis of ACC can be due to hormone hypersecretion and/or tumor mass and metastasis. The majority of ACC are usually secreting tumors when careful hormonal investigations are performed. By contrast with benign adrenocortical tumors (that usually secrete a single class of steroid), ACC can secrete various types of steroids (glucocorticoids, androgens, and mineralocorticoids). Cosecretion of androgens and cortisol is the most frequent and highly suggestive of a malignant adrenocortical tumor. Cortisol oversecretion (classified as "ACTH-independent Cushing's syndrome" in case of ACC) can induce centripetal obesity, protein wasting with skin thinning and striae, muscle atrophy (myopathy), diabetes, hypertension, psychiatric disturbances, gonadal dysfunction, osteoporosis…

Imaging of Adrenocortical Cancer

Imaging is an essential diagnostic step for ACC. It is important for both, not only for the diagnosis of malignancy of an adrenal mass but also for the extension work-up. Adrenal computed tomography scan (CT-scan) is a very informative imaging procedure for adrenocortical tumors. In ACC, it shows a unilateral mass, which is most often large (above 5–6 cm, typically 10 cm and above), lowering the kidney. MRI can also be used in the diagnosis of liver nodules and venous invasions. More recently studies have demonstrated that ACCs almost invariably have a high uptake of 18-fluorodesoxyglucose ((18)-FDG). Thus (18)-FDG PET scan appears to distinguish between benign and malignant adrenal tumors. This simple, nontraumatic imaging procedure also participates in the extension work-up.

Pathology and Molecular Analysis

As often with endocrine tumors, the diagnosis of malignancy of adrenocortical lesions is not always easy for the pathologist. Combinations of various histological parameters allowing the calculation of a "score" for a given tumor have been developed. The most widely used is the Weiss score made of nine different items. It is assumed that a score above three is most likely associated with a malignant tumor. Since the Weiss score has limitations and is dependant on the experience of the pathologist, there is an effort to develop molecular markers of malignancy. IGF-II overexpression and allelic losses at 17p13 have been suggested as useful markers. Immunohistochemistry of Cyclin E or Ki-67 that are higher in malignant adrenocortical tumors has also been suggested in the literature as potential useful tools.

Prognosis of Adrenocortical Cancer

The overall prognosis of ACC is poor with a 5 year survival rate below 35% in most series. Among the various clinical parameters that have been shown to impact on ACC prognosis, tumor staging has been demonstrated as one of the most important. The MacFarlane staging is the most commonly used and relies on surgical finding and extension work-up. Four different stages are differentiated with this score. Stage 1 and Stage 2 tumors are localized to the adrenal cortex and present a maximum diameter below or above 5 cm, respectively. Locally invasive tumors or tumors with regional lymph node metastases are classified as Stage 3, whereas Stage 4 consists of tumors invading adjacent organs or presenting with distant metastases. The prognosis of Stage 1 and 2 tumors is better than that of Stage 3 or 4 tumors. A better survival is usually reported in younger patients. Some pathological features as a high mitotic rate or atypical mitotic figures have been shown to be associated with a poor prognosis.

In the future, it is expected that molecular tools will help to a better prediction of the prognosis of ACC. Gene profiling approach can already differentiate malignant from benign tumors.

Treatment of Adrenocortical Cancer

Surgery of the adrenal tumor is the major treatment of Stage 1 to 3 ACC. It can also be discussed in Stage 4 patients. Only complete tumor removal can lead to long term remission. Radiofrequency thermal ablation of liver and lung metastasis below 4–5 cm of maximal diameter can be an alternative to surgical removal. Chemoembolization has also been used for liver metastasis. Surgery of bone metastasis can be indicated to reduce fracture risk, or, in case of spinal localization, neurological symptoms. Radiation therapy is usually considered as not very effective to control tumor growth. However, it has been recently suggested that tumor bed radiation therapy could help to prevent local recurrence after surgical removal.

When complete tumor removal is not possible, or in case of recurrence, medical treatment with O,p'DDD (ortho, para', dichloro-, diphenyl-, dichloroethane, or Mitotane) is recommended. It has both an anticortisolic action and a cytotoxic effect on the adrenocortical cells. Objective tumor regression could be observed in 25–35% of the patients. A mitotane blood level of

at least 14 mg/l seems to improve the tumor response rate. However, the side effects of mitotane (mainly digestive and neurologics) often limit the ability to reach this suggested optimal level. Since O,p'DDD can induce adrenal insufficiency, substitutive glucocorticoid and mineralocorticoid therapy should be associated. Several cytotoxic chemotherapy regimens have been used in ACC. They are usually considered in patients with tumor progression under mitotane therapy reaching the plasma blood level of 14 mg/l or presenting severe side effects limiting its use. Various drugs have been used and the experience is still limited. It is currently accepted that the combined treatment with Cis-platine, Etoposide, Doxorubicin (EDP regimen) associated with O,p'DDD, and Streptozotocin also given with O,p'DDD are the better regimens. However, there is obviously an important need for prospective controlled studies and for new therapies in patients with advanced ACC.

Adrenocortical Tumors

Definition

Adrenocortical tumors (ACT) are divided into two histologic groups, depending on several criteria. Large tumors (>200 g) with nuclear atypia, more than five mitoses on 50 high-power fields, vascular and capsular invasion, broad fibrous bands, and extensive necrosis are highly suggestive of carcinoma. Small tumors without the mentioned features are considered to be adenomas. In children, distinguishing between adenoma and carcinoma is difficult because the histologic features of small and large lesions overlap. Only about 20% of childhood ►adrenocortical tumors are classified as adenomas.

Adrenomedullin

Enrique Zudaire, Franck Cuttitta
NCI Angiogenesis Core Facility, National Cancer Institute, National Institutes of Health, Advanced Technology Center, Gaithersburg, MD, USA

Definition

Adrenomedullin (AM) is a member of the ►calcitonin superfamily of peptides. It is produced in virtually every organ by many different cell types and it is secreted into the plasma where it occurs at picomolar concentrations. Over the past several years AM has increasingly received the attention of the scientific community by virtue of its implication in many normal and disease states.

Characteristics

Adrenomedullin is a small peptide (52 amino acids) first isolated from a ►pheocromocytoma in 1993. It was initially described as a hypotensive peptide although after more than a decade of research and about 2,000 published articles published, AM is now recognized as a pluripotent peptide-hormone implicated in many normal and pathological processes ranging from vascular tone and diabetes to ►angiogenesis and embryogenesis/ ►carcinogenesis.

Adrenomedullin: Peptide and Gene Structure

Adrenomedullin is generated as part of a larger precursor molecule named preproadrenomedullin (preproAM) (Fig. 1). PreproAM is 185 amino acids long and contains an N-terminal 21 amino acid signal peptide which is cleaved during the transport of the molecule across the cell membrane to produce the 164 amino acids prohormone proAM. Further processing of proAM by endopetidases generates four peptides termed proadrenomedullin N-terminal 20 peptide (PAMP), mid-regional pro-adrenomedullin (proAM 45–92), adrenomedullin (AM) and adrenotensin (proAM 153–185). From these, PAMP, ProAM 45–92 and AM are present in plasma and PAMP, AM and Adrenotensin are biologically active peptides. Both PAMP and AM peptides are produced as a ►glycine (Gly)-extended inactive peptides which coexists in plasma with the active form generated

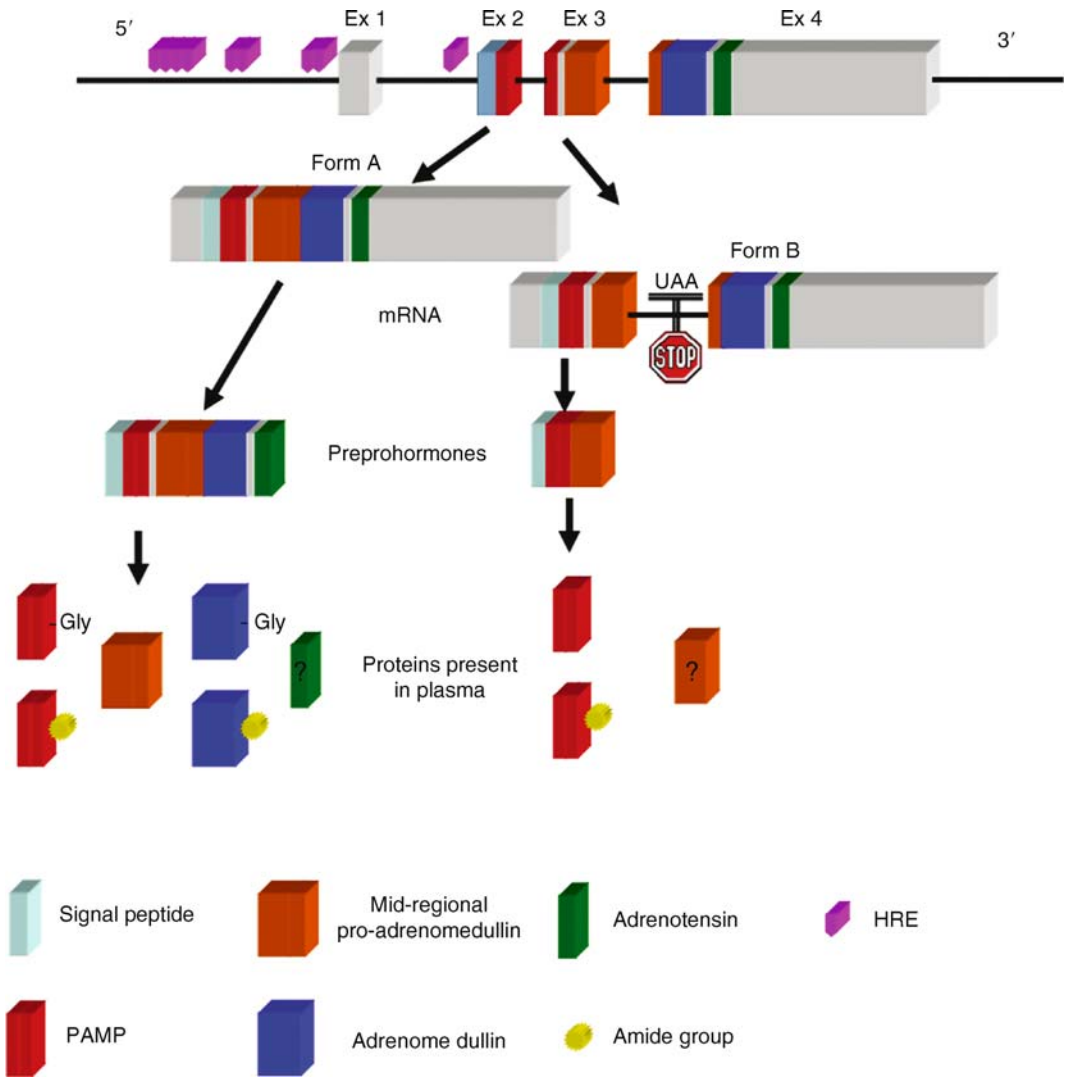
upon enzymatic ►amidation. AM shares homology with several vasoactive peptide members of the calcitonin superfamily including calcitonin, calcitonin gene related peptide (CGRP), amylin and intermedin. Members of this family share the presence of an intramolecular disulfide bond which generates a six-member ring structure and an amidated carboxy terminal, both of which are required for biological activity.

In humans, the single locus of the adrenomedullin gene is located in the short arm of chromosome 11. The complete gene (2,319 bp) contains four exons and three introns which are ►alternatively spliced during the transcription process to generate two different transcripts (Fig. 1). The shortest mRNA form includes exons 1–4 and therefore codes for a complete preprohormone which results in stoichiometric amounts of the four peptides referred above. The longest transcript incorporates the third intron that contains an early termination codon, resulting in a truncated preprohormone which only expresses PAMP.

AM is an ancient gene that, based on our current knowledge, first appeared in the starfish with a potential dual function of neurotransmission and host defense. It shows a remarkable degree of conservation in genomic organization and peptide structure from fish to humans which supports its critical role in species survival.

Signal Transduction

As most soluble peptides, AM transduces its signal upon interaction with a receptor located in the cellular surface. The discovery of the AM receptor in 1998 represented a novel paradigm in the field of ►G-protein couple receptor (GPCR) signaling. A functional receptor for AM requires physical interaction in the cellular



Adrenomedullin. Figure 1 Genomic organization of the AM gene.

membrane of the seven transmembrane domain receptor calcitonin-receptor-like-receptor (CRLR) and either the receptor-activity-modifying protein (RAMP) 2 or RAMP3. CRLR has two alternative pharmacological profiles that are conferred by association to the accessory proteins RAMP1 (producing the CGRP receptor) and RAMP2/3 (producing the AM receptor). Therefore, the expression pattern of functional AM receptors is determined by the presence of these two components. In healthy individuals, RAMP2/3 is equally expressed among most tissues, excluding lung, female reproductive system and adipocytes which show higher levels of expression. CRLR expression although lower, parallels that of RAMP2 which suggests that the majority of CRLR signaling units in the body are complexed with RAMP2 to produce adrenomedullin receptors. Modest but robust changes in the expression of the complex CRLR-RAMP2 have been reported in certain physiological and disease states such as pregnancy, sepsis and ►cancer. The same physiological conditions are related to high levels of AM expression. Other stimuli which result in coordinated regulation of AM, CRLR and RAMP2 include hypoxia, endocrine hormones and inflammatory cytokines.

Upon binding to its receptor AM induces cAMP elevation through an adenylyl cyclase-PKA mediated pathway. While multiple reports including the seminal paper by Kitamura have consistently demonstrated cAMP mediated effects of AM, other more scarce ones have shown cAMP independent actions such as vasodilation via elevation of Ca^{2+} and K^{+}-ATP, and activation of endothelial nitric oxide synthase. AM also activates Akt, ►mitogen-activated protein kinase and focal adhesion kinase in endothelial cells which mediate its angiogenic potential.

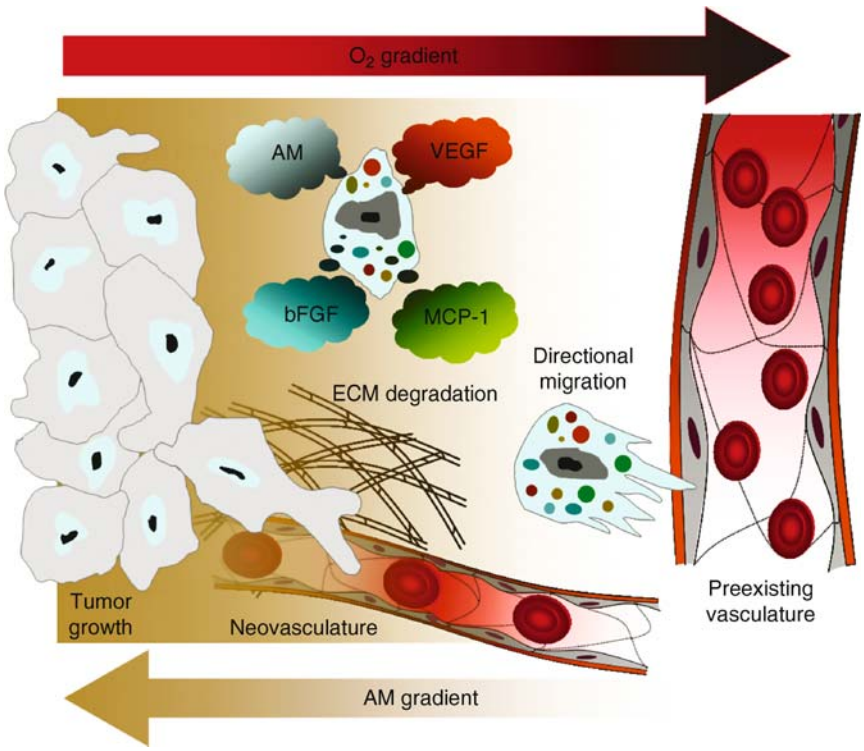
AM Serves as a Common Language Between the Different Cellular Components of the Tumor Microenvironment

Many disease states have been reported to modulate the expression of AM including cancer. As we mentioned before, AM was originally isolated from an adrenal gland tumor. A wealth of subsequent studies have found that AM and its receptor are overexpressed in many human cancers and tumor cell lines establishing an ►autocrine loop mechanism that tumor cells exploit to maintain an autonomous proliferative state. AM is intimately intertwined at several levels in the multistep process of tumor development. At the initial stage of tumor growth, rapid accumulation of malignant cells results in the establishment of an avascular nutrient-depleted ►hypoxic environment. Low oxygen tension within and surrounding the tumor body triggers a number of survival mechanisms which allow neoplastic cells to overcome this inhospitable microenvironment. Many of these encompass the upregulation of AM's expression. In fact one, if not the most important driving force for AM upregulation in tumor cells is hypoxia. Cellular responses to hypoxia are mediated through a well known hypoxia inducible factor (HIF)-dependent mechanism. HIF is a heterodimeric transcription factor which is stabilized under hypoxic conditions and binds to specific DNA sequences denoted hypoxia response elements (HRE) which are present in the ►promoter regulatory region of the AM gene (Fig. 1). Hypoxia also upregulates the expression of the AM receptor gene in many tumor types hence establishing a rational explanation behind the aforementioned autocrine growth mechanism underlying carcinogenesis (Fig. 2).

As tumor derived AM is released into the microenvironment it establishes a peptide gradient which ultimately disseminates to reach a teeming collection of cell types known to be able to respond to this peptide and to be involved in further development of the tumor, including the cancer cell itself. AM not only stimulates tumor cell proliferation via its mitogenic activity but also by involving an antiapoptotic state.

Although the advantageous effects of AM for the tumor cell are apparent, its actions are not restricted to this compartment within the tumor. On the contrary, AM acts as an integrative molecule allowing the crosstalk between all different compartments within the tumor microenvironment. As an example, AM is a ►migratory factor for different inflammatory cells, including ►mast cells. Mast cells migrate towards the tumor mass following the preestablished tumor-derived AM gradient. Hence, as mast cells approach the tumor they are exposed to increasingly higher concentrations of AM. Only when certain concentration of AM is reached in the proximity of the tumor, mast cells degranulate liberating to their immediate milieu numerous inflammatory factors (including AM) which not only enhance the tumor progression but also perpetuate the inflammatory process. AM is also implicated as a potential immune system suppressor, inhibiting macrophage function and acting as a negative regulator of the complement cascade, protective properties which help cancer cells circumvent immune surveillance.

One of the most significant features distinctive of hypoxic tumors is their ability to induce angiogenesis. Tumor-induced angiogenesis is a pathological condition that results in ectopic neovascularization. Of most therapeutic interest is the finding that AM is an essential factor that regulates normal and pathological vascularization. AM was first described as a potent hypotensive peptide although its connection to the normal and pathological biology of the vascular system is much deeper than initially thought. AM is an essential factor for the normal development of vasculature as revealed by mice lacking the AM gene in mice which is embryonically lethal due to abnormal vascularization. AM also induces pathological neovascularization via



Adrenomedullin. Figure 2 Model of the AM/tumor cell/inflammatory cells relationship in human carcinogenesis. The microenvironment around the tumor is hypoxic and stimulates expression of AM by the tumor cells. Tumor-derived AM is released into the microenvironment setting up a concentration gradient of peptide that contributes to angiogenesis and attracts distal MCs to infiltrate the tumor site. Neovasculature makes possible tumor metastasis and it is used as a point of entrance for inflammatory cells (i.e. MC). As MCs migrate up the peptide gradient, higher AM concentrations are reached stimulating MC-derived angiogenic factors (AM, VEGF, bFGF, MCP-1) expression and ultimately release at the tumor site. AM mediates a paracrine tumor survival effect (direct mitogen, angiogenic factor, and anti-apoptosis), and functions as a paracrine recruitment factor drawing additional MCs to the area, thus perpetuating the inflammatory process and enhancing tumor promotion.

CRLR-RAMP2 present in the endothelial cells. Angiogenesis is a multistep process which commences with the growth of endothelial cells which is enhanced by tumor derived AM. AM also prevents hypoxia-triggered apoptosis in endothelial cells enhancing the neovascularization process. Additionally, AM participates in the remodeling of the extracellular matrix and tridimensional rearrangement of endothelial cells in the tissue which results in the establishment of the new intratumoral vasculature by stimulating migration and tube formation of endothelial cells. AM increases the permeability of the endothelial cells in the newly established vasculature which supplies the tumor with the necessary nutrients for expansion additionally it creates an access route for inflammatory cells which are attracted to the tumor site and migrate in following gradients of ►chemoattractant and migratory factors produced by the tumor, such as AM. The same route can simultaneously be utilized by tumor cells as the entrance point to the vascular system facilitating the metastasis process. The invasive capability of tumor cells is thus enhanced by AM.

Concluding Remarks

Conclusions gleaned from the studies carried over the past fourteen years portrait AM as a molecular connector with competence to entangle and allow communication between the different cellular components of the tumor machinery which conspire under the tumor cell direction to promote cancer. It is not only the direct effect that AM has on tumor cells but also its ability to interact with all these cellular elements which makes this peptide an attractive therapeutic target for cancer. The collective research effort is shifting from trying to discern whether AM is a causative agent of cancer to better understanding its central role as a multifaceted exchange currency among the multiple cellular players involved in tumor development. Strategies utilizing blocking agents aimed at disruption of this loop might be proven successful to impede tumor growth.

Adriamycin

Tsutomu Takahashi, Akira Naganuma
Laboratory of Molecular and Biochemical Toxicology, Graduate School of Pharmaceutical Sciences, Tohoku University, Sendai, Japan

Synonyms

Doxorubicin; 14-Hydroxyldaunorubicin

Definition

Adriamycin is an antineoplastic ►anthracycline antibiotic isolated from cultures of *Streptomyces peucetius* var. *caesius*. It is widely used in the treatment of various different types of cancers. Proposed mechanisms for its antitumor activity include intercalation into DNA, inhibition of ►topoisomerase II, and promotion of free-radical formation. However, the clinical utility of this drug is seriously limited by the development of cardiomyopathy and ►myelosuppression.

Characteristics

Chemical Properties

Adriamycin is an orange–red compound, soluble in water and aqueous alcohols, moderately soluble in anhydrous methanol, and insoluble in nonpolar organic solvents. It consists of an aglycone (adriamycinone), a tetracyclic ring with adjacent quinone–hydroquinone groups in rings C-B, coupled with an amino sugar (daunosamine). It is generated by C-14 hydroxylation of its immediate precursor, ►daunorubicin (see Fig. 1). Semisystematic derivatives of adriamycin include ►epirubicin, an axial-to-equatorial epimer of the hydroxyl group at C-4′ in daunosamine, and ►pirarubicin, 4′-O-tetrahydropyranyl-adriamycin, etc.

Clinical Aspects

Therapeutic Applications

Adriamycin has a broad antitumor spectrum. It is used to treat hematopoietic malignancies such as leukemias, lymphomas (non-Hodgkin disease, ►Hodgkin disease) and ►multiple myeloma, and different solid tumors (breast, thyroid, gastric, ovarian, bronchogenic, head and neck, prostate, cervical, pancreatic, uterine and hepatic carcinomas, as well as transitional cell bladder carcinomas, ►Wilms tumor, ►neuroblastoma, and soft tissue and bone sarcomas). Adriamycin is applied as a component of combination chemotherapy, rather than a monotherapy. Adriamycin-based combination chemotherapy regimens include ABVD (Adriamycin, Bleomycin, Vinblastine, Dacarbazine) for non-Hodgkin disease, CHOP (Cyclophosphamide, Adriamycin, Vincristine, Prednisone) for ►Hodgkin disease, and M-VAC (Methotrexate, Vinblastine, Adriamycin, Cisplatin) for urothelial carcinoma.

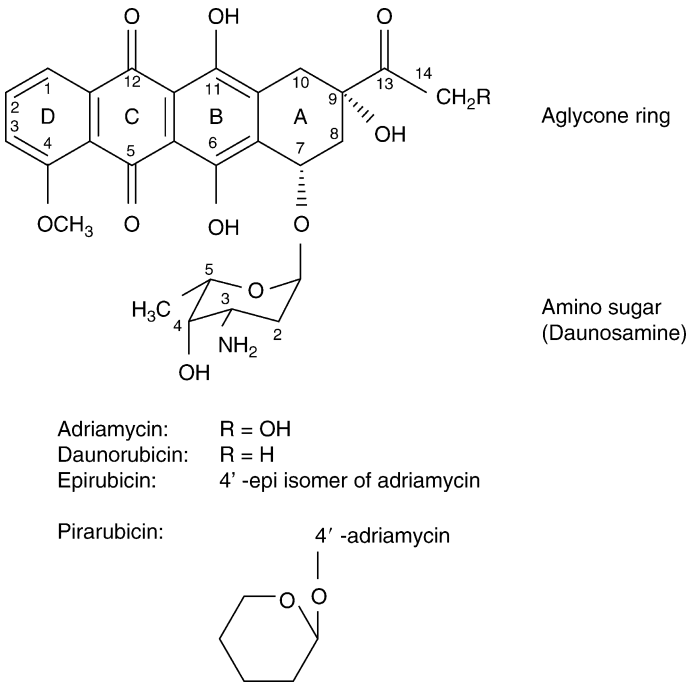
Pharmacokinetics

Adriamycin is rapidly cleared from the plasma, quickly taken up and only slowly eliminated from organs such as the spleen, lungs, kidneys, liver, and heart. It does not cross the blood–brain barrier. Adriamycin is converted to an active metabolite, adriamycinol, through a two-electron reduction of the side chain C-13 carbonyl moiety by NADPH-dependent cytoplasmic aldo/keto reductase or carbonyl reductase. It is converted to inactive metabolites in the liver and other tissues, and predominantly excreted in the bile.

Clinical Toxicities

The usual toxic side effects of adriamycin including stomatitis, nausea, vomiting, alopecia, gastrointestinal disturbance, and dermatological manifestations, are generally reversible. The dose-limiting side effects of the anthracyclines including adriamycin are myelosuppression and cardiotoxicity. Myelosuppression with leukopenia, neutropenia, and occasionally thrombocytopenia is dose-related and potentially life-threatening.

Cardiotoxicity is characteristic of the anthracycline antibiotics, of which adriamycin is the most toxic. Adriamycin-induced cardiotoxicity can be acute, chronic, or delayed. The acute effect is not dose-related, and is characterized by sinus arrhythmias and/or abnormal electrocardiographic (ECG) changes (nonspecific ST-T wave change, prolongation of QT interval). Acute toxicity of this type is transient and rarely a serious problem. Chronic cardiotoxicity is a much more serious problem, being related to cumulative dose. It is irreversible and leads to dilative cardiomyopathy and congestive heart failure (CHF), usually unresponsive to cardiotonic steroids (digitalis) and β-blockers. The risk of developing CHF increases markedly at total cumulative doses in excess of 500 mg/m^2. Moreover, the effects of this chronic cardiotoxicity may manifest precipitously without antecedent ECG changes. The risk of life-threatening cardiac dysfunction can be decreased by regular monitoring of endomyocardial



Adriamycin. Figure 1 Structures of adriamycin and its analogues.

(EM) biopsy histopathological changes and left ventricular ejection fraction (LVEF) as measured by the multigated radionuclide angiography (MUGA) method and/or echocardiography (ECHO). Finally, adriamycin can also cause delayed cardiotoxicity, possibly, related to the dose. This occurs after an asymptomatic interval, mostly in people who were treated as children.

Several approaches have been proposed to overcome adriamycin cardiotoxicity and that of the anthracycline antibiotics generally. Administration by slow continuous intravenous infusion (over 48–96 h) rather than the standard bolus injection decreases the likelihood of chronic cardiotoxicity. ►Dexrazoxane (ICRF-187), an iron chelator that prevents the formation of complexes between adriamycin and iron, and subsequent production of ►reactive oxygen species (ROS), is sometimes used as a cardioprotectant. However, it may decrease antitumor activity. Liposomal encapsulation is designed to increase safety and efficacy by decreasing cardiac and gastrointestinal toxicity through decreased exposure of these tissues to the drug, while effectively delivering it to the tumor. Polyethyleneglycol-coated (Pegylated) liposomal adriamycin (Doxil (USA), Caelyx (UK)) is currently used for treating AIDS-related ►Kaposi sarcoma, refractory ovarian cancer, and some other solid tumors. In order to improve therapeutic efficacy and decrease side effects by promoting drug accumulation inside tumors, the water-soluble N-(2-hydroxypropyl) methacrylamide (HPMA) copolymer, magnetic targeted carriers, and ►immunoliposome conjugates with the specificity of whole monoclonal antibodies (e.g. antibodies against CD19 or MUC-1) or FAB' fragments have been developed as carriers of adriamycin.

In further efforts to decrease the risk of developing cardiotoxicity, several derivatives of adriamycin or daunorubicin, such as epirubicin, pirarubicin, ►idarubicin, and ►aclarubicin have been developed. Although these agents may be less cardiotoxic than adriamycin itself, they do have a decreased antitumor activity.

Pharmacological Mechanisms

Mechanisms of Action

Several mechanisms appear to contribute to the cytotoxic effects of adriamycin, including inhibition of DNA replication and repair; inhibition of RNA and protein synthesis via intercalation of the aglycone portion of the molecule between adjacent DNA base pairs, especially G-C base pairs; promotion of the cleavage of DNA by formation of adriamycin-topoisomerase II-DNA ternary complexes; inhibition of topoisomerase I; and direct binding to the cell membrane. Formation of free radicals is another major mechanism of cytotoxicity. One-electron reduction of the quinone moiety in the C ring of adriamycin by some flavin-containing enzymes (mitochondrial NADH dehydrogenase, microsomal NADPH-cytochrome P450 reductase, and xanthine oxidase) generates adriamycin-semiquinone radicals. These rapidly react with oxygen

to form superoxide anions, which then generate hydrogen peroxide and hydroxyl radicals in the presence of redox-active metals such as iron (III) and copper (II). The final result is DNA damage and lipid peroxidation. The semiquinone radical can be transformed into an aglycone C7-centered radical that also mediates cellular damage by DNA alkylation and lipid peroxidation. Adriamycin can bind to metal ions such as iron, copper, and manganese, by forming adriamycin–metal complexes, which may lead to generation of ROS and damage to cell membranes.

Mechanisms of Resistance

Development of resistance to the drug is a major obstacle in chemotherapy with adriamycin. Drug efflux pumps are important for defending cells against anticancer drugs. The acquisition of adriamycin resistance involves promotion of excretion of the drug by overexpressing the ATP-binding cassette (ABC) transporters ►P-glycoprotein (P-gp)/ABCB1, ►multidrug resistance-associated proteins (MRPs)/ABCC (MRP1, MRP2, and MRP6 etc.), and breast cancer resistance protein (BCRP)/ABCG2. P-gp transports hydrophobic compounds including adriamycin, while MRP1 and BCRP can extrude predominantly these glutathione conjugates. In addition, RalA-binding protein 1 (RALBP1)/Ral-interacting protein of 76 kDa (RLIP76) is a nonclassical ABC transporter involved in drug excretion. RALBP1 catalyzes ATP-dependent efflux of xenobiotics including adriamycin as well as its glutathione conjugates. In fact, the level of expression of these efflux pumps correlates with the clinical efficacy of adriamycin. ►Glutathione-S transferases (GSTs) are a family of enzymes involved in the cellular detoxification of xenotoxins. Adriamycin and its metabolites (adriamycinol) are conjugated with glutathione by GSTs and transported by MRPs and BCRP, etc. Increased expression of GSTs, especially GSTπ, also confers adriamycin resistance by promoting detoxification.

Lung resistance protein (LRP), the 110 kDa major vault protein (MVP), is a main component of vaults, which are multisubunit structures that may be involved in nucleocytoplasmic transport, and is involved in resistance to anticancer drugs including adriamycin. LRP may affect the intracellular distribution of adriamycin, but the detailed mechanisms remain unknown. Furthermore, a relationship between adriamycin resistance and qualitative and quantitative changes in the expression of topoisomerase II, a major target for adriamycin, has been reported.

Mechanisms for Development of Cardiotoxicity

The molecular mechanisms leading to adriamycin-induced cardiotoxicity may include lipid peroxidation by generation of ROS, abnormalities in intracellular calcium homeostasis through inhibition of sarcomeric reticulum Ca^{2+}-ATPase (SERCA2), Na^{+}-K^{+}-ATPase and Na^{+}-Ca^{2+} exchanger of sarcolemma, inhibition of mitochondrial creatine kinase, and interaction with cardiolipin, which is a phospholipid of the inner mitochondrial membrane in the heart. Adriamycin also promotes apoptosis by activation of p38 mitogen-activated kinases (►MAPK) in cardiac muscle cells. Moreover, adriamycin downregulates the expression of genes for sarcomeric proteins (such as α-actin, myosin, troponin I, and myofibrillar creatine kinase) and for proteins involved in calcium homeostasis in the sarcomeric reticulum, such as SERCA2, cardiac muscle ryanodine receptor (RYR2), calsequestrin, and phospholamban, by suppression of transcription factors (e.g. MEF2C, HAND2, and GATA4) and/or activation of a the transcriptional repressor Egr-1.

Adriamycinol (doxorubicinol), a secondary alcohol metabolite, may also be involved in the development of adriamycin-induced cardiotoxicity, via enhancing the inhibitory effects of SERCA2, Na^{+}-K^{+}-ATPase, and Na^{+}-Ca^{2+} exchanger of sarcolemma. Adriamycinol also inhibits the iron-regulatory protein/iron-responsive element (IRP/IRE) system, which plays a crucial role in iron homeostasis, and may lead to cardiotoxicity.

Adult Stem Cells

Rikke Christensen, Nedime Serakinci
Anatomy and Neurobiology, Institute of Medical Biology, University of Southern Denmark, Odense, Denmark

Synonyms

Somatic stem cells; Tissue stem cells; Postnatal stem cells

Definition

An undifferentiated cell found in a differentiated tissue that can renew itself and (with certain limitations) differentiate to yield all the specialized cell types of the tissue from which it originated.

Characteristics

Adult ►stem cells are defined as undifferentiated tissue-specific stem cells with extensive self-renewal capacity, which can proliferate to generate mature cells of the tissue of origin. The primary roles of adult stem cells are to maintain and/or regenerate the cells of damaged tissues. Adult stem cells were first described in organs and tissues characterized by high cell turnover, such as blood, gut, testis, and skin but have to date also been isolated from many other organs and tissues including brain, bone marrow, liver, heart, lung, retina, and skeletal muscle.

Stem cells differ from ►somatic cells with their different potentials and their proliferation ability. There are three kinds of stem cells: Embryonic, germinal, and adults stem cells that are classified according to their developmental potential ranging from totipotency to unipotency. The fertilized oocyte and the blastomere up to the 8-cell stage are considered as totipotent (►totipotent stem cells) as they can differentiate to generate a complete organism. ►Embryonic stem cells, the cells derived from the inner cell mass of the blastocyste, are pluripotent (►pluripotent stem cells) and have the ability to differentiate into cells and tissues from all three germ layers: the endoderm, the ectoderm, and the mesoderm. ►Germinal stem cells are also pluripotent and are derived from so-called primordial germ cells and give rise to the gametes (sperm and eggs) in adults. In contrast, adult stem cells are generally believed to be multipotent (►multipotent stem cells) or unipotent (►unipotent stem cells) which means that they can only give rise to progeny restricted to the tissue of origin. Hematopoietic stem cells (►HSC), bulge stem cells in the hair follicle, and mesenchymal stem cells (►MSC) are examples of multipotent stem cells, which can differentiate into multiple cell types of a single tissue, whereas epidermal stem cells, myosatellite cells of muscle, and endothelial progenitor cells are examples of unipotent stem cells, which only give rise to one mature cell type. Recently, some studies have shown that many adult tissues may contain cells with pluripotent capacity capable of generating differentiated cells from an unrelated tissue. This process is termed ►stem cell plasticity.

In most tissues/organs renewal is compensated by tissue-specific stem cells. The stem cells normally divide very rarely, but stimuli caused by damaged or injured tissue or a need to generate progeny to maintain the tissue can induce proliferation and produce daughter cells that can differentiate into the specific cell lineages of the respective tissue type. Stem cell division typically leads to the formation of committed progenitor cells with more limited self-renewal capacity as e.g., transit amplifying cells in the epidermis or lymphoid or myeloid progenitors in the bone marrow. Tissue progenitor or transit amplifying cells provides an expanded population of a proliferating tissue that differentiate into more mature and determined cells that eventually no longer proliferates and die. To maintain the balance in the adult tissues/organs, the number of progenitor/stem cells that proliferates must be equal to the number of cells that determinedly differentiate and die. If the number of proliferating cells is higher than the number of cells that maturate and die, it will give the primary feature of a cancer. Studies have shown that many of the pathways that regulate normal stem cell proliferation are dysregulated and cause neoplastic proliferation in cancer cells. Therefore, cancer may be considered a disease of dysregulated cellular self-renewal capacity.

Adult stem cells reside in a special ►microenvironment termed the stem cell niche. Stem cell niches are composed of a group of cells that provide a physical anchorage site and extrinsic factors that control stem cell proliferation and differentiation and enable them to maintain tissue homeostasis. Deregulation of the niche signals has been proposed to lead to cancer. A decrease in proliferation-inhibiting signals, or an increase in proliferation-promoting signals, may lead to excessive stem cell production and thereby development of cancer stem cells (see later). Investigation of the interaction between stem cells and their niche may reveal possible targets for cancer treatments. For example, the blocking of proliferation signals, enhancing of antiproliferative signals or induction of differentiation from the stem cell niche may be used to target the cancer stem cells. It has furthermore been suggested that targeting the stem cell niche may prevent cancer metastasis. Some cancers metastasize to sites that cannot be explained by circulation distribution, lymphatic drainage or anatomic proximity. These sites may, however, provide favorable niches that support the survival of the cancer stem cells.

Much effort is put into the identification of ►stem cell markers to be able to isolate the stem cells of interest. Isolation of stem cells makes it possible to enhance the knowledge of stem cell identity and to use them therapeutically.

Therapeutic Potential

Adult stem cell transplantation has been used in several years for the treatment of ►hematological malignancies and lymphomas. The main purpose of stem cell transplantation in cancer treatment is to make it possible for patients to receive very high doses of chemotherapy and/or radiation. High-dose chemotherapy and radiation can severely damage or destroy the bone marrow while killing cancer cells. Before treatment, bone marrow or peripheral blood stem cells are harvested from the patient itself (for autologues transplantation) or from a donor (for allogen transplantation), frozen down, and then transplanted after the patient has received high doses of chemotherapy, radiation therapy, or both. The transplanted healthy stem cells replace the stem cells destroyed by high-dose cancer treatment and allow the bone marrow to produce healthy cells.

Stem cells in general, due to their high proliferative capacity and long-term survival in comparison to somatic cells, make them very ideal candidates to use for regenerative medicine and cell replacement therapy. Lately, there has been an increasing interest in the potential use of adult stem cells in cell replacement strategies and in tissue engineering, including gene therapy. This current interest rose due to the discovery of adult stem cells with pluripotential capacity and/or transdifferentiating (►transdifferentiation) ability, which means that cells from one tissue can differentiate into mature and functional cells of another tissue. There are reports that HSCs under certain conditions can evolve into cells of neural lineage, liver, muscle, skin, and endothelium; skeletal muscle stem cells can evolve into blood cells and neural cells; and hair follicle stem cells can evolve into neural lineage cells. Other adult stem cells that can be induced to a different cell type include MSCs, cardiac muscle stem cells, neural stem cells, and testis-derived stem cells. These cells have the advantage that they can be used as autologous transplants and have been proposed as an attractive alternative to ►embryonic stem cells in genetic therapy.

An alternative approach for therapeutic use of stem cells is to use them as cellular vehicles. It has been demonstrated that genetically modified MSCs can be used to target delivery of anticancer agents and ►suicide gene therapy vectors to tumor cells. Upon administration, MSCs can target microscopic tumors, proliferate and differentiate, and contribute to the formation of a network of cells surrounding the tumor (tumor stroma). MSCs genetically modified to express interferon beta has, for example, been shown to inhibit the growth of tumor cells by local production of interferon beta. MSCs are not the only stem cells that have been used as shuttle vectors for delivery of gene therapies into growing tumors. It has also been demonstrated that neural stem and progenitor cells migrate selectively to tumor loci in vivo in mice. These studies clearly suggest that a stem cell-directed prodrug therapy approach may have great use for eradicating tumors as well as to treat the residual cancer cells remaining after therapy.

Genetic manipulation of adult stem cells may also be used to increase the functionality and proliferative capacity of these cells. HSCs are one of the most promising candidates for correction of single gene disorders as e.g., ►cystic fibrosis and ►hemoglobinopathies, due to their capability of targeting solid organs and high success rate in their isolation by using a combination of surface markers. Infants with forms of ►severe combined immunodeficiency syndrome have successfully been treated with genetically engineered bone marrow stem cells. The stem cells were harvested from the patients, a functional gene inserted, and the genetically modified cells reintroduced to the same patient. To increase the success of chemotherapeutic treatment, drug resistant HSCs have been produced by introduction of the ►multidrug resistance gene with the aim of limiting the myelosuppressive effects of standard chemotherapeutic agents on the stem cells. However, even though adult stem cells have shown to carry great potential to function as therapeutic agents for targeting human diseases such as cancer, degenerative and chronic diseases, they do have some restrictions such as having limited self-renewal capacity. This limitation can be overcome by the introduction of immortalizing genes that increases the cells proliferative capacity. ►Telomerase has been, in this connection, highlighted among the numerous genes that are capable of immortalizing stem- or progenitor cells. However, suggested oncogenic potential of ►immortalized cells release caution that before the therapeutic use of stem cells in the clinic, a thorough screen for transformation phenotype is required.

Cancer Stem Cells

The theory that cancer stem cells (►cancer stem-like cells and ►stem-like cancer cells) are involved in many types of cancer has recently gained popularity. There are many similarities between adult stem cells and cancer stem cells. Both have the ability to self-renew and differentiate into more mature diversified cells. Cancer stem cells and normal stem cells share many cell surface markers and utilize many of the same signal transduction pathways.

Cancer stem cells have been identified in most types of hematopoietic malignancies, including acute myeloid leukemia, chronic myeloid leukemia, acute

lymphoblastic leukemia, and multiple myeloma. Recently, cancer stem cells have also been isolated from solid tumors such as breast, lung, and brain tumors. The cancer stem cells only represent approximately 1% of the tumor, making them difficult to detect and study. Studies have shown that cancer stem cells may cause tumors when transplanted into a secondary host indicating that the cancer stem cells can initiate and repopulate a tumor. A study of human leukemia shows that the normal hematopoetic stem cell and the neoplastic clone share common molecular mechanisms governing proliferation which is supportive of the normal hematopoetic stem cell being a target for transformation. Due to stem cells are able to divide over the lifespan of the individual they seem to allow accumulation of a number of mutations and perhaps epigenetic changes (►epigenetics) that cause neoplastic development. In addition, it has been shown that adult stem cells can be targets for neoplastic transformation by introducing the telomerase gene into a purified stem cell. The transduced cell line showed characteristic alterations of neoplastic development such as contact inhibition, anchorage independence, and in vivo tumor formation in immunocompromised mice. All these findings give a very large support to the existence of cancer stem cells and the strong links between normal adult stem cells and cancer stem cells suggest that stem cells are targets for neoplastic transformation. Cancer stem cells may also be derived from differentiated cells. Loss of the ►tumor suppressor genes $p16^{Ink4}$ and $p19^{Arf}$ combined with constitutive activation of the EGF receptor (►EGFR) caused loss of differentiation in mature brain astrocytes and the cells regained stem cell properties.

The identification of cancer stem cells strongly suggests that these cells are the key targets for future therapeutic development as they fuel the replicative capacity of the cancer. Therefore, as much as understanding the nature of a cancer cell it is very crucial to understand the neoplastic potential of the stem cells. Analysis of the differences between adult stem cells and cancer stem cells is very important to be able to specifically target the cancer stem cells whilst sparing the normal stem cell population. Several studies indicate that some stem cell markers are expressed differently in normal and cancer stem cells and these may be potential targets in the development of future cancer treatments.

Adult T-cell Leukemia

Definition

ATL; A leukemia of mature T lymphocytes (►T cells) developing in adults, resulting from infection with the ►human T-cell leukemia virus (HTLV) and characterized by circulating malignant T-lymphocytes, skin lesions, lymphadenopathy (enlarged lymph nodes), hepatosplenomegaly (enlarged liver and spleen), hypercalcemia (high blood calcium), lytic ("punched out") bone lesions, and a tendency to infection. There are four categories of ATL, based on the aggressiveness of the disease – smoldering, chronic, lymphoma, and acute.

Adult Tissue Stem Cells

Definition

These cells are set aside during development in order to provide a source for replenishment of tissue over time in response to damage or simply wear and tear.

Aflatoxins

Thomas E. Massey, Katherine A. Guindon
Department of Pharmacology and Toxicology, Queen's University, Kingston, ONT, Canada

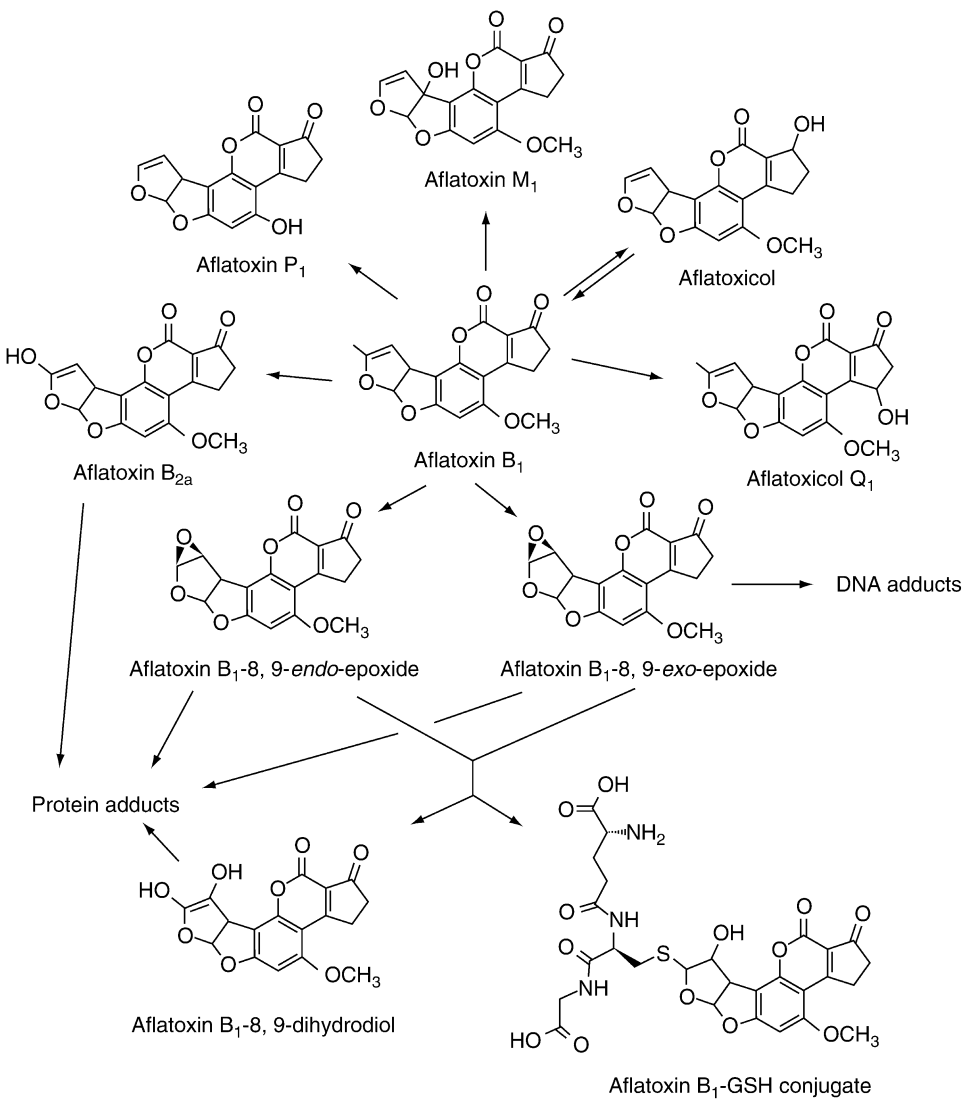
Definition
Mycotoxins are contaminants of a number of agricultural products, including peanuts, corn, and other grains in warm and moist conditions. Human exposure to aflatoxins is primarily through ingestion and results in acute hepatic necrosis, marked bile duct hyperplasia, acute loss of appetite, wing weakness, and lethargy.

Characteristics
In the early 1960s, an outbreak of hepatotoxic disease in turkeys, which became known as turkey "X" disease, gained the attention of many investigators worldwide. This condition was characterized by acute hepatic necrosis, marked bile duct hyperplasia, acute loss of appetite, wing weakness, and lethargy. It was deduced that the condition was caused by consumption of peanut meal contaminated with a mycotoxin, which is a toxin of fungal origin. The culprit fungi in turkey "X" disease turned out to be strains of *Aspergillus flavus, A. parasiticus, and A. nomius,* and thus the term aflatoxins was coined for the toxic metabolites. More specifically, *A. flavus* and *A. parasiticus* can produce aflatoxins B_1, B_2, G_1, G_2, and M_1. These mycotoxins can contaminate a number of agricultural products, including peanuts, corn, and other grains in warm and moist conditions. Human exposure to aflatoxins is primarily through ingestion. In addition to outbreaks of liver failure and gastrointestinal bleeding in Southeast Asia and Africa having been attributed to aflatoxins, ►liver cancer incidence was observed to be elevated in regions with high endemic aflatoxin concentrations. The two major risk factors for human ►hepatocellular carcinoma, the fifth most common cancer worldwide, are hepatitis B infection and ingestion of aflatoxins.

Aflatoxin B_1 (AFB_1), the most prevalent and carcinogenic of the aflatoxins, is classified as a group 1 carcinogen (carcinogenic to humans) by the International Agency for Research on Cancer. Although the majority of AFB_1 research has focused on its hepatic effects, AFB_1 also targets other organs, including the lung and the kidney. In the lung, exposure to inhaled AFB_1, particularly from contaminated grain dusts, has been linked to ►respiratory cancers (►Lung cancer). Due to a significant proportion of ingested mycotoxin being excreted via the urine, the renal nephron is exposed to AFB_1 and its metabolites. AFB_1 accordingly alters kidney function, and is a known renal carcinogen.

Biotransformation

AFB_1 is defined as a procarcinogen, as its bioactivation is required for carcinogenicity (Fig. 1). The initial metabolism of AFB_1 involves four types of reactions: *O*-dealkylation, hydroxylation, epoxidation, and ketoreduction. The enzymes responsible for the metabolism include members of the ►cytochrome P450 family (CYPs), prostaglandin H synthase (PHS), lipoxygenase (LOX), and a cytosolic NADPH-dependent reductase. In experimental animals, CYPs involved in AFB_1 bioactivation include members of 1A, 2B, 2C, and 3A subfamilies. In humans, there are multiple p450 isozymes implicated, including CYP1A2, CYP2A3, CYP2B7, CYP3A3, and CYP3A4. CYP3A4 is thought to play a predominant role in the metabolism of AFB_1 in human liver; although CYP1A2 has the highest affinity for AFB_1 at low concentrations, it is expressed at much lower levels than CYP3A4. PHS and LOX are involved in ►xenobiotic bioactivation by catalyzing the oxidation of ►arachidonic acid to produce lipid



Aflatoxins. Figure 1 Biotransformation of AFB_1.

peroxyl radicals, which are known epoxidizing agents. Cooxidation by PHS and LOX may be a significant mechanism of AFB_1 bioactivation in extrahepatic tissues such as lung, which has high PHS and LOX expression, but overall P450 activity is lower than that in the adult liver.

Regardless of the enzyme catalyzing the reaction, epoxidation of AFB_1 results in formation of AFB_1-8,9-epoxide, which can exist in both *endo* and *exo* conformations. The *exo*-epoxide is the isomer implicated in the ►alkylation of DNA, with its reactivity being at least 1,000 fold greater than that of the *endo*-epoxide. Hydroxylated metabolites of AFB_1 include AFM_1, AFQ_1, AFP_1, and AFB_{2a}. The formation of aflatoxicol from AFB_1 is reversible, and therefore aflatoxicol is considered to be a "reservoir" for AFB_1 rather than a bioactivation or ►detoxification product.

The two pathways for AFB_1-epoxide detoxification are glutathione conjugation and epoxide hydrolysis, with glutathione conjugation being quantitatively the most important (Fig. 1). Glutathione conjugation is catalyzed by ►glutathione-S-transferases (GSTs), which can be highly polymorphic. Human GSTM1-1 (hGSTM1-1), which is absent in ~50% of individuals, has the highest activity towards AFB_1 *exo*-epoxide, but the importance of this polymorphism in AFB_1 carcinogenicity has not yet been clearly established. AFQ_1, AFP_1, and AFB_{2a} are not highly mutagenic and therefore are considered to be detoxification products. They can form glucuronide or sulfate conjugates, which are excreted. AFM_1, a metabolite of AFB_1 identified in milk and urine, is less biologically active than AFB_1, but regardless is a potent carcinogen. The AFM_1-epoxide can also bind to DNA, forming AFM_1-N^7-guanine.

Carcinogenesis

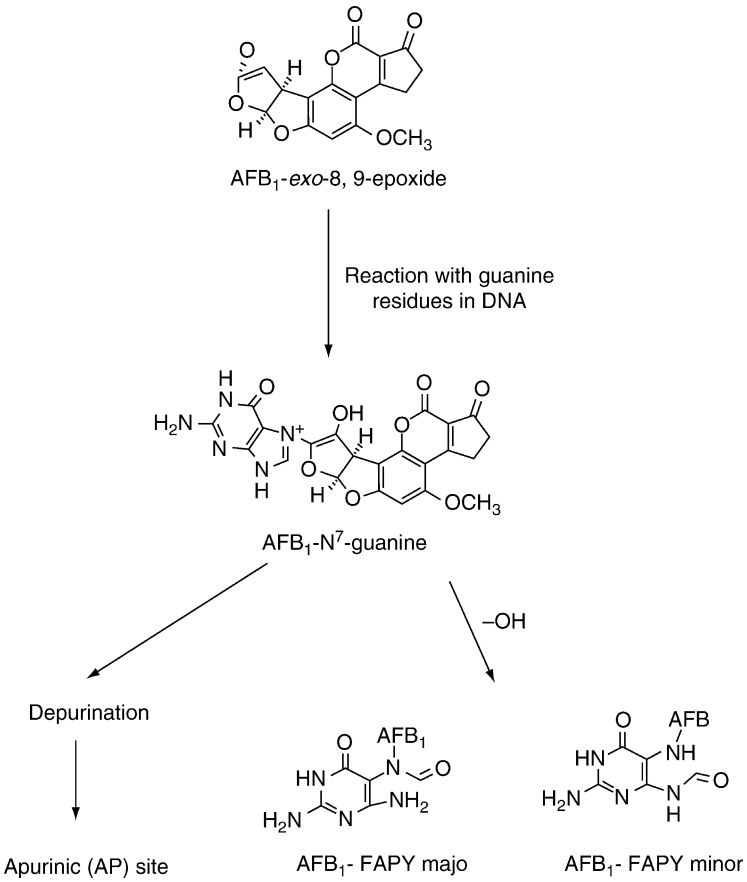
AFB_1 is considered to be a complete carcinogen, possessing activity as both an initiator and a promoter. Initiation occurs by ►DNA damage, as well as cytotoxicity, which stimulates cell division, thus promoting tumor formation. There are many characteristics of AFB_1 that makes it a useful tool for investigating ►chemical carcinogenesis. First, the metabolites of AFB_1 have been extensively investigated and their toxicity elucidated. Second, the toxicity of AFB_1 is determined by a balance between bioactivation and detoxification of the AFB_1-8,9-epoxide. Third, there exists multiple mechanisms of bioactivation that can be compared in terms of carcinogenic metabolites produced. Fourth, not only does the susceptibility of a species/tissue relate to ►DNA repair capabilities (►Repair of DNA), but AFB_1 itself has effects on DNA repair activity. Fifth, the specific AFB_1-DNA adduct formed can be used to predict the mutagenic responses. Finally, the parent compound and several metabolites fluoresce, facilitating detection.

The *exo* epoxide of AFB_1 can alkylate proteins and ►nucleic acids, with the second guanine from the 5′ end in guanine di- and trinucleotide sequences in DNA being the favored target. The major adduct formed by the *exo*-epoxide is 8,9-dihydro-8-(N^7-guanyl)-9-hydroxy AFB_1, also known as AFB_1-N^7-Gua (Fig. 2). AFB_1-N^7-Gua can undergo three reactions: release of AFB_1-8,9-dihydrodiol restoring guanine; depurination resulting in an apurinic site in DNA; and base-catalyzed hydrolysis to form the AFB_1-formamidopyrimidine adduct (AFB_1-FAPY). AFB_1-FAPY, representing a significant proportion of AFB_1 adducts *in vivo*, exists in equilibrium between two rotameric forms, designated AFB_1-FAPY major and AFB_1-FAPY minor. The structure of AFB_1-FAPY has not been completely defined, although the proposed structure is presented in Fig. 2. It has also been shown that metabolism of AFB_1 can lead to formation of 8-hydroxy-2′-deoxyguanosine in rat, duck, and woodchuck liver and in mouse lung. G to T transversion, the most frequently observed mutation induced by AFB_1, results from DNA alkylation and subsequent AFB_1-N^7-Gua formation, and possibly by the ►oxidative DNA damage as well. A proportion of mutations in DNA formed by AFB_1 occurs at the base 5′ to the modified guanine, or even further away, due to helical distortion resulting from the AFB_1 adduct.

►*P53*, a ►tumor suppressor gene considered the "guardian of the genome," has controls on cell cycle, DNA repair, and ►apoptosis. *P53* is the most frequently targeted gene in human carcinogenesis, with a mutation frequency of 50% in most major cancers. In geographical regions with a high dietary exposure to AFB_1, such as China and Sub-Saharan Africa, mutations in *p53* have been implicated AFB_1-induced human liver tumorigenesis. AFB_1 produces mutations at the 3rd base of codon 249 in *p53*, causing a G→T transversion, and an amino acid substitution (arginine to serine), and thus a structural alteration of this tumor suppressor protein. This may result in deregulation of the cell cycle, and thus loss of tumor suppression by *p53*. The K-►*ras* proto-►oncogene, important in ►signal transduction, is often implicated in human and mouse lung tumors. AFB_1-induced point mutations at specific "hot spots" (e.g. codons 12 and 13) of the K-*ras* gene, which cause activation of the protein, occur in AFB_1-induced mouse lung tumorigenesis and rat hepatocarcinogenesis.

Repair

In mammals, ►nucleotide excision repair (NER) is important for protection against AFB_1-induced carcinogenesis. NER is a DNA repair process that deals with a wide array of DNA helix-distorting lesions that affect normal base pairing, thus altering transcription and replication. In *E. coli*, NER is responsible for the repair of both AFB_1-N^7-Gua and AFB_1-FAPY. In yeast, NER



Aflatoxins. Figure 2 AFB_1-*exo*-8,9-epoxide and DNA damage.

is also the main repair pathway, although ▶homologous recombination is also involved in the repair of AFB_1-induced damage. In mammals, NER is important in protection against AFB_1-induced carcinogenesis. NER is the main repair mechanism for the AFB_1-N^7-Gua adduct. AFB_1-FAPY is repaired less efficiently by mammalian NER than is AFB_1-N^7-Gua, an effect that is attributed to AFB_1-FAPY being less distortive of DNA architecture. Apurinic sites generated by AFB_1-DNA adduct formation are repaired by base excision repair (BER), although insertion of an incorrect base is a frequent occurrence.

Species/Tissue Susceptibility

Susceptibility to the toxic and carcinogenic effects of AFB_1 varies between species, as well as between different tissue types. In humans, the liver is the main target for this toxin. In rat, duck, and trout, administration of AFB_1 results in hepatocarcinogenesis, whereas this is not the case in the mouse, monkey, hamster, and mouse. The reason for this has been attributed to differences in AFB_1 biotransformation and DNA repair. For example, the mouse is susceptible to pulmonary carcinogenesis by AFB_1, regardless of the route of administration, but does not develop hepatocarcinogenesis. The mouse liver expresses an alpha-class GST with high specific activity towards the *exo*-epoxide, and higher NER activity as compared to the rat liver. On the other hand, mouse lung has lower DNA repair activity than does liver. AFB_1 is able to alter NER activity (by inhibition or elevation) in different animal species and organs, which may contribute to differential susceptibility to the mycotoxin's carcinogenicity.

Aggressive Fibromatosis in Children

Marry M. van den Heuvel-Eibrink
Department of Pediatric Oncology/Hematology, ErasmusMC-Sophia Children's Hospital, Rotterdam, The Netherlands

Synonyms
Aggressive fibromatosis; Desmoid tumor

Definition
►Aggressive fibromatosis (AF) is a rare soft tissue tumor and rare in childhood with high potential for local invasiveness and recurrence. Primary ►surgery with ►negative margins is the most successful primary treatment modality for ►children with ►AF. Positive resection margins after surgery indicate a high risk for ►relapse. Multicenter prospective (randomized) trials are necessary to clarify the role of and best strategy for ►treatment in pediatric AF after ►incomplete surgery. For this purpose, ►chemotherapy or alternatively ►radiotherapy can be considered, each with its own potential side effects in consequence.

Characteristics
Aggressive fibromatosis (AF) (►Supportive care) is a soft tissue tumor, which arises principally from the connective tissue of muscle and the overlying fascia (aponeurosis). The previously most used synonym is ►desmoid tumor. The histological pattern is characterized by elongated fibroblast-like cells. Although AF is a nonmetastasizing tumor with benign histological features, it has a significant potential for local invasiveness (►Invasion) and ►recurrence. The overall incidence of

AF in children is 2–4 new diagnoses per 1 million a year. Childhood AF has an age distribution peak at approximately 8 years (range 0–19 years) with a slight male predominance.

Clinical Presentation

The typical clinical presentation of AF is a painless, slowly growing, deep-seated mass. Predilection sites are shoulder, chest wall and back, thigh, and head/neck. Children with AF of head/neck have shown to be to be younger at diagnosis than children with AF at other sites. From 1986 until 2004, ten pediatric AF case series reported a total of 206 patients. In 64 of the reviewed patients site of involvement and age at diagnosis were specified. The children with AF of head/neck had a median age of 3.6 years at diagnosis (range 0.2–9.9 years), whereas the children with AF of trunk/limb had a median age of 7.8 years (range 0.0–15.7 years) ($p<0.01$). This difference in age distribution may be influenced by referral and selection bias; however, it may reflect the site distribution in different age groups in children with AF.

Diagnostic Approach

The diagnosis of AF is based on histology. It arises principally from the connective tissue of muscle and the overlying fascia (aponeurosis). The fibromatosis lesion is characteristically poorly circumscribed and infiltrates the surrounding tissue, which is usually striated musculature. The proliferation consists of elongated fibroblast-like cells of uniform appearance surrounded by and separated from one another by abundant collagen, with little or no cell-to-cell contact. The cells lack hyperchromasia or atypia and the mitotic rate is variable. Using immunohistochemistry, the spindle muscle cells stain strongly with vimentin, whereas smooth muscle actin (SMA) and muscle-specific actin stain variable. Rare cases also stain with desmin and S-100.

Pathogenesis

The pathogenesis of AF is suggested to be multifactorial, i.e., genetic predisposition, endocrine factors, and trauma seem to play an important role. Local physical trauma before developing AF was reported in 20% of 108 reported pediatric AF patients from three studies. Apparent chromosome aberrations and nonrandom X-chromosome inactivation in adult and pediatric AF suggests a true neoplastic character (Chromosome translocations). This is supported by a report of eight pediatric AF cases in one study, of which five (63%) had an abnormal karyotype (two at initial diagnosis, and three at relapse) with trisomy 8 (n = 4) and trisomy 20 (n = 1) being the only recurrent features (►Chromosome translocations). Sporadic cases of adult AF contain a somatic mutation in either the adenomatous polyposis coli (APC) gene (21%), identified on chromosome 5q22 and associated with familial adenomatous polyposis (FAP), or β-catenin gene and protein expression (52%) (►APC Gene in Familial Adenomatous Polyposis; ►APC/β-Catenin Pathway).

A high prevalence of ►desmoid tumor has been reported in 126/880 (14.3%) of adult FAP patients with proven APC gene mutation. Insulin-like growth factor binding protein 6 (IGFBP-6) appears directly down-regulated by the β-catenin/TCF complex in adult AF, and implies a role for the IGF axis in the proliferation of AF. In addition, a high prevalence of AF (38%) was reported for patients with Gardner syndrome. In contrast, in a review of all reported pediatric AF studies no patient with a history of familial AF or FAP, and only two patients with Gardner syndrome was seen. This illustrates that routine karyotyping has a relatively limited value, and the significance of the APC and β-catenin genes in the pathogenesis of childhood AF and their value for differentiating fibroblastic tumors has not yet been established. In adults, a correlation between tumor growth rate and the level of endogenous estrogen was suggested in female patients, because of high amounts of estrogen receptors (ER) in their tumor tissue. These are important findings as the presence of antiestrogen binding sites (AEBS) distinct from ER are suggested to play a role in treatment with antiestrogens in adult ►AF02254. So far, in two studies, only four children with AF were tested and did not express ER, indicating that the role of expression of ER and AEBS in pathogenesis of childhood AF may be limited.

Treatment

As these tumors at presentation clinically mimic other more malignant soft tissue tumors like ►rhabdomyosarcoma, non-ossyfying ►Ewing sarcoma sooner or later pediatric AF patients come to the attention of a pediatric oncologist. However, as the tumor is heterogeneous with regards to site and extension, treatment strategy in each individual patient is ideally determined by a multidisciplinary team which consists of pediatric oncologists, surgeons, and radiotherapists, supported by the diagnostic expertise of pediatric radiologists and pathologists. Aggressive fibromatosis still lacks general recommendations for its clinical management. Although spontaneous regression has been observed in sporadic cases, surgery is generally the primary treatment modality in adults and children with AF, unless there is a risk of significant mutilation and/or functional impairment. Seven of ten pediatric AF studies report treatment of the primary tumor, and all generally treated their patients (n = 168) with initial surgery. The other three series report treatment of recurrent tumor, two of them initially treated their patients (n = 15) with chemotherapy [vinblastine (VBL) and methotrexate (MTX)], whereas in the third study (n = 4) radiotherapy 01859 was administered.

Relapse rate in the reviewed children with primary AF was approximately 50%. Most relapses (89%) have been observed within 3 years, and nearly all (97%) by 6 years, although relapse after 10 years has been reported. All relapses are local or regional with a pattern consistent with infiltrative growth. Three deaths are reported, caused by invasive tumor destruction of vital organs (►Progression), all three located in the head/neck region.

In 85 pediatric patients in whom primary surgery was performed, information on resection margins and relapse was available. Remarkably, only 16% of the patients with ►free microscopically margins after surgery relapsed, versus 67% of patients with positive margins ($p<0.01$). In case of positive resection margins, 74% of patients without additional therapy relapsed, versus 40% of patients who received adjuvant treatment ($p = 0.064$). Adjuvant treatment consisted of chemotherapy (n = 8) or radiotherapy (n = 2) (►Adjuvant therapy). Although this is a retrospective analysis, which implies disadvantages like selection biases, the high risk for relapse in case of positive resection margins may indicate that the role of adjuvant treatment in patients with positive margins needs further exploration. In adults, the standard approach for patients with microscopically positive margins after surgery is adjuvant radiotherapy resulting in a high local control rate of approximately 80%, which is therefore considered to be beneficial regardless of surgical margins. In pediatric patients the high doses of radiotherapy (55–60 Gy) necessary for tumor control in AF harbors a large risk for growth problems and development of secondary malignancies (►Radiation Sensitivity; ►Radiation-Induced Sarcomas after Radiotherapy).

One pediatric AF study reported 11 children with partially excised or recurrent lesions who received radiotherapy, and who had at least 3-year follow-up. Four (36%) children relapsed, including two of five who had a dose of ≥50 Gy. In contrast, another pediatric AF study reported 11 of 13 (85%) children with relapse after irradiation, including 6 of 8 who had a dose of ≥50 Gy. The role of radiotherapy in childhood AF as adjuvant treatment in case of SP is not yet established and needs further prospective randomized. studies which will not only evaluate response and survival but also late sequelae.

The use of chemotherapeutic and other systemic agents might be a reasonable alternative to avoid radiotherapy in the growing child. However, also chemotherapy carries the risk for potentially adverse side effects, like second malignancies, fertility problems, and cardiotoxicity. A recent review concerning mainly adult AF reported a median overall response rate of 50% (range 17–100%) with combination chemotherapy [doxorubicin, actinomycin-D, methotrexate (MTX), and vinca alkaloids], in 16 single-arm studies. Reviewing all pediatric AF cases treated with chemotherapy in total, 27 out of 187 pediatric patients were treated with chemotherapy only at initial diagnosis (n = 10) or at relapse (n = 17). A combination of VBL and MTX was the most common reported regimen. Response on chemotherapy only was complete remission (CR) in 26%, partial remission (PR) in 18%, whereas stable disease (SD) was found in 30%, progressive disease (PD) in 11%, and response was not reported in 15% of the reviewed cases. Overall relapse rate (RR) after treatment with chemotherapy only was 26%.

Comparing the relapse rate (respectively 74% versus 50%) of 46 pediatric patients with positive margins after primary surgery may suggest an advantage in outcome of adjuvant treatment with chemotherapy (n = 8), as compared with patients who did not receive adjuvant treatment (n = 38), however, numbers of cases are small and derived from different series. This illustrates that the role of chemotherapy in childhood AF is not yet established and should be further explored. Currently, a collaborative study of MTX/VBL chemotherapy for children with AF is initiated. Based on the reported experiences, the response of pediatric AF to chemotherapy has shown to be slow and it has been suggested that treatment should be continued for prolonged periods from 12 to 18 months. The chronic and prolonged course that many of these children with AF endure as a result of these slow-growing lesions suggests that the use of (combinations of) noncytotoxic drugs, like antiestrogens, ►nonsteroidal anti-inflammatory drugs (NSAIDs), imatinib mesylate, interferon-alpha (IFN-α), and ►retinoic acid for part of their treatment might be reasonable treatment options to explore.

Side Effects in Survivors

So far, information on toxicity of treatment is available from five pediatric AF case series (n = 128) with a median follow-up time of 4 years (range 0–25 years). Two studies reported a limited range of motion of the primary area as the most frequent late complication (42%). Severe short-term toxicity of treatment was reported in three patients, two died of cardiotoxicity after treatment with doxorubicin and one died of severe radiation induced dermatitis with chronic ulcers. During this short median follow-up, one secondary malignancy was reported; a papillary carcinoma of the thyroid gland, which developed 11 years after radiotherapy.

Conclusion

Primary surgery with negative margins is the treatment of choice for children with AF. In case of unresectable tumors, the use of chemotherapy and/or noncytotoxic drugs in children with AF could be a reasonable alternative. Positive margins after surgery indicate a high

risk for relapse. Multicenter prospective (randomized) trials are necessary to clarify the role of and best strategy for adjuvant treatment in pediatric patients with aggressive fibromatosis.

Aging

Cynthia C. Sprenger, Stephen R. Plymate, May J. Reed

Department of Medicine, Division of Gerontology and Geriatric Medicine, University of Washington, Seattle, WA, USA

Definition

Aging is defined at many levels, from the mitotic age of cells to the organismal-wide aging of tissues and organs. The appearance of cancer is only one clinical manifestation of the aging process. Age-associated ►epithelial cancers, such as ►breast cancer, ►colon cancer and ►prostate cancer, however, contribute significantly to the morbidity and mortality of the elderly and are the second leading cause of death.

Characteristics

Aging

During an organism's lifespan almost every aspect of its phenotype will undergo modification. The complexity of aging has led to a plethora of ideas about the specific molecular and cellular causes and how these alterations lead to age-associated diseases, such as epithelial cancers. Underlying all of these theories is the assumption that aging occurs from the bottom-up beginning with damage to DNA and proteins and ending with organismal frailty, disability, and disease. There is a vast amount of evidence to support the following aging theories: ►somatic mutation, telomere loss, mitochondrial damage, and altered proteins and waste accumulation. Somatic mutation theory suggests that age-related accumulation of ►DNA damage demonstrates a decline in DNA repair mechanisms, while the telomere loss theory argues that telomere shortening confers a finite lifespan to many human ►somatic tissues. Shortening of telomeres leads not only to a loss of chromosome replicative ability but also to an increased propensity for recombination events, such as chromosomal translocations, that may induce oncogenesis. The mitochondrial theory makes a connection between age-related accumulation of mutations in mitochondrial DNA and impaired ATP production and thus reduced tissue bioenergenesis. Finally, the altered proteins and waste accumulation theory argues that accumulation of damaged proteins, due to either a decline in the function of chaperone proteins or proteosomes, leads to cellular damage, which then contributes to a range of age-related disorders. There is increasing consensus that all of these mechanisms interact to play a role in aging.

Epithelial Cancers

The body defends itself against epithelial cancers by halting replication of damaged cells either through ►apoptosis, in which the cell dies, or by ►senescence, in which the cell replicatively arrests but remains metabolically active. Both of these mechanisms are important in preventing the formation of epithelial tumors in the young. As one ages, the number of senescent cells increases. The accrual of these senescent cells may alter the ►microenvironment of the tissue such that cells harboring preneoplastic damage are permitted to proliferate and eventually undergo transformation. Senescent cells may contribute to this milieu, in part, by secreting paracrine factors that compromise tissue structure and function. Consequently, senescence inhibits cancer formation early on, but with time the build up of senescent cells alters the microenvironment to one that promotes the growth of epithelial cancers.

Cellular Senescence

Most studies on senescence and cancer focus on the role played by senescent fibroblasts in the transformation of epithelial cells. Fibroblasts can undergo senescence as a result of various processes including: ►replicative exhaustion (telomere shortening), ►oxidative stress, DNA damage, ►epigenetic changes to ►chromatin organization, or activation of ►oncogenes such as ►Ras, all of which appear to signal primarily through ►p53-dependent pathways, although some oncogenes trigger senescence via p16. Once a cell has entered senescence, its transcriptome is altered such that genes associated with wound healing (e.g. ►inflammatory cytokines, ►epithelial growth factors, and ►matrix metalloproteinases (MMPs)) are activated.

The alteration in gene expression affects not only the senescent fibroblast itself, but the cells surrounding it as well. Senescent fibroblasts that were co-cultured with breast or prostate epithelial cells increased the proliferation and tumorigenicity of those epithelial cells, both *in vitro* and *in vivo*.

Epithelial cells can also undergo senescence due to oxidative stress, DNA damage, epigenetic changes, or activation of oncogenes. The pathways that trigger epithelial senescence include both p53- and p16/►pRb-dependent as well as independent pathways. While the specific genes triggered by senescence can vary between the two cell types, the pattern of activation is similar: senescent-associated genes exhibit chromosomal clustering. Genes up-regulated in senescent fibroblasts include various cell cycle proteins, interleukins, ►growth factors, integrins, MMPs, and caspases. Those up-regulated in senescent epithelial cells include various cell cycle proteins, epithelial growth factors, transcription factors, integrins, ►laminins, ►fibronectin, MMPs, and ►tissue inhibitors of metalloproteinases (TIMPs). It is important to note that not all of these genes were up-regulated in all samples or studies, only that these genes have been mentioned in various studies on senescence. In addition, it remains to be seen which genes trigger senescence and which are activated during senescence.

Alterations in the Microenvironment

Tissue architecture is important for maintaining proper cellular function and thus serves as a protective mechanism against diseases, including cancer. Accordingly, a defining characteristic of epithelial cancers is ►loss of tissue architecture. The microenvironment, which includes the ►extracellular matrix (ECM) (collagens, laminins, nidogens, proteoglycans) and soluble factors that are released by the cells or transmitted by other organs (hormones, cytokines, growth factors, enzymes), can serve as a powerful tumor suppressor, keeping damaged cells in check. A microenvironment that provides the correct cues can revert cells containing preneoplastic as well as oncogenic mutations back to a normal phenotype. But tissue architecture is not static: it is continually undergoing alterations due to the processes of living. The traditional focus in cancer has been on interactions between cells and various growth factors. However, there is increasing interest in other components of the extracellular space as well as in the bi-directional cross-talk between the ECM and cells. The ECM interacts with cells via cognate receptors on the cell membrane, including integrins and syndecans. These receptors are connected to the cytoskelton of the cell, which is connected to the nuclear matrix and chromatin. Thus signals travel back and forth between the ECM and the cell that regulate gene expression and, in turn, protein expression, which then alters the make-up of the microenvironment. This bidirectional interaction between ECM and cells is termed dynamic reciprocity.

The appearance of cancer cells disrupts the microenvironment and thereby destroys tissue architecture. Moreover, many oncogenic epithelial cells overexpress matrix metalloproteinases. These enzymes degrade various proteins in the basement membrane, including collagens and laminins. The subsequent disruption of the ECM allows the transformed epithelial cells to migrate into the stroma and form tumors. In breast and prostate carcinomas, the microenvironment consists of transformed epithelial cells, ►reactive stroma, recruited blood vessels, and infiltrating immune cells such as macrophages, lymphocytes, and leukocytes. Numerous studies also demonstrate that components of the ECM, such as collagen and laminin, are modified by and contribute to further tumor growth. Alterations in ECM protein are mirrored by changes in cell membrane receptors, such as integrins and ►growth factor receptors.

Tumor Progression in Aging

Whereas aging confers the greatest risk of developing cancer (as discussed above), it is widely accepted that most histologically similar epithelial tumors behave less aggressively in the aged. This longstanding impression arose from clinical studies in humans and was further supported by animal models, in which young and aged mice received identical inocula of tumor cells and were subsequently monitored for tumor growth and aggressiveness. Proposed mechanisms have focused on age-related deficits in immune mediated responses that directly and indirectly promote tumor growth (such as a lack of inflammatory cells and their associated cytokines) and decreased ►angiogenesis. It has been argued that the less permissive milieu of tissues is an adaptive response to the greater risk of cancer conferred by senescence and environmentally induced changes in the epithelial and stromal cells.

Implications for Treatment

A major difficulty with assessment of treatment options in the elderly is that many solid tumor treatment protocols have not been tested and optimized for the elderly. Many ►clinical trial phase-II and -III treatment protocols stop recruitment at age 75 years. This is a problem since bone marrow recovery may be compromised by age and drug dosages may need to be modified due to age-related changes in drug metabolism and clearance. Additionally, standard therapies used for younger individuals may be inappropriate and further contribute to morbidity of the elderly, especially for some cancers, such as prostate, which may have a natural history that extends beyond the patient's expected lifespan. Finally, it is important to understand the cell biology of senescence since many chemotherapeutic agents function by halting cell replication through induction of a senescent phenotype. The

ability to induce cell senescence in a cancer cell should create a new class of therapeutic agents for cancer treatment in the elderly.

Synonyms

Senescence-associated chronic inflammation

Definition

Aging: Aging encompasses a set of interconnected processes that contributes to decline in performance, productivity and health ultimately culminating in death with the passage of time.

Inflammation: Inflammation is fundamentally a protective response occurring in the vascularized connective tissue to any insult the ultimate goal of which is to eliminate the organism which was the cause of cell injury (such as microbes, toxins) and the consequences of such injury (such as necrotic cells and tissues).

Characteristics

A unified theory has been sought to explain how the single physiological process of aging may lead to diverse pathological events culminating in diverse aging-associated pathological conditions in different organs, such as Alzheimer's, Parkinson's and other neurodegenerative disorders, rheumatoid arthritis, atherosclerosis, macular degeneration, etc., The free radical theory of aging, as proposed by Harman, is the most plausible and currently acceptable mechanism to explain the aging process. The central premise of this theory proposes that aging and its related disease processes are the net result of free radical-induced damage and the inability to counterbalance these harmful effects by antioxidative defenses. The generation of reactive oxygen and nitrogen species (ROS and RNS) activates redox sensitive transcription factors leading to the generation of pro-inflammatory molecules and a state of chronic inflammation. On the other hand, chronic inflammation itself results in the generation of ROS and RNS thus activating a feedback loop that amplifies the process of damage and deterioration. This oxidative stress and the subsequent chronic inflammation have been implicated as a mitigating factor for almost all of aging-associated maladies.

The hallmarks of chronic inflammation, infiltration of macrophages and circulating levels of pro-inflammatory chemical mediators are observed in aging-associated diseases. Activated macrophages (microglia) are observed in the senile plaques and surrounding tissue in the brain of patients with Alzheimer's disease versus similar regions in control brains. Activated microglia are also detected in affected regions in Parkinson's disease and Amyotropic Lateral Sclerosis (ALS). Similarly, many activated macrophages are found in arterial plaques of atherosclerosis and in infracted heart tissue even years after an acute event. The presence of these activated macrophages/microglia may on one hand be beneficial, and on the other hand be harmful. While, the activated macrophages release toxic materials injurious to viable host tissues, they also have phagocytic potential and an ability to destroy invading pathogens. In a state of persistent inflammation the injurious events overwhelm the protective balance leading to chronic degeneration.

ROS and RNS generated from the activated macrophages induce oxidative stress and free radical-induced injuries are evident in AD cortex, PD substantia nigra and ALS spinal cord in the form of modification of proteins by glycation, the existence of low molecular weight compounds that have been oxidized and nitrated (such as 4-hydroxynonenal, malondialdehyde, 3-nitrotyrosine, 3-nitro-4-hydroxyphenylacetic acid, 5-nitrotocopherol and 8-hydroxy-deoxyguanosin) and peroxidation of lipids.

Additional evidence is the presence of the chemical mediators of inflammation in aging-associated diseases. The tangles and plaques of AD contain activated complement fragments C4d and C3d. The membrane attack complex (MAC) derived from the activation of the complement cascade is evident in dystrophic neuritis in AD brain and in substantia nigra in PD indicating autolytic attack. The mRNAs for complement proteins

are sharply upregulated in affected regions of AD and PD brains and also in infarcted heart tissue.

Cytokines play important roles as pro-inflammatory mediators and studies have documented increased blood level of pro-inflammatory cytokines such as IL-1, IL-6, TNF-α and IL-8 in aged individuals as compared to young individuals. Plasma levels of TNF-α were positively correlated with IL-6 and acute phase proteins such as C-reactive proteins (CRP) in 126 centenarians, indicating an interrelated activation of the entire inflammatory cascade. However, the increase in circulating inflammatory parameters is far from levels seen during acute inflammation indicating that aging is associated with a chronic low-grade inflammatory activity. In a large study of 1,727 elderly Americans aged 70 years or older, age was associated with increased circulating plasma levels of IL-6.

Polymorphisms in the promoter and untranslated regions that favor increased expression of pro-inflammatory genes, such as IL-1β, have been observed in patients with AD and PD. Inheritance of the polymorphic allele of apolipoprotein E4 (apoE4) in combination with the high-risk allele of TNF-α significantly increases the risk of AD. Similarly simultaneous inheritance of high-risk alleles for IL-1αα889 and IL-1β+3953 significantly increases the odds ratio for developing AD.

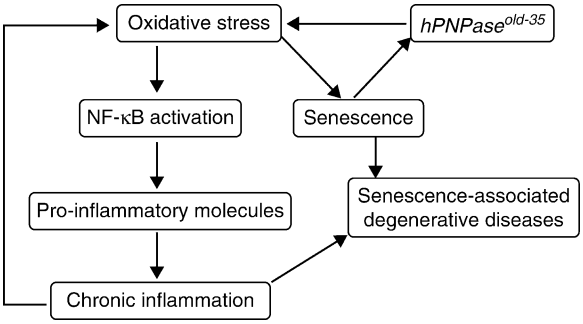
The association between increased plasma levels of TNF-α and atherosclerosis was demonstrated in 130 humans aged 81 years. The individuals with high TNF-α concentrations showed a significant clinical diagnosis of atherosclerosis. Multiple studies have established an association between elevated levels of IL-6 and diseases of old age. IL-6 induces the production of C-reactive protein (CRP), an important risk factor for myocardial infarction. High concentrations of CRP predict the risk of future cardiovascular disease in apparently healthy men. IL-8 plays a crucial role in initiating atherosclerosis by recruiting monocytes/macrophages to the vessel wall, which promotes atherosclerotic lesions and plaque vulnerability. Type 2 diabetes, atherosclerosis and cardiovascular diseases have common antecedents. High plasma TNF-α concentrations were shown to predict insulin insensitivity with advancing age in 70 healthy humans with a large age range. Elevated levels of IL-6 and CRP predicted the development of type 2 diabetes in healthy women. In another study, elevated serum IL-6 levels predicted future disability in older adults especially by inducing muscle atrophy. IL-6 and CRP also play a pathogenic role in several diseases such as osteoporosis, arthritis and congestive heart failure all of which have increasing incidence with age. Moreover, increased serum levels of IL-6 and IL-8 have been detected in patients with chronic obstructive pulmonary diseases and chemokines such as IL-8 and RANTES play important roles in the pathogenesis of these diseases. Various inflammatory mediators, such as IL-1, TNF-α, IL-6, IL-8, RANTES, MMP-3 are responsible for chronic inflammatory rheumatoid diseases, such as osteoarthritis and rheumatoid arthritis both of which occur during aging.

In vitro studies and experiments in animals also establish an intricate relationship between aging and inflammation. Gene expression analysis by microarray in human hepatic stellate cells confirms that replicative senescence in these cells is associated with a pronounced inflammatory phenotype characterized by upregulation of pro-inflammatory cytokines, including IL-6 and IL-8. An aging-induced pro-inflammatory shift in cytokine expression profile has been observed in rat coronary arteries.

How does the pro-inflammatory shift occur during aging? A prominent mechanism by which ROS modulates diverse intracellular molecular processes is by regulating the activity of transcription factors, most notably nuclear factor (NF)-κB. By turning on pro-inflammatory mediators such as TNF-α, IL-1, IL-6, IL-8, IFN-γ, iNOS, ICAM-1, VCAM-1, COX-2 and acute phase proteins, NF-κB functions as a central transcription factor for the development of chronic inflammatory diseases.

Unfortunately very few studies were carried out in aging humans to establish a clear correlation between NF-κB activation and chronic inflammation. Strong NF-κB DNA binding and COX-2 transcription was detected in aging and in sporadic AD superior temporal lobe neocortex. An increase in constitutive NF-κB DNA binding in older animals over young animals has been demonstrated in multiple studies. A gradual rise in ROS was evident in kidneys from Fischer rats from 6 to 24 months of age and this increase correlated with an age-dependent augmentation in binding of NF-κB and elevated expression of cyclogenase-2 (COX-2), an NF-κB-responsive enzyme involved in pro-inflammatory prostanoid synthesis. Vascular smooth muscle cells from 18-month old rats showed considerably higher NF-κB DNA binding than that from new-born rats which correlated with increased expression of inducible nitric oxide synthase and intracellular adhesion molecule-1, two pro-inflammatory molecules, in old smooth muscle cells upon inflammatory stimulation. A similar age-dependent elevation in NF-κB DNA binding has been reported in mouse and rat liver and heart and in rat brain indicating a potential involvement of NF-κB in regulating aging-associated chronic inflammation.

The molecular events leading to the generation of ROS and the development of chronic inflammation during aging are still not deciphered. Recent studies show that human polynucleotide phosphorylase ($hPNPase^{old\text{-}35}$) might be the key element linking aging with the inflammatory process. $hPNPase^{old\text{-}35}$ is a 3′-5′ exoribonuclease involved in mRNA degradation (Fig. 1). Its expression is induced during senescence



Aging-Associated Inflammation. Figure 1 Schematic representation flowchart showing the proposed involvement of *hPNPase*$^{old-35}$ in senescence associated degenerative diseases. See text for details.

and ectopic overexpression of *hPNPase*$^{old-35}$ induces a senescent phenotype in normal and cancer cells. Overexpression of *hPNPase*$^{old-35}$ generates ROS with resultant increase in NF-κB DNA binding and increased production of proinflammatory cytokines such as IL-6, IL-8, RANTES and MMP-3. These effects might be inhibited by an anti-oxidant *N*-acetyl-L-cysteine (NAC).

AHNP

Definition

Is a small designer molecule with a structure that allows it to bind to p185 ►HER/neu. Is functionally similar to the anti-p185HER2/neu monoclonal antibody ►Herceptin (synonym ►Trastuzumab). The AHNP mimetic specifically binds to p185HER2/neu with high affinity with the result of inhibition of proliferation of p185HER2/neu-overexpressing tumor cells inhibition of both colony formation in vitro and growth of p185HER2/neu-expressing tumors in ►nude mice. In addition, the mimetic sensitizes the tumor cells to ►apoptosis when used in conjunction with ►ionizing radiation therapy or ►chemotherapy. AHNP mimetic has a biological efficiency spectrum that is similar to that of Herceptin. One of the advantages of this antibody-mimic is that it can be synthesized in vitro in large quantities.

Ajuba

Definition
A member of the zyxin family of cytoskeletal adaptor proteins. It localizes in the cytosol, at cell-substratum and cadherin-mediated cell-cell junctions and shuttles to the nucleus under certain conditions. Ajuba contains three several copies of a LIM domain at its carboxyterminus and a proline-rich pre-LIM region. Interaction partners include Grb2, GLT-1, α-catenin, F-actin, Aurora A, p130Cas, PIPKIα, atypical protein kinase C scaffold protein p62, TRAF6, PKCζ, LATS2, and the SNAG domain. Ajuba plays a role in cell proliferation

and cell migration, and is a negative regulator of the Wnt signaling pathway.

►Lipoma Preferred Partner

AKT

Definition

Akt is the mammalian homologue of retroviral oncogene v-akt encoding a serine/threonine protein kinase, also termed protein kinase B (PKB). It is a serine/threonine protein kinase, the cellular homolog of the viral transforming oncogene v-Akt. The c-Akt protein contains a ►pleckstrin homology domain and a catalytic kinase domain. c-Akt is activated by translocation to the cell membrane mediated by its lipid-binding pleckstrin homology domain and enzymatic activation by specific phosphorylation events. These phosphorylations are mediated by protein kinases that are themselves activated by phosphatidylinositol-3′-kinase. Scatter factor-induced activation of c-Akt results in a cell survival signal that renders cells resistant to apoptosis.

Protein kinase B

Definition

Akt, also called protein kinase B, represents a serine/threonine protein kinase subfamily. Three members of this family have been cloned to date, namely, AKT1/PKBα, AKT2/PKBβ, and AKT3/PKBγ. The overall homology of between these three isoforms is >85% at amino acid level.

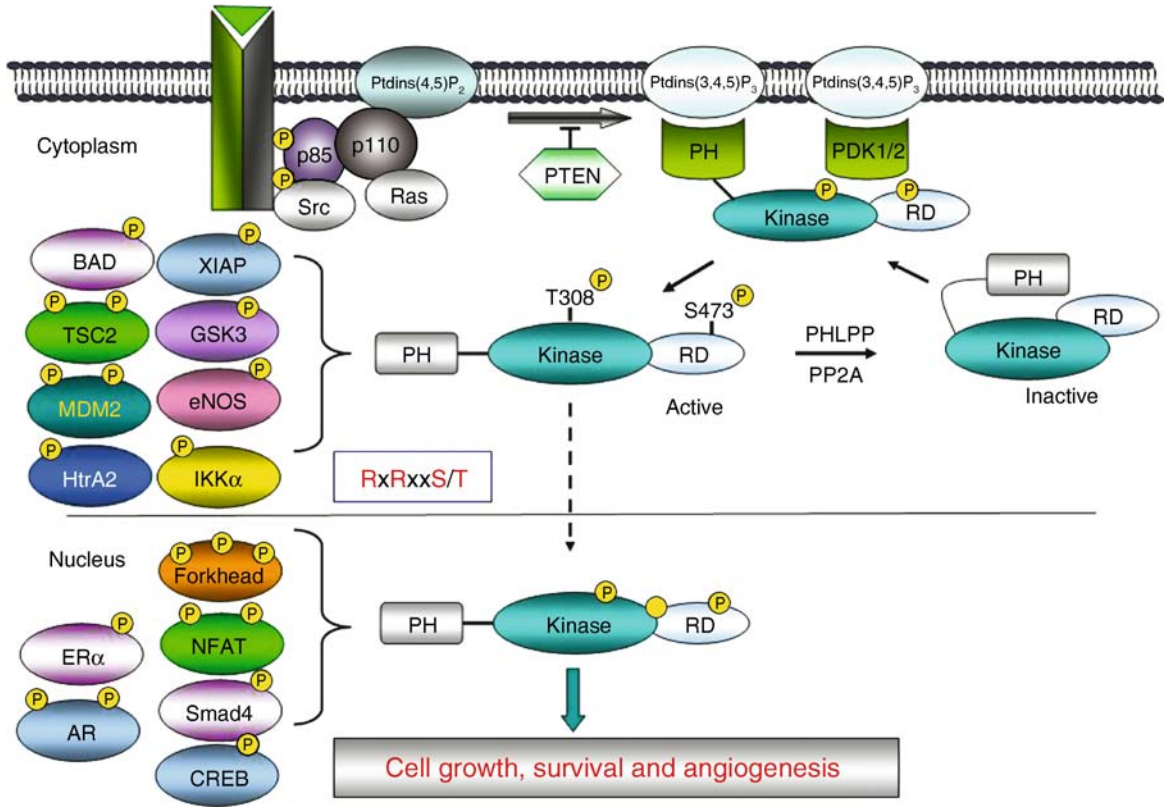
Characteristics

AKT1, *AKT2*, and *AKT3* share a very similar structure, which contains an N-terminal pleckstrin-homology (PH) domain, a central kinase domain, and a serine/threonine-rich C-terminal region (Fig. 1). The PH domain and C-terminal region between these three isoforms are more diverse (homology 73–84% at amino acid level) as compared to the kinase domain (90–95%), suggesting that PH and C-terminal regions may represent functional difference between AKT1, AKT2 and AKT3. All three members of Akt localize to the cytoplasm, however, they could translocate to the nucleus upon activation. In addition, they are located on different human chromosome (AKT1 on 14q32, AKT2 on 19q13.1–13.2, and AKT3 on 1q44).

Akt in Human Malignancy and Different Function of Akt Family Members

Although *AKT1*, *AKT2* and *AKT3* display high sequence homology, there are clear differences between these three members in terms of biological and physiological function: (i) *AKT1* expression is relatively uniform in various normal organs whereas high levels of *AKT2* and *AKT3* mRNA are detected in skeletal muscle, heart, placenta and brain; and (ii) overexpression of wild type AKT2, but not AKT1 and AKT3, transforms NIH 3T3 cells. Amplification of the *AKT2* has been observed in 15% of human ovarian carcinomas and 20% of human pancreatic cancers. Infrequent mutations of the Ak have been also detected in human cancer. However, activation of Akt kinase due to alterations of its upstream molecules occurs up to 50% of all human tumors, and thus Akt is a critical target for anti-cancer drug discovery.

Recently, increasing evidence suggests that AKT members have different cellular functions. Of note, knockout of individual AKT member resulted in distinct phenotypes. *AKT1*-deficient mice exhibited a uniform reduction in organ size, while *AKT2*-null mice develop typical type II diabetes, and *AKT3*-deficient mice displayed a selective impairment of brain development. Moreover, although *AKT1*- and *AKT3*-deficient brains are reduced in size to comparable degree, the absence of AKT1 reduces neuronal cell number, whereas the lack of AKT3 results in smaller and fewer cells. In tumor biology and invasion process, overexpression of only AKT2, not AKT1 or AKT3, recapitulated the invasive effects of PI3K in breast cancer cells. Additionally, only the expression of dominant negative AKT2, not its counterparts, inhibited invasion induced by either activation of PI3K or overexpression of Her2/Neu. These observations suggest that AKT1 and 3 may be acting more in a cellular growth and survival role, while AKT2



Akt Signal Transduction Pathway. Figure 1 Proposed pathways of Akt signaling. Activation of Akt through the PI3-kinase pathway involves recruitment of the Akt to the cell membrane by means of PH domain binding to product of PI3-kinase: PI(3,4,5)P3, promoting a conformational change in Akt which results in phosphorylation of Thr^{308} and Ser^{473} by PDK1 and "PDK2," respectively. Upon its release from the membrane, Akt would become available to phosphorylate a number of molecules to induce cell growth, survival and angiogenesis (KD = Kinase domain, RD = regulatory domain).

may be more involved in regulating cellular metabolism, mobility, invasion and metastasis.

Signal Transduction

Akt is activated by a variety of stimuli, including growth factors, protein phosphatase inhibitors, and cellular stress in a PI3-kinase dependent manner. Activation of Akt depends on the integrity of the pleckstrin homology (PH) domain, which mediates its membrane translocation, and on the phosphorylation of Thr^{308} and Ser^{473}. Phosphoinositides, PtdIns-3,4-P2 and PtdIns-3,4,5-P3, produced by PI3K bind directly to the PH domain of Akt, driving a conformational change in the molecule, which enables the activation loop of Akt to be phosphorylated by PDK1 at Thr^{308}. Full activation of AKT1 is also associated with phosphorylation of Ser^{473} within a C-terminal hydrophobic motif characteristic of kinases in the AGC kinase family. Although the role of PDK1 in Thr^{308} phosphorylation is well established, the mechanism of Ser^{473} phosphorylation is controversial (Fig. 1). A number of candidate enzymes responsible for this modification have been put forward, including ILK, DNA-dependent kinase, and the rictor-mTOR complex. The activity of Akt is negatively regulated by tumor suppressor PTEN, which is frequently mutated in human malignancy. *PTEN* encodes a dual-specificity protein and lipid phosphatase that reduces intracellular levels of PtdIns-3,4,5-P3 by converting them to PtdIns-4,5-P2, thereby inhibiting the PI3K/Akt pathway (Fig. 1). In addition, recent studies have identified PHLPP phosphatase dephosphorylation of the Ser^{473} leading to inactivation of Akt. Akt phosphorylates and/or interacts with a number of molecules to exert its normal cellular functions, which include roles in cell proliferation, survival, angiogenesis and differentiation. A couple dozens of molecules have been identified to be downstream targets of Akt, including TSC2, XIAP, Bad, FOXO, IKKα, ASK and EZH2. The vast majority of Akt substrates contain Akt phosphorylation consensus sequence **RXRXXS/T** (R is arginine; S/T is serine/threonine).

Akt Pathway as a Target for Cancer Intervention

Since Akt functions as a cardinal nodal point for transducing extracellular (growth factor and insulin)

and intracellular (receptor tyrosine kinases, Ras and Src) oncogenic signals, it presents an exciting new target for molecular therapeutics. Lipid-based inhibitors of Akt were the first to be developed, including perifosine, PX-316 and phosphatidylinositol ether lipid analogues, which were designed to interact with the PH domain of Akt. In addition, several Akt antagonists have been identified using high-throughput screening of chemical libraries and rational design. These inhibitors include Akt/PKB signaling inhibitor-2 (API-2), 9-methoxy-2-methylellipticinium acetate, the indazole-pyridine A-443654, and isoform-specific canthine alkaloid analogues. Following its identification in a screen of the NCI diversity set, API-2 was shown to inhibit Akt kinase activity and stimulate apoptosis of xenografts of human cancer cells exhibiting high Akt activity. API-2 is a tricyclic nucleoside that previously showed antitumor activity in phase I and phase II trials conducted, but multiple toxicities, including hepatotoxicity, hyperglycemia, thrombocytopenia, and hypertriglyceridemia, precluded further development. The recent identification of Akt inhibition as a mechanism underlying API-2 activity has provided new interest in studying this drug and raises the possibility that lower doses may inhibit Akt and induce tumor cell apoptosis without the previously associated side effects.

Alcohol Consumption

Helmut K. Seitz, Sebastian Mueller
Department of Medicine, Salem Medical Center, Heidelberg, Center of Alcohol Research Liver Disease and Nutrition and University of Heidelberg, Heidelberg, Germany

Definition

Alcohol is a widely used stimulant, toxin and nutrient, depending on doses and drinking pattern. Its chronic abuse damages almost all cells in the human body and results in organ injury, including the development of certain cancers.

Characteristics

Alcohol is responsible for 390,000 cancer cases worldwide, representing 3.6% of all cancers (5.2% in men and 1.7% in women). In February 2007 the International Agency for Research on Cancer (IARC) invited 26 scientists from 15 countries to evaluate the evidence for ethanol and ethanol-containing beverages as a cancer causing agent. The experts reviewed all epidemiological and experimental studies covering this topic and came finally to the following conclusion:

"Regular alcohol consumption is associated with an increased risk for cancer of the oral cavity, pharynx, larynx, esophagus, liver, breast and colorectum. There is substantial mechanistic evidence in humans deficient in aldehyde dehydrogenase that ►acetaldehyde derived from the metabolism of ethanol contributes to causing maligant esophageal tumors.

The studies demonstrate that ethanol and not the type of alcoholic beverage is responsible for the tumor risk."

Epidemiology

Cancer of the Upper Aerodigestive Tract

A large number of prospective and case-control studies have shown that the risk for Upper Aerodigestive Tract (UADT) cancer is significantly dose-dependent, increased two- to threefold at a daily consumption of 50 g of ethanol or more. Smoking has an additionally synergistic effect. A carefully performed French study showed an 18-fold increased risk for esophageal cancer when 80 g of ethanol were consumed daily. Twenty cigarettes per day increased cancer risk by a factor of 5. However, drinking and smoking were associated with 44-fold increased cancer risk. Other factors which increase the ►alcohol mediated cancer risk are oral bacterial overgrowth (poor oral hygiene and dental status) as well as ►gastroesophageal reflux disease (GERD).

Hepatocellular Cancer (HCC)

HCC develops in 1–2% per year of patients with alcoholic liver ►cirrhosis of the liver every year. The risk for HCC is between 4.4- and 7.3-fold at an alcohol dose of 80 g/day. HCC in a non-cirrhotic liver is extremely rare. Chronic alcohol consumption also increases HCC risk in patients with other liver diseases such as chronic hepatitis B and C, hereditary hemochromatosis and non-alcoholic fatty liver disease (NAFLD). Patients with chronic ►hepatitis C have a threefold increased risk when they consume 80 g of ethanol or more as compared to hepatitis C alone. In hepatitis B patients ethanol in doses of 40 g or more shortens the development of a HCC by approximately 10 years.

Breast Cancer

A clear cut dose-dependent association between alcohol intake and breast cancer has been reported in more than 100 publications. The risk starts at a dose of 18 g of alcohol per day. According to a meta analysis of 38 studies, one, two or three drinks increase breast cancer risk by 10, 20 and 40%. Every additional 10 g of alcohol increase breast cancer risk by 7%. At 50 g of alcohol daily, cancer risk is enhanced by 50%. In the United States it has been calculated that 4% of all newly diagnosed breast cancer cases are due to alcohol, resulting in a total of approximately 8,000 cases per year.

Colorectal Cancer

More than 50 prospective- and case-control studies found a positive association between colorectal cancer and alcohol consumption. According to pooled data from eight cohort studies and data from a recent meta analysis, a 1.4-fold increased cancer risk was found in patients with an alcohol intake of more than 50 g as compared to non-drinkers. Excessive alcohol consumption also favors high risk polyp or colorectal cancer occurrence among patients with adenomas. Five out of six studies also showed an increased risk for colorectal polyps following chronic alcohol consumption as compared to abstinence. Epidemiologic studies also underline the importance of the lack of dietary factors such as methionine and folate which modulate the ethanol-associated colorectal cancer risk.

Mechanisms of Alcohol Mediated Carcinogenesis

Acetaldehyde

Acetaldehyde is the first metabolite of ethanol oxidation. Acetaldehyde binds to proteins and DNA; it has been found to be mutagenic and carcinogenic in animal experiments. The most convincing evidence for the role of acetaldehyde as cancer causing agent comes from genetic linkage studies in populations who accumulate acetaldehyde following alcohol consumption. Fifty percent of Japanese have a mutation of the ►acetaldehydehydrogenase (ALDH)2 gene which codes for an ALDH enzyme with low activity. When these individuals drink alcohol, acetaldehyde accumulates in the blood, and they develop a flush syndrome with tachycardia, nausea and vomiting. In addition, acetaldehyde also accumulates in the saliva, rinses the mucosa of the upper aerodigestive tract, and may enter the mucosal cells, resulting in DNA adduct formation. Homocygotes of the polymorphism for ADH1B and ADH1C. ALDH2 2/2 Ten percent of the Japanese population, who have zero ALDH activity, are incapable of consuming alcohol, even in small doses. Despite the unpleasant side effects of flushing, however, heterocygotes of the ALDH2 2/1, 40% of the Japanese population with low ALDH activity, may consume alcohol. These individuals have a significant increased cancer risk for upper aerodigestive tract cancer, in particular esophageal cancer and for colorectal cancer. This gene mutation does not exist in Caucasians. However, Caucasians have a gene polymorphism for the ADH1B and ADH1C gene. While the ADH1B*2 allele encodes for an ADH enzyme with a 40-fold increased acetaldehyde production as compared to the ADH1B*1 allele, the ADH1C*1 allele encodes for an enzyme with a 2.5-fold increased ADH activity as compared to the ADH1C*2 allele. Thus, heavy drinkers who are homozygous for the ADH1C*1 allele not only have an increased concentration of acetaldehyde in their saliva, but also seem to have an increased risk for upper aerodigestive tract cancer.

Considerable amounts of acetaldehyde can also be produced from ethanol by microorganisms in the oral cavity and in the colon. Therefore, poor oral hygiene leading to bacterial overgrowth is a risk factor in the alcoholic for cancer of the oral cavity.

Oxidative Stress

►Reactive oxygene species (ROS) are generated during the oxidation of ethanol via ►cytochrome P-4502E1, and during intramitochondrial reoxidation of NADH generated by ethanol oxidation through ►alcoholdehydrogenase. This is especially relevant in the liver. ROS cause lipiperoxidation, and lipidperoxidation products such as 4-hydroxynonenal can bind to DNA, forming exocyclic DNA-etheno adducts with mutagenic and carcinogenic properties.

Under normal conditions ROS are neutralized by the anti-oxidative defense system, which, however, is severely altered by chronic ethanol consumption.

Altered Methyl Transfer

Chronic ethanol consumption results in a significant reduction of S-adenosyl-methionine (SAMe), the active methyl donor. This is due to multiple effects of ethanol and acetaldehyde on enzymatic reactions leading to the generation of SAMe, including folate deficiency. The lack of SAMe results in a reduction of all methylation processes. With respect to ►carcinogenesis the most important methylation process is the methylation of cytosine bases within the DNA. This DNA hypomethylation results in a dimished silencing of oncogenes and therefore favors carcinogenesis.

Reduced Retinoic Acid

Chronic ethanol consumption results in a decrease of retinol and ►retinoic acid (RA) in the liver, associated with an activation of the AP-1 gene resulting in an increased expression of c-jun and c-fos and finally hepatocellular hyperproliferation associated with increased cancer risk. The decrease of RA is predominantly due to the ethanol-mediated induction of CYP2E1, since CYP2E1 is also responsible for the metabolism of RA and retinol. An enhanced metabolism of RA and retinol induced by CYP2E1, results in the generation of metabolites with apoptotic properties. In this context it is important to note that the concomitant administration of ß-carotin for the prevention of bronchial cancer and the use of alcohol in a dose of more than 12 g/day increases, instead of decreasing, the risk of bronchial carcinomas in smokers.

Specific Mechanisms (Cirrhosis, Gastroesophageal Reflux Disease, Estrogens)

In the liver, cirrhosis caused by chronic ethanol consumption is a prerequisite for the development for a HCC due to mechanisms not clearly understood, but predominantly due to chronic inflammation with inflammation-driven oxidative stress and proliferative changes during the development of cirrhosis. HCC in a non-cirrhotic alcoholic liver is extremely rare.

Gastroesophageal reflux disease (GERD) is an additional factor, which favors carcinogenesis in the esophagus due to acid-mediated chronic inflammation of the esophageal mucosa. GERD is favored by alcohol, since alcohol decreases the tonus of the lower esophageal sphincter which facilitates GERD.

Increased ►estrogens levels due to alcohol consumption, even in small quantities, is most likely an important pathophysiologic factor to explain the increased risk of breast cancer in regular drinkers. The mechanism by which alcohol increases estradiol levels is not known.

Alcoholic Beverages Cancer Epidemiology

Paolo Boffetta, Mia Hashibe
Gene-Environment Epidemiology Group, International Agency for Research on Cancer, Lyon, France

Definition

Drinking beverages that contain ethanol such as wine, beer, or hard liquors. Other alcoholic beverage types are specific to certain geographic regions or countries such as rice wine in East Asia or arrack in India. In some cultures, alcoholic beverages are also made locally or in the home.

Characteristics

A causal link has been established between alcohol drinking and cancers of the oral cavity, pharynx, esophagus, liver and breast. For other cancers, a causal association is suspected. The importance of alcohol as a human carcinogen is often underestimated. There is increasing evidence of an important role of genetic susceptibility to alcohol-related cancer, and knowledge on possible mechanisms of the carcinogenic action of alcohol has evolved in recent years.

The major non-neoplastic diseases caused by alcohol drinking are alcoholic polyneuropathy, alcoholic cardiomyopathy, alcoholic gastritis, depression and other mental disorders, hypertension, hemorragic stroke, liver cirrhosis and fibrosis, as well as acute and chronic pancreatitis. In addition, alcohol drinking is a major cause of several types of injuries, and alcohol consumption during pregnancy is associated with various adverse effects including fetal alcohol syndrome, spontaneous abortion, low birth weight, prematurity, and intrauterine growth retardation. On the other hand, there is strong evidence that moderate consumption of alcohol reduces the risk of ischemic heart disease, ischemic stroke, and colelithiasis.

Epidemiology of Alcohol-Related Cancer

A causal relationship between elevated alcohol drinking and ►oral squamous cell carcinoma, and that of pharynx, larynx and esophagus have been demonstrated. In epidemiological studies of this group of tumors, an effect of heavy alcohol intake and a linear relationship with both duration and amount of drinking have been consistently shown. A synergism between alcohol drinking and tobacco smoking has been demonstrated, and has become since a paradigm of interaction of two environmental factors in human carcinogenesis.

Studies on the association of alcohol drinking and adenocarcinoma of the esophagus have not been consistent. Some studies reported risk estimates for adenocarcinoma of the esophagus and gastric cardia together on the order of 1.5- to 4-fold increases in risk. Many of the studies that have reported risk estimates for adenocarcinoma of the esophagus have tended to be small, while the larger studies have reported no association with ever alcohol consumption and no indication of dose-response relations.

Heavy alcohol intake increases the risk of ►hepatocellular carcinoma. Dose-response relations between the amount of alcohol consumed and the risk of hepatocellular carcinoma have been demonstrated. The most likely mechanism of alcohol-related liver carcinogenicity is through development of liver cirrhosis, although alternative mechanisms such as alteration in the hepatic metabolism of carcinogens may also play a role. Alcoholic liver cirrhosis is probably the most important risk factor for hepatocellular carcinoma in populations with low prevalence of ►HBV and ►HCV infection, such as North America and northern Europe. Synergistic interactions on the risk of liver cancer are also thought to occur between tobacco and alcohol, and between HBV/HCV and alcohol. (Hepatitis Virus-Associated Hepatocellular carcinoma).

The association between alcohol consumption and the risk of breast cancer has been reported fairly consistently in numerous studies, though the risk is thought to be moderate. The association is observed among both premenopausal and postmenopausal women, though it is unclear whether the period of life in which drinking occurs modifies the carcinogenic effect of alcohol. Although the magnitude of the excess risk of breast cancer due to alcohol drinking is not very large, the high incidence of this cancer results in a large number of cases.

Several studies have provided evidence, although not fully consistent, of an association between elevated intake of alcohol, and increased risk of colorectal adenoma and adenocarcinoma. Dietary factors such as low folate intake are thought to increase the risk of colorectal cancer by 2- to 5-fold, and alcohol adversely affects folate metabolism. There may be a synergistic interaction between alcohol consumption and low folate intake, or alcohol may be acting through folate metabolism to increase colorectal cancer risk. Since risk estimates reported suggest a moderate association between alcohol drinking and the risk of colorectal cancer, residual confounding by such dietary factors or other strong risk factors for colorectal cancer is of concern. However, it is doubtful that residual confounding is entirely responsible for the observed increases in colorectal cancer risk due to alcohol consumption. Though the effects may be moderate, there does appear to be a causal relationship between alcohol consumption and colorectal cancer risk.

There is no consistent evidence that alcohol drinking influences the risk of cancers of the stomach, pancreas, lung, endometrium, bladder or prostate. In the

case of ovarian and kidney cancers, the evidence from epidemiological studies is of a possible protective effect, but further investigation is necessary to clarify the relationships. The risk of non-Hodgkin lymphoma was reported to be reduced among alcohol drinkers: this effect, if real, might differ by lymphoma type, which may explain the inconsistencies in results of earlier studies of alcohol and lymphoma.

Mechanisms of Alcohol Carcinogenicity

The mechanisms by which alcoholic beverages exert their carcinogenic effect are not fully understood, and, as in the case of other multi-site carcinogen, they are likely to differ by target organ. Table 1 lists the main mechanistic hypotheses, together with a subjective assessment of the strength of the available supporting evidence. The table is restricted to mechanisms known or suspected to operate in cancers with an established association with alcohol drinking.

Ethanol in its pure form does not act as a carcinogen in experimental models, and one explanation is that alcoholic beverages act as a solvent for penetration of carcinogens through the mucosa of upper aero-digestive organs. Although this mechanism would explain the synergistic effect of tobacco smoking and alcohol drinking, it would not account for the increased risk observed among never smokers.

The primary metabolite of ethanol, acetaldehyde, is a plausible candidate for the carcinogenic effect of alcoholic beverages although direct evidence linking acetaldehyde as a cause of cancer in humans is lacking. Acetaldehyde forms ►adducts to DNA in human cells in vitro, as well as in rats chronically exposed to ethanol. In experimental models, acetaldehyde inhalation has been shown to cause tumors of the respiratory tract, particularly adenocarcinomas and squamous-cell carcinomas of the nasal mucosa in rats and laryngeal carcinomas in hamsters. It also damages hepatocytes, leading to increased proliferation. Autoantibodies against acetaldehyde-modified proteins have been detected in blood and bone marrow of alcohol abusers. Overall, studies strongly suggest that DNA damage occurs in humans following heavy alcohol consumption, and acetaldehyde can be responsible for it. The increasing evidence of a role of polymorphism in enzymes implicated in the oxidation of ethanol and acetaldehyde in modulating alcohol-related cancer risk further supports the hypothesis of a mechanistic role of acetaldehyde.

Production of ►reactive oxygen species and nitrogen species is an additional possible mechanism of alcohol-related carcinogenesis. ►Oxidative stress leads to ►lipid peroxidation, whose products are reactive electrophilic compounds reacting with DNA to form exocyclic DNA adducts, and reactive aldehydes. This mechanism can be particularly relevant to liver carcinogenesis and might explain the synergistic effect of alcohol and viral infection. In the liver, oxidative stress is induced by alcohol via induction of CYP2E1, stimulation of parenchymal cells in response to cytokines and activation of Kupffer cells.

Heavy alcohol intake may lead to nutritional deficiencies by reducing the intake of foods rich in micronutrients, by impairing intestinal absorption, and by altering metabolic pathways. The most relevant effect appears to be on folate metabolism, resulting in alteration in DNA ►methylation and, hence, control of genes potentially involved in carcinogenesis. Intake, absorption and metabolism of vitamin B12 and vitamin B6, may also be affected by alcohol intake, resulting in further alterations of DNA methylation pathways. Vitamin A deficiency has also been proposed as alcohol-mediated carcinogenic mechanism. Alcoholics have a lower level of serum vitamin A and β-carotene, and vitamin A metabolism is altered by chronic alcohol intake.

Alcoholic Beverages Cancer Epidemiology. Table 1 Possible mechanisms of carcinogenicity of alcoholic beverages

Mechanism	Potential Target Organs
Strong evidence[a]	
DNA damage by acetaldehyde	Head and neck, esophagus, liver
Increased estrogen level	Breast
Moderate evidence[a]	
Solvent for other carcinogens	Head and neck, esophagus
Production of reactive oxygen and nitrogen species	Liver, others?
Alteration of folate metabolism	Colon and rectum, breast, others?
Weak evidence[a]	
DNA damage by ethanol	Head and neck, esophagus, liver
Nutritional deficiencies (e.g. vitamin A)	Head and neck, others?
Reduced immune surveillance	Liver, others?
Carcinogenicity of constituents other than ethanol	Head and neck, esophagus, liver, others?

[a]Subjective assessment of strength of supportive evidence.

Alcohol drinking can reduce immune surveillance, thus favoring cancer development as well as metastatic potential. This hypothesis is supported by experimental data showing reduced resistance to metastasis of alcohol-exposed mice.

Components of alcoholic beverages other than ethanol, including impurities and contaminants, have been proposed to increased risk of cancer among drinkers. ►Polycyclic aromatic hydrocarbons have been found in dark hard liquors, and N-nitrosoamines have been detected in beers, but in general information on composition of alcoholic beverages, and in particular hard liquours, is limited. If components in alcoholic beverages represented an important factor contributing to carcinogenicity, one would predict a role of type of beverage in determining the risk.

These mechanisms are mainly relevant to head and neck, liver and colorectal carcinogenesis; in the case of breast cancer, the main hypothesis to explain alcohol carcinogenicity is increased ►estrogen level. The evidence is strongest for postmenopausal women using ►hormone replacement therapy, but the available data suggest an effect also in other groups of women. Additional possible mechanisms include increased susceptibility to endogenous and exogenous carcinogens, and greater invasiveness potential. An effect mediated by folate metabolism, mentioned above for colorectal cancer, would be also relevant to breast carcinogenesis.

Conclusions

Alcohol drinking is one of the most important known causes of human cancer, second only to tobacco smoking, chronic infections, and possibly overweight/obesity (obesity and cancer risk). With the exception of ►aflatoxin, for no single dietary factor there is such a strong and consistent evidence of carcinogenicity. In the case of breast and colorectal cancer, two major human neoplasms, a causal association with alcohol drinking has been established only recently, and the public health implications of these associations have not been not fully elucidated. In many countries, people of lower socioeconomic status or education consume more alcohol, which contributes to social inequalities in cancer burden.

Given the linear dose-response relationship between intake of alcohol drinking and the risk of cancer, control of heavy drinking remains the main target for cancer control. For example, the most recent version of the European Code Against Cancer recommends keeping daily consumption within two drinks (about 20–30 g alcohol) for men and one drink for women. Total avoidance of alcohol, although optimal for cancer control, cannot be recommended from a broader public health perspective, in particular in countries with high incidence of cardiovascular diseases.

►Alcohol Consumption

Aldehyde Dehydrogenases

Definition

A group of NAD (P)-dependent enzymes that catalyze the oxidation of aldehydes to their corresponding acids. Seventeen forms exist in humans and they are present in all tissues. Several of these forms are important in detoxification of anticancer drugs.

►Alkylating Agents
►Detoxification
►Hepatic Ethanol Metabolism

Aldehydes

Definition

An organic molecule containing a -COH group; reactive aldehydes originate from lipid peroxidation of cellular membranes.

►Inflammation

Aldo-Keto Reductase

Definition

A superfamily of enzymes that catalyze the NADPH-dependent reduction of numerous carbonyl-containing compounds; substrates include, not only xenobiotics, but also monosaccharides, prostaglandins and steroid hormones. Some isoenzymes may also catalyze the oxidation of alcohols to aldehydes and ketones; detoxication.

►Detoxification
►Reductases

Aldose Reductase

Definition

It is the first and rate-limiting enzyme of polyol pathway of glucose metabolism that converts glucose to sorbitol with the help of cofactor, reduced nicotinamide adenine dinucleotide phosphate (NADPH). It is a monomeric, cytoplasmic enzyme with broad substrate specificity. This enzyme efficiently reduces oxidative stress-induced lipid aldehydes and their glutathione conjugates, steroids, and phospholipids. Newly discovered function of aldose reductase is to work as an excellent nonsteroidal anti-inflammatory agent. Inhibition of this enzyme has been shown to prevent inflammatory response including the progression of human colon cancer cells in nude mice xenografts. Since this enzyme is known to be involved in the pathophysiology of secondary diabetic complications, its inhibitors are being used for these disorders in Japan and are in phase-III clinical trials in the United States.

►Nonsteroidal anti-inflammatory drugs
►Inflammation

Alemtuzumab

Definition

A recombinant DNA-derived humanized monoclonal antibody directed against the cell surface glycoprotein CD52. Alemtuzumab is an IgG1 kappa with human variable framework and constant regions, and complementarity-determining regions derived from a rat monoclonal antibody. This agent selectively binds to CD52, thereby triggering a host immune response that results in lysis of CD52 + cells. CD52 is a glycoprotein expressed on the surface of essentially all normal and malignant B cells and T cells, a majority of monocytes, macrophages and natural killer cells (NK cells).

►Chronic Lymphocytic Leukemia

ALK

Definition

Anaplastic lymphoma kinase; a cell surface receptor protein with enzymatic activity (phosphorylation) originating from the alk gene.

►ALK Protein
►Anaplastic Large Cell Lymphoma

ALK Protein

Karen Pulford
Department of Clinical Laboratory Sciences, University of Oxford, John Radcliffe Hospital, Oxford, UK

Synonyms

ALK; Anaplastic lymphoma kinase; Anaplastic lymphoma kinase; Ki-1; CD246

Definition

Anaplastic lymphoma kinase (ALK) is a ►receptor tyrosine kinase with a potential role in early neural and muscle development. ALK phosphorylates intracellular molecules for the transduction of signals from the exterior of the cell to the nucleus. Aberrant expression of full-length ALK receptor proteins has been reported in ►neuroblastoma and ►glioblastoma while the presence of ALK fusion proteins in ►anaplastic large cell lymphoma has resulted in the identification of the tumor entity ALK-positive anaplastic large cell lymphoma. ALK is a rare example of a receptor tyrosine kinase that is expressed in both hematopoietic and non-hematopoietic tumors.

Characteristics

ALK Protein – Structure, Distribution and Function in Normal Tissues

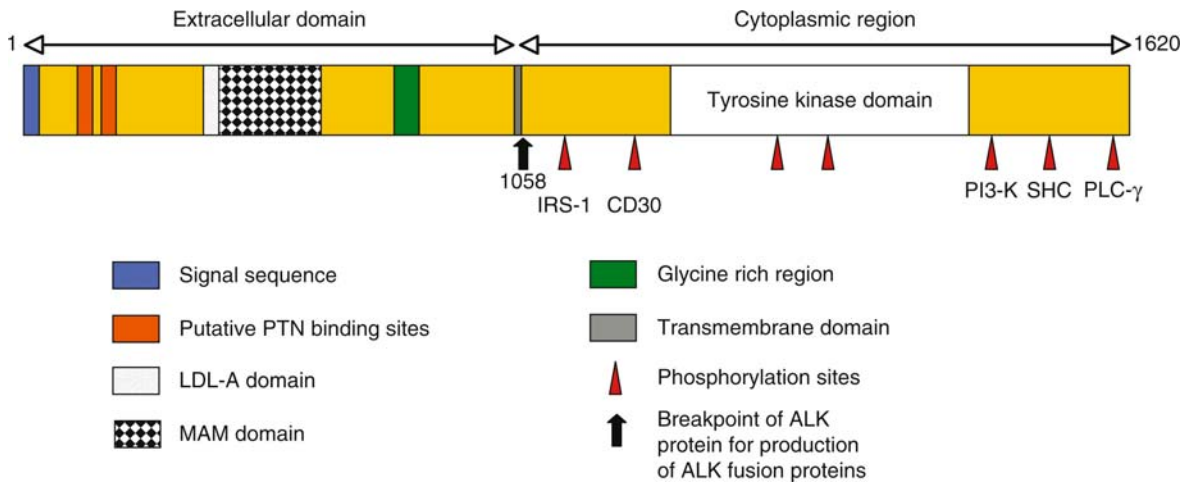
The *anaplastic lymphoma kinase (ALK)* gene (HUGO approved name anaplastic lymphoma kinase (Ki-1)) was originally identified on chromosome 2 at position p23 in the t(2;5)(p23;q35) translocation associated with anaplastic large cell lymphoma. The ALK protein product is a 200 kD ►receptor tyrosine kinase protein and a member of the ►insulin receptor superfamily bearing significant homology to ►leucocyte tyrosine kinase (LTK), Other members of the insulin receptor subfamily include: ►insulin growth-1 receptor (IGF-1R), TRK neurotrophin receptors, MET and cFOS. ALK is a highly conserved single-chain transmembrane protein of 1,620 aminoacids in the human (Fig. 1), 1,621 aminoacids in the mouse and 1,701 aminoacids in Drosophila. The ALK protein was given the designation of CD246 at the VIIth Leucocyte Typing Workshop. Full details on the ALK can be obtained from the following websites: http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db = gene&cmd = Retrieve&dopt = Graphics&list_ uids = 238 at and http://symatlas.gnf.org/SymAtlas/.

Initial studies described the presence of *ALK* mRNA in human fetal liver, brain, testis, placenta and the enteric innervation. Subsequent studies also identified *Alk* mRNA in the central and peripheral nervous system, as well as in testis, ovary and midgut of fetal rats and mice while *DAlk* was detected in the brain, ventral nerve and gut musculature of Drosophila during embryonic development. The expression of both *Alk* mRNA and Alk protein decreased rapidly in rodent neonates while ALK protein was detected in only rare scattered cells in the brain in humans. Both of these findings are suggestive of a role for ALK in early neural development. The use of DAlk mutants also provided evidence for its role in the development of the ventral mesoderm in Drosophila.

The ligand(s) for full length ALK are at present, still unknown. Possible candidates include a neurotrophic factor and the two heparin-binding growth factors ►pleiotrophin and ►midkine. *In vivo* experiments using flies expressing loss-of-function mutant *DAlk* genes have identified ►Jelly belly protein (Jeb) as a ligand for DAlk in Drosophila. The expression of both Jeb and dAlk proteins were essential for activation of the ►RAS/MAP kinase pathway in visceral gut muscle development. In common with other receptor tyrosine kinases, binding of ligand to the extracellular receptor of ALK results in dimerization of the ALK proteins with permitting the subsequent autophosphorylation and creation of binding sites on the intracellular regions of ALK protein for downstream signaling molecules. Interactions between full length ALK and members of the ►MAP-Kinase pathway, IRS-1 and c-Cbl have been identified in the differentiation of neurites. Other proteins involved in ALK signaling pathways are discussed below with reference to the ALK fusion proteins.

ALK Protein and Cancer

ALK is a receptor tyrosine kinase that has been implicated in the development of both non-hematopoietic as well as hematopoietic tumor development.



ALK Protein. Figure 1 Diagram of the human full length ALK and ALK fusion proteins. The extracellular region contains 16 N-glycosylation sites. The presence of these increases the size of ALK from a predicted 170 kD up to 200 kD. Recognition sites of some of the major intracellular interacting proteins are indicated. The arrow at aminoacid 1,058 indicates the site of cleavage of the ALK protein occurring as a result of the t(2;5)(p23q35) translocation.

Full Length ALK

The expression of full length ALK protein has been reported in a number of mesenchymal tumors such as malignant peripheral nerve sheath tumors and leiomyosarcoma. *ALK* mRNA has also been detected in cell lines arising from ►rhabdomyosarcoma, ►neuroblastoma, ►melanoma, ►glioblastoma and ►breast cancer. The precise role of ALK protein in oncogenesis is uncertain at present although there is evidence that ALK signaling may be a limiting factor in glioblastoma.

ALK Fusion Proteins

In contrast to the situation with full length ALK protein, *in vivo* and *in vitro* studies have led to the conclusion that ALK fusion proteins play a primary role in tumor development. Indeed the aberrant expression of ALK fusion proteins in lymphoid cells is a marker of malignancy.

Structure

Translocations affecting the *ALK* gene result in the production and expression of chimeric ALK fusion proteins. The most common translocation is the t(2;5)(p23;q35), involving the *ALK* gene at 2p23 and the ►*nucleophosmin (NPM)* gene at 5q35, resulting in the expression of the ►NPM-ALK fusion protein. Twelve other variant ALK fusion proteins have been identified (listed below in Table 1).

All of these proteins consist of the N-terminal of the partner proteins and the intracytoplasmic region of ALK containing the tyrosine kinase domain (Fig. 2a). With the exception of ►MSN-ALK and ►MYH9-ALK, all of the fusion proteins contain the final 563 amino acids of ALK while MSN-ALK and MYH9-ALK contain the final 567 and 566 amino acids, respectively.

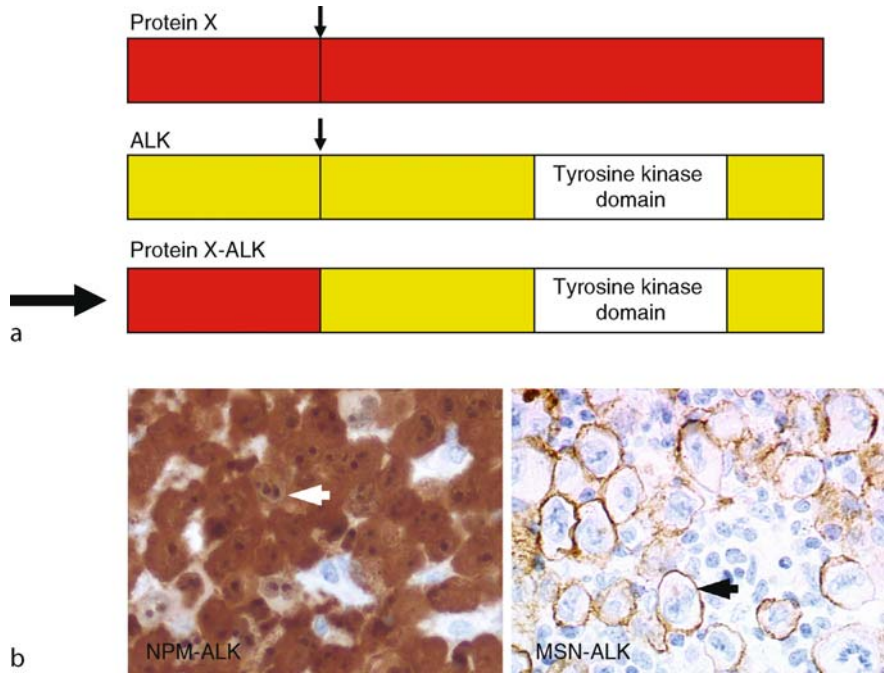
Distribution

Partner proteins of 11 ALK fusion proteins all contain an oligomerization domain in their amino-region. The presence of these domains permits the formation, not only of homodimers of ALK fusion proteins, but also heterodimers of the ALK fusion protein and the normal wild type partner protein. Variations of this mechanism may occur with the MSN-ALK and MYH9-ALK proteins. The ability of the ALK-fusion proteins to dimerise results in each of the ALK fusion proteins having a characteristic subcellular distribution. NPM-ALK, for example, has a nuclear, nucleolar and cytoplasmic localization due to the presence of NPM-ALK homodimers in the cytoplasm of the cell while the presence of a nuclear localization motif present in wild type NPM results in a nuclear and nucleolar distribution

ALK Protein. Table 1 Characteristics and distribution of ALK fusion proteins

Fusion protein	Chromosomal translocation	Subcellular location	Size fusion protein (kD)	Expression in tumors
NPM-ALK	t(2;5)(p23;q35)	Nucleus, nucleolus and cytoplasm	80	ALCL, B cell lymphoma
TPM3-ALK	t(1;2)(p25;p23)	Cytoplasm	104	ALCL, IMT
TFG-ALK_S		Cytoplasm	85	
TFG-ALK_L	t(2;3)(p23;q21)	Cytoplasm	97	ALCL
TFG-ALK_{XL}		Cytoplasm	113	ALCL
ATIC-ALK	inv(2)(p23q35)	Cytoplasm	96	ALCL
CLTC-ALK	t(2;17)(p23;q23)	Granular cytoplasmic	250	ALCL, B cell lymphoma IMT
MSN-ALK	t(2;X)(p23;q11–12)	Cell membrane-associated	125	ALCL
TPM4-ALK	t(2;19)(p23;p13.1)	Cytoplasm	95–105	ALCL, IMT
ALO17-ALK	t(2;17)(p23;q25)	Cytoplasm	ND	ALCL
RANBP2-ALK	t(2;2)(p23;q13) or inv(2)(p23q11–13)	Nuclear periphery	160	IMT
MYH9-ALK	t(2;22)(p23;q11.2)	Cytoplasm	220	ALCL
CARS-ALK	t(2;11;2)(p23;p15;q31)	Cytoplasm	130	IMT

NPM = nucleophosmin; TPM3 = Tropomyosin 3; ►TFG = ►TRK-fused gene; ►ATIC = 5-aminoimidazole-4-carboxamide ribonucleotide formyltransferase/IMP cyclohydrolase (ATIC); also known as PurH; ►CTLC = ►Clathrin heavy chain; ►MSN = ►moesin; ►TPM4 = ►Tropomyosin 4; ►ALO17 = Unknown gene, ALK lymphoma.
oligomerization partner on chromosome 17; ►RANBP2 = ►RAN binding protein also known as Nup358; ►MYH9 = ►Non-muscle myosin heavy chain; ►CARS = Cysteinyl-tRNA synthetase enzyme.
►IMT = inflammatory myofibroblastic tumor.



ALK Protein. Figure 2 Structure and distribution of ALK fusion proteins. (a) The general mechanism of translocations affecting genes encoding ALK and a partner protein (Protein X). As a result of the translocation (shown by the *small arrows* and *dotted lines*), the N-terminus of Protein X is joined to the intracytoplasmic region of ALK to produce a chimeric Protein X-ALK protein. (b) Immunoperoxidase labeling of tissue sections from cases of anaplastic large cell lymphoma to illustrate the different subcellular distribution patterns of ALK fusion proteins. NPM-ALK is present in the nucleus, nucleolus and cytoplasm of the tumor cells (*white arrow*) while MSN-ALK is present at the cell membrane (*black arrow*).

of ►NPM/NPM-ALK heterodimers (Fig. 2b). Other "variant" ALK fusion proteins exhibit a variety of distribution patterns again determined by the identity of the partner protein (Table 1 and Fig. 2b).

Function

Another consequence of an oligomerization domain in the ALK fusion proteins is that it mimics ligand-mediated aggregation of the full length ALK protein with the subsequent constitutive activation of the ALK tyrosine kinase domain. This results in the aberrant activation of multiple downstream signaling pathways involved in mitogenesis and ►apoptosis. Examples of these pathways include the ►AKT signal transduction pathway, Janus kinase and signal transducer and activator of transcription (JAK/STAT), BCL2, GRB2, JNK, ►FOX03A, phospholipase Cγ (PLC-γ), ►phosphatidylinositol 3-kinase (PI3K) and MAP Kinase. NPM itself may also play a role in tumor development through activation of p53. Proteomics-based studies have confirmed the complexity of NPM-ALK signaling pathways in cell proliferation, cellular structure and migration, protein synthesis and the ability of cells to evade apoptosis. Proteins identified in this way include additional adaptor molecules (suppressors of cytokine signaling, ►Rho family proteins and RAB35), kinases (such as MEK kinase 1 and protein kinase C) and phosphatases (meprin, PTPK and protein phosphatase 2 subunit). One potential role of the ALK fusion proteins in oncogenesis is the relocation of interacting proteins away from their normal site of activity within the cell. FOX03A, for example, is redirected to the cytoplasm rather than to the nucleus. Further studies are, however, necessary to understand fully the mechanisms employed by ALK proteins in cell proliferation, differentiation and survival in both normal and disease states.

Tumor Types

Although representing only 5% of ►non-Hodgkin lymphomas (NHL), ALK-positive anaplastic large cell lymphoma constitutes 40% of pediatric large cell tumors. These CD30-positive tumors are of T and null phenotype. NPM-ALK is the most common ALK fusion protein being expressed in 60–80% of the cases, ►TPM3-ALK is detected in about 15% of cases while ►ATIC-ALK, TFG-ALK and ►CLTC-ALK fusion proteins are present in approximately 8% of tumors. The other ALK fusion proteins are present in the remaining 2% of ALK-positive lymphomas. The differential diagnosis

of ALK-positive anaplastic large cell lymphoma is important since these lymphomas are associated with a good prognosis with an overall 5-year survival of 71–80% compared to only 15–46% for ALK-negative anaplastic large cell lymphoma.

ALK fusion proteins may also be implicated in the development of other tumors. ►NPM-ALK and ►CLTC-ALK have been reported in a small subset of CD30-negative B cell lymphoma, while ►TPM3-ALK, ►TPM4-ALK, ►RanBP2-ALK and ►CLTC-ALK fusion proteins have been identified in ►inflammatory myofibroblastic tumors.

Therapeutic Options

Current treatments include the use of various combination chemotherapy protocols originally developed for T-cell lymphoblastic tumors and high-grade B–cell non-Hodgkin lymphomas. Autologous and allogeneic stem cell transplantation techniques have also been utilized. However, 20–30% of patients fail to respond to current treatment regimens and so improved therapeutic options still continue to be sought. One approach is to use ALK as a specific target through the use of ALK specific tyrosine kinase inhibitors (a paradigm is the ABL kinase inhibitor imatinib mesylate or Gleevec used in chronic myeloid leukemia), ALK ribozymes and small interfering RNA probes. Recognition of ALK as an immunogenic tumor-associated antigen has also highlighted its use as a potential target for ►immunotherapy, either for antibody-based therapies for treatment of tumors expressing full length ALK protein or through the use of T-cell mediated immunity in the case of tumors bearing intracellular ALK fusion proteins. Another avenue that has shown promise is the use of small molecule inhibitors affecting proteins involved in the ALK signaling pathways, examples of this include the ansamycin class of natural ►HSP90 inhibitors.

In conclusion, the ALK receptor tyrosine kinase and ALK fusion proteins have been implicated in a diverse range of cellular functions. However, despite major advances, in depth analysis of the signaling pathways is necessary to unravel the full role of this RTK in both normal and neoplastic cells and tissues.

Alkylating Agents

Lakshmaiah Sreerama
Department of Chemistry, St. Cloud State University, St. Cloud, MN, USA

Definition

Alkylating agents (*al-ka-LAYT-ing AY-jints*) are a family of anticancer drugs that interfere with cell's DNA and inhibit cancer cell growth. They are so named because of their ability to add alkyl groups to negatively charged groups on biological molecules such as DNA and proteins. Alkylating agents are among the first group of chemicals determined to be useful in ►cancer chemotherapy. They remain to be the most important components of modern chemotherapeutic protocols (individually or in combination with other drugs) because of their proved and significant clinical anticancer activities.

Characteristics

Discovery of alkylating agents as anticancer drugs has its origin in the use of sulfur mustard gas for warfare during World War I. Sulfur mustard gas was not

only fetal but it also showed ►myelosuppression/immunosuppression in its victims as well as in animal models. The latter observation lead to the development of less volatile mustargen (mechlorethamine) with strong antitumor activity against lymphomas and other cancers. Eventually mustargen (nitrogen mustard) was developed for clinical use to treat ►Hodgkin disease. Following the discovery of mustargen, less toxic and more clinically effective nitrogen mustard derivatives, e.g., ►cyclophosphamide, and other alkylating agents in clinical use today were developed (Table 1).

Alkylating agents, as suggested by their names contain reactive alkyl groups. An alkyl is an ►univalent reactive group containing only ►carbon and ►hydrogen atoms arranged in a chain with a general formula of C_nH_{2n+1}, e.g., *methyl*, CH_3 (derived from ►*methane*) and *butyl* C_4H_9 (derived from ►*butane*). Alkylating agents used as anticancer drugs are cable of reacting with biological molecules such as DNA and proteins, and disrupt cellular function by either killing the cell or by prevent its growth. The most common biological functional moiety alkylated by these compounds is guanine, a nucleobase. The anticancer activities of alkylating agents are caused in two ways. (i) Through cross-linking two different DNA strands via the reaction with guanine nucleobases present on the opposing strands of DNA and (ii) Preventing/affecting the activities of critical DNA processing enzymes and there by stimulating apoptosis via the reaction with guanine nucleobases on a single DNA strand. The cross-linking of DNA makes it impossible to uncoil DNA during cell division thus preventing its growth. Based on the reactivity, alkylating agents are of two types; (i) monofunctional (monoalkylating; alkylate nucleobases on one DNA strand) and (ii) bifunctional (dialkylating; alkylate nucleobases on both DNA strands and cross-link them).

Classification

Alkylating agents currently used as anticancer drugs are divided into five major classes. The examples of the clinically used agents (most common) under each of these classes and their clinical utility are shown in Table 1.

Mechanism of Action

Alkylating agents are a diverse group of chemical compounds with a common characteristic of forming positively charged (electrophillic; electron poor) alkyl groups in aqueous solutions under physiological conditions. The positively charged alkyl groups are capable of reacting with basic/negatively charged (nucleophillic; electron rich) groups present in DNA and proteins/peptides. Such reactions lead to adding alkyl groups at oxygen, nitrogen, phosphorous, or sulfur atoms (nucleophillic centers) and thus altering the biological

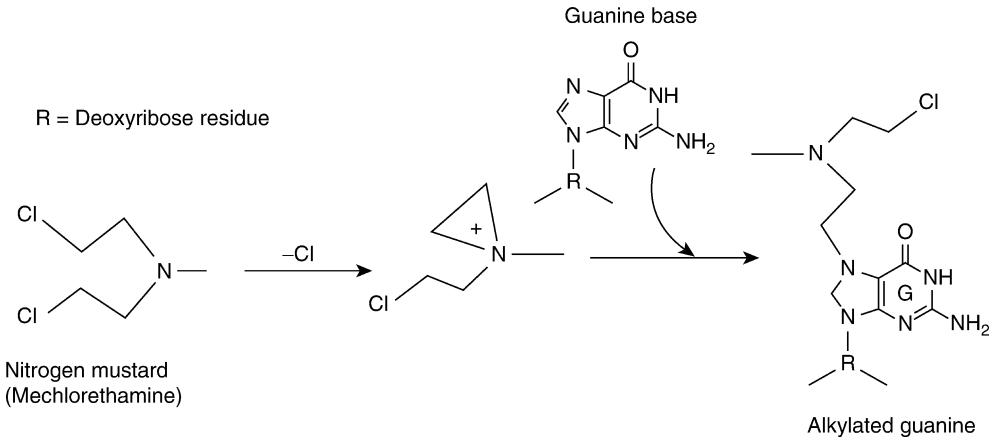
Alkylating Agents. Table 1 Classification of clinically used alkylating agents

Class	Clinically used agents	Cancer/other disease treated
Nitrogen mustards	Cyclophosphamide	►Breast cancers, most lymphomas, and ►childhood cancers
	Ifosfamide	
	4-Hydroxycyclophosphamide	High dose therapies in conjunction with bone marrow transplantation
	Mafosfamide	
	Melphalan	Multiple myeloma, melanoma, and sarcomas
	Chlorambucil	B-cell chronic lymphocytic ►leukemia and immunosuppressive therapy for autoimmune diseases
Aziridines and epoxides	Thiotepa	Breast, ovarian, and ►bladder cancers
	Mitomycin C	►Esophageal, breast, and bladder cancers
	Dianhydrogalactitol	Breast, cervical, and brain cancers
Alkyl Sulfonates	Busulfan	Bone marrow transplantation for Chronic myelogenous leukemia
Nitrosoureas	BCNU [*N*,*N*′-Bis(2-chloroethyl)-*N*-nitrosourea]	►Brain tumors (glioma, ►glioblastoma, medulloblastoma, and astrocytoma), multiple myeloma, and lymphoma
	CCNU [*N*-(2-chloroethyl)-*N*′-cyclohexyl-*N*-nitrosourea]	
	MeCCNU [*N*-(2-chloroethyl)-*N*′(4-methylcyclohexyl)-*N*-nitrosourea]	
Hydrazine and triazine derivatives	Procarbazine	Hodgkin lymphoma and certain brain cancers such as glioblastoma multiforme astrocytoma, and ►melanoma
	Dacarbazine	
	Temozolomide	

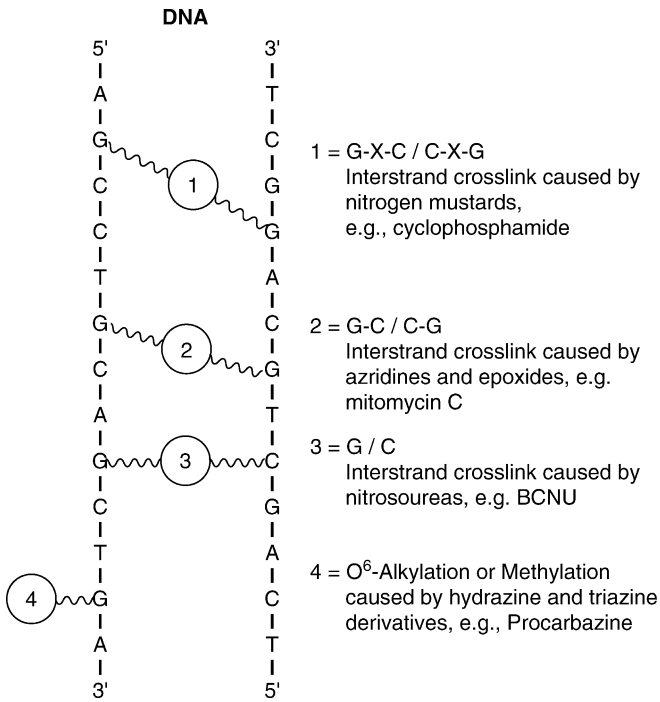
function of DNA and proteins. The most important reaction of alkylating agents with regard to their antitumor activity is their reactions with DNA nucleobases. The most preferred DNA nucleobase for alkylation is guanine and the alkylation preferentially occurs at N7 position on guanine (Fig. 1). Other nucleobases alkylated and the atomic positions at which alkylation occurs in order of preference include N1 and O6 positions of guanine, N1, N3, and N7 positions on adenine, N3 position on cytosine and O4 position of thymidine.

DNA Cross-Links

Various techniques used to elucidate the reactions of alkylating agents with DNA and the possible basis for their anticancer activities has lead to identifying at least four different types of DNA adducts (DNA cross-links) (Fig. 2). Nitrogen mustard (mustargen) and its derivatives, e.g., cyclophosphamide, as well as alkylsulfonates, e.g., busulfan, produce interstrand cross-links in -G-X-C-/-C-X-G- configuration of DNA double helix in greater frequency. The cross-link



Alkylating Agents. Figure 1 Reaction between nitrogen mustard and guanylate residue on DNA at N7 position of guanine.



Alkylating Agents. Figure 2 Schematic representation of alkylation (interstrand cross-links and *O*-alkylation) of DNA by alkylating agents.

involves the N7 atoms of the guanylates in the -G-X-C-/-C-X-G- configuration of the DNA double helix (cross-link 1; Fig. 2). Aziridine and epoxide alkylating agents produce DNA cross-links in -G-C-/-C-G- configuration of DNA. Agents such as thiotepa and dianhydrogalactitol in this class drugs react with N7 position of the guanylate groups. Whereas mitomycin C reacts with the extracyclic N2 atom of the amino group in guanylates (cross-link 2, Fig. 2). Nitrosoureas such as BCNU produce DNA cross-links between a guanine and a cytidine in a -G-/-C- base-pair configuration of the DNA double helix (cross-link 3; Fig. 2). Hydrazine and triazine derivatives such as procarbazine, dacarbazine, and temozolomide decompose to produce a methyl diazonium ion which in turn will methylate guanines on DNA at O6 position (cross-link 4, Fig. 2). Other types of guanylate-alkyl cross-links of type 4, e.g., O6-ethylguanine and O6-benzylguanine, have also been observed.

Molecular Pharmacology, Drug Resistance and Clinical Efficacy

Metabolism:

Alkylating agents are strong electrophiles and react with many biological nucleophiles within the tumor cells. Many of these reactions result in inactivation/detoxification of alkylating agents and thus lead to drug resistance.

The most abundant and principal nucleophile in the cell is ►glutathione (GSH; concentrations in mM levels). The cysteine sulfhydryl (nucleophile) reacts with alkylating agents both in enzyme and no-enzyme catalyzed reactions resulting in glutathione conjugates. The glutathione conjugates of alkylating agents are generally nontoxic. The enzyme catalyzed conjugation of alkylating agents to GSH is catalyzed by ►glutathione S-transferases (GSTs). Tumor cells resistant to alkylating agents commonly have increased levels GSTs. Inhibitors of GSTs such as sulfasalazine and inhibitors of ►gamma-glutamylcysteine synthase (a rate limiting enzyme in the synthesis of GSH) such as buthionine sulfoximine have been shown to reverse the resistance originating due to elevated levels of GSH in both in vitro and in vivo settings.

GSH conjugates of some alkylating agents, e.g., melphalan and chlorambucil, are good substrates for ►ATP-binding cassette membrane proteins (membrane transporter multidrug resistance proteins; MDR; ►P-glycoprotein) and modulation of these enzyme systems is also believed improve clinical efficacy of alkylating agents.

Thiol groups in ►metallothionein enzymes have been shown to sequester alkylating agents such as chlorambucil, melphalan, and phosphoramide mustard (activated cyclophosphamide) and cause resistance. This has been proved by transfection and overexpression, as well as induced expression of genes coding of metallothionines in tumor cells. Modulation of this enzyme system is also expected to increase efficacy of alkylating agents.

Cyclophosphamide and its analogs (nitrogen mustard derivatives) are prodrugs and undergo extensive metabolism. During their metabolism three aldehyde intermediates, viz., aldophosphamide, acrolein, and chloroacetaldehyde are formed. Although all three aldehydes are toxic to cells, the pivotal aldehyde metabolite of the three is aldophosphamide as it gives rise to the DNA alkylating mustard that is finally responsible for the anticancer activity of these agents. ►Aldehyde dehydrogenases catalyze NAD-dependent oxidation of aldehydes in tumor cells. These enzymes have also been shown to oxidize aldophosphamide and cause resistance to cyclophosphamide and its derivatives in various tumor cell models in both in vitro and in vivo settings. Inhibitors of aldehyde dehydrogenases have been shown to reverse resistance to cyclophosphamide and its analogs, as well as increase their efficacy in vitro. Relatively large concentrations of aldehyde dehydrogenases are naturally present in critical normal cells such as bone marrow stem cells, intestinal progenitor cells, and the liver cells. Accordingly, these normal cells are protected from toxicities due to cyclophosphamide and its analogs.

The main mechanism by which alkylating agents present their anticancer properties is via alkylation of DNA. Alkylation further leads to the formation various DNA adducts (Fig. 2) which in turn is responsible for inhibition of tumor cell growth. Removal of such adducts is yet another mechanism by which tumor cells become resistant to alkylating agents.

►O6-Alkylguanine-alkyltransferase has been shown to remove alkyl groups from the O6 position of guanine. This process leads to alkylation of the enzyme alkyltransferase and the alkylated enzyme is rapidly degraded. This mechanism has been shown to be very effective against DNA methylating agents such as procarbazine and temozolomide. The same enzyme has also been shown to remove other alkyl and aryl groups, e.g., dealkylation of O6-ethylguanine and debenzylation of O6-benzyguanine. Inhibitors of O6-alkylguanine-alkyltransferase have been successfully used to prevent resistance to certain clinically used alkylating agents, e.g., BCNU.

DNA cross-links of type 1–3 (Fig. 2) have been shown to be removed via ►nucleotide excision repair and poly(adenosine diphosphate-ribose) polymerase pathways, however the exact mechanism by which this is achieved is not clear.

Toxicology

The most common toxicities associated with administering alkylating agents to treat cancers are as follows.

1. Hematopoietic toxicity – In general, the clinical dose-limiting toxicity for alkylating agents is hematopoietic toxicity, particularly suppression of granulocytes and platelets exhibited for 8–16 days after treatment. The toxicity usually disappears after 20 days and granulocytes and platelets return to their normal levels.
2. Gastrointestinal toxicity (nausea and vomiting) – Damage to the gastrointestinal tract is a toxicity that frequently occurs with high-dose regimens of alkylating agents. These toxicities are characterized by mucositis, stomatitis, esophagitis, and diarrhea. This toxicity can be managed by administering corticosteroids and antiemetics.
3. Gonadal toxicity – Treatments with alkylating agents have been shown to cause testicular lesions leading to depletion of sperm in male patients and decrease in ovarian follicles in female patients.
4. Pulmonary toxicity – Pulmonary toxicities characterized by interstitial pneumonitis and fibrosis leading to dyspnea and nonproductive cough that may lead to cyanosis, pulmonary insufficiency, and death have also been observed in patients treated with alkylating agents.
5. Alopecia – Although the association between an alkylating agents and alopecia was first described with busulfan therapy, this toxicity is predominantly associated with cyclophosphamide and ifosfamide therapy. Alopecia is caused by introduction of nicks in the hair fibers due the temporary stoppage in synthesis of hair in hair follicles by alkylating agents.
6. Teratogenicity – All therapeutically used alkylating agents cause teratogenicity (developmental defects) in animal models. Fetal malformations have been observed in mothers receiving alkylating agents in the first trimester of pregnancy but not second and third trimesters.
7. Carcinogenicity – Reports of the incidence of leukemia and increased frequency of incidence of solid tumors have been reported in patients receiving therapies that include alkylating agents.
8. Immunosuppression – Alkylating agents have been shown to inhibit antibody production. All alkylating agents produce some degree of immunosuppression however severe immunosuppression is caused by cyclophosphamide and its analogs, and chlorambucil. Accordingly, therapies that include high dose cyclophosphamide or chlorambucil without bone marrow transplantation are now being used to treat some autoimmune diseases.

Definition

This field of study refers to the evaluation of the association between allergy and cancer, usually with the hypothesis of allergic status as a protective factor in cancer development.

Characteristics

The presence of allergic disorders has been suggested to be related to cancer development, although this association remains controversial. In particular, the presence of atopic allergic disorders, including allergic asthma and hay fever for example, has been suggested to confer a protective effect against cancer overall and at several sites.

►Atopic disorders are characterized by the inherited predisposition to produce high levels of ►immunoglobulin E (IgE) in response to allergens commonly present in the environment. Upon ►allergen re-exposure, a cascade of events occur leading to a two-phase

(immediate and late) inflammatory immunological response. Atopic disorders arise due to a complex set of genetic and environmental factors and their interactions that remain to be fully elucidated. The prevalence of atopy varies according to a variety of geographic, environmental, and demographic factors and has recently been suggested to be increasing in many western countries. Although atopic disorders have been commonly assumed to offer little benefit to the individual, it has been hypothesized that this atypical, ►Th2-dominated, immune response may in fact represent a state of enhanced or hyperactive immune function.

The immune system has long been recognized as playing a potential role in cancer development (►Immunoprevention of cancer). ►Immune surveillance theory suggests the ongoing search for and eradiation of cancer cells by the immune system as a self-protective mechanism against the development of cancer. Traditionally, it has been the ►Th-1 response however, that has been thought to play a predominant role. The role of the immune system in cancer development can be clearly observed by the fact that individuals who are ►immunosuppressed or immunodeficient tend to display higher rates of certain types malignancies. It is possible that certain groups may exhibit an enhanced ability for immune surveillance, including those with a history of atopic allergy. The hypothesized state of enhanced immune function and immune surveillance among individuals with atopic allergic disorders may be related to cancer development.

Epidemiological Studies

The association between allergy and cancer has been examined in a number of ►analytic epidemiological studies. Over 100 studies conducted throughout the world have evaluated some aspect of the association between a history of allergy and cancer occurrence. Although many of these studies have suggested an association between allergy and cancer, either overall or at a specific cancer site, it is difficult to draw conclusions due to insufficient evidence, inconsistent findings, and limitations of previous studies. The nature of the relationship also likely depends on the cancer site studied.

Previous epidemiological studies have tended to be associated with a variety of limitations associated with exposure assessment, confounding, and certain types of bias. The majority of previous studies have relied on self-reported history of allergy disorders as an indicator of allergic status. Few studies have evaluated ►skin prick testing or serum allergen-specific IgE levels in relation to cancer occurrence and few large prospective studies exist.

It remains unclear if an allergic history is associated with overall cancer occurrence. Although results from a number of early case-control or cohort studies suggested an inverse association, results from more recent larger cohorts although suggestive, in total have provided little clear evidence for an association. Perhaps the strongest evidence for an association between a history of allergy and cancer overall are results from an analysis of a large prospective cohort of nearly 1.2 million US adults followed for 18 years. A statistically significant 12% reduction in the risk of overall cancer mortality among participants who reported a history of both asthma and hay fever at baseline was reported, however, the results among never smokers attenuated slightly.

Among cancer site-specific studies, strong inverse associations have been reported in studies of pancreatic cancer and brain cancer (glioma), although there remain a variety of limitations (►Pancreas cancer, basic and clinical parameters; ►brain tumors). A recent study combining the results of previous published studies (a ►meta-analysis) reported a statistically significant 18% and 29% reduction in risk of pancreatic cancer associated with a history of any allergy or atopy respectively. Results from a number of studies, including a large international case-control study with eight study centres reported a statistically significant inverse association between risk of glioma and a history of any allergic disease, where this study noted a 40% in risk. Numerous other inverse associations have been reported at other cancer sites; however the results findings remain to be confirmed.

Contrasting these findings, lung cancer has tended to be found to be positively associated with a history of asthma, however certain limitations including potential misclassification and differential recall bias in previous studies are still of concern. This positive association, if causal, is thought not to be related to an overall immune response, but rather to local processes of repeated inflammation, cell regeneration, and free radical production due to the allergic lung disease increasing the occurrence of malignancy.

Biological Details

At this point in time, no precise explanation has been put forward to explain an overall inverse association between a history of allergy and cancer risk. Enhanced immune surveillance is most often suggested when inverse associations are reported in the epidemiologic literature. The atopic immune response involves the release of a number of factors including histamine, leukotrienes, and chemotactic factors among others from IgE-mast cell complexes upon allergen exposure. The resulting response initially involves smooth muscle contraction, mucus secretion, vasodilation, and a loss of microvascular integrity which is then followed by the infiltration and activation of eosinophils, neutrophils, Th2-type CD4+ cells, and macrophages that typically lasts for several hours. It remains unclear however, how

this overactive immune response to common environmental agents may be related to the development of cancer. Allergy medications have also been investigated in relation to cancer occurrence; however few associations have been reported.

Overall, although it is plausible that enhanced immune surveillance in individuals with a history of allergy may be associated with reduced cancer risk; specific evidence remains limited and controversial. Further understanding of such a potential association may be relevant for the development of cancer prevention and treatment options.

Synonyms

Allogeneic cellular immunotherapy; Allogeneic hematopoietic stem cell transplantation; Allogeneic bone marrow transplantation

Definition

Allogeneic cell therapy consists of chemoradiotherapeutic conditioning therapy followed by transplantation of hematopoietic stem cells and lymphocytes isolated from allogeneic healthy donors to generate an effective graft-versus-malignancy immune response in patients with treatment-refractory malignant disorders.

Characteristics

Rationale

Allogeneic hematopoietic stem cell transplantation (HSCT) aims to break autologous immunotolerance towards malignant cells in tumor-bearing patients. The treatment approach is based on the alloreactive graft-versus-malignancy effect that is mainly mediated by T cells of donor origin. These donor T cells are infused together with allogeneic hematopoietic stem cells (HSC) at the time of transplantation or originate from donor HSC in the patient thereafter. Allogeneic HSCT is capable of inducing long-term disease control in patients with chemotherapy-refractory leukemias and other ►hematological malignancies.

Procedure

Allogeneic HSCT requires chemoradiotherapeutic conditioning therapy to allow the engraftment of subsequently infused allogeneic HSC and lymphocytes of donor origin. Preclinical as well as clinical research has demonstrated that the long-term leukemia control following allogeneic HSCT depends on the immunological graft-versus-leukemia (GVL) effect rather than on the intensity of the pre-transplant ►chemoradiotherapy. This important observation led to a change of paradigm shifting the antileukemic effect of the allo-transplantation procedure from the preparative cytostatic drugs to alloreactive immune effector cells. Consequently, reduced-intensity conditioning (RIC) regimens were developed that do not irreversibly destroy recipient hematopoiesis, but are sufficiently immunosuppressive to permit the engraftment of allogeneic HSC. This results in an initial co-existence of donor and recipient hematopoiesis ('mixed hematopoietic ►chimerism') that can be gradually shifted to complete hematopoietic donor chimerism by modulating the post-transplant immune system using immunosuppressive agents or ►donor lymphocyte infusions (DLI). The majority of these non-myeloablative RIC regimens are combinations of 1–3 different chemotherapeutic drugs and low-dose total body irradiation. Compared to conventional myeloablative conditioning protocols based on high-dose radiochemotherapies, RIC regimens carry a much lower treatment-related morbidity and mortality allowing the use of allogeneic cell therapy in patients until 60–70 years of age or in patients with significant co-morbidities.

The allogeneic HSC donors are healthy related and unrelated volunteers who are matched with the patients for ►human leukocyte antigen (HLA) class I and II molecules. Although transplantation of donor HSC with single or multiple HLA allele or antigen disparities is feasible, this increases the risk of immune-mediated graft rejection and ►graft-versus-host disease (GVHD). The HSC can be harvested either by bone marrow aspiration during general anesthesia or by apheresis. The apheresis procedure requires the prior mobilization of HSC into the peripheral circulation by a 3 to 5-day treatment course with recombinant human ►granulocyte-colony stimulating factor (G-CSF). HSC express the hematopoietic ►stem cell marker CD34 that enable their detection in clinical samples by ►flow cytometry.

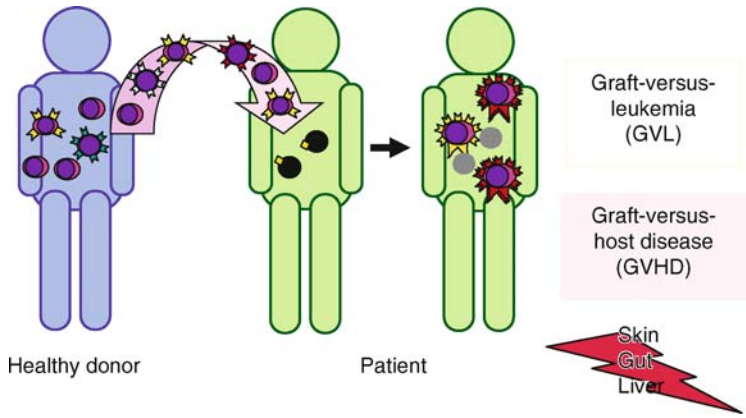
After conditioning therapy and transplantation of the HSC allograft, the patient enters a 1–3 week-long period with a low neutrophil cell count (►neutropenia) in which the patient is susceptible to bacterial and fungal infections. The hematopoietic engraftment is indicated by the re-occurrence of circulating neutrophils. These neutrophils are of donor origin which can be verified by analyzing the proportion of donor and patient derived DNA in chimerism assays. Early graft rejection is prevented by treating the patient with immunosuppressive medication, mainly consisting of the calcineurin inhibitors cyclosporine A and tacrolimus, the antimetabolite methotrexate, and T-cell depletion antibodies. The strong suppression of T cell immunity increases the risk of infections with opportunistic agents of which herpes family viruses (e.g. cytomegalovirus, varizella zoster virus, ►Epstein-Barr virus) and pneumocystis carinii have the greatest clinical significance during the first 1–2 years after transplantation. The drug-induced immunosuppression is also necessary to lower the incidence and severity of GVHD.

GVHD is a life-threatening complication of allogeneic HSCT in which donor T cells attack the tissues of the transplant recipient after perceiving host tissues as antigenically foreign. GVHD is mainly directed against epithelial tissues of the skin, liver, and gastrointestinal tract. Other GVHD target organs include the hematopoietic tissues such as bone marrow and thymus, and the lungs in the form of idiopathic pneumonitis. Clinically, GVHD is divided into acute and chronic forms. The acute form is observed within the first 100 days post-transplant, and the chronic form occurs following day 100 after HSCT. Chronic GVHD damages the above mentioned organs, but also causes changes to the connective tissues including skin and exocrine glands. If the GVHD is severe and requires intense immunosuppressive treatment, the patient may develop serious infections as a result of the immunosuppression and may die of infection. Moderate forms of GVHD are associated with a lower incidence of relapse of the underlying malignant disease, and, therefore, require no escalated immunosuppressive treatment.

If the patient develops disease relapse after allogeneic HSCT, donor lymphocyte infusions (DLI) can be administered to augment the GVL effect. The DLI are collected from the original stem cell donor by apheresis without prior G-CSF treatment. DLI therapy is most efficient in patients with low disease burden. Moreover, DLI carry a superior GVL effect in chronic leukemias compared with acute leukemias. This may rely on disease-inherent factors such as the growth kinetic and immunogenicity of leukemic blasts that favors efficient immune reactions in chronic leukemias over their acute counterparts. The major complication of DLI therapy is an accompanying severe GVHD reaction, particularly if high lymphocyte doses are administered.

Mechanisms

The therapeutic success of allogeneic HSCT relies on the GVL immune effect that is closely linked to GVHD (Fig. 1). However, there are a considerable number of patients who develop efficient GVL reactions in the absence of GVHD. The main effectors that induce the GVL reaction as well as the GVHD are T lymphocytes of donor origin. In allogeneic HLA-identical HSCT, the donor lymphocytes generate a ►T cell response against



Allogeneic Cell Therapy. Figure 1 Donor-derived T lymphocytes infused into the leukemia patient are key mediators of the alloreactive graft-versus-leukemia effect (GVL) and the graft-versus-host disease (GVHD). Main GVHD target organs are skin, gut, and liver.

a group of proteins (called ►minor histocompatibility antigens, minor Hag) that are genetically polymorphic between donor and recipient. The peptide epitopes derived from minor Hag are presented by HLA molecules on recipient cells, and there are well-described examples of HLA class I and II associated minor Hag recognized by $CD8^+$ and $CD4^+$ donor T cells, respectively. It is comprehensible that minor Hag exclusively expressed in the hematopoietic tissue lineage promotes the engraftment of donor hematopoiesis as well as the GVL effect, while minor Hag with an ubiquitous expression pattern including epithelial tissues will facilitate the development of GVHD.

There is also increasing evidence that donor T cells can recognize non-polymorphic antigens that are de novo expressed or over-expressed on leukemic cells of the recipient. Hematopoietic minor Hag and leukemia-associated antigens are ideal candidates to re-direct donor immunity specifically against the hematopoietic recipient cells including leukemia, either by vaccination with ►cancer vaccines or by ►adoptive immunotherapy. A great deal of current research on allogeneic HSCT involves attempts to separate the undesirable GVHD aspects of T cell pathophysiology from the desirable GVL effect.

For many leukemia patients lacking an HLA-matched hematopoietic stem cell donor, transplantation of HLA-incompatible HSC remains the only curative treatment option. In haplo-identical transplantation, the donor shares only one haplotype with the recipient. Because disparate HLA alleles are strongly immunogeneic targets of alloreactive T cells, these regimens require concomitant T cell depletion to prevent graft rejection and severe GVHD. Several research groups have demonstrated that in HLA-mismatch transplantation settings incorporating extensive T cell depletion, the main immunological effector cells are ►natural killer cells of donor origin that recognize recipient hematopoietic (including leukemia) cells lacking the expression of natural killer cell inhibitory receptors.

Clinical Aspects

Allogeneic HSCT is a curative treatment modality for patients with insufficient hematopoietic stem cell function such as aplastic anemia, and for patients with chemotherapy-refractory forms of hematological malignancies including ►chronic myeloid leukemia, ►acute myeloid leukemia, and ►acute lymphoblastic leukemia. Ongoing studies explore the role of allogeneic HSCT in patients with ►Hodgkin disease, non-Hodgkin's lymphoma, and ►chronic lymphocytic leukemia. With the development of less-toxic RIC regimens, many groups are currently trying to establish allogeneic HSCT for the treatment of diseases with a dysfunctional immune system, e.g. autoimmune disorders and solid tumors such as ►renal carcinoma. The general idea is to first generate stable hematopoietic donor chimerism in the patient as a platform allowing in a second step the re-direction of immunity using adoptively transferred donor lymphocytes with beneficial specificity.

Alpha-Fetoprotein

Definition

AFP is a fetal serum protein that shares sequence homology with albumin. Serum levels of AFP are typically elevated in patients with hepatocellular carcinoma and in men with nonseminomatous germ cell tumors (NSGCT). Although AFP levels >400 ng/ml are highly associated with HCC, not all HCC secrete AFP. It may also be elevated in patients with cirrhosis,

viral hepatitis, drug or alcohol abuse as well as pregnancy, and may be used for screening of fetal spinal cord defects and placental disease.

Definition

AFP or alpha-fetoprotein is a serum protein of mammalian fetuses that is hardly detectable in healthy adults. Its re-occurrence in serum of adults may often attest to specific malignancy especially in high-risk patients, such as those with hepatocellular carcinomas (►hepatocellular carcinoma, ►hepatoblastoma) and chronic hepatitis B or C virus infection (►hepatitis associated hepatocellular carcinoma). It also serves in evaluation (►serum biomarkers, ►surrogate endpoints) of therapy and disease progress in patients with embryonal carcinomas (►germ cell tumors, ►platinum refractory testicular germ cell tumors).

Characteristics

The studies of fetal serum proteins came from different corners: from researchers interested primarily in the development of proteins and from those studying proteins of tumor-bearing laboratory animals. These two groups were at the beginning not very aware of each other's results. The fetal protein history began with the physicochemical and biochemical studies of serum proteins, which depended, as this often happens in the laboratory endeavor, on the development, improvement and refinement of laboratory methods. In the field of serum proteins, the electrophoretic and immunochemical techniques (►proteomics) were of crucial importance, especially in the case of fetal proteins, where usually only minute volumes of sera were available. Studies of electrophoretic patterns of serum proteins in human fetuses showed some considerable differences when compared with the sera of adults. Thus, in 1956 Bergstrand and Czar, using filter paper electrophoresis reported on the special fetal band, (called substance X) which was located between albumin and alpha-1 globulins. Substance X was absent from maternal sera and from sera of healthy adults. Also, Halbrecht and Klibanski reported similar findings in the same year. The first immunochemical studies of the substance X were done by Muralt and by Masopust in 1961 and 1962, respectively. Using antisera to fetal serum proteins (rabbits were immunized with the human fetal sera), an additional precipitin line with alpha globulin mobility was observed on immunoelectrophoresis (IEP) of human fetal serum, however, it was not present in adult sera. This fetal component was called independently "alpha-foeto-proteine" by Muralt and "fetoprotein" by Masopust. These findings resembled older observations in large animals; in 1944 Pedersen studied bovine fetal sera by ultracentrifugation and found a distinct gradient, not present in sera of adult animals. The fraction was named fetuin. Thus, it was believed by some that the human fetoprotein was related to fetuin and the term "human fetuin" was used in some papers on human fetoprotein. Physicochemical properties of fetuin, which was found to be a typical glycoprotein, were studied by a number of workers; its physiological and pathologic properties attracted much less interest. Because fetuin and fetoprotein were present in higher concentrations in fetuses and undetectable in adults, they were sometimes called "feto-specific proteins."

Immunochemical Techniques

For the detection of feto-specific proteins, the immunochemical techniques became the methods of choice in the 1960s. Antisera to these proteins were prepared by the immunization of animals, usually rabbits, with fetal sera. To obtain specific antisera to feto-specific proteins, the antisera were absorbed with the sera of adult men or animals. The absorbed antisera should contain only the antibodies directed to the feto-specific protein(s) of a given species. In some cases, the absorbed antisera showed two to three precipitin lines on IEP of fetal serum. Sometimes, in human fetal sera, two lines with the absorbed antiserum were observed. The line in alpha zone of IEP was that of human fetoprotein, the other line, in beta position, was sometimes incorrectly, without justification, called beta fetoprotein. The lines showed no antigenic relationship each to other. For this reason, the original term "fetoprotein" was changed to "alpha fetoprotein" and consequently the abbreviation of AFP came to life. The term "beta-fetoprotein" ceased to be used since the beta protein was later identified as fetal ferritin.

AFP in Pathology

In 1964, a study of a possible occurrence of AFP in sera of patients was started. The putative presence of AFP was

tested by double radial immunodiffusion (Ouchterlony test). After hundreds of negative results, a patient was identified, who had a definitely detectable serum concentration of AFP. The diagnosis of this patient, confirmed histopathologically at the autopsy, was that of hepatocellular carcinoma. In 1966 and 1967, the occurrence of AFP in four children with a malignant growth of embryonic character was reported. One of them was a 5 year-old boy with embryonal cell carcinoma of the left testicle (►testis cancer, ►childhood cancer, ►germinoma) and another patient was a 14 year-old girl with malignant teratoblastoma of the right ovary (►ovarian cancer, ►ovarian tumors during childhood and adolescens). Also, Abelev published in 1967 the finding of "alpha fetal globulin" in patients with embryonal testicular cancer. Several pediatric patients with non-cancerous liver diseases, such as infectious hepatitis and some unspecified hepathopathies were identified, who had detectable AFP serum levels. A highly sensitive technique, radioactive single radial immunodiffusion (employing the second, 125 Iodine-labeled antibodies to the primary antiAFP immunoglobulin fraction), enabled to quantify previously undetectable levels of AFP in various body fluids. By such means, AFP serum levels of patients with hepatocellular carcinomas were studied in a correlation with their individual histopathologic findings. A further increased sensitivity of AFP quantitation was facilitated by the development of a radioimmunoassay. This technique made the quantitation of AFP in healthy persons such as pregnant women a routine test in clinical laboratories. In the 1970s, a number of reviews on AFP were published along the studies of AFP physicochemical properties. The first studies on serum concentrations of AFP and their changes in the course of diseases were done in those years. Thus, the impact of the therapy could be evaluated and monitored in some malignancies.

Fetuin versus AFP

In the early years, AFP was considered by some investigators to be a protein similar to bovine fetuin and therefore called "human fetuin." Fetuin was isolated from fetal calf serum and the antisera were prepared to fetuin, and to serum proteins of human and bovine fetuses. With the use of absorbed antiserum to calf serum, an additional protein component was detected in alpha zone of bovine fetal serum, which was not detectable in sera of adult animals. This component could be considered as a "bovine fetoprotein." Antiserum to this protein did not react with isolated fetuin and conversely the specific antiserum to fetuin did not react in immunodiffusion experiments with the "bovine fetoprotein." The protein was not detected in adult healthy animals; it was, however, found in sera of two, out of four, adult cows with hepatocellular carcinomas (►comparative oncology). No antigenic relationship was observed in double radial immunodiffusion and the precipitin lines of fetuin and "bovine fetoprotein" crossed each other, showing thus the pattern of antigenic non-identity.

AFP in laboratory Animals

Rat sera were studied electrophoretically already in the 1950s. A "fetal" protein was detected by Beaton (1961) in the macroglobulin fraction of starch gel electrophoresis. This protein migrated as an alpha-2 globulin in electrophoretic media without molecular sieve effect (filter paper) and slowly in starch gel. Therefore, it was called "alpha-2 slow globulin." The protein was found in sera of rat fetuses and newborns, as well as in pregnant rats, but not in healthy, non-pregnant adult rats. It was present, however, in sera of tumor-bearing rats and in animals with various inflammatory processes, e.g. with turpentine abscess. Another alpha globulin was found by Darcy in fetal rat sera; it was also present in sera of pregnant animals and adult rats with tumors and/or with inflammations. Protein was also detectable in much lower concentrations in healthy, non-pregnant rats. Wise in 1963, using two-dimensional electrophoresis (filter paper-starch gel) demonstrated in rat fetal sera special proteins, named "fetal postalbumins" (two electrophoretic bands), which were not present in sera of adult animals. Altogether, at least three fetal components were reported in rats. To address this question, rabbit antiserum directed to rat fetal serum proteins was prepared. The absorbed antiserum (with the serum proteins of adult, healthy, non-pregnant animals) did not react with sera of adult, healthy non-pregnant rats, or with the protein described by Darcy. It did react, however, with three different proteins on IEP of fetal rat sera; two of them located in alpha-2, and one in alpha-1 globulin zone. The antibody to the protein in alpha-2 zone could be absorbed with the serum from an adult rat with turpentine abscess. This protein was also detected immunochemically in extracted proteins from macroglobulin position in starch gel electrophoresis of fetal serum. The protein obviously corresponded to alpha-2 slow globulin of Beaton. The other precipitin line in alpha-2 globulin zone was stainable with lipid stains (Red Oil and Sudan Black B), and represented most probably a lipoprotein-esterase found by Stanislawski–Birencwajg in fetal rat serum. The precipitin line in alpha-1 zone, present in sera of fetuses, absent from sera of adult rats, either healthy or with the acute inflammation, was considered to be a typical feto-specific protein, probably related to human AFP. However, no cross- reaction was seen by immunodiffusion between human AFP and antiserum to rat fetal proteins. To prepare a monospecific antiserum to alpha Ft protein, it was important to remove the antibodies to alpha-2 slow globulin, e.g. by using sera of adult rats with some inflammatory pathology. In 1963, Abelev reported the finding of "embryonal alpha globulin" in serum of adult mouse with transplatable

hepatoma; the globulin was also present in sera of fetal mice (►mouse models).

Much progress has been done since the early modest beginnings of AFP research. Presently, a review of AFP literature shows almost fifteen thousand papers related to the topic (►AFP-modern).

Definition

Alpha-fetoprotein (AFP) is a 68.7 kDa plasma protein synthesized primarily by the fetal liver and embryonic yolk sac that is highly homologous with human albumin. Widely expressed in the fetal liver, AFP mRNA is down-regulated in post-natal hepatocytes. Serum AFP levels are used clinically for detection, confirmation and follow-up of human ►hepatocellular carcinoma (HCC) and non-seminomatous ►germ cell tumors, although lack of sensitivity and specificity complicate its use.

Characteristics

Alpha-fetoprotein (AFP) is a 590 amino-acid plasma protein that shares 40% amino acid and 40–44% nucleotide sequence homology with human serum albumin and is a member of the albumin gene superfamily. The AFP gene covers approximately 22 kB of DNA and has 15 exons and 14 introns. The human albumin gene lies 14.5 kB upstream to its AFP homologue. Regulation of AFP protein production occurs mainly at the transcriptional level. In human cells, the AFP enhancer region contains binding sites for several liver-enriched transcription factors (HNF1-4, C/EBP) which control tissue specific expression. Expression of AFP also appears to be positively regulated by NFκB, by steroids via retinoid X receptors as well as by interactions with extracellular matrix.

AFP is normally expressed by villous trophoblasts in the human placenta during pregnancy and by fetal hepatoblasts. In fetal and newborn rats, AFP mRNA can be detected at low levels in the kidney, pancreas, heart and gastrointestinal tracts as well. In early postnatal life, AFP production is repressed in normal hepatocytes and silenced in non-hepatic parenchymal cells.

The mechanisms for the repression or silencing of AFP expression have largely been characterized. In mice, an unlinked locus called alpha-fetoprotein regulator 1 (Afr1) on chromosome 15 appears to interact with the AFP promoter region; repression of Afr1 appears to be associated with postnatal repression of AFP expression. The AFP promoter may also interact with Ku inducing a hairpin tertiary structure that may abrogate HNF1 binding to the promoter. Postnatal repression of AFP expression in the liver has also been shown to be ►p53- and ►TGFβ1-dependent whereas genetic silencing primarily involves epigenetic mechanisms that concomitantly silence the upstream albumin gene.

In the adult liver, AFP expression is present but repressed. In situ hybridization studies confirm the presence of minute quantities of AFP mRNA, but at levels generally below the sensitivity of immunohisto-chemical detection. In the setting of hepatocyte regeneration, e.g. ischemic injury, surgical resection, and chronic viral hepatitis, in ►hepatoblastoma as well as in a subset of hepatocellular carcinoma (HCC) (and rarely ►cholangiocarcinoma) AFP expression is de-repressed. AFP production also occurs in non-seminomatous germ cell tumors such as choriocarcino-ma, mixed germ cell tumors and teratomas. In fetal and newborn rats, AFP mRNA can be detected at low levels in the kidney, pancreas, heart and gastrointestinal tracts as well. Rarely in adults, non-hepatic/non-germ cell malignancies such as ►gastric cancer, pancreatic cancer, endometrial cancer, colon cancer, and ►ovarian cancer are associated with loss of silencing of AFP expression.

The critical activities of AFP *in vivo* remain poorly defined. Many cell types including vascular endothelium and T-cells express receptors for AFP. AFP administration in human cell lines has been associated with differential expression of FasL and ►TRAIL relative to fas and ►TRAIL receptor, leading to postulation of a role for AFP in escape from tumor immunosurveillance. AFP also appears to inhibit ►TNF

receptor 1-signalling-mediated tumor cell apoptosis. Paradoxically, some studies suggest a pro-apoptotic role for AFP in tumor cells lines via interactions with X-linked inhibitor of apoptosis protein (XIAP). Other studies postulate that AFP may mediate anti-inflammatory effects that suppress autoimmunity and anti-fetal immune responses during pregnancy, possibly via inhibition of CD4 T-cell proliferation.

Serum AFP determinations has two main clinical uses. First, it is used to screen women during pregnancy for fetal developmental abnormalities. Second, AFP is used as a tumor marker for hepatocellular carcinoma (HCC) and non-seminomatous germ cell tumors.

Serum AFP determinations have been used since the late 1960s to detect hepatocellular carcinoma despite limitations in its sensitivity and specificity. While AFP levels greater than 400 ng/ml are considered diagnostic of HCC, such elevations are rarely present. The sensitivity and specificity of AFP determinations also appears to be dependent on the underlying cause of liver disease that results in HCC development. Using a cutoff of 20 ng/ml, sensitivity ranges from 41% to 65% and specificity ranges from 80% to 94%.

The role of serum AFP in screening programs for HCC in patients with cirrhosis remains controversial. It remains unclear if the addition of AFP determinations to routine imaging examinations, e.g. ultrasound every 6 months, provides any incremental benefit.

Current guidelines from the United Network of Organ Sharing (UNOS) in the United States support the use of AFP levels greater than 400 ng/ml to confirm the presence of HCC when a hypervascular lesion on CT or MRI imaging is seen. Exception points may be petitioned from UNOS to provide the rare individual patients with AFP levels greater than 400 ng/ml but no visible tumor to increase the priority of such patients for liver transplantation.

Several glycoforms (AFP-L1, -L2 and -L3) of AFP have been resolved based on differences in glycosylation groups. Lectin-reactive AFP (AFP-L3) in some studies has been associated with intrahepatic cholangiocarcinoma. In other studies a high percentage of total AFP made up of the L3 fraction has been associated with hepatocellular carcinomas. Measurement of specific glycoforms is not in routine clinical use.

Alternative Lengthening of Telomeres (ALT)

Definition

Alternative lengthening of telomeres (ALT) is a telomere maintenance mechanism that does not involve telomerase, which probably involves recombination. It is found in a minority of cancers and immortalized cell lines. A minority of immortalized cell lines and cancers have no detectable telomerase activity and maintain their telomeres by an alternative mechanism. Although the details are not yet known, it is likely to be a recombinational mechanism in which one telomere uses another telomere (or itself via looping back) as a template for synthesis of new telomeric DNA. Cells that maintain their telomeres by ALT characteristically have very heterogeneous telomere lengths, ranging from undetectable to extremely long.

Alu Elements

Christine M. Morris
Cancer Genetics Research Group, University of Otago at Christchurch, Christchurch, New Zealand

Definition

The most abundant class of dispersed repeat elements in the human genome, and one member of the family of short interspersed repeat elements (SINEs). An estimated one million copies comprise about 10% of DNA in human cells.

Characteristics

Structure

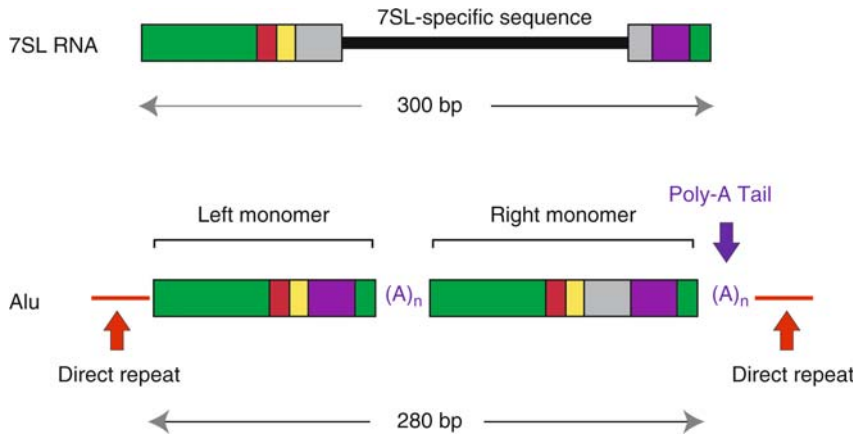
Alu elements are 280 bp in length, and consist of two similar monomers that have homology to, and were originally derived from, the ►7SL RNA gene (Fig. 1). Individual Alu elements are flanked by direct repeats, end in a 3′ A-rich tract, and the left monomer contains an internal RNA polymerase III promoter which directs transcription initiation to the first residue of the element. Alu are ►retrotransposable elements, and several subfamilies, mobilized from different "source" genes at different evolutionary times, can be recognized on the basis of their sequence divergence and diagnostic bases. Some of the more recently integrated subfamilies are polymorphic, occupying regions on some chromosomes that are not occupied at the same locus on others.

Function

The function of Alu elements has been subject to intense investigation, debate and speculation over the past two decades. Proposed roles include modulation of chromosome structure and packaging of DNA around ►nucleosomes, initiation or switch sites for DNA replication, regulation of gene transcription through Alu-specific protein binding domains, RNA editing as preferential templates for adenosine-to inosine (A-to-I) substitution by the ►ADAR family of enzymes, and regulation of translation by RNA transcribed from Alu elements. Although Alu expression increases in cells stressed by chemical agents or viral infection, most human Alu repeats are silent in somatic cells, with only the minor, evolutionarily younger subgroups actively transcribed. Consistent with the latter observations, CpG sites in the majority of Alu sequences are normally fully methylated in most somatic cell types, a state which is considered to suppress expression and therefore transposition. However, Alus located adjacent to CpG islands show sequence features amenable to an unmethylated state, and which may therefore have increased mobility. Alu elements are also differently methylated in male and female germ cells, with at least a subset of the recently integrated Alus being almost completely unmethylated in sperm DNA.

Role in Human Cancer

Alu-mediated gene rearrangement underlies several important constitutional diseases, including familial



Alu Elements. Figure 1 Alu elements have a dimeric structure that originated from 7SL RNA. Colored areas show 7SL sequences present in the Alu repeat consensus.

cancers. Different mechanisms for these rearrangements include recombination between homologous or non-homologous regions of Alu elements at different locations within a gene, or on the same or different chromosomes, expansion of 3′ polynucleotide tracts to form fragile sites, or disruption of coding regions of functional genes by transpositional insertion of actively transcribed Alu elements. Instability of 3′ polynucleotide tracts may also indicate a DNA ►mismatch repair deficiency.

Because of their high density in the human genome, non-random chromosomal distribution and the high degree of homology between individual elements, Alu repeats are also recognized candidates to mediate somatically acquired gene rearrangements with neoplastic potential. Specific underlying mechanisms for involvement of Alu in somatic rearrangements have only recently begun to be explored, with possibilities including promotion of DNA exchange by sequences within Alu that share homology with known recombinogenic ►translin DNA-binding motifs or the ►χ-like Alu core sequence, preferential recombination between DNA regions that are localized within Alu-rich clusters on the same or different chromosomes, or otherwise unknown features of individual Alu elements that predispose to recurrent recombination events associated with some ►breakpoint cluster regions.

AME Transcription Factor

Vitalyi Senyuk
Department of Medicine (M/C 737), College of Medicine Research Building, University of Illinois at Chicago, Chicago, IL, USA

Synonyms

RUNX1/MDS1/EVI1; AML1/EVI-1

Definition

AME is an aggressive oncoprotein (chimeric transcription factor) associated with several types of ►acute myeloid leukemia (AML), myelodysplastic syndrome (MDS) and myeloproliferative disorders (MPD).

Characteristics

The legendary discovery of chromosomal translocations by Janet D. Rowley in 1972 has revolutionized leukemia research and therapy by allowing biological interrogation and classification of these disorders. Several recurring translocations have been identified and the participating genes cloned and characterized at the molecular level. One such recurring abnormality is the balanced translocation between the long arms of chromosomes 3 and 21, t(3;21)(q26;q22), originally discovered in a patient with

therapy-related chronic myelogenous leukemia (CML) which is classified as an MPD.

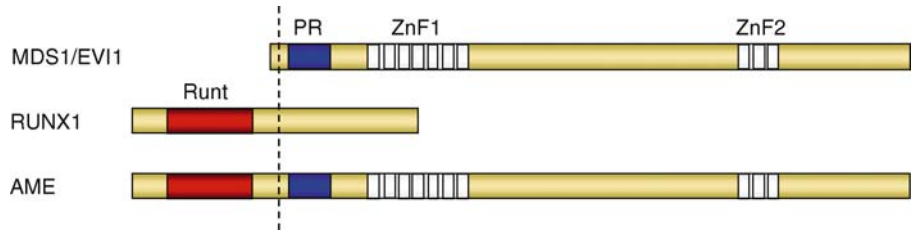
The t(3;21) is a complicated chromosomal rearrangement that employs a mechanism of intergenic splicing to generate several ►fusion genes of which *AME* is perhaps the best characterized and the most important. Among the less frequent translocations involving *RUNX1* (also known as *AML1, CBFA2*, and *PEBP2*) *AME* is the only fusion gene that has been cloned and characterized at the molecular level. *AME,* obtained by in frame fusion of the truncated *RUNX1* and *MDS1/EVI1 (ME)* genes, is controlled by the *RUNX1* promoter which becomes active during the execution of multiple steps of hematopoietic program, especially during the development of myeloid lineage.

The t(3;21) is a relatively rare translocation infrequently seen in *de novo* leukemias. It was observed in ~1% of AML, MDS and MPD cases, and often associated with secondary leukemia that arises in patients previously treated with ►alkylating agents or topoisomerase inhibitors for other malignancies. In particular, the t(3;21) was detected in the patients after administration of cytostatic drugs such as busulphan, teniposide, etoposide, hydroxyurea, ►fludarabine, ►5-fluorouracil and others. There is no unique clinical picture of t(3;21)-associated leukemias such as restriction to a certain FAB (French-American-British classification) category and it has been classified as M1, M2, M4 and M7 subtypes. The common morphologic feature of t(3;21)-positive AML is minimally differentiated blasts with prominent nucleoli and scant cytoplasm. There is no age or gender specificity for t(3;21)-associated diseases but, as for many other ►cancers, older individuals are at higher risk. In contrast to many other translocations, the t(3;21) causes a very aggressive myeloid leukemia/►blast crisis of CML characterized by a low response to the existing therapeutic treatments and a poor prognosis. In the largest clinical investigation of t(3;21) patients published to date, the majority of AML patients died between 1 week and 8.5 months (median 2 months) after presentation whereas MPD patients survived 1–21 months (median 6.5 months) after presentation.

RUNX1 is a DNA-binding subunit of the transcription factor CBF which is essential for hematopoiesis and is involved in several chromosomal abnormalities associated with human leukemias. RUNX1 consists of an N-terminal DNA-binding domain called Runt with homology to the product of the *Drosophila* segmentation gene *Runt* and a C-terminal activation domain. ME is a zinc-finger transcription factor related to the leukemia-associated protein ecotopic viral integration 1 site (EVI1) of unknown function. ME contains a conserved N-terminal region, called PR domain, two sets of DNA-binding zinc finger domains, a proline-rich central domain, and an acidic C-terminal domain. AME consists of the DNA-binding domain Runt of RUNX1 fused to almost the entire ME (Fig. 1).

Forced expression of AME upregulates the cell cycle and blocks granulocytic differentiation of the murine hematopoietic cell line 32Dcl3, and delays the myeloid differentiation of normal murine bone marrow progenitors *in vitro*. The exact mechanisms of AME oncogenic activation are unknown and several possibilities exist. Also, as with many other oncoproteins, most probably AME alone is insufficient to transform a healthy normal cell into leukemic one and additional cooperating genetic abnormalities are necessary. It has been shown that the majority of AME-positive patients have, in addition to t(3;21), several other chromosomal abnormalities readily detected by cytogenetic analysis: translocations, deletions and duplications the most common of which is t(9;22)(q34;q11) found in CML patients.

One of the first investigated properties of AME was its effect on a subset of target promoters regulated by both parent proteins. RUNX1 is generally considered a transcription activator through its C-terminus, which interacts with several transcription coregulators and regulates critical genes in hematopoiesis. ME is also considered a transactivator, and both parent proteins act as antagonists of AME. Therefore, it was suggested that AME could act as a bifunctional transcription factor possessing the ability to bind to and repress/deregulate both the RUNX1- and ME-dependent promoters. In support of this hypothesis, it was shown that AME directly interacts with the corepressors C-terminal binding protein (CtBP) and ►histone deacetylase 1 (HDAC1) which are often a



AME Transcription Factor. Figure 1 Diagram of ME, RUNX1 and the fusion protein AME. The Runt, PR and two zinc finger (ZnF) domains are shown. The vertical dashed line indicates the breakpoint fusion.

part of big repressor complexes transiently formed at the promoter sites. AME has distinct regions for HDAC1 and CtBP binding and, taking in consideration that both corepressors are able to dimerize and interact to each other, one AME molecule can recruit several molecules of the corepressors. AME represses the target promoters by CtBP-dependent and CtBP-independent mechanisms, probably reflecting the dual nature of this protein. *In vitro* CtBP enhances not only AME repression potential but also the ability of AME to upregulate growth and deregulate differentiation in murine hematopoietic cells, suggesting that AME repression is necessary for its oncogenic activity. However, the transcription properties of AME are more complicated because it also interacts with histone acetyltransferases p300/CBP-associated factor (P/CAF) and general control of amino-acid synthesis 5-like (GCN5), which are generally considered as co-activators of transcription. Both P/CAF and GCN5 efficiently acetylate the central region of AME *in vivo*, but the function of this modification and its role in oncogenesis are still unknown.

Similar to many other fusion proteins that are activated by chromosomal translocations in human leukemia, AME is able to oligomerize and displays a complex pattern of self-interaction that involves at least three oligomerization regions, which are the proximal and the distal zinc finger domains and the Runt domain. The distal zinc finger domain is quite important in AME oligomerization because it mediates the interaction with the other two domains and an internal deletion that removes the three zinc finger motifs virtually sufficient to repair (though not completely) the self-renewal and differentiation programs of normal murine bone marrow progenitors *in vitro*. *In vitro*, this domain efficiently co-operates with CtBP in disrupting normal hematopoiesis and the internal deletion and a point mutation that abolishes CtBP binding re-establishes almost completely the hematopoietic differentiation in murine cells. Probably AME belongs to a growing group of chimeric transcription factors which inappropriately maintain high local concentration of corepressors at the specific promoter sites because of their ability to oligomerize, resulting in the deregulation of genes involved in differentiation, ►apoptosis, and proliferation.

It is highly possible that the aggressiveness of AME as an oncoprotein is in part mediated by AME ability to abrogate the growth-inhibitory effect of ►transforming growth factor β (TGF-β) that controls cell expansion and inhibits proliferation of different cell types. The repression of TGF-beta signaling depends on the ability of the proximal zinc finger of AME directly interact with and repress ►Smad3, an intracellular mediator of TGF-β signaling. It should be noted that in contrast to AME, ME co-operates with TGF-β and increases the sensitivity of hematopoietic cells to its stimulus.

AME is also indirectly involved in deregulation of the hematopoietic program. It has been shown that CCAAT/enhancer-binding protein α (C/EBPα), a crucial transcription factor for normal granulopoiesis, is suppressed at translation level by more than 90% in AME-expressing U937 cells. In AML patients harboring t(3;21) the C/EBPα level is reduced even more whereas in AML patients without the t(3;21) C/EBPα is not affected. The mRNA levels remain unchanged in both cases indicating that AME does not affect C/EBPα transcription. Most probably AME acts through an intermediate effector, ►calreticulin, a ubiquitous multifunctional calcium-binding protein, which expression is strongly correlated with both, AME expression and C/EBPα suppression.

It has been shown in reporter gene assays and in Rat1 fibroblasts that AME stimulates activator protein 1 (►AP-1) activity with dependence on the distal zinc finger domain. AP-1 activation may increase cell proliferation potentially contributing to AME oncogenic properties.

A ►mouse model of AME-positive leukemia, generated by bone marrow transplantation of *AME*-expressing cells using BALB/c mice, showed that AME induces acute myeloid leukemia with a latency of 5–13 months indicating that additional genetic abnormalities are necessary for leukemogenesis. The disease was clonal in origin and resembled human acute myelomonocytic leukemia (AML FAB-M4). It has been also shown in this model that AME efficiently co-operates with breakpoint cluster region/abelson tyrosine kinase (►BCR/ABL), a product of t(9;22) frequently seen in CML patients. Both proteins together are able to block myeloid differentiation during the pre-leukemia stage and induce AML within 1–4 months.

The second mouse model for AME utilized bone marrow infection and transplantation using C57BL/6 mice. The animals displayed a variety of clinical features that are observed in essential thrombocythemia (ET) that resulted in their death after 8–16 months. The molecular etiology of ET, which is classified as an MPD, is poorly understood. Recently an activating somatic point mutation (V617F) of Janus kinase 2 (Jak2) was identified in MPD patients. Nonetheless, this mutation was not detected in ~50% of ET patients, indicating that some other molecular mechanisms exist and t(3;21) could be one of them.

The differences between these two mouse models can be explained by taking into consideration that the BALB/c strain of mice is well known to have a higher tumor incidence as compared with C57BL/6 mice (because it has a mutated *inhibitor of Cdk4/alternative reading frame (INK4a/ARF)* locus that at least partially disables $p16^{Ink4a}$, a ►tumor suppressor protein which is frequently mutated in many cancers).

A mouse model of AME knock-in has been also reported. The heterozygous mutant embryos obtained

by breeding of AME chimeric male (ICR strain) and wild type female (C57BL/6 strain) were not viable and died of fetal liver hematopoiesis failure at around day 13.5E. Fetal liver hematopoietic progenitor cells from these mice displayed increased self-renewal capacity and impaired erythropoiesis. In addition, myeloid and megakaryocytic cells appeared dysplastic indicating that AME induces multiple defects in several myeloid lineages. Interestingly, the majority of AME chimeric mice demonstrated sudden death at the age of about 7 months without any significant signs of any disease whereas one of them developed a disease resembling megakaryoblastic leukemia at 5 months of age.

Since 1987, when the t(3;21) was described for the first time, our knowledge about AME has increased vastly, however the prognosis of patients with this abnormality is still extremely poor. Hopefully, the cumulative efforts of different research groups will provide new approaches for the search of a treatment for this selected group of patients.

[2]Department of Biological Chemistry, University of Padua, Italy

Definition

Amine oxidases (AOs) are a class of enzymes which is heterogeneous in terms of structure, catalytic mechanisms, and substrate specificity. ►Biogenic amines, mono, di, and polyamines as well as *N*-acetyl amines, are oxidatively deaminated by AOs in a reaction that consumes O_2 to produce the corresponding aldehydes,

ammonium ions, and ►hydrogen peroxide (H_2O_2) according to the following reaction:

$$E_{ox} + R - CH_2 - NH_3^+ \rightarrow E_{red} - NH_3^+ + RCHO$$

$$E_{red} - NH_3^+ + O_2 \rightarrow E_{ox} + NH_4^+ + H_2O_2$$

(E_{ox} = oxidized enzyme E_{red} = reduced enzyme)

Characteristics

Two classes of AOs can be described, which contain different prosthetic groups: the FAD-dependent AOs (FAD-AOs) containing the flavin adenin dinucleotide (FAD), and the copper-dependent AOs (Cu-AOs) containing copper and an organic cofactor produced by the copper self-catalyzed posttranslational oxidation of a tyrosine residue, i.e., TPQ (trihydroxyphenylalanine quinone).

The FAD-AOs are subdivided in monoamine oxidase A and B (MAO A, MAO B), polyamine oxidase (PAO) and the recently discovered spermine oxidase (SMO). The two latter enzymes are cytosolic, catalyze the oxidation of secondary amino groups, and participate in the interconversion metabolism of polyamines. MAOs are tightly bound to a component of the mitochondrial outer membranes.

Cu-AOs are often also named SSAO (semicarbazide sensitive amine oxidase) because of their inhibition by semicarbazide, which binds the organic cofactor. When strictly necessary, the name of the best substrate is used to characterize the enzymes. For instance, Cu-AOs, which oxidize diamine, histamine, and elastin, are named diamine oxidase (DAO), histaminase, and lysyl oxidase (LXAO), respectively. LXAO contains, instead of TOPA quinone, lysyl tyrosyl quinone. Sometimes, a single enzyme, such as the enzyme purified from pig kidney, may display both DAO and histaminase activities, so that the name may not imply a specific enzyme.

The X-ray structure is available for several Cu-AOs, PAO, and MAO B.

Functions

A plethora of physiological functions, sometimes in contrast with one another, is ascribed to AOs. Although the exact molecular mechanism of their biological activity is not well-defined, a role of these enzymes in various processes through the action of either substrates or reaction products is postulated. Evidences have accumulated on the physiopathological relevance of polyamines, histamine, hydrogen peroxide, and aldehydes in cell death and ►differentiation, ►allergic diseases, and ►postischemic reperfusion damage.

Histamine is considered to be a main factor involved in allergic diseases. A plant Cu-AO, showing high histaminase activity, counteracts acute allergic asthma-like reaction in actively sensitized guinea pigs. The same enzyme modulates cardiac anaphylactic response in guinea pig. Protective effects of the plant enzyme were also observed in myocardial ischemia and reperfusion injury in in vivo rats. Bovine serum Cu-AO was shown to present an antioxidant effect, in vitro, against electrolytically induced ►reactive oxygen species (ROS) (O_2^-, OH, $^1O_2$) . Among other physiopathological functions ascribed to AOs are, for example, the involvement of MAO in psychiatric diseases like schizophrenia, by regulating the dopamine metabolism, and of Cu-AOs in cataract, by the lens damaging effect of amine oxidation products.

A primary involvement of AOs was demonstrated in cancer growth inhibition and progression, especially by means of aldehydes, H_2O_2, and other ROS, the AOs-mediated products of biogenic amines oxidation. Aminoaldehydes were shown to interact with nucleotides or with DNA. Microinjection of Cu-AO into chick embryo fibroblast, rat cells, and glioma cells caused the inhibition of ►DNA damage and protein synthesis. Tumor cells, with higher polyamines content than the normal controls, were more sensitive to the injected AOs. When an immobilized Cu-AO was injected into the peritoneal cavity of Swiss mice, 24 h after viable Ehrlich ascites tumor cells (►ascites) transplantation or into a mouse (►melanoma) model, a strong inhibition of tumor growth was observed. An induction of tumors in rat bowels (►colon cancer) was observed on inhibition of DAO by aminoguanidine. An induction of tumors in rats was observed after carcinogenic treatment combined with PAO inhibition. Both H_2O_2 and aldehydes contribute to cytotoxicity, as demonstrated by incubation of Chinese hamster ovary cells with purified bovine serum AO in the presence of spermine. Catalase, the enzyme involved in H_2O_2 elimination, is absent in many tumor cells and thus ►apoptosis occurs. The direct relationship between AOs, apoptosis, and cancer appears to be related to the regulation of biogenic amines and their metabolic products. H_2O_2 is considered to be a mediator of apoptotic cell death but the mechanism is unclear. H_2O_2 produced by MAO-catalyzed monoamines oxidation seems extremely important for apoptosis induction by considering the fact that MAO inhibitors are able to prevent apoptosis in human melanoma cells and that catalase inhibits the apoptosis induced by polyamines or their analogs and cathecolamines. The catalytic products of active amine oxidation are strong inducers of mitochondrial ►membrane permeability transition (MPT). Taken together, these results indicate that active amines, operating as AO substrates, play a critical role in controlling apoptosis through their effects on MPT and the ►respiratory chain activity by means of fluctuations in their concentrations. The conclusions of the above results may be that apoptosis is induced by polyamines through their oxidation products. Other studies exist demonstrating instead the ability of polyamines to protect

cells from apoptosis. This discrepancy can be explained by taking into account the protective effect of the same polyamines, probably due to a scavenging action of ROS.

A crucial role of AOs in cancer promotion has also to be considered. High levels of DAO activity were occasionally found in rapidly growing tissues, while in some patients, even affected by metastatic tumors, the level of circulating DAO was unaltered. A strong correlation between serum AO activity and the factor responsible for ►angiogenesis was recently found in non-small cell lung cancer patients. DAO activity in the small intestine mucosa was reported to increase in parallel with the degree of cell maturation, being highest in differentiated villus tip cells and lowest in the proliferative compartment. It was also found to increase in regenerating rat liver, with a peak between 16 and 48 h after partial hepatectomy. DAO activity peaks at the outset of growth and falls during the logarithmic growth phase of the cells. An increasing degree of malignancy associated with an increase of MAO A activity and decrease of MAO B and Cu-AOs activities in chemically-induced mammary cancer in the rat has been observed. Elevated activity of AO was found in skeletal metastases of prostatic cancer (►Prostate cancer, clinical oncology). DAO and arginase, an enzyme that catalyses the synthesis of ornithine from arginine, increase in tumor tissues as compared with benign prostatic hyperplasia. A linear correlation between arginase and DAO activities was observed in patients with cancer.

A high concentration of PAO and DAO was found in the cervical intraepithelial neoplasia. The rise from normal conditions seems to produce cytological changes and to play a role in the aethiology of ►cervical cancer. DAO activity is present at high levels both in tumor tissues and in biological fluids of tumor-bearing subjects. A correlation between the degree of tumor malignancy and their levels of AO activity has been observed in astrocytomas, where the activity is proportional to the degree of malignancy. The oxidation products of biogenic amines should also be carcinogenic. Acrolein, produced from the oxidation of spermine and spermidine by AOs, appears to be both carcinogenic and cytotoxic. This compound is considered to be a component of a universal cell growth regulatory system. It may act as mediator of cell transformation under oxidative stress when cells are pretreated with benzopyrene, a major carcinogenic found in cigarette smoke. The oxidation products of spermine, spermidine, and putrescine should be cofactors in the development of cervical cancer.

The balance between the cell content of biogenic amine oxidizing enzymes and antioxidizing enzymes appears to be a crucial point for cancer inhibition or progression. As a general conclusion, the cancer inhibition/promotion effect of AOs might be explained by taking into consideration the full pattern of the enzymes contained in the cells. A long-lasting imbalance of antioxidizing enzymes and AOs activity may be carcinogenic, while AOs are rapidly cytotoxic for cancer cells, because of their higher biogenic amines concentration in comparison with normal cells.

Definition

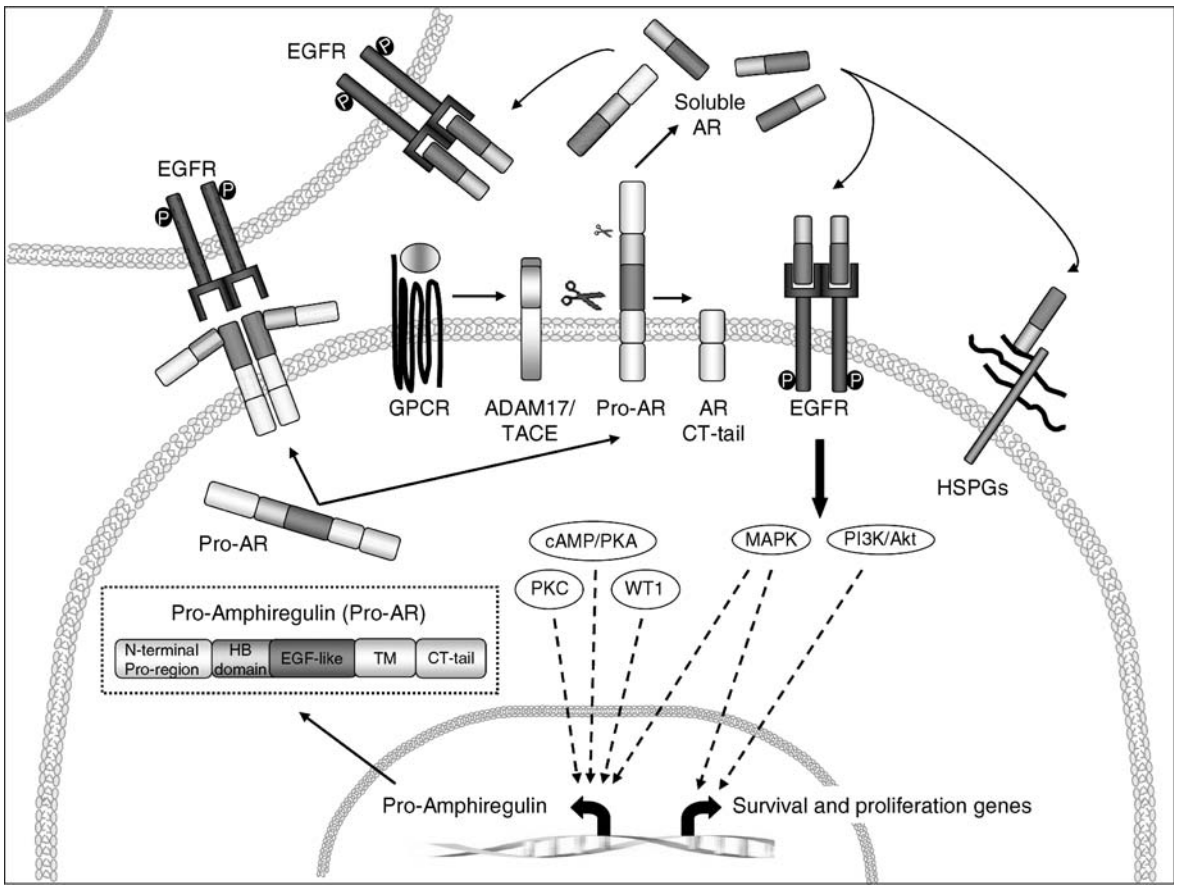
Amphiregulin (AR) is a growth factor that belongs to the ►epidermal growth factor receptor (EGFR) family of ligands. AR was originally described as a regulator of cell growth present in the conditioned media of MCF-7 breast tumor cells. AR has been implicated in different physiologic processes including mammary gland and bone development, lung and kidney branching morphogenesis, and trophoblast growth. The expression of AR is upregulated in a variety of cancerous tissues, and signaling triggered by AR is believed to be important in tumorigenesis.

Characteristics

The AR human gene spans 10 kb in the genomic DNA and it is composed of six exons, upon transcription it produces a 1.4 kb mRNA. AR gene shows broad constitutive expression, being more prevalent in human ovary and placenta although it is also expressed in pancreas, cardiac muscle, testis, colon, breast, lung, spleen, and kidney, whereas it is undetectable in liver. Transactivation of AR promoter and AR gene expression can be induced by the ►Wilms' tumor suppressor and through the activation of the ►protein kinase c (PKC), mitogen associated protein kinase (►MAPK), and ►cyclic AMP/protein kinase A (cAMP/PKA) pathways (Fig. 1). AR is synthesized as a 252-amino acid transmembrane glycoprotein, also known as transmembrane precursor or pro-form (Pro-AR) (Fig. 1). Pro-AR consists of a hydrophilic extracellular N-terminus (or ectodomain), a hydrophobic transmembrane domain (TM), and a hydrophilic cytoplasmic C-terminus (CT-tail) (Fig. 1). In the extracellular N-terminus we can distinguish an N-terminal pro-region containing glycosylation sites followed by a heparin-binding domain and an EGF-like region (Fig. 1). The EGF-like region is



Amphiregulin. Figure 1 Transcription of the AR gene can be activated in response to the WT1 protein and the PKC, cAMP/PKA or MAPK signaling pathways. AR is synthesized as a membrane-anchored precursor (Pro-AR) encompassing an EGF-like domain, a heparin-binding domain (HB), a transmembrane region, and a carboxy-terminal cytosolic tail (CT-tail). Upon digestion by the protease TACE/ADAM17, soluble AR forms are shed from the cell surface and can interact with the EGFR in an autocrine or paracrine fashion, or bind to heparan-sulfate proteoglycans (HSPG) in the extracellular millieu. Alternatively, the yuxtacrine interaction of membrane-anchored Pro-AR with the EGFR is also possible. Shedding of AR by TACE/ADAM17 can be enhanced in response to activation of ►G-protein coupled receptors (GPCRs). Binding and activation of the EGFR by AR triggers growth and survival signals essential for the tumor cell.

shared by other members of the ►EGF family of ligands. At the plasma membrane Pro-AR undergoes proteolytic cleavage to release the mature soluble factor in a process known as "ectodomain shedding." Cleavage of Pro-AR at two N-terminal sites gives rise to two major soluble forms of ~19 and ~21 kDa. Alternatively, Pro-AR cleavage can produce a larger 43-kDa soluble protein corresponding to the entire extracellular domain. Cleavage of Pro-AR at the cell surface can be mediated by tumor necrosis factor-α converting enzyme (TACE), a member of the disintegrin and metalloproteinase (ADAM) family also known as ►ADAM17 (Fig. 1). Shedding of AR allows the autocrine or paracrine interaction of the mature ligand with its cognate receptor, the ►EGFR (also known as ErbB1), a transmembrane protein endowed with tyrosine kinase activity, although yuxtacrine interaction between membrane-bound Pro-AR and the EGFR has also been observed (Fig. 1). Binding of AR to EGFR triggers key intracellular signaling pathways, such as the mitogenic MAPK and survival ►PI3K/Akt pathways, which have been demonstrated to participate in the transduction of AR effects (Fig. 1).

Amphiregulin Structure, Expression, and Function

AR was originally identified as a factor capable of inhibiting the growth of certain carcinoma cell lines, while stimulating the proliferation of normal cells, a fact that motivated its denomination. In fact, depending on its concentration and the nature of the target cell AR promotes the growth and survival of most cell types, both normal and transformed. AR gene overexpression

has been frequently demonstrated in cancerous tissues like colon, breast, bladder, prostate, pancreas, lung, ovary, squamous cell carcinomas, hepatocarcinoma, and myeloma cells. Besides changes in AR gene expression, different stimuli can also influence the availability of this growth factor through the stimulation of Pro-AR cleavage at the cell membrane. This is achieved by the activation of TACE/ADAM17 in response to agonists acting through GPCRs in a process termed ►EGFR transactivation (Fig. 1). The existence of EGFR transactivation involving the release of AR has been demonstrated in a variety of cancer cells, suggesting that AR could be an important mediator between diverse stimuli acting on GPCRs and the activation of protumorigenic signals conveyed through the EGFR. Interference with AR production by means of specific antisense RNAs or ►siRNAs, or treatment with AR neutralizing antibodies, has been shown to revert many of the neoplastic phenotypic traits of cancer cells in vitro, even though the expression of other EGFR ligands was preserved in these cells. This suggests that AR plays a nonredundant role in carcinogenesis. Observations performed in vivo also lend support to a role for AR in the initiation and maintenance of the neoplastic properties of tumor cells. For instance, tissue-specific transgenic overexpression of AR in pancreas results in enhanced cell cycle progression, and in mice older than 1 year it induces dysplastic changes and premalignant alterations. Although, so far most of the evidences that support a role for AR in cancer development and progression have been gathered under experimental conditions, there are also clinical studies that point in the same direction. In this regard, a significant correlation has been established between elevated tumor tissue AR mRNA levels and poor survival in bladder carcinoma patients, or elevated serum AR concentrations and increased mortality in non-small cell lung cancer patients.

In summary, the current knowledge on AR in cancer suggests that increased availability of this growth factor can provide transformed cells with a selective advantage. Targeted inhibition of AR expression or action may therefore represent a useful therapeutic strategy for a wide variety of cancers.

Amplification

Manfred Schwab
Tumour Genetics (B030), German Cancer Research Center, DKFZ, Heidelberg, Germany

Definition

Amplification is the selective increase in DNA copy number either intracellularly, as a local genomic change, or experimentally, by polymerase chain reaction (►PCR). Increase in the level of mRNA or protein should not be referred to as amplification.

Characteristics

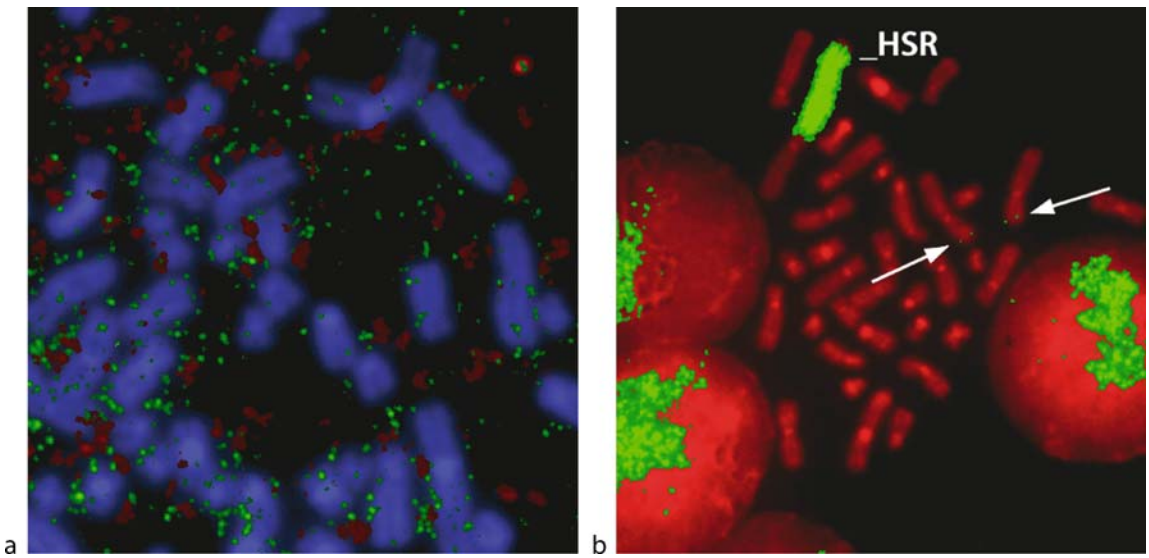
Intracellular amplification results in a selective increase in gene copy number with the consequence of elevated gene expression. Gene amplification has been seen in three different settings

- Scheduled amplification as part of a developmental gene expression program, e.g. chorion genes in ovaries of the fruitfly *Drosophila melanogaster* or actin genes during myogenesis in the chicken
- Unscheduled amplification during acquisition of cellular ►drug resistance. For example; amplification of the gene encoding dihydrofolate reductase (*DHFR*) can result in up to 1,000 gene copies per cell with the consequence of cellular resistance against methotrexate.
- Unscheduled amplification of cellular genes involved in growth control (►oncogenes) during ►tumor progression. Amplification of oncogenes can result in up to several hundred gene copies and enhanced gene expression. Usually large DNA stretches (from 100 Kb up to several Mb) are amplified, and therefore ►syntenic genes in addition to the particular oncogene can be co-amplified due to their close linkage to the oncogene. Alternatively, different ►non-syntenic oncogenes can amplify independently in the same cell. The prototypic human cancer with oncogene amplification is ►neuroblastoma. Here, the amplified gene, *MYCN*, is a ►biomarker for patient management.

Amplified DNA can be visualized cytogenetically as a ►homogeneously staining region within chromosomes (►HSR), as ►double minutes (►DM) or as ►C-bandless chromosomes (CM) (Fig. 1).

Cellular Regulation

Amplification can follow different pathways, the "onion skin model" and "breakage fusion-bridge" (BFB) cycles (Fig. 2) both fit experimental observations.

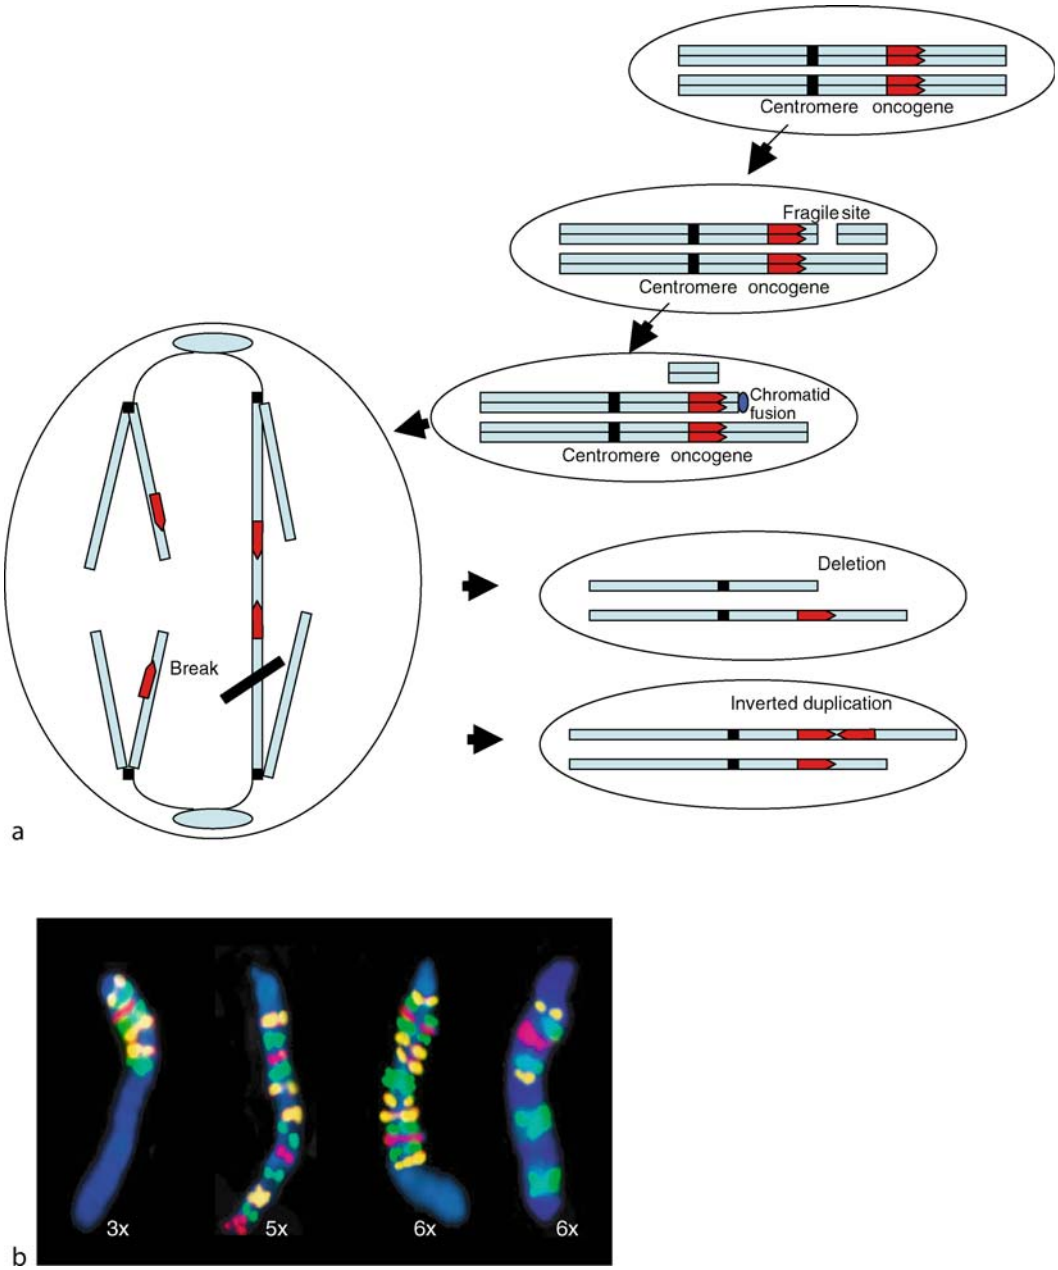


Amplification. Figure 1 Cytogenetics of *MYCN* amplification in neuroblastoma cells. Chromosomal fluorescence in situ hybridization (FISH). High-level *MYCN* amplification appears in human neuroblastoma cells as two alternative cytogenetic manifestations: (a). Double minutes (DMs) (*left*), this tumor cell has in addition to amplified *MYCN* (*red*) amplification of another oncogene *MDM2* (green). The two oncogenes are non-syntenic (2p24, and 12q13–14, respectively), and the amplification is the result of two independent genetic events. (b). Homogeneously staining region (HSR) (*right*), multiple copies are amplified in an HSR on chromosome 12 (with strong signal), while single copy gene is retained on the two parental chromosomes (*arrows*). The retention of *MYCN* at 2p24 indicates that not the original *MYCN* gene but rather a copy, presumably the result of extra-replication, has been amplified. Note also the strong signal in interphase nuclei which allows detection of amplified *MYCN* in tumor biopsies when chromosomes cannot be prepared.

Little is known about genomic or environmental elements involved in amplification. Unscheduled amplification presumably is a sporadic event that can become stabilized under selective pressures, i.e. cytostatic drugs or if cells acquire a growth advantage within a certain tissue architecture.

Clinical Relevance

Resistance against cytostatic drugs poses a big problem in cancer therapy. Amplified oncogenes contribute to tumor progression, many different oncogenes have been found amplified (e.g. ►*RAS*, ►*MYC*, ►*MYCN*, ►*MYCL*, *HER-2* [►*HER-2/neu*], ►*ABL*, etc.), in some



Amplification. Figure 2 Breakage-fusion-bridge (BFB) cycles in early stages of amplification. (a). BFB cycles start from common ►fragile sites, where a DNA break can occur in both ►sister chromatids. DNA repair systems will be recruited to the break and may join the free DNA ends of the two sister chromatids to form a dicentric chromosome, one that has two centromers. At anaphase, where sister chromatids are moved to the daughter cells, the dicentric chromosome at some point will break. Of the two daughter cells, one will carry a deletion, the other an inverted duplication of DNA, which is equivalent to a low-level amplification. By subsequent BFB cycles, the level of amplification can increase. (b). Low level amplification as the result of BFB cycles. FISH image, where each color shows the position and copy-number of a particular DNA sequence.

tumor types the oncogene status provides information about patient prognosis: Amplified *MYCN* indicates poor prognosis for stage 1–3 neuroblastoma; and amplified HER-2 indicates unfavorable outcome in a subgroup of ►breast cancer.

Amplified in Breast Cancer 1

Jianming Xu
Department of Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX, USA

Synonyms

Nuclear receptor coactivator 3; NCoA3; Steroid receptor coactivator-3; SRC-3; Receptor-associated coactivator 3; RAC3; Thyroid hormone receptor activator molecule 1; TRAM-1; Coactivator ACTR; p300/CBP-interacting protein; p/CIP; AIB1

Definition

AIB1 is a 160 kDa intracellular protein that enhances gene expression though interacting with nuclear hormone receptors and some other transcription factors and serving as a transcriptional coactivator. The AIB1 gene is amplified and overexpressed in some human breast tumors.

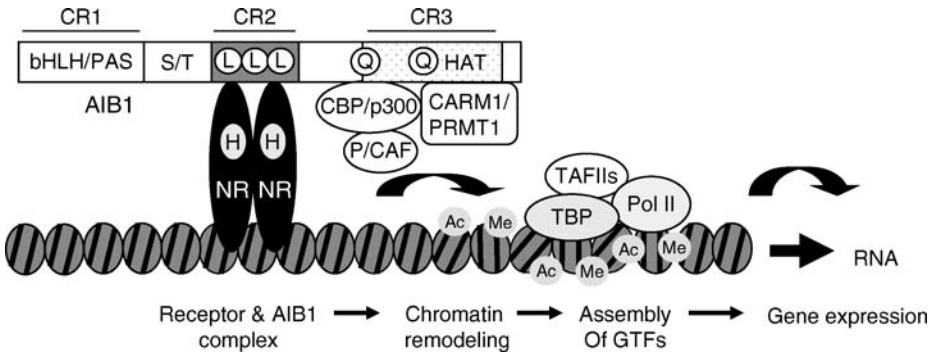
Characteristics

Molecular Structure and Functional Domains

The human AIB1 gene is located in chromosome 20 and it encodes for a 160-kDa intracellular protein with 1402 amino acid residues. AIB1 is a member of the p160 steroid receptor coactivator (SRC) family that also includes SRC-1 and the transcriptional intermediary factor 2 (TIF2). AIB1 contains multiple structural and functional domains (Fig. 1). The N-terminal basic helix-loop-helix/Per-Ah receptor nuclear translocator-Sim (bHLH/PAS) domain is the most conserved region in the molecule with ~70% sequence similarity to the respective regions of SRC-1 and TIF2. The bHLH/PAS domain contains a nuclear localization signal, which is required for AIB1 to get into the cellular nucleus where AIB1-regulated gene transcription takes place and where AIB1 degrades in a proteasome-dependent manner. The bHLH/PAS domain also can interact with certain transcription factors such as myogenin to mediate their transcriptional functions. The serine/threonine (S/T) rich domain contains many serine and threonine residues and some of these residues are targets of serine/threonine kinases. The phosphorylation status of AIB1 is related to its interaction specificity and affinity with transcription factors and other coactivators. A sequence in the S/T domain is also found to interact with transcription factor E2F1. Through interaction and function with ►E2F1, AIB1 can play a role in direct regulation of cell cycle. Following the S/T domain is the second conserved region of AIB1 with ~60% sequence similarity to SRC-1 and TIF2. This region contains three LXXLL (L, leucine, X, any amino acid) α-helix motifs that are responsible for interaction with the ligand-binding domain of nuclear receptors in a hormone binding-dependent manner. The third conserved region located in the C-terminus of AIB1 has ~50% sequence similarity to SRC-1 and TIF2 and contains two poly-glutamine stretches and a weak histone acetyltransferase activity. This domain can steadily interact with CREB (cAMP response element-binding protein) binding protein (CBP) and p300, which are strong histone acetyltransferases. This domain also can interact with the coactivator-associated arginine methyltransferase (CARM1) and the protein arginine methyltransferase 1 (PRMT1), which are histone methyltransferases.

Functional Mechanisms

Two transcriptional activation domains of AIB1 have been identified. The first one is located in the region that interacts with CBP or p300 and the second one is located in the region that interacts with CARM1 or PRMT1 (Fig. 1). The transcriptional activation function of AIB1 is mainly executed through these acetyltransferases and methyltransferases, which are chromatin-remodeling enzymes. In the case of steroid hormone-regulated gene expression, hormone binding triggers a series of events for steroid receptors, including the dissociation of heat shock proteins, change of receptor conformation, receptor dimerization and DNA binding. Importantly, the hormone binding also induces the steroid receptors expose their coactivator-binding motifs in their ligand-binding domains and allows coactivators such as AIB1 to be recruited to the enhancer region of the nuclear receptor target genes. Through the further interaction of AIB1 with CBP, p300, the p300 and CBP-associated factor (p/CAF), CARM1 and PRMT1, a steroid receptor-directed



Amplified in Breast Cancer 1. Figure 1 Schematic presentation of the structure and function of AIB1. CR1, CR2 and CR3, conserved regions 1, 2 and 3 in the p160 SRC family; bHLH/PAS, the basis helix-loop-helix/Per-Ah receptor nuclear translocator-Sim domain; S/T, the serine and threonine-rich domain; L, L and L, the three LXXLL motifs responsible for interaction with nuclear receptors; Q and Q, the two glutamine-rich regions; HAT, the histone acetyltransferase domain; H, hormone; NR, nuclear receptors; CBP, the CREB (cAMP response element-binding protein) binding protein; p300, the 300 kDa protein homologous to CBP; p/CAF, the p300 and CBP-associated factor; CARM1, the coactivator-associated arginine methyltransferase 1; PRMT1, the protein arginine methyltransferase 1; TBP, the TATA binding protein; TAFIIs, TBP-associated general transcription factors (GTFs); Pol II, RNA polymerase II.

transcriptional activation complex is built up on the hormone response elements of their target gene. This protein complex uses its protein acetyltransferase and methyltransferase activities to remodel the chromatin structure, to facilitate the assembly of general transcription factors on the promoter and thereby to promote target gene transcription. In addition to steroid receptors and other nuclear receptors, AIB1 also serves as a coactivator for certain other transcription factors such as E2F1, AP-1 and Ets transcription factors.

Physiological Function

AIB1 mRNA is expressed in many different human tissues and cell lines when examined by Northern blot analysis. Detail analyses with mouse tissues revealed that AIB1 is mainly expressed in the mammary gland epithelial cells, oocytes, vaginal epithelial layer, hepatocytes, smooth muscle cells, endothelial cells, and the hippocampus and olfactory bulbs of the brain. At this time, our knowledge regarding the *in vivo* physiological function of AIB1 is mainly learned from the AIB1 knockout mice. AIB1-deficienct mice have a much lower levels of insulin like growth factor-I and 17β-►estradiol in their circulation. Accordingly, these mice are smaller in size and they exhibit delayed puberty, retarded mammary gland development and reduced female reproductive function. In addition, AIB1 plays a beneficial role in estrogen and ►estrogen receptor-mediated vascular protection after vessel injury by enhancing estrogen receptor function and contributes to the control of acute inflammatory responses by inhibiting the production of pro-inflammatory cytokines.

Role in ►Cancer

The AIB1 gene is amplified (or increased in the number of gene copies) in about 5–10% human breast tumors. The AIB1 mRNA is overexpressed in about 30–60% breast tumors, depending on the resources of reports. However, some study only found about 10% of breast tumors that have elevated AIB1 protein levels. AIB1 overproduction is observed in breast tumors both positive and negative to the estrogen receptor α. In ►tamoxifen-treated patients, high levels of AIB1 are associated with the HER2/Neu expression, the tamoxifen resistance and the lower disease-free survival rates. In the cultured ►breast cancer cells, AIB1, together with the estrogen and estrogen receptor, enhances ►cyclin D1 expression and cell cycle progression. Down regulation of AIB1 in breast cancer cells inhibits cell proliferation, cell motility and anchorage-independent growth in the culture and tumor formation in the immune-deficient mice. Animal experiments further demonstrate that AIB1-deficient mice are resistant to either transgenic ►oncogene- or chemical ►carcinogen-induced mammary gland tumorigenesis. The transgenic v-Ha-ras oncogene can no longer induce mammary gland tumors in the ovariectomized AIB1 knockout mice, suggesting that inhibition of AIB1 function and removal of ovarian ►hormones may be a potential strategy to control breast tumorigenesis. On the other hand, it has been demonstrated that overexpression of AIB1 in the mouse mammary epithelial cells is sufficient to induce a high frequency of mammary gland tumors, indicating that AIB1 is an oncoprotein. Similar to the role of AIB1 in breast cancer, AIB1 is also found to be overexpressed in certain human prostate

tumors and to play a detrimental role in prostate epithelial tumorigenesis in mouse models.

Amrubicin

Michiko Yamamoto, Noriyuki Masuda
Department of Respiratory Medicine, Kitasato University School of Medicine, Sagamihara, Kanagawa, Japan

Synonyms

(+)-(*7S,9S*)-9-acetyl-9-amino-7-[(2-deoxy-β-D-erythro-pentopyranosyl)oxy]-7,8,9,10-tetrahydro-6,11-dihydroxy-5,12-naphthacenedione hydrochloride; SM-5887

Definition

The anthracyclines tested clinically so far have been limited to those produced by fermentation or semisynthetic processes. In contrast, 9-aminoanthracycline, amrubicin is a fully synthetic drug. Amrubicin differs from daunosamine in that it contains a 9-amino group and a simple sugar moiety (Fig. 1).

Characteristics

Amrubicin is converted to its active 13-hydroxy metabolite, amrubicinol, in the liver, kidney, and tumor tissue, through reduction of its C-13 ketone group to a hydroxy group. Despite the similarity of its chemical structure to that of a representative anthracycline, doxorubicin, amrubicin's mode of action differs from that of doxorubicin. Amrubicin and amrubicinol are inhibitors of DNA topoisomerase II, which exert their cytotoxic effects by stabilizing a topoisomerase II-mediated cleavable complex (►Topoisomerase enzymes as drug targets), and are approximately only one-tenth as potent as doxorubicin in producing DNA intercalation.

Preclinical Studies

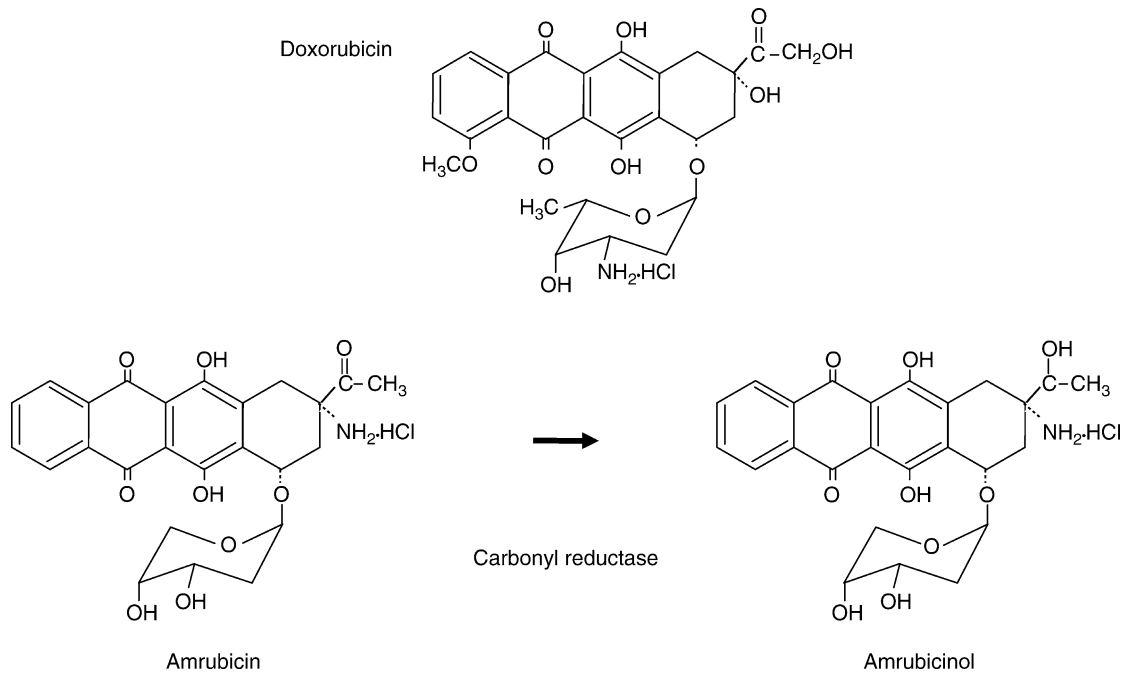
In in vitro experiments, amrubicin and its metabolite amrubicinol have been found to be active against a broad spectrum of human cell lines established from cancers of the lung, prostate, urinary bladder, colon, kidney, pancreas, and uterus. Amrubicinol has been shown to exhibit a 20- to 220-fold more potent antitumor activity in vitro than amrubicin itself, being as potent as doxorubicin. In addition, amrubicin and amrubicinol have also been demonstrated to show some degree of noncross resistance with doxorubicin.

Amrubicin has been shown to be more effective against five human xenografts (one breast cancer, one ►lung cancer, and three gastric cancers), equally effective against two gastric cancers, and less effective against two tumor (one lung and one gastric cancer). Amrubicin caused dose-dependent weight loss, ataxia, myelosuppression, and hair loss in mice after a single intravenous (i.v.) injection. The maximum tolerated (MTD) for such administration was estimated to be 25 mg/kg in four mouse strains. Cardiotoxicity is one of the dose-limiting toxicities of anthracyclines. However, amrubicin showed little delayed-type cardiotoxicity in rabbit and dog experimental models. Furthermore, amrubicin did not aggravate the doxorubicin-induced myocardial injury.

Clinical Studies

Amrubicin Monotherapy

Phase I/II Trial of Amrubicin Given Daily for Three Consecutive Days Every 3 Weeks. Based on the finding that amrubicin exhibited enhanced antitumor efficacy against six of eight cell lines when it was given for five consecutive days instead of on a single day at the MTD dose, a phase I/II trial of amrubicin for three consecutive days was carried out in patients with advanced nonsmall cell lung cancer (NSCLC). In the phase I study, four patients were enrolled at dose level 1 (40 mg/m^2/day) and four at dose level 2 (45 mg/m^2/day). No dose-limiting toxicity (DLT) was observed at these dose levels. At dose level 3 (50 mg/m^2/day), three of five patients experienced DLTs (leukopenia, neutropenia, thrombocytopenia, or gastrointestinal toxicities). The MTD and recommended dose (RD) were determined to be 50 and 45 mg/m^2/day, respectively, from the results of this trial. Seven partial responses (PR) were observed in a total of 28 patients of the phase I/II study, with an overall response rate of 25%.



Amrubicin. Figure 1 Chemical structure of amrubicin and its active metabolite, amrubicinol.

Multicenter Phase II Study of Amrubicin in Patients with Advanced NSCLC. Sixty-one previously untreated patients with stage III or IV NSCLC were entered in this study. Amrubicin was administered by a single i.v. injection daily at the dose of 45 mg/m^2/day for three consecutive days every 3 weeks. One complete response (CR) and 16 PR were observed, with an overall response rate of 27.9%. The median survival time (MST) was 9.8 months. The major toxicity was myelosuppression. The incidences of grade 3 or 4 toxicity were 72.1% for neutropenia, 52.5% for leukopenia, 23.0% for anemia, and 14.8% for thrombocytopenia.

Phase II Study of Amrubicin in Previously Untreated Patients with Extensive-Stage Small Cell Lung Cancer. Thirty-five previously untreated patients with extensive-disease small cell lung cancer (ED-SCLC) were entered in the study. Amrubicin was given by daily i.v. infusion at the dose of 45 mg/m^2/day for three consecutive days every 3 weeks. Of 33 eligible patients, 3 showed CR and 22 showed PR, with an overall response rate of 75.8% (95% confidence intervals (CI), 57.7–88.9%). The MST and 1-year survival were 11.7 months and 48.5%, respectively. The most common toxicity was hematologic toxicity.

Phase II Trial of Amrubicin for the Treatment of Refractory or Relapsed Small Cell Lung Cancer: Thoracic Oncology Research Group Study 0301. SCLC patients with measurable disease who had been treated previously with at least one platinum-based chemotherapeutic regimen were entered into the trial. Amrubicin was administered at a reduced dose of 40 mg/m^2 per day × 3 days every 3 weeks, in view of the prior chemo- and radiotherapy. Sixty patients (16 refractory and 44 sensitive) were enrolled. The grade 3 or 4 hematologic toxicities comprised neutropenia (83%), thrombocytopenia (20%), and anemia (33%). Febrile neutropenia was observed in three patients (5%). The nonhematologic toxicities were mild. The overall response rates were 50% (95% CI, 25–75%) in the refractory group and 52% (95% CI, 37–68%) in the sensitive group. The overall survival and 1-year survival in the refractory group and sensitive group were 10.3 and 11.6 months, and 40 and 46%, respectively. Thus, it was concluded that amrubicin shows significant activity against SCLC, with predictable and manageable toxicities.

Amrubicin Combination Chemotherapy

Phase I-II Study of Amrubicin and Cisplatin for Previously Untreated Patients with Extensive-Stage Small Cell Lung Cancer. This trial was performed to determine the MTDs for combined amrubicin and cisplatin therapy and to assess the efficacy and safety of these drugs at their RD. Patients with histologically or cytologically proven measurable ED-SCLC, no previous chemotherapy, and good prognostic factors were entered into this trial. Amrubicin was administered on days 1–3 and cisplatin on day 1, every 3 weeks. Four patients were enrolled at dose level 1 (amrubicin 40 mg/m^2/day and cisplatin 60 mg/m^2) and three patients at dose level

2 (amrubicin 45 mg/m^2/day and cisplatin 60 mg/m^2). The MTD and RD were found to be at level 2 and level 1, respectively. The response rate at the RD was 87.8% (36/41). The MST and 1-year survival rate were encouraging, 13.6 months and 56.1%, respectively.

Phase I and Pharmacologic Study of Irinotecan and Amrubicin for Advanced NSCLC. We conducted a phase I trial of irinotecan (CPT-11), a topoisomerase I inhibitor, combined with amrubicin. The aim was to determine the MTD and DLT of amrubicin combined with a fixed dose of CPT-11 in patients with advanced NSCLC. Eleven patients were treated with amrubicin on days 1–3, combined with 60 mg/m^2 of CPT-11 on days 1 and 8, every 3 weeks. The starting dose of amrubicin was 25 mg/m^2, and the dose was escalated in 5 mg/m^2 increments until the MTD was reached. The 30 mg/m^2 of amrubicin dose was one dose level above the MTD, since three of the five patients experienced DLT, namely, diarrhea and leukopenia. Amrubicin did not affect the pharmacokinetics of CPT-11, SN-38, or SN-38 glucuronide. There were five PRs among the 11 patients, with an overall response rate of 45%. The RD for phase II studies was determined to be 60 mg/m^2 for CPT-11 (days 1 and 8) and 25 mg/m^2 for amrubicin (days 1–3), administered every 21 days.

Conclusion

The preclinical studies described above show that amrubicin has a unique mechanism of action as an anthracycline derivative and a broad spectrum of antitumor activity. The results of clinical studies of amrubicin as a single agent or as one of the drugs in combination regimens for lung cancer have been promising. To determine the exact usefulness of amrubicin in the treatment of SCLC, two randomized trials are now underway in Japan; one of cisplatin + amrubicin versus cisplatin + irinotecan in previously untreated patients of ES-SCLC, and one of amrubicin versus carboplatin + etoposide in elderly patients with ES-SCLC.

Although amrubicin has been investigated over the last decade, many of its characteristics remain unclear. Further studies exploring the usefulness of amrubicin as a single agent or as an agent administered in combination with other cytotoxic agents as well as novel molecule-targeted drugs for the treatment of other malignancies are warranted. Lastly, since all the trials with amrubicin have been conducted in Japan, the results of clinical studies to define the benefits and risk associated with amrubicin for cancer therapy conducted overseas are eagerly awaited.

Synonyms

Ki1 lymphoma

Definition

Anaplastic large cell lymphoma (ALCL) was originally described in 1985 as a separate entity among the ►non-Hodgkin lymphomas (NHL); it is characterized by the cohesive proliferation of large cells expressing the CD30/Ki1 antigen on their membrane. The World Health Organization more recently stated that the term ALCL should be applied to tumors with a T-cell or null phenotype, thus further restricting the identification of this specific subtype of ►lymphoma.

Characteristics

Systemic ALCL accounts for 2–8% of all ►lymphomas (►Malignant lymphoma, hallmarks and concept) but represents ~10–15% of NHL of childhood. In addition to the primary systemic disease, a form of ALCL limited to the skin is also recognized. Isolated cutaneous ALCL may spontaneously remit, but can also progress to a more aggressive disease.

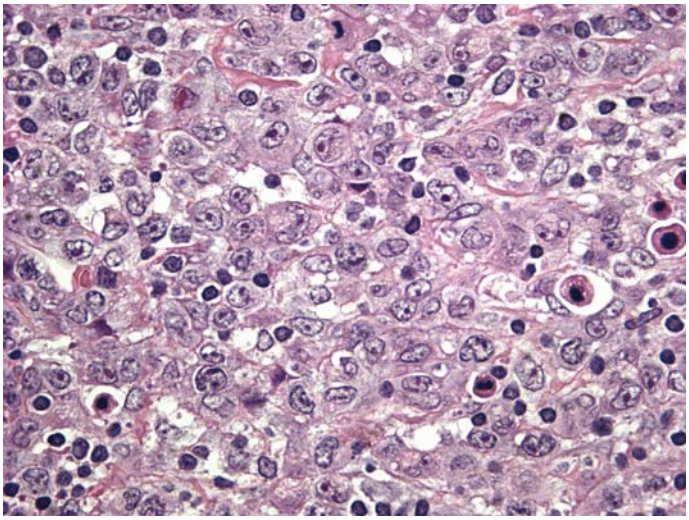
Systemic ALCL has some clinical features that are less common in other NHL subtypes: patients at diagnosis often have B-symptoms (fever, weight loss, sweats) as in Hodgkin lymphoma, mediastinal (►Mediastinum) and extranodal involvement, including skin, bone, and soft tissues. Among lymph nodes, the inguinal nodes are often site of disease, particularly in childhood, and rather frequently lymphadenopathy may be painful. Central nervous system and bone marrow are rare sites of disease, although with more sensitive techniques bone marrow may have submicroscopic infiltration of lymphoma cells more often than previously expected. Clinical differences have been reported between ►ALK (anaplastic lymphoma kinase)-positive and ALK-negative subtypes. Patients with ALK-positive ALCL are significantly younger and have a better prognosis that the negative counterpart, suggesting that ALK-positivity, rather than age, may confer distinct and relevant clinical features to systemic ALCL. Secondary ALCL may arise in the progression of other lymphomas, most commonly during the course of T-cell NHL, mycosis fungoides, Hodgkin lymphoma or lymphomatoid papulosis, and has a poor outcome. Except for the cases of very aggressive disease, ALCL may show multiple recurrences that respond to therapy, although eventually a considerable number of patients die despite intensive treatment.

Diagnosis

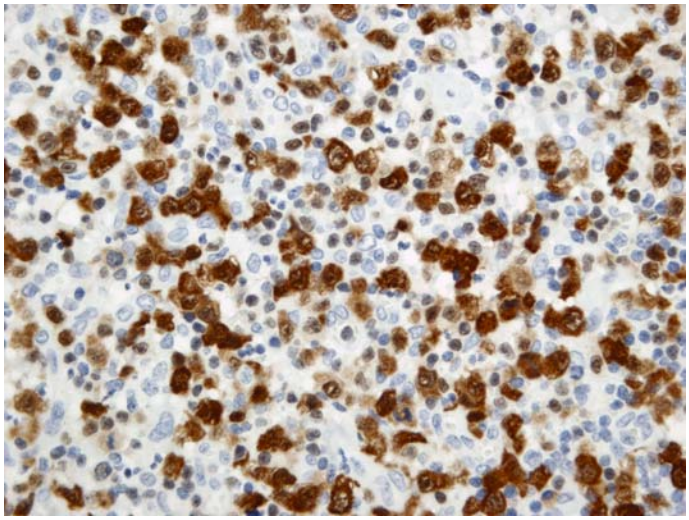
Diagnosis of ALCL relies on histopathology and immunophenotyping, but for a complete characterization of the tumor, chromosomal analysis and molecular genetic studies are warranted. It is now clear that ALCL includes several variants: classical or common type (corresponding to the original description of the disease) that accounts for ~60–70% of the cases, lymphohistiocytic variant, giant cell-rich, small cell type, and mixed. The large cell-rich type is characterized by multinucleated cells, often with Reed-Sternberg-like features that make the differential diagnosis with Hodgkin lymphoma (►Hodgkin disease) sometimes difficult. Irrespective of the histotype, neoplastic ALCL cells are characterized by a distinctive phenotypic profile. They express CD30, a cell membrane glycoprotein, found in activated lymphoid cells, the epithelial membrane antigen (EMA) and T-cell antigens including CD3. Perforin and granzyme B are also expressed in the majority of the cases and, together with absence of CD15 expression, they are useful markers in the differential diagnosis with Hodgkin disease. The development of antibody against the ALCL kinase (ALK) (►ALK protein) has further refined the immunohistochemical analysis of ALCL. Expression of ALK occurs in tumors carrying ►chromosomal translocations that involve the corresponding gene. The most common rearrangement between chromosome 2 and 5 causes strong ALK positivity of neoplastic cells in the nucleus and cytoplasm (Figs. 1 and 2), whereas other chromosomal translocations involving *ALK* produce accumulation of the translocation product at the cytoplasmic level only. ALK reactivity of tumor cells has diagnostic relevance given that ALK is not detected in normal lymphocytes or in Hodgkin lymphoma cells and only few cases of rare forms of lymphoma and nonlymphomatous tumors (inflammatory myofibroblastic tumors, rare neuroblastoma, and rhabdomyosarcoma) show ALK reactivity. Ultimately, combination of morphological, immunophenotypic, and genetic analysis allow the diagnosis of ALCL and the differentiation of this lymphoma from other tumors.

A peculiar aspect to consider is the differentiation of cutaneous ALCL from other CD30-positive lymphoproliferative disorders including lymphomatoid papulosis. In this case, because the great majority of isolated cutaneous ALCL is ALK-negative, clinical observation and evolution of the disease are of foremost importance. In addition, because skin involvement in the context of a systemic ALCL may bear prognostic implications, suspect skin involvement must be documented through biopsy.

Imaging procedures used in the diagnosis and staging of ALCL are similar to other NHL. Special attention should though be given to the examination of soft tissues and skin, given the relatively high frequency of involvement of those sites. Chest x-ray is usually sufficient to detect a mediastinal mass, but a CT scan of the neck, thorax, and abdomen should always be obtained to define the extent of disease. Ultrasound is routinely used for diagnosis and monitoring of lymph nodes, abdominal organ involvement, including liver, spleen, kidney, and soft tissues. This technique is easy to perform and can give accurate information not only for diagnostic purposes, but also to evaluate tumor response to treatment and during follow-up, once treatment is completed. Whole skeletal ►scintigraphy may be useful, especially in cases with bone pain, and should be complemented with x-ray of positive bones.



Anaplastic Large Cell Lymphoma. Figure 1 This panel depicts the classic variant of anaplastic large cell lymphoma with numerous large tumor cells that often contain horseshoe- or kidney-shaped nuclei, distinct nucleoli and abundant cytoplasm.



Anaplastic Large Cell Lymphoma. Figure 2 This panel immunohistochemical staining of anaplastic large cell lymphoma containing the chromosomal translocation t(2;5) originating the NPM–ALK fusion protein. Nuclear and cytoplasmic reactivity to an anti-ALK specific monoclonal antibody is detectable in most lymphoma cells (brownish color) Pictures were a courtesy of Dr. E. S. d'Amore, Institute of Pathology, University of Padua, Italy.

Brain MRI or CT scan are usually performed, but central nervous system involvement at diagnosis is infrequent in ALCL. More recently ►positron emission tomography (►PET) with 18-fluorodeoxyglucose (FDG) has been introduced in the routine evaluation of ALCL patients, mainly for staging. Lymphoma cells characteristically have a higher uptake of FDG compared with normal cells and this gives high activity features to the vital tumor mass. Because a high reactivity may also be seen in other nonmalignant tissues with high glucose metabolism, including reactive lymph nodes and inflammatory tissues, PET findings have to be interpreted with caution at present, until large prospective clinical studies where this recent technology is routinely applied are completed.

To completely define the extent of the disease, as in other NHL, bone marrow biopsy and bone marrow smear should be performed and analyzed for the presence of tumor cells, as well as a lumbar puncture to exclude the presence of lymphoma cells in the central spinal fluid.

Genetics

The ►chromosomal translocation t(2;5)(p23;q35) was originally reported in patients with malignant histiocytosis, which indeed represented ALCL cases diagnosed according to old criteria. Break of chromosome 2 and subsequent fusion to chromosome 5 in a reciprocal chromosome rearrangement is the main genetic feature of ALCL. As a result, the *ALK* gene on chromosome 2 is juxtaposed to the nucleophosmin (►*NPM*) gene on chromosome 5. The ►*NPM–ALK* fusion gene gives rise to a fusion protein composed of ALK and NPM domains that can be detected by ►immunohistochemistry using an anti-ALK monoclonal antibody. While *ALK* is not usually expressed in normal tissues, except in few neuronal cells, *NPM* gene encodes a shuttle protein that undergoes dimerization in the cytoplasm and in this conformation can move to the nucleus. In the cytoplasm of NPM–ALK-positive ALCL cells, heterodimers between NPM and NPM–ALK are formed that, while retaining the ability to move to the nucleus, are reactive against the anti-ALK antibody. This explains the cytoplasmic and nuclear reactivity of ALCL cells harboring the t(2;5) translocation. The wide use of antibodies to ALK protein revealed that about 10% of the ALK-positive ALCLs showed an immunohistochemical reactivity confined to the cytoplasm. Molecular genetic studies demonstrated that those cases were associated to a series of different chromosomal translocations, all involving the *ALK* gene, but with partners other than *NPM*. The deriving fusion genes all cause hybrid protein overexpression that lack the shuttling properties of NPM-containing fusion proteins, thus preventing them from nuclear localization. From the functional point of view, NPM–ALK can dimerize and as such it possesses constitutive tyrosine kinase activity, mimicking the normal functional activity of the ALK receptor in normal cells upon binding and oligomerization by its specific ligand. A number of experimental data suggest that NPM–ALK has a causative role in tumorigenesis of ALK-positive ALCL, although it may need concomitant events. In fact, NPM–ALK displays transforming activity in both hematopoietic and fibroblastic cell lines in vitro.

Overall, ~90% of childhood ALCLs are positive for the ALK-hybrid protein, whereas this percentage is only 50–60% in adult ALCLs. As suggested by clinical studies, ALK-positivity, not only is a relevant tool in the

diagnosis of ALCL, but represents also a prognostic marker in that ALK-positive ALCLs fare better than ALK-negative lymphomas in the adult population.

Therapy

Treatment of ALCL, similarly to other NHL, is almost exclusively based on chemotherapy. The therapeutic approach has witnessed a variety of chemotherapy regimens, ranging from acute lymphoblastic leukemia-type regimens lasting 24 months to shorter chemotherapy more frequently used in aggressive B-cell lymphomas. Differently from most European studies where ALCL is considered as a separate entity, in North America all large cell lymphomas, regardless of the histologic subgroup and ►immunophenotype, are treated according to the same chemotherapy scheme.

Primary systemic ALCL in adults has been treated mostly with CHOP (cyclophosphamide, vincristine, prednisone), CHOP-derived chemotherapy, and MA-COP-B (methotrexate, adriamycin, cyclophosphamide, vincristine, prednisone, and bleomycin) regimens, but occasionally patients have been treated with Hodgkin lymphoma-type chemotherapy (e.g., ABVD regimen).

Collaborative trials have been conducted in childhood and adolescence ALCLs. Overall results were comparable with very different treatment strategies, ranging from leukemia-like treatment, such as modified LSA2-L2 protocol, to chemotherapy regimes derived from B-cell NHL as the BFM (Berlin-Frankfurt-Munster) and the French and British Pediatric Hemato-Oncology Society protocols. The latter are based on the administration of short (usually 5-days) courses of rather high-intensive chemotherapy (based on the rotational use of corticosteroid, anthracyclines, cyclophosphamide or ifosfamide, cytarabine, methotrexate, epipodophyllotoxin) administered at intervals of ~3 weeks. With these treatments, 60–75% of patients obtain cure of their disease and do not experience disease recurrences. Similar results were obtained with the APO regimen in the Children's Oncology Group (USA) that includes higher cumulative doses of anthracyclines without ►alkylating agents (cyclophosphamide/ifosfamide) or epipodophyllotoxins.

Treatment intensity and/or duration have been differentiated based on various risk factors. Although stage of disease has some relevance, in the adult population a high International Prognostic Index (IPI) score, high serum lactate dehydrogenase levels, ALK-negativity and expression of the surface antigen CD56 have been associated to a significant lower outcome. In children and young adults, possibly because of the very high frequency of ALK-positivity, ALK expression does not seem to be a relevant prognostic indicator, whereas high stage of disease, elevated lactate dehydrogenase levels, and specific site of disease, including liver, spleen, lung, and skin involvement, seem to be associated to a less favorable prognosis.

A distinct clinical condition is represented by the isolated cutaneous ALCL. Once other disease localizations have been excluded, given that spontaneous regression of the lesions can occur, a strict monitoring of the patient is often preferred, postponing initiation of chemotherapy when signs of lymph nodes or other organ involvement is demonstrated.

A peculiar aspect of ALCL is that most patients who relapse respond well to salvage therapies. Although early disease recurrences can be extremely aggressive, moderate intensity chemotherapy, including single drug treatment with vinblastine, can achieve long-lasting remission. In case of resistant disease or very aggressive relapse, high-intensive chemotherapy with bone marrow transplant has also been used both in children and adults. Further studies are needed to definitively establish the benefit of bone marrow transplant in ALCL and to identify the subpopulations of patients who may benefit from such a treatment approach.

Anaplastic Lymphoma Kinase

Definition

Anaplastic lymphoma kinase (ALK) is a receptor tyrosine kinase (RTK) having an extracellular, a single transmembrane, and an intracellular domain containing the tyrosine kinase activity. ALK belongs to the insulin receptor subfamily of RTKs, most closely related to leukocyte tyrosine kinase receptor. It localizes mostly in neuronal cells and may play a role in the nervous system development and maintenance. ALK and some of the ALK partners or closely related genes are found implicated both in anaplasic large cell lymphoma and in inflammatory myofibroblastic tumors.

Definition
The androgen receptor or AR is a member of the steroid/thyroid receptor superfamily, in which all members share basic structural and functional homology. The AR is an intracellular ligand (androgen)-dependent transcription factor, which regulates the expression of genes that control cell proliferation, ►apoptosis, ►angiogenesis and differentiation in many hormonally regulated tissues including the prostate. It is an important regulator of male sexual differentiation and maturation.

Characteristics

The biological function of androgen is mediated through the androgen receptor. Except for the spleen and bone marrow, the androgen receptor is ubiquitously expressed in human organs. The human androgen receptor gene is more than 90-kb long, and is present as a single allele located at chromosome Xq11.2–12. The AR gene has eight exons and possesses a coding region of 2757 bp. This region encodes a 110 KDa protein (919 amino acids) with four distinct functional domains: a conserved Zn-finger DNA-binding domain (exons 2 and 3), a hinge region (exon 4), a COOH-terminal ligand-binding domain (exons 4–8), and a less conserved and structurally flexible amino (NH2)-terminal transactivation domain (exon 1).

Structure–Function Relationships between Different Domains of Androgen Receptor that are Required for its Transcriptional Activity

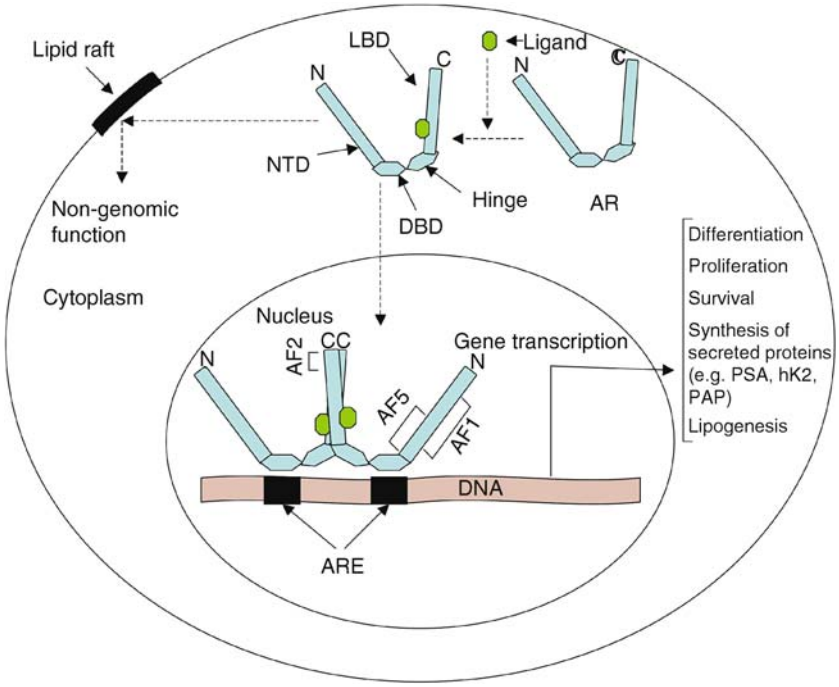
Regulation of Unliganded AR

Unbound AR in the cytoplasm remains in an inactive but androgen responsive state as part of a large dynamic heterocomplex composed of heat shock proteins, co-chaperones, and tetratricopeptide repeat containing proteins. This large complex helps to modulate the ligand-binding domain (LBD) of AR into a relatively stable, partially unfolded, and inactive intermediate which has a high affinity for the potent biologically active androgen, dihydrotestosterone. The androgen-free LBD and the associated chaperone proteins inactivate the function of the transactivation domain of AR. This transactivation domain becomes constitutively active in the mutant AR lacking a ligand-binding domain (LBD). As such, this molecular chaperone complex and the LBD of AR prevent unwanted activation of AR in the absence of androgen

Regulation of Ligand-Bound AR

Because of their lipophilic nature, androgens cross the cell membrane, both passively, and actively via the transport protein, megalin. Once within the cell the androgen binds to the AR, which is stabilized and translocated into the nucleus. Within the nucleus the AR homo-dimerizes and recruits transcriptional cofactors to the promoters and enhancers of AR-target genes, thus facilitating their transcription (Fig. 1). Androgen binding to the LBD of AR induces an overall change in AR structure leading into an active conformation which is characterized by dissociation of the receptor–chaperone complex. However, molecular chaperones also play important roles in the events downstream of AR activation such as translocation to the nucleus, transcriptional activation, transcription complex disassembly and degradation. LBD relieves its inhibitory function upon androgen binding. AR LBD configuration is highly structured and resembles other steroid receptors' ligand-binding domains.

1. AR DNA Binding Domain and Hinge Region: Androgen binding to the LBD initiates a conformational change of AR leading to several secondary effects important for AR transcriptional activity.



Androgen Receptor. Figure 1 A schematic diagram of AR structure and its functions.

One such effect is the unmasking of the bipartite nuclear-localization signal (NLS) that overlaps the DNA-binding domain and hinge regions (amino acid 625–671). Another weak NLS (amino acid 722–805) is present in the LBD of AR, which is also exposed upon androgen binding. The NLS is recognized by an import protein that mediates translocation of the AR through the nuclear-pore complex. AR homodimerization occurs in the nucleus upon treatment with ligand. Both the DNA and ligand-binding domains of AR are involved in subsequent receptor dimerization. The stronger hydrophobic interaction occurs between the ligand-binding domains.The binding of AR dimer to the specific androgen response elements (ARE) of a gene occurs in a co-operative manner. The DNA binding domains of AR, like other nuclear receptor superfamily members, consist of two zinc fingers that provide the structural basis required for ARE recognition in the promoter region of a gene. The consensus ARE is a 6 bp palindromic core sequence (5′-AGEACA-3′) separated by a three nucleotide spacer. Sequences outside the DNA binding domain also play a role in AR-DNA binding.

2. AR AF-2 Domain: A hydrophobic protein-protein interaction surface known as Activation Function-2, or AF2, is present at the carboxy-terminal, and also becomes accessible after androgen binding to AR. AF2 is the potential binding site for AR co-activators such as the p160 family (TIF2, SRC1, and AIB1). These co-activators enhance AR transcriptional activity by modulating AR conformation and by recruiting cofactors to the promoter. Ligand binding also induces interaction of AF2 with a specific motif (FXXLF) (F = phenylalanine, L = leucine and X = any aminoacid) in the NH2-terminal activation domain of AR. The interaction of NTD and LBD or N/C interaction is important for AR transcriptional activity. Although the mechanistic details of how this interaction leads to AR activity are not precisely known, it appears that ligand binding induces intramolecular folding of AR, leading to the interaction between NTD and LBD. This influences receptor dimerization in the nucleus and reduces ligand degradation from LBD, AR protein dissociation, AR chromatin binding ability and receptor transactivation.
3. AR N-Terminal Transactivation Domain: The N-terminal transactivation domain (NTD) of AR is longer and structurally different as compared to other steroid receptors. The highly flexible and disordered domain containing NTD is largely globular in nature. Association with coactivators and transcription factors helps to induce folding in the domains of the NTD to optimize efficient binding. Due to the allosteric nature of binding, the AR NTD is able to bind a broad spectrum of transcriptional coactivators, co-repressors and other factors. Therefore the AR NTD may be responsible for mediating androgen-regulated expression of genes whose functions consist of protein folding, trafficking and secretion, metabolism, cytoskeletal rearrangement, cell cycle regulation and signal transduction. *AF1 and AF5 Domain of NTD*: There are two major overlapping activation functions present in the AR NTD, AF1 (amino acids 142–485) and AF5 (amino acids 351–528). These regions contain microsatellite repeats, protein-protein interaction surfaces, and phosphorylation and sumoylation sites. AF1 is considered the major transactivation domain that binds to basal transcription factors, co-regulators, cell cycle regulatory proteins, heat shock proteins etc. The interaction with molecules like TIFIIF increases folding in the AF1 domain and facilitates further protein-protein interactions for the formation of a transcriptionally competent receptor complex. Unlike AF1, activation of AF5 is ligand independent. An inhibitory domain within AF5 inhibits the DNA-binding domain of AR from binding to AREs. *Glutamine and Glycine Repeats*: AR NTD contains two polymorphic trinucleotide repeat segments that encode polyglutamine and polyglycine tracts. The first trinucleotide repeat sequence, CAG, spans amino acids ~58–78, and encodes the amino acid glutamine. The second stretch consists of GGN repeats that encode glycines and span amino acids ~449–472. Shortened trinucleotide repeat stretches result in increased AR activity and are often associated with prostate cancer predisposition. On the other hand, overexpansions of the CAG repeat (more than 40) correlate with a significant decrease in AR activity and are associated with diseases such as X-linked Spinal and Bulbar Muscular Atrophy (SBMA), also known as Kennedy's disease. Both the polyglutamine and polyglycine repeat size appear to regulate the N/C interaction and thereby influence AR activity. *FXXLF and WXXLF Motifs*: The AR NTD also contains two short, highly conserved peptide motifs that mediate the ligand-dependent N/C interaction as discussed previously. These motifs are FXXLF (in humans FQNLF), ranging from amino acids 23–27 and WXXLF (in humans WHTLF), ranging from amino acids 434–438. *AR Co-regulators*: AR functions as a tripartite receptor system involving AR itself, the androgens and AR coregulators. AR interaction with either co-activators or co-repressors enhances or represses its transcriptional activity, respectively, without affecting the basal levels of transcription. Possible mechanisms of co-regulator function include modulation of chromatin structure, promotion of AR post-translational modifications and control of androgen/AR binding affinity, AR expression, AR stability, AR nuclear translocation, and AR recruitment of transcription machinery.

4. Post-translational Modification of AR: Post-translational modification of AR is one of the key mechanisms regulating its function. One of the major post-translational modifications of AR is phosphorylation. These phosphorylation sites may be the sites for possible cross-talk between peptide growth factors and the AR signaling axis, which is important for normal prostate epithelial cell growth and function as well as for the progression of cancer. Most of the phosphorylation sites reside in the NTD at different serine residues. However, recent findings suggest that Src kinase mediates phosphorylation at tyrosine 534 of AR, and therefore acts as a potential regulator of AR transcriptional activity. Another post-translational modification is acetylation of AR at the hinge domain (at lysine residues 630, 632 and 633) by Histone Acetyl Transferases such as p300, p/CAF, and TIP60. This modification regulates recruitment of co-regulators as well as the growth properties of the AR. Acetylation is also required for regulation of the AR by the AKT, PKA and JNK signaling pathways. Sumoylation of AR at two specific domains (NRM1 and NRM2 at NTD) also appears to be important for AR activation, localization and degradation.

Nongenomic Function of AR

Recently, a nongenomic mechanism for AR function independent of its transcriptional activity has been postulated. This nongenomic event is very rapid (2–15 min) and activates signaling events such as the Src/Raf1/ERK, ►PI3K-AKT, and IL-6-STAT3 pathways. Interestingly, membrane lipid rafts are considered to be the privileged site for this AR-mediated nongenomic signaling. Upon androgen binding most of the ARs translocate to the nucleus and act as transcription factors. The few remaining cytosolic ARs may then enter into ►caveolin positive or negative rafts to initiate different signaling pathways.

Androgen Receptor in Human Physiology and Pathology

Androgen and AR are not only necessary for the initiation of prostate development; they are also important factors for the survival, proliferation, secretary function, morphology, angiogenesis and differentiation of the adult prostate gland. AR is also important for Wolffian duct development and spermatogenesis in males. Various clinical disorders due to functional abnormalities of AR have been reported, suggesting that a wide range of physiological responses and developmental processes are mediated by AR.

Androgen Receptor and ►Prostate Cancer: Approximately 80–90% of prostate tumors are dependent on androgen at the initial diagnosis, suggesting the importance of AR signaling in all stages of ►prostate carcinogenesis. A recently developed bioinformatics approach known as Cancer Outlier Profile Analysis (COPA) together with standard genomic techniques has identified recurrent gene fusions of the 5′ untranslated region of the TMPRSS2 gene to ►ETS transcription factors (ERG or ETV1) in human prostate cancer tissues. Interestingly, this gene fusion enables expression of the fused product under the control of AR, as the TMPRSS2 promoter contains an ARE. This ►TMPRSS2-ETS fusion appears to be frequent in prostate cancer and might be an initiating event for prostate cancer, underscoring the importance of AR-mediated signaling in prostate cancer.

Both the tumor epithelia and adjacent stroma express AR. Retardation of tumor growth occurs in response to androgen ablation therapy. Until now, the primary therapy for advanced (locally extensive or metastatic) prostate cancer consists of androgen ablation by pharmaco-therapeutic or surgical means. Eventually, the tumor recurs due to a transition from androgen-dependence to a highly aggressive and androgen-depletion-independent (refractory) phenotype. The detailed molecular mechanism underlying the development of the androgen refractory phenotype of prostate cancer is poorly understood. As such, it has been difficult to develop effective treatments for this stage of the disease. Disruption of androgen receptor function inhibits proliferation of androgen refractory prostate cancer, demonstrating the importance of AR even at subnormal physiological levels of androgen. Mechanisms for ligand-independent AR reactivation include AR mutation, gene amplification, increased stability and nuclear localization, co-regulators and cross talk between different signal transduction pathways. Recent studies also suggest an acquired capacity of recurrent prostate tumors to biosynthesize testicular androgens from adrenal androgens or cholesterol, thereby reactivating the AR.

Targeting AR for Therapy: Androgen ablation therapy, which is achieved by pharmaco-therapeutic (steroidal and non-steroidal antiandrogens) or surgical (subcapsular or subepididymal bilateral orchiectomy) means, is the standard initial systemic therapy for locally advanced or ►metastatic prostate cancer. This therapy is based on inhibiting the synthesis of active androgen or inhibiting the physiological androgen from binding to AR. Novel therapeutic strategies for the androgen-depletion-independent stage of prostate cancer will focus on inhibiting expression of AR, blocking the binding of AR coactivators, and enhancing the binding of AR co-repressors. Using intelligent high-throughput screening and structural and computational chemistry, it may be possible to develop peptide antagonists, ►small molecules or antisense oligonucleotides that target AR-coactivator binding surfaces. Potential drugs targeting the N-terminal domain may also prevent or delay the progression of both hormonal-dependent and -independent prostate cancer.

Definition

Any agent that affects cell division and the mitotic spindle apparatus resulting in the loss or gain of whole chromosomes, thereby inducing ►aneuploidy.

►Micronucleus Assay

Aneuploidy

Definition

Aneuploidy is a condition with the abnormal number of chromosomes due to missing or extra chromosomes, as a result, the number of chromosomes by aneuploidy is not a multiple of the haploid set. Normal diploid organisms have 2n chromosomes, where n is the chromosome number in the haploid set. A change in the number of chromosomes can lead to a chromosomal disorder. Aneuploidy is common in tumor cells.

Aneuploidy

Subrata Sen
Department of Molecular Pathology (Unit 951), The University of Texas, M.D. Anderson Cancer Center, Houston, TX, USA

Definition

Aneuploidy refers to the presence of either less than or more than the normal diploid number of

chromosomes in a cell. Such losses or gains (aneusomy) of chromosomes may involve segments of chromosomes or complete chromosomes leading to major imbalances in the genetic makeup of the affected cells. Instead of the two copies of structurally intact homologous chromosomes (disomy) present in a normal cell, aneuploidy may result in the loss of one chromosome (monosomy) or both homologous chromosomes (nullisomy) as well as gain of one chromosome or more to each homologous pair of chromosomes (trisomy, tetrasomy etc.) in a cell. Occasionally, gain of one or more copies of the entire haploid set of chromosomes (triploidy, tetrapolidy etc.) or loss of one haploid set of chromosomes (haploidy) have also been reported.

Characteristics

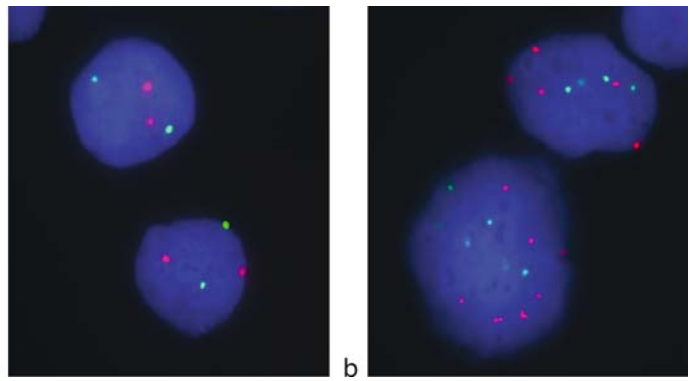
►Chromosomal instability in the form of aneuploidy, is one of the most common genetic anomalies detected in human cancer cells. While von Hansemann had, at the end of the nineteenth century, first discussed the biological consequences of chromosome segregation errors based on observations of abnormal mitoses in human cells, possible contribution of aneuploidy in tumorigenic transformation of cells resulting from multipolar mitosis was later proposed by Theodore Boveri at the beginning of the twentieth century. Germline inheritance of aneuploid condition often leads to developmental defects and somatic origin of similar anomalies are frequently associated with malignant phenotypes. It has been convincingly demonstrated that aneuploidy arises due to underlying genetically determined chromosomal instability in malignant cells. Discovery and functional characterization of genes regulating faithful segregation of chromosomes required for the maintenance of chromsomal stability in somatic cells have helped elucidate the genetic pathways involved in the process. Recent findings of tumor suppressor genes and DNA mismatch repair genes as upstream regulators of these pathways have provided compelling evidence in favor of aneuploidy being a genetically determined phenomenon associated with cancer. Whether aneuploidy is a cause or consequence of cancer has long been debated. Although the physiological relevance of aneuploidy in cancer still remains a subject of investigation, increasing number of observations, over the years, have revealed frequent changes in gene copy number in conjunction with changes in chromosome copy number in cancer cells during cancer initiation and/or progression processes. These observations made in primary tumors with in situ hybridization (ISH) and comparative genomic hybridization (CGH) techniques have revealed that specific chromosome aneusomies sometimes correlate with distinct tumor phenotypes. In addition, aneuploid tumor cell lines and in vitro transformed rodent cells have been reported to display an elevated rate of chromosome instability, thus indicating that aneuploidy is a dynamic chromosome mutation event associated with transformation of cells. Finally and most importantly, a number of genes regulating chromosome segregation have been found aberrantly expressed in human cancer cells and genetically engineered mice expressing abnormal levels of some of these genes have been reported to display higher incidence of aneuploidy associated with tumor development. These findings provide a new direction towards understanding the molecular mechanisms responsible for the origin of aneuploidy in cancer and the knowledge is expected to help design novel cancer therapeutic strategies in the future.

Aneuploidy in Cancer

Aneuploidy involving one or more chromosomes has been commonly reported in human tumors. It is estimated that aneuploidy, is the most prevalent genetic change recorded among over 20,000 solid tumors analyzed thus far. These observations were originally made using classical cytogenetic techniques late in a tumor's evolution and were difficult to correlate with cancer progression. More recent studies have reported an association of specific non-random chromosome aneuploidy with different biological properties such as loss of hormone dependence and metastatic potential.

Classical cytogenetic studies of analyzing metaphase chromosomes from tumor cells had serious limitations in scope since these were applicable only to those cases in which mitotic chromosomes could be obtained. Because of low spontaneous rates of cell division in primary tumors, analyses depended on cells either derived selectively from advanced metastases or those grown in vitro for varying periods of time. In both instances, the metaphase chromosomes analyzed represented only a subset of the tumor cell population. The two major advances in analytical cytogenetic techniques, in-situ hybridization (ISH) and comparative genomic hybridization (CGH), have allowed better resolution of chromosomal aberrations in freshly isolated tumor cells. ISH analyses with chromosome-specific DNA probes can be performed on interphase nuclei and allow assessment of numeric chromosomal anomalies within tumor cell populations in the contexts of whole nuclear architecture and tissue organization (Fig. 1). CGH allows genome-wide screening of chromosomal anomalies without the use of specific probes, even in the absence of knowledge of the chromosomes involved. While both techniques have certain limitations in terms of their resolution power, they nonetheless provide a better approximation of chromosomal changes occurring among tumors of various histology, grade and stage compared with what was possible with the classical cytogenetic techniques.

DNA ploidy measurements, have also been performed with flow cytometry and cytofluorometric methods. Although these assays underestimate chromosome ploidy



Aneuploidy. Figure 1 Fluorescence in-situ hybridization (FISH) analyses of normal ovarian epithelial cells (a) and human ovarian cancer cells (b) performed with chromosome 20 short arm (*labeled with red fluorescent dye*) and long arm probes (*labeled with green dye*). Note the presence of two copies of chromosome 20 in normal epithelial cells in (a) but five to seven copies of chromosome 20 as evidence for aneuploidy in the cancer cells (b).

due to the possibility of a gain occasionally masking a loss in the same cell, several studies employing these methods have concluded that DNA copy number changes or *DNA aneuploidy* correlates with poor prognosis in different cancers. A few published examples of aneuploidy in cancer are mentioned in the following discussion that deal with DNA ploidy measurements as well. Most of these observations are correlative without a direct proof of specific involvement of genes on the respective chromosomes. However, more recent findings on the role of specific genes in regulating chromosome segregation and maintenence of chromosomal stability together with the development of mouse models genetically manipulated to either up regulate or down regulate some of these genes displaying increased incidence of tumors associated with aneuploidy provide strong evidence in favor of aneuploidy playing a critical role in the tumorigenesis process.

In ►renal cancer, either segmental or whole chromosome aneuploidy appears to be uniquely associated with specific histologic subtype. Tumors from patients with hereditary papillary renal carcinomas (HPRC) commonly show trisomy of chromosome 7, when analyzed by CGH. Germline mutations of a putative oncogene MET have been detected among patients with HPRC. It was demonstrated that an extra copy of chromosome 7 results in nonrandom duplication of the mutant ►MET allele in HPRC, thus implicating this trisomy in tumorigenesis. The study suggested that mutation of MET may render the cells more susceptible to errors in chromosome replication, and clonal expansion of cells harboring duplicated chromosome 7 reflects their proliferative advantage. In addition to chromosome 7, trisomy of chromosome 17 in papillary tumors and also of chromosome 8 in mesoblastic nephroma are commonly seen. Association of specific chromosome imbalances with benign and malignant forms of papillary renal tumors not only contributes to understanding of tumor origins and evolution but also implicate aneuploidy of the respective chromosomes in the tumorigenic transformation process.

In ►colorectal cancer, aneuploidy is common occurrence. Molecular allelotyping studies have suggested that the limited karyotyping data available from these tumors actually underestimate the true extent of these changes. Losses of heterozygosity, reflecting loss of the maternal or paternal allele in tumors, are widespread and often accompanied by a gain of the opposite allele. Thus, for example, a tumor could lose a maternal chromosome while duplicating the homologous paternal chromosome leaving the tumor cell with a normal karyotype and ploidy but an aberrant allelotype. It has been estimated that on an average, cancer of the colon, breast, pancreas and prostate may lose 25% of the alleles and it is not unusual for a tumor to have lost over half of all its parental alleles. In clinical settings, DNA ploidy changes indicate high risk of developing premalignant changes among patients with ulcerative colitis and also lymph node metastasis among patients with gastric carcinoma. Similarly, chromosome copy number alterations or aneuploidy has been detected in pre cancerous lesions of colon, cervix, head and neck, esophagus and bone marrow. Between 60% and 80% of colorectal polyps from individuals with adenomatous polyposis syndrome, predisposed to develop colorectal cancer have been reported to show aneuploid changes. Comparative analysis of genomic alterations in AdAPC driven mouse intestinal tumors have identified loci syntenic with human chromosomes 1, 12, 9 and 22 that are frequently gained or lost in familial adenomas and sporadic colorectal cancers suggesting that genetic mechanisms manifested in the form of aneuploidy are conserved across species The molecular karyotype of amplified chromosomal segments (amplotype) generated from colorectal cancer was reported to indicate that over representation of loci on chromosomes 8 and 13 may be critical for metastatic colorectal cancer.

Incidence of chromosome aneuploidy has also been evaluated as a marker of risk assessment and prognosis in several other cancers. Analyzing aneuploidy in non-surgically obtained squamous epithelial cells offers a promising non-invasive tool to identify individuals at high risk of developing head and neck cancer. Interphase FISH studies have revealed extensive aneuploidy in tumors from patients with head and neck squamous cell carcinomas (HNSCC) and also in clinically normal distant oral regions from the same individuals. It has been suggested that a panel of chromosome probes for FISH analyses may serve as an important tool to detect subclinical tumorigenesis and for diagnosis of residual disease. The presence of aneuploid or tetraploid populations are commonly seen in 90–95% of esophageal adenocarcinomas, and when detected in ►Barrett esophagus, a premalignant condition, predicts progression of disease.

Aneuploidy in most solid tumors coexist with structural chromosomal aberrations giving rise to complex karyotypes. Such karyotypic complexities could be reflective of similar underlying mechanisms responsible for the origin of both kinds of chromosomal aberrations as well as their selective value for the evolution of malignant cells during carcinogenesis. These possibilities appear credible in view of the findings that tetraploid p53 null mouse mammary epithelial cells show an increased frequency of whole chromosome missegregation and chromosomal rearrangements together with increased propensity to give rise to malignant mammary epithelial cancers. Despite complex karyotypes, different cancers also show shared minimal regions of gains and losses of specific chromosomes. By analyzing such regions of genomic imbalances in various solid tumors, karyotypic pathways of evolution of cancers involving specific chromosomal aneusomies have been described. For pancreatic cancer, the recurrent early imbalances included loss of chromosomes 1, 5, 7, 8, 15, 17, and 18 while the late recurrent imbalances were identified as gain of chromosomes 2, 6, 7, 11 and loss of chromosome 19.

Besides clinical correlative observations, role of aneuploidy in oncogenesis has also been supported by *in vitro* and *in vivo* transformation experiments performed with human and rodent cells. These studies revealed that aneuploidy is induced at early stages of transformation. Transgenic mouse models with chromosome segment-specific duplications and deletions have been generated to investigate the effect of chromosome ploidy alterations during development. Three duplications for a portion of mouse chromosome 11 syntenic with human chromosome 17 were established in the mouse germline. Mice with duplication of 1 Mb chromosomal DNA developed corneal hyperplasia and thymic tumors. The findings document a direct role of chromosome aneusomy in tumorigenesis. More recent developments of mouse models with targeted upregulation or down regulation of genes regulating chromosome segregation giving rise to increased incidence of aneuploidy and cancer have further strengthened the idea of aneuploidy being a *cause* driving tumorigenesis rather than a *consequence* of cancer.

Aneuploidy as a "Driving Force" and not a "Consequence" in Cancer

The presence of numerical chromosomal alterations in a tumor does not mean that the change arose as a dynamic mutation due to genomic instability. While aneuploidy as a dynamic mutation due to genomic instability in tumor cells would occur at a certain measurable rate per cell generation, a consequential state of aneuploidy is expected to be fixed in similar tumors at an unpredictable random rate possibly decided by differences in environmental factors such as humoral, cell substratum, and cell-cell interaction differences of the tumor and normal cell microenvironments. It could be argued that despite similar rates of spontaneous aneuploidy induction in normal and tumor cells, the latter are selected to proliferate due to altered selective pressure in the tumor cell microenvironment while the normal cells are eliminated through activation of apoptosis. Alternatively, it could be postulated that selective expression or overexpression of anti-apoptotic proteins or inactivation of proapoptotic proteins in tumor cells may counteract default induction of apoptosis in G2/M phase cells undergoing missegregation of chromosomes.

To investigate if aneuploidy is a dynamic mutational event, different human tumor cell lines and transformed rodent cell lines have been analyzed for the rate of aneuploidy induction. When grown under controlled *in vitro* conditions, such conditions ensure that environmental factors do not influence selective proliferation of cells with chromosome instability. In one study, Lengauer and colleagues provided evidence by FISH analyses that losses or gains of multiple chromosomes occurred in excess of 10^{-2} per chromosome per generation in aneuploid colorectal cancer cell lines. The study further concluded that such chromosomal instability appeared to be a dominant trait. Utilizing another *in vitro* model system of Chinese hamster embryo (CHE) cells, Duesberg and colleagues have also obtained similar results. With clonal cultures of CHE cells, transformed with nongenotoxic chemicals and a mitotic inhibitor, these authors demonstrated that the majority of the transformed colonies contained more than 50% aneuploid cells, indicating that aneuploidy would have originated from the same cells that underwent transformation. All the transformed colonies tested were tumorigenic. It was further documented that the ploidy factor, representing the quotient of modal chromosome number divided by the normal diploid number, in each clone correlated directly with the

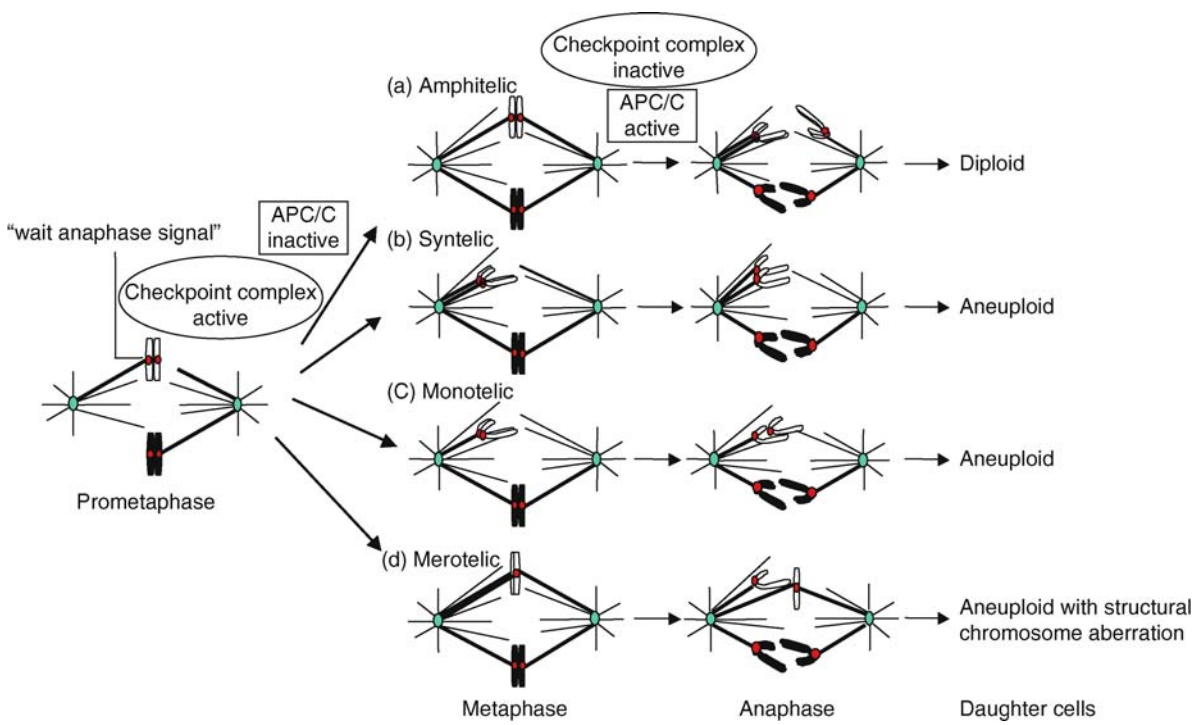
degree of chromosomal instability. Thus chromosomal instability was found proportional to the degree of aneuploidy in the transformed cells, and the authors hypothesized that aneuploidy is an effective mechanism of destabilizing the genome, and changing normal cellular phenotypes.

Genetic Mechanisms of Aneuploidy in Cancer

Numerical chromosomal aberrations giving rise to aneuploidy result when chromosomes are mis-segregated unequally to the daughter cells during mitotic cell division process. Failure to correct mis-attachments of kinetochores with spindle microtubules through mitosis is the major cause of such chromosome mis-segregation. The cell cycle control mechanism that ensures faithful equal segregation of chromosomes during mitosis is referred to as the mitotic checkpoint or the spindle assembly checkpoint (Fig. 2).

The mitotic checkpoint prevents chromosome mis-segregation and aneuploidy by inhibiting metaphase to anaphase transition in cells until the sister kinetochores of all the replicated chromosomes attach appropriately to the spindle microtubules from the two opposing poles in the cell. This form of attachment is known as *amphitelic attachment* and until such time as this attachment is achieved, mitotic checkpoint proteins recruited to the unattached kinetochores generate a diffusible signal (*wait anaphase signal*) that inhibits the anaphase promoting complex/cyclosome (APC/C) from facilitating the degradation of the substrates necessary for transition from metaphase to anaphase and mitotic exit. Thus with an active mitotic checkpoint, inappropriately attached sister kinetochores, such as those with both kinetochores attached to the same pole known as *syntelic attachment* or others with only one kinetochore attached to one pole known as *monotelic attachment* or to the two opposing poles known as *merotelic attachment*, are prevented from proceeding to anaphase with the likely outcome of giving rise to aneuploidy. Aberrant expression of the checkpoint proteins leading to weakening of the mitotic checkpoint, however, allows mis-segregation of inappropriately attached sister chromatids to proceed to anaphase leading to the generation of aneuploid daughter cells.

Chromosome segregation errors may also result in cells with centrosome anomalies giving rise to multipolar spindles. Among the mitotic processes implicated in cancer, defects in centrosome function have been frequently suggested to be involved in a wide variety of malignant human tumors. Centrosomes play a central role in organizing the microtubule network in interphase cells and the mitotic spindle during cell division. Multipolar mitotic spindles have been observed in human cancers *in situ* and abnormalities in the form of supernumerary centrosomes, centrosomes of aberrant size and shape, as well as aberrant phosphorylation of centrosome proteins have been reported in prostate, colon, brain and breast tumors. It is conceivable that cells with abnormal centrosomes may missegregate chromosomes producing aneuploid cells. The molecular genetic mechanism(s)



Aneuploidy. Figure 2 Mitotic checkpoint regulation of chromosome segregation.

regulating centrosome structure/function that are aberrant in cancer cells remain to be elucidated. The presence of supernumerary centrosomes in aneuploid p53-deficient fibroblasts, and over expression of the centrosome associated kinase Aurora-A/STK15 and PLK1 in human cancers have further validated the possibility that aberrant centrosome function is involved in aneuploidy and oncogenesis.

A number of genes involved in the mitotic checkpoint pathway and those regulating chromosome segregation have been found to be aberrantly expressed in human cancer cells raising the possibility that aberrant expression of the respective mitotic checkpoint and chromosome segregation regulatory proteins contribute to the origin of aneuploidy in cancer (Table 1).

In addition to the genes with known functions in mitotic checkpoint and chromosome segregation, mutant alleles of tumor suppressor genes, AdAPC, BRCA1 and BRCA2 have also recently been shown to induce aneuploidy in murine fibroblasts derived form mice expressing mutated forms of these proteins. Similarly, murine fibroblasts lacking the mismatch repair gene Msh2 also reveal widespread aneuploidy indicating that mutations in this gene may be contributing to tumorigenesis by inducing DNA mismatch repair defects and aneuploidy.

Complementing these findings on the likely involvement of aneuploidy inducing genes in the tumorigenesis process, two recent publications on genetically engineered mice aberrantly expressing genes involved in the regulation of chromosome segregation further advance the case for aneuploidy being a *cause* of cancer with some caveats. In one of these studies mice heterozygous for Cenp-E gene, involved in the alignment of chromosomes on mitotic spindle, were reported to develop cancer accompanied by an increase in age dependent whole chromosome aneuploidy although Cenp-E heterozygosity inhibited tumorigenesis in animals lacking the tumor suppressor gene p19/ARF. In the second study mice over expressing the mitotic checkpoint protein Mad2 developed a wide range of tumors with extensive chromosomal rearrangements. However, silencing of Mad2 after tumor formation had no effect on tumor growth, suggesting that Mad2 over expression acts early to promote tumorigenesis. Together, these studies indicate that, like other types of genetic instability, aneuploidy promotes susceptibility to cancer rather than make it obligatory. The concept gains further credence from observations in the human genetic disease *mosaic variegated aneuploidy*, associated with inactivated mitotic checkpoint gene Bub1b, which reveal constitutional aneuploidy and predisposition to develop cancer.

Aneuploidy. Table 1 Genes-Proteins Regulating Chromosome Ploidyin Cancer

Gene name	Function	Mutation/altered expression	Human cancer	Animal models of cancer
Cenp-A	Kinetochore assembly	Upregulated	Yes	
Bub 1	Mitotic checkpoint	Mutated/upregulated/ downregulated	Yes	
Bub R1	Mitotic checkpoint	Mutated/upregulated/ downregulated	Yes	
Bub 3	Mitotic checkpoint	Upregulated/downregulated	Yes

KIF 4	Motor protein			Yes
Aurora-B	Chromosome segregation	Upregulated	Yes	
PTTG (Securin)	Sister chromatid cohesion	Upregulated	Yes	
Survivin	Chromosome segregation	Upregulated	Yes	
Aurora-A	Chromosome segregation	Upregulated	Yes	Yes
PLK 1	Chromosome segregation	Upregulated	Yes	
Nek 2	Chromosome segregation	Upregulated	Yes	
Brca1	Tumor suppressor	Mutated/downregulated	Yes	Yes
Brca2	Tumor suppressor	Mutated	Yes	Yes
AdAPC	Tumor suppressor	Mutated/downregulated	Yes	Yes
Msh2	DNA mismatch repair	Mutated/upregulated/ downregulated	Yes	Yes

Conclusions

The role of aneuploidy as a cancer causing mutation event helps resolve the paradox that with known mutation rate in somatic cells (~10^{-7} per gene per cell generation), tumor cell lineages cannot accumulate enough mutant genes during a human life time. Evidence from human tumor cytogenetic and molecular genetic studies provide compelling evidence in favor of aneuploidy being directly involved in the development of tumor phenotypes. Results from clinical findings support a correlation between origin of aneuploidy and tumorigenic transformation of cells. Molecular genetic analyses of tumor cells suggest that mutations/aberrant expression of genes involved in controlling mitotic checkpoint and chromosome segregation play critical roles in causing chromosome instability leading to aneuploidy in cancer.

Angiogenesis

Arjan W. Griffioen
Angiogenesis Laboratory, Department of Pathology, Maastricht University, Maastricht, The Netherlands

Synonyms

Formation of new blood vessels; Neovascularization

Definition

Angiogenesis is the formation of new capillary vasculature out of pre-existing blood vessels under the regulation of growth factors and inhibitors. It occurs in physiological (e.g. wound healing, ovulation, placental growth) and pathological (e.g. cancer, arthritis, inflammation) conditions.

Characteristics

The formation of new blood vessels out of pre-existing capillaries, the process that is called angiogenesis, is a sequence of events that is of key importance in a broad array of physiologic and pathologic processes. Normal tissue growth such as in embryonic development, wound healing and the menstrual cycle is characterized by dependence on new vessel formation for the supply of oxygen and nutrients as well as for removal of waste products. Also, in a large number of different and non-related diseases, formation of new vasculature is involved in abnormal physiology. Among these pathologies are diseases such as tissue damage after reperfusion of ischemic tissue or cardiac failure, where angiogenesis is low and should be enhanced to improve disease conditions. In a larger number of diseases excessive angiogenesis is part of the pathology. These diseases include cancer (both solid and hematologic tumors), cardiovascular diseases (atherosclerosis), chronic inflammation (rheumatoid arthritis, Crohn's disease), diabetes (diabetic retinopathy), psoriasis, endometriosis and adiposity. These diseases may benefit from therapeutic inhibition of angiogenesis.

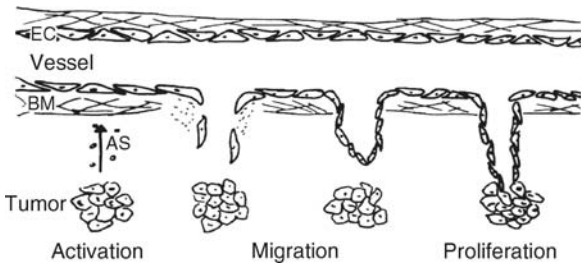
The initial recognition of angiogenesis being a therapeutically interesting process, began in the oncological arena in the early 1970s, when the hypothesis was put forward that tumors are highly vascularized and therefore most vulnerable at the level of their blood supply [1]. It was hypothesized that the process of angiogenesis might be a target for therapy. Since then, it was only after the discovery of the first compounds with specific angiostatic effects in the early 1990s, that the research field of angiogenesis rapidly expanded and provided an increasing body of evidence that inhibition of angiogenesis could attenuate tumor growth [2,3].

The endothelial cells that line the blood vessels play a pivotal regulatory role in the execution of angiogenesis. The sequence of events in endothelial cells that follow the initiation of angiogenesis by exposure to (e.g. tumor derived) angiogenic stimulation consists of:

- Synthesis of proteases that degrade the extracellular matrix
- Migration towards the stimulus
- Proliferation to increase the number of endothelial cells
- Differentiation in order to form a functional vessel (see Fig. 1)

Negative interference in the different steps of the angiogenesis cascade enables different approaches for treatment of cancer:

- Neutralization of angiogenic factors – anti-growth factor antibodies (Avastin), dominant negative growth factor receptors



Angiogenesis. Figure 1 The angiogenesis cascade of endothelial cell activation, degradation of the extracellular matrix and the basement membrane, migration and proliferation. EC, endothelial cell; BM, basement membrane; AS, angiogenic stimulus.

- Inhibition of growth factor receptors – anti-growth factor receptor antibodies
- Desensitization of growth factor mediated intracellular signalling pathways – ►receptor tyrosine kinase inhibitors
- Inhibition of ►matrix metalloproteinases
- Inhibition of endothelial cell ►adhesion
- Inhibition of endothelial cell ►migration
- Inhibition of endothelial cell growth/proliferation

Clinical Aspects

Although the field of angiogenesis research is rather new, the first compounds with angiostatic activity (►Anti-angiogenic drug) have been approved by the US Food and Drug Administration [4]. Most of these compounds are based on interference with growth factors produced by the tumor. Avastin is a monoclonal antibody that blocks ►vascular endothelial growth factor. Other currently approved compounds act through inhibition of signaling (kinase-inhibitor function) of growth factor receptors. Other angiogenesis inhibitors that directly act on endothelial cells are currently in development. One of the advantages of anti-angiogenic therapy is believed to be the lack of induction of resistance to the therapy. This is explained by the fact that endothelial cells are genetically stable cells that are considered not to mutate into drug resistant variants. Although this is a beneficial feature of the anti-angiogenic approach, it is expected that inhibitors of angiogenesis will mainly be used in the future in combination with other anti-cancer modalities such as chemotherapy, irradiation and/or ►immunotherapy.

Angiotensin

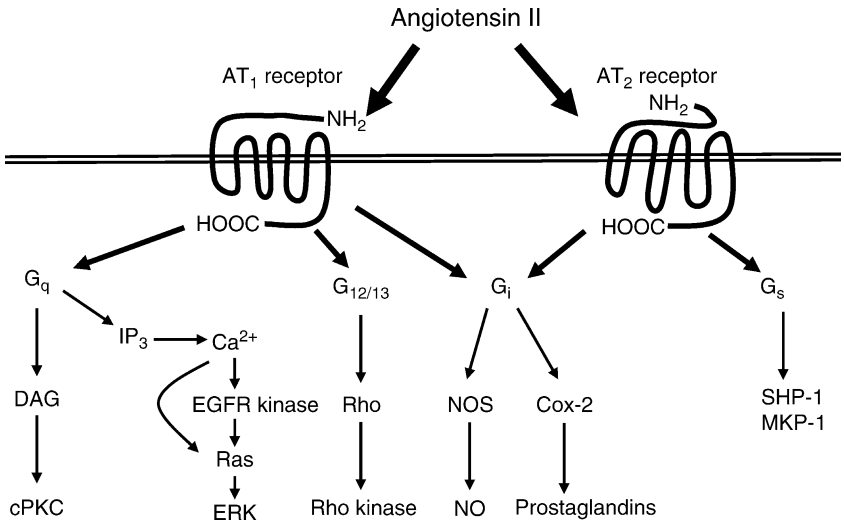
Definition

The angiotensin peptides (angiotensin I, II, III, IV and -(1–7)) are derived from the precursor angiotensinogen by sequential processing proteases such as renin, angiotensin I-converting enzyme (ACE), chymase and other peptidases. Among these peptides, angiotensin II has been well studied and is shown to be the most biologically active peptide. This peptide hormone production system is called the renin-angiotensin system and is one of the phylogenetically oldest hormone systems that has been conserved throughout evolution. The renin-angiotensin system plays a key role in the maintenance of arterial blood pressure and fluid and electrolyte homeostasis. There are two well-defined receptors of angiotensin II (subtype 1 (AT_1) and subtype 2 (AT_2)), both of which are seven trans-membrane, ►G-protein coupled receptors and are encoded by different genes (AT_1 (agtr1), 3q21–25; AT_2 (agtr2), Xq22–23). The major isoform, AT_1 receptor, is expressed in a wide variety of tissues. The AT_2 receptor, the second major isoform, is expressed abundantly in fetal mesenchymal tissues, but its expression decreases significantly immediately after birth. The AT_2 receptor expression level is low in adult tissues but is inducible and functional under pathophysiological conditions. In addition to these angiotensin II receptors, leucyl/cystinyl aminopeptidase and *Mas*-related G-protein coupled receptor member F have been identified as receptors for angiotensin IV and angiotensin-(1–7), respectively.

Characteristics

Angiotensin II Signaling in Carcinogenesis

The renin angiotensin system plays a key role in fluid homeostasis and in blood pressure control. Circulating renin, produced by the juxtaglomerular apparatus of the kidney, and other tissue renin cleaves angiotensinogen to angiotensin I. Angiotensin I-converting enzyme (ACE) catalyzes the subsequent production of the active peptide angiotensin II. Angiotensin II stimulates a variety of biologically important actions, such as vasoconstriction, aldosterone release and cell proliferation. A large portion of these biological actions are executed by locally generated angiotensin II in an autocrine and paracrine manner. The diversity of angiotensin II-induced biological reactions is determined through the expression of two receptors and their coupling with various ►G-proteins. The AT_1 receptor is expressed in a wide variety of tissues and is mainly responsible for most angiotensin II-dependent actions in cardiovascular/renal tissues. The AT_1-mediated angiotensin II signaling stimulates an increase in vasoconstriction (Gq), cardiac hypertrophy (Gq), cell mortality ($G_{12/13}$), nitric oxide (Gi) and ►prostaglandin (Gi) formation (G-proteins in the parenthesis indicate their specific roles, Fig. 1). AT_1-mediated signaling also stimulates production of various growth factors such as ►EGF, basic-FGF, TGF-β and ►VEGF. AT_2 receptor-mediated angiotensin II actions are also diverse, and this diversity is also determined through Gi and Gs protein coupling. Protein tyrosine and serine/threonine



Angiotensin II Signaling. Figure 1 Schematic illustration for diverse angiotensin II signaling.

phosphatase activation (Gs), nitric oxide/cGMP and arachidonic acid/prostaglandin production (Gi) are involved in the mechanism of AT_2 receptor-mediated biological reactions (Fig. 1). The AT_2 receptor can function to counteract AT_1 receptor-mediated angiotensin II bioreactions. However, the AT_1 and AT_2 receptors can also unidirectionally mediate the angiotensin II signal. Angiotensin II also stimulates FGF-2 expression through both the AT_1 and AT_2 receptors. In addition, the AT_2 receptor mediates ►apoptosis in a few types of cells derived from cardiovascular and neuronal tissues *in vitro*.

The stimulation of cell proliferation by angiotensin II-AT_1 signaling has been studied in various cancer cell lines such as ►breast cancer, pancreatic cancer, ►ovarian cancer and prostate cancer. The activation of AT_1 stimulates growth factor pathways such as tyrosine kinase phosphorylation and induces phospholipase C, leading to activation of downstream proteins such as MAPK, JNK and STAT pathways. Furthermore, AT_1 signaling also stimulates ERK1/2 via ►epidermal growth factor receptor (EGFR) transactivation. The AT_1 signaling-induced shedding of heparin-binding EGF by stimulation of metalloproteinases causes the transactivation of EGFR. However, since it is implied that the involvement of transactivation of EGFR by AT_1 signaling is dependent on cell type, pathophysiological significance of angiotensin II-AT_1-dependent EGFR transactivation in carcinogenesis is not yet clear.

Clinical Aspects

Angiotensin II induces the expression of protooncogenes, such as *c-fos* and *c-myc*, and promotes cell proliferation and growth through the AT_1 receptor. AT_1 receptor signaling also stimulates the expression of hypoxia-inducible factor (HIF) 1α and VEGF, which causes resultant neovascularization, a requirement for solid tumor growth. Accordingly, angiotensin II is a mitogenic and pro-angiogenic factor. The AT_1 receptor expression has been shown in the tissues of breast cancer, ovarian cancer, pancreatic cancer, melanoma, prostate cancer and bladder cancer. There is a strong positive relationship between the expression level of the AT_1 receptor and ovarian cancer malignancy and the survival rate of AT_1 positive ovarian cancer patients is significantly lower than the AT_1 negative patients. ACE is also detected in tumor stroma of several types of cancers. These observations suggest that local renin-angiotensin system exists in these various cancer tissues and the AT_1 receptor-mediated angiotensin II signaling may play a significant role in tumor growth. Subcutaneous tumor xenografts in AT_{1a}-KO mice demonstrated that AT_1 signaling in host stromal fibroblasts is also an important regulator of tumor-associated ►angiogenesis. Angiogenesis is an important support mechanism in tumor development. Angiotensin II can directly stimulate capillary network formation by up-regulation of VEGF production in endothelial cells and vascular smooth muscle cells. VEGF is known as a strong angiogenic factor in a variety of cancers. VEGF promotes endothelial cell proliferation, migration and survival. An ACE inhibitor attenuates VEGF-mediated tumor growth, accompanied with the suppression of neovascularization in the tumor and VEGF-induced endothelial cell migration. VEGF expression is up-regulated by AT_1 signaling not only in cancer cells but also in tumor-associated stromal cells including fibroblasts and infiltrated macrophages. Angiotensin II-AT_1 signaling also induces tumor-associated macrophage infiltration. Angiotensin II significantly induced cyclooxygenase-2 (►COX-2) expression in the mouse lung stromal fibroblasts through AT_1 signaling. Prostaglandin E_2, the main product of COX-2 is known to have a

pro-angiogenic effect as well. In fact, the COX-2 inhibitors reduced tumor growth accompanied by an anti-angiogenic effect on tumor tissue. The expression levels of COX-2, and VEGF appears to be tightly associated since VEGF stimulates COX-2 mRNA expression and prostaglandin E_2 increases VEGF mRNA expression in vascular endothelial cells. The COX-2-specific inhibitor suppresses tumor angiogenesis by decreasing VEGF expression in a rat colon cancer model. Furthermore, the selective COX-2 inhibitor Celecoxib and ACE inhibitors or AT_1 receptor antagonists synergistically inhibited colon cancer growth. Accordingly, angiotensin II-AT_1 signaling promotes tumor growth by upregulation of both COX-2 and VEGF expression in cancer cells and stromal cells (Fig. 2).

Attenuation of the AT_1 receptor function by a clinically employed AT_1-specific receptor antagonist has been shown to block lung metastasis of renal cell carcinoma in mice.

A potential mechanism underlying the AT_2 receptor-dependent modification of carcinogen susceptibility appears to be in part due to a modulation of cytochrome P450 expression and stromal fibroblast-dependent support of tumor growth. In addition to angiotensin II receptor blockers, ACE inhibitors retard the growth of cancer cells *in vitro*. ACE inhibitors also inhibit angiogenesis and the growth of tumor xenografts in rats. Therefore, the renin-angiotensin system is an important component in both cancer and cardiovascular diseases.

Epidemiological Study of the Effect of ACE Inhibitors on Cancer Risk

Although the ACE inhibitors (e.g. captopril, lisinopril, enalapril or perindpril) have demonstrated significant anti-tumor effects in *in vitro* studies or animal studies, results of epidemiological studies are not consistent with these studies. In 1998, Lever *et al*. reported that ACE inhibitors decreased the risks of cancer, particularly breast and lung cancer for the first time. However, most of the other epidemiological studies did not find any clear association between ACE inhibitors and risk of cancer. Although it remains unclear the reason for these controversial results, the variety of conditions among studies (the use of different ACE inhibitors, populations, the dose and duration of treatment) might cause these different results. Since angiotensin II is produced not only by ACE but also by other enzymes such as chymase, ACE inhibitors can not completely block the effect of angiotensin II. Therefore, an epidemiological study to determine the association between AT_1 receptor inhibitors and risk of cancer will also be required. Perhaps the most critical issue is that there is no ACE inhibitor or AT_1 receptor blocker case controlled study. There is a strong negative correlation between the expression levels of AT_1 in ovarian cancer tissue and the 5-year survival ratio of patients. Although the sample number is small, this study indicates that angiotensin II signaling has a crucial impact on some types of cancer prognosis. Taken together, angiotensin II signaling is an important component in carcinogenesis and is a potential target for chemoprevention/therapy for various cancers.

Aniline

Definition

Is an aromatic amine. It is a colorless, oily liquid, originally obtained from indigo, a blue dyestuff derived from several plants, by distillation. Today it is largely manufactured from coal tar or nitrobenzene as a base from which many brilliant dyes are made.

Aniridia

Definition
Congenital absence of the iris.

►Nephroblastoma

Ankyrin Repeat

Definition
One of the most common protein–protein interaction motifs. Ankyrin repeats are tandemly repeated modules of about 33 amino acids consisting of two alpha helices separated by loops.

►Gankyrin

ANLL

►Acute Myeloid Leukemia

Ann Arbor Staging System

Definition
Is a staging system for lymphomas, both in Non-Hodghia lympsoma and in Hodghin lymphoma.

Local disease on one side of the diaphragm is stage I-II, on both sides of diaphragm is stage III. Stage IV denotes one or more extranodal sites not contiguous with lymph nodes. A and B denote with or without constitutional symptoms (fever, night sweats, weight loss);

Anoikis

Steven M. Frisch
Mary Babb Randolph Cancer Center and Department of Biochemistry, West Virginia University, Morgantown, WV, USA

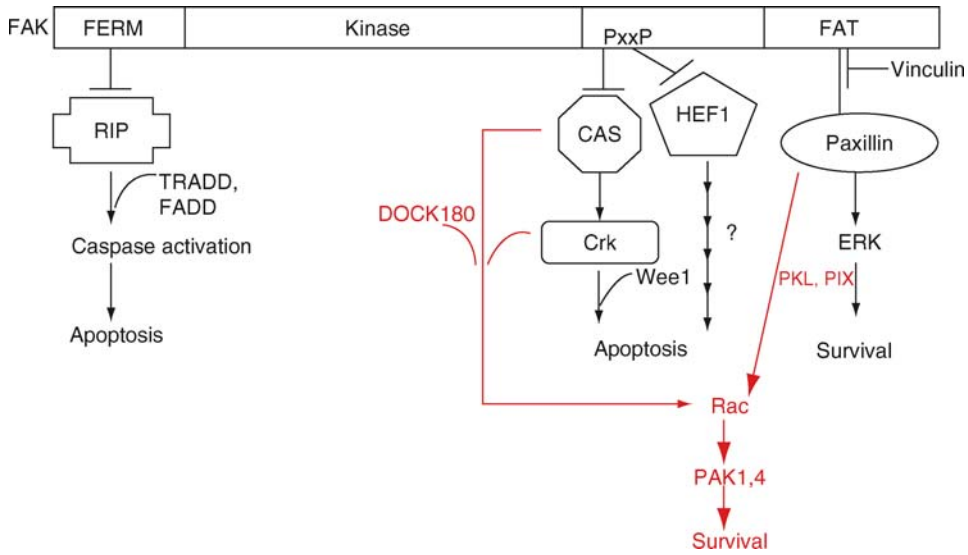
Synonyms
Detachment-induced cell death; Integrin-mediated death

Definition
Apoptosis that is suppressed by extracellular matrix.

Characteristics
Cells that are released from extracellular matrix attachment or cells that are attached to an inappropriate type of matrix are normally programmed to undergo apoptosis. This phenomenon prevents the re-attachment and possible mis-localized colonization of epithelial cells shed during normal turnover, for example, in the gastrointestinal tract. Metastatic tumor cells have undergone genetic or epigenetic changes that invariably render them resistant to anoikis, permitting them to survive during metastasis and underscoring the cancer relevance of this phenomenon. Anoikis is primarily a property of epithelial and endothelial cells, and the epithelial-to-mesenchymal transition (EMT) of tumor cells is accompanied by resistance to anoikis. Accordingly, many activated oncogenes confer anoikis-resistance.

Mechanisms
The prevailing current opinion is that anoikis occurs when survival signaling by ligated integrins is interrupted. An alternative, non-mutually exclusive mechanism is that unligated integrins may also trigger apoptosis by recruiting and activating certain caspases, a phenomenon that has been termed "Integrin-Mediated Death/IMD." However, the data to support this latter view are incomplete at present. This effect, if eventually demonstrated, would represent a novel mechanistic explanation of anoikis.

Survival signaling by integrins is complex. Two pivotal effectors are the ERK sub-family of MAP-kinases and the kinase known as Akt/PKB. ERKs can promote cell survival through several different effects, including: (i) phosphorylation and inactivation of the pro-apoptotic action of the Bcl-2 family member BAD; (ii) down-regulation of the pro-apoptotic Bcl-2 family member Bim and up-regulation of Bcl-xl; (iii) phosphorylation and inactivation of caspase-9. Akt activates several other survival pathways, through other effects: a. inactivation of Glycogen Synthase Kinase-3, which regulates both Wnt/APC/beta-catenin/LEF-1 signaling as well as certain pro-apoptotic transcription factors; b. activation of the pro-survival transcription factor complex NF-kB;



Anoikis. Figure 1 A partial diagram of mechanisms by which FAK promotes cell survival, counteracting anoikis.

c. inactivation of the p73-associated co-factor, YAP; (iv) phosphorylation and inactivation of caspase-9.

Upstream of these kinases, Focal Adhesion Kinase (FAK) contributes substantially to integrin-mediated cell survival. Epithelial cells containing a constitutively active FAK construct are resistant to anoikis, and many human tumors over-express FAK protein. Thus, FAK is considered a potential anti-cancer drug target.

FAK, usually in a complex with c-src, can activate ERKs through several pathways, including: (i) by binding paxillin and augmenting signaling through p21-activated kinase (PAK), the p130cas/crk complex and an exchange factor (PIX) for rac-related GTPases, which are, in turn, important factors in determining anoikis-sensitivity; (ii) by activating the Ras/Raf/MEK/ERK pathway through Grb2/sos1 interaction. FAK can also activate PI3-kinase, activating Akt. FAK can also rescue cells from anoikis by inactivating the pro-apoptotic activity of RIP1, a death receptor adaptor protein. The multiple pathways by which FAK counteracts anoikis are diagrammed in Fig. 1.

Certain Bcl-2 family members now have an established role in anoikis. Although the translocation of Bax to mitochondria occurs in detached cells, a recent report shows that it is the conformational change of Bax rather than its translocation per se that is rate-limiting. Mitochondrial permeabilization by Bax is regulated by several factors, including the "BH3 domain-only" Bcl-2 family members, Bim and Bmf. Both of these latter factors play an important role in anoikis, and they are both regulated transcriptionally as well as post-translationally by their association/dissociation with respect to the actin cytoskeleton.

Several highly cancer relevant genes have been implicated in regulating anoikis recently, two of which are non-integrin proteins involved in cell adhesion and one is a receptor. First, E-cadherin is a major invasion suppressor protein involved in epithelial cell-cell adhesion that is frequently down-regulated in carcinoma cells. Interestingly, mouse genetics data show that cells lacking E-cadherin (in a p53-null background) are resistant to anoikis, indicating that epithelial cells are normally sensitized to anoikis through E-cadherin-mediated cell interactions. This has important implications for the mechanism by which EMT allows tumor cells to resist anoikis.

Second, the neurotrophin receptor protein, trkB, that is over-expressed in pancreatic and prostate tumors, is a potent activator of the PI3-kinase/Akt pathway and thus renders these tumor cells resistant to anoikis, providing an opportunity for trkB-based therapy.

The third is carcinoembryonic antigen (CEA), which is over-expressed on the surface of a variety of tumor cells, appears to program tumor cells to resist anoikis by causing integrin clustering and ensuing survival signaling.

Finally, the Integrin-Linked Kinase (ILK) plays an important role in anoikis because it potently activates Akt as well as promoting EMT, both of which counteract cell death strongly; it also links integrin and growth factor receptor signaling.

Anoikis

Definition

The disruption of interactions between extracellular matrix and specific cognate integrins triggers apoptosis in epithelial cells, in a process termed "anoikis."

►Stem Cells

Anomalous Pancreaticobiliary Ductal Junction

Definition

APBDJ is a congenital malformation at the level of the confluence of the pancreatic and bile ducts. In this disease, the absence of a septum between the ducts results in the formation of a common channel for the bile and pancreatic fluid. APBDJ is classified as three types: a bp type, in which the insertion of the bile ducts is in the pancreatic duct; a pb type, in which the pancreatic duct joins the common bile duct; a Y type, in which there is a long common channel.

►Lysophosphatidylcholine

Anorexia

Definition

Loss of appetite.

[2]University of Oxford, Cancer Research UK, Weatherall Institute of Molecular Medicine, John Radcliffe Hospital, Headington, Oxford, UK

Synonyms

Hypoxia; Severe hypoxia; Extreme hypoxia

Definition

Literal definition. Anoxia literally means absence of oxygen (O_2), and has been described as the state where no O_2 (0% O_2) is detected in the tissue.

Conceptual definition. Anoxia has been referred to as extremely low levels of oxygen that trigger secondary responses, additional to the adaptive response of cells to hypoxia, which means low levels of oxygen supply to tissues. Cellular fates in hypoxia can be death, survival, continued proliferation, quiescence, senescence, differentiation, which would depend on the severity of hypoxia and the genetic background of the cell type.

Hypoxia is essentially a functional definition, because there are marked normal differences in the body in oxygen tension, e.g. venous versus arterial circulations in general, but renal medulla arteries have much lower pO_2 than pulmonary veins. Thus a decrease in the normal O_2 for a tissue or organ, sufficient to induce a molecular or physiological response would be an operational definition.

The distinction of terminology between hypoxia and anoxia is important because in hypoxia cells have a much better chance to adapt and survive compared to anoxia. The key biological differences relate to the pathways induced, the much greater death rate, and absence of oxygen in anoxia versus hypoxia.

Characteristics

Oxygen is absolutely essential for life, so the molecular mechanisms underlying responses to low oxygen are central to the cell. The cell has to be able to sense the level of oxygen present so to respond appropriately. For example, when the cell senses hypoxia, such as during intensive exercise, signaling pathways of anaerobic metabolism are switched on, which enables the cell to produce energy and survive under anaerobic conditions, and can be considered as a normal physiological process. This is via the ►hypoxia inducible factor 1 (HIF) pathway.

From a medical point of view, anaerobic metabolism as a consequence of hypoxia is not identical with a pathological situation of anoxia, as exemplified by the oxygen deficit accumulated through extreme exercise. Therefore, it would be important for cells to discriminate and distinguish between hypoxia and anoxia. Whereas the consequences of hypoxia are that of an adaptive response, which ensure cellular survival, the consequences of anoxia could initially be survival, but followed eventually by cell death with time, where cells cannot adapt anymore.

Experiments performed with *Caenorhabtitis elegans* have demonstrated that sensing anoxia is a separate pathway to sensing and adapting to hypoxia. Such distinction between hypoxia and anoxia is also conserved in mammals. It is now well established that tumors also contain areas of hypoxia and anoxia, and the phenomenon of sensing and discriminating between hypoxia and anoxia has recently been emerged and demonstrated in cancer cells and tumors.

In vitro Creation of Hypoxia and Anoxia

Several units have been used to describe the amount of oxygen present. It has been proposed that the partial pressure of oxygen be given in the SI unit kiloPascal (kPa (1,000 N/m^2)) to be in line with international

agreements. 1 kPa equals 10 Bar or 7.5 Torr (or mmHg where 760 mmHg equals 100% O_2). In gas mixtures containing 10,000 ppm (parts per million) of oxygen, the partial pressure is 1 kPa. Most reports have used the unit mmHg or % O_2 to refer to the amount of oxygen used in experiments. The use of ambient air has been referred to the "normal oxygen tension" (normal levels of oxygen) or normoxia as means of control, to which hypoxia is compared to. Typically, experiments testing the effects of hypoxia tend to culture cells in incubators with a gas mix of 5% CO_2 and 95% N_2 until the desired level of hypoxia is reached. The hypoxic cells are then compared to cells cultured in normoxic incubators (normoxia, which is defined as 21% O_2) which consist of ambient air and 5% CO_2.

Anoxia has been achieved in vitro by using incubators with an atmosphere of 5% CO_2, 90% N_2, 5% H_2 and a palladium catalyst to scavenge traces of oxygen. Alternatively, a continuous flow of 95% N_2 and 5% CO_2 has been used. Such conditions have achieved O_2 levels lower than 0.1% and even 0.001% O_2 in tissue cultures of moderate to low cell density, and therefore anoxia has been addressed as O_2 levels <0.1 or 0.001% in several publications.

In vitro normoxia, defined as 21% O_2 (160 mmHg, pO_2), is at least 4 times higher than the physiological in vivo normoxia in most arterial beds. Therefore it has been proposed to make in vivo conditions the standard against which in vitro values should be measured. In venous blood, there is an average 5.3% O_2 (or 40 mmHg O_2), and while some tissues have higher than average oxygen levels, in some tissues (and especially solid tumors) oxygen levels are lower than the average. 21% O_2 is not physiological, especially for tumors where oxygen levels of around 1% (5–10 mmHg) can be a borderline between well and poorly oxygenated tumors. Thus, normally oxygenated (>10 mmHg or 1% O_2) tumors are mostly hypoxic compared to in vitro conditions of 21% O_2, and express HIF1, indicating that many tumors live under hypoxia. The in vitro conditions of hypoxia and anoxia coincide well with oxygen measurements performed with polarographic O_2 electrode needles on patient tumors, which have demonstrated extremely low levels of oxygen such as <2.5 mmHg (<0.3% O_2), including 0 mmHg (0% O_2).

Causes and Consequences of Tumor Anoxia

Areas of low oxygen in tumors may be a consequence of several mechanisms such as abnormal tumor vasculature, limited tissue perfusion, and tumor-associated or therapy-associated ►anemia leading to a reduced oxygen transport capacity of the blood. Over the past decade, clinical studies with oxygen electrodes and molecular markers have shown oxygenation patterns in human tumors to be heterogeneous with respect to the severity and duration of exposure to levels of low oxygen, ranging from 10 mmHg to below 2.5 mmHg including 0 mmHg.

Two types of tumor hypoxia (which if prolonged or severe will lead to anoxia) can be distinguished: perfusion-limited and diffusion-limited hypoxia. Hypoxia will precede anoxia and consequently anoxic tissues will have had induction of hypoxic pathways too. Perfusion-limited or acute hypoxia/anoxia is transient and may be a result of severe structural and functional abnormalities of the tumor microvessels. These abnormalities cause disturbance in the blood supply, leading to temporal shutdown of vessels, gradients of oxygen and nutrients, and even reversal of blood flow. Lack of oxygen can also be caused by an increase in diffusion distances between cells and O_2, resulting in diffusion-limited O_2 supply, leaving cells chronically deprived of oxygen and other nutrients. Over this course of chronic hypoxia and/or anoxia some cells die, but some survive due to mutations in death pathways. This results in areas of ►necrosis that demarcate areas of hypoxia and anoxia, also termed perinecrotic region.

Whereas adaptation to hypoxia is a survival mechanism, anoxia can result in cell death, and has been viewed by some as a protective mechanism to prevent possible cellular transformation associated with anoxic cellular damage. Control of gene expression during anoxia is emerging as an important cellular response, distinct from the response to hypoxia. One feature of cancer is that tumor cells can escape the death pathway of hypoxia and anoxia, attributed to defects in several death pathways, and/or activation of survival pathways. Escaping anoxic cell death could result in selection of cells that have diminished death potential, which results in a more aggressive and therapy resistant tumor type.

The HIF and p53 Interaction Relevant to the Hypoxic and Anoxic Cellular Fate

Under tissue culture normoxia the transcription factor HIF-1α is unstable, degraded and virtually undetectable. As soon as cells experience hypoxia, HIF1α is rapidly stabilized and induced (see hypoxia chapter), regulating majority of the adaptive/survival genes such as glycolytic enzymes and ►VEGF. HIF1α is also induced by anoxia, but several reports have shown that prolonged anoxia results in downregulation of HIF1α in vitro. This in vitro finding has also been observed in some human tumors, which have shown lack of HIF1α expression in perinecrotic anoxic regions. Of some importance to this understanding is the interplay between HIF-1α and the pro-apoptotic transcription factor/tumor suppressor p53.

p53 is expressed at low levels in unstressed cells due to degradation by the ►proteasome. Upon exposure to extremely low levels of oxygen, termed severe hypoxia, close to or equivalent with anoxia, p53 is stabilized,

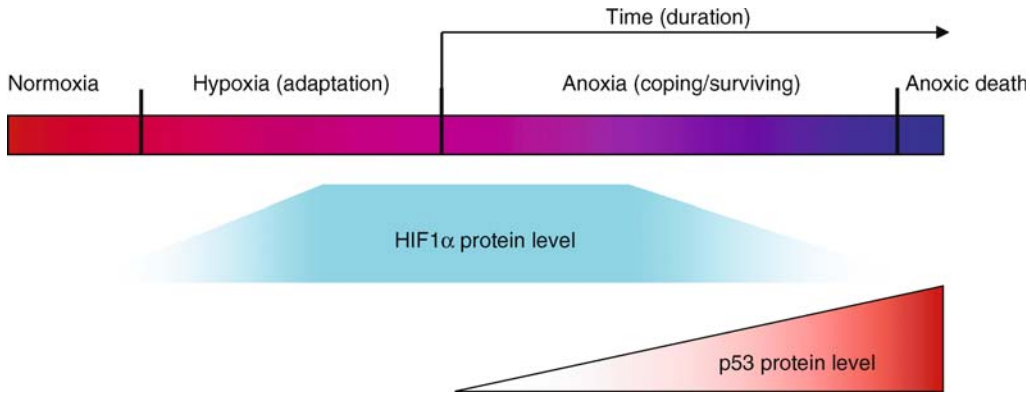
becomes active and facilitates cell death. There has been evidence that HIF1α can interact/bind together with p53, and it has been suggested that p53 accumulation does not overlap with HIF1α accumulation in response to hypoxia but rather to a prolonged period of severe hypoxia or anoxia. Accumulation of p53 in severe hypoxia/anoxia has been shown to both inhibit HIF1α transcriptional activity and reduce the HIF1α protein levels, which might explain why some reports have observed HIF1α levels to decline under prolonged anoxia. This scenario might have implications for prolonged anoxia-induced cell death. In hypoxia, transactivation of HIF1α could serve to protect cells enabling adaptation and survival. In anoxia, inhibition and destruction of HIF1α via p53 may result in a switch from an adaptive hypoxic response into an anoxic death response (Fig. 1). This HIF1α-p53 interactive pathway is one potential mechanism that could determine cellular fate when hypoxia and anoxia need to be discriminated by the cell. This cellular fate of hypoxia versus anoxia can become deregulated in cancer. Tumor cells defective in p53 can escape the anoxic death, and endure longer periods of anoxia, resulting in selection of more aggressive cancer cells.

Oxygen Sensing/Signaling Pathways Relevant to Anoxia

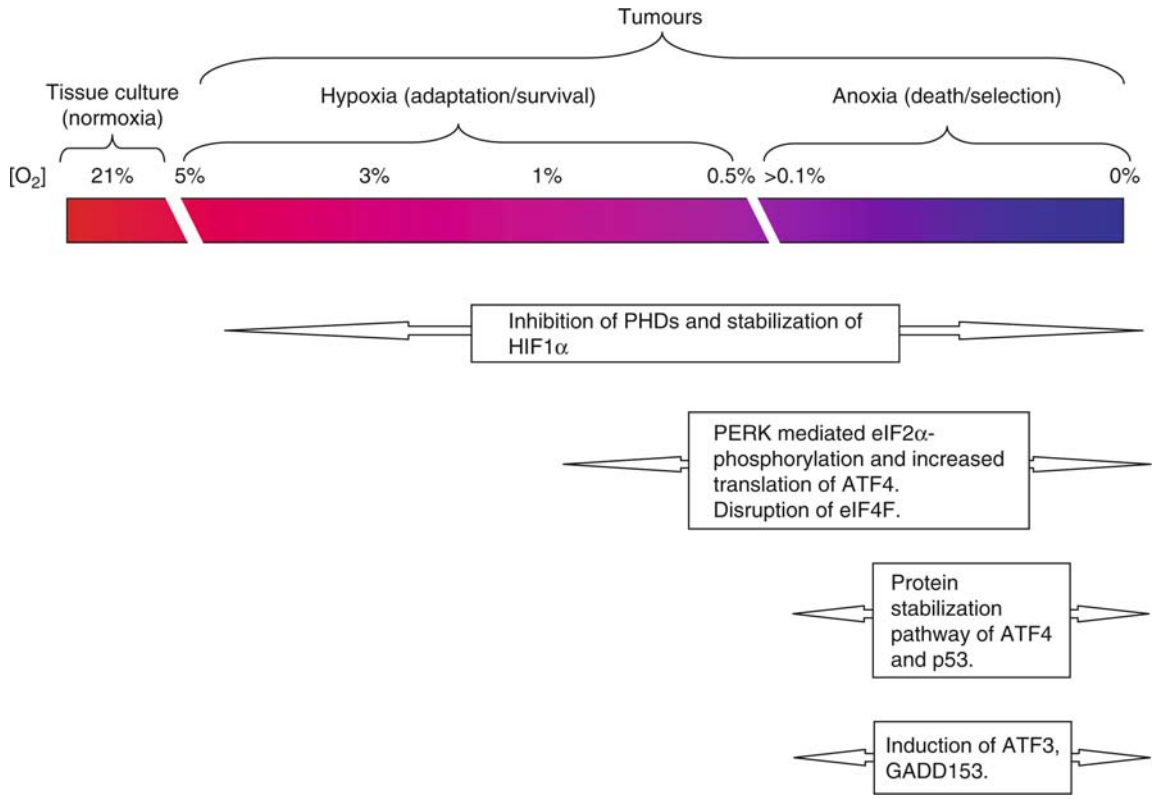
Several distinct oxygen sensing/signaling pathways have been discovered that together determine the cellular response to hypoxia and anoxia. The best characterized of these is a transcriptional response initiated by oxygen-dependent stabilization of HIF1α in hypoxia and anoxia. The stability of HIF1α and its transcriptional activity are regulated by oxygen-dependent hydroxylation of specific amino acid residues. Hydroxylation at two prolyl residues (Pro 402 and Pro 564 in human HIF1α) enables interaction of HIF1α with the von Hippel-Lindau protein (pVHL) that targets HIF1α to proteasomal degradation. These hydroxylations are catalyzed by a series of three closely related HIF prolyl hydroxylases, known as orthologs of C. elegans Egl-9, designated as PH (prolyl hydroxylase) domain containing enzymes (PHD), i.e. prolyl hydroxylases (PHD1, PHD2, PHD3). Transcriptional activity of HIF1α is controlled by hydroxylation of an asparaginyl residue (Asn 803 in human HIF1α), catalyzed by a HIF asparaginyl hydroxylase, also termed factor inhibiting HIF (FIH). Hydroxylation at this site blocks transcriptional activation. The HIF hydroxylases are all iron (II)- and 2 oxoglutarate dependent dioxygenases that have an absolute requirement for molecular oxygen. In hypoxia and anoxia, therefore, hydroxylation is reduced, which allows HIF1α to accumulate by escaping proteasomal degradation. The PHDs could be considered as O_2 sensors of the hypoxia and anoxia HIF1α pathway (Fig. 2).

Anoxia results in induction of several factors including the ATF/CREB (activating transcription factor/cyclic AMP response element binding protein) family of basic region-leucine zipper (bZip) transcription factors such as ATF3 and ATF4, the CCAAT/enhancer binding protein (C/EBP) transcription factor family member ►GADD153, and the transcription factor ►XBP1. Such anoxic response is independent of HIF1α and is mediated by the ►unfolded protein response (UPR), which activates the ►PERK kinase, ►IRE1 and ►ATF6, and takes place after the hypoxic HIF response (Fig. 2). The signaling from downstream effectors of IRE1, PERK and ATF6 merges in the nucleus to activate transcription of UPR target genes.

The regulation of mRNA translation has emerged as an important mediator of the cellular response to hypoxia and anoxia. Distinct mechanisms of translational control have shown to discriminate between initial and prolonged conditions of in vitro generated anoxia. Anoxia results in inhibition of global mRNA



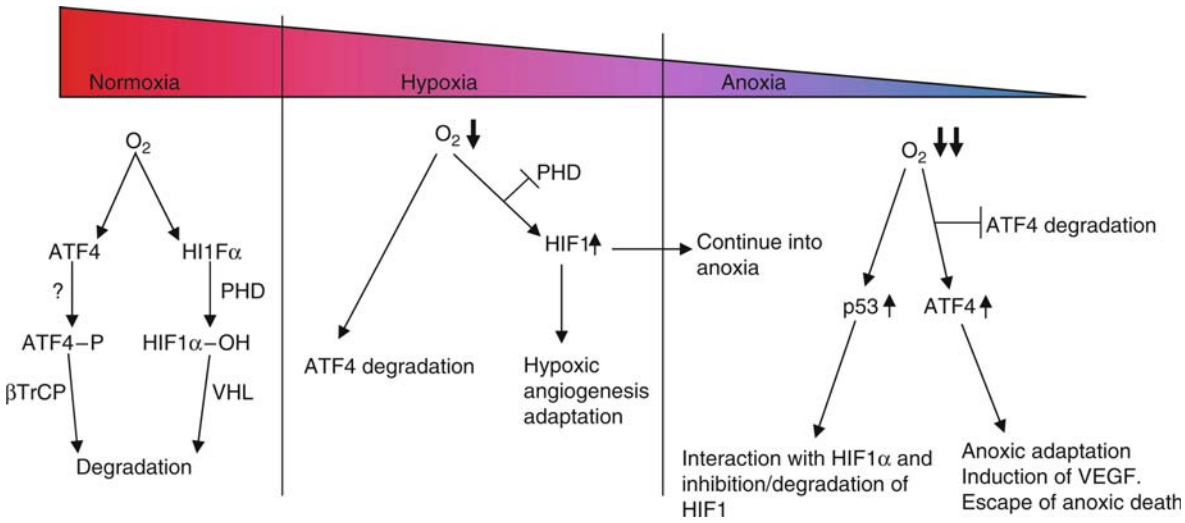
Anoxia. Figure 1 Proposed model (adapted from Schmid T et al [5]) showing the relation of HIF1α and p53 in hypoxia and anoxia. Hypoxic activation of HIF1α is attenuated when p53 starts to accumulate. With progressing time under anoxia p53 accumulates further and promotes HIF1α destruction. Cell survival versus apoptosis is one distinction between extreme end points of hypoxia and anoxia.



Anoxia. Figure 2 Oxygenated tumors are mostly hypoxic compared to in vitro conditions of 21% O_2 and express HIF1α over a broad range of oxygen level, which is sensed primarily by PHDs. Secondary responses, after the induction of HIF1α in hypoxia, include translational control and protein stabilization pathways, which are more specific to sensing anoxia, rather than hypoxia, and can result in induction of factors such as ATF3, ATF4, and GADD153.

translation, which is a biphasic response. A central mediator of the initial translational response to anoxia is phosphorylation of the ►eukaryotic initiation factor 2α (eIF2α) by PERK protein kinase. Phosphorylation of eIF2α in anoxia is extremely rapid, whereas under hypoxia eIF2α is phosphorylated to a smaller degree, and requires prolonged hypoxic exposure. Cells can also distinguish between initial and prolonged anoxia by eliciting a biphasic inhibition of translation. The first phase is due to transient eIF2α phosphorylation, and the second phase of translation inhibition correlates with disruption of the cap binding complex eIF4F. The initial anoxic response of translational inhibition may be important during acute anoxia in tumors, which could be important for enduring anoxia. Although the phosphorylation of eIF2α results in global translational reduction, it specifically induces/increases the translation of ATF4 mRNA, subsequently increasing ATF4 protein levels, which is important for anoxia survival. Indeed, acute anoxic stress (2 h) has shown to be capable of eliciting a cytoprotective pathway, improving the survival of transformed cells following prolonged anoxic stress (24 h), resulting in the clonogenic outgrowth of a population of adapted cells.

Another important mediator of the cellular response to anoxia may be protein stabilization pathways. HIF1α is stabilized and induced rapidly at hypoxic conditions of 5% O_2. Upon reoxygenation it is rapidly degraded. In contrast to HIF1α, the transcription factor ATF4 is not induced by such hypoxic conditions, but is induced by anoxia (Figs. 2 and 3). Like HIF1α, ATF4 protein is unstable and degraded in presence of oxygen. Therefore, modulation of protein degradation pathways seems to be part of a sensing mechanism of both hypoxia and anoxia, but whereas the PHD pathway of HIF1α degradation is blocked in hypoxia, hypoxic degradation of ATF4 is still active. The exact mechanism of ATF4 stabilization in anoxia remains unclear, but under normal oxygen levels of tissue culture ATF4 is degraded by two mechanisms: (i) ATF4 stability modulated by the ►$SCF^{\beta TrCP}$ class of ubiquitin ligase and (ii) ATF4 stability modulated by the histone acetyltransferase p300 (HAT p300). ATF4 contains the βTrCP recognition motif DSGXX(X)S and when the serine of this motif is phosphorylated it results in interaction with βTrCP and subsequent degradation by the proteasome. Histone acetyltransferase p300 induces ATF4 stabilization by inhibiting ATF4/βTrCP



Anoxia. Figure 3 Diagram demonstrating similarities and differences between HIF1α and ATF4 in discriminating between hypoxia and anoxia. Whereas both HIF1α and ATF4 are degraded in normoxia, only HIF1α is induced in hypoxia, whereas ATF4 and p53 are induced in anoxia. In all cases, different protein degradation pathways are involved. Which kinase phosphorylates ATF4 with subsequent recognition by βTrCP targeting ATF4 to proteasomal degradation remains unknown and is shown as?

interaction and subsequent degradation. How this relates to anoxic stabilization of ATF4 remains unknown (Fig. 3). Other mediators of the cellular response to anoxia include mRNA stability pathways and the ►MAPK pathway. The transcription factor ATF3 has been shown to be induced by anoxia. PHDs have been suggested to be potentially involved in regulation of ATF3 induction in anoxia, but a precise role remains unclear. ATF3 mRNA has been shown to be more stable in anoxia compared to normoxia, and translation of ATF3 is also increased in anoxia in a PERK dependent manner. Induction of ATF3 in MKK7 knock-out primary mouse embryonic fibroblasts is fully blocked, which has suggested that the MKK7 pathway might be part of mediating the induction of ATF3 in anoxia. Thus, multiple pathways can converge into regulating ATF3 in anoxia.

Therapeutic Implications of Anoxia

Hypoxia and anoxia are known to directly or indirectly confer resistance to X- and gamma-radiation, and some chemotherapies leading to treatment failures. Many classical radiobiological studies have shown that anoxic cells (O_2 below 0.5 mmHg) are maximally resistant to the lethal effects of irradiation. Therefore, both hypoxia and anoxia are therapeutic problems.

Factors that are induced by anoxia, such as ATF3 and ATF4 have shown to be potentially involved in ►tubulogenesis, induction of VEGF and ►angiogenesis, cell survival, and metastasis. In response to anoxia, protein synthesis is decreased by 60–70% within 1 h, and remains significantly repressed for up to 24 h, but is completely reversible upon reoxygenation. Hence, in anoxia some cells might survive, be selected for and continue to grow upon reoxygenation. Indeed, cells that lack downstream targets of PERK (for example ATF4) and IRE1 (for example XBP1) have shown to be sensitive to anoxia compared to wt cells that contain ATF4 or XBP1. Such anoxic survival is not entirely dependent on HIF1, and cells that are deficient in HIF1 are not more sensitive to anoxia compared to wt cells that contain HIF1. Thus, downstream targets of PERK and IRE1 are important for surviving and adapting to anoxia, as apposed to hypoxia where HIF1 mediates the major survival pathway. Targeting HIF1 alone might select for more aggressive cells with an intact anoxic response pathway.

In addition to hypoxia, anoxia might confer a total separate drug resistance pathway to hypoxia. For example, overexpression of the anoxic factor ATF4 has shown to result in multidrug resistance, and hence, cells under anoxia that induce ATF4 may become selected to a treatment resistance phenotype, if only the hypoxia cascade of HIF1α is targeted.

Ansamycin Class of Natural Product Hsp90 Inhibitors

Hong Zhang, Lin Zhang
Biogen Idec, San Diego, CA, USA

Synonyms

Benzoquinone ansamycin; Geldanamycin; GM

Definition

Ansamycins are a family of antibiotics with antitumor activity. These include geldanamycin (GM), herbimycin A and the macbecins, all of which contain benzoquinone structures. These antibiotics induce tumor cell death via inhibition of the heat shock protein 90 (►Hsp90) chaperone complex and induce the degradation of key client proteins that are required for tumor survival.

Characteristics

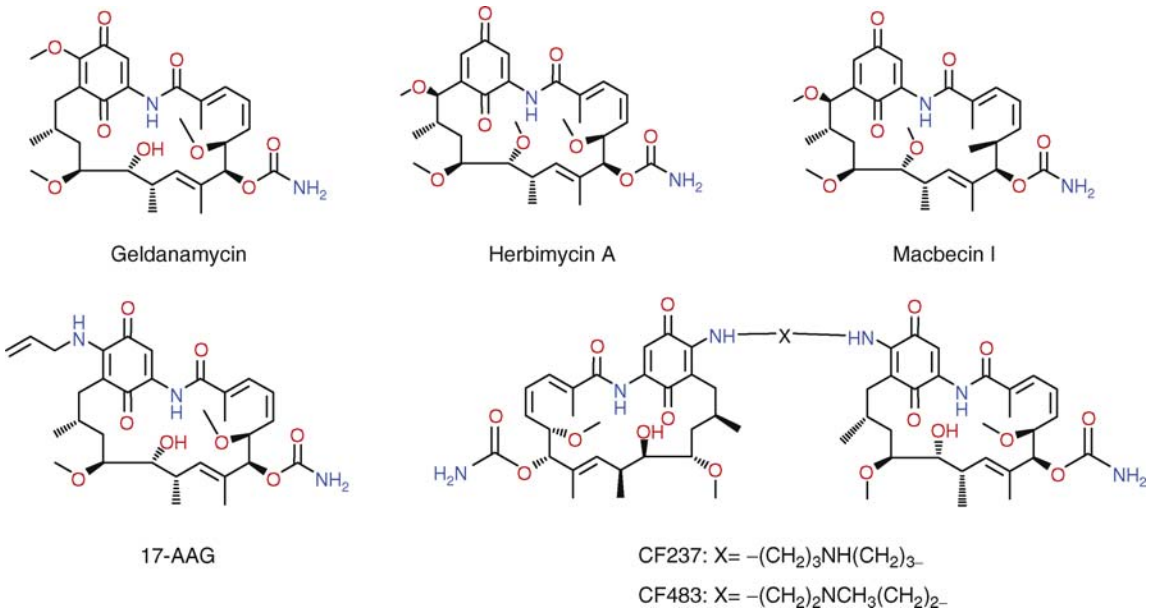
Ansamycins, especially benzoquinone ansamycins, such as herbimycin and geldanamycin, were the first natural product Hsp90 inhibitors identified. Both molecules contain a benzoquinone moiety, which distinguishes them from other ansamycins and confers selectivity for Hsp90 inhibition. Since discovery, these molecules have been widely explored due to their broad-spectrum antitumor activity.

Benzoquinone ansamycins were initially discovered as naturally occurring antibiotics in the fermentation broth of Streptomyces *hygroscopicus* in 1970, with activity against the growth and development of protozoa. Later studies revealed that these molecules possess anti-tumor activity due to their ability to reverse v-Src-induced transformation in cells. However, no direct effect on v-Src was observed *in vitro* experiments, suggesting that they worked by targeting some other factors and indirectly affected v-Src activity. Affinity purification with immobilized GM as bait demonstrated that these molecules exert their function by binding to the Hsp90 chaperone complex and that v-Src activity was blocked because v-Src is an Hsp90 "client" protein that is dependent upon the chaperone for stability and/or function. Co-crystallization of Hsp90 and GM at later time demonstrated that GM bound tightly to the ATP-binding pocket of Hsp90 at the N-terminal of the protein, therefore confirmed that Hsp90 is the true target of benzoquinoid ansamycins.

As the first Hsp90 inhibitor, GM has proved to be of great value in identifying new Hsp90 client proteins and in understanding the biology of Hsp90. Hsp90 is a conserved molecular chaperone that mediates the maturation and stability of a set of cancer-associated proteins which are crucial in oncogenesis. These proteins are collectively referred to as "clients," the members of which are continually growing and include a wide variety of key proteins and kinases that are crucial for carcinogenesis, such as steroid receptors, EGFR family members, IGFR, c-MET, Raf-1 kinase, AKT, Bcr-abl, mutant p53, CDK4 and many other oncogenic molecules. Hsp90 functions as a super-chaperone complex in association with various co-chaperones. Binding of GM or its derivatives to Hsp90 disrupts the complex and sends the dependent client proteins to be degraded in proteasome. This results in simultaneous interruption of many signal transduction pathways and eventually leads to cell death, especially in tumors whose survival and growth depend on Hsp90 client proteins.

Anti-Tumor Activity

Numerous studies with GM demonstrated that the molecule had significant anti-tumor activity *in vitro* and in human xenograft models. However, the molecule also exhibited intolerable hepatotoxicity in animals, rendering it unsuitable for clinical development. Subsequent screening among GM derivatives led to the identification of 17-allyamino-17-demethoxygeldanamycin (17-AAG), that differs from GM at the 17-position (Fig. 1). The co-crystal structure of GM bound to Hsp90 revealed that the quinine ring binds Hsp90 towards the surface of the protein, leaving the 17-position at the entrance of the pocket. This suggested that modification of this position would not affect its anti-tumor activity. Indeed, 17-AAG retained the antiproliferative ability of GM and demonstrated broad-spectrum cytotoxicity against the NCI60 panel. In animal studies, 17-AAG showed reduced hepatotoxicity, but comparable



Ansamycin Class of Natural Product Hsp90 Inhibitors. Figure 1 Benzoquinone ansamycins and its derivatives.

anti-tumor activity. Furthermore, 17-AAG exhibited selectivity for cancerous versus normal tissue where it preferentially bound to the Hsp90 complex in tumors and thus accumulate to high concentration. 17-AAG became the first HSP90 inhibitor to enter clinical trials in cancer patients in NCI-sponsored phase I studies in 2001. The drug was generally well tolerated. Hepatotoxicity was dose-limiting and may be in part related to formulation. Clinical activity has been observed in patients treated with 17-AAG both as a single agent and in combination with trastuzumab, bortezomib or standard chemotherapeutic agents. The responsive tumor types include myeloma, breast cancer, prostate, lung, melanoma, GIST and acute myeloid leukemia. The drug is currently under phase III investigation.

Although 17-AAG is promising in clinical trials, it is poorly soluble, difficult to formulate and has limited bioavailability. Numerous efforts have been made to overcome these problems, including formulation optimization, such as KOS-953, a cremophor-based formulation of 17-AAG, and CNF1010, a nanoemulsion of 17-AAG. Alternatively, more soluble ansamycin analogs, including 17-DMAG and IPI-504 (a quinine reduced form of 17-AAG), are also under phase I evaluation. Although phase I trials are not designed for examining antitumor activities, responses from patients have been observed. Apart from ansamycin derivatives, several companies have also developed small molecule inhibitors with totally novel chemical structures, which are either in early clinical or late discovery stages.

During the development of Hsp90 inhibitors, we also noticed that 17-AAG showed a limited duration of its effects on target proteins and lost antiproliferative activity precipitously under conditions of brief cellular exposure. Since active Hsp90 exists as obligate dimer and the two ATP binding sites are in close apposition in the multichaperone complex, we reasoned that two GM moieties separated by an optimized flexible linker might be able to engage both ATP sites simultaneously and may therefore inhibit Hsp90 more efficiently. GM dimers were originally reported by Zheng FF et al. These early compounds were relatively weak Hsp90 inhibitors that primarily induced the degradation of the most sensitive Hsp90 client, HER-2, but were largely ineffective on other clients. By screening an internally generated library of GM dimers linked at 17-position, we identified some active dimeric ansamycins, represented by CF237 and CF483 (Fig. 1), which readily cause Hsp90 inhibition and client protein degradation. The dimers are more potent under conditions of limited exposure compared to 17-AAG, whose biochemical and cellular effects were relative transient. This presumably results from continuous binding of dimeric compounds to dimeric Hsp90, as dissociation does not occur until both GM moieties dissociate from their binding sites concomitantly. This long-lived binding leads to prolonged biological activity in tumor cells even after the compound was removed, a situation which more closely reflects physiological conditions. Indeed, dimer-treated cells displayed markedly reduced client protein levels for at least 48 h after drug removal; in comparison, 17-AAG induced only transient suppression of the same clients and the pathways they control. The dimers were also retained for longer in tumor xenografts and displayed superior antitumor activity in vivo, especially when the drugs were given at long intervals.

Dimeric drugs with improved biological activity have been reported. Vancomycin dimers show enhanced antibiotic effect against both susceptible and drug-resistant gram-positive bacteria than that of the parent monomer. In a mammalian system, longer-acting bivalent modulators against dimerizing target, G-protein-coupled β2-adrenergic receptor, was also recorded. The binding of high-affinity dimeric Hsp90 inhibitors to their target may be essentially irreversible, but these compounds do not form covalent adducts with the Hsp90. Therefore, they should not inherit the drawbacks of irreversible inhibitors, which can result in increased toxicity. Indeed, the dimeric ansamycin was well tolerated at effective doses in xenograft studies. Moreover, the prolonged acting of dimeric compounds on Hsp90 may increase the range of susceptible tumors due to sustained inhibition of the target. For example, both CF237 and CF483 are active in Rb negative and Bcl-2 overexpressing cells, while 17-AAG is not. It is believed that continuous suppression of client proteins induced by dimers depletes the essential elements for survival and leaves no field for the activated oncoprotein to carry out its function. All these results indicate that monomeric and dimeric ►Hsp90 inhibitors have distinct biological profiles and work differentially toward target inhibition. However, on the other side of the coin, the greater mass of dimeric compounds (~1,200 kDa) would likely retard their permeation through the tightly packed cells and fibrous stroma that characterize solid tumor masses. Similarly, the slow dissociation of dimers from their target would not favor penetration of the drug to distant extravascular sites. Although activity was observed with CF237 and CF483 in solid tumors in preclinical models, the limitations should be considered for future applications.

Since cancer cells normally accumulate multiple mutations, inhibition of single pathway is usually not sufficient to suppress tumor growth. Therefore targeting Hsp90 and hence its chaperoned proteins and pathways becomes increasingly intriguing in cancer therapy. In addition, tumor cells frequently develop resistance by mutating the target protein and escaping apoptotic cell death. It is becoming clear that mutant oncoproteins are more reliant on Hsp90 for maturation and function, thus making Hsp90 inhibitors particularly attractive in resistant tumors and in the scenario where tumor growth is driven by mutated client proteins, such as mutant EGFR in non small cell lung cancer or mutant BRaf in melanoma, even though the wild type counterparts of these two proteins are not Hsp90 clients.

The promising results from 17-AAG and its derivatives in clinical trials are encouraging researchers to develop more potent Hsp90 inhibitors. The beneficial effect of novel drugs with diverse chemical structures has to be determined clinically, and in turn, clinical results will drive the design of superior generations of Hsp90 inhibitors.

Anterior Pituitary Gland

Definition

The pituitary gland which is a master-regulatory endocrine gland situated in the pituitary fossa of one of the skull bones referred to as the sphenoid, consists of two parts that are called the anterior and posterior pituitary. The anterior pituitary secretes hormones that include, prolactin, thyroid stimulating hormone (TSH),

growth hormone (GH), adrenocorticotrophin (ACTH), luteinising hormone (LH), and follicle stimulating hormone (FSH).

►Multiple Endocrine Neoplasia Type 1

ANTH

Definition

AP180 N-terminal Homology domain. A primary sequence of amino acids that is found in endocytic adaptor proteins and binds to inositol lipids. This binding is thought to be necessary for promoting a number of steps in endocytosis.

►Huntingtin Interacting Protein 1 (HIP1)

Anthocyanins

Definition

A group of natural antioxidants widely distributed in colored fruits and vegetables.

►Chemoprotectants

Anthracycline

Definition

Anthracyclines, consisting of daunosamine and tetrahydro-naphthacene-dione, are a class of chemotherapeutic agents used to treat many cancers. These compounds exhibit cytotoxic activity through intercalation into DNA, inhibition of topoisomerase II, and the production of free radicals. In cancer chemotherapy with anthracyclines, the serious problem is the side effects, cardiotoxicity and bone marrow depression, and the emergence of the drug-resistance.

Anti-HER2/Neu Peptide Mimetic

Alan Berezov, Ramachandran Murali, Mark I. Greene
Department of Pathology and Laboratory Medicine & Abramson Cancer Center, University of Pennsylvania, Philadelphia, PA, USA

Synonyms

AHNP

Definition

AHNP is a rationally designed biologically active ►peptidomimetic that mimics an ►anti-Her2/neu monoclonal antibody (Mab)'s anti-tumor function. AHNP is the smallest antibody fragment, which is derived from the ►complementarity determining region (CDR) heavy chain 3 (H3) of the anti-HER2/neu antibody rhuMab 4D5 (►Herceptin (trastuzumab)).

Receptor Characteristics

The ►epidermal growth factor (EGF) family of ►tyrosine kinase receptors includes four structurally related members: erbB1 (EGFR, HER1), erbB2 (HER2/neu, p185), erbB3 (HER3), and erbB4 (HER4). ErbB receptors are crucial for mediating cell proliferation, differentiation, and survival. They are glycoproteins composed of an ectodomain, a single transemembrane region, and a cytoplasmic tyrosine kinase domain flanked by noncatalytic regulatory regions. The ectodomain contains four subdomains: L1, S1, L2, and S2, where L and S are acronyms for large and small, respectively. These subdomains are also referred to as subdomains I–IV. Subdomains II and IV are Cys-rich subdomains. A family of ligands, EGF-like peptide growth factors, binds to the ectodomain of erbB receptors, leading to the formation of homo- and heterodimers. However, HER2/neu is an unusual member of the erbB family. It dimerizes in a ligand-independent manner. Moreover it is apparently ligandless, since no authentic ligand that directly binds to it has yet been defined. Dimerization consequently stimulates the intrinsic tyrosine kinase activity of the receptors, triggering tyrosine autophosphorylation in the cytoplasmic domain. Phosphorylated tyrosine residues serve as docking sites for intracellular signaling molecules involved in the regulation of signaling cascades. Thus the dimeric species are considered the active form and responsible for signaling. Persistent signaling contributes to tumorigenesis.

Her2 Regulation

Deregulated expression of erbB receptors, in particular, erbB1 and Her2/neu, has been implicated in the development and malignancy of numerous types of human cancers. Hence, various strategies have been developed to target erbB receptors, including antireceptor MAbs, toxin-MAb and toxin-erbB ligand conjugates, synthetic tyrosine kinase inhibitors, and antisense therapy. We have demonstrated that MAbs to the extracellular domain of Her2/neu can downmodulate the receptor from the cell surface, resulting in a reduction in the malignant phenotype and a conversion of the cell phenotype into a more normal one in vitro and in retardation of tumor growth in vivo. This early work has been translated into the creation of humanized anti-receptor antibody (Herceptin or trastuzumab), which has been approved for the treatment of metastatic ►breast cancer. Other anti-erbB receptor antibodies or antibody like molecules are currently under development as therapeutic agents.

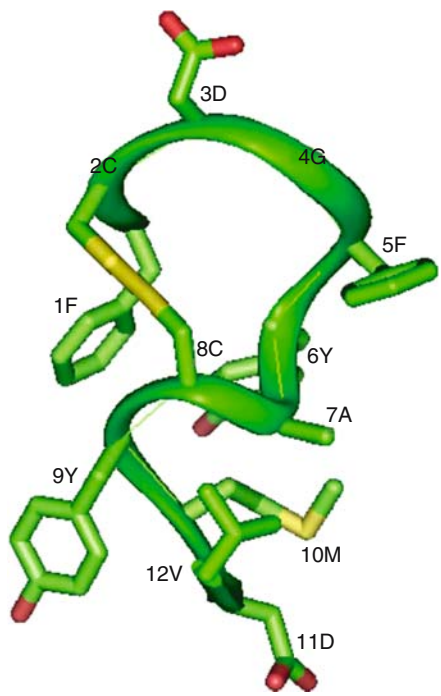
AHNP Characteristics

Rational for Design of AHNP

An antibody is large, difficult to produce and expensive to synthesize and purify. Due to their large size they often are impeded at the periphery of solid tumors and are unable to enter inside the tumor mass. Several studies have reported the creation of smaller antibody fragments such as ►single chain antibody (ScFv). These single chain antibodies have limited antitumor activity to date. A promising alternative approach to overcome the limitations of high-molecular-weight therapeutics is to design mimetic peptides derived from the antigen-binding site of antibodies. The advantages of peptidomimetics over therapeutic proteins include the ease of manufacturing, low immunogenity and potential applicability to a wider range of disease targets, including those inside the cell.

AHNP

A 1.5 kDa anti-HER2 peptide mimetic (AHNP) (Fig.1) derived from the structure of the CDR-H3 loop of the anti-HER2 rhu MAb 4D5 has been designed with demonstrated in vitro and in vivo activities in disabling HER2 tyrosine kinases are comparable to the MAb. AHNP has been shown to bind to the rhu MAb 4D5 epitope on Her2/neu with submicromolar affinity. It inhibited proliferation of Her2/neu-overexpressing tumor cells and colony formation in vitro, as well as growth of Her2/neu-expressing tumors in athymic mice. In addition, AHNP sensitized the tumor cells to ►apoptosis when used in conjunction with ionizing radiation or ►chemotherapeutic agents. AHNP was as effective as Herceptin in reducing tumor size and more effective in its ability to block proliferation.



Anti-HER2/Neu Peptide Mimetic. Figure 1 NMR structure of AHNP.

AHNP Analogs

To further develop AHNP as an anti-tumor agent and as a radiopharmaceutical for tumor imaging, a number of derivatives of AHNP have been designed. Structure–function analysis of AHNP analogs was used to optimize their biophysical and therapeutic properties. Some of the designed AHNP analogs had improved binding properties, solubility, and cytotoxic activity relative to AHNP. Residues in the exocyclic region of AHNP appeared to be essential for high-affinity binding. The study also led to important observations of the analog properties that are essential for their biological activities. Kinetic and equilibrium analysis of peptide-receptor binding for various AHNP analogs revealed a strong correlation between peptide-binding characteristics and their biological activity. For AHNP analogs, dissociation rate constants have been shown to be better indicators of peptide biological activity than receptor-binding affinities. This study has demonstrated that the well-documented biological effects of antibodies, accounting for their applications in tumor therapy, can be mimicked by much smaller antibody-based cyclic peptides with potentially significant therapeutic advantages.

AHNP as a Drug Carrier

Due to high specificity of AHNP to the HER2/neu receptor, it has been used as a ►drug delivery agent against HER2/neu-overexpressing tumors in vitro and in vivo. The breast tumor targeted peptide carrier P3-AHNP has been developed by conjugating AHNP with a modified HIV TAT-derived cell-penetrating peptide. A signal transducers and activators of transcription 3 (STAT3)-inhibiting peptide conjugated to this peptide carrier (P3-AHNP-STAT3BP) was delivered more efficiently into HER2/neu-overexpressing than HER2/neu low-expressing cancer cells in vitro and successfully decreased STAT3 binding to STAT3-interacting DNA sequence. P3-AHNP-STAT3BP inhibited cell growth in vitro, with HER2/neu-overexpressing 435.eB breast cancer cells being more sensitive to the treatment than the HER2/neu low-expressing MDA-MB-435 cells. Compared with HER2/neu low-expressing MDA-MB-435 xenografts, i.p. injected P3-AHNP-STAT3BP preferentially accumulated in 435.eB xenografts, which led to more reduction of proliferation and increased apoptosis and targeted inhibition of tumor growth. This novel peptide delivery system provided a sound basis for the future development of safe and effective new-generation therapeutics to cancer-specific molecular targets.

In another study, the HER2/neu-targeting/neutralizing function of AHNP was exploited by coupling AHNP to a mitochondriatoxic proapoptotic peptide PAP. The engineered chimeric peptide, BHAP, selectively triggered apoptosis in HER2/neu-overexpressing tumor cells and inhibited growth of HER2/neu-overexpressing human mammary xenografts established in SCID mice. BHAP was selectively internalized by human breast cancer cells through HER2/neu-mediated endocytosis and induced apoptosis in vitro and in vivo. The peptide was effective against HER2/neu-overexpressing cells, even those that have been previously described as Herceptin resistant. To increase the avidity of the chimeric peptide for HER2/neu, a tetrameric form has been created through ►streptavidin binding of ►biotin-labeled BHAP. Tetramerization resulted in a significant (19–80 fold) improvement of the efficacy of BHAP against the HER2/neu positive breast cancer cells.

►Taxol (paclitaxel) has been coupled to a bivalent form of AHNP for targeting the chemotherapeutic drug to HER2-overexpressing cells. The prodrug conjugate released Taxol after receptor-mediated internalization resulting in selective toxicity towards HER2/neu positive cells.

The studies where AHNP was used as a tumor-targeting agent have demonstrated a ►context independent nature of its biological activity. Indeed, AHNP could effectively carry drugs to tumor cells when it was included either in the middle of the chimeric construct or at the amino or carboxy termini. This important property facilitates the design of AHNP-drug conjugates and can largely explain the popularity of AHNP as a ►drug carrier agent.

AHNP in Breast Cancer Diagnosis

Since AHNP show antitumor effect in an context-indpendent manner, it was used in a highly sensitive tumor detection technique, termed as “IDAT”. Furthermore, AHNP was engineered as a fusion protein containing AHNP and a ►non-immunoglobulin (Ig) protein scaffold, streptavidin (SA) to improve the receptor-binding and pharmacological properties of AHNP. The recombinant tetrameric protein, AHNP-SA bound to the HER2/neu receptor with high affinity, inhibited proliferation of HER2/neu overexpressing cells and reduced tumor growth induced by HER2/neu-transformed cells. These studies suggest that the tetrameric form of AHNP, as an antibody-surrogate molecule, can be used for tumor diagnosis.

Relevance to Cancer Therapy

►Monoclonal antibody therapy provides high target specificity, but has limitations and challenges in drug development because of the large size of the therapeutic agent resulting in high cost and significant delivery problems. Therapeutic antibodies are efficient against hematologic malignancies. Such targeted antibodies reactive against solid tumors are less efficacious due to barriers that limit their entry into the tumor tissues. The main barriers for antibody transport into tumor mass are dense ►extracellular matrix (ECM) and high interstitial pressure in the tumor. Due to these barriers, therapeutic

molecules must diffuse across the tumor mass. Since the rate of diffusion is inversely proportional to the molecular radius, large antibody molecules diffuse very slowly. Thus, diffusion of antibodies across solid tumors usually takes weeks to months making larger tumor masses especially difficult to treat with monoclonal antibody therapy. To overcome the ►pharmacokinetic limitations of the antibodies, several studies report design of lower molecular weight constructs including ►Fab and Fab′2 fragments, ScFvs, multivalent ScFvs, minibodies, bispecific antibodies, and camel variable functional heavy chain domains. Diffusion of a smaller fragment such as ScFv into tumors is usually faster than that of a full antibody, but could still take up to a month. Tumors are known to be genetically unstable and may acquire resistance if antibody therapies are slowed down by poor penetration. AHNP is the smallest antibody fragment that has been shown to possess anti-tumor effects comparable to an anti-Her2/neu antibody in vivo. Because of their significant advantages over antibodies in terms of molecular weight, tumor penetration and ability to be easily conjugated with cytotoxic drugs, AHNP-like peptide mimetics are expected to be very effective for tumor therapy.

Conclusions

AHNP is the first rationally designed small antibody fragment containing molecule that possesses the ability to reduce tumor growth when used either alone, or in combination with cytotoxic drugs. Its specificity also has been shown to be useful in tumor diagnostics. Due to its small size AHNP is amenable for further modification to create molecular species for clinically useful tumor therapy. AHNP represents a new paradigm in antibody based tumor therapy.

Anti-Inflammatory Drugs

Hui Y. Lan
Department of Medicine, The University of Hong Kong Li Ka Shing Faculty of Medicine, Hong Kong, China

Synonyms

Nonsteroidal anti-inflammatory drugs (NSAIDs)

Definition

Anti-inflammatory drugs include steroid and nonsteroidal anti-inflammatory drugs (also called ►NSAIDs). Generally, they are used to relieve clinical symptoms such as ►inflammation, swelling, stiffness, and pain.

Characteristics

Steroid Anti-Inflammatory Drugs

Steroid anti-inflammatory drugs such as ►glucocorticoids are hormones naturally produced by the adrenal gland with a variety of important physiological activities within the body. They are prescribed for treatment of diseases such as adrenal insufficiency, arthritis, asthma, ►inflammatory bowel disease, transplant rejection, and the graft-versus-host disease. Glucocorticoids are also a very effective anticancer drug for childhood ►acute lymphoblastic leukemia (ALL), as well as in other lymphoid malignancies. The immune suppressive effect and anticancer therapy of glucocorticoids is mediated by the glucocorticoid receptors to specifically induce ►programmed cell death (also called apoptosis) on lymphocytes in lymphoid tissues. Thus, glucocorticoids are pivotal in the treatment of ►ALL clinically.

Glucocorticoids have been used in huge amounts in the last 40 years. Unfortunately, long-term use of steroids is associated with very severe side effects, including obesity, hyperlipidemia (higher levels of lipid contents in blood), hyperglycemia (higher levels of blood glucose), and hypertension (an increase in blood pressure).

Nonsteroidal Anti-Inflammatory Drugs

►NSAIDs are commonly prescribed medications for the inflammation of arthritis and other inflammatory diseases such as in tendinitis and bursitis. There are two classes of NSAIDs, including a classical NSAIDs (aspirin, sulindac, and various related agents) and ►cyclooxygenase-2 (COX-2) inhibitors (►celecoxib, rofecoxib, and others). All classical NSAIDs act as nonselective inhibitors of the enzyme ►cyclooxygenase and are able to inhibit both COX-1 and COX-2 enzymes with a predominant effect on COX-1, whereas COX-2 inhibitors bind selectively to COX-2. Both COX1 and COX1 are able to catalyze arachidonic acid, resulting in synthesis of ►prostaglandins (PGs) including PGD2, PGE2, prostacyclin, PGF2alpha, and thromboxane. PGs regulate various pathophysiological processes such as inflammatory reaction, gastrointestinal cytoprotection. NSAIDs alleviate pain and inflammation by counteracting the COX activities, thereby inhibiting prostaglandins and thus reducing or eliminating inflammation and pain.

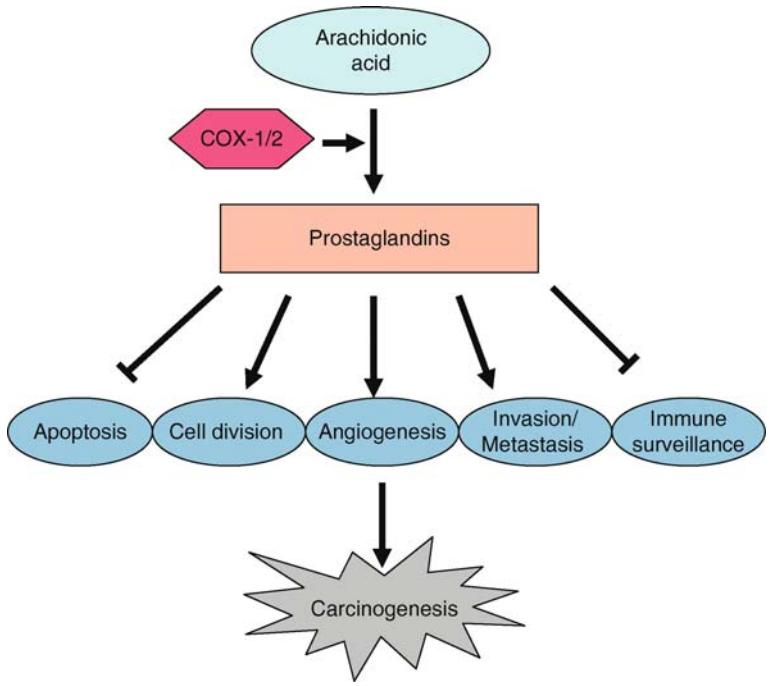
It is becoming increasingly apparent that many cancers are associated with a chronic inflammatory response such as the development of gastric carcinoma in patients with ►*Helicobacter Pylori* infection. Indeed, the tumor microenvironment such as tumor stroma, tumor-associated ►macrophages, cytokines, ►chemokines, and reactive oxygen/nitrogen species contributes significantly to the ►carcinogenesis. Signaling pathways that link inflammation with cancer include the COX-2, NF-kappaB, and phosphatidyl inositol 3-kinase (PI3K)/Akt pathways. Thus, therapies against the inflammatory process also act as either treatment or prevention of cancers.

Increased levels of COX-2 expression have been reported in carcinomas of the colon, stomach, breast, esophagus, cervix, lung, liver, prostate, and pancreas. High levels of COX-2 expression appears to be involved in the development of cancer by promoting ►cell division, inhibiting ►apoptosis, stimulating ►angiogenesis, altering cell adhesion and enhancing ►invasion and metastasis, and influencing ►immune surveillance (Fig. 1). All these actions result in cancer development and progression. The inhibition of COX-2 activity by NSAIDs blocks these activities and thus may account for the anticarcinogenic activity of these drugs.

In addition to mechanisms that involve the inhibition of COX-2, mechanisms independent of COX-2 also participate in the anticarcinogenic activities of NSAIDs. Celecoxib mediates antitumor effects through the inhibition of a signaling pathway called phosphoinositide-dependent kinase-1 (PDK-1)/Akt, which is Cox-2-independent. Thus, blockade of PDK-1/Akt by celecoxib in cancer cells triggers programmed cell death. However, such an observation has not yet been described for rofecoxib. Thus, each traditional NSAID appears to have its own, more or less specific, COX-independent anticancer mechanisms, which requires further investigation.

Side Effects of NSAIDs

Long-term use of NSAIDs, which inhibit both COX-1 and COX-2, is associated with serious side effects. Some 10–50% of patients are unable to tolerate NSAID treatment because of abdominal pain, diarrhea, bloating, heartburn, and upset stomach. Approximately 15% of patients on long-term NSAID treatment develop ulceration (an open wound) of the stomach and duodenum. The worse is that those with unaware of their ulcers are at risk of developing serious ulcer complications such as bleeding or perforation of the stomach. These side effects have been attributed to the inhibition of COX-1, which mediates gastroprotective prostaglandin production. To overcome these side effects associated with COX-1 inhibition, selective COX-2 inhibitors, such as celecoxib and rofecoxib, were developed with fewer gastrointestinal side effects than traditional NSAIDs. Nevertheless, the group of COX-2 inhibitors, including celecoxib, rofecoxib, valdecoxib, etoricoxib, and lumiracoxib, is under critical investigation because increased risk of cardiovascular side effects such as an increase in blood pressure, stroke, and myocardial infarction have been reported after long-term use of rofecoxib and of valdecoxib. Thus, for those taking NSAIDs for more than 1 or 2 months or in large amounts, consultation



Anti-Inflammatory Drugs. Figure 1 Mechanisms of COX inhibitors in anticancer. Both COX1 and COX1 are able to catalyze arachidonic acid and stimulate synthesis of prostaglandins (PGs), which play a role in carcinogenesis by promoting cell division, inhibiting apoptosis, stimulating angiogenesis, enhancing invasion and metastasis, and influencing immune surveillance. Administration of the COX-1/2 inhibitors blocks COX-1/2 activities and thus reduces prostaglandins, resulting in prevention or treatment of cancers.

with the doctor the good that it can do as well as the risks of taking it is highly advised.

Antiangiogenesis

Dan G. Duda
Steele Laboratory for Tumor Biology, Department of Radiation Oncology, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA

Definition

The prevention or inhibition of the process of new blood vessel formation by endothelial cells from pre-existing adjacent vessels (►angiogenesis).

Characteristics

Rationale for Antiangiogenesis for Therapy

Formation of new blood vessels is one of the hallmarks of ►cancer. Therefore, preventing this process – antiangiogenesis – has emerged as a potential therapeutic strategy to halt cancer growth. This was based on the concept promoted by Dr. Judah Folkman (Harvard Medical School, Boston, USA) that new blood vessel formation plays a determinant role in tumor growth and progression to ►metastasis. Given its importance in tumor progression and treatment, angiogenesis has prompted enormous interest in the oncology field over the last few decades. But angiogenesis plays a central

role in other pathological states such as vascular diseases, benign tumors, obesity or atherosclerosis. In cancer and other diseases, the new vessels form due to the chronic overexpression of multiple proangiogenic factors: for example, ►Vascular Endothelial Growth Factor A (VEGF-A or ►VEGF), ►basic Fibroblast Growth Factor (bFGF), and ►Placental-derived Growth Factor (PlGF). As a result, the new vessels are immature and structurally and functionally abnormal. This in sharp contrast to angiogenesis during physiological states (embryonic and postnatal development, wound healing, the menstrual cycle, and pregnancy); in these cases, angiogenesis is tightly regulated spatially and temporally by well-balanced endogenous pro- and antiangiogenic factor expression, and the resulting vessels are fully functional and specialized for organ-specific functions. More recently, Dr. Rakesh K. Jain (Harvard Medical School, Boston, USA) has proposed that antiangiogenic therapy may restore the balance between pro- and antiangiogenic factors, and "normalize" structurally and functionally tumor vasculature. Preclinical and clinical data have validated this hypothesis. The ►vascular normalization concept may be critical for combinations of antiangiogenic therapy with cytotoxic therapies for cancer, but also for a variety of other diseases (see below).

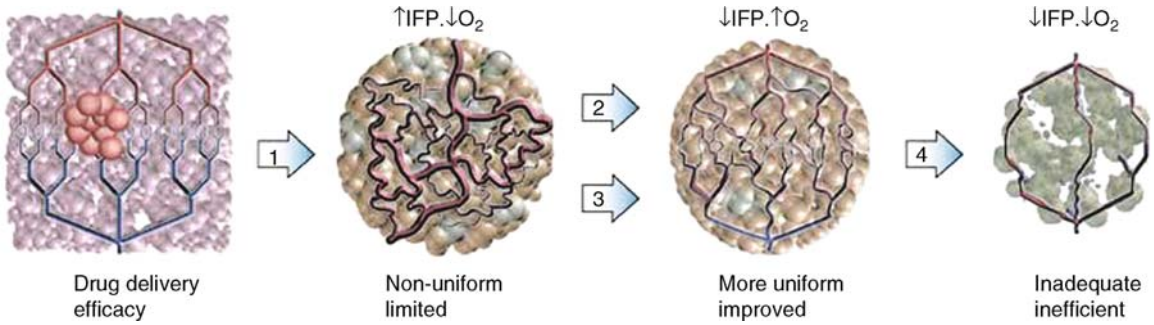
Molecular and Cellular Players in Angiogenesis: Potential Targets for Antiangiogenesis

Specific and efficient targeting of the new vessels that form in pathological states requires an in depth understanding of the cellular and molecular events that lead to angiogenesis in each disease type. For cancer therapy, such specificity and efficiency has not been achieved to date, presumably due to the complexity of the angiogenesis process and the heterogeneity of tumors.

Several strategies have been proposed and are currently under clinical development.

First, antiangiogenesis strategies have been developed to target specific molecules responsible for angiogenesis in cancer. Most of our knowledge in angiogenesis to date derives from studies of VEGF. VEGF is overexpressed by most cancers and is a main player in diseases such as macula degeneration and obesity. However, VEGF is also a key component of physiological angiogenesis. Moreover, VEGF may modulate vasculogenesis (i.e., de novo formation of new blood vessels from endothelial precursor cells), a ►neovascularization process complementary to angiogenesis. Finally, VEGF is a highly pleiotropic cytokine and exerts effects on nonendothelial cells that express VEGF receptors such as hematopoietic cells or cells of the nervous system. A similar complexity emerges from current studies of other proangiogenic factors such as bFGF, PlGF, or ►stromal-derived factor 1 alpha (SDF1α), to name just a few. These factors are also expressed in many tumors and can compensate for VEGF during anti-VEGF therapy. Therefore, molecular and cellular target identification and validation remains of great interest in the antiangiogenesis field (Fig. 1).

A second strategy is to use endogenous factors that are inhibitors of angiogenesis. Upregulation of the expression or exogenous delivery of recombinant protein for factors such as endostatin, tumstatin,



Antiangiogenesis. Figure 1 Potential mechanisms of action of antiangiogenesis on tumor vasculature. Angiogenesis helps tumors make the transition from in situ carcinoma to frank carcinoma (1). At this stage, tumors become hypervascular, but the vessels are leaky and the blood flow is spatially and temporally heterogeneous. This leads to increased interstitial fluid pressure and focal hypoxia, creating barriers to delivery and efficacy of therapeutics. The mechanism of action of the antiangiogenesis may be twofold: inhibition of new vessel formation and killing of immature tumor vessels (2); and normalization of the remaining vasculature by decrease in macromolecular permeability and hypoxia, and improvement of blood perfusion (3). Another effect of antiangiogenesis may be the direct killing of cancer cells in subsets of tumors. Regardless of the mechanisms involved, antiangiogenesis alone is not curative because it cannot kill all cancer cells. In the longer term, it leads to a vasculature that is inefficient for drug delivery (4) and to tumor relapse using alternative pathways for neovascularization. Reproduced with permission, from [5].

canstatin, thrombospondin, and other blood circulating proteins may counteract the overexpression of tumor-derived proangiogenic factors.

Third, proliferating endothelial cells in the angiogenic tissue may be a good target for cytotoxic regimens such as radiotherapy or chemotherapy. Thus, continuous or frequent exposure of the endothelium to cytotoxic treatment may also have an antiangiogenic effect.

Finally, therapies that directly target the cancer cells, either nonspecifically (with chemo and/or radiotherapy) or specifically (with newer molecularly targeted agents), may indirectly affect angiogenesis by killing the main source of the proangiogenic factors – the cancer cells. Increasing evidence has been recently offered to support the concept that tumor associated mesenchymal cells (fibroblasts, myofibroblasts, and perivascular cells) and hematopoietic cells (monocyte/machrophages, neutrophils) play key roles in pathologic angiogenesis. However, to date their roles in antiangiogenesis, or as a potential target for antiangiogenesis, are incompletely understood.

The Antiangiogenesis Strategy in Cancer Patients

While basic researchers continue to explore a multitude of pro- and antiangiogenic pathways as therapeutic targets, so far only the approaches blocking VEGF have proven their utility in the clinic. Many of the early trials for antiangiogenic agents yielded disappointing results. This was in contrast to the efficacy of antiangiogenic agents seen in preclinical models of cancer. But after over three decades of basic research and clinical development, two antiangiogenesis approaches have yielded survival benefit in patients with metastatic cancer in randomized, placebo-controlled phase III trials. In one approach, the addition of bevacizumab (a VEGF-specific antibody, Avastin®, Genentech/Roche) to standard therapy improved overall and/or progression-free survival in colorectal, lung, breast, and renal cancer patients. In the second approach, multitargeted agents that block growth factor pathways in both endothelial and cancer cells (such as sunitinib, Sutent®, Pfizer and sorafenib, Nexavar®, Bayer, and Onyx) demonstrated clinical benefit in gastrointestinal stromal tumor, renal cell carcinoma and hepatocellular carcinoma patients. In contrast, bevacizumab failed to increase survival with chemotherapy in patients with previously treated and refractory metastatic breast cancer and in pancreatic cancer patients. Furthermore, the addition of vatalanib (PTK787, Novartis), a selective VEGF ►receptor tyrosine kinase inhibitor, to conventional cytotoxic therapy did not show a similar benefit in metastatic colorectal cancer patients. These contrasting responses raise critical questions about how these agents work in patients and how to combine them optimally. Specifically, what are the mechanisms of action of antiangiogenic agents? And how can we monitor the effects of antiangiogenesis? Significant research is currently undertaken to answer these questions. The answers will provide invaluable insight on how these agents work, and facilitate an optimized use of antiangiogenesis in the clinic.

Antiangiogenesis for Ocular Diseases

The other application of antiangiogenesis – currently approved by the Food and Drug Administration of the United States for use in patients – is age-related wet macular degeneration. This disease is the result of VEGF-driven angiogenesis and increased permeability and edema into the retina, which causes partial or complete loss of vision. Novel treatments using a VEGF inhibiting aptamer (Macugen®, Eyetech/Pfizer) or antibody fragment (Lucentis®, Genetech) have been demonstrated to efficiently block VEGF and angiogenesis. A number of antiangiogenic agents are currently being tested in other ocular diseases such as diabetic retinopathy.

Mechanisms of Action of Antiangiogenic Agents

Several mechanisms of antitumor action have been proposed for antiangiogenic agents in cancer patients. This is in part due to the fact that proangiogenic growth factor receptors (e.g., VEGF receptors) can be expressed not only on endothelial cells in tumors, but also on subsets of malignant cells. In preclinical models, these agents have demonstrated direct antivascular effects, blockade of angiogenesis, and regression or delay of tumor progression in mice. More recent studies have proposed and demonstrated an anti-"vasculogenic" effect of VEGF blockers, manifested through the blockade of recruitment of blood-borne endothelial precursors in tumors. Based on preclinical observations, our laboratory has proposed in 2001 a new hypothesis that antiVEGF agents can "normalize" tumor vasculature. Since then, this hypothesis has been validated in mouse models of mammary and brain tumors.

Emerging clinical data is beginning to shed light on the potential mechanisms of action of antiangiogenesis in humans. In rectal cancer patients, using multiple functional, cellular, and molecular investigations, we demonstrated that bevacizumab has antivascular effects. In brief, bevacizumab alone reduced the tumor tissue vascular density approximately by half at day 12 after first infusion, reduced significantly the tumor blood flow evaluated by computed tomography (CT), and the number of blood ►circulating endothelial cells (CECs), and ►circulating progenitor cells (CPCs) evaluated by flow cytometry. Clinically, bevacizumab treatment produced a less hyperemic/hemorrhagic appearance of the tumor, but with no significant regression. While the significant pruning of tumor vasculature led to a significant increase in cancer cell death by ►apoptosis, it also led to a more mature (perivascular cell covered)

tumor vasculature, and a stable or increased cancer cell proliferation. Twelve days after bevacizumab therapy alone, the tumor interstitial fluid pressure was consistently decreased. Collectively, these findings suggested that in human tumors, similar to mouse models, the tumor microenvironment was normalized by the reduction of the excessive vascularization and potentially sensitized the tumor to the subsequent cytotoxic therapy. Imaging studies landed more supportive data for the normalization hypothesis: despite the significant reduction in vessel density and blood flow, the 18-Fluorodeoxyglucose-uptake measured by positron emission tomography (a measure of tumor metabolic activity) and the permeability surface area product (proportional to the penetration of tracer in tumor) evaluated on CT scans did not significantly change at day 12. Whether the increase in tumor cell apoptosis was due to a direct or indirect effect of bevacizumab is currently unclear. In recurrent ►glioblastoma patients, a panVEGF receptor tyrosine kinase inhibitor (AZD2171, AstraZeneca) normalized tumor vasculature for at least 28 days, decreased tumor enhancement volume on magnetic resonance imaging (MRI), and significantly reduced peritumor edema throughout the course of treatment. The relative vessel size measured by MRI was reduced during the "normalization window," but increased as tumors relapsed.

These mechanistic insights bring great hope that antiangiogenic agents are not only active antitumor agents, but they may increase survival in many tumor types by acting in synergism with conventional or new molecularly targeted anticancer therapies.

►Biomarkers of Antiangiogenesis

Biomarker identification and validation for this novel type of therapy are currently facing important hurdles. Unlike preclinical models, the phase III bevacizumab experience in metastatic colorectal cancer patients did not identify *p53*, *k-ras*, or *b-raf* status, VEGF or TSP2 expression, or microvascular density at baseline as predictive markers of response. No surrogate marker for antiangiogenesis has been yet validated for bevacizumab, sunitinib, or sorafenib therapy.

Our results in rectal cancer patients demonstrated that bevacizumab decreased tumor microvascular density and the number of viable CECs, consistent with an antivascular effect. Whether these changes have predictive value is currently being investigated in ongoing trials at multiple institutions. Plasma angiogenic proteins have also been investigated in multiple trials of antiangiogenic agents. We reported that the plasma levels of VEGF and PlGF are significantly elevated in cancer patients receiving bevacizumab or AZD2171. Other groups have reported similar observations with a variety of antiVEGF agents and have also found a decrease in soluble VEGF receptor 2 levels in plasma. These data strongly suggest a potential "pharmacodynamic biomarker" value for these markers. Of great interest for the field would be to identify biomarkers that predict disease progression through antiVEGF therapy. Although we were unable to identify significant changes in bFGF in the rectal cancer patients, our data from a recently completed phase II trial of AZD2171 in recurrent glioblastoma patients showed a significant correlation between bFGF and SDF1α and tumor progression. These differences may be due to the excellent clinical response in rectal cancer patients, or to disease or agent specificity. In addition, we discovered that viable CECs correlate with progression of glioblastoma during antiangiogenic therapy, while CPCs predicted relapse after drug interruptions. With the development of improved flow cytometric and protein array analysis techniques and subsequent standardization, circulating cell, and plasma protein measurements hold great promise for identification of valid biomarkers for antiangiogenesis.

Toxicity of Antiangiogenesis

The toxicity of targeted antiangiogenic agents is considered relatively mild, but serious side effects have occurred in rare instances, including treatment-related deaths due to hemorrhage or bowel perforations. Experimental studies have shown that, in 11 of the 17 healthy organs studied, VEGF blockade can significantly decrease the number of normal capillaries. In cancer patients, most antiVEGF agents often induce proteinuria, hypertension, thyroid-stimulating hormone elevation and gastrointestinal toxicity, but agent specific toxicities have also been reported. In addition, the long-term effects of antiangiogenesis in patients with less advanced cancers or other pathologies remain to be established.

Future Directions in Antiangiogenesis

The major directions for the immediate future are further understating of the mechanisms of action and identification of the first biomarkers for antiangiogenesis. Achieving this would allow optimization of current treatment protocols and reduction of the adverse effects.

First, identifying the vascular "normalization window" in patients would allow synergistic combinations with chemotherapeutics or radiation. Second, understanding the mechanisms of vessel pruning and cancer cell apoptosis induced by antiVEGF therapy, and tumor escape from it, may allow further sensitization of tumor cells to cytotoxic therapies. Third, characterization of the effect of antiangiogenesis on host-derived cells contribution to cancer growth and relapse after treatment would allow judicious and more effective approaches to therapy involving these cells. To this end, new biomarkers and improved imaging techniques will play a major role in monitoring the effects and stratifying the patients with the ultimate goal of individualized therapy.

Antiangiogenic

Definition

Refers to a chemical or biological agent that inhibits formation of new blood vessels (►angiogenesis).

►Methoxyestradiol

Antibodies to Self Antigens

►Autoimmunity and Prognosis in Cancer

Antibody

Definition

Is a protein that binds specifically to a particular substance – its antigen. Each antibody molecule has a unique structure that enables it to bind specifically to its corresponding antigen, but all antibodies have the same overall structure and are known collectively as immunoglobulins or Igs. Antibodies are produced by plasma cells in response to infection or immunization, and bind to and neutralize pathogens or prepare them for uptake and destruction by phagocytes.

►Sjögren Syndrome
►Bispecific Antibodies

Antibody-Dependent Cell Mediated Cytotoxicity

Definition

ADCC is a passive immune response in which the Fc fragment of a (therapeutic) monoclonal antibody binds or ligates activating immunoglobulin Fc receptors, e.g., Fc RI (CD64), Fc RIIa (CD32a), Fc RIIc (CD32c) or Fc RIII (CD16), present on monocytes, macrophages, granulocytes and natural killer (NK) cells, driving cytotoxic effector functions to target membrane-associated antigens.

►Immunotherapy
►Immunoprevention
►Diabody
►Bispecific Antibodies

Antibody Fragments

Definition

Recombinant immunoglobulin fragments produced in bacteria or in yeast. These fragments include Fabs, Fv and engineered Fv (scFv, dsFv), their variants minibodies, CRABs, multifunctional and multi-specific diabodies, triabodies, tetrabodies) and fusion constructions (immunodrugs, immunotoxins, BRM). *Applications:* in vivo radioimmunodetection and in situ radiotherapy, drug, toxin and BRM-targeted delivery, ►detoxification of drugs and toxins, direct or indirect neutralization of viruses and microorganisms, effects on cell receptors and ligand, substitution of whole antibodies in immunoaffinity purification procedures, homogeneous diagnostic assays and catalysis.

►Radioimmunotherapy

Antibody Microarray

Definition

Is a specific form of protein microarray in which a collection of capture antibodies are spotted and fixed on

a solid surface (such as glass, plastic, and silicon chip) for the purpose of detecting antigens. Arraying antibodies with different specificities allows the testing of single or multiple samples for many targets. After antibodies are printed in a defined array, a conventional immunoassay protocol is performed and the completed assay slide is evaluated on a slide reader adapted to the detection method. While consuming only minuscule amounts (<μl scale) of reagents, ultrasensitive assays (zeptomole range) can readily be performed in a highly multiplexed manner. It is often used for detecting protein expressions from cell lysates in general research and specific biomarkers from serum or urine for diagnostic applications.

►Proteinchip
►Microarray (cDNA) Technology

Anticancer Therapeutic Synergy

Definition

It is not uncommon for the therapeutic effect of two anticancer drugs on a particular cancer to be greater than the effect of each drug treatment alone, or the sum of the individual effects. The presence of one drug enhances the effects of the second. This is called a synergistic effect or synergy, and the drugs are sometimes described as showing anticancer synergism.

►Cisplatin

Anticipation

Definition

A phenomenon whereby an increase in severity and/or an earlier age of onset of disease is seen in succeeding generations. In diseases such as fragile-X syndrome this phenomenon is due to continued expansion of the associated trinucleotide repeat.

►Fragile Sites
►Cowaten Syndrome

Antiestrogens

Definition

It is referred to those drugs natural or man-made that are blocking the synthesis of estrogen or that abrogate the interaction of the estrogen with its receptor.

►Estradiol
►Fulvestrant
►Estrogenic Hormones

Antigen

Definition

Molecules recognized by the immune system as non-self (including parts of bacteria, viruses and malignant cells). Is any molecule that can bind specifically to an antibody. Their name arises from their ability to generate ►antibodies. However, some antigens do not, by themselves, elicit antibody production; those antigens that can induce antibody production are called immunogens.

►Sjögren Syndrome
►Cancer-Berlinc (CG) Antigens
►HLA Class I
►Cancer-Germline (CG) Antigens
►Prostate-Specific Membrane Antigen (PSMA)

Antigen of the Cromer blood group

►Decay-Accelerating Factor

Antigen-Presenting Cells (APCs)

Definition

Antigen-presenting cells are highly specialized cells that can process antigens and display their peptide

fragments on the cell surface together with molecules required for T-cell activation. The main antigen-presenting cells for T cells are ►dendritic cells, macrophages, and B cells.

►Sjögren Syndrome
►Autoantibodies
►Peptide Vaccines
►T-cell Response
►DNA Vaccination
►Accessory Cells

Antigen–Antibody Complexes

Definition

Antigen–antibody complexes are noncovalently associated groups of ►antigen and ►antibody molecules that can vary in size from small soluble complexes to large insoluble complexes that precipitate out of solution; they are also known as immune complexes.

►Sjögren Syndrome

Antihormonal Therapy

Definition

►Endocrine Therapy.

Antihormones

Definition

Antihormones are steroid receptor antagonist, either steroidal or nonsteroidal compounds, that compete for binding with the steroid hormone and prevent activation of receptors.

►Progestin

Antilipid Peroxidation

Definition

Halting the process that makes fatty acids/lipids get rancid by oxidation.

►Grape Seed Extract

Antimetabolite

Definition

A chemical with similar structure to a substance required for normal biochemical reactions, yet different enough to interfere with the normal functions of the cell.

Substance class of anticancer drugs that are synthetic derivatives of physiological metabolites, e.g., 5-fluorouracil and methotrexate.

►ABC-Transporters
►Fluorouracil

Antinuclear Antibody

Definition

ANA; An autoantibody directed against a substance in the cell's nucleus.

Antioxidant

Definition

Antioxidant is any substance that, when present at low concentrations compared with those of an oxidizable substrate, significantly prevents or delays the oxidation of that substrate. Neutralizes free radicals and prevents cell damage that may lead to cancer. Any nutrient or chemical that reacts with and neutralizes free radicals to prevent oxidative damage to cells (e.g. oxidation of lipid membranes, DNA damage). A good biological

antioxidant is able to accept an unpaired electron to form a free radical intermediate with a relatively long half-life in the normal biologic environment. There is a complex intracellular enzymatic antioxidant system, including superoxide dismutases, catalase, and enzymes of the glutathione peroxidase family. Nonenzymatic antioxidants include arginine, vitamins A, C, E, β-carotene, glutathione, polyphenols, and minerals (selenium and zinc).

►Oxidative Stress
►Lipid peroxidation
►Phytoestrogens
►Coffee Construmption
►Carotenoids
►Oxidative DNA damage
►Reactive Oxygen Species

Antioxidant Capacity

Definition

Is the ability of a substance to inhibit oxidation protecting body cells from detrimental effects due to oxidation.

►Polyphenols
►Oxidative stress
►Autioxidant

Antioxidant Defenses

Definition

Are intrinsic compounds (e.g. albumin, glutathione, uric acid) and enzymes (catalase, superoxide dismutase) that can convert, scavenge or inactivate free radicals (►oxidative DNA damage). Dietary ►antioxidants, such as carotenoids, vitamins E and C, aid this process.

Antioxygen

Definition

Scavenge oxygen free radicals.

►Grape Seed Extract

Antiproliferative

Definition

Cancerous cells go through an exponential growth by doubling. Each generation of cells doubles in numbers compared to the previous generation. It refers to a chemical or biological agent inhibits this cell growth (proliferation).

►Methoxyestradiol

Antipyretic

Definition

The drugs that prevent or reduce body temperature (fever).

►Nonsteroidal anti-inflammatory drugs

Antiradical

Definition

Scavenge free radicals.

►Grape Seed Extract

Antisense DNA Therapy

Bruno Calabretta
Thomas Jefferson University, Kimmel Cancer Institute, Philadelphia, PA, USA

Definition

Refers to the introduction of short antisense strands of DNA, which then bind with target mRNA. Many cancers are due to overexpression of the genes that promote cell proliferation, called tumor suppressor

genes. Antisense RNA might be able to inhibit this overexpression. Antisense DNA is single stranded DNA of various length that is complementary to the mRNA of a given gene. The antisense DNA binds to the mRNA and, by mechanisms that are not completely understood, inhibits its natural function, i.e., translation into protein. Antisense nucleic acids are widely used to study the effect of genes in cultured cells. The potential of antisense nucleic acids in gene therapy, for instance to therapeutically downregulate the expression of overexpressed genes, is being evaluated.

Characteristics

It is increasingly clear that the process of tumorigenesis is intimately associated with the accumulation of specific genetic abnormalities. This recognition has led to the design of novel therapeutic strategies based on suppressing the activity of genes involved in tumorigenesis. Gene expression can be disrupted by a variety of methods targeted to the gene itself (e.g. homologous recombination), to the gene's transcriptional product (e.g. antisense strategies), or to the gene's protein product (e.g. expression of proteins with dominant-negative activity). These strategies are usually successful in tissue culture where cells subjected to gene transfer can be identified and expanded; they are, however, of limited value in anti-cancer DNA therapies where it is essential that many tumor cells carry and/or express the exogenous DNA sequences that can disrupt the function of the genes responsible for the growth advantage of neoplastic cells. Among the strategies directed to the suppression of gene expression, the most widely used (at least in preclinical models) involves the so-called "antisense" oligodeoxynucleotides (ODNs). ODNs are short (15–20 nucleotides) single-stranded DNA sequences synthesized as exact reverse complements of the desired mRNA target's nucleotide sequence. Compared to longer DNA molecules, ODNs should exhibit more favorable cell uptake while preserving high specificity of sequence complementarity to the mRNA target. Once the ODNs form a specific DNA-mRNA duplex, translation of the message might be prevented and mRNA degradation promoted by activation of RNase H that cleaves the RNA component of the DNA-RNA duplex. The potential for highly specific targeting of mRNA transcripts of cancer genes contrasts with the mechanism(s) of action of conventional anti-cancer chemotherapeutic agents, which block enzymatic pathways or randomly interact with nucleic acids irrespective of the cell phenotype. Anti-cancer chemotherapeutic agents exploit differences in biochemical or metabolic processes (e.g. growth rate) between normal and cancer cells for the preferential killing of neoplastic cells. In contrast, antisense ODNs have the potential to exploit the presence of genetically defined characteristics that distinguish neoplastic cells and are responsible for their growth advantage over normal cells. In recent years, the antisense strategy for cancer therapy has progressed from in vitro culture studies to investigations in animal models, and now to clinical studies. The principles underlying the in vitro experiments such as choice of target mRNA, oligonucleotide design, assessment of antisense effects apply also to the in vivo studies. We describe here the current state of progress toward gene-directed antisense-based therapies, primarily from studies in animal models and phase I clinical investigations in hematological malignancies.

Target Choice and Oligonucleotide Design

The choice of the target mRNA selected for inhibition by antisense ODNs is dictated by the biology of a particular disease process and by the ability to predict the effects that may be achieved by inhibiting the expression of a particular cancer gene. For example, the bcr/abl (►BCR-ABL1) transcripts of chronic myelogenous leukemia (►CML) cells serve as an ideal target because of the role of the BCR/ABL oncoprotein in hematopoietic cell transformation and in the maintenance of the leukemic phenotype. Since bcr/abl genes are only found in leukemic cells, targeting their mRNA transcripts might also provide the advantage of a specific effect against tumor cells. Targeting ►BCL-2 mRNA in lymphomas with the t(14;18) translocation is appropriate not only for the disease-causing effect of ►BCL-2 expression but also for the importance of interfering with anti-apoptotic pathways in drug response. Thus, ►BCL-2 antisense ODNs, in addition to their direct effects on target cells, may also sensitize these cells to chemotherapeutic agents that promote ►apoptosis. In most published studies, the sequence of the ODN targeting mRNA transcripts of a disease-causing gene is selected empirically with a preference for the mRNA transcription initiation sequence or the nucleotides surrounding the translation initiation codon. However, there are now novel approaches of oligonucleotide design based on the use of the DNA chip (►microarray (cDNA) technology) technology and hybridization with labeled RNA to dissect accessible sites in the mRNA tertiary structure.

Early investigations of ODN-targeting of growth-regulatory mRNA transcripts employed natural DNA; the realization that natural ODNs are rapidly cleaved by endo-and exonucleases led to the development of nuclease-resistant ODNs by modification of the internucleotide linkages. The most common modification is the replacement of the nonbridging oxygen atoms in the phosphate group with a sulfur group. This type

of modification generates the so-called phosphorothioate ODNs extensively used in preclinical studies and in phase I clinical trials. The phosphorothioate modification results in several desirable properties such as nuclease resistance, water solubility, and activation of RNase H. Nevertheless, it presents also certain disadvantages, including impaired uptake caused by the polyanionic nature of phosphorothioate ODNs, and non-sequence-dependent effects attributed to charge interactions between phosphorothioate ODNs and proteins in the extracellular environment, on the cell surface, and intracellularly. A number of strategies have been utilized to minimize the undesirable effects of the phosphorothioate ODNs while preserving their useful properties. Since these modified phosphorothioate ODNs have not been tested sufficiently in vitro and in in vivo models, we will focus on first-generation phosphorothioate ODNs with regard to delivery, subcellular trafficking, pharmacodynamics, and applications in mouse models and in humans.

Delivery, Subcellular Trafficking, and Pharmacodynamics of ODNs

Native and phosphorothioate ODNs are polyanionic molecules that cross cell membranes inefficiently. There is evidence that ODN uptake is time- and concentration-dependent. Below a concentration of 1 mmol/l, uptake of phosphorothioate ODNs is predominantly via a receptor-like mechanism, while fluid-phase endocytosis appears to predominate at higher concentrations. Several receptor-like proteins potentially involved in ODNs uptake have been identified, but evidence that they are responsible for ODNs uptake is still lacking. In culture, ODN uptake may be enhanced by a number of procedures directly or indirectly modifying the permeation properties of the ODNs. The most common methods are ►electroporation and streptolysin treatment which result in physical disruption or enhanced permeabilization of cell membranes. Such procedures are impractical for in vivo studies, which, at present, rely on the administration of naked DNA. Inside the cells, ODNs accumulate in vacuoles, presumably endosomes and lysosomes, and slowly redistribute to the cytoplasm and nucleus where they may interact with their target mRNA molecules. Accordingly, strategies that promote the release of ODNs from endosomal structures may enhance the ODN's antisense effects. Pharmacokinetics and metabolism of antisense ODNs have been investigated in a variety of animal systems and also in few human trials. In most reports, the analyses were carried out after intravenous or intraperitoneal administration. Approximately 30% of the injected dose is excreted in the urine within 24 h and intact material is detected in most tissues up to 48 h, and up to 7 days in liver and kidney, the organs where most ODNs accumulate. Plasma clearance is biphasic with an initial half-life of 15–25 min and a second half-life of 20–40 h. Potential toxic effects of ODNs administration have been reported in rodents and in primates. Mice receiving high doses of phosphorothioate ODNs show decreased platelet counts probably related to the polyanionic charge of the ODNs. Cardiovascular toxicity, rapid peripheral vasodilatation and death have been reported in monkeys. These effects were noted after rapid bolus administration of large doses, while slow infusion of similar doses appeared to be well tolerated.

Clinical Applications of Antisense ODNs in Hematological Malignancies

Early clinical experiences with antisense ODNs have been reported by groups targeting oncogene or apoptosis regulators. These studies were based on encouraging anti-tumor effects of systemically delivered ODNs in mice injected with leukemia or lymphoma cells of human origin. For example, the disease process induced by Philadelphia1 leukemia cells was suppressed by the systemic delivery of antisense ODNs targeting ►BCR-ABL or c-►myb transcripts. In particular, the anti-leukemia effects of the bcr/abl antisense ODNs was markedly enhanced by the combination with low-doses of ►cyclophosphamide. In the context of ►chronic myelogenous leukemia (CML), oligodeoxynucleotides targeting ►BCR-ABL or c-myb mRNA have been used as marrow purging agents in the chronic as well as accelerated phase of the disease. Eight patients with CML in advanced phase were subjected to autologous bone marrow transplantation after bone marrow purging with bcr/abl antisense ODNs.

Infusion of the ODN-treated cells was followed by prompt engraftment and hematologic reconstitution in all patients. Evaluation of anti-leukemia effects by standard cytogenetic analysis and fluorescence in situ hybridization showed a complete karyotypic response in two cases and a minimal or no response in the other six. Survival of transplanted patients exceeded three years in some cases, but it is not clear that the protocol had therapeutic efficacy.

However, lack of toxicity, prompt hematopoietic reconstitution, and karyotypic response in some cases, are all encouraging observations for designing additional clinical trials. In a different study, eight CML patients were subjected to bone marrow transplantation using autologous hematopoietic progenitors (CD34+) cells that were pre-treated with antisense ODNs targeting the mRNA transcripts of the c-myb gene, a key regulator of normal and leukemic hematopoiesis. After transplantation, seven of eight patients engrafted. Of these, four patients showed 80–90% normal metaphases

3 months post autologous bone marrow transplant, suggesting that the antisense ODNs treatment eliminated the majority of Philadelphia1 CML cells. These patients showed hematologic improvement during the period (6–24 months) following the bone marrow transplant.

Eighteen patients with refractory acute myelogenous leukemia were also treated by continuous infusion of c-myb antisense ODNs at dose levels ranging from 0.3 to 2.0 mg/kg/day for 7 days. There was no treatment-related toxicity, but only one patient showed a therapeutic response.

Studies in a mouse model of lymphoma with the t(14;18) associated with BCL-2 overexpression have demonstrated dose-dependent disease eradication in most mice treated with antisense ODNs targeting a segment of the BCL-2 open reading frame.

On the basis of these preclinical data, BCL-2 antisense ODNs were given via a continuous subcutaneous infusion for 2 weeks to lymphoma patients with high BCL-2 expression and resistant to conventional therapies. Therapeutic responses assessed by computed tomography scanning were demonstrated in six out of nine patients. The specificity of the antisense effects was validated by showing a decrease in BCL-2 levels in lymph node aspirates taken at different times after initiating the antisense ODNs therapy.

Prospects for Antisense DNA Therapy

Continuous advances in understanding the genetic basis of tumorigenesis are leading to the identification of an ever-increasing number of gene targets for antisense ODNs-based therapies. Most disease-causing genes identified by molecular genetics belong to the class of cell-cycle and apoptosis regulators. Accordingly, antisense ODNs may be used individually or in combination against these targets; moreover, antisense ODNs might be combined with conventional chemotherapeutic drugs to enhance apoptosis susceptibility of tumor cells. It might therefore be conceivable that various therapeutic strategies involve ODNs that target tumor-causing genes. Considering this, the success of antisense ODNs-based anti-tumor therapies is likely to depend on the development of antisense ODNs as effective therapeutic agents. Delivery of sufficient amounts of ODNs to tumor cells remains an important problem. Administration procedures that may guide ODNs to tumor cells are of great interest; in a recent in vitro study, neuroblastoma cells were targeted on the basis of the expression of the neuroectodermal-specific GD2 disialoganglioside by antibody-coupled neutral liposomes encapsulated with c-myb antisense ODNs. Although it is unknown if such an approach may function in vivo, this is an example of a potentially useful strategy. The delivery of sufficient amounts of ODNs to tumor cells does not guarantee that they will find the mRNA targets once inside the cells. Thus, methods promoting the intracellular trafficking of ODNs, to enhance the access to as many as possible mRNA target molecules, will be invaluable for efficacious ODNs-based therapies. The development of novel classes of ODNs with fewer non-specific interactions to non-target molecules will also improve the efficacy of antisense ODNs therapies.

If the goal of making effective ODN drugs is to be achieved, these and other problems need to be addressed.

While the principles underlying ODNs-based therapies remain highly attractive, the field of DNA therapeutics is now at a crossroad where rigorous validation in clinical trials is necessary.

Antisense Nucleic Acid

Definition

Are nucleic acids (single-stranded DNA or RNA of various length) that are complementary to the mRNA of a certain gene. The antisense nucleic acid binds to the mRNA and, by mechanisms that are not completely understood, inhibits its natural function, i.e., translation into protein. Antisense nucleic acids are widely used to study the effect of genes in cultured cells. The potential of antisense nucleic acids in gene therapy, for instance to downregulate the expression of overexpressed genes, is being evaluated.

Antiserum

Definition

Serum that contains antibodies.

Antitoxins

Definition

Antibodies that interlock with and inactivate toxins produced by certain bacteria.

Antitumor Vaccines

Definition

Represent relatively new therapeutics for cancer. Such vaccines consist of tumor-associated components (tumor antigens) plus an ►adjuvant (non-specific activator) which may be a cell, such as a ►dendritic cell (DC), or a specially formulated compound capable of activating various immune cells. Most recent therapeutic vaccines for cancer have been prepared with patients' own DC which are cultured and pulsed or loaded with tumor-derived antigens. Antitumor vaccines can be administered to patients as a single modality therapy or in combinations with cytokines, antibodies or chemotherapeutic drugs. Most efficacious antitumor vaccines induce autoimmune sequelae in patients, especially those who achieve clinical responses following vaccination.

►Autoimmunity and Prognosis in Cancer

Antizyme Inhibitor

Chaim Kahana
Department of Molecular Genetics, Weizmann Institute of Science, Rehovot, Israel

Definition

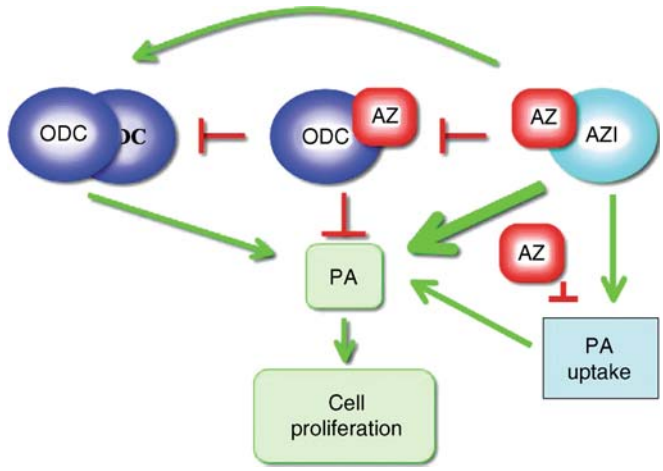
AzI is an ►ornithine decarboxylase (ODC)-related protein that functions as a positive regulator of the ►polyamines biosynthesis pathway thus contributing to enhanced cellular proliferation.

Characteristics

AzI is a cellular protein that shares high homology with ODC, the first rate-limiting enzyme of the polyamine biosynthesis pathway. However, in contrast to ODC, AzI retains no ornithine decarboxylating activity. The Polyamines spermidine, spermine, and their precursor putrescine are organic polycations that are essential for cellular proliferation. Depletion of cellular polyamines results in growth cessation that will resume upon provision of exogenous polyamines. The exact mechanisms by which polyamines affect cellular functions were not yet identified. Optimal cellular polyamine balance is the net result of their biosynthesis, degradation, uptake catabolism, and excretion. Polyamines biosynthesis is executed by the two highly regulated enzymes, ODC and S-adenosylmethionine decarboxylase, followed by the action of the two constitutively active enzymes, spermidine and spermine synthase. ODC is unique in being a short-lived protein whose degradation is performed by the 26S ►proteasome without requiring ►ubiquitination, the standard way of marking proteins for degradation. Instead, its degradation is greatly stimulated by interaction with a polyamine-induced protein known as antizyme (Az). Az expression is regulated at the translational level by a polyamine induced ribosomal frameshifting constituting a cellular polyamine sensing mechanism. Recently, it was demonstrated that Az as a central regulator of the cellular polyamine metabolism is itself subjected to regulation by a molecule termed AzI.

AzI was originally identified as a factor capable of inhibiting Az activity. Following its characterization and cloning, it was revealed that AzI is highly homologous to ODC, exhibits the same homodimeric structure, but lacks ornithine decarboxylating activity. AzI binds Az with higher affinity than ODC. The interaction between AzI and Az neutralizes Az functions leading to stabilization of ODC and to increased polyamine uptake activity, resulting in augmented cellular proliferation (Fig. 1).

Several independent lines of evidence support the notion that AzI is a regulator of cellular proliferation and tumor development. AzI was demonstrated to be upregulated in gastric tumor and in some tumor cell lines including Ras transformed cells. The AzI gene is located in a chromosomal segment whose amplification was connected with the development of prostate and ovarian cancer. Forced overexpression of AzI increased cell proliferation while downregulation of AzI by specific ►siRNA inhibited cell proliferation. Like ODC also AzI is transcriptionally induced by growth promoting stimuli. While it is clear that AzI regulates cell growth by negating Az functions, it was also suggested that AzI might function also in an Az-independent manner by regulating ►cyclin D1 stability.



Antizyme Inhibitor. Figure 1 Regulation of cellular polyamines. Cellular polyamines are provided through their synthesis initiated by the activity of ornithine decarboxylase (ODC) and through their uptake from external sources. Antizyme (Az) regulates both processes, it binds ODC monomers resulting in their inactivation and in their degradation and it reduce polyamine uptake via a yet undefined mechanism. Antizyme inhibitor (AzI), that has higher affinity to Az compared to that of ODC, traps Az into a stable complex leading to ODC stabilization and increased polyamine production. In parallel, Az neutralization increases polyamine uptake. This dual direction increase in the cellular polyamine level results in increased cellular proliferation.

Definition

Activating protein-1 (AP-1) is a transcription factor usually consisting of a member of the Jun family and a member of the Fos or ATF family of proto-oncogenes. AP-1 is activated in response to cytokines, growth factors, and stress factors during cell differentiation, tumor formation, or mitogenic response.

Characteristics

Much of our present knowledge about transcription factors comes from the discovery and study of the activating protein-1 (AP-1) family. AP-1 (and the transcription factor NFκB) has served to detect one of the decisive DNA binding motifs required for gene regulation by a variety of extracellular signals including growth factors, cytokines, tumor promoters, such as the phorbol ester TPA (12-*O*-tetradecanoyl-phorbol-13-acetate), and carcinogens, for example UV irradiation and other DNA damaging agents. One of its members, the heterodimer Fos-Jun was found in the mid 1980s, as a protein complex containing the viral ►oncogene product Fos without a clue of its function. The term AP-1 was coined for an activity that supports both basal and inducible transcription of several genes containing AP-1 binding sites (5′-TGA$^{G}/_{C}$TCA-3′), also known as TPA-responsive elements (TRE), in their promoter region. AP-1 was purified from cell extracts by TRE-based affinity chromatography and despite multiple rounds of purification, the AP-1 preparations contained several distinct polypeptides. Within a year it became evident that these polypeptides correspond to members of *jun* and *fos* gene families and that the first member of the Jun family, c-Jun, represents the cellular homologue of the transforming oncogene (v-Jun) of the chicken retrovirus ASV-17. At present, the Jun protein family

consists of c-Jun, JunB, and JunD and the Fos protein family consists of c-Fos, FosB, Fra-1, and Fra-2. During the past decade additional proteins, such as members of the ATF family have been identified (mostly by yeast-two-hybrid screening), which share structural homologies and form heterodimeric complexes predominantly with Jun proteins (see below) to bind to TRE-like sequences.

General Structure of the AP-1 Subunits

According to its function in controlling gene expression the prototype of a transcription factor has to comprise at least two properties: a region of the protein that is responsible for binding to a specific DNA recognition sequence (DNA binding domain) and a second region that is required for transcriptional activation (transactivation domain) following DNA binding.

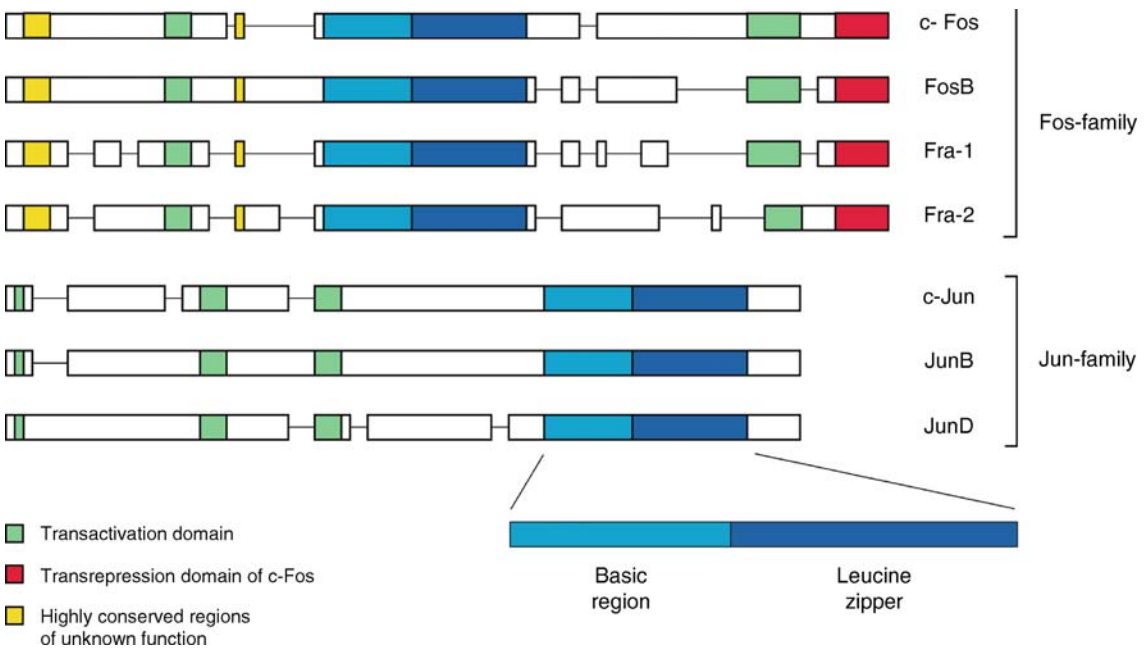
DNA Binding Domain

The DNA binding domain is evolutionarily conserved between the Jun, Fos, and CREB/ATF proteins, thus defining the protein family called "bZip" proteins. bZip stands for the amino acid sequences of the two independently acting sub-regions of the DNA binding domain: the "basic domain", which is rich in basic amino acids and responsible for contacting the DNA, and the "leucine-zipper" region, which is characterized by heptad repeats of leucine being part of the well known "4–3 repeats" forming a coiled-coil structure. The latter domain is responsible for dimerization, which is a prerequisite for DNA binding (Fig. 1). In addition to the leucines other hydrophobic and charged amino acid residues within the leucine zipper region are responsible for specificity and stability of homo- or heterodimer formation between the various Jun, Fos, or CREB/ATF proteins. The Fos proteins do not form stable homodimers but heterodimerize efficiently with the Jun proteins. The Jun proteins can form homodimers, although with reduced stability compared to Jun/Fos or Jun/ATF. Jun–Jun and Jun–Fos dimers preferentially bind to the 7-bp motif 5′-TGA$^{G}/_{C}$TCA-3′ whereas Jun-ATF dimers or ATF homodimers prefer to bind to a related, 8-bp consensus sequence 5′-TTACCTCA-3′. Therefore, individual AP-1 dimers are expected to regulate specific subsets of AP-1 target genes depending on the characteristics of the AP-1 site in their promoter.

In addition to the "classical" AP-1 members (Jun, Fos, ATF) on the basis of DNA sequence specificity and heterodimer formation with Jun and Fos proteins, several new bZip proteins have recently been defined. These include Maf and Maf-related proteins, Smads and Jun-dimerizing partners (JDPs). The exact function of these proteins in AP-1-regulated process is still largely ill-defined. Binding of AP-1 to DNA also supports binding of other transcription factors to adjacent or overlapping binding sites (composite elements) to allow the formation of larger complexes. The interaction of NFAT and Ets proteins with DNA on the IL-2 and collagenase promoters, respectively, serves as paradigms for this type of protein–protein interaction.

Transactivation Domain

In contrast to the well-defined DNA binding domain the structural properties of the domains in the AP-1 proteins



Ap-1. Figure 1 Structural organization of the Fos and Jun proteins.

mediating transcriptional activation of target genes (transactivation domain, TAD) are still poorly understood. The activity of the TAD can be transferred to heterologous DNA binding domains, such as the yeast transcription factor GAL4. By employing such chimeric proteins, which in contrast to the wild-type proteins do not depend on a dimerization partner, critical amino acids in the TADs could be identified. Moreover, it is clear that the various Jun, Fos, and ATF proteins greatly differ in their transactivation potential. Usually, c-Jun, c-Fos, and FosB are strong transactivators, whereas JunB, JunD, Fra-1, and Fra-2 exhibit only weak transactivation potential. Under specific circumstances, they may even act as repressors of AP-1 activity by competitive binding to AP-1 sites, or by forming inactive heterodimers with c-Fos, FosB, or c-Jun. Most importantly, transactivation studies using fusion proteins led to the identification of protein kinases, which bind to and phosphorylate AP-1 proteins in the TAD in response to extracellular signals thereby controlling expression of AP-1 target genes.

Transcriptional and Posttranslational Control of AP-1 Activity

Regulation of AP-1 net activity in a given cell can be achieved through changes in transcription of genes encoding AP-1 subunits, control of the stability of their mRNA, posttranslational processing and turn-over of preexisting or newly synthesized AP-1 subunits, and specific interactions between AP-1 proteins and other transcription factors or co-factors.

The *jun* and *fos* genes are members of a class of cellular genes, termed early response or "immediate-early" genes. They are characterized by a rapid and transient activation of transcription in response to changes of environmental conditions, such as growth factors, cytokines, tumor promoters, carcinogens and expression of certain oncogenes. Since this type of regulation of promoter activity is also observed in the absence of ongoing protein synthesis, it is generally accepted that preexisting factors, whose activity gets altered by changes in posttranslational modification (described in detail in the subsequent section), are responsible for the regulation of promoter activity.

Transcriptional Activation

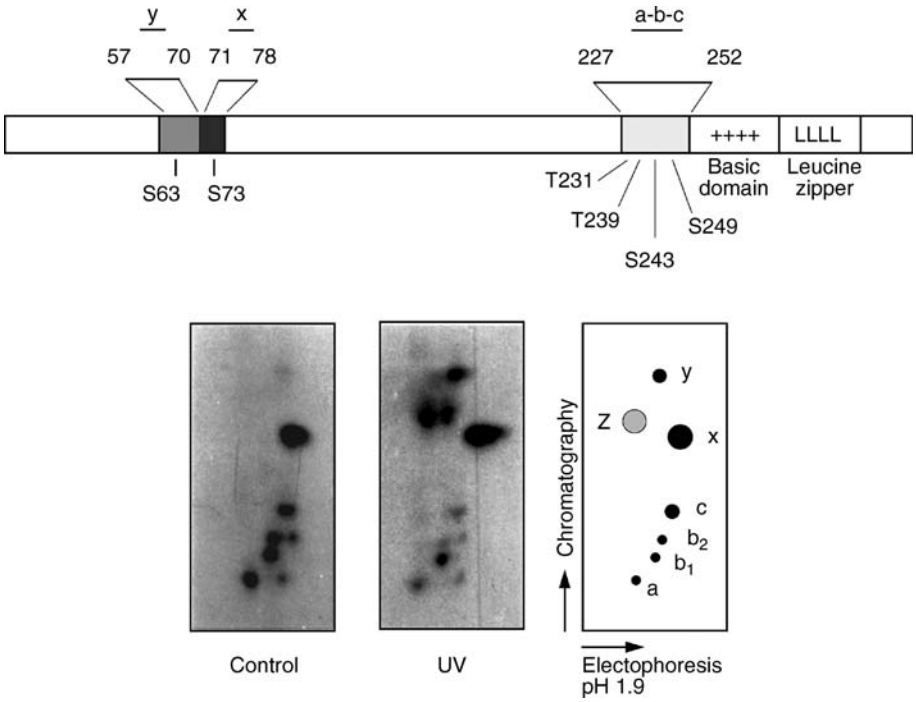
Most of our current knowledge on transcriptional activation of immediate early genes is derived from studies on deletion and point mutations within the *c-fos* and *c-jun* promoters, combined with in vitro and in vivo footprinting analyses. The serum response element (SRE) is required for induced transcription in response to the majority of extracellular stimuli including growth factors and phorbol esters. The ternary complex containing the transcription factor p67-SRF and p62-TCF, which stands for a class of related proteins described as Elk/SAP, specifically bounds to this element. Changes in the phosphorylation pattern of SRF and, predominantly, TCF regulates *c-fos* promoter activity by these stimuli. Other elements include the cAMP response element (CRE) and the Sis-inducible enhancer (SIE), which is recognized by the STAT group of transcription factors. These factors are at the receiving end of the Jak/Stat signaling pathway initiated by specific classes of cytokines. The element responsible for negative autoregulation of the *c-fos* promoter has not yet been identified conclusively.

Analysis of deletion mutants within the *c-jun* promoter identified two AP-1-like binding sites (Jun1, Jun2), which are recognized by Jun/ATF heterodimers or ATF homodimers and are involved in transcriptional regulation in response to the majority of extracellular stimuli affecting *c-jun* transcription. In response to ►G-protein coupled receptor activation (e.g., the muscarinic acetylcholine receptor), or treatment EGF and other growth factors with the AP-1 sites and an additional element in the *c-jun* promoter recognized by MEF2 proteins cooperate in transcriptional control of the *c-jun* gene. Similar to the factors binding to the *c-fos* promoter, the activity of factors binding to the *c-jun* promoter is regulated by their phosphorylation status.

Regulation of AP-1 Activity

The most critical members of the class of protein kinases regulating the activity of AP-1 in response to extracellular stimuli are mitogen-activated protein kinases (►MAPKs). Depending on the type of stimuli, these proline-directed kinases, can be dissected into three subgroups. The extracellular signal-regulated kinases (ERK-1, -2) are robustly activated by growth factors and phorbol esters, but are less efficiently activated by cytokines and cellular stress-inducing stimuli (UV irradiation, chemical carcinogens). In contrast, Jun-N-terminal kinases (►JNK-1, -2, -3), also known as stress-activated kinases (SAPK), and a structurally related class, p38 MAP kinases (p38α, -β, -γ), are strongly activated by cytokines and environmental stress, but are poorly activated by growth factors and phorbol ester. These kinases themselves are under strict control of upstream kinases and phosphatases, which are part of individual signaling pathways initiated by specific classes of extra- and intracellular stimuli (e.g., growth factors, DNA damaging agents, oncoproteins). This network, which exhibits a high degree of evolutionary conservation between yeast, drosophila, and mammals is, however, far too complex to be discussed in greater detail in this review (for in-depth information on this subject see [5]).

ERK1 and ERK2 carry out mitogen-stimulated phosphorylation of JunD and phosphorylation of distinct serine residues at the C-terminus of c-Jun and Fos family members, have also been postulated to depend



Ap-1. Figure 2 *Top*: schematic diagram of the human c-Jun protein. Amino acids are numbered. The numbers on top refer to the trypsin cleavage sites that lead to the appearance of phosphopeptides after in vivo labeling of cells with ^{32}P-orthophosphate. The location of the tryptic peptides "a–c" in the DNA binding domain and peptides "x" and "y" in the transactivation domain are indicated. *Bottom*: Autoradiogram of in vivo labeled c-Jun protein, isolated by immunoprecipitation from untreated and UV-treated cells, digested with trypsin and separated by gel electrophoresis into two dimensions. On the right the positions of the tryptic peptides are schematically illustrated. Peptide "z" most likely represents a peptide-containing residual phosphorylation at threonine-89 and/or threonine-91 of c-Jun.

on the ERK pathway. The JNK/SAPKs were originally identified by their ability to specifically phosphorylate c-Jun at two positive regulatory sites (Ser-63, Ser-73) residing within the TAD (Fig. 2). Hyperphosphorylation of both sites, which was originally identified by 2D-phospho-amino acid-peptide mapping (peptides x, y in Fig. 2), is observed in response to stress stimuli as well as oncoprotein expression and is required for transcriptional activation of numerous c-Jun target genes. The JNKs can also phosphorylate and potentiate the activity of JunD and ATF-2. Notably, the nuclear protein Menin that is encoded by the tumor suppressor gene *MEN1* specifically interacts with JunD and inhibits ERK- and JNK-dependent phosphorylation of JunD, but also of c-Jun. The amino acids that are phosphorylated on ATF2 by JNKs also serve as phospho-acceptor sites for p38, while Ser-63 and -73 of c-Jun are not affected by p38. Most likely, hyperphosphorylation of Jun and ATF proteins results in a conformational change of the TAD allowing more efficient interaction with co-factors, such as CBP, which facilitate and stabilize the connection with the RNA polymerase II/initiation complex to enhance transcription of target genes. In addition to enhanced transactivation, phosphorylation-dependent changes in the half-life of Jun and Fos proteins have been observed. In nonstimulated cells, the DNA binding domain of c-Jun becomes phosphorylated at multiple site (peptide a, b2, and c in Fig. 2) by GSK-3 and/or casein kinase II (CK-II) resulting in reduced DNA binding. In response to extracellular stimuli, such as UV, phosphorylation is reduced leading to enhanced DNA binding. The mechanism (reduced activity of the kinase or enhanced activity of a phosphatase) has not yet been defined conclusively. Recently, GSK3 mediated phosphorylation of c-Jun was also detected at the C-terminus creating a high affinity binding site for the E3 ligase Fbw7, which targets c-Jun for ►poly-ubiquitination and proteosomal degradation.

In addition to phosphorylation, other mechanisms of posttranslational processing have been identified, which regulate AP-1 activity including redox-dependent DNA binding and regulation of nuclear localization.

The mutual interference between AP-1 and steroid hormone receptors, particularly the glucocorticoid receptor (GR) represents another extensively analyzed example of protein–protein interaction-based crosstalk. In this context, there is experimental evidence that the

anti-inflammatory and immunosuppressive activities of glucocorticoids are mediated, at least in part, by GR-mediated repression of AP-1 activity. In addition to GR, numerous transcription factors (e.g., C/EBP, Ets, Gata, MyoD, NFAT, NFκB, Runx, Smad, SP-1, Stat, TCF, and the Lim-only protein YY1), transcriptional co-factors (e.g., alphaNAC, Jab1, p300/CBP, TAF1, TAF4b, TAF 7, Trip6, and WWOX), subunit of the chromatin remodeling complex (e.g., SWI/SNF and HDAC3), as well as other types of cellular proteins (e.g., DexD/H-box RNA helicase RHII/Gu and BAF60a) have been found to physically interact and modulate AP-1 activity. In most cases, the exact mechanism of interaction between AP-1 and these proteins remains to be determined.

AP-1 in Physiology and Pathology

The generation of genetically modified mice harboring genetic disruption and/or transgenic overexpression, as well as the availability of genetically defined mutant cells isolated from these animals represent a major breakthrough in our understanding of the regulatory functions of AP-1 subunits Table 1–2. Distinct and overlapping phenotypes of the individual knockout

Ap-1. Table 1 Knockout and knockin mouse models

Genotype	Phenotype	Affected tissues
c-Jun$^{-/-}$	Embryonic lethality at E12.5	Liver, heart
c-Jun$^{AA/AA}$ for c-Jun	Rescue of embryonic lethality and resistance to epileptic seizures and neuronal apoptosis induced by excitatory amino acid kinate	Liver, heart, CNS
JunB for c-Jun	Rescue of embryonic lethality until birth	Liver, heart
JunD for c-Jun	Rescue of embryonic lethality until birth	Liver, heart
c-Jun$^{\Delta/\Delta}$ Alfp-Cre	Impaired postnatal hepatocyte proliferation and liver regeneration	Liver
c-Jun$^{\Delta/\Delta}$ Bal1-Cre	Malformation of axial skeleton	Skeleton
c-Jun$^{\Delta/\Delta}$ Col2a1-Cre	Increased apoptosis of notochordal cells, fusion of ventral bodies, and scoliosis of axial skeleton	Skeleton
c-Jun$^{\Delta/\Delta}$ K5-Cre	Eye lid closure defect	Skin
c-Jun$^{\Delta/\Delta}$ Nestin-Cre	Impaired axonal regeneration	CNS
JunB$^{-/-}$	Embryonic lethality at day E8.0 to E10	Extraembryonic tissue, placenta
JunB$^{\Delta/\Delta}$Col1a2-Cre	Pronounced epidermal hyperplasia, disturbed differentiation and prolonged inflammation	Skin, immune system
JunB$^{\Delta/\Delta}$LysM-Cre	Osteopetrosis	Skeleton
JunB$^{\Delta/\Delta}$ More-Cre	Osteopenia and myeloproliferative disease	Immune system, Skeleton
JunB$^{-/-}$ Ubi-JunB	Myeloproliferative disease Altered T-helper 2-cell differentiation, impaired allergen-induced airway inflammation, and osteoporosis-like phenotype	Immune system, Skeleton
c-Jun$^{\Delta/\Delta}$JunB$^{\Delta/\Delta}$ K5-Cre-ER	Psoriasis-like phenotype	Skin
JunD$^{-/-}$	Male sterility, growth retardation, cardiomyocyte hypertrophy, and impaired T-helper-cell differentiation	Testis, heart, immune system
c-Fos$^{-/-}$	Osteopetrosis and accelerated light-induced apoptosis of photoreceptor cells	Skeleton, CNS
c-Fos$^{-/-}$ H2Kb-Fra1	Rescue of osteopetrosis and photoreceptor cell apoptosis	Skeleton, CNS
c-Fos$^{\Delta\Delta}$ Nestin-Cre	Impaired long-term memory and synaptic plasticity	CNS
FosB$^{-/-}$	Nurturing defect	CNS, hypothalamus
Fra1$^{-/-}$	Embryonic lethality at E9.5	Extraembryonic tissue, placenta
Fra1$^{\Delta/\Delta}$ More-Cre	Osteopenia	Skeleton
Fra2$^{-/-}$	Postnatal lethality and defective chondrocyte differentiation	Skeleton
Fra2$^{\Delta/\Delta}$ Coll2a1-Cre	Defective chondrocyte differentiation and kyphosis-like phenotype	Skeleton

−/− conventional knockout, Δ/Δ Cre-induced conditional knockout.

Ap-1. Table 2 Transgenic mouse models

Genotype	Phenotype	Affected tissues
H2kb-c-Jun	None	None
UbiC-JunB	Increased bone mass	Skeleton
CD4-JunB	Altered T helper cell differentiation	Immune system
UbiC-JunD	Reduced peripheral T- and B-cells and impaired T-cell activation	Immune system
H2Kb-c-Fos	Osteosarcoma	Skeleton
H2Kb-FosB	None	None
Tcrb-ΔFosB	Impaired T-cell differentiation	Immune system
NSE-ΔFosB	Osteosclerosis and impaired adipogenesis	Bone, fat tissue
H2Kb-Fra1	Osteosclerosis	Bone
CMV-Fra2	Ocular malformation	Anterior eye structure
H2Kb-Fra2	Increased bone mass	Bone

mice induced by defects in cells or tissues in which the subunit was particularly important or where its absence became rate-limiting, support the notion that AP-1 subunits exhibit unique but also common functions in vivo. As a general rule derived from all studies, the AP-1 family members must be present in a complementary and coordinated manner in order to ensure proper development or physiology of the organism.

Conventional knockout approaches demonstrate that expression of JunD, c-Fos, and FosB is dispensable for normal embryogenesis Table 1. However, *junD* null mice develop age-dependent defects in reproduction, hormone imbalance, and impaired spermatogenesis in male and cardiomyocyte hypertrophy that is enhanced by chronic moderate pressure overload. Additionally, *junD* deficiency impacts T helper cell differentiation. An important regulatory role for JunD in lymphocyte maturation and activation is supported by reduced peripheral T- and B-cell populations in transgenic mice with ectopic JunD overexpression. Whereas, adult $fosB^{-/-}$ females nurture insufficiently, tissue-specific overexpression of ΔFosB, a naturally occurring truncated form of FosB that arises from alternative splicing of the *fosB* transcript, causes impaired T-cell differentiation or osteosclerosis, respectively. Lack of c-Fos expression in adult animals causes an accelerated light-induced ▶apoptosis of photoreceptor cells as well as osteopetrosis and further experimental evidence support that c-Fos is a master regulator of osteoclastogenesis. Noteworthy, both phenotypes could be rescued by transgenic Fra-1 overexpression in $c\text{-}fos^{-/-}$ animals in a dose-dependent manner implicating that Fra-1 is an important c-Fos target gene in vivo.

In contrast to the AP-1 subunits discussed so far, c-Jun, JunB, Fra1, and Fra2 expression is indispensable for embryonic development or postnatal survival Table 1. While *c-jun* null embryos die at midgestation (E12.5) due to failure in heart and liver development, lethality of *junB* (E8.0 to E10) and *fra1* (E9.5) deficient embryos is caused by placentation failure due to multiple defects in the extra-embryonic tissue. These data suggest that JunB and Fra1, possibly as heterodimers, address common target genes responsible for the generation of a functional placental labyrinth. Knockin approaches revealed complete restoration of c-Jun dependent defects during embryogenesis by JunB and JunD indicating that spatial and temporal regulation of Jun protein expression may be more important than the coding sequence of the individual family member (Table 1). Finally, Fra-2-deficient mice die shortly after birth, are growth retarded, and show defective chondrocyte differentiation.

Embryonic or postnatal lethality largely prevented functional studies in vivo and therefore, conditional tissue- and cell-type specific ablation has become an important tool to study the regulation and function of AP-1 subunits in physiological and pathological processes Table 1. These approaches confirmed initially seen phenotypes during embryogenesis, but also revealed novel nonoverlapping and common functions of distinct AP-1 family members in adult animals, specifically in skeletal and bone morphogenesis, the immune system, skin homeostasis, and the central nervous system. In adult mice, *c-jun* deficiency results in axial skeleton malformation accompanied by accelerated apoptosis of notochordal cells, fusion of ventral bodies, and scoliosis, while compromised JunB or Fra-2 expression is associated with defective endochondral ossification partially due to impaired chondrocyte differentiation. Postnatal and cell-type specific loss of *junB* also causes osteopenia or osteopetrosis, respectively, due to failure in osteoblasts and osteoclast differentiation and physiology. Again, *junB* or *fra*-1 deficiency in osteoblasts (osteopenia) or overexpression

in transgenic mice (osteosclerosis and increased bone mass) results in comparable phenotypes. Furthermore and similar to JunD, JunB is required for a proper regulation of T-helper-cell-specific cytokine expression and differentiation that is also confirmed by T-cell specific JunB overexpression in transgenic mice (Table 2).

Animal studies further unraveled an important role of c-Jun in skin development and homeostasis as an important regulator of keratinocyte proliferation as well as differentiation through transcriptional regulation of the epidermal growth factor receptor (EGFR). In contrast, JunB can antagonize keratinocyte proliferation and an inducible down-regulation of both, c-Jun and JunB, in epidermal keratinocytes causes a psoriatic-like phenotype with epidermal hyperplasia as well as deregulated cytokine expression. Finally, specific ablation of AP-1 subunits in cells of the central nervous system revealed crucial functions for c-Jun in axonal regeneration upon transection of the facial nerve and for c-Fos in long-term memory and synaptic plasticity.

Importantly, primary and immortalized cells could be isolated from almost all mice lacking individual AP-1 members. Analysis of fibroblasts revealed that c-Jun acts as positive regulator of the cell cycle by suppressing ►p53 and indirectly the p53 target gene ►p21. Moreover, loss of c-Jun results in reduced ►cyclin D1 activity, while its overexpression was found to upregulate cyclin D levels. On the other hand, JunB contributes to both positive and negative regulation of cell-cycle progression by induction of the cyclin-CDK inhibitor p16, down-regulation of c-Jun and cyclin D expression, or transcriptional activation of cyclin A. JunD-deficient fibroblasts exhibit specific alterations in cell proliferation depending of p53 and p19-ARF expression. Moreover, data from fibroblasts lacking both c-Fos and FosB established a critical role of these AP-1 subunits in cyclin D expression, whereas fibroblasts lacking either c-Jun or c-Fos cannot be transformed by oncogenes, such as ►Ras and Src, providing additional evidence for a critical role of AP-1 members in the control of cell proliferation and transformation. In addition to these cell-autonomous effects, critical and antagonistic functions of c-Jun and JunB on cell proliferation in trans were observed using knockout fibroblasts in an in vitro skin equivalent model system with primary human keratinocytes.

As described before, AP-1 activity is also greatly enhanced upon treatment of cells with genotoxic agents, implying that AP-1 target genes are involved in the cellular ►stress response, such as DNA repair, induction of survival, or initiation of the apoptotic program. Detailed studies demonstrate that AP-1 subunits, depending on the cell type and quality of the stimuli, are involved in both anti- and pro-apoptotic responses. As an example, fibroblasts lacking the c-Fos protein are hypersensitive to UV irradiation compared to wildtype cells, which is caused by a higher rate of apoptosis rather than the inability to repair damaged DNA. However, *c-fos*$^{-/-}$ deficiency results in the loss of light-induced apoptosis of photoreceptor cells in retinal degeneration. In contrast to *c-fos*$^{-/-}$ fibroblasts, the ability of *c-jun*-deficient fibroblasts to undergo apoptosis is greatly reduced due to the absence of CD95 (Fas/APO)-ligand induction. Vice versa, c-Jun overexpression induced apoptosis in fibroblasts. Reduced CD95-L induction was also observed in cells from mice expressing a c-Jun mutant protein, which lacks the critical JNK/SAPK phosphorylation sites in its transactivation domain (JunAA). Reduced apoptosis in response to genotoxic agents was also observed in mice lacking members of the JNK/SAPK family of protein kinases, suggesting that c-Jun and ATF proteins are the major substrates of JNK/SAPKs to mediate the cellular stress response. However, primary liver cell cultures and erythroblasts derived from *c-jun*$^{-/-}$ embryos exhibit increased apoptotic rates. Finally, while JunD participates in anti-apoptotic regulation, JunB appears to be part of a pro-apoptotic pathway through negative regulation of anti-apoptotic genes, at least in myeloid cells.

AP-1 Subunits in Cancer

As described previously, AP-1 activity is enhanced in cells that are stimulated by agents promoting cell proliferation. Moreover, oncogenic versions of c-Jun and c-Fos have been isolated from retroviruses, and various membrane-associated or cytoplasmic oncogenes (e.g., Ras, Src, Raf) permanently upregulate AP-1 abundance as part of their transforming capacity, suggesting that AP-1 members play an important role in cell proliferation and transformation. Initial evidence for this assumption has been obtained by blocking AP-1 activity either through expression of a transdominant-negative c-Jun mutant, by expression of antisense sequences, or by microinjection of Jun- and Fos-specific antibodies. Under these conditions cell-cycle progression was disturbed in cultured cells and the efficiency of oncoprotein-mediated ►cell transformation was reduced. However, different lines of evidence suggested that members of the Jun and Fos families play specific roles during these processes or may even antagonize each other.

Genetic analysis of AP-1 function in transgenic mice revealed that overexpression of c-Fos induces ►osteosarcoma formation. More recently, expression of transdominant-negative or phosphorylation-defective mutants and studies using knockout mice confirmed an essential contribution of distinct AP-1 subunits not only in osteosarcoma formation, but also ►skin carcinogenesis, intestinal tumors, liver tumors, lymphomas, and ►rhabdomyosarcomas.

These studies demonstrate that JNK-dependent phosphorylation of c-Jun as well as RSK-2 dependent phosphorylation of c-Fos on Ser-362 are essential

for osteosarcoma formation in mice and may also be important for human osteosarcomas. Additionally, expression and phosphorylation of c-Jun is critically implicated in skin tumor formation, whereas c-Fos function is absolutely required for malignant ►progression in mouse models of skin carcinogenesis. Tissue-specific ablation of c-Jun also reduces tumourigenesis in the APC (Min) mouse model of intestinal cancer and chemically induced ►hepatocellular carcinoma, respectively. During chemically induced liver tumourigenesis c-Jun prevents apoptosis by antagonizing p53 activity and thereby contributes to early-stage hepatocellular cancer development. In contrast to c-Jun, JunB was identified as a potential tumor suppressor gene, at least in hematopoietic cells, since inactivation of JunB in postnatal mice result in a transplantable myeloproliferative disorder eventually progressing to blast crisis and resembling early human chronic myelogenous leukaemia (CML). More recently, JunB has also been shown to inhibit proliferation and transformation of B-lymphoid cells and to function as a gatekeeper for B-lymphoid leukemia. Surprisingly, *p53/c-fos* double knockout mice develop highly proliferative and invasive rhabdomyosarcomas suggesting tumor suppression also by the c-Fos oncogene under specific conditions.

Despite a broad knowledge concerning genes, which harbor AP-1 binding sites in their regulatory elements, only a few directly regulated AP-1 target genes have been identified, which are affected in AP-1 null mice or cells derived thereof and may critically contribute to cellular transformation and tumor formation in vivo. In addition to AP-1 target genes involved in cell proliferation, differentiation, and apoptosis, the most well-characterized AP-1-responsive genes in cancer are those implicated in ►signal transduction (e.g., EGFR), ►chromatin remodeling (e.g., DMNT1, HDAC3), ►invasion (e.g., ►MMPs, ►uPA), ►metastasis (e.g., ►CD44, ►osteopontin), and ►angiogenesis (e.g., VEGF). Some of these target genes support the notion that AP-1 critically contributes to the aggressive spread of malignant tumor cells and metastasis that is a major cause of death in cancer patients (for in-depth information on this subject see [5]).

Despite the fact that AP-1 has been identified two decades ago, it still maintains a lot of its mystery. Further research on tissue-specific inactivation of AP-1 members and the identification of subunit-specific target genes may yield an even more complex picture of function and regulation of AP-1.

AP2

Definition

AP2 is a heterotetrameric protein constituted of four polypeptides, called adaptins: α and β2 (~ 100 kD each), and σ2 (~ 25 kD) and μ2 (~ 50 kD). α and β2-adaptins both bind to clathrin, whereas μ2 binds to receptor tails; the α subunit further binds to several accessory endocytic proteins in a spatially and temporally organized fashion. AP2 is also often spelled as AP-2.

APAF-1

Definition

Apoptotic protease activating factor 1 (APAF-1), also known as CED4, binds to caspase 9 (apaf-3) to activate caspase 3, resulting in apoptosis. It is an ubiquitously expressed cytoplasmic protein of 1194 aa and 135 kD. The human gene maps to 12q22.

Definition

APAF-1 was identified in 1997 as a homolog of *C. elegans* cell death 4 (►*CED-4*) gene. APAF-1 is a cytoplasmatic protein of 1194 aminoacids able to bind ►cytochrome-c and contributing to ►caspase-9 activation. APAF-1 protein exists in cells in an inactive monomeric form. Signals that activate the ►intrinsic pathway of apoptosis (such as developmental cues, genomic stress, endoplasmic reticulum stress, cytotoxic damage, ►hypoxia, growth factor deprivation, and cell detachment) lead to ►mitochondria outer membrane permeabilization (MOMP). As a result of MOMP, cytochrome-c, a component of the mitochondrial respiratory chain, present in the intermembrane space, is released from mitochondria into the cytosol, where it binds to APAF-1. Upon binding of cytochrome-c, in the presence of dATP/ATP, APAF-1 undergoes a conformational change. This triggers APAF-1 oligomerization into a heptameric complex named apoptosome. The APAF-1-cytochrome-c apoptosome is a wheel–like multiprotein particle with seven spokes and a central hub that is able to recruit and activate the initiator caspase-9. In turn, caspase-9 activates other effector caspases, such as caspase-3 and caspase-7, which execute the cell death program.

Characteristics

APAF-1 Gene Structure and Regulation

The *APAF1* gene, encoding the APAF-1 protein, spans about 55 kb of genomic region mapping on chromosomal band 12q22, between the polymorphic markers D12S296 and D12S346. Several allelic variants of the *APAF1* gene have been described. Some of these alleles (such as the E777K, N782T, C450W, and Q465R variants) have been shown to segregate with major depression (MDD) in families where a significant linkage had been found previously between MDD and markers at 12q22. The intron–exon structure of the *APAF1* gene comprises 26 introns and 27 exons. The APAF-1 mRNA is ubiquitously expressed in human adult and fetal tissues and yields a 130 kDa cytoplasmatic protein. The *APAF1* gene is one of the transcriptional targets of ►p53 in DNA damage-induced apoptosis. A genomic region upstream of the APAF-1 transcription start site (at -604 to -570 relative to the transcriptional start site) contains two consensus palindromic sequences defined as p53-responsive elements. Expression of the gene is promoted also by ►UVC irradiation which enhances translation of *APAF1* by a cap-independent mechanism facilitated by internal ribosome entry (►IRES) elements located in the 5′-UTR of the gene.

APAF-1 Protein Structure

The APAF-1 protein belongs to the superfamily of AAA^+ (AAA^+) proteins. AAA^+ proteins form large ring-shaped complexes acting as energy-dependent unfoldases of macromolecules. Most AAA^+ proteins have a single ATPase domain containing a canonical phosphate-binding (P-loop) domain. In the APAF-1 protein the AAA^+ ATPase domain is located between an N-terminal caspase recruitment domain (►CARD) and a C-terminal domain containing several ►WD-40 repeats. The overall structure of the APAF-1 protein is as follows: (i) an N-terminal ►CED-3-like domain (aminoacids 1–89) named CARD that binds to the CARD domain of procaspase-9; (ii) a CED-4 homologous domain (aminoacids 94–412) containing a P-loop sequence that binds dATP/ATP and a putative Mg^{2+}-binding site; (iii) a C-terminal regulatory domain (aminoacids 412–1194) containing 12 WD-40 repeats involved in the regulation of APAF-1. APAF-1 has different splice isoforms. These include APAF-1L, APAF-1XL, APAF-1M, and APAF-1XS. These alternative APAF-1 forms differ in the number of WD-40 repeats (12 or 13) and/or for the presence of additional sequences inserted between the CARD and the CED-4 homologous domains.

Assembly and Structure of the Apoptosome

The inactive form of APAF-1 is thought to form a compact monomer containing bound dATP. According to current models, when cytochrome-c binds to the C-terminal regulatory region of APAF-1, it promotes dATP hydrolysis (dATP→dADP). Subsequently, nucleotide exchange (dATP for dADP) takes place leading to an "active monomer" conformation that is poised to apoptosome assembly. Analysis of the apoptosome structure first at 27 Å and more recently at 12.8 Å resolution, by electron cryomicroscopy, has confirmed that the heptameric complex is a wheel-like structure with seven spokes radiating from a central hub. The N-terminal CARD domains of seven APAF-1 molecules contribute to build the central hub of the apoptosome (the "CARD ring"). The CARD ring represents the active center of the apoptosome where interaction with procaspase-9 takes place. At this level, procaspase-9 molecules may bind to the apoptosome, by CARD–CARD interactions with the hub domain.

Activation of procaspase-9 molecules is then thought to occur by an intermediate step requiring the formation of caspase-9 dimers. The C-terminal regulatory regions of each of the seven APAF-1 molecules in the apoptosome contribute an arm and a Y shape domain ending with two lobes. Each lobe, made of six or seven WD-40 repeats (depending on the APAF-1 isoform) folds as a ►β propeller, and a cytochrome-c molecule binds between the two β propellers.

Positive and Negative Regulation of Apoptosome Function

The apoptosome is subjected to positive and negative regulatory interactions with several molecules. In general, activation or inhibition of APAF-1 function may be achieved by mechanisms that interfere with: (i) APAF-1 oligomerization; (ii) APAF-1 interaction with caspase-9 or cytochrome-c; (iii) caspase-9 activation. Examples of positive regulators are: (i) NAC, a CARD-containing protein that associates with APAF-1 and promotes the activation of procaspase-9 by the apoptosome; (ii) Nucling, a protein that binds the apoptosome promoting its translocation to the nucleus and the activation of apoptosome-associated caspase-9; (iii) PHAPI, a protein that promotes caspase-9 association with the apoptosome. Examples of negative regulators of the apoptosome include: (i) IAP proteins, as ►XIAP, that can associate with the apoptosome and inhibit caspase-9; (ii) heat shock proteins (HSP) that can bind to cytochrome-c (as Hsp27) thus preventing its association with APAF-1, or that can bind to APAF-1 (as Hsp70 and ►Hsp90) and prevent caspase-9 activation; (iii) posttranslational modifications of apoptosome components, as exemplified by phosphorylation of caspase-9 at serine 196 (by ►AKT), at threonine 125 (by ERK), or at serine 144 (by PKC) that prevent caspase-9 activation, or recruitment to the apoptosome; (iv) a caspase-9 splice variant (named Casp-9γ), retaining only the CARD domain but lacking the catalytic domain, that may compete with functional caspase-9 for binding to the apoptosome.

APAF-1 Expression and Apoptosome Regulation in Cancer

Most of the chemotherapeutic drugs used in the treatment of cancer promote apoptosis by the mitochondrial pathway that leads to cytochrome-c release and apoptosome assembly. As resistance to apoptosis is one of the hallmark of cancer, alterations in APAF-1 expression and apoptosome function have been shown to be common in both solid tumors and hematological malignancies. Loss of expression of *APAF1* gene was initially described in advanced ►melanoma, by a mechanism involving ►methylation-induced transcriptional silencing and ►allelic imbalance (►loss of heterozygosity). *APAF1* ►promoter methylation and allelic imbalance have been described even in tumors other than melanoma. For example, reduced mRNA levels for *APAF1* has been shown in primary acute myeloblastic leukemia cells, due to ►CpG methylation in a region between +87 and +128 of the *APAF1* gene. Similarly, methylation of *APAF1* gene has been described in ►carcinomas of the bladder and in clear cell ►renal carcinomas. Allelic imbalance for *APAF1* gene, associated with reduced *APAF1* mRNA levels, has been described in ►colorectal carcinomas.

Defects of APAF-1 expression may be a marker of neoplastic transformation and/or tumor ►progression. In human melanoma, expression of APAF-1 protein is lower in neoplastic cells than in melanocytes and decreases with increasing thickness of the primary tumor as well as in the progression from primary lesion to metastatic disease. In ►nonsmall cell lung cancer patients, the subcellular localization of APAF-1 has been shown to represent a significant prognostic factor. In fact, nuclear localization of APAF-1 was associated with 5-year survival rates of 89% compared to 54% in patients with cytoplasmic localization of APAF-1 in the tumor cells. This suggests that nuclear translocation of APAF-1 may be associated with an apoptosis-prone phenotype of the neoplastic cells.

Inactivation of the *APAF1* gene, first shown in human melanoma, provides evidence for a mechanism that may prevent the execution of the apoptotic program in neoplastic cells following cytotoxic stress. The initial evidence indicated that reduced/absent APAF-1 protein expression was associated with chemoresistance of melanoma cells to DNA damaging drugs that mediate apoptosis by the p53 pathway. Reduction of APAF-1 protein can be achieved in neoplastic cells even by sequestration in discrete subcellular domains, not only by reduced protein expression as in melanoma cells. In Burkitt lymphoma cells, APAF-1 has been shown to be associated with discrete domains of the plasma membrane, instead of being free in the cytosol. Such APAF-1 sequestration prevents apoptosome formation in the presence of cytochrome-c and is associated with resistance to etoposide in Burkitt lymphoma.

Altered regulation of apoptosome assembly and function is another antiapoptotic strategy activated in neoplastic cells. For example, the constitutively active tyrosine kinase ►Bcr–Abl of chronic myelogenous leukemia has been shown to inhibit interaction of caspase-9 with APAF-1. Reduced caspase-9 binding to the apoptosome, not explained by reduced levels of caspase-9 or APAF-1, has been proposed as a chemoresistance mechanism even in ►ovarian cancer. In nonsmall cell lung cancer, a defect in apoptosome function has been linked to overexpression of the inhibitor of apoptosis XIAP that binds to the processed form of caspase-9, thus suppressing activation of downstream effector caspases.

Apoptosome-Dependent and -Independent Pathways of Apoptosis in Normal and Neoplastic Cells

The role of the APAF-1 pathway in apoptosis depends on the cell-context and on the specificity of the pro-apoptotic signal. In some experimental models, and in some human tumors, APAF-1 expression and function has been shown to be required for apoptosis in response to different proapoptotic drugs. For example, in mouse embryonic fibroblasts from mice lacking APAF-1 (APAF-$1^{-/-}$ mice), susceptibility to apoptosis induced by the ►proteasome inhibitor bortezomib is inhibited. In human leukemic cells, apoptosis promoted by etoposide requires caspase-10 activation, but small interfering RNA-mediated downregulation of APAF-1 prevents etoposide-mediated caspase-10 activation and inhibits apoptosis.

On the other hand, thymocytes from APAF$1^{-/-}$ mice have normal susceptibility to Fas-mediated cell death, indicating that APAF-1 is dispensable for the execution of apoptosis by the extrinsic pathway (Extrinsic pathway of apoptosis) (i.e., ►death receptor-induced apoptosis). In addition, thymocytes from mice expressing a mutant cytochrome-c unable to bind APAF-1 have been shown to be susceptible to apoptosis regulated by the ►intrinsic pathway (and induced by stimuli as etoposide, γ and ►UV irradiation). In these cells caspase-9 and caspase-3 could be activated after γ-irradiation, in spite of the absence of APAF-1 oligomerization, indicating the existence of apoptosome-independent, caspase activation pathways in response to cytotoxic stress.

Apoptosome-independent pathways of cell death in response to chemotherapeutic drugs exist in neoplastic cells. These pathways may promote apoptosis even when APAF-1 is not expressed, although APAF-1 expression can amplify the cellular response to some drugs. In melanoma cells, APAF-1 expression has been shown to be dispensable for caspase-9 activation and apoptosis promoted by drugs as ►cisplatin, camptothecin, betulinic acid, and etoposide. In agreement with these results, analysis of APAF-1 expression in a panel of 60 cell lines used for drug screening, and including the most frequent solid tumors and leukemias, has not provided evidence for APAF-1 as a major determinant of drug sensitivity.

APC/β-Catenin Pathway

Pat J. Morin
National Institute on Aging, NIH, Baltimore, MD, USA

Synonyms

The terms Wnt pathway and APC/β-catenin pathway have been used interchangeably. Because some Wnt proteins have β-catenin-independent effects, and since β-catenin can be affected by upstream pathways other than Wnt, the term APC/β-catenin is used here

Definition

The APC/β-catenin pathway is a signal transduction pathway important in development and tumorigenesis.

Signaling by this pathway is defined as the stabilization of β-catenin and transcriptional activation of several target genes.

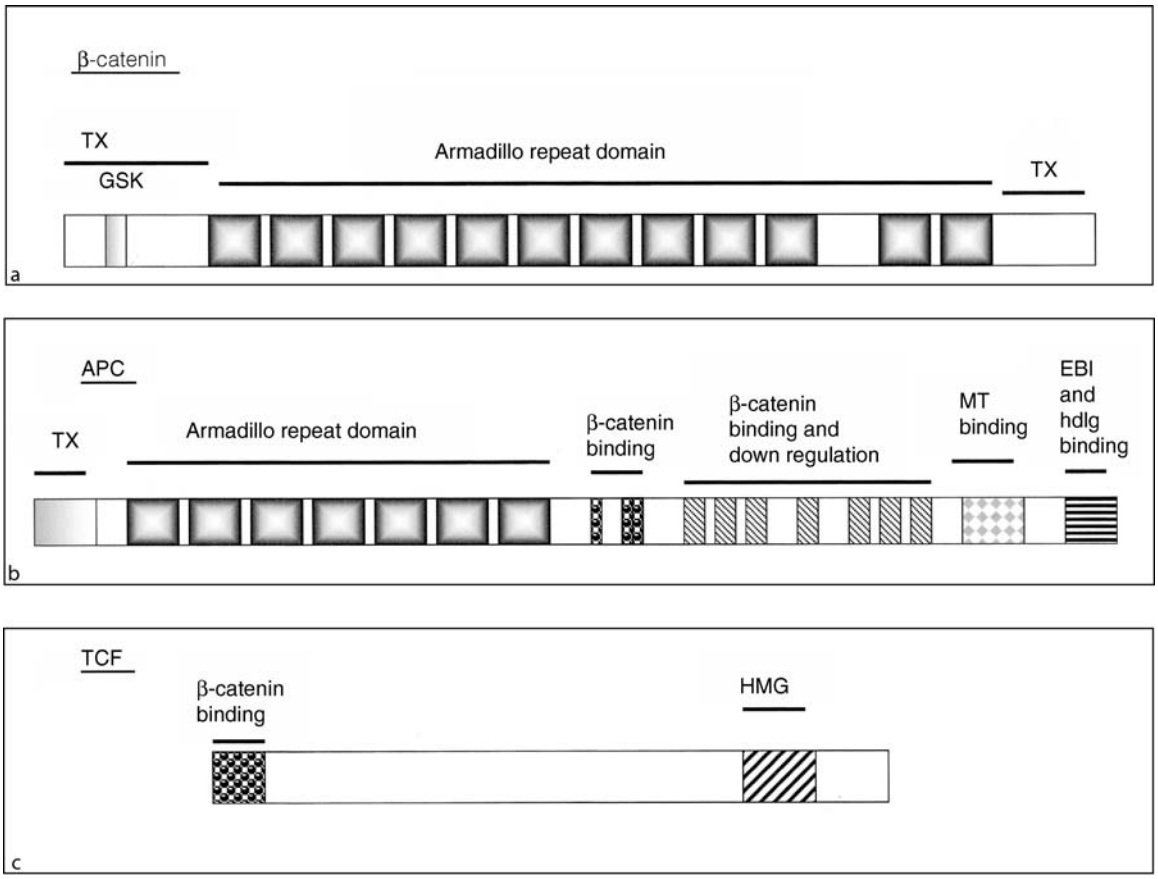
Characteristics

►β-Catenin is a multi-functional protein with roles in adhesion and signal transduction. The adhesion properties of β-catenin reflect its ability to interact with ►E-cadherin at the cellular membrane, and the alteration of this important cellular function has been associated with an increased invasion potential of cancer cells. In addition to this important role, β-catenin is also found in a cytoplasmic/nuclear pool and is believed to act as a signal transduction molecule. Cytoplasmic/nuclear β-catenin (sometimes called free β-catenin) can associate with the T cell factor (TCF) family of transcription factors and activate transcription of specific genes. The TCFs provide the DNA binding domain while β-catenin contains the transcriptional activation domain (Fig. 1). Transcriptional target genes of the pathway include cMYC (►MYC family), ►Cyclin D1 and MMP-7. APC/β-catenin signaling is regulated mainly through degradation of β-catenin at the protein level (see below). This regulation is complex, and inappropriate activation of the pathway can facilitate the development of several malignancies in humans and in animal models.

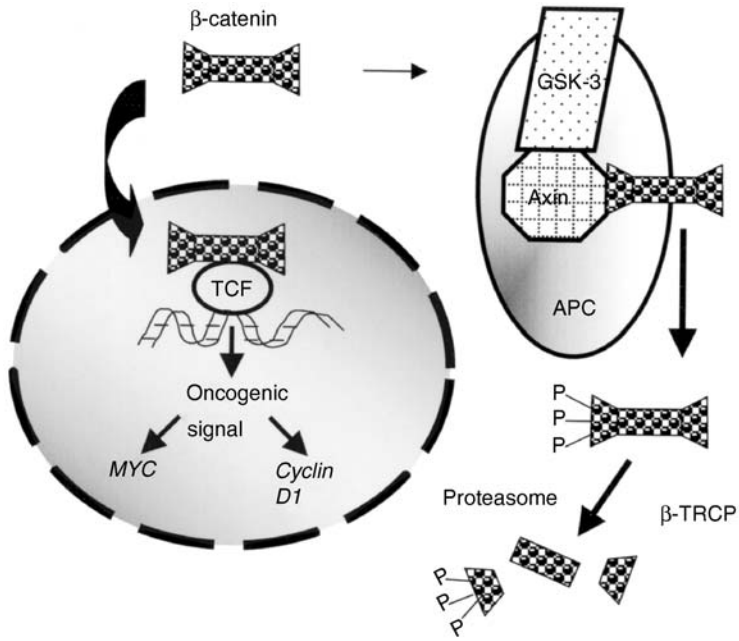
The pathway is highly conserved through evolution and the Drosophila melanogaster homolog of β-catenin, Armadillo, interacts with Drosophila TCF (Pangolin) to activate genes important for cellular fate determination during fruit fly embryonic development. Studies of the wingless pathway in Drosophila and Xenopus have been instrumental in unraveling the regulation of this pathway in normal and cancer cells.

Regulation

Normally, in differentiated cells, β-catenin protein is constantly degraded through the ubiquitin-►proteasome pathway. β-catenin is earmarked for degradation through



APC/β-Catenin Pathway. Figure 1 Schematic representation of the β-catenin, APC, and TCF proteins. (a) β-catenin protein, showing the transcriptional activation domains, Armadillo repeats, and the N-terminal GSK-3-β phosphorylation domain (GSK). (b) APC, showing armadillo repeats, β-catenin binding and downregulation domains and the microtubule binding region. Also shown are the binding domains for EB1 and the human discs large protein. (c) A simplified representation of the TCF family of proteins showing the β-catenin binding site, as well as the DNA-binding HMG domain.



APC/β-Catenin Pathway. Figure 2 APC/β-catenin signaling pathway. In the absence of signaling, β-catenin is targeted by the APC complex for proteasome degradation. When stabilized, β-catenin interacts with TCF to activate transcription of genes such as c-Myc and Cyclin D1. See text for details.

phosphorylation of specific residues at its N-terminus by GSK3β. The ubiquitin ligase β-TRCP can bind phosphorylated β-catenin, which is then polyubiquitinated (►ubiquitination). This effectively targets β-catenin for proteasome degradation. The phosphorylation and ubiquitination of β-catenin is regulated by a large complex of proteins that include GSK3β, Axin and APC (Fig. 2). In addition to its action on β-catenin, GSK3β phosphorylates APC and Axin but the consequences of these phosphorylation events are unclear. It appears that Axin increases the ability of GSK3β to phosphorylate β-catenin, since GSK3β phosphorylation of β-catenin is inefficient in vitro. APC has been suggested to act as a scaffold for these phosphorylation events. APC, a protein believed to be exclusively cytoplasmic, was shown to be present in the nucleus. In addition, APC contains a nuclear export signal (NES) and may be involved in shuttling β-catenin from the nucleus to the cytoplasmic degradation complex. The regulation of the complex and the roles of the different proteins within the complex are incompletely understood. The multifaceted regulation of β-catenin likely reflects the importance of the pathway in development and in tumorigenesis.

Clinical Relevance

The APC/β-catenin pathway is deregulated in several common human cancers. APC mutations are the cause of FAP (►APC gene in Familial Adenomatous Polyposis), a familial colon cancer predisposition syndrome. Genetic testing of FAP families allows the identification of individuals at risk of colon cancer and the establishment of appropriate management options. In addition, APC mutations are found in 80% of all sporadic cases of colon cancer. Mutations of APC lead to a lack of regulation of the β-catenin protein and inappropriate activation of the downstream genes. Interestingly, in sporadic colon tumors without APC mutations, β-catenin itself is frequently mutated. The mutations typically affect GSK3β phosphorylation sites in the N-terminus of β-catenin, leading to a protein resistant to phosphorylation and subsequent degradation. While mutations in APC are not frequently observed in cancers other than colon, mutations in β-catenin have been reported in several human malignancies such as melanoma, colon cancer, prostate cancer and skin cancer. Axin, another member of the pathway is also found mutated in liver cancer. Cellular consequences of the activation of the APC/β-catenin pathway are unclear but several lines of evidence suggest that the pathway is important for the maintenance of stem cell characteristics, including longevity. In any event, it is clear that many human malignancies gain a selective advantage through activation of this pathway. Selective inhibition of β-catenin activation may represent a useful therapeutic strategy for a large number of cancers.

Definition

Familial adenomatous polyposis (FAP) is a dominant condition predisposing to the development of multiple colorectal adenomas (polyps) during adolescence. Adenomatous polyps are benign tumors that can degenerate into malignant adenocarcinomas and subsequently into metastases if the affected segment of the bowel is not surgically resected (Fig. 1a and b).

Characteristics

FAP affects on the average 1 in 10,000 individuals and, although the polyps represent the hallmark of the disease, it might be regarded as a condition of the whole body since it is often characterized by a number of extraintestinal manifestations involving all three embryonic lineages:

- Tumors of the stomach, duodenum, and of the biliary tree
- ►Osteomas, desmoids (Fig. 2), liver tumors, and dental abnormalities
- Epidermal cysts of the skin, congenital hypertrophies of the retinal pigment epithelia (►CHRPE), and endocrine tumors

Of these tumors, the duodenal polyps and the abdominal desmoids occur respectively in 44% and 13% of the FAP patients. Next to colorectal cancer (►colon cancer) and eventual metastases, these tumors represent the most clinically relevant complication of the disease.

The most benign manifestation of FAP, the CHRPE in the eye, is found to be consistently associated in about 80% of the cases even before the appearance of the polyps in the large bowel, thus representing a very useful diagnostic biomarker.

FAP is an autosomal dominant condition with very high ►penetrance (close to 100%). Germline mutations in the adenomatous polyposis coli (APC) gene are responsible for FAP. APC encodes for a large (312 kD) and multifunctional protein involved in several biological processes ranging from cell ►adhesion, migration, and signal transduction.

APC Gene in Familial Adenomatous Polyposis. Figure 2 Surgical specimen of a large andominal desmoid tumor resected from a patient with familial adenomatous polypoics.

APC is nowadays considered as the gene for colorectal cancer as somatic APC mutations occur early in the adenoma-carcinoma sequence and are found in the vast majority (>85%) of sporadic adenomas and carcinomas. Functional studies have shown that APC plays a critical role in controlling WNT signal transduction (►WNT signaling) by regulating β-catenin levels in the cytoplasm, and this feature is likely to represent APC's tumor suppressive function. Indeed, colorectal tumors with an intact APC contain oncogenic β-catenin mutations that alter phosphorylation sites which make the protein resistant against proteolytic degradation. The ►WNT signal transduction pathway plays a critical role in a broad range of biological processes such as differentiation, cell polarity, and the specification of cell fate (for a schematic representation of the WNT pathway see http://www.ana.ed.ac.uk/rnusse/pathways/pathway.html). In the absence of the WNT stimulus, a multi-protein complex composed of GSK3, Axin, Conductin, and APC, earmarks β-catenin for proteolytic degradation. In the presence of the secreted WNT glycoproteins, these interact with the frizzled receptors thereby inhibiting the formation of the above complex and β-catenin degradation. Accumulation of β-catenin in the cytoplasm results in its translocation to the nucleus where it complexes with TCF transcription factors thereby activating downstream target genes. Hence, loss of APC in mammalian cells or oncogenic activation of β-catenin, leads to constitutive signaling and cell transformation due to uncontrolled activation of downstream target genes.

A large number of disease-causing mutations in individuals affected by FAP have been characterized. The vast majority of APC mutations identified to date are clustered within the 5′ half of the gene (upstream of codon 1600) and are predicted to result in the truncation of the corresponding protein products.

Genotype–phenotype Correlations

The identification of a large number of mutations, together with the availability of the corresponding clinical data, offers a unique opportunity to establish genotype–phenotype correlations at the APC gene. Mutations located close to the 5′ end of the APC gene result in a generally mild and variable FAP phenotype, the so-called attenuated adenomatous polyposis coli (AAPC), characterized by a variable and reduced polyp multiplicity and a delayed age of onset. Mutations beyond APC codon 1600 are rare and are also often associated with attenuated phenotypes. Consistent correlations between germline mutations at the APC gene and FAP extraintestinal manifestations such as ►desmoid tumors, CHRPE's, and osteomas have also been reported.

Apoptosis

Shigekazu Nagata
Osaka University Medical School, Osaka, Japan

Synonyms
Programmed cell death

Definition
Apoptosis is a T cell death process which occurs during development and aging of animals. It is also induced by cytotoxic lymphocytes (CTL), anti-cancer drugs, γ- or UV-Tradiation, a group of cytokines called death factors and deprivation of survival factors.

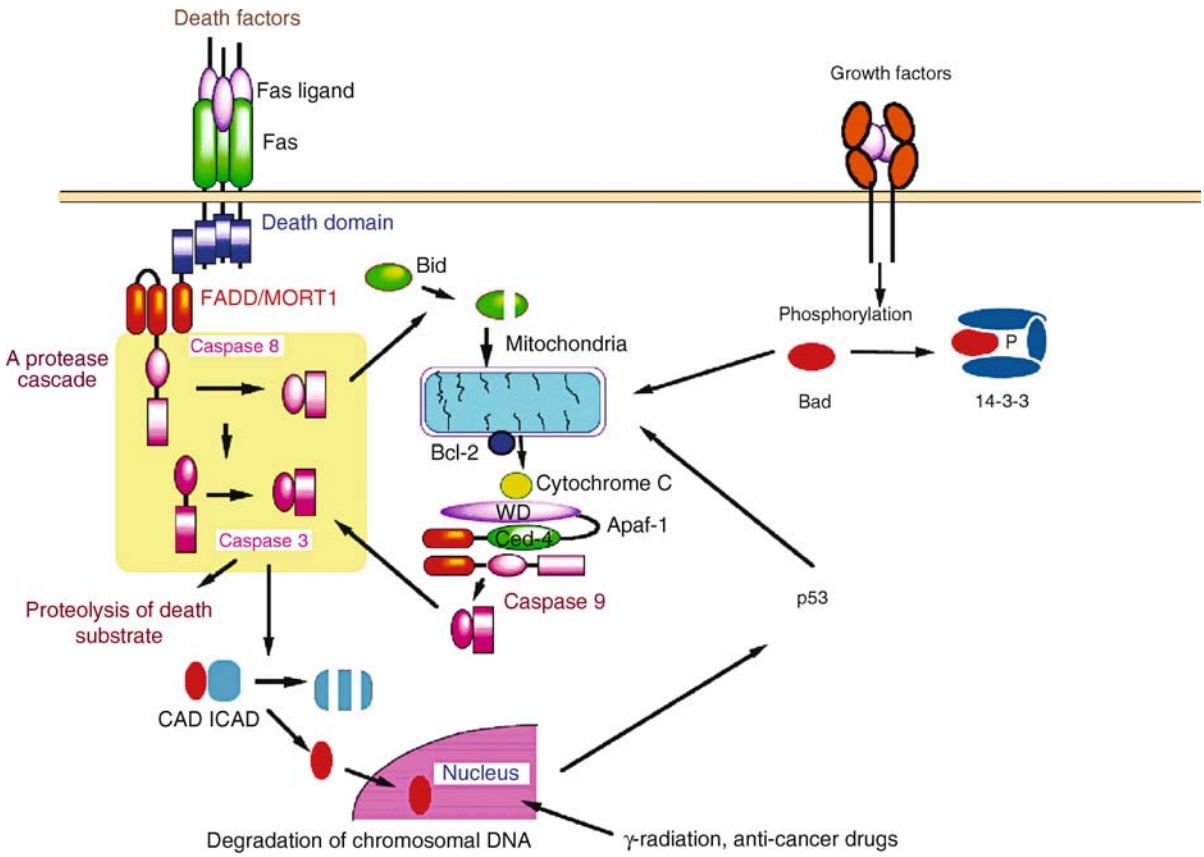
Characteristics
Apoptosis was initially characterized by morphological changes of dying cells. During apoptosis cells shrink, and microvilli on the plasma membrane disappear. The nucleus is also condensed and fragmented. At the final stage of apoptosis the cells themselves are fragmented

with all cellular contents inside. One of the biochemical hallmarks of apoptosis is the fragmentation of chromosomal DNA into ►nucleosome size units (180 bp).

Apoptotic cells can be recognized by staining of the condensed nuclei with fluorescence dyes Hoechst or DAPI. Apoptotic cells expose phosphatidylserine to the cell surface, which can be stained with fluorescently labeled annexin V. The fragmented DNA can be detected by ►TUNEL (terminal deoxynucleotidyltransferase-mediated UTP end labeling) procedure, or by electrophoresis of the isolated DNA on an agarose gel, which yields a ladder of DNA fragments with a unit size of 180 bp.

Cellular Regulation

Apoptosis is mediated by a family of proteases called ►caspases that are activated by processing from its inactive precursor (zymogen). Thirteen members of the human caspase family have been identified. Some of the family members are involved in apoptosis, and these can be divided into two subgroups. The first group consists of caspase 8, caspase 9, and caspase 10,



Apoptosis. Figure 1 Signal transduction for apoptosis. Inducers of apoptosis are categorized into three groups (death factors, genotoxic anti-cancer drugs, and factor deprivation). Fas ligand, a representative of death factors, binds to Fas receptor, and causes its trimerization. The trimerized death domain in the Fas cytoplasmic region recruits pro-caspase 8 through a FADD/MORT1 adaptor, and forms a DISC. The pro-caspase 8 is autoactivated at DISC, and becomes a mature active enzyme. Two routes have been identified to activate caspase 3 by caspase 8. In one route, caspase 8 directly processes pro-caspase 3 in the downstream, and caspase 3 cleaves various cellular proteins including ICAD. CAD is released from ICAD, and degrades chromosomal DNA. In another route, caspase 8 cleaves Bid, a pro-apoptotic member of Bcl-2, which translocates to mitochondria to release cytochrome C into the cytosol. Bcl-2 or Bcl-xL, anti-apoptotic members of the Bcl-2 family, inhibits the release of cytochrome C, the mechanism of which is not well understood. The cytochrome C then activates caspase 9 together with Apaf-1, and caspase 9 in turn activates caspase 3. The genotoxic anti-cancer drugs such as etoposide and γ-radiation generate damage in chromosomal DNA. The signal seems to be transferred to mitochondria in a p53-dependent manner by as yet an identified mechanism. This releases cytochrome C from mitochondria, and activates caspase 9 as described above. The apoptosis induced by factor-deprivation is best studied with IL-3-dependent myeloid cell lines. In the presence of IL-3, the signal from the IL-3 receptor causes phosphorylation of Bad, a pro-apoptotic member of the Bcl-2 family. The phosphorylated Bad is trapped by an adaptor called 14–3–3. In the absence of IL-3, non-phosphorylated Bad is released from 14–3–3, and translocates to mitochondria to release cytochrome C to activate caspase 9.

which contain a long prodomain at the N-terminus and function as initiators of the cell death process. The second group contains caspase 3, caspase 6, and caspase 7, which have a short prodomain and work as effectors, cleaving various death substrates that ultimately cause the morphological and biochemical changes seen in apoptotic cells. The other effector molecule in apoptosis is ►Apaf-1 (apoptotic protease activating factor), which, together with cytochrome C, recruits pro-caspase 9 in an ATP (or dATP)-dependent manner, and stimulates the processing of pro-caspase 9 to the mature enzyme.

The other regulators of apoptosis are the ►Bcl-2 family members. Eighteen members have been identified for the Bcl-2 family, and divided into three subgroups based on their structure. Members of the first subgroup, represented by Bcl-2 and Bcl-xL have an anti-apoptotic function. Members of the second subgroup, represented by ►Bax and Bak (►BAK1), as well as members of the third subgroup such as ►Bid and ►Bad are pro-apoptotic molecules.

The signal transduction pathway for a death factor (►Fas ligand)-induced apoptosis has been well elucidated. Binding of Fas ligand to its receptor results in the formation of a complex (disc, death-inducing signaling complex) consisting of FAS/APO-A/CD95, FADD and pro-caspase 8. Pro-caspase 8 is processed to an active enzyme at the disc. There are two pathways downstream of caspase 8. In some cells, such as thymocytes and fibroblasts, caspase 8 directly activates 3. In type II cells such as hepatocytes, caspase 8 cleaves Bid, a member of the Bcl-2 family. The truncated Bid then translocates to mitochondria and stimulates release of cytochrome c, which activates caspase 9 together with Apaf-1. The activated caspase 9 causes processing of pro-caspase 3 to the mature enzyme. In addition to the death factors, anti-cancer drugs, γ-irradiation or factor-depletion induce apoptotic cell death. Although cytochrome C is released from mitochondria during apoptosis induced by these stimuli, the molecular mechanism that triggers the release of cytochrome C from mitochondria is not known (Fig. 1).

Caspase 3 activated downstream of the caspase cascade activates a specific DNase (CAD, caspase-activated DNase). CAD is complexed with its inhibitor, ICAD (inhibitor of CAD), in proliferating cells. When caspase 3 is activated in apoptotic cells, it cleaves ICAD to release CAD. CAD then causes DNA fragmentation in the nuclei.

Clinical Relevance

Blocking of apoptosis by loss-of-function mutations of apoptosis-inducing molecules such as Fas, Fas ligand and caspases, or overexpression of apoptosis-inhibitory molecule such as Bcl-2, causes cellular hyperplasia. In some cases it leads to tumorigenesis, as evident in B-cell lymphomas, which over-express Bcl-2 due to the translocation of the Bcl-2 gene to the immunoglobulin gene locus. Some multiple myeloma and non-Hodgkin lymphoma carry loss-of-function mutations in the Fas gene. Somatic mutation in the Fas gene can also be found in patients of autoimmune diseases called Canale-Smith syndrome or ►autoimmune lymphoproliferative syndrome (ALPS).

Exaggeration of apoptosis causes tissue damage. For example, administration of Fas ligand, exposure to γ-irradiation, or treatment with a high dose of glucocorticoid kill test animals by causing massive apoptosis in the liver or thymus. Hepatitis, insulitis, graft-versus-host disease, and allergic encephalitis are due to the excessive apoptosis by Fas ligand expressed on CTL. Apoptotic cells are detected in the brain of ischemia

or Alzheimer patients, suggesting that apoptosis is at least in part responsible for the disease manifestation in these patients.

A proper dose of anti-cancer drugs or γ-irradiation can kill cancer cells by activating the apoptotic death program in the target cells. Some cancer cells are resistant to these drugs by an unknown mechanism. It is hoped that elucidation of the molecular mechanism of apoptosis leads to development of an efficient cancer therapy (Table 1).

Apoptosis-inducing Factor (AIF)

Definition

Is a 57 kDa flavoprotein and is involved in the execution phase of ►apoptosis. Following apoptotic signals, AIF translocates from the intermembrane space of mitochondria to the nucleus contributing to chromatin condensation and fragmentation of the nucleus. It is suggested that it may also induce the translocation of cytochrome c from mitochondria to the cytoplasm.

Apoptosis-Induction for Cancer Therapy

Edwin Bremer, Wijnand Helfrich
Groningen University Institute for Drug Exploration (GUIDE), University Medical Center Groningen, Department of Pathology & Laboratory Medicine, Section Medical Biology, Laboratory for Tumor Immunology, Groningen, The Netherlands

Definition

►Apoptosis is a highly coordinated ►homeostasis mechanism that ensures the timely and safe removal of superfluous, damaged, or dangerously altered cells without causing collateral damage. Imbalances in apoptosis have been implicated in a variety of pathological conditions, including cancer. Tumor cells typically have an elevated threshold for endogenous pro-apoptotic signals, which can lead to a dangerously extended cellular life span and progressively malignant behavior. Conventional cancer treatment, such as ►chemotherapy and/or ►ionizing radiation therapy, overcomes apoptosis resistance by inducing extensive and indiscriminate damage in all rapidly dividing cell types, including many normal cell types. Consequently, the therapeutic efficacy of conventional cancer therapeutics is usually limited by their severe side-effects. Therefore, cancer researchers have focused on the design of new strategies that more selectively tip the balance of cellular fate of cancer cells towards apoptosis, while sparing normal cells.

Characteristics

In every cell a variety of pro- and anti-apoptotic receptors and signaling molecules are involved in a continuous decision-making process on whether it is safe to live or better to die by apoptosis. The decision to activate apoptosis can originate from within the cell itself and, alternatively, from surrounding tissue or immune effector cells. In the course of ►malignant progression cancer cells evolve mechanisms to evade the activation of apoptosis, most notably by acquiring cancer-specific intracellular aberrancies in the apoptotic machinery. Many of these aberrancies have been identified in recent years and as such have become promising targets for cancer-selective therapy. Indeed, the design of targeted agents that selectively induce apoptosis in cancer cells is a rapidly moving field which has yielded novel promising anti-cancer strategies. Roughly spoken, these strategies can be divided in (i) those aimed at (re)-activation of intracellular pro-apoptotic systems, (ii) those aimed at inhibition of intracellular anti-apoptotic systems, and (iii) those aimed at selective delivery of additional external pro-apoptotic stimuli to cancer cells.

Re-activation of Intracellular Pro-Apoptotic Systems

One of the most commonly found aberrancies in cancer cells is the inactivation of the ►tumor suppressor protein ►p53. P53 is a transcription factor central to many of the cell's anti-cancer mechanisms. When needed, p53 can induce ►growth arrest, ►senescence, and apoptosis in order to maintain genetic integrity. In normal cells, p53 is maintained quiescent by the protein HDM-2, which binds to p53, inhibits its action, and promotes degradation of p53 by the ►proteasome. However, upon intracellular stress, e.g. resulting from UV radiation or drugs that induce ►DNA-damage,

p53 is rapidly activated by ►phosphorylation at sites within the HDM2-binding region. As a result, HDM-2 dissociates and p53 activates the cellular response to stress, which in most cases is the activation of cell death by apoptosis. The importance of p53 is evidenced by the fact that p53 is inactivated in over 50% of human tumors. Furthermore, tumors that do express a functional p53 often overexpress HDM-2.

These notions have led to the rational design of drugs that aim to reactivate the functionality of p53 in cancer cells. Research focused on p53 reactivation is two-fold. One aim is to reactivate mutant p53, a second aim is to release the HDM-2 mediated block on functional p53. An interesting example of the first strategy is the compound called PRIMA-1, which stands for p53-dependent reactivation and induction of massive apoptosis-1. PRIMA-1 selectively restores activity of mutant p53 and thereby potently activates apoptosis. An interesting example of the second strategy is the compound called RITA, which stands for reactivation of p53 and induction of tumor cell apoptosis. RITA inhibits the HDM-2/p53 interaction by binding to p53, which also leads to potent p53-mediated apoptosis induction, without significant toxicity towards normal cells.

Inhibition of Intracellular Anti-Apoptotic Systems

Many cancer cell types are characterized by upregulation of members of the so-called ►Inhibitor of Apoptosis Protein (IAP) family. IAPs represent an integral checkpoint during apoptosis that by inhibition of key proteases, the so-called caspases, can block the execution of apoptosis. Of particular interest is XIAP (X-linked IAP), which has been shown to directly inhibit various pivotal caspases. Intriguingly, this direct caspase-inhibitory activity appears to be a unique feature of XIAP that is not shared by the other IAPs.

A group of polyphenylurea compounds selectively inhibit XIAP. These compounds release the blockade of XIAP on effector caspases, resulting in potent and selective apoptosis induction, while normal cells appear to be resistant. In experimental animal models, these XIAP inhibitors strongly retarded the growth of human tumors, providing an intriguing insight in the apoptosis-prone nature of cancer cells. Apparently, relieving the XIAP anti-apoptotic brake is sufficient to reveal an intrinsically higher sensitivity of cancer cells to apoptosis than normal cells.

Selective Delivery of Additional External Pro-Apoptotic Stimuli

Highly specialized immune effector cells possess a variety of mechanisms to eliminate cancerous cells, including the targeted induction of apoptosis. However, due to the complexity of the immune system, direct therapeutic manipulation for cancer therapy has proven to be difficult. Nevertheless, several of the pro-apoptotic effector molecules of these immune cells have a promising therapeutic potential in their own right.

►TNF-related Apoptosis Inducing Ligand (TRAIL) is normally expressed on immune effector cells as a transmembrane protein. TRAIL can also be cleaved from the cell surface, yielding a functional soluble derivative (sTRAIL) that retains pro-apoptotic activity. Several recombinant forms of sTRAIL have been generated, all displaying promising therapeutic activity towards malignant cell types, with minimal activity towards normal cells.

The tumor-selective binding of sTRAIL, as well as its family member ►sFasL (Fas Ligand), can be strongly enhanced by genetic fusion to a tumor-selective antibody fragment. Binding of such fusion proteins to cell surface-expressed target antigens converts the soluble death ligands into membrane-bound molecules capable of cross-linking agonistic death receptors in an autocrine and paracrine manner. In this way also neighboring tumor cells devoid of target antigen can be effectively eliminated by the so-called bystander effect. This bystander effect solely depends on accretion of fusion proteins to the cell surface of targeted cells and does not require further cellular processing other than intact death receptor signaling pathways. Proof of principle for this approach has been obtained for sTRAIL and sFasL in both solid tumors and leukemia with no or minimal activity towards normal cells.

Perspectives for Selectively Tipping the Apoptotic Balance in Cancer

The future direction in cancer therapy strongly points to the selective induction of apoptosis in cancer cells by targeting cancer-cell specific aberrancies in the apoptotic machinery. However, an important question that remains to be fully addressed is how "selective" cancer-cell selective apoptosis induction is and ultimately can be. In particular, since apoptosis is a pivotal process in both normal and cancer cells, it remains to be determined whether specific induction of apoptosis in cancer cells is feasible without causing harm to normal cells. Single-agent therapy is likely to be not selective and/or effective enough and combinatorial strategies will be required. The most promising combinations of anti-cancer drugs will be those that work along different or complementary apoptotic signaling routes with non-overlapping toxicities towards normal cells.

Such rationally designed combinatorial strategies will only be feasible when specific cancer-related aberrancies can be rapidly diagnoses in individual patients. Therefore, development of reliable, cost-effective and high-throughput diagnostic tools will have to be pursued for each of the cancer-selective strategies to be successful. Taken together, as more and

more cancer-selective strategies designed to target the molecular aberrations in apoptosis regulation in cancer cells are being developed, the application of tumor-selective apoptosis induction in a clinical setting is slowly turning into reality.

Type I Programmed Cell Death

Definition

►Apoptosis is an evolutionarily conserved, genetically regulated form of Programmed Cell Death that is driven by ►caspases.

Characteristics

Apoptosis is a major tumor suppression mechanism and mechanism of tumor cell killing by anti-cancer drugs consequently, the study of apoptosis is an important aspect of cancer research. Apoptotic cell death occurs when a family of about twelve cysteine-directed proteases called caspases are activated. Apoptotic caspases fall into two broad categories, initiator caspases, which start the apoptotic cascade and effector caspases, which disassemble the cell. Other members of the caspase family such as caspase-1 play a less important role in apoptosis and are instead involved in processing pro-inflammatory cytokines. Apoptosis is characterized by specific morphological changes in the dying cell including degradation of the cytoskeleton, membrane blebbing, nuclear condensation and fragmentation, DNA degradation and the formation of apoptotic bodies. An important aspect of apoptotic cell death is the translocation of phosphatidyl serine from the inner cell membrane to the outer cell membrane. This serves as a signal for apoptotic cell ►phagocytosis resulting in orderly disposal of the cell corpse with little inflammation. These morphological characteristics are caused by caspase cleavage of particular substrates (amounting to several hundred separate proteins) and provide the basis for methods that are used to assess apoptosis such as the ►TUNEL assay, which detects cleaved DNA after the activation of a caspase-dependent nuclease in apoptotic cells. Other commonly used assays directly measure the presence of caspase-cleaved substrates or the active form of effector caspases such as ►caspase-3. Such methods are often used to assess levels of apoptosis in tumors during development and treatment of cancer. Caspases do not completely degrade theirs substrates, instead cleavage usually occurs at one or two sites in the protein resulting in fragmented proteins with altered activity. The fate of the cell depends on an integration of both pro- and anti-apoptotic signals, which are constantly being received from extracellular and

intracellular sources. The net effect is that either the pro-apoptotic signals will win out and cause a cell to cross its apoptotic threshold and activate the apoptotic machinery sufficiently to lead to cell death or, the cell will fail to cross this threshold and thus remain alive. Therefore a key concept in understanding apoptosis regulation is that each of the various signaling pathways that impinge upon apoptosis are not necessarily more or less important than any other. Although one signal may appear to make all the difference and cause the cell to undergo apoptosis, this signal is not necessarily a stronger apoptotic stimulus than all the others. Instead, it may be just enough to tip the balance over the apoptotic threshold. A consequence of this is that when one tries to manipulate apoptosis, for example, during cancer treatment, it may be difficult to identify any single pathway that is most important for determining the ultimate fate of the cell. Another genetically controlled form of Programmed Cell Death (Type II programmed cell death or autophagic cell death) occurs through ►autophagy. Although there are close connections between apoptosis and autophagy, autophagic cell death does not occur as a result of caspase activation and the morphological changes associated with this form of death (e.g. formation of large number of vesicles in the cell) is quite different from apoptosis.

Death Receptor Signaling

►Death receptors are members of the ►Tumor Necrosis Factor (TNF) superfamily that directly activate apoptotic caspases to stimulate the death receptor or "extrinsic" apoptosis pathway. The best understood death receptors are ►Fas/APo-1/CD95, which signals in response to ►Fas ligand, ►TNFR1, which signals in response to ►TNFα, and two receptors for TNF-Related Apoptosis Inducing Ligand (►TRAIL) called ►TRAIL receptor 1 or DR4, and ►TRAIL receptor 2 or DR5. Death receptor signaling is important in cancer treatment and tumor surveillance. Recombinant TRAIL and agonistic antibodies that recognize TRAIL receptors kill tumor cells while leaving most normal cells unscathed and several clinical trials have been performed to test if these agents may be useful to treat cancer. Fas ligand and TNFα are toxic when administered systemically, which has limited their use as anti-cancer treatments, although TNF is used clinically in isolated limb perfusion treatments. Signaling via the death receptors is also important in mediating the effects of other chemotherapeutic agents. TRAIL signaling is important in mediating tumor cell killing by ►NK cells and T cells, which leads to reduced ►metastasis and inhibition of TRAIL signaling in human tumors has been associated with metastatic disease and poor clinical prognosis. In addition, lymphocyte-induced tumor cell killing by Fas Ligand acts as an anti-tumor mechanism. This mechanism can however be turned on its head by tumor cells, which can sometimes release soluble forms of Fas Ligand to kill lymphocytes that are infiltrating into the tumor.

The various death receptors function as trimers, however the active signaling complex consists of two or more of these trimers and usually involves the formation of large aggregates with many trimer subunits. Apoptosis induction by all the known death receptors relies upon an adaptor protein called ►FADD, which upon ligand binding to the receptor interacts with the intracellular death domains of Fas and the TRAIL receptors, or, in the case of TNFR1 signaling, interacts with a second adaptor protein called ►TRADD rather than the receptor itself. FADD also binds to ►caspase-8 and the receptor/FADD/caspase-8 complex forms the basis of the Death Inducing Signaling Complex, also known as the ►DISC. In the DISC, ►caspase-8 forms catalytically active dimers leading to activation of downstream effector caspases such as caspase-3 that digest cellular proteins to cause apoptotic cell death. ►FLIP, a catalytically inactive homolog of caspase-8, also regulates this step by being recruited to the DISC where it modulates caspase-8 activation. Overexpression of FLIP occurs in various human tumors providing a mechanism by which death receptor signaling can be inhibited during tumor development. In addition to caspase activation, other signaling pathways leading to ►NFκB activation and activation of the ERK, JNK and p38 MAP kinase (►MAP kinase) pathways are induced; other cytoplasmic complexes that form after the DISC generate these signals, which can counteract the pro-apoptotic signaling caused by caspase activation.

Mitochondrial Regulation of Apoptosis

Diverse stimuli including most anti-cancer agents and cell damaging events cause release of mitochondrial proteins to activate the other apoptosis pathway – the mitochondrial apoptosis pathway, also called the "intrinsic" pathway. Members of the ►Bcl-2 family regulate caspase activation and apoptosis induced by stimuli that work through this pathway. There are more than twenty Bcl-2 family proteins that contain a series of conserved protein domains (BH1, 2, 3 and 4) and fall into two broad classes; those that stimulate apoptosis such as ►Bax and ►Bak and those that inhibit it such as ►Bcl-2 and ►Bcl-xL. Broadly speaking the anti-apoptotic Bcl-2 family proteins prevent release of proteins from the mitochondria while the pro-apoptotic proteins promote release of mitochondrial proteins. Bcl-2, Bcl-xL, Bax and Bak possess multiple ►BH3 domains, however, some of the pro-apoptotic family members contain only one of the conserved BH domains. These BH3-only proteins can only kill in cells that possess functional Bax or Bak and serve as sensors of cellular damage/stress and allow control over the initiation of cell death from diverse kinds of stimuli.

They are expressed in particular subcellular locations and monitor particular kinds of death stimuli. For example, two BH3-only proteins called Noxa and ►PUMA are induced by the tumor suppressor ►p53 and are critical for apoptosis following DNA damage (Bax is also a p53 target). Death receptors activate the intrinsic pathway through cleavage of ►Bid, a BH3 protein that is cleaved by caspase-8 and then translocated to mitochondria. This step allows the signal from the death receptor to be amplified by the mitochondrial apoptosis pathway. Other BH3-only proteins regulate cell death after detachment from the extracellular matrix, a process called ►anoikis, alterations in the cytoskeleton, and activation of intracellular signaling transduction pathways regulated by various protein kinases and phosphatases. The mechanisms by which the various pro- and anti-apoptotic proteins work is incompletely understood. However a major aspect of this mechanism is through direct protein-protein interactions where the BH3 domain of the pro-apoptotic BH3-only proteins interacts in a groove on the surface of the anti-apoptotic proteins that is formed by the BH1, 2 and 3 domains. This titrates the anti-apoptotic proteins thus allowing Bax and Bak to promote mitochondrial protein release. In addition conformational changes and intracellular translocations are induced in Bax and Bak by stressors, which activate their pro-death activities. Mitochondrial recruitment of other proteins, including p53 can also have similar effects leading to release of proteins from mitochondria. This mechanism of p53-mediated apoptosis is separate from its ability to regulate expression of pro-apoptotic BH3-only proteins.

Whatever the upstream signals leading to activation of the mitochondrial apoptosis pathway, the end result is release of proteins that reside in the intermembrane space between the inner and outer mitochondrial membranes into the cytoplasm. The most important of these proteins is ►cytochrome c. Released cytochrome c interacts in the cytoplasm with ►Apaf-1, ►caspase-9 and dATP to form a protein complex called the ►apoptosome. This complex activates caspase-9, which then activates effector caspases such as caspase-3 leading to cell death. Other mitochondrial proteins are also released from the intermembrane space. These include: Apoptosis Inducing Factor, ►AIF, an NADH oxidase that is important for efficient oxidative phosphorylation and a protector against oxidative stress. When AIF is released from the mitochondria, it can translocate to the nucleus where it causes caspase-independent chromatin and DNA condensation and degradation. Another protein released from the mitochondria is ►Smac/DIABLO an inhibitor of a class of proteins called Inhibitors of Apoptosis Proteins, ►IAPs. IAPs bind directly to caspases to inhibit their activity and, in some cases, to promote caspase ubiquitylation and degradation via the proteosome. Thus, a concerted mechanism whereby activation of the apoptosome by cytochrome c occurs simultaneously with Smac/Diablo-mediated inhibition of the IAPs promotes efficient activation of the caspase cascade. Other released mitochondrial proteins include Endonuclease G, an endonuclease that digests nuclear DNA and Omi/HtrA2, a serine protease, which can also inhibit IAPs.

Endoplasmic Reticulum Regulation of Apoptosis

A third pathway that regulates apoptosis occurs in response to ►endoplasmic reticulum stress (ER stress). Proper ER function is required for regulation of protein synthesis, trafficking and secretion, vesicle trafficking, lipid and membrane biosynthesis. Dysfunction of the ER leads to a set of adaptive pathways called the ER stress response, which usually allows the cell to restore ER homeostasis, however excessive and/or sustained ER stress triggers apoptosis. These processes are important in the regulation of tumor growth and progression and are, for example, critical for tumor cell survival and growth in hypoxic tumors. ER-specific stressors that lead to apoptosis are also potential therapeutic agents for treating cancer. The signaling pathways that regulate ER stress-induced apoptosis are less well understood than those regulating the death receptor and mitochondrial apoptotic pathways. In addition, extensive crosstalk with these other pathways occurs. For example, several members of the Bcl family that regulate the mitochondrial pathway are also found at the ER. Bax and Bak are located at the ER membrane where they regulate apoptosis induced by ER-specific stressors. This can be achieved through regulation of calcium levels in the ER; upon induction of ER stress, calcium is released from the ER in a Bax and Bak-dependent manner that can be inhibited by ER-targeted Bcl-2. The elevation of cytosolic calcium levels leads to activation of calcium-regulated proteases called ►calpains which can, in turn, activate caspases and stimulate apoptosis. The initiator caspases involved in ER stress-induced apoptosis may differ in different organisms. In mice caspase-12 is associated with the ER membrane and is activated by ER stress-induced apoptosis and required for cell death in response to ER stress. This can lead to caspase-9 activation via a mechanism that is independent of Apaf-1 and the apoptosome. However in most humans the caspase-12 gene is mutated so that it is not an active protease. In human cells, caspase-4 may be an initiator caspase responsible for ER stress-induced apoptosis.

Other mechanisms involved in ER stress-induced apoptosis are activated as a result of the ER stress response itself. Upon accumulation of unfolded proteins, the unfolded protein response (UPR) is induced.

This leads to activation of an ER-localized transcription factor called ATF6, which binds to an ER protein called ►BiP/GRP78, which functions as a chaperone protein. During ER stress BiP is titrated away from ATF6 allowing its translocation to the Golgi where it is cleaved by the same enzymes that regulate sterol-controlled gene expression. This cleavage allows ATF6 to translocate to the nucleus where it activates transcription of various target genes that encode chaperone proteins and other UPR targets that help the cell recover from the ER stress and targets that promote apoptosis. One ATF6 target gene encodes a transcription factor called CHOP, which can inhibit expression of Bcl-2 and increase expression of the TRAIL receptor DR5 providing a direct link to the other apoptotic signaling pathways that promotes apoptosis. A second BiP target is IRE1, which interacts directly with Bax and Bak to provide a physical link between the core apoptotic machinery and a regulator of the UPR. IRE1 can also interact with TRAF2, an adaptor protein that is involved in cytokine signaling including the TNFR signaling pathway. The IRE1/TRAF2 interaction can, in turn, recruit a protein kinase called ASK1, a pro-apoptotic kinase that activates the JNK MAP kinase, which can be either pro- or anti-apoptotic depending upon the cellular context.

Regulation of Apoptosis by Tumor Suppressors and Oncogenes

A complex network of signaling pathways that involve numerous ►tumor suppressors and ►oncogenes regulates apoptosis. As might be expected, oncogenes, which promote tumor growth often inhibit apoptosis while tumor suppressors promote apoptosis. For example, ►Bcl-2 was initially identified as a result of a translocation between chromosomes 14 and 18 that links the immunoglobulin heavy chain locus to the Bcl-2 gene. This leads to overexpression of Bcl-2 and causes follicular B-cell lymphoma. The recognition in the late 1980s that the oncogenic activity of Bcl-2 is achieved through its ability to block cell death was a paradigm shifting event that led to the now widely accepted view that defective apoptosis and not just increased cell growth is a central step in tumor development. Other oncogenes that inhibit apoptosis include ►Akt and ►Mdm2, which inhibits the tumor suppressor p53. Tumor suppressors including p53 and the lipid phosphatase ►PTEN directly promote apoptosis and a major aspect of their tumor suppressor activity is achieved through this mechanism and mutation during tumor development inactivates these mechanisms. p53 activates apoptosis by several mechanisms, the best understood of which is the activation of various target genes including ►BH3 proteins that are components of the apoptotic machinery and inactivation of p53 occurs in many tumors. The primary mechanism by which PTEN promotes apoptosis is through its inhibition of the ►PI3k signaling pathway leading to reduced levels of Akt kinase activity. Akt phosphorylates numerous downstream pathways that directly or indirectly regulate the core apoptosis machinery; examples include the BH3 only protein ►Bad, ►IκB, which is an inhibitor of NFκB, Mdm2 and caspase-9. Activation of the Akt pathway as a result of PTEN inactivation or activation of growth factor receptors by molecules such as the ►Insulin Like Growth factors is associated with tumor development and progression and reduced response to therapy.

Other defects that arise during tumor development can also affect the apoptotic machinery. Examples include epigenetic alterations such as promoter ►methylation of caspase-8, TNFR1 and Apaf1, which reduce expression of key components of the death receptor and mitochondrial apoptotic pathways respectively. Apoptosis inhibitors that are overexpressed in tumors including ►survivin, a member of the IAP family that is one of the most commonly overexpressed genes in human tumors. Other overexpressed proteins are Insulin-like growth factors and their receptors, which are strong activators of the PI3 kinase pathway, FLIP, the negative regulator of death receptor signaling, ►decoy receptors (DcR1 and DcR2), which inhibit TRAIL signaling and FAP1, an inhibitor of Fas signaling. In addition to p53 and PTEN mutations, inactivating mutations in Bax occur in colon cancers while various mechanisms in many tumors activate the transcription factor NFκB. This inhibits apoptosis largely through the activation of various IAP genes and anti-apoptotic Bcl family members. However, the picture is not simply that oncogenes inhibit apoptosis while tumor suppressors promote apoptosis. Instead, and somewhat counter-intuitively, oncogenes often promote apoptosis while bona fide tumor suppressors can inhibit it. For example c-Myc (►Myc) a transcription factor that promotes cell cycle progression, which is activated in very many tumors also sensitizes the tumor cell to apoptosis by diverse stimuli. Similarly, the ►E2F transcription factors that are major drivers of the cell cycle and viral oncogenes that activate E2F such as the ►adenovirus E1a protein or inactivation or loss of the ►retinoblastoma (Rb) tumor suppressor also sensitizes cells to apoptotic stimuli. This sensitization arises in part because core components of the apoptotic machinery such as caspases, BH3 proteins and Apaf1 are expressed by the same E2F driven-promoters that drive the genes required for cell cycle progression. This mechanism means that dividing cells express genes that promote apoptosis at the same time as they express genes required for DNA synthesis and cell division. As a result, tumor cells where the Rb pathway is inactivated

and/or Myc and E2F transcription factors are activated are not necessarily more resistant to apoptosis. Indeed, they may be closer to their apoptotic threshold and easier to kill than normal cells, which are not undergoing aberrant cell cycle progression. The apoptosis sensitization caused by oncogenes such as ►c-Myc oncogene also explains some aspects of the phenomena of oncogene co-operation where a single oncogenic event is not sufficient to cause tumor growth unless it is combined with another defect. For example increased expression of either Myc or Bcl-2 on their own may not be sufficient to cause tumor growth but the two together usually can cause tumor growth. This happens because the growth signals caused by Myc are counteracted by increased apoptosis sensitivity, however when Bcl-2 is also expressed in the cell the anti-apoptotic effects of Bcl-2 counteract the Myc-induced apoptosis sensitization leading to robust growth of the tumor.

Apoptosis Regulation During Cancer Treatment

Much of the interest in apoptosis as it relates to cancer involves understanding the mechanism by which anti-cancer drugs induce tumor cell apoptosis, elucidating the ways that cancer cells subvert the effects of the drug by avoiding these mechanisms and finding new ways to manipulate these pathways to make more effective cancer treatments. Although one of the hallmarks of cancer is the acquisition of defects in apoptosis regulation, most tumor cells are not inherently resistant to apoptosis. In fact, because of the apoptosis sensitization by oncogenes tumor cells may be closer to their apoptotic threshold than normal cells. In a growing tumor, anti-apoptotic mechanisms are keeping the tumor cells alive, however these mechanisms are only just keeping the cell below its apoptotic threshold and the price that the tumor cells pay for their continued growth is that they are perilously close to undergoing apoptosis. This effect explains part of the preferential killing of tumor cells compared with most normal cells (the therapeutic window) by cytotoxic chemotherapy including DNA damaging agents, drugs that interfere with the cytoskeleton and metabolic inhibitors – these treatments provide an extra pro-apoptotic signal that are enough to push the tumor cells over the edge. The sensitization to apoptosis also occurs in other cycling cells and partly explains why side effects caused by cytotoxic chemotherapy usually affect fast growing normal cells such as the epithelia that line the gastrointestinal tract and bone marrow. Like the cycling tumor cells, these normal cells are growing rapidly and are therefore close to their apoptotic threshold, thus upon damage caused by the chemotherapy, they may undergo apoptosis. Most of the current anti-cancer drugs (DNA damaging agents, cytoskeleton-targeted agents and metabolic inhibitors) induce apoptosis primarily by activating the mitochondrial apoptosis pathway through particular Bcl-2 family proteins. For example the BH3-only protein ►Bim is activated by ►Taxol, while ►PUMA is activated by several DNA damaging drugs leading to mitochondrial dysfunction by the mechanisms. Thus, anti-apoptotic mechanisms such as Bcl-2 overexpression that affect the mitochondrial pathway can confer tumor cell resistance to the treatment. However the other pathways of apoptosis regulation can also be involved in therapeutic tumor cell killing. For example, some DNA damaging agents induce expression of death receptors and inhibition of death receptors can, at least in animal models, reduce the efficacy of cytotoxic chemotherapy.

An exciting new approach to cancer treatment that arises from our understanding of apoptosis signaling is to directly target the apoptotic regulators. Several such approaches are in clinical development including direct activation of death receptors using recombinant ►TRAIL and antibodies that activate the TRAIL receptors. Similarly, although systemic delivery of ►TNFα is toxic, recombinant TNFα is used clinically in isolated limb perfusion procedures as a therapy for localized soft tissue ►sarcomas and ►melanomas. Other strategies that can directly target apoptosis regulators include small molecules that disrupt specific protein-protein interactions between Bcl-2 family members, which can be used to selectively inhibit the anti-apoptotic proteins and activate apoptosis. Agents that disrupt the p53-Mdm2 interaction can also promote tumor cell apoptosis. Other "targeted" therapeutic agents target apoptosis regulators more indirectly. For example, the proteasome inhibitor Velcade, which is useful in treating ►multiple myeloma has its therapeutic effect in large part through inhibition of NFκB signaling. This occurs because the inhibition of the proteasome prevents the degradation of the NFκB inhibitor IκB. The reduction in NFκB activity leads to decreased expression of IAP proteins and anti-apoptotic Bcl-2 family members thus pushing the tumor cells over their apoptosis threshold. As we develop a better understanding of apoptosis signaling mechanisms it will hopefully be feasible to refine and extend these kinds of strategies to more effectively treat cancer.

Appendiceal Epithelial Neoplasms

Paul H. Sugarbaker
Washington Cancer Institute, Washington Hospital Center, Washington, DC, USA

Synonyms

Pseudomyxoma peritonei; Colloid carcinoma; Cystadenocarcinoma; Mucinous cystadenocarcinoma; Appendiceal mucinous tumor of uncertain malignant potential; Borderline appendiceal mucinous tumor

Definition

►Appendiceal epithelial neoplasms include a broad spectrum of tumors that vary greatly in their biological aggressiveness. Usually, they produce copious mucus as do normal appendiceal epithelial cells. The tumors usually rupture the wall of the appendix prior to diagnosis causing widespread peritoneal dissemination of the disease. New treatment options are directed at definitive treatment of the peritoneal surface component of this disease which will cause death from intestinal dysfunction unless properly managed.

Characteristics

Epithelial Appendiceal Neoplasms

Table 1 summarizes the unique characteristics of these tumors and contrasts them with colorectal cancer. Appendiceal neoplasms show varying amounts of invasiveness. About 75% are non-invasive and grow slowly, allowing patients to survive a decade or longer even without specialized treatments. However, some appendiceal tumors are very invasive, progress rapidly, and can cause death 1–2 years after the initial diagnosis.

Nearly all patients with these tumors have ►peritoneal dissemination at the time of diagnosis, a notable contrast with colorectal cancer, in which only about 15% of patients present with ►carcinomatosis. Progression is usually confined to the peritoneal space, and most patients with minimally invasive tumors die from loss of intestinal function as the mucinous tumors expand within the abdomen and pelvis.

Most patients with appendiceal neoplasms have no lymphatic or hematogenous ►metastases; 2% of patients have ►metastases in the lymph nodes and 2% in the liver; thus extensive ►local-regional treatments can eliminate the disease. Surgical management of the primary tumor is usually appendicectomy or caecectomy, and an appendiceal lymph-node dissection is needed to rule out regional lymph-node metastases.

Appendiceal ►mucinous neoplasms spare the small bowel, which qualifies them for aggressive local-regional treatment. Even though large volumes of mucinous neoplasm are sometimes located within the greater and lesser omentum, the space between the liver and the diaphragm, and within the pelvis, the small bowel is usually free of disease. Carmignani and

Appendiceal Epithelial Neoplasms. Table 1 Contrasting features of appendiceal neoplasms and colorectal cancer

	Appendiceal epithelial neoplasm	Colorectal cancer
Incidence (cases per year in USA)	1500	150,000
Mucinous histology	85%	15%
Aggressiveness pathology	10%	95%
Lymph-node metastases at initial diagnosis	2%	50%
Liver metastases at initial diagnosis	2%	20%
5-year survival with traditional surgical treatment	30%	70%
10-year survival with combined treatment	60%	NA

colleagues reported that the constant peristaltic activity of the small bowel prevents neoplastic cells from adhering to its surfaces or to the small-bowel mesentery, except to the part of the jejunum that is adjacent to the ligament of Treitz and the terminal ileum or ileocecal-valve area, which are tethered by a short mesentery to the retroperitoneum.

Before surgery confirms the diagnosis, patients with ►intestinal type adenocarcinoma of the appendix are usually diagnosed with appendicitis, a right lower quadrant abscess, or a tumor mass. In contrast, mucinous appendiceal adenocarcinomas usually have developed a free perforation before diagnosis, causing the tumor to spread to the ovary, or to present as peritoneal carcinomatosis within a hernia sac. An aggressive ►mucinous adenocarcinoma can invade the retroperitoneum and appear as a mucus accumulation in the buttock or thigh. Also, the tumor could invade the abdominal wall with an enterocutaneous fistula or the bladder with an enterovesical fistula. The right ureter can also be invaded by a mucus-containing tumor. If symptoms other than increasing abdominal girth or appendicitis arise, the tumor is probably aggressive.

Pseudomyxoma Peritonei Syndrome

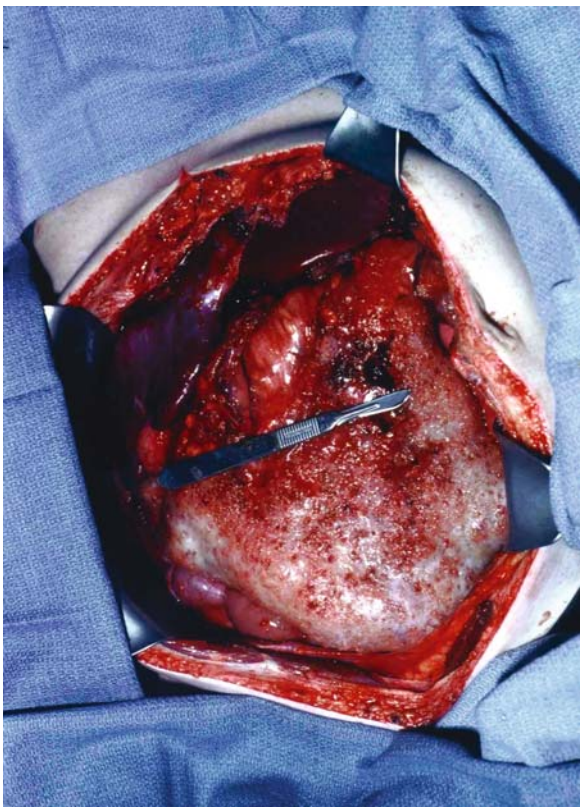
These less aggressive mucinous appendiceal epithelial neoplasms constitute a large proportion of the cases of appendiceal neoplasms. They have a high propensity for spread to peritoneal surfaces, but almost never metastasize through lymphatic channels into lymph nodes, or through venules into the liver. After the tumor ruptures the wall of the appendix (Fig. 1), ►adenomucinosis can progress for months or even years within the abdomen and pelvis without causing any symptoms. As the disease progresses, the peritoneal cavity becomes filled in a characteristic pattern with mucinous neoplasm and mucinous ►ascites. The greater omentum is thickened (omental cake) and infiltrated extensively by the tumor (Fig. 2). All parts of the abdomen that entrap malignant cells also contain tumor, including the undersurface of the right and left hemidiaphragms, the right subhepatic space, the splenic hilus, the right and left abdominal gutters, and the pelvis and cul-de-sac. An important clinical feature of ►pseudomyxoma peritonei is that tumors spare the mobile portions of the small bowel, and the involved parietal and visceral peritoneal surfaces can thus be removed by ►peritonectomy (Fig. 3).

The symptoms and signs of pseudomyxoma peritonei differ greatly from those of appendiceal adenocarcinoma. The most common symptom in both men and women with pseudomyxoma peritonei syndrome is a gradually increasing abdominal girth. Women often develop an ovarian mass, usually on the right side, which is commonly diagnosed at a routine gynecological examination, and men can have new-onset hernia as the next most frequent symptom. The hernia sac is filled by mucin, a mucinous tumor, or both. The third most common presenting feature is appendicitis, a clinical manifestation of a ruptured appendiceal mucocele with local inflammation.

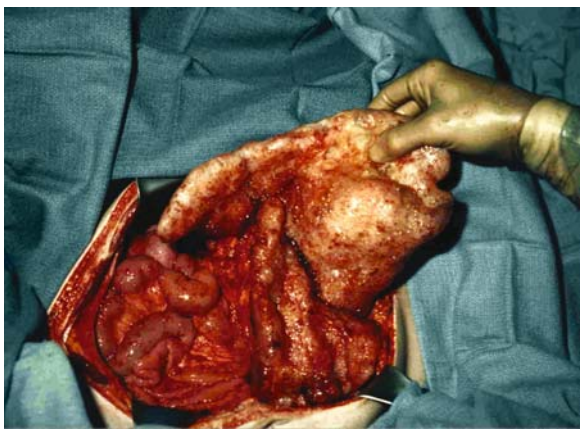
Appendiceal Epithelial Neoplasms. Figure 1 Distal portion of appendix has ruptured from pressure of mucin accumulation within mucocele.

Pseudomyxoma peritonei syndrome can also develop months or even years after planned laparoscopic appendicectomy, if a mucocele is found and ruptures during the procedure. Table 2 shows the symptoms and signs of pseudomyxoma peritonei syndrome as reported by Esquivel and Sugarbaker.

When a patient presents with increasing abdominal girth as a result of presumed malignant ascites, diagnosis is usually established with a paracentesis or laparoscopy and biopsy. In many women with this disease an ovarian tumor will be found. In all instances, paracentesis or laparoscopy with a biopsy should be done directly within the midline and through the linea alba. These sites can be excised as part of a midline abdominal incision. No lateral puncture sites or port sites should be used because they cause the tumor to seed into the abdominal wall causing difficulty with eradication of the disease.



Appendiceal Epithelial Neoplasms. Figure 2 Omental cake characteristic of pseudomyxoma peritonei syndrome.



Appendiceal Epithelial Neoplasms. Figure 3 Mucinous tumors spare the mobile portions of the small bowel.

Treatment

Treatment options for malignant diseases are determined by the anatomical location of the cancer and by its biological aggressiveness. Appendiceal epithelial neoplasms differ greatly from other gastrointestinal cancers in both these categories. Unfortunately, in the past, statistics have been combined for appendiceal neoplasms and colorectal cancer. The international classification of disease designates appendiceal neoplasms together with colorectal cancer. This disease has a unique natural history and requires very different management as compared to colon cancer.

Management in Absence of Peritoneal Dissemination

In patients with invasive non-mucinous adenocarcinoma (►intestinal type) of the appendix, a right hemicolectomy may improve the survival achieved with routine appendicectomy. Patients with invasive intestinal type appendiceal adenocarcinoma with lymph nodes involved should receive a right hemicolectomy either at the appendectomy procedure or at a subsequent time. When the surgeon finds aggressive tumor in the appendix during an appendectomy the mesoappendix should be resected and emergency cryostat sectioning performed. If the bowel is prepared adequately and if adenocarcinoma is identified in lymph nodes, a right hemicolectomy should be done immediately. In some patients, a caecectomy with preservation of the ileocecal valve has been used, and this procedure is recommended if the appendiceal lymph nodes are negative by cryostat sectioning.

Management of Mucinous Neoplasms with Peritoneal Dissemination

Tumor tissue is removed from the abdominal gutters, pelvis, right subhepatic space, and right and left subphrenic spaces by use of a greater omentectomy, lesser omentectomy, splenectomy, and peritonectomy. The probability that a peritonectomy will eradicate the tumor from all surfaces in the abdomen and pelvis is controlled by two factors: the size of the tumor and its invasive capabilities. A small tumor will have negligible or no extension through the serosal layer, so that peritonectomy with electrosurgical dissection (Fig. 4) will result in a small but adequate margin of resection. In a larger tumor, ►invasion through the serosal layer is expected, yet, on structures undamaged by deeper electrosurgical dissection such as the liver, a negative margin is still possible. However, larger tumors on small-bowel surfaces will need resection to eradicate mucinous adenocarcinoma. By contrast, adenomucinous nodules will not invade through the serosal layer and can be resected adequately by peritonectomy from small bowel surfaces.

For mucinous appendiceal neoplasms that are perforated at the time of surgery and that result in peritoneal carcinomatosis or pseudomyxoma peritonei, peritonectomy is combined with ►intraperitoneal chemotherapy.

After resection, and with the abdomen open, the peritoneal space is washed thoroughly with warm (41.5°C) chemotherapy solution containing mitomycin C and doxorubicin by the surgeon's hand with gauze debridement of all surfaces. Also, a window of time

Appendiceal Epithelial Neoplasms. Table 2 Frequency of symptoms and signs of pseudomyxoma peritonei syndrome

Appendiceal Epithelial Neoplasms. Figure 4 Peritonectomy using electroevaporative surgery for removal of carcinoma implants.

exists in the early postoperative period when all intraperitoneal surfaces are available for treatment with intraperitoneal ►fluorouracil. Consistent exposure of all peritoneal surfaces to intraperitoneal chemotherapy can be achieved if the chemotherapy is used during the first week after surgery. As the postoperative 5-fluorouracil solution remains in the abdominal and pelvic space, the solution can be distributed by turning the patient alternately on to their right and left side and into the prone position.

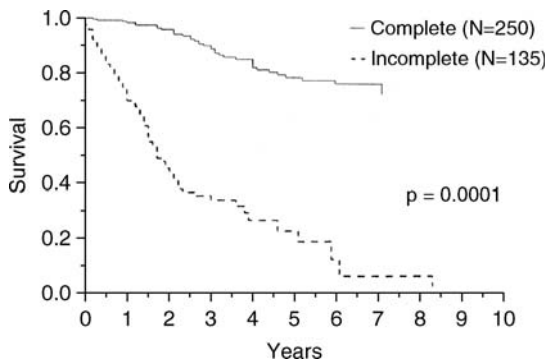
In a prospective investigation of this technique, perioperative intraperitoneal chemotherapy increased the frequency of anastomotic disruptions. Patients who have had previous extensive surgery who need many hours of adhesion lysis, are more likely to develop fistulas after surgery, presumably because of the combined effects of damage to the small bowel from electrosurgical dissection of adhesions (seromuscular damage), and systemic effects of intraperitoneal chemotherapy on the intestine (mucosa and submucosa damage).

►Adjuvant bidirectional chemotherapy (combined intravenous and intraperitoneal) is recommended for patients who have peritoneal dissemination of high-grade appendiceal mucinous neoplasm. Second-look surgery is recommended about 6 months after the ►cytoreduction in some patients, usually those who need ostomy closure. If small tumor foci are found on the peritoneal surface of the abdomen or the pelvis at the staging celiotomy, the nodules are resected and a final treatment with intraperitoneal chemotherapy may be necessary.

Definitive treatment of peritoneal carcinomatosis or pseudomyxoma peritonei should be done in a timely way. Every non-definitive ►debulking surgical intervention makes potentially curative cytoreductive surgery more difficult and because the ►peritoneum acts as the first line of defense against peritoneal dissemination, every effort should be made to keep it intact for optimum results in these procedures. Also, whereas the small bowel is spared early in the natural history of mucinous appendiceal neoplasms and pseudomyxoma peritonei, the fibrous adhesions that inevitably result after several surgical procedures will become infiltrated by tumor, leading to widespread involvement of the small bowel. Eventually, safe cytoreduction becomes impossible, and the effects of the intraperitoneal chemotherapy by itself are not adequate to keep the patient free of disease.

Outcomes

The results of treatments for peritoneal surface dissemination of appendiceal neoplasms have been unexpectedly good. In 385 patients with either peritoneal adenomucinosis or mucinous carcinomatosis who were followed up for an average of 37.6 months, all had documented peritoneal surface disease, and most had large tumors. After cytoreductive surgery, all patients had their abdomen inspected for residual disease and the ►completeness of cytoreduction was scored for all patients on the basis of the size of remaining tumors. Figure 5 shows the survival of patients who had a ►complete cytoreduction compared with those who had an incomplete cytoreduction. In statistical analysis of these data, survival did not differ significantly between patients with near complete cytoreductions and those with grossly incomplete cytoreductions. Furthermore, the only variable that was an independent predictor of survival was the completeness of cytoreduction (complete *vs.* incomplete).



Appendiceal Epithelial Neoplasms. Figure 5 Survival by cytoreduction of 385 patients with peritoneal dissemination of appendiceal epithelial neoplasms treated by cytoreduction and perioperative intraperitoneal chemotherapy.

Survival differed between patients with ►adenomucinosis and those with hybrid or ►mucinous adenocarcinoma ($p < 0.0001$). Patients with non-invasive disease are therefore more likely to benefit from this treatment strategy. No significant differences were noted between patients with hybrid histology and those with mucinous adenocarcinoma. Furthermore, patients with negligible or moderate extent of previous surgery had an improved survival compared with those who had had extensive previous surgery ($p = 0.001$).

This finding shows the importance of the peritoneum as a protective barrier in patients in whom the tumor has spread to this site. Multiple previous dissections had a negative effect on survival when all patients were included in the analysis, but not when patients who had had complete cytoreduction were excluded, suggesting that previous debulking can worsen prognosis by impeding complete removal of the tumor in some patients. Debulking surgery with incomplete cytoreduction allows neoplastic cells to implant on abdominal and pelvic surfaces that have been cleared of peritoneum. Once these neoplastic cells implant deep to the peritoneum, removal with an adequate margin is unlikely.

Analysis of 21 patients with ►adenocarcinoid of the appendix with peritoneal carcinomatosis showed that median survival of patients who had complete cytoreduction and intraoperative and postoperative intraperitoneal chemotherapy was 18.5 months (range 3.2–95.1); 5-year survival was 25%. In some patients, an attempt at complete resection is warranted. If debulking results in gross residual disease, only palliative surgical efforts associated with low morbidity and mortality are indicated because survival is limited.

Extensive cytoreductive surgery combined with early postoperative intraperitoneal chemotherapy is associated with high morbidity. Nevertheless, only 2–10% of patients who receive this treatment die. Anastomotic leaks were more common in these patients than in those who have conventional surgery (5%). Overall morbidity in patients with grade III–IV disease was 20–50%. No morbidity or mortality was associated directly with administration of intraperitoneal chemotherapy. Rather, the frequency of complications depended on the extent of the surgery, number of peritonectomy procedures, and time needed to complete the cytoreduction.

Traditionally, appendiceal epithelial neoplasms have been managed by serial debulking, which removes the bulk of the disease. Although the midabdomen can be cleared by suctioning the mucous neoplasm, washing the intestinal surfaces, and resection of the greater omentum, disease often remains around the liver and deep in the pelvis. Because the tumor recurs after 2–3 years, debulking is often repeated, but is more difficult at a second operation. After three or four debulkings, loops of the small bowel become encased with scar

tissue and mucinous neoplasm, and further surgery is impossible. The function of the gastrointestinal tract is gradually restricted by the accumulation of a large mucinous tumor now embedded within the scar tissue, and the patient dies from long-term starvation. Sometimes, systemic chemotherapy can be of transient benefit.

Approaches to Management

Appendiceal neoplasm with peritoneal dissemination could be an indolent disease process. The assessment of any treatment regimen should allow for a minimum of 10 years' follow-up, and follow-up of 20 years would be ideal. A 20-year follow-up with cytoreductive surgery and perioperative intraperitoneal chemotherapy was reported by Sugarbaker and colleagues, who showed that patients who had complete cytoreduction for less-aggressive disease had a projected survival of 70% at 20 years, a sharp contrast with the results achieved with serial debulking. However, these results should be interpreted with the knowledge that these treatment strategies have not been compared directly. These positive results have led to establishment of treatment centers for appendiceal neoplasm in the USA and in nearly all countries in Europe.

In the UK, combined treatments have become a part of the overall plan for healthcare. Moran and colleagues have established a treatment center dedicated to management of appendiceal malignant diseases and pseudomyxoma peritonei syndrome, to which any patient enrolled in the UK National Health Service, from anywhere in the UK, can be referred. The center, based in Basingstoke, UK, started treatment for this disease in 1994, and about 40 cytoreductions are done there every year. Because of the large number of patients needing treatment for appendiceal malignant diseases with peritoneal surface dissemination, a second treatment center was established in 2002 in Manchester, UK. These centers show that referral to a treatment center is now standard practice for this disease in the UK and allows doctors to use standard treatments, improve treatment regimens, and refine the surgical skills needed for optimum management of these patients. This approach has improved patient care and reduced costs because patients can be referred early before disease progresses to a symptomatic state.

A New Standard of Care

Ideally, new treatments should evolve through the clinical trials process. A phase III trial should be undertaken to compare traditional treatment options with new treatments. However, until such data are available, the issue remains of which treatment option is best for these patients. The available evidence suggests that cytoreductive surgery with perioperative intraperitoneal chemotherapy should replace serial debulking as the standard of care for patients with peritoneal spread of appendiceal epithelial neoplasms.

However, phase III trials are difficult to do in this setting because they would need to compare a potentially curative treatment option with a palliative one. Patients are thus likely to be reluctant to be randomized, no matter how carefully the trial is designed and explained. Follow-up of about 20 years would be needed to assess the best treatment plan. However, such long-term follow-up would mean that meaningful data might never be available within the lifetime of the principal investigator. Furthermore, the disease is uncommon and only a few institutions, especially those designated as pseudomyxoma peritonei treatment centers, can accumulate sufficient numbers of patients to give meaningful results. The only trial that would accumulate sufficient patients for assessment over a reasonable time would be a multinational trial with most of the institutions participating from the USA and Europe, meaning the expense and the coordination would be prohibitive. Acceptance of combined treatment as the standard of care would allow treatment centers to investigate new and possibly more effective local-regional treatment strategies that can improve the overall results and decrease morbidity and mortality by prospective randomized studies. The skills, judgments, and treatments offered vary between the many treatment centers, and results of treatment might not therefore be consistent. With experience, the morbidity and mortality associated with cytoreductive surgery and intraperitoneal chemotherapy should lessen, as should objections to this procedure. Physicians at experienced centers learn that addition of chemotherapy as a planned part of cytoreductive surgery improves patient care rather than results in excessive morbidity and mortality. Correct selection of patients is an important part of successful treatment of this disease.

Summary of Changes in Management of Appendiceal Epithelial Neoplasms

Several distinct changes are needed to the surgical techniques used to treat patients with peritoneal dissemination of an appendiceal mucinous neoplasm. Because chemotherapy has little effect on large tumors, definitive cytoreduction should be attempted to reduce the cancer within the abdomen and pelvis to its smallest volume. Such reduction requires use of peritoneal stripping, now commonly referred to as peritonectomy, in which the patient often needs to spend many hours in the operating theatre. Frequently, the abdomen is left without peritoneal surfaces except for that found on the small bowel. This approach is a change from the previous conservative surgical approach to peritoneal carcinomatosis.

Several changes are also needed in the use of chemotherapy in these patients. Administration of chemotherapy should change from intravenous to intraperitoneal with maximum doses of mitomycin, doxorubicin and 5-fluorouracil. Intraperitoneal chemotherapy should be

done perioperatively to contact all abdominal and pelvic surfaces before wounds start to heal. Once fibrinous deposits become organized, chemotherapy will not be able to reach residual tumors and local recurrence will occur where the surfaces are adherent. Perhaps most important for favorable results, selection of patients for treatment should change. Patients should receive maximum cytoreductive surgical procedure and perioperative chemotherapy as a first time management strategy. The target of these treatments should be directed at minimal residual disease on both the parietal and visceral surfaces. Patients with metastases that cannot be resected or with gross residual disease of the peritoneal surface after cytoreductive surgery has been done should be excluded from a curative approach. With these changes in surgical approach and chemotherapy administration, patients with peritoneal dissemination of appendiceal mucinous tumors could have an improved survival.

Characteristics

Over the past two decades, a large body of data has been generated that demonstrates the feasibility of antibodies for tissue targeting. The first FDA approval

of a humanized monoclonal antibody for the treatment of cancer came in 1997 when rituximab (Rituxan) entered the market for the treatment of patients with relapsed or refractory low-grade or follicular, CD20 positive, B-cell non-Hodgkin's lymphoma. A wide variety of ligand-drug conjugates are now under clinical development or in clinical practice today. For example, Gemtuzumab (Mylotarg) is an FDA approved chemoimmunoconjugate for the treatment of Acute Myelogenous Leukemia. Mylotarg, and is one of four FDA approved therapeutic conjugates. There are many others that are currently in various stages of clinical and pre-clinical development. In addition to antibodies, there is a growing list of ligand classes under development that are capable of binding to target antigens with high affinity and specificity. One example is nucleic acid ligands referred to as ►aptamers, which are small in size, potentially non-immunogenic, easy to synthesize, characterize, modify, and exhibit high specificity and affinity for their target antigen. In the short time since the groups of Jack Szostak and Larry Gold independently described the methodology for *in vitro* selection of aptamers, known as ►SELEX, these ligands have been explored for a variety of applications, as therapeutics, diagnostics and research enablers. Aptamers have also been exploited as targeting molecules for cell- or tissue-specific delivery of controlled release polymer drug delivery vehicles. Recently we described the first proof-of-concept drug delivery vehicles utilizing aptamers for targeted delivery and have gone on to show efficacy of these vehicles in tumor reduction *in vivo*.

Aptamers are single stranded DNA, RNA or unnatural oligonucleotides that have been selected *in vitro* from a pool of ~10^{14} to 10^{15} random oligonucleotides for their ability to bind to a target molecule. Aptamers have a molecular weight in the 6–25 kDa range and derive their name from the Latin word "aptus" meaning "to fit." Aptamers fold through intramolecular interaction to create tertiary conformations with specific binding pockets which bind to their target molecules with high specificity and affinity. This tertiary conformation is analogous to the globular shape of tRNA.

Unlike antisense compounds, which are single-stranded nucleic acids that affect the synthesis of a targeted protein by hybridizing to the mRNAs that encodes it, aptamers may inhibit a protein's function through directly binding to it. Aptamers typically bind with an equilibrium dissociation constant (Kd) in the range of 10 pM to 10 μM to a wide array of molecular targets including other nucleic acids, proteins, peptides and small molecules. Aptamers can be described by a sequence of approximately 15–80 nucleotides (A, U, T, C, and G). The conformation of the ►aptamer confers specificity for a target molecule through interacting with multiple domains, or a binding pocket. Small changes in the target molecule can foil interactions and thus aptamers can distinguish between closely related but non-identical targets. For example, specific RNAs were identified that have a high affinity for the bronchodilator theophylline (1,3-dimethylxanthine) yet exhibit a >10,000 times weaker binding affinity to caffeine (1,3,7-trimethylxanthine) which differs form theophylline only by the substitution of a methyl group at the nitrogen atom N7 position. Based on their unique molecular recognition properties, aptamers have found great utility for applications in areas such as *in vitro* and *in vivo* diagnostics, analytical techniques, imaging, and therapeutics.

Although aptamers are highly stable and may tolerate a wide range of temperature, pH (~4–9) and organic solvents without loss of activity, these molecules are susceptible to nuclease degradation or renal clearance *in vivo*. Therefore, their pharmacokinetic properties must be enhanced prior to *in vivo* applications. Several approaches have been adopted to optimize the properties of aptamers such as: (i) capping their terminal ends, (ii) substituting naturally occurring nucleotides with unnatural nucleotides that are poor substrates for nuclease degradation (i.e. 2′-F, 2′-OCH3 or 2′-NH2 modified nucleotides), (iii) substituting naturally occurring nucleotides with hydrocarbon linkers, and (iv) use of L-enantiomers of nucleotides to generate mirror image aptamers commonly referred to as spiegelmers. Aptamers can also be stabilized using locked nucleic acid modifications to reduce conformational flexibility. Alternatively, a nuclease resistant aptamer may be selected *de novo* using a pool of oligonucleotides with 2′-F or 2′-OCH3 modified nucleotides. Through combining some of these strategies, an aptamer's half life can be prolonged from several minutes to many hours. To prolong the rate of clearance of aptamers, their size may be increased by conjugation with polymers such as polyethylene glycol (PEG).

►Nanoparticles are referred to structures that are in the 1–100 nm scale in at least one dimension, and may have any form including spherical, cylindrical or pancake like. To put this size range in perspective, a small molecule, a virus, a bacterium, and the cross section of a human hair are around 1, 100, 1,000, and 100,000 nm, respectively. Several classes of materials have been used for the development of nanoparticles including organic and inorganic biomaterials. Biodegradable polymer nanoparticles which are a type of organic nanoparticles, have been extensively investigated for cancer therapy. Polymeric nanoparticles can be designed to have a prolonged systemic circulating half-life by conjugating, or adsorbing sterically amphiphilic polymers such as polyethylenglycol (PEG) to the particle surface. These nanoparticles can be used to release the encapsulated drugs at a controlled rate surface or bulk erosion, diffusion, or swelling followed

by diffusion, in a time or condition dependent manner. The rate of drug release can be controlled by modification of the polymer side chain, development of novel polymers, or synthesis of copolymers. In general, these biodegradable polymer systems can provide drug levels at an optimum range over a longer period of time than other drug delivery methods, thus increasing the efficacy of the drug and maximizing patient compliance, while enhancing the ability to use highly toxic, poorly soluble, or relatively unstable drugs. Liposomes are another type of nanoparticles made of amphiphilic unilamellar/multilamellar membranes of natural or synthetic lipids. Lipids are characterized by a hydrophilic head group and a hydrophobic tail. Doxorubicin encapsulated liposome (Doxil) was the first liposome to gain FDA approval in 1995 and have potent antineoplastic activity against a wide range of human cancers including Kaposi's sarcoma and ovarian cancer. A variety of other nanoparticles platforms including dendrimers, nucleic acid based nanoparticles, nanoshells to name a few have been, or are currently being, developed for drug delivery applications.

The conjugation of aptamers to nanoparticles can result in the development of therapeutic or diagnostic conjugates. Covalent conjugation of aptamers to nanoparticles can be achieved most commonly through succinimidyl ester – amine chemistry which results in a stable amide linkage or through maleimide – thiol chemistry. Potential non-covalent strategies include affinity interactions (i.e. streptavidan-biotin) and metal coordination (i.e. between polyhistidine tag at the end of the aptamer and Ni^{+2} chelates with immobilized nitrilotriacetic acid on the surface of the polymer particles). When aptamers are conjugated to drug encapsulated nanoparticles, these ►bioconjugates can direct the delivery of therapeutic agents in a targeted manner to specific cells or tissue. The payload of nanoparticles may include small molecule drugs such as chemotherapeutics; protein based therapeutics such as antibodies or hormones; nucleic acid therapeutics such as anti-sense oligonucleotide, RNAi or gene therapy vectors; or agents for neutron capture therapy or photodynamic therapy. Aptamers may also be bound to imaging nanoparticles to facilitate diagnosis and identification of tumor metastases. For example, it may be useful to bind aptamers to optical imaging agents including fluorophores and quantum dots (nanocrystals) or MRI imaging agents such as magnetic nanoparticles for detection of small foci of cancer metastasis. Multiplex systems comprising drug laden nanoparticle aptamer conjugates together with imaging agents represents a prospective avenue to future research.

Arachidonic Acid

Definition

It is an omega-6 fatty acid with carbon chain length of 20. An unsaturated fatty acid that occurs in most animals fats, which is a precursor of ►prostaglandins. Usually it is esterified in phospholipids (especially phosphatidylethanolamine, phosphatidylcholine, and phosphatidylinositides) of biological membranes. Under oxidative stress, the ►phospholipase A2 (PLA2) enzyme catalyzes the release of arachidonic acid from membranes. It is oxidized by lipoxygenases and cyclooxygenases into three classes of lipid mediators: prostaglandins/thromboxanes, leukotrienes and lipoxins. Its metabolites play important roles in acute/chronic ►inflammation and ►carcinogenesis.

Arachidonic Acid Pathway

Henk J. van Kranen, Christine L. E. Siezen
National Institute of Public Health and Environment, Bilthoven, The Netherlands

Synonyms

Cyclooxygenase; COX; metabolism; Lipoxygenase; LOX; metabolism; Eicosanoid signaling

Definition

The arachidonic acid pathway describes the biosynthesis of ►eicosanoids from arachidonic acid (AA) including its formation from omega-6 polyunsaturated fatty acids (PUFAs) and the synthesis of eicosanoids from eicosapentaenoic acid (EPA) including its formation from omega-3 PUFAs. Eicosanoids are short-lived biologically potent, autocrine or paracrine acting, lipid signaling molecules.

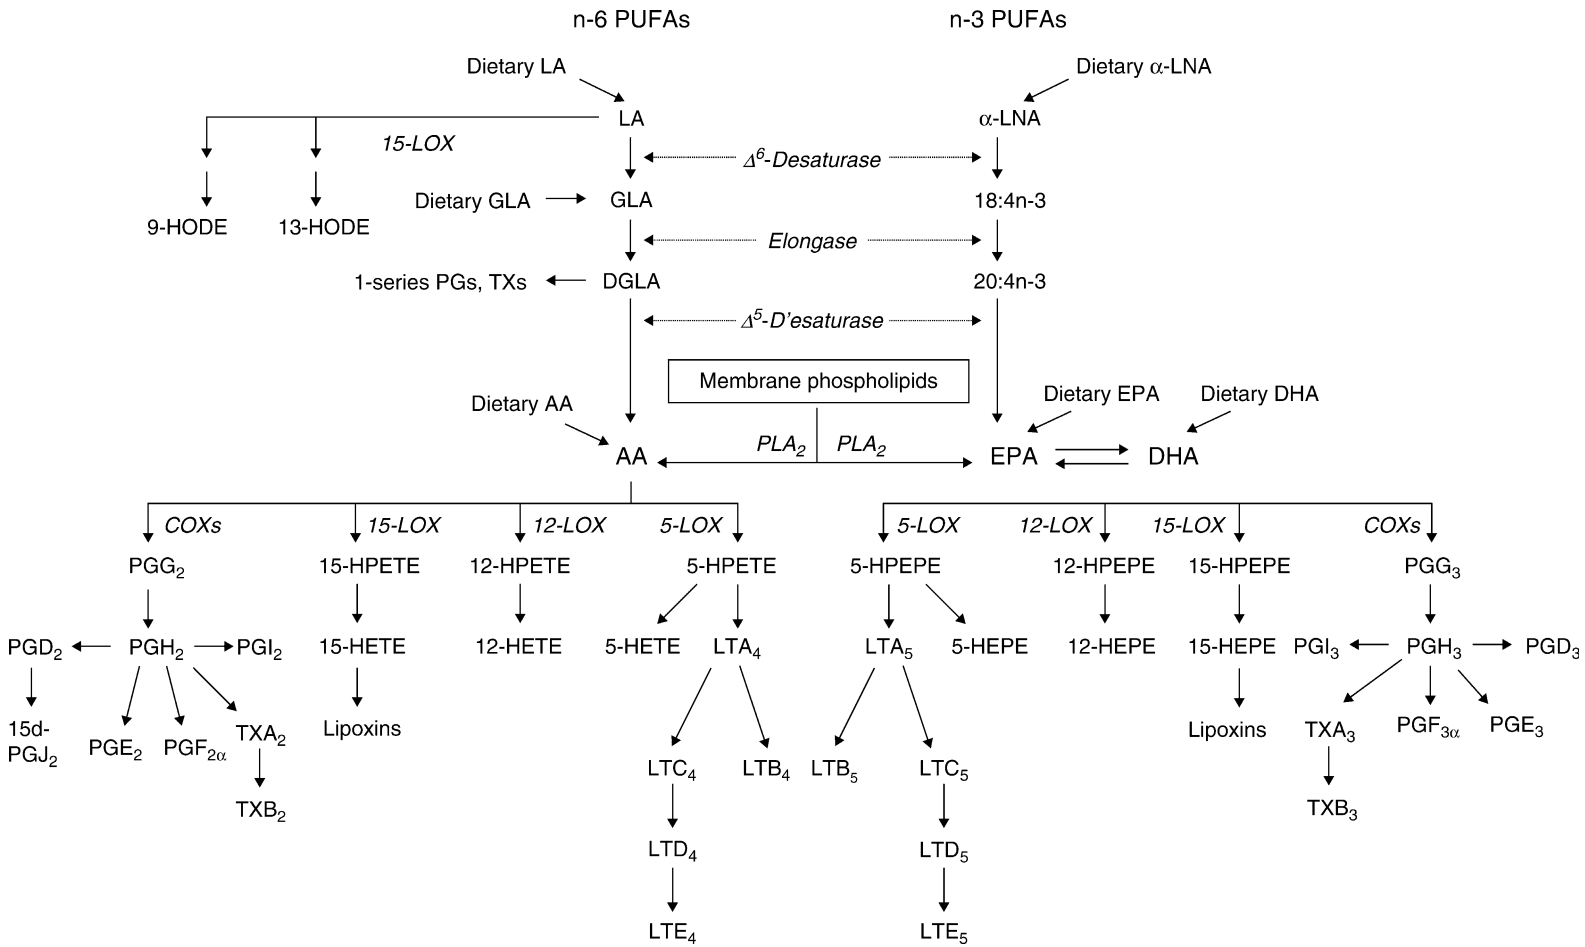
Characteristics

The AA pathway is involved in many physiological processes including ►inflammation and cancer. The pleiotropic effects of modulating this pathway are manifold and are depending on the levels of fatty acids from (dietary) substrates, which in turn modulate the level of eicosanoid precursors (AA and EPA) determining the amounts of eicosanoid lipid mediators actually produced. Initial and still ongoing research on the pharmacological inhibition of inflammatory reactions by ►nonsteroidal antiinflammatory drugs (NSAIDs) is one of the major disciplines/fields of research contributing to our current understanding of the AA pathway, including all its tissue-specific differences.

Fatty Acids as Dietary Precursors

PUFAs that enter the body through our diet are first metabolized via a series of enzymatic changes into the eicosanoid precursors arachidonic acid (AA) and EPA. The main PUFA in our diet is linoleic acid (LA), a member of the omega-6 (n-6) family of PUFAs that have their first double bond at the sixth carbon from the methyl terminus. The omega-3 (n-3) PUFA family, with the first double bond at the third carbon atom, has as its parent compound α-linolenic acid (ALA) (see Fig. 1). Both LA and ALA are converted in several steps by tissue-specific elongases and desaturases into AA and EPA. The latter two can be directly obtained from the diet as well. These eicosanoid precursors are incorporated and stored into cell membranes until they are released by different members of the phospholipase A_2 (PLA_2) family of enzymes, thereby producing free AA and EPA.

The hypothesis that omega-3 PUFAs have a protective effect against (colorectal) cancer originates from observational studies with Greenland Eskimos and a Japanese population. These populations are characterized by a significantly lower incidence of colorectal cancer, and by a fish-enriched diet containing substantially more omega-3 PUFAs compared to Western diets. This protective effect is lost after migration to Western countries like the US, and adoption of the Western lifestyle. The accompanying shift in balance between omega-6 and omega-3 fatty acids is hypothesized to play an important role in cancer promotion and development. Epidemiological prospective studies, however, have not been very consistent and a recent meta analysis even suggested no protective effect at all of omega-3 PUFAs for cancer in general. However, drawing of general conclusions is hampered by the many uncertainties that exist in the way exposure to omega-3 PUFAs is estimated (food frequency questionnaires, analysis of fatty acids in sera or bodyfat biopsies) as well as by tissue- and cancer type specific differences. Furthermore, animal and in vitro studies keep reinforcing a potential protective effect of increased omega-3 PUFA intake on (intestinal) cancer. For example, dietary supplementation with fish oil and/or EPA/DHA decreases tumor number in chemically induced animal models of colorectal tumors as well as in APC-Min mice (►APC-min mouse). Omega-3 PUFAs have also been shown to induce apoptosis and suppress cell growth in vitro.



Arachidonic Acid Pathway. Figure 1 Overview of the arachidonic acid pathway adapted from Larsson et al. [1].

There are several proposed mechanisms by which omega-3 PUFAs can exert their protective effect on tumor formation, as reviewed by Larsson et al. [1]. One of the major mechanisms leads to the suppression of omega-6 PUFA-derived eicosanoids. Higher intake of omega-3 PUFAs, compared to the omega-6 variety, would result in a decrease in available AA for eicosanoid production through the incorporation of the omega-3 PUFAs into membrane phospholipids. This effect is further enhanced by competition between omega-3 and omega-6 PUFAs for the elongases and desaturases that convert these PUFAs, since omega-3 PUFAs have a higher affinity for these enzymes. Omega-3 PUFAs can also directly inhibit cyclooxygenases (COX) (see next section) and compete with omega-6 PUFAs for COX-2 to form ►prostanoids. Moreover, EPA is the preferred substrate for the lipoxygenase (LOX) enzymes that utilize both AA and EPA, resulting in an increase in omega-3 PUFA-derived leukotrienes.

Production of Eicosanoids – from AA and EPA by COX and LOX Pathways

AA and EPA are the central eicosanoid precursors in the majority of mammalian cells and are released by phospholipases from cell-membrane bound phospholipids. The biosynthesis of eicosanoids from AA and EPA is controlled by two major metabolic routes, the COX and LOX pathways. Via these routes, AA is converted into 2-series prostanoids (►Prostaglandins, PGs; prostacyclins, PGIs; and thromboxanes, TXs) and 4-series leukotrienes, and EPA is converted into 3-series prostanoids and 5-series leukotrienes (see Fig. 1). The COX enzymes, also called prostaglandin-endoperoxide synthase (PTGS), catalyze the formation of prostanoids. There are three COX isozymes, the constitutively expressed COX-1, the inducible COX-2, and the more recently identified COX-3 which is actually a splice variant of COX-1, probably producing a truncated inactive protein. The LOX family of enzymes, including 5-LOX, 8-LOX, 12-LOX, and 15-LOX, catalyzes the formation of leukotrienes, "hydroxy fatty acids," and lipoxins. Carcinogenesis in humans and experimental animals is consistently linked to aberrant arachidonic acid metabolism through these COX and LOX pathways.

Regarding COX, tumor development in several different tissues is frequently associated with overexpression of COX-2 in both premalignant and malignant stages, indicating that activation of COX-2 may be an early event in carcinogenesis. This overexpression often starts in tissues adjacent to the transformed epithelium giving rise to "activated" stroma. Expression of COX-2 is induced by numerous growth factors, cytokines and oncogenes, and regulated both transcriptionally and posttranscriptionally, especially through increased mRNA stability. Several pathways are involved and interconnected in the modulation of COX expression and are discussed in more detail in the section on "Interactions with cancer signaling pathways." Both genetic and pharmacologic studies support a causal role of COX in cancer development. Genetic inactivation of COX-2 strongly reduces tumor formation in several animal model systems including the classical two-stage mouse skin cancer model, and in Apc mutant mouse models. These effects are not limited to COX-2 but also apply in part to COX-1. These data are corroborated by pharmacologic intervention studies using both nonselective COX inhibitors, like ►aspirin and other NSAIDS and COX-2 selective inhibitors. The subsequent reduction in tumor formation has been documented in numerous experimental animal model studies, but also in patients with familial adenomatous polyposis (FAP) and supports the outcome of many epidemiological studies suggesting a chemoprotective effect of long-time regular use of these drugs.

With respect to LOX, the situation is less clear and seems more complicated, illustrated by the identification of six LOX genes so far in humans (and seven in mice) and the different profiles of LOX that have been observed in human and rodent tissues. A general but oversimplified picture emerging is to divide the LOX genes/enzymes into "procarcinogenic" and "anticarcinogenic" isoforms. 5-LOX and p12-LOX are considered "procarcinogenic" because they can induce proliferation, antiapoptotic effects, angiogenesis and metastasis, whereas 15-LOX(1 + 2), l + e12-LOX and 8-LOX are considered "anticarcinogenic" because they are associated with differentiation, growth inhibition, and apoptosis.

Signaling by Eicosanoids

There are several mechanisms involved in eicosanoid signaling, which are frequently divided into COX-dependent and COX-independent routes. The COX-dependent tissue-specific production of prostaglandins, leukotrienes, and thromboxanes represents the major route in the formation of lipid mediators. The most prominent example in relation to cancer is prostaglandin E2 (PGE_2)-mediated signal transduction through its G-protein-coupled EP2 receptor, which has been demonstrated to play a pivotal role in (intestinal) carcinogenesis (see also the last section). Another important topic is the type of substrate that is used by the COX and LOX enzymes for the formation of eicosanoids (see also the previous sections). The 3-series prostanoids and 5-series leukotrienes derived from omega-3 PUFAs are generally considered to be less inflammatory and inhibiting tumor formation, whereas the 2-series prostanoids and 4-series leukotrienes derived from omega-6 PUFAs are believed to be proinflammatory and contain several tumor promoting

properties, including increased cell proliferation, inhibition of apoptosis, and stimulating angiogenesis

A variety of other effects, in part COX-independent, have been put forward from research on the effects of (high concentrations) of NSAIDs and its derivatives. An example of a COX-independent process includes the induction of apoptosis directly by AA through the production of ceramide and the mediation of apoptotic signaling by the LOX-15 production of 13-S-HODE. Furthermore, leukotriene production can be reduced due to the inhibition of LOX-5 by nitric oxide-releasing aspirin. Lastly and less clarified, eicosanoids may exert their biological effects in an intracrine way, similar to specific PUFAs, as activating ligands of transcription factors of the ►PPAR family, especially PPARγ and PPARδ.

NSAIDS and Eicosanoid Signaling

NSAIDs, of which aspirin is the best known example, are a class of drugs mainly used for analgesic purposes and to reduce inflammation, and are also used as anticoagulants for individuals at increased risk of cardiovascular disease. From the effects on high risk individuals (Gardner syndrome), it became apparent that NSAIDs also played an active role in the protection against (colorectal) cancer. Numerous epidemiological studies have found associations between regular use of NSAIDs and decreased risk of (colorectal) cancer and adenomas. Animal studies have also given clear indications about the protective effect of NSAIDs. The mechanisms of action of NSAIDs are generally divided into COX-dependent and COX-independent mechanisms. The ability of NSAIDs to inhibit the COX enzymes was originally thought to represent the main underlying mechanism of action, thereby reducing the production of prostanoids and increasing the pool of free AA, resulting in immune modulation, inhibition of tumor angiogenesis, and promotion of apoptosis. One of the first clues that other enzymes might play a role in the mechanism of action of NSAIDs, the COX-independent mechanisms, came from studies on the sulindac metabolites sulindac sulfone and sulindac sulfide. More recently, other enzymes within the pathway have been considered as targets for NSAIDs. Based on in vitro studies 15-LOX1 and PLA2G4A have been implicated as alternative targets of NSAID (aspirin) action. Two subtypes of the PPAR family, which can be activated by the products of the AA pathway, can also act as direct targets of NSAIDs. Sulindac can bind to PPARδ, after which its activity and protein expression is downregulated, inducing apoptosis. NSAIDs can also act as ligands for another receptor subtype, PPARγ. In contrast to PPARδ, this subtype has been shown to be activated by sulindac, which resulted in growth inhibition and apoptosis of cancer cells.

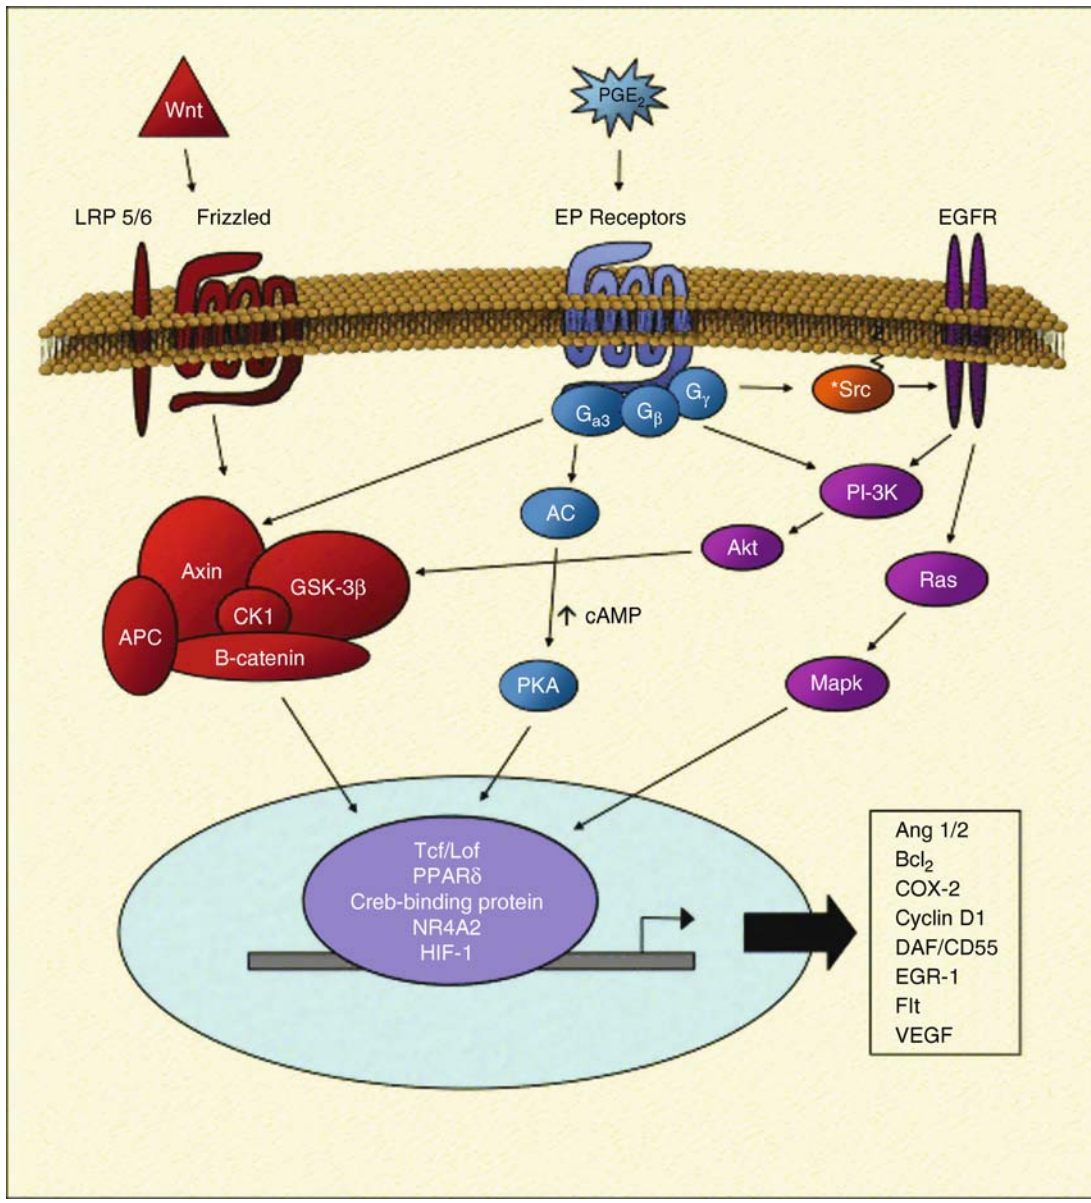
Other recent research in the field of lipid mediators has further linked omega-3 PUFAs and NSAIDs to inflammation. It is now hypothesized that increased omega-3 PUFA intake not only results in decreased production of proinflammatory eicosanoids due to competition with AA, but also produces mediators with potent antiinflammatory effects of their own. Moreover, new evidence suggests that acetylation of COX-2 by aspirin does not only result in complete inhibition of the COX activity of the enzyme, but induces a conformational change resulting in a shift to a LOX function, producing potent lipoxins. This prompted others to study the effect of omega-3 PUFA metabolites derived from acetylated COX-2 on inflammation. They found that these mediators could resolve inflammation, and subsequently called them resolvins. An orphan receptor ChemR23 was identified as a specific receptor of the EPA-derived resolvin RvE1, which inhibits activation of NF-κβ by TNF-α, and is among other tissues also expressed in the gastrointestinal tract. It is likely that these mediators play an important role in reducing inflammation in the GI tract, and that omega-3 PUFAs and aspirin exert their protective effect on colorectal cancer partly through this pathway.

Over time, the serious gastric toxicity of NSAIDS, resulting from the inhibition of COX-1, stimulated the development of specific COX-2 inhibitors, the so-called ►Coxibs. Although highly effective in cancer prevention, their improved risk profile for gastric toxicity seems to occur at the expense of cardiovascular toxicity.

Finally, pharmacokinetics and genetics of NSAID metabolism have been documented to greatly influence the chemopreventive potential of various NSAIDs. Polymorphisms in metabolic activation (CYP2C9) and elimination pathways (UGTs) but also in the AA pathway (COX-2) have been demonstrated to interact with NSAIDs with respect to (colorectal) cancer risk.

Interactions with Cancer Signaling Pathways

At present many molecular signaling pathways linked to cancer have been identified. It is also becoming increasingly clear that the interactions between cellular signaling pathways are key to the (phenotypic) outcome of the molecular signaling circuitry. Two important pathways, the canonical Wnt signaling pathway and one of the RAS effector pathways, the PI3K/AKT pathway have been recently demonstrated to functionally interact with PGE_2-EP2 receptor signaling providing another example of signal modulation by cross-talk between an G-protein-coupled receptor and growth factor receptors. The integrating picture can be summarized by recognizing that the $G_{\alpha s}$ and $G_{\beta\gamma}$ subunits of the EP2 receptor display different downstream signaling properties (Fig. 2). Next to activating adenylatecyclase (AC) and subsequently PKA, it was demonstrated that the $G_{\alpha s}$ subunit is also capable to



Arachidonic Acid Pathway. Figure 2 Prostaglandin induced transactivation of the canonical Wnt and EGFR signaling pathways, adapted from Buchanan and Dubois [5].

associate directly with axin, destabilizing the signaling complex, which leads to an increase in β-catenin and resulting in activation of Wnt signaling. Another way of destabilizing the same complex is to inactivate GSK-3β by phosphorylation. It was also demonstrated that PI3K and AKT could be activated through the Gβγ subunit of the EP2 receptor, leading to inactivation of GSK-3β. In summary, PGE2 seem to exert its G-protein-coupled signaling through axin, GSK-3β and PKA, but how these signals are integrated is still far from clear.

The role of NF-κβ signaling, producing a proinflammatory transcription factor, as an important central player in cancer development and progression is well documented and still intriguing. Activated NF-κβ has been linked to many cancer promoting processes including cellular proliferation, apoptosis suppression, invasion, and angiogenesis, and depending on tissue context also to tumor suppression. Normally, NF-κβ is ►sequestered in the cytoplasm by IkB. A variety of receptors and afferent signals activate IKK, which phosphorylates IkB, tagging it for degradation. The "liberated" NF-κβ can now translocate to the nucleus where it activates ~150 different genes, including COX-2. Well known inflammatory conditions introduced by infectious agents like for example *Helicobacter pylori*

in the stomach and HBV in the liver are established risk factors for respectively gastric and liver cancer. However, the persistent activation of NF-κβ is also documented to result in the loss of the tumor suppressor protein CYLD, leading to the benign human syndrome called ►cylindromatosis. Further details of the interplay between NF-κβ signaling and the AA pathway are eagerly awaited.

Archaea

Definition

A unique group of microorganisms classified as bacteria (Archaeobacteria) but genetically and metabolically different from all other known bacteria. They appear to be living fossils, the survivors of an ancient group of organisms that bridged the gap in evolution between bacteria and the eukaryotes (multicellular organisms).

ARE

Antioxidant response element, is a *cis*-acting DNA regulatory element which is located in the 5′-flanking region of many cytoprotective phase 2 genes and causes increased transcription of the target gene after binding by the Nrf2 complex.

►Phase 2 Enzymes

ARF

Definition

Is an alternatively spliced product of the INK4a locus. When triggered by E1A, myc or E2F or other illegitimately activated oncogenes, ARF binds MDM2. This leads to a rise of the p53 level, causing growth arrest and/or apoptosis.

Synonyms

ARF; alternative reading frame; $p14^{ARF}$; human; $p19^{ARF}$; mouse

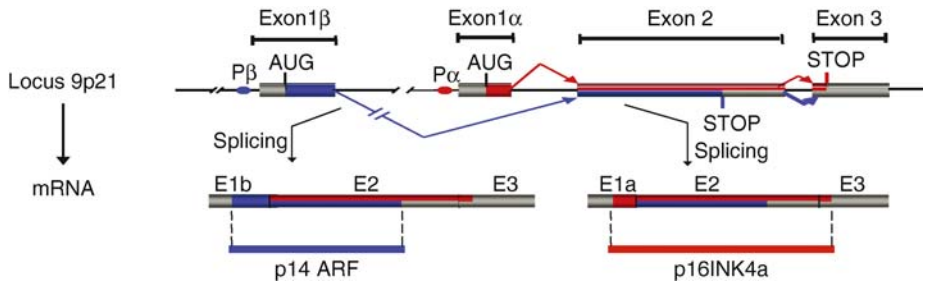
Definition

ARF (alternative reading frame), is a ►tumor suppressor protein that accumulates in the nucleolus in response to aberrant oncogenic/hyperproliferative signals and induces cell cycle arrest in G1/S or G2/M transition and ►apoptosis. Consistent with its tumor suppressor status, ARF inactivation (deletion, promoter methylation) impairs cellular response to oncogenic stress, and frequently occurs in a wide spectrum of cancers (30–40% of cancers).

Characteristics

Genomic alterations of the 9p21 chromosome region occur in various types of human solid tumors and hematological malignancies. Most, if not all, involve the *CDKN2* locus, where the *INK4a* and *ARF* genes are superimposed. Both gene products result from alternative splice transcripts in different reading frames (Fig. 1) and have been functionally characterized as tumor suppressor genes.

1. $p16^{INK4a}$ is the prototypic member of the *INK* (►*INK4*) gene family that encodes inhibitors of



ARF Tumor Suppressor Protein. Figure 1 Schematic representation of the genomic *INK4a/ARF* locus. Exons are depicted by boxes. Coding regions of *ARF* are colored in blue, those of *INK4a* in red, untranslated regions are in grey. ARF and INK4a promoters are indicated respectively by Pβ and Pα. *INK4a*/*ARF* locus utilizes alternative first exons and shares downstream exons to encode two totally unrelated tumor suppressors.

►cyclin-dependent kinases 4 and 6 and induces cell cycle arrest by negatively regulating Rb (►Retinoblastoma protein, biological and clinical functions) phosphorylation.

2. The *ARF* gene encodes a small basic nucleolar protein: $p14^{ARF}$ in human (132 amino acids, 14 KDa) and $p19^{ARF}$ in mouse (169 amino acids, 19 kDa). $p14^{ARF}$ and its murine homologue $p19^{ARF}$ only share 50% sequence identity. The N-terminus region of ARF (exon 1β) is the most conserved among species and retains the main functions of the protein (cell cycle arrest, nucleolar localization, and MDM2 binding). However, the C-terminal domain of ARF also presents functional domains and is needed for efficient nucleolar localization of $p14^{ARF}$ as well as for interaction with specific partners.

ARF is induced in response to aberrant oncogenic or hyperproliferative signals (►ras), ►E2F, E1A, MYC (►Myc oncogene)…, or DNA damage. The growth suppressive function of ARF mainly depends on its ability to regulate ►p53 stability, but recent data indicate that ARF also exerts p53-independent functions.

p53-Dependent Functions of ARF

The ARF–MDM2–p53 Pathway

The major pathway through which ARF exerts its control on cell cycle progression is currently designed as the ARF–MDM2–p53 pathway (Fig. 2.1). Upon mitogenic activation, ARF is expressed in the nucleolus and shuttles into the nucleoplasm where it directly binds to MDM2, which functions as a negative regulator of p53 through its ►E3-ubiquitine ligase activity. The ARF–MDM2 interaction results in the inhibition of p53 ubiquitination and proteasomal degradation. Accordingly, p53 is stabilized and induces upregulation of antiproliferative genes leading to cell cycle arrest or apoptosis. The exact mechanism whereby ARF stabilizes p53 is still not clear. Initial data suggested that the expression of ARF was correlated with MDM2 delocalization from the nucleus to the nucleolus but ARF can also stabilize p53 without relocating MDM2 into nucleoli. Moreover, additional feedback loops regulate this pathway as p53 is able to modulate its own activity by stimulating MDM2 transcription and repressing ARF (Fig. 2.1).

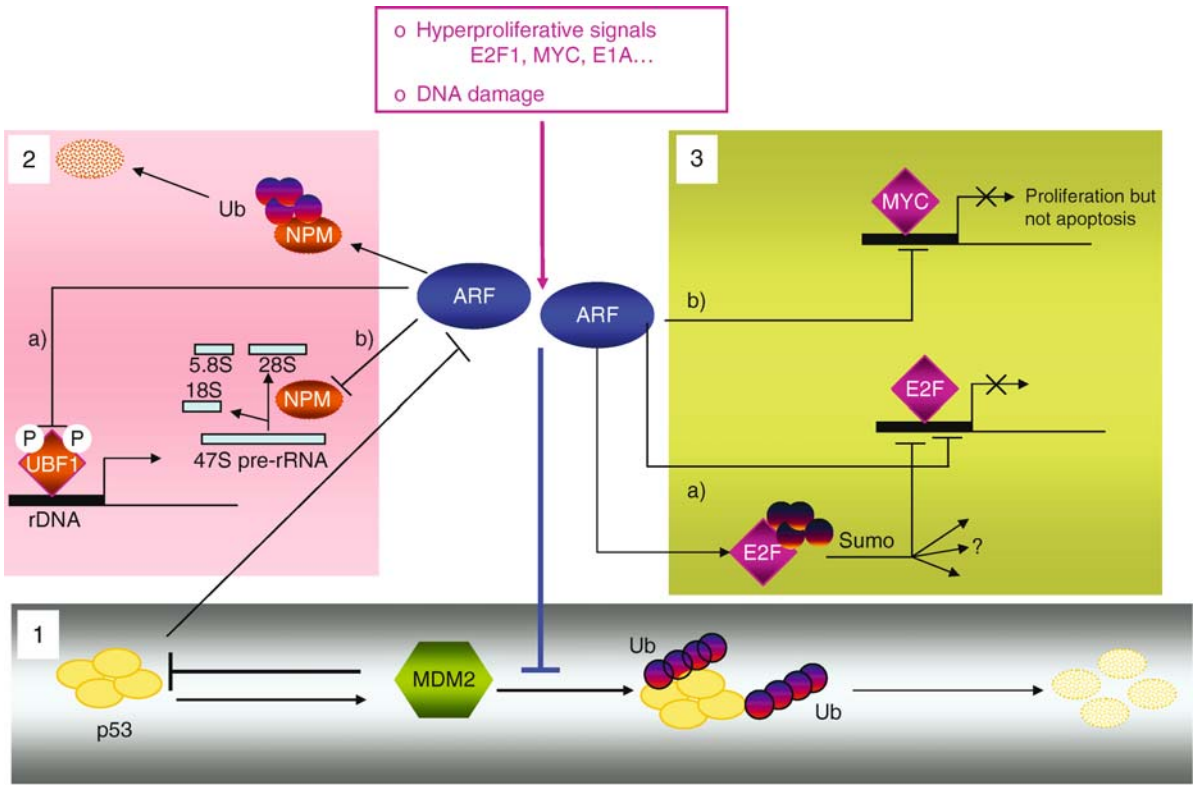
ARF and Replicative Senescence

The induction of $p19^{ARF}$ and p53 by activation of the ARF–MDM2–p53 pathway in mouse embryonic fibroblasts (MEFs) results in premature senescence or apoptosis depending on the cellular context. The alteration of either ARF or p53 function is sufficient to bypass senescence and immortalize MEFs. In contrast, $p14^{ARF}$ expression does not correlate with the onset of senescence in human fibroblasts in which replicative senescence seems to be preferentially mediated by $p16^{INK4a}$.

p53-Independent Functions of ARF

Mice lacking ARF ($ARF^{-/-}$) essentially develop sarcomas and lymphomas and to a lesser extent gliomas. Mice lacking p53 ($p53^{-/-}$) develop with short latency lymphocytic lymphomas but also sarcomas, a phenotype similar to that observed with ARF-null mice. Double ($ARF^{-/-}$ $p53^{-/-}$) or triple knockout (KO) mice ($ARF^{-/-}$, $p53^{-/-}$, $MDM2^{-/-}$) develop with decrease latency a wide spectrum of tumors, suggesting that ARF is involved in alternative pathway(s) to exert its antiproliferative function. Moreover, $p19^{ARF}$ re-expression in triple-KO MEFs is sufficient to induce cell cycle arrest.

The investigation of the p53-independent functions of ARF led to characterize many proteins that physically and/or functionally interact with ARF. The biological relevance of most of these interactions remains unclear, however some of these led to characterize new functions or cellular pathways involving the ARF protein.



ARF Tumor Suppressor Protein. Figure 2 p53-dependent and independent functions of ARF. (1) The ARF–MDM2–p53 pathway (grey frame): ARF binds to MDM2 and exerts a negative control on MDM2-mediated p53 degradation. p53 tightly regulates its own activity by stimulating *MDM2* and repressing *ARF* transcription through a direct binding on their promoters. ARF exerts a negative control on ribosome biogenesis (pink frame). (a) Phosphorylated UBF1 is required for the RNA polymerase I-dependent transcription of the 47S pre-rRNA. Human ARF binds to the transcription factor UBF1 and partially inhibits its phosphorylation, impairing the recruitment of the transcriptional complex on the rDNA promoter. (b) By interfering with the nucleolar protein NPM/B23 within preribosomal particles, ARF induces NPM/B23 degradation and partially reduces 28S rRNA maturation. ARF is a transcriptional regulator (green frame). (a) $p14^{ARF}$ interacts with the transcription factor E2F1. ARF delocalizes E2F1 to the nucleolus and inhibits its transcriptional activity. Recently, ARF has also been shown to enhance the sumoylation of E2F1. The significance of ARF-induced sumoylation is not clear yet, but it could regulate the functions of ARF partners in different ways. (b) When overexpressed, MYC directly associates with the *ARF* promoter and upregulates ARF expression. In turn, ARF associates with MYC and inhibits the transcription of genes required for cell cycle progres.

ARF Negatively Regulates Ribosome Biogenesis

In murine cells, $p19^{ARF}$ has been shown to associate in very high molecular weight complexes with NPM/B23, a multifunctional protein involved in the maturation of the 32S rRNA into 28S rRNA (Fig. 2.2). These complexes are detected in the granular component of nucleolus and correspond to mature preribosomal particles. Given the high amounts of NPM/B23 in the nucleolus when compared with ARF, all ARF molecules are bound to only a fraction of NPM/B23, suggesting that NPM/B23 could sequester ARF into the nucleolus to avoid its binding with some of its nuclear targets. The human homologue $p14^{ARF}$ also colocalizes with NPM/B23 and has been shown to promote its ubiquitination and degradation, resulting in the decrease of mature 28S rRNA levels. The interaction of ARF with NPM/B23 delays rRNA processing and induces a partial cell growth arrest.

Several molecular models connecting the p53-dependent and -independent activities of ARF have recently emerged, based on the consequence of ARF–NPM/B23 interaction on the cellular localization of both partners, and can be summarized as follows: in response to oncogenic insults, ARF is rapidly and highly expressed in nucleoli where it binds to NPM/B23 and interferes with rRNA maturation to inhibit cell growth in a MDM2 and p53-independent manner. Upon DNA damage or other stress signals, ARF shuttles from the nucleolus and is redistributed in the nucleoplasm, where it binds MDM2 to activate the so-called ARF–MDM2–p53 pathway and inhibit cell proliferation.

In addition, recent data indicate that human $p14^{ARF}$ specifically associates with the transcription factor UBF1 and partially inhibits Pol I-dependent transcription of rRNA (Fig. 2.2). UBF1 is hypophosphorylated upon $p14^{ARF}$ expression and unable to recruit the transcriptional complex. These results suggest that ARF could exert a negative regulation of ribosome biogenesis at both transcriptional and posttranscriptional levels through independent pathways. Moreover, human $p14^{ARF}$ has been described to interfere with polysome formation and could in that way complement p53-dependent functions through the negative regulation of protein translation.

ARF and the Control of Transcription

ARF expression can be induced in response to aberrant hyperproliferative signals conveyed by the E2F1 transcription factor. In turn, ARF physically associates with E2F1 and regulates its functions in different ways. Upon ARF expression, E2F1 is delocalized from the nucleus to the nucleolus and its transcription activity is inhibited (Fig. 2.3). Moreover, the presence of ARF is correlated with a dramatic rate of E2F1 proteolysis. Recent data indicate that $p14^{ARF}$, through its interaction with the SUMO-E2 conjugating enzyme can promote the sumoylation of some of its binding partners including E2F1. SUMO is an ubiquitin-like protein that covalently associates to proteins and alters alternatively their stability, subcellular localization, or their function in cell cycle progression. In consequence, $p14^{ARF}$ could diversely regulate its own functions by targeting the sumoylation of its partners.

ARF is also induced upon MYC overexpression, and leads to cell cycle arrest or apoptosis through the stabilization of p53. In turn, ARF has been shown to physically associate with MYC and inhibit some of its functions, characterizing a negative feedback loop, independent of p53 or MDM2 (Fig. 2.3). It is not clear whether this interaction occurs in the nucleolus, suggesting a sequestration of MYC in this compartment, or takes place in the nucleoplasm after ARF exclusion from nucleoli. Anyhow, ARF directly interacts with two functional regions of MYC: the C-terminal domain required for its heterodimerization with MAX, and the amino-terminal transcriptional regulatory (activation or repression) domain.

MYC is a dual transcription factor that regulates genes to either stimulate cell proliferation or induce apoptosis. $p19^{ARF}$ participates in both mechanism and differentially controls MYC transcriptional activity depending on the target genes; the transcription of MYC-responsive genes involved in G1 to S phase progression is dramatically decreased upon $p19^{ARF}$ expression. Chromatin immunoprecipitation experiments suggest that this control of MYC functions could depend on the binding of ARF on selected MYC-responsive promoters. In fact, ARF binding doesn't inhibit the recruitment of MYC–MAX on those promoters, but alters the activation of different cofactors such as TRRAP and TIP 60. These coactivators are responsible for chromatin remodeling through their respective helicase and histone acetyl transferase (HAT) activity. Their association with ARF specifically maintains chromatin in a condensed state and block MYC activation of proliferating genes. In contrast, ARF has not been shown to modify MYC ability to repress transcription or activate apoptosis.

Conclusion

The *INK4a/ARF* locus encodes two unrelated tumor suppressor genes, $p16^{INK4a}$ and ARF, initially considered to regulate cell proliferation through independent pathways:

The first mechanism elucidated, by which ARF inhibits cell proliferation, was its ability to block MDM2-dependent p53 degradation. As the tumor suppressor function of the protein still remained in p53 deficient cells, new partners have been characterized and delineate new modes of action. By interacting with nucleolar proteins like NPM/B23 or UBF1, ARF can limit ribosome biogenesis independently of p53 and MDM2. Moreover, ARF can interact in the nucleoplasm with transcription factors and control the expression of target genes by varied mechanisms such as transcription factor degradation or delocalization, inhibition of promoter binding, inhibition of promoter activity. Interestingly, the control of E2F1 transcriptional activity by ARF characterizes this protein as a regulator of the RB pathway, and delineates a functional connection between the two tumor suppressors encoded by the INK4a/ARF locus.

The emerging notion is that the ability of ARF to control cell proliferation is tightly dependant on its cellular localization. In particular, the pivotal role of NPM/B23 in ARF nucleolar functions should be considered to improve therapeutic strategies restoring a functional p53 pathway.

Arginine

Jason A. Zell
Cancer Prevention Program, Division of Hematology/Oncology and Epidemiology, Department of Medicine, School of Medicine, Chao Family Comprehensive Cancer Center, University of California, Irvine, CA, USA

Definition

►Arginine is a "semi-essential" amino acid that is a key component of several metabolic pathways. Excess arginine, however, has been implicated in ►carcinogenesis in animal model systems and also in humans.

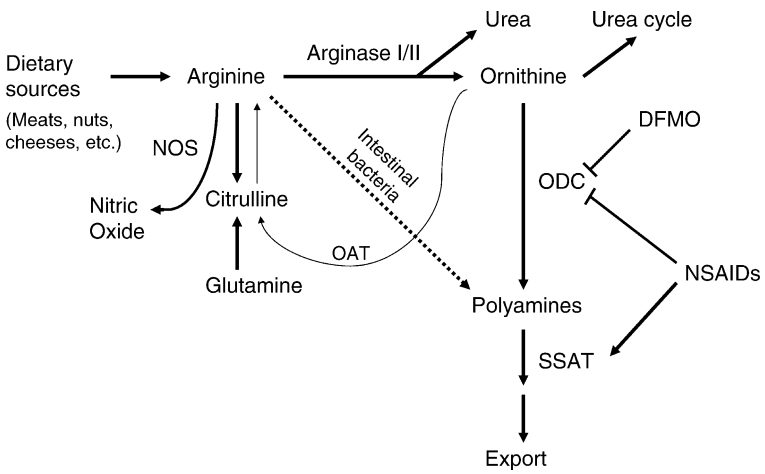
Characteristics

Arginine Metabolism

Arginine is derived from dietary sources and is also synthesized by the kidney. It is considered to be a "semi-essential" amino acid because many conditions affect its synthesis (i.e. sepsis, burns, inborn errors of protein metabolism), resulting in dependence on exogenous arginine supplementation. Dietary sources rich in arginine include all types of meat, nuts, and certain other foods (cheeses, etc.). Arginine is important for protein synthesis, wound healing, spermatogenesis, and it is involved in numerous metabolic pathways. Arginine is well-described as a component of the urea cycle, which is involved in the processing and cellular export of ammonia. L-arginine is a key substrate in the biosynthesis of ►nitric oxide (NO), and the ►polyamines (i.e. putrescine, spermidine, and spermine). These naturally-occurring arginine-derived substances (i.e. nitric oxide and the polyamines) have long been the focus of carcinogenesis research. Thus the majority of investigations on arginine and cancer relate to carcinogenesis research related to these important arginine-derived compounds. Arginine is catabolized primarily by arginase I in the liver for processing of waste via the urea cycle. In the kidney and small bowel, arginase II catabolizes arginine in the mitochondria. A simplified schema for arginine metabolism is provided in (Fig. 1).

Nitric Oxide, Polyamines, Carcinogenesis, and Chemoprevention

Arginine is catabolized by the enzyme nitric oxide synthase (NOS) to form citrulline and nitric oxide (NO).



Arginine. Figure 1 Arginine as the central substrate for polyamine and nitric oxide metabolism. Alternate pathways and inhibitors of these pathways are indicated. NOS, nitric oxide synthase; DFMO, difluoromethylornithine; ODC, ornithine decarboxylase; NSAIDs, non-steroidal anti-inflammatory drugs; SSAT, spermidine/spermine *N*1-acetyltransferase; OAT, ornithine aminotransferase.

Nitric oxide is a signaling molecule with well-defined vasodilatory properties. Three main isoforms of NO synthases exist: NOS1 (neuronal NOS), NOS2 (inducible NOS), and NOS3 (endothelial NOS). Nitric oxide has been implicated in numerous aspects of carcinogenesis. However, nitric oxide has also been observed to inhibit carcinogenesis – thus the biology of nitric oxide is complex, and further research is needed to clarify the role of nitric oxide and NOS in various carcinogenesis models. Nitric oxide has been reported to be involved in cell migration, tumor invasiveness, and angiogenesis in murine mammary adenocarcinoma cell lines. Based on promising experimental data, the field of ►chemoprevention continues to dedicate significant research into inhibitors of inducible-nitric oxide synthase (NOS2). Various NOS2 inhibitors have been developed, and tested in animal carcinogenesis models. For example, selective NOS2 inhibitors have been shown to inhibit colonic aberrant crypt foci (i.e. colorectal adenoma ►preneoplastic lesions) in rat colon carcinoma model systems.

The hepatic arginases convert L-Arginine to ornithine, which is converted directly to putrescine via the rate limiting enzyme of polyamine synthesis: ►ornithine decarboxylase (ODC). In excess, polyamines have been shown to promote tumorigenesis in epithelial tissues in human and murine systems. The field of chemoprevention has long-sought to capture a therapeutic advantage of this finding, through polyamine inhibition via the irreversible ODC-inhibitory agent α-►difluoromethylornithine (DFMO). In experimental studies using murine models, inhibition of polyamines with DFMO suppresses arginine-induced tumorigenesis. In humans, phase IIa clinical biomarker trials of oral DFMO on high-risk populations have demonstrated polyamine inhibition in target tissues (prostate and colorectum). These polyamine-inhibitory effects were sustained during the treatment period (3–12 months), and administration of DFMO resulted in a favorable toxicity profile.

Arginine and Cancer: Experimental Studies

Various cell culture and animal models have demonstrated a carcinogenic role of arginine. In cell culture experiments, viability of malignant cells has been demonstrated to be dependent on arginine supplementation. Normal cells become quiescent in an arginine-deficient medium, whereas malignant cells die. A series of relevant murine and rat studies have been performed demonstrating the effects of dietary arginine intake on model systems of cancer. Rodents treated with L-arginine exhibit increased growth of carcinomas and sarcomas, and treatment with D-arginine inhibits carcinogenesis. Hepatic arginase and arginine deiminase are enzymes that degrade arginine and have been investigated as potential anticancer agents. Experimental results demonstrate that human breast cancer cells have express high levels of arginase. For example, arginase-inhibition results in decreased proliferation of human breast cancer cells. Dietary arginine supplementation has been demonstrated to increase tumor size in familial adenomatous polyposis (FAP) mouse models, and also increase the intestinal tumor number in these mice in a dose-dependent manner. The increase in tumor number was found to be due to an increase in high-grade tumors, in a manner dependent on *Nos2*. This process is inhibited dramatically by treatment with DFMO, various ►non-steroidal anti-inflammatory drugs (NSAIDs, which modulate polyamine metabolism, Fig. 1), or a combination of these agents. Thus an experimental basis for arginine-induced tumorigenesis has been established, and various inhibitory agents and mechanisms are being developed to antagonize this process.

Arginine and Cancer: Epidemiologic Studies

Methods of epidemiologic assessment of arginine intake in cancer research is typically from 24-h food recall or food frequency questionnaires, which collect data on the type and quantity of ingested foods. Further analysis with food composition tables must then be performed to calculate estimated arginine intake for each study participant. Alternatively, serum arginine levels have been tested in epidemiologic studies, and these patient serum levels correlate fairly well with corresponding data from food recall questionnaires.

As mentioned, arginine is primarily derived from meat, and it is estimated that approximately 40% of daily arginine intake comes from meat consumption in Western and European diets. It is a common misunderstanding that high arginine content is restricted to beef. In fact, pork, chicken, various fish, and shellfish have similarly high arginine levels when compared to beef. While a large body of epidemiologic data have associated meat consumption with risk of epithelial cancers (particularly colorectal cancer), the contribution of arginine to this risk is unknown. However, among colorectal cancer patients it has been demonstrated that total dietary arginine intake highly associated with meat consumption quantity, and that meat consumption was associated with poor survival in familial colorectal cancer patients. Such findings implicate potential gene-environment modifying effects between arginine and an unknown genotype(s) among familial colorectal cancer patients – possibly involving the nitric oxide (e.g. *Nos2*) or polyamine synthetic pathway (e.g. *Odc*).

Arginine and Cancer: Clinical Aspects

The putative benefits of arginine restriction on cancer have led to translational applications among cancer patients. However, limited data are available to demonstrate the efficacy and tolerability of such treatments.

Determining the safety of arginine restriction among cancer patients (i.e. as a tertiary cancer prevention

strategy) is of great importance in ►clinical trial development, since these patients often have special nutritional requirements, or cachexia. As noted, many clinical studies have focused on polyamine inhibition through various agents such as DFMO or NSAIDs. Data on the safety and tolerability of arginine restriction among cancer patients is quite limited, however. Interestingly, severe arginine restriction has been prescribed to pediatric patients with gyrate atrophy of the eye (the result of an enzymatic dysfunction leading to excess arginine production and resultant retinal morbidity) without untoward events. Such children are given a prescribed arginine-restricted dietary regimen with amino acid supplementation – which delays disease progression. This dietary regimen is quite stringent and adherence is difficult, but it has demonstrated sustained efficacy in children treated over a period of many years.

Various strategies for arginine restriction have been attempted in the setting of clinical trials, including early-phase clinical trials of pegylated-arginine deiminase (an arginine-degrading enzyme derived from *Mycoplasma*) among hepatocellular carcinoma (HCC) patients. Treatment of HCC patients with arginine deiminase was shown to be well tolerated, despite depletion of plasma arginine levels over a 3-month period, and modest efficacy has been reported. Other investigators have reported responses of various tumors to arginase treatment. Currently, our group at the University of California, Irvine is developing a phase IIa clinical biomarker trial involving arginine restriction among ►colon cancer patients. The goal of this study is to favorably alter surrogate endpoint biomarkers of polyamine metabolism through dietary arginine restriction and oral aspirin therapy. Modest arginine dietary restriction (i.e. ~50% decrease in daily intake) will be prescribed individually to each study participant after a thorough dietary assessment. The customized dietary regimens will be prescribed in a manner that will not restrict total protein intake. Thus the prescribed regimens are not particularly stringent, and are expected to result in good compliance. Safety and tolerability assessments are critical components of this trial, as significant toxicity is not expected.

As more data emerge from clinical trials involving arginine restriction (through various mechanisms) among cancer patients, the optimal delivery methods and management issues will be discovered. However, until then, such approaches remain investigational, and broad-based dietary recommendations directed at cancer patients can not be supported.

Arginine-Depleting Enzyme Arginine Deiminase

Synonyms

ADI

Definition

►Arginine deiminase (ADI; EC 3.5.3.6) is an enzyme from prokaryotes that has been used to deplete arginine in the treatment of arginine-requiring ►cancers.

Characteristics

To starve cancer cells through amino acid deprivation can be a strategy in cancer therapy. Specific amino acids are required for the growth of certain tumor cells while normal cells can synthesize sufficient amounts for their own needs. For example, an enzyme called asparaginase has been used to deplete ►asparagine in the treatment of ►acute lymphoblastic leukemia and a few sub-types of non-Hodgkin lymphoma (►Malignant Lymphoma, Hallmarks and Concepts) because these cancers lack asparagine synthetase and are ►auxotrophic for asparagine. Asparaginase degrades both asparagine and glutamine. The antitumor activity of this enzyme is due to its ability to degrade asparagine, and some of its deleterious side effects were due to its degradation of glutamine.

ADI is an enzyme that hydrolyzes arginine to generate energy in many parasitic microorganisms including ►*Mycoplasma arginini* and *Mycoplasma hominis*. This enzyme has potent anticancer activities. Some cancers have an elevated requirement for arginine (Arginine and Cancer), such as metastatic ►melanoma

and ►hepatocellular carcinoma (HCC). These cancer cells are unable to produce arginine and therefore take it from the blood since they need it for their rapid growth. ADI catalyzes the hydrolysis of arginine to citrulline, is currently being used as a chemotherapeutic agent against these arginine-requiring cancers and has gained much attention in recent clinical trials. ADI appears to degrade only arginine and does not appear to metabolize any other amino acids. When administrating ADI to patients with metastatic melanoma or HCC, it destroys the arginine present in the blood, and the cancer cells are thus deprived of their supply, and they cannot grow and eventually die.

Sensitivity of Cancer Cells to ADI-Treatment

Arginine is a ►non-essential amino acid for humans and mice because it can be synthesized from citrulline in two steps via the ►urea cycle enzymes ►argininosuccinate synthetase (ASS) and ►argininosuccinate lyase (ASL). ASS catalyzes the conversion of citrulline and aspartic acid to argininosuccinate. Argininosuccinate is then converted to arginine and fumaric acid by ASL. Some melanomas, HCCs and ►prostate carcinomas (►Prostate Cancer, ►Clinical Oncology) do not express ASS mRNA but do express ASL mRNA. Although it is not known why these cancer cells are unable to express ASS, there is ample evidence that ASS deficiency results in the arginine ►auxotrophy.

The sensitivity of various cell lines to ADI has been reported to be dependent upon the expression of ASS, the rate-limiting enzyme in the conversion of citrulline into arginine. Resistance to ADI-treatment may correlate with cellular ASS activity, allowing cell survival by conversion of the product of the ADI reaction, i.e. citrulline to arginine. Many ASS-positive HCC cell lines are resistant to ADI-treatment, although most require arginine for proliferation. Recombinant human ►arginase has been reported as an arginine-depleting enzyme for killing ASS-positive tumors which expressed ASS, but not ►ornithine transcarbamylase (OTC), the enzyme that converts ornithine, the product of degradation of arginine with recombinant human arginase, to citrulline, which is converted back to arginine via ASS. Recent data suggest that the growth of OTC-deficient HCC tumor cells (ASS-positive and ADI-resistant) in mice is inhibited by treatment with ►pegylated recombinant human arginase, which is in clinical trials and development by Bio-Cancer Treatment International Limited. Arginine deprivation causes many types of tumor cells to die, because they cannot recover or convert urea cycle intermediates into arginine.

Mechanisms of Anti-Tumor Activity of ADI

As a promising enzyme in the treatment of tumors without ASS expression, ADI has shown its anti-proliferative and anti-angiogenic activities in a variety of cancer cells and endothelial cells *in vitro* and *in vivo*. The exact mechanism of its anti-tumor activity remains unclear. To elucidate the mechanisms, many data have been collected. For example, the *Mycoplasma arginini* ADI inhibits the growth of mouse hepatoma cell line MH134 *in vitro*, and its concentration required for 50% growth inhibition (IC_{50}) is about 10 ng/mL. The IC_{50} value of the *Mycoplasma hominis* ADI against the same cell line is about 100 ng/mL. Arginine restores, in a dose-dependent manner, the growth of mouse MH134 hepatoma and Meth A fibrosarcoma cell lines that have been inhibited by ADI, indicating that the tumor cell growth inhibition caused by ADI originates from the depletion of the essential nutrient arginine. ADI is also effective at nanogram quantities per milliliter in Chinese Hamster Ovary (CHO) cells, HeLa cells (human epithelial cells from a fatal cervical carcinoma (►Cervical Cancers)), human T cells and T lymphoblastoid cell lines, but not B-precursor and myeloid cell lines. Renal cell carcinoma (RCC) (►Renal Carcinoma) does not express ASS and is also sensitive to arginine deprivation via ADI. RCC cells treated with ADI showed growth retardation in a dose dependent manner. ADI also exerted *in vivo* anti-proliferative effect on the allografted renal cell carcinoma (RENCA) tumor cells and prolonged the survival of tumor-bearing mice.

ADI may inhibit cell proliferation not only by depletion of arginine, but also by mechanisms involving the cell cycle and death signals. Low concentrations of ADI inhibit proliferation of various cultured cells by arresting the cell cycle in G1- and/or S-phase with higher ADI concentrations leading to subsequent ►apoptosis. For T lymphoblasts, ADI induces apoptotic cell death and cell cycle analysis shows that G1→S transition is blocked in these ADI-treated cells, with increase of apoptotic nuclei in the sub-G1 fraction. Recent data suggest that ADI inhibits proliferation of human leukemia cells more potently than asparaginase by inducing cell cycle arrest and apoptosis. This inhibition of cell proliferation involves cell growth arrest in the G1- and/or S-phase and eventually apoptotic cell death. For human leukemic CEM cells, ADI suppresses expression of c-myc, a potential key regulator of cell proliferation and apoptosis, and increases expression of p27Kip1 cyclin-dependent kinase inhibitor.

Since arginine is involved in several pathways for regulation and maintenance of cellular functions, such as protein synthesis, polyamine synthesis, and ►nitric oxide (NO) production, ADI may modulate these physiological pathways. Human mammary adenocarcinoma (MCF-7) (►Breast Cancer) and human lung carcinoma (A549) (►Metastasis Signaling) cells, express diverse ASS activity which regenerates arginine, have different sensitivity to ADI. In A549 cells, the anti-proliferative activity of ADI might be due to the

inhibition of protein synthesis, but not polyamine synthesis. Recent data suggest that ADI inhibits ►*de novo* synthesis of protein in cells with low ASS activity, but not in cells with high ASS activity, due to the fact that the lack of extracellular arginine in protein synthesis can be replaced by the regenerated arginine via ASS and ASL in the cell. Polyamine synthesis is not affected by ADI, even in cells with no ASS activity. Therefore, inhibitory effect of ADI on the proliferation of ADI-sensitive tumor cells is most likely due to the inhibition of *de novo* protein synthesis.

On the other hand, arginine is the precursor of NO, and the latter modulates ►angiogenesis. ADI is a selective modulator for NO production via inducible (iNOS) and endothelial (eNOS) nitric oxide synthases. Hydrolysis of plasma arginine to citrulline by ADI suppresses lipopolysaccharide-induced NO synthesis. ADI treatment affects tube-like (capillary) formation of human umbilical vein endothelial cells. Inhibition of angiogenesis by ADI is reversed when a surplus of exogenous arginine is provided, indicating that its anti-angiogenic effect (►Antiangiogenesis) is primarily due to arginine depletion. Recent data suggest that acting as an anti-angiogenic agent (►Anti-Angiogenic Drug), ADI inhibits *in vivo* growth of neuroblastomas with unfavorable properties and that these effects are potentiated by simultaneous irradiation. Combination of ADI with irradiation does not increase tumor hypoxia. The anti-proliferative and anti-angiogenic effects of ADI might be a consequence of protein synthesis that involves cell growth and tumorigenesis and polyamine synthesis that involves cell proliferation and differentiation. Due to its two-pronged attack as both an anti-proliferative and an anti-angiogenic agent, ADI may be highly beneficial in cancer therapy.

Clinical Trials

Phoenix Pharmacologics Inc. is developing ADI-PEG-20 (ADI conjugated to polyethylene glycol 20,000 molecular weight), a pegylated ADI for the potential treatment of HCC, for which the Food and Drug Administration (FDA) and the European Agency for the Evaluation of Medicinal Products have granted the drug Orphan Drug status, and melanoma, for which the FDA has also awarded ADI-PEG-20 Orphan Drug status. In addition, ADI-PEG-20 is being investigated for the potential treatment of influenza virus infection and hepatitis C virus infection. The *Mycoplasma hominis* ADI has been mutated and is produced by recombinant technology in E. coli. It is formulated with PEG to decrease its immunogenicity and to increase its circulating half-life *in vivo*.

Reported in 2004, ADI-PEG-20 was used to lower plasma arginine to treat patients with unresectable HCC in phase I/II studies. Pharmacodynamic studies indicated an ADI-PEG-20 dose level of 160 U/m^2 was sufficient to lower plasma arginine from a resting level of ~130 μmol/L to below the level of detection (<2 μmol/L) for more than 7 days. This therapy appeared to be well tolerated, even in patients who had no detectable plasma arginine for three continuous months of therapy. Of the 19 patients enrolled, two had a complete response, seven had a partial response, seven had stable disease, and three had progressive disease. The median survival for the 19 patients enrolled on this study was 410 days.

Reported in 2005, ADI-PEG-20 was also used to treat patients with metastatic melanoma in phase I and II studies. After treatment, plasma arginine levels in individuals with metastatic melanoma were lowered; NO levels also were lowered. There were no grade 3 or 4 toxicities directly attributable to the drug. Six of 24 phase I to II patients responded to treatment (five partial responses and one complete response; 25% response rate) and also had prolonged survival. However, ADI-PEG-20 does have a number of shortcomings. First, ADI is a bacterial enzyme and antigenicity may still be a problem despite ►pegylation. In phase II studies that have been reported, autoantibodies were detected as early as the fifth week and continued to increase with treatment. This may potentially render the drug ineffective on prolonged treatment. Second, ADI converts arginine to citrulline and free ammonia, which could pose problems in patients with cirrhosis liver and hepatic decompensation with further elevation of ammonia levels, leading to prehepatic encephalopathy in man. Third, ADI product citrulline is readily recyclable and rescues cells not only from arginine-free medium but also from arginase-induced deficiency. This has led to the major limitation of ADI: it only kills cancer cells that are ASS deficient. ASS expression has been detected in some tested human tumor biopsy specimens which might cause the tumors to be resistant to ADI therapy.

Armadillo Family

Definition

Arm family; a family of proteins that are characterized by a central protein domain that is composed of a series of imperfect 42 amino acid repeats (arm motifs). The family includes the Drosophila protein armadillo and its vertebrate homologues β-catenin and plakoglobin. β-catenin is a structural protein in adherens junctions and has an important signaling function in the APC/β-catenin pathway. Plakoglobin is interchangeable with β-catenin in adherens junctions and is a structural constituent of desmosomes. Plakoglobin may act as a signaling molecule in the ►APC/β-catenin pathway.

►Desmosomes

Synonyms

Aromatase; Estrogen synthase; CYP 450_{arom}

Definition

Estrogens are involved in numerous physiological processes including the development and maintenance of the female sexual organs, the reproductive cycle, reproduction, and various other neuro-endocrine functions. These ►hormones have crucial roles in certain disease states, particularly in mammary and endometrial hyperplasias and ►breast cancers.

Estrogens are biosynthesized from androgens by the ►cytochrome P450 enzyme complex called "aromatase" first discovered in 1955.

Characteristics

Composition

The aromatase enzyme complex is bound in the endoplasmic reticulum of the cell and is comprised of two major proteins. One protein is cytochrome $P450_{arom}$, a hemoprotein that converts C_{19} steroids (androgens) into C_{18} steroids (estrogens) containing a phenolic A ring. The second protein is NADPH-cytochrome P450 reductase, which transfers reducing equivalents to cytochrome $P450_{arom}$. Three moles of NADPH and three moles of oxygen are used in the conversion of one mole of substrate into one mole of estrogen product.

Distribution and Regulation

In premenopausal women, the enzyme is expressed in the ovarian granulosa cells of large preovulatory follicles and syncytiotrophoblasts of the placenta during pregnancy. Additionally, former theca interna cells of early to mid luteal phase corpus luteum are the major source of aromatase in premenopausal ovaries. Aromatase is not found in pre-pubertal infant ovaries. In addition, aromatase is expressed in a number of other tissues throughout the body. The most important site of non-ovarian estrogen is adipose tissue where production increases with age and is the primary source of circulating estrogen in post-menopausal women. However, aromatase levels in breast tissue have been found to be several fold higher levels that found in plasma. A number of reports indicate that aromatase activity and mRNA is present in normal breast tissue and breast tumors. Approximately, 60% of the ►breast cancers express aromatase activity. Although gonadal aromatase is regulated by follicle stimulating hormone, aromatase in extra-gonadal sites is regulated by other factors such as glucocorticoids, cAMP and prostaglandin E_2. Thus, in postmenopausal women, estrogen synthesis is independent of pituitary-ovary feedback regulation. Furthermore, the expression of aromatase is highest in or near breast tumor sites.

Expression

Human aromatase is encoded by CYP19, a single-copy gene on 15q21.2 and is expressed in the endoplasmic reticulum. CYP19 comprises ten exons, with exons II through X encoding the open reading frame of aromatase. At least nine different first exons are known to encode unique 5′-untranslated regions of aromatase mRNA. Each first exon has its own upstream promoter region. First exons and corresponding promoters are used alternatively in a tissue or cell-specific manner, enabling tissue or cell-specific regulation of aromatase. For example, the most proximal promoters, PII and I.3, are used predominantly for the gonads, whereas promoter 1f drives brain-specific transcription of aromatase, and promoter I.4 is used for adipose tissue and skin. The most distal promoter, I.1, located 100 kb upstream of exon II, is used almost exclusively for the placenta. Each promoter displays different *cis*-elements to which cell specific transcription factors bind. Accordingly, tissue or cell-specific expression and regulation of aromatase is realized by the level of promoter selection and by the cell-specific profiles of transcription factors. The first step toward understanding the regulation of aromatase expression in a specific tissue is to elucidate the associated promoter use.

Aromatization Reaction

Aromatization of androgens to estrogens is last in the series of reactions in steroid biosynthesis is the rate limiting step for estrogens synthesis. Therefore, there are no steroids normally produced downstream to be affected by inhibition of aromatase. Aromatization of androstenedione, the preferred substrate, occurs via three successive oxidation steps, with the first two being hydroxylations of the angular C_{19} methyl group and characteristic of P450 hydroxylations. The final oxidation step involves aromatization of the A ring of the steroid molecule and loss of the C_{19} carbon atom as formic acid. Although the mechanism of the third and last step remains unclear, it is thought to involve nucleophilic attack of the 19-aldehyde by the reduced ferrous peroxy intermediate to produce a peroxo hemiacetal that decays as a consequence of *cis* elimination of the 1β-hydrogen by the proximal oxygen atom and results in aromatization of the A ring of the steroid and formic acid release. Analysis of the reduced ferrous peroxy intermediate indicates that the 1β-hydrogen removal by the proximal oxygen of the peroxo hemiacetal intermediate encounters a high energetic barrier (>60 kcal/mol) that is enzymatically inaccessible. Furthermore, the resulting species do not directly fragment to the experimentally observed formic acid and aromatized steroid products. It has been reported that steroid models that contain the 2,3-enol moiety have a markedly lower barrier for 1β-hydrogen atom abstraction (<7 kcal/mol) due to the ability of the enolized A ring to delocalize the impending radical. Formation of the 2,3-enol appears to be necessary as transition states containing the 2,3-enol moiety and the 19-gem diol decay directly to the aromatized product, formic acid, and the aqua-bound model cytochrome P450 enzyme. Analysis of the reaction vectors indicate that the second hydrogen transfer occurs with a concerted, nonsynchronous mechanism without an energetic barrier. Thus, the final catalytic step of aromatase appears to involve the cytochrome P450 oxene intermediate, 1β-hydrogen atom abstraction, and release of formic acid. Although aromatase shares common features with the other P450

enzymes the unique characteristics of the aromatization reaction, involving loss of the C19 carbon and conversion of steroidal A ring to an aromatic ring provide the opportunity to develop inhibitors selective for $P450_{arom}$. The importance of selective inhibition is that potent inhibitors bind to the target enzyme with high affinity. Because only low concentrations of the drug are required to suppress the enzyme, interactions with other enzymes is unlikely to occur. For example, 11β-hydroxylase mediates the synthesis of the adrenal steroid cortisol and is inhibited along with aromatase and other P450 enzymes by general inhibitors of steroid biosynthesis, such as aminoglutethimide. This compound was used in breast cancer treatment in the 1960s, initially to produce medical adrenalectomies but later was used to inhibit aromatase in conjunction with cortisol replacement. However, because of its lack of selectivity, this compound is a relatively weak aromatase inhibitor and causes a number of toxicities in patients.

Since aromatase has both an iron-containing and a steroid-binding site there are two possible ways inhibitors may interact with the enzyme. Aromatase inhibitors have been traditionally divided into the two classes of Type I and Type II inhibitors.

Type I Inhibitors of Aromatase

Type I or mechanism based inhibitors of aromatase include steroidal structural analogs of the substrate Δ4A. These are competitive inhibitors of the enzyme androstenedione and interact with the substrate binding site of the enzyme. This leads to covalent bond formation with the nucleophilic site of the enzyme leading to irreversible enzyme inhibition. Since, the inhibitor binds irreversibly to the target site, a new enzyme molecule must be produced for estrogen synthesis to occur.

Formestane

First selective aromatase inhibitor: Investigations on the development of aromatase inhibitor began in 1970s and have expanded greatly in the past three decades. The initial approach taken to develop the first selective AI was to design substrate analogs based on the structure of Δ4A. These inhibitors have chemical substituents at various positions on the steroid nucleus. Modifications at C4 have produced several effective inhibitors including 4-OHA (4-hydroxyandrostenedione). Other structural modifications can be made on the B-ring of the steroid nucleus.

Following initial ►clinical trials in the 1980s, 4-OHA was introduced into the market in 1993 as the first selective inhibitor under the name formestane (LENTARON® Ciba-Geigy, now Novartis) with the indication for the treatment of advanced breast cancer in postmenopausal women. In clinical trials, weekly deep intramuscular injections with 500 mg of formestane to unselected breast cancer patients resulted in a 60% suppression of plasma ►estradiol levels and an overall response rate of almost 30%. Similar responses, obtained with a daily oral administration of 500 mg, were however indicative of a lower bioavailability by this route.

Exemestane

Subsequently AIs with improved oral activity were developed. This resulted in exemestane (Aromasin®) which received US FDA approval in 1999 for treatment of advanced breast cancer.

Type II Inhibitors of Aromatase

Non-Steroidal Reversible Inhibitors. Type II inhibitors are reversible inhibitors of aromatase and include nitrogen containing compounds such as letrozole (Femara) and anastrozole (Arimidex). The nitrogen in these compounds reacts and forms a co-ordinate bond with the heme atom of the P450 enzyme complex. These inhibitors are based on known P450 enzyme inhibitors, such as ketoconazole and are more likely to inhibit multiple P450 enzymes in addition to aromatase. Type II inhibitors can have lower specificity than type I inhibitors, for example Type II inhibitors also include aminoglutethimide which inhibits 11β-hydroxylase and cortisol production. However, the newer, third generation AIs such as letrozole and anastrozole exhibit a great degree of specificity for aromatase, are very potent and have good bioavailability. In post-menopausal women, letrozole decreases plasma concentration of estradiol, estrone and estrone sulfate by 75–95% from baseline with maximal suppression achieved within 2–3 days of treatment initiation. At clinically used dosage, letrozole does not impair adrenal synthesis of glucocorticoids or aldosterone.

In 1998, letrozole was approved for the treatment of advanced breast cancer in post-menopausal women with hormone receptor positive or unknown breast cancer who had failed prior ►tamoxifen treatment (second-line). In 2001, FDA approved letrozole for first-line treatment of postmenopausal women with hormone receptor positive locally advanced or metastatic breast cancer.

Applications and Indications

AIs are approved by US-FDA for the treatment of post-menopausal hormone dependent (►ER positive or unknown) as a first-line treatment and after tamoxifen relapse. Recent reports of the MA-17 and IES clinical trials suggest that AIs are effective in early breast cancer following tamoxifen. Based on data from these and other multiple, large randomized trials, it was recommended by the American Association of Clinical Oncology (ASCO) technology assessment panel that optimal ►adjuvant hormonal ►therapy for a postmenopausal woman with receptor-positive breast cancer include an aromatase inhibitor as initial therapy or after treatment with tamoxifen. Clinical data shows advantage of AI over

tamoxifen for as long as 10 years. AIs are well tolerated with less gynecological symptoms than tamoxifen. A low incidence of bone toxicity and muculoskeletal effects are associated with AI compared to tamoxifen.

Some of the newer studies also show AIs may have advantages over clomiphene citrate for ovarian stimulation (ovulation induction).

Aromatic Amine

Definition

Is an amine (-NH_2, -NH-) with an ►aromatic hydrocarbon substituent, whose structure usually contains one or more benzene rings (►benzene and leukemia). ►Aniline is an example. Acetylation of aromatic amines by ►Arylamine N-Acetyltransferases is an important ►bioactivation pathway of many drugs including those involved in ►carcinogen metabolism.

►Carcinogen Metabolism

Aromatic Hydrocarbon

Definition

A hydrocarbon that contains one or more benzene rings that are characteristic of the benzene series of organic compounds.

►Benzene and Leukemia
►Polycyclic Aromatic Hydorcarbons
►Arsenic

Arp2/3

Definition

A seven-subunit protein involved in the regulation of actin filament assembly; ►E-Cadherin.

►E-Cadherin

Arp2/3 Complex

Definition

Actin-related protein 2/3 complex is a protein complex consisting of seven subunits that is responsible for initiating actin polymerization in cells. It is localized within ►lamellipodia and provides the driving force for lamellipodia extension during cell ►motility.

►Cortactin

Array-based comparative genomic hybridization

Definition

Array-based comparative genomic ►hybridization (array CGH) is a technique to assay the genome for identifying chromosomal segments with copy number alterations. This technique utilizes printed microarrays (►Microarray (cDNA) technology) to perform a simultaneous analysis of selected genomic regions or even

the entire genome. These arrays can be based on printed genomic material (►BACs), cDNAs, or ►oligonucleotide fragments and are analyzed by the same apparatus and software used for cDNA microarray analysis.

Characteristics

DNA sequence copy number changes have been shown to play an important role in the pathogenesis of cancer. Array CGH is a further development of CGH, which was originally used to detect ►chromosomal imbalances. CGH allowed the detection of chromosomal copy number changes in cell and tissue samples but, unfortunately, conventional CGH has a low resolution. This problem has been overcome by the introduction of array-based CGH (array CGH). This technique is based on differential labeling of a test sample and reference DNA that are cohybridized on a slide with several thousand DNA clones representing specific regions of the human genome.

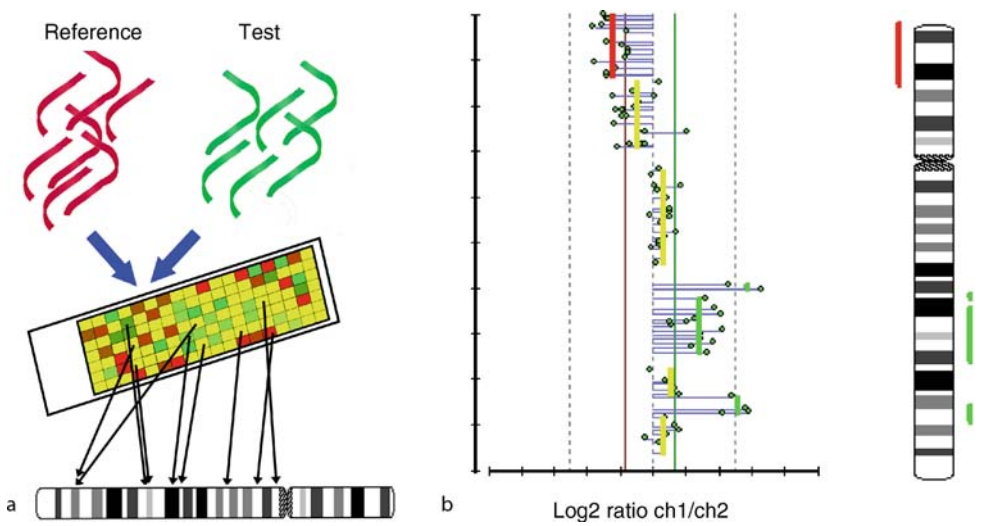
Since chromosomal copy numbers cannot be measured directly, two samples of genomic DNA (reference and test DNAs) are differentially labeled with fluorescent dyes and competitively hybridized to known mapped sequences spotted onto a slide (Fig. 1a). Because the fluorescence intensity is related to the copy number of single clones, the ratio of intensity between test and reference samples will be null in cases of equal amount of fluorescent signal or either negative or positive in cases of low copy number or high copy number of test DNA clones, respectively. The fluorescence intensity ratio for the labeled DNA populations is computed and a fluorescence profile is generated for each chromosome according to the physical position of their corresponding probe on the genome (Fig. 1b). By this method, array CGH can provide improved quantitative accuracy, resolution, and dynamic range compared to conventional CGH, and the measurements can be referenced directly to the positions on the genome sequence.

The difficulty in obtaining the correct result depends on many factors. The types of aberration, for example, strongly influences the array CGH analysis. It is much easier to detect large increases/decreases in copy number due to ►amplifications/►deletions of large genomic regions than single copy gains and losses of affecting small genomic DNA fragments. Heterogeneity of cells in the tumor sample, for example, the presence of normal cells within tissues, and different protocols used for tissue fixation can cause problems. Obviously, another important factor is the type of array CGH technology used providing different results in terms of reproducibility and resolution with different abilities to correctly identify genomic DNA gains or losses.

There are many different types of probes used to generate slides for array CGH analysis. The platforms initially developed used mainly BAC, ►YAC, or ►PAC clones. Recently, synthetic oligonucleotides have been introduced as an alternative substrate for array CGH, and today this approach seems to offer the highest resolution.

Clinical Applications

Chromosomal alterations represent an important feature of tumors that, up to now, have not been investigated exhaustively due to the low resolution of conventional array methods. Compared to microscopic chromosomal cytogenetic techniques, array CGH analyses provide



ArrayCGH. Figure 1 (a) Two DNA samples, isolated from "test" and "reference" cells, are labelled with two different dyes and competitively hybridized to genomic clanes which are spotted onto a slide. (b) The fluorescent signal intensity ratios, measured at each array spot, are normalized and a fluorescent profile is generated for each chromosome.

many advantages because they have the present in tumor cells. For this reason, the role of array-based CGH technology in cancer research is to detect new rearrangements or genomic alterations important for neoplastic transformation and to provide a more accurate diagnosis of cancer. In fact, a more accurate diagnosis of genomic alterations could be of patient's benefit because pathologists and clinicians can better classify and define each single tumor providing a more effective and specific approach to patient care. A wide spectrum analysis could provide important information for a more accurate prognosis as well as helping to predict the outcome to a specific cancer treatment.

Array CGH could also be useful for analyzing not only chromosomal rearrangement but also ►epigenetic alterations, which are another important feature of tumor cells. Hypermethylation of CpG islands in promoter regions is known to be associated with silencing of ►tumor suppressor genes, whilst conversely, ►hypomethylation events are associated with ►oncogene activation. For this reason, a technique that provides an analysis of the vast majority of ►methylation alterations present in tumor cells could be very useful to clarify the mechanism of tumor transformation. Using array CGH methods, it is possible to check the methylation status of genomic DNA combining CpG-island array and differential methylation hybridization techniques (DMH).

Finally, crucial information can be obtained by the ability of array CGH to detect focal homozygous deletions in regions of frequent heterozygous deletions or loss of heterozygosity because these alterations can provide important information to detect specific tumor suppressor genes. Unfortunately, alterations that do not change copy number cannot be detected by this technique. However, the development of array CGH analyses based on ►single nucleotide polymorphism (SNP) profiling could override this problem being an important tool for tumor characterization.

The main limitation for array CGH to be used in clinical environment is the high price of array CGH platforms that do not permit a rapid diffusion in laboratory and clinical practices. However, in the next few years it is possible to predict an increment of this technique and a parallel decrease of cost per sample with a larger diffusion in diagnostic applications and standardization of different protocols and applications.

Arrhenoblastoma

Definition

Arrhenoblastoma is a rare cancer of the ovaries. The cancer cells produce and release high level of a male sex hormone testosterone, which may cause the women to develop male physical characteristics, including facial hair and a deep voice. While the tumor can occur at any age, it develops most often in young adults.

Arsenic

Ann M. Bode, Zigang Dong
The Hormel Institute, University of Minnesota, Austin, MN, USA

Definition

►Arsenic is a "trace element" that is found naturally in the environment. A "trace element" refers to chemical elements present or required in minute quantities. Arsenic (As) is considered to be an important factor in human health. Humans are exposed to arsenic through the air, drinking water, and food. No documented evidence exists that would support a beneficial biological function or documented clinical deficiency in humans. Arsenic has been associated with cancer as far back as 1887, and current evidence suggests a positive correlation between arsenic exposure and increased risk for developing various cancers, especially ►skin cancer.

Characteristics

Arsenic is a metalloid that is found in various oxidation states, depending on the pH and the presence of oxidizing and reducing substances. Arsenite (As^{3+}) and arsenate (As^{5+}) forms are the main forms of arsenic found in drinking water.

Arsenic compounds are classified as inorganic or organic arsenic. Inorganic arsenic is usually combined with oxygen, chlorine, or sulfur, whereas organic arsenic is found in combination with carbon and hydrogen. The inorganic forms of arsenic are more toxic compared to the organic forms. The trivalent forms of arsenic are more toxic and react with thiol groups. On the other hand, the pentavalent forms are less toxic but uncouple cellular oxidative phosphorylation.

The odorless and tasteless properties of most arsenic compounds make them attractive poisons. Arsenic has been called the Poison of Kings and the King of Poisons because of its use by the ruling class to murder one another and its potency and discreetness. One of the most notorious poisoner in the nineteenth century was Goeie Mie ("Good Mary") of Leiden, The Netherlands, who poisoned 102 friends and relatives by giving them As_2O_3 in hot milk after opening life insurance policies in their names. Arsenic acts by disrupting ATP production ultimately leading to death due to multisystem organ failure. Physiologically, both As^{3+} and As^{5+} bind to sulfhydryl groups, but As^{3+} has about a tenfold greater affinity for binding than As^{5+}. Arsenic tends to accumulate in the skin, hair, oral mucosa, and esophagus probably because it can bind with sulfhydryl groups of keratin commonly found in these tissues. In addition, arsenic can be found at high levels in tissues such as hair, nails, skin and lungs, which are rich in cysteine groups.

History of Use

Arsenic compounds were mined by the early Chinese, Greek, and Egyptian civilizations and were used for medicinal purposes, including treatment of syphilis and arthritis. The compound arsenic was probably first identified and isolated by Albertus Magnus (Albert the Great, 1193–1280), a German alchemist, in 1250. Arsenic was mixed with vinegar and chalk and eaten or rubbed on their faces and arms by women during the Victorian era to improve their complexion. In 1878, Dr. Thomas Fowler created "Fowler's solution," a combination of arsenic and potassium bicarbonate. "Fowler's solution" was used to treat leukemia and Hodgkin's disease, but also eczema, psoriasis, and asthma. In 1910, Nobel laureate Paul Ehrlich developed salvarsan (organic arsenical) that was used to treat syphilis and trypanosomiasis (sleeping sickness). Arsenic was used to treat leukemia until the 1970s at which time its use in Western countries was almost totally discontinued due to the advent of more effective chemotherapy and radiotherapy in addition to its perceived toxicity and potential carcinogenicity. However, the clinical use of arsenic has experienced a major resurgence. Arsenic trioxide is now considered to be an effective treatment for relapsed and/or refractory ►acute promyelocytic leukemia (APL) and has been approved by the FDA for general treatment of APL.

Paradox of Arsenic

As^{3+} and its monomethylated and dimethylated derivatives are associated with risk for cancers of the skin, ►lung, ►bladder, kidney, and/or ►liver. Thus arsenic is a well-established human ►carcinogen, but paradoxically, arsenic trioxide is also an extremely valuable therapeutic tool for treating hematological malignancies, including various leukemias and ►multiple myeloma. In particular, arsenic has been very useful in treating relapsed or all-trans-►retinoic acid (ATRA)-resistant APL patients. Arsenic has also been reported as effective against ►neuroblastoma, ►esophageal carcinoma, ►gastric cancer, ►hepatocellular carcinoma, head and neck cancer, ►cervical cancer, ►prostate cancer, ►transitional cell cancer, ►glioblastoma, ►renal cell carcinoma, and ►breast cancer.

This creates a paradox for which no unified agreement has yet been reached regarding the molecular mechanisms that determine whether arsenic will act as a carcinogen or as an effectual chemotherapeutic agent. The suggestion has been made that high doses of arsenic result in toxicity, whereas lower doses induce cellular differentiation. Another key element contributing to the puzzle has been the nonresponsiveness of animal models to tumorigenesis induced by oral administration of arsenic alone. This suggests that arsenic may act to enhance mutagenicity induced by other carcinogens or it may function as a cocarcinogen, acting by inhibiting repair of carcinogen induced DNA damage. Furthermore, a diverse sensitivity to arsenic exists among individuals and this variation may be related to differences in metabolism. The metabolism of arsenic in humans occurs through alternating steps of reduction and methylation. Cellular glutathione (GSH) can reduce arsenate (As^{5+}) nonenzymatically, but evidence also indicates that arsenate reductase may catalyze the GSH reduction of As^{5+} to As^{3+}. As^{3+} is then methylated to form monomethylarsonic acid (MMA), which is further methylated to dimethylarsenic acid (DMA). The relative contributions of these metabolites to the toxicity and ►carcinogenesis of arsenic have not yet been fully elucidated.

Mechanisms of Action – Cancer Causing Effects of Arsenic

The precise mechanisms of arsenic's cancer-causing effects have been elusive most likely because arsenic's

effects are enigmatic. Arsenic has not been shown conclusively to be an initiating or a promoting agent of carcinogenesis in animals, thus making its classification as a carcinogen difficult, and in contrast to classic tumor promoting agents, its effects are not reversible. In addition, the majority of scientific evidence does not suggest that arsenic is a mutagen in vivo, although it has been shown to interact with DNA to cause damage. Arsenic's ability to contribute to carcinogenesis has been suggested to be associated primarily with genotoxicity (chromosome abnormalities), ►oxidative stress, and alteration of cellular ►signal transduction pathways.

Genotoxicity

Exposure to arsenic compounds can result in the induction of chromosomal abnormalities, including micronuclei formation, deletions, sister chromatid exchanges, and aneuploidy in both humans and animals. Arsenic, and especially the methylated trivalent form, seems to have potent clastogenic activity (i.e., causes breaks in chromosomes). Some suggest that whether arsenic acts as a clastogen or an aneugen (i.e., agent that affects cell division and the mitotic spindle apparatus resulting in the loss or gain of whole chromosomes, thereby inducing an aneuploidy) is related to dose (i.e., high dose = clastogen). Arsenite appears to induce gene amplification at the *dhfr* locus in both human and animal cells. Arsenite can also increase telomerase activity to promote cellular proliferation.

Possible Involvement of Reactive Oxygen Species (ROS)

►Reactive oxygen species, such as superoxide anion, hydrogen peroxide, singlet oxygen, and hydroxyl radical, might be involved in both the initiation and promotional stages of carcinogenesis. Low levels of ROS can act as second messengers to mediate gene expression, whereas high levels are suggested to result in cell damage and death. ROS causes damage through lipid peroxidation, modification of DNA including base-pair mutations, rearrangements, deletions, insertions, and sequence amplifications. ROS have been reported to be involved in ►cell transformation signaling. ROS can damage DNA and proteins both directly and indirectly. Exposure to arsenic results in the induction of oxidative stress-associated enzymes such as heme oxygenase and NADPH oxidase in various human and animal cell lines. Induction of these enzymes appears to increase production of ROS, which can cause DNA damage. Elevated levels of characteristic DNA adducts (i.e., 8-hydroxy-2′-deoxyguanosine) associated with oxidative injury have also been observed in various tissues that are common sites of arsenic-induced carcinogenesis. Because arsenic has a high affinity for the thiol groups of proteins, GSH levels and the activity of various antioxidants and ROS scavenging proteins all contribute to a protective effect against arsenic-induced production of ROS. Arsenite has been reported to suppress excision and ligation thereby inhibiting the DNA repair process. It might directly interfere with DNA ligase activity or indirectly interfere through ROS production.

Aberrations in Signal Transduction

The toxic effects of arsenic are very likely related to arsenic's ability to induce or impair various signal transduction pathways. In particular, arsenic may act as a carcinogen by activating pathways associated with proliferation to induce cell transformation or tumor development or it may act as a chemotherapeutic agent by inducing death (►apoptosis) of tumor cells. Arsenic is reported to increase tyrosine phosphorylation of receptor tyrosine kinases (i.e., ►epidermal growth factor receptor) and nonreceptor tyrosine kinases (i.e., Src), which is associated with abnormal cell signaling leading to uncontrolled cell growth and cancer. Arsenic has been reported to stimulate activator protein-1 (►AP-1) and to either activate or suppress nuclear factor kappa B (NFkappaB). AP-1 and NFkappaB are transcription factors that induce the transcription of genes known to have a major role in determining whether cell transformation or apoptosis will occur. Arsenic clearly induces either transformation or apoptosis in many cell types and the carcinogenic and anticarcinogenic actions of arsenic could very well share a common molecular mechanism that is related to length of arsenic exposure (e.g., chronic vs. acute), level of exposure (high dose vs. low dose), and/or species of arsenic exposure (e.g., arsenite, arsenate, MMA, DMA). Based on these assumptions, the possibility exists that the key to arsenic's actions is the extent to which it disrupts the normal control of apoptosis through its influence on signaling pathways, including the ►mitogen-activated protein kinases (MAPKs) that can lead to activation of AP-1 or NFkappaB.

Arsenic as a Therapeutic Agent

APL is a relatively rare malignancy characterized by a chromosomal translocation t(15;17), which fuses the retinoid acid receptor (RAR)α on chromosome 17 to the promyelocytic leukemia (PML) gene on chromosome 15. The PML–RARα fusion gene and the resulting protein product, PML–RARα, are thought to be responsible for APL pathogenesis. The addition of ATRA to chemotherapy has proven to be an effective treatment. Importantly, arsenic trioxide is now considered to be an important and effective treatment for relapsed and/or refractory APL patients. Similar to ATRA, arsenic trioxide appears to act by inducing differentiation and apoptosis in APL cells expressing the PML fusion protein

Arsenic Trioxide

Definition

As_2O_3 is a secondary material processed from the ore of arsenic bearing rocks. It is a highly toxic chemical substance, which is not only readily absorbed by the digestive system, but also absorbed through inhalation and skin contact. In Chinese medicine, arsenic trioxide is used externally as a caustic to remove dead tissue for the treatment of furuncle, carbuncle, ulcer, scrofula, and hemorrhoid. For internal use, it is used in minute quantities as an antiasthmatic agent. Although arsenic trioxide has been shown to be a human carcinogen, it is also a chemotherapeutic drug with the efficacy to induce ►apoptosis in ►cancer cells. Arsenic trioxide has been approved by the United States to treat ►acute promyelocytic leukemia that is unresponsive to the first line therapy or recurrent after treatment. It is also being studied in the treatment of other types of cancer, such as ►multiple myeloma.

Aryl Hydrocarbon Receptor

Robert Barouki
INSERM UMR-S 747, Université René Descartes Paris, Paris

Synonyms

Dioxin receptor; Xenobiotic receptor

Definition

The Aryl Hydrocarbon Receptor is a protein that recognizes a variety of usually plane hydrophobic ►xenobiotics, as well as a few endogenous compounds. Upon activation, the AhR triggers a signaling and transcriptional program leading to adaptive cellular processes and toxic effects.

Characteristics

Historical Perspective

Xenobiotic Stress

Exposure of cells and organisms to foreign compounds called ►xenobiotics leads to an adaptive response, which consists in the induction of a variety of xenobiotic metabolizing enzymes (XMEs), ultimately leading to the metabolization, ►detoxification , and elimination of these putative toxic compounds. In analogy with other cellular stresses, this adaptive response could be termed xenobiotic stress. It is best illustrated in the case of hydrophobic and plane compounds such as polyaromatic hydrocarbons (PAH, for example ►benzopyrenes) or halogenated polyaromatic hydrocarbons (►dioxins), which trigger a similar response and induce a subset of xenobiotic metabolizing enzymes as well as specific transporters. Xenobiotic metabolizing enzymes are classified as phase 1 enzymes such as ►cytochromes P450 (CYP), which add a reactive chemical function (hydroxyl, epoxyde) to the xenobiotic and phase 2 enzymes, usually transferases that conjugate an organic hydrophylic group (glucuronate, ►gluthathione, etc.) to the reactive function. This metabolic pathway renders these hydrophobic compounds less toxic, more hydrophilic, and therefore facilitates their elimination. This pathway can be involved in ►carcinogen metabolism. In addition to the metabolic aspects, a critical parameter of xenobiotic stress is the recognition of the xenobiotics and the induction of the genes encoding phase 1 and phase 2 XMEs and transporters. Genetic and biochemical studies using a variety of cell lines that are more or less sensitive to dioxin and PAHs allowed the identification of their receptor, the Aryl Hydrocarbon Receptor. Other similar studies allowed the determination of the other components of this signaling pathway which was initially viewed as a response to the exposure to the toxic PAH and dioxin-like compounds.

Physiological Effects

In addition to its function as a detector of toxic xenobiotics, there have been considerable speculations about possible physiological functions of the AhR that have been supported by a large body of observations. First, several nontoxic plant-derived molecules such as indolic compounds, ►flavonoids, and ►polyphenols were found to be potent ligands of the AhR. Furthermore, endogenous compounds such as tryptophan derivatives, bilirubin, and sterols were also described as ligands of the AhR. A critical argument in favor of a physiological role of this receptor came from the analysis of the phenotype of AhR−/− ►knockout mice. These AhR-deficient mice exhibited a number of defects, among which small liver

size, probably due to a congenital vascular defect, alterations in thymus and cardiovascular development, as well as decreased fertility. While these defects may be due to a deficiency in cellular modulators such as ►retinoic acid or various growth factors and ►cytokines, they point to a function of the AhR in cellular differentiation and development. Such functions are supported by observations made in nonvertebrate organisms. Drosophila, the AhR orthologs are involved in antenna and leg morphogenesis and, in *Caenorhabditis elegans*, the AhR ortholog appears to be required for the differentiation and migration of GABAergic neurons. In these species, there is no evidence for the involvement of AhR orthologs in xenobiotic detection. In conclusion, the control of cell fate, cell proliferation and migration is a likely endogenous function of the AhR and AhR orthologs.

A Link Between Environment and Cancer?

Most of the studies devoted to the AhR have focused on its function as a mediator of its ligands toxicity. The most studied ligand is the prototypical dioxin: 2,3,7,8-tetrachloro-dibenzoparadioxin, TCDD, Dioxin) since it is widely accepted that most, if not all effects of this pollutant, are related to the activation of the AhR. Dioxins are usually present in the environment as a mix of chlorinated congeners. Sevetyfive possible congeners have been identified and their toxicity is systematically expressed in relation to that of Dioxin by means of a "Toxic Equivalent" quantification factor (TEQ). Dioxin's toxic effects are numerous and include teratogenicity, immunosuppression, metabolic and endocrine disruption, skin toxicity such as chloracne and keratosis and cancer. Dioxin is considered by the ►IARC as a human carcinogen. This conclusion is mostly based on its mechanism of action and on animal studies and therefore relies primarily on the ability of dioxin to activate the AhR. Dioxin displays a carcinogenic effect on a wide variety of tissues and organs. In rodents, most studies have focused on liver carcinogenesis in which dioxin behaves as a cancer promoter. In humans, according to epidemiological studies, it is believed that dioxin is a relatively weak nonspecific carcinogen that could mildly increase the risk to develop a variety of tumors such as non-Hodgkin lymphomas, sarcomas, and breast cancer. The difference between the sensitivity of the various species to the carcinogenic effect of Dioxin (high in some rodent species, mild in human) correlates well with the affinity of the AhR for Dioxin in these species. Furthermore, AhR−/− knockout mice are resistant to the carcinogenic effects of Dioxin. In addition, overexpression of a constitutively active AhR in mice leads to the development of stomach and liver cancers. All these observations establish a firm link between the carcinogenicity of dioxin and the activation of the AhR. Other carcinogens also exert their effects at least partially through the AhR. Benzo(a)pyrene, a PAH present in tobacco smoke and Diesel particles also binds and activates the AhR. Although the mechanisms of its carcinogenicity are distinct from those of dioxin, it has been shown that AhR−/− mice are resistant to benzo(a) pyrene toxicity.

Authors have also searched for evidence of the implication of the AhR in cancer independently of its ligand. One such evidence came from mice overexpresssing a constitutively active AhR, which develop stomach and liver cancers, suggesting that AhR activity is sufficient for such a toxic effect. Conversely, ►immortalized mouse embryo fibroblasts carrying deleted AhR genes exhibited less tumorigenicity than wild type fibroblasts in xenograft mouse models. The other evidence was provided by the examination of *AhR* gene polymorphisms in various human cancers leading, in particular, to the finding that one polymorphism adversely affects survival in patients suffering from soft tissue sarcoma.

The Signaling Pathway

The AhR is localized in the cytoplasm of most cells and is associated with a number of ►chaperone proteins such as ►Hsp90, p23, and XAP, in a conformation exhibiting a high affinity for Dioxin. Upon ligand binding, this complex is sequentially dissociated and the AhR is translocated into the nucleus where it forms a heterodimer with a transcription factor called AhR Nuclear Translocator (ARNT). AhR and ARNT have similar structures including a DNA binding and heterodimerization b►HLH domain and a PAS domain that also contributes to heterodimerization and, only in the case of the AhR, harbors the ligand-binding pocket. The heterodimer then binds to specific DNA responsive sequences, interacts with coactivators and other transcription factors, alters the chromatin structure, and regulates transcription of the target genes. The classical target sequence is called XRE (Xenobiotic Responsive Element); however, alternative sequences called XRE II have been identified. In addition to this classical gene regulation pathway, a number of other AhR signaling pathways have been described including the interaction between this receptor and the transcription factor ►NFkB, the hypophosphorylated ►retinoblastoma protein and the corepressor SMRT and the ►estrogen receptor are the ►progesterone receptor. Furthermore, the AhR has been shown to activate, with rapid or long-term kinetics, several protein kinases such as ►Src, p38 ►MAPK, and Jun kinase. These pathways may be relevant for the carcinogenic effects of several AhR ligands.

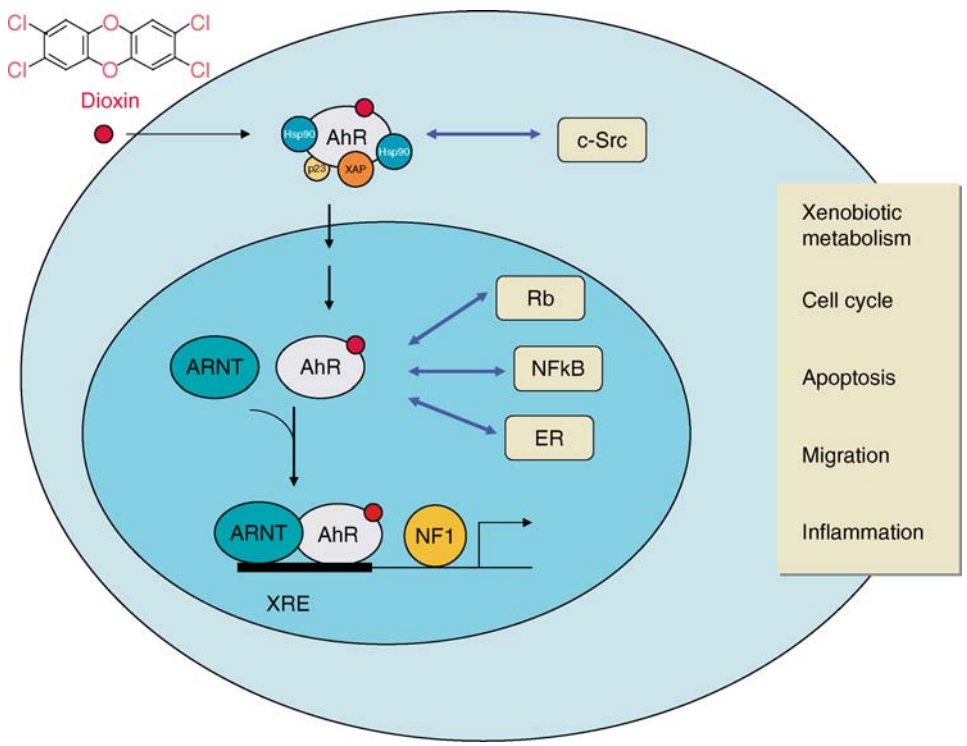
Gene Expression and Biological Pathways

Initial studies on the AhR have focused on its adaptive and putative toxic functions related to the induction of xenobiotic metabolism. The so-called AhR gene battery includes mostly XMEs such CYP1 proteins, glutathione – S transferase (GST) and UDP-glucuronosyl transferase

(UGT). Further biological and large scale genomic studies have shown that the AhR also regulates a number of genes unrelated to xenobiotic stress. Targets of the AhR include proteins involved in cell cycle control such as p27, p21, cJun, SOS1, in cell signaling such as HES1 and IGFBP-1, in cell–cell interaction and migration such as HEF1, ►E-cadherin, and ►MMPs. Some of these regulations have not yet been firmly linked to a biological or toxic effect. These observations suggest that AhR ligands may exert part of their biological or toxic effects independently of the xenobiotic metabolism pathway. Ligands of the AhR (or the AhR alone) could alter cell cycle control, cell fate determination and ►migration. Furthermore, a number of cytokines have been shown to be the target of the activated AhR, which establishes a link between this receptor and inflammation. In the mouse ovary, the AhR is involved in the regulation of aromatase gene expression, which adds another crosstalk between the AhR and hormonal effects. It should be noted that many of these regulations by the AhR could be tissue specific. Repression of some genes has also been reported but was less well characterized. For example, the antagonism between the AhR and estrogen signaling in breast tissue could account for the repression of the pS2 gene.

Mechanisms of Carcinogenicity of AhR Ligands

Different mechanisms could account for the carcinogenicity of the AhR ligands. In the case of PAH such as benzo(a)pyrene, it has been clearly shown that the metabolism of these compounds by the CYP enzymes generates highly reactive metabolites that display ►DNA damage and strong mutagenicity. Phase 2 enzymes detoxify these intermediate metabolites. The balance between phase 1 and phase 2 enzyme activities is maintained through the coordinate regulation of the expression of their genes by the AhR pathway and the ►Nrf2-►oxidative stress signaling pathway. Evidence from both human and animal studies suggests that the xenobiotic metabolizing pathways are protective as long as the fine-tuning between the different enzymes is maintained. ►Genotoxicity could result from an unbalance between the enzymes of the successive phases. The mechanisms of



Aryl Hydrocarbon Receptor. Figure 1 Signaling pathways and functions of the AhR. The AhR is localized in the cytoplasm and interacts with several chaperones such as Hsp90, p23 and XAP. Upon binding to dioxin, the complex dissociates sequentially, the AhR enters the nucleus, interacts with ARNT and the heterodimer binds to target sequences called XREs. The active receptor interacts with transcription factors such as NF1 and activates the transcription of target genes. In addition to this classical pathway, signaling through the AhR could also be mediated through interaction with other regulatory proteins such as c-Src, Rb, NFkB and the ER. Some of the main cellular functions controlled by the AhR are listed to the right. These pathways and functions could contribute to the role of the AhR during the various steps of carcinogenesis.

carcinogenicity of dioxin are distinct from those of PAHs. Indeed, dioxin is not metabolized by the XMEs, which partially accounts for its long half-life (seven years in human). Furthermore, dioxin is not genotoxic. However, the induction of CYP enzymes leads to oxidative stress and therefore to a possible indirect toxicity. Dioxin is considered as a potent cancer promoter, at least in rodents. Such an effect could be mediated by the modification of the gene expression program following AhR activation. The genes that are possibly responsible are those involved in proliferation. However, dioxin also induces several genes implicated in ►apoptosis. To explain this paradoxical effect, it has been suggested that dioxin could promote the proliferation of clones which exhibit resistance to apoptosis and cell cycle arrest. Several other mechanisms could account for the cancer promotion activity of dioxin: increase in ►oxidative stress and ►inflammation, activation of tyrosine kinases such as ►Src, complex interaction with the estrogen signaling pathway. Furthermore, cancer progression could also be stimulated by AhR ligands, since it was shown that the activation of this receptor leads to an increase in cell mobility and plasticity which could be mediated by a number of target gene products.

AhR as a Pharmacological Target

Because of its implication in several pathological processes, AhR was considered as a relevant pharmacological target. Several antagonists, including including plant ►polyphenols or endogenous compounds such as 7-keto-cholesterol, were identified. Other compounds named SahRMs (Selective AhR Modulators) were found to modulate the activity of the AhR in that they prevented the induction of XMEs but did not affect the antagonism between the AhR and the estrogen receptor, a property that is relevant for breast cancer therapy. Several dietary plant constituents have been shown to be activators of both the AhR and the ►Nrf-2 signaling pathways offering potential applications in ►chemoprevention. More generally, pharmacological studies of the AhR have shown that this receptor displays a considerable diversity in its response to different types of ligands, each type selectively activating an overlapping set of pathways and genes. Thus, the signals initiated by pollutants such as dioxin and PAHs and by polyphenols or other dietary plant compounds appears to be distinct. This diversity of the response that has yet to be characterized at a structural and molecular level constitutes the grounds for further pharmacological investigation of this receptor.

Arylamine

Definition

Aromatic amine.

Arylamine *N*-Acetyltransferases

Neville J. Butcher, Rodney F. Minchin
School of Biomedical Sciences, University of Queensland, St Lucia, QLD, Australia

Synonyms

NAT

Definition

The arylamine *N*-acetyltransferases (NATs; EC 2.3.1.5) are ►phase II enzymes that catalyze the transfer of an acetyl group from acetyl coenzyme A to ►aromatic amine, ►heterocyclic amine or hydrazine substrates. Acetylation catalyzed by NATs is an important biotransformation pathway for many drugs and cancer causing agents that we are exposed to on a daily basis.

Characteristics

There are three human NAT genes. Two encode functional proteins and are designated *NAT1* and *NAT2*, and the third is a pseudogene (*NATP1*) that encodes a truncated nonfunctional protein. All are located on the short arm of chromosome 8 and have been mapped to 8p21.3–23.1, a region commonly deleted in human cancers. Both functional NATs are encoded by single intronless exons and the protein-coding regions share an 87% nucleotide homology and are 870 base pairs in length. NAT1 and NAT2 are cytosolic proteins having an approximate molecular mass of 33 kDa and each consists of 290 amino acids, sharing an 81% homology. NAT1 is ubiquitously expressed and has been identified in both fetal and adult tissues, while NAT2 expression is only evident approximately 12 months after birth and is restricted to the liver and gut. The active site of NAT enzymes contains the catalytic triad cysteine-histidine-aspartate, which is similar to that of the cysteine protease superfamily of proteins.

The importance of exposure to aromatic and heterocyclic amines present in cigarette smoke, car exhaust fumes, and foodstuffs in the etiology of certain toxicities including cancer is well established. Like most chemical carcinogens, arylamines require ►bioactivation in order to exert their oncogenic effects. ►Carcinogen metabolism is a complex process and involves competing reactions that can lead to either ►detoxification or bioactivation. The NATs are versatile enzymes that are able to catalyze both *N*-acetylation and *O*-acetylation reactions. Generally, *N*-acetylation is a detoxification step that produces non-toxic stable *N*-acetates that can be eliminated from the body. An exception is *N*-acetylation of the bladder carcinogen ►benzidine, which is part of the bioactivation process. Bioactivation of arylamines involves an initial *N*-oxidation reaction catalyzed predominantly by ►cytochrome P450 1A2, but also by prostaglandin H synthase and myeloperoxidase. The resultant *N*-hydroxy arylamines and/or their nitroso intermediates are able to react with cellular macromolecules, but subsequent *O*-acetylation by NATs yields highly reactive *N*-acetoxy esters (electrophiles) which can form covalent adducts with nucleophiles such as DNA and protein. ►Adducts to DNA are an essential step in the initiation of ►chemical carcinogenesis.

NATs acetylate a number of important carcinogens. Some compounds, such as the carcinogenic aromatic amines 2-aminofluorene, benzidine, 4-aminobiphenyl, 4,4-dichloroaniline and 2-naphthylamine, and the ►food-derived heterocyclic amines 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP) and 2-amino-3,4-dimethyl-imidazo[4,5-*f*]quinoxaline (MeIQx) are *N*-acetylated to varying degrees by both NATs. Generally, *O*-acetylation of the *N*-hydroxy metabolites of carbocyclic arylamines is catalyzed selectively by NAT1, whereas NAT2 *O*-acetylates *N*-hydroxy metabolites of the dietary heterocyclic amine carcinogens.

Acetylation Polymorphism

The acetylation ►polymorphism was one of the first described examples of a ►pharmacogenetic defect affecting ►xenobiotic biotransformation capacity in human populations, and was discovered following the introduction of isoniazid therapy for the treatment of tuberculosis during the 1950s. Since the human *NAT2* locus was established as the site of the acetylation polymorphism, the study of *NAT2* allelic variation has been an area of intense investigation. To date, 36 different *NAT2* alleles have been detected in human populations. Each of the variant alleles is comprised of between 1 and 4 ►SNPs, of which 16 have been identified, located in the protein-coding region of the gene. The correlation between NAT2 ►genotype and ►phenotype is well established. Moreover, there is a gene-dosage effect. Individuals who are homozygous for slow *NAT2* alleles have a slow acetylator phenotype, individuals heterozygous for slow *NAT2* alleles have an intermediate acetylator phenotype, and individuals who lack slow *NAT2* alleles have a rapid acetylator phenotype. Historically, NAT1 was thought to be genetically invariant and referred to as "monomorphic." However, wide inter-individual variability in NAT1 activities was suggestive of a genetic polymorphism. The first reported allelic variation at the *NAT1* locus was in 1993, and marked the beginning of a systematic survey of *NAT1* genotypes. To date, 26 different *NAT1* alleles have been detected in human populations, but only a small number of these alter phenotype. The frequency of slow acetylator alleles for NAT1 is low. The most common NAT1 variant in caucasians is *NAT1*10*, which reportedly results in a rapid acetylator phenotype. Both NAT1 and NAT2 show considerable interethnic variability. In Caucasian and African populations, the frequency of the NAT2 slow acetylation phenotype varies between 40 and 70%, while that of Asian populations, such as Japanese, Chinese, Korean, and Thai, range from 10 to 30%.

Clinical Relevance

Because of the role of acetylation in the metabolic activation and detoxification of arylamine and heterocyclic amine carcinogens, acetylator polymorphisms can modify cancer risk associated with chemical exposures. Unlike the relatively rare but highly penetrant genes involved in familial cancers, those genes responsible for biotransformation polymorphisms have low penetrance and cause only a moderate increase in cancer risk. Nevertheless, their widespread occurrence in the general population suggests they are a significant contributor to individual risk. Many ►cancer epidemiology studies have reported associations between

acetylator status and risk of bladder, colon, breast, head and neck, lung, and ►prostate cancer. However, inconsistent reports have meant that the relationship between phenotype and risk remains unclear. For example, several studies have implicated the rapid phenotype as an increased risk factor for ►colon cancer, whereas others have been unable to confirm this finding. Geographical differences, ethnicity, lack of study power, dietary differences and differences in other risk factors between study groups have been suggested as reasons for variable results from independent studies. Recent reports suggesting that NAT activity may be altered by environmental factors and substrate-dependent down-regulation also may explain why inconsistent associations have been seen. When acetylator phenotype has been linked to carcinogen exposure, more consistent results have been reported. For example, the rapid phenotype has emerged as a strong risk factor for colon cancer in those individuals who have a higher exposure to the food-derived heterocyclic amines. Similarly, the association between slow acetylator status and urinary ►bladder cancer is more consistently observed when exposure is taken into consideration. Individual risks associated with NAT phenotypes are small, but increase when other susceptibility genes and carcinogen exposures are included in the analysis.

Asbestos

Eugene D. Weinberg
Biology and Medical Sciences, Indiana University, Bloomington, IN, USA

Definition

Asbestos is a commercial term for a group of crystalline silicates that are composed of long thin fibers. Formerly, the noncombustible mineral was incorporated into a great variety of industrial and building materials. However, asbestos can be easily broken into tiny microscopic fibers and inhaled. In the lungs, the indestructible fibers may, over time, increase in size due to acquisition of ►ferritin/hemosiderin from proximal dying macrophages. After many years, the inhaled fibers can be carcinogenic. Thus commercial use of asbestos has been banned.

Characteristics

Carcinogenic Action of Iron

During the past seventy years, authors of scores of clinical and laboratory studies have reported that one of the many dangers of excessive/misplaced iron is its ability to initiate and to promote neoplastic cell growth. Initiation occurs via iron-catalyzed formation of reactive oxygen radicals (►Reactive oxygen species; ►Oxydative stress) that, when generated in close proximity to DNA, can cause point mutations, cross linking, and DNA strand breaks (►DNA damage). Promotion of neoplastic cell growth by iron occurs via its ability to suppress the tumorcidal action of macrophages and to serve as an essential nutrient for unrestricted cancer cell growth.

Excessive iron enters the body by inhalation, ingestion, or, less often, by injection. Misplaced iron most commonly occurs in conditions of erythrocyte or hepatocyte destruction. A frequently reported example of the association of iron loading with tissue site-specific neoplasia is the development of respiratory tract cancers in humans and animals who have inhaled iron compounds. Items that routinely serve as vehicles for inhaled iron include tobacco smoke (►Tobacco carcinogenesis; Smoking addiction), iron-contaminated coal dust and sand, urban and subway air particulates, iron dross released in mining and industrial processing of ferriferous materials, and, not least, iron-containing asbestos fibers.

Asbestos: A Vehicle for Iron

Asbestos is a commercial term employed for a group of crystalline silicate fibers. The group is divided into amphibole and serpentine configurations. Examples of the former include ►crocidolite, amosite, and ►tremolite; of the latter, ►chrysotile. Crocidolite, amosite, and green tremolite contain high levels of iron and are much more carcinogenic than chrysotile which contains very little iron. Inhalation of carcinogenic forms of asbestos can result, after many years, in carcinoma of lungs (►Lung cancer), esophagus (►Esophageal cancer), and stomach (►Gastric cancer) as well as ►mesothelioma of pleura, peritoneum, and pericardium. In cell cultures and in animal models, strong iron chelators (►Chelators as anticancer drugs) as well as oxygen radical scavengers decrease the toxicity of asbestos.

Following phagocytosis of inhaled iron-containing asbestos by alveolar ►macrophages, iron is leaked (mobilized) over time into low molecular mass pools. Cytotoxicity of asbestos samples is directly proportional

to the amount of mobilized iron. Asbestos fibers not only can release iron but also can acquire the metal as a deposit on their surfaces. The deposit consists of ferritin/hemosiderin derived from proximal decaying macrophages.

Iron coated fibers are termed ►ferruginous bodies. In one study, for example, crocidolite, amosite, or chrysotile injected into rat pleura bound, respectively, 240, 135, or 25 nmol Fe/mg. Accumulation of ferruginous bodies on macrophage cell membranes may kill the defense cells. Moreover, the metal can become catalytically active to result in further oxidant damage.

►Erionite, a ►zeolite silicate of aluminum, calcium, and magnesium, contains no iron but is far more able to cause human mesothelioma than can either crocidolite or amosite. Erionite has an internal cage-like surface area up to fifty-fold greater than crocidolite. Thus when inhaled it acquires a very large quantity of iron. Unlike native erionite, the iron laden fibers catalyze single strand DNA breaks. Destruction of DNA by iron-erionite is prevented by iron chelators.

The iron-dependent mutagenicity of asbestos has been verified by treatment of Chinese hamster cells with crocidolite. A doubling of mutation rate occurred. The increase could be prevented by use of iron-free medium with crocidolite samples from which redox active iron had been removed by the iron chelator, ►deferoxamine (Chelators as anticancer drugs).

Asbestos: Usage and Banishment

For many decades, asbestos was incorporated in such products as brake pads and linings, cement pipes and shingles, cigarette filters, fireproof gloves, flooring and roofing materials, gas masks, hot pipe coverings, and sound proofing material. Although the principal type of asbestos employed was chrysotile, particular samples were contaminated with varying amounts of iron. The elevated risk of carcinomas and mesotheliomas occurred not only in miners and fabricators of iron-contaminated asbestos but also in members of their families as well as in persons who lived downwind from the mines and factories.

Villagers and rural inhabitants who live near asbestos outcroppings likewise are at serious risk of respiratory tract cancers and mesotheliomas. Additional persons at risk include installers of products that contain iron-contaminated asbestos as well as users of those products in which asbestos leaking has developed.

Presently, if building materials are leaking asbestos, the product should be removed by trained biohazard specialists. The latter wear protective masks and clothing. If clothing items are to be reused, they must be laundered carefully in a commercial cleaning establishment rather than in the homes of the biohazard workers.

It has been estimated that, in the U.S., at least eleven million persons have had occupational exposure to asbestos between 1940 and 1979, of whom 2000 die each year of mesothelioma. Since 1979, in the U.S., the commercial use of asbestos in most applications has been banned.

Ataxia Telangiectasia

Definition

AT is an autosomal recessive human disorder. The gene maps to 11q22. AT is a multisystem disease characterized by progressive cerebellar ataxia, oculocutaneous telangiectasia, radiosensitivity, predisposition to lymphoid malignancies and immunodeficiency with defects in both cellular and humoral immunity. Ataxia is the presenting symptom and is usually recognized at the age of 12–14 months, the patient is confined to a wheelchair before adolescence. Telangiectasia has a later onset, usually is observed between 2 and 8 years of age; telangiectasias can affect the eyes, the ears and the butterfly area of the face. The major debilitating features are the progressive neurological abnormalities and immunodeficiency. Chromosome instability with apparently random breaks is a characteristic cytogenetic feature, and it is a common notion that the genomic instability in AT is a major cause of cancer in AT patients, in keeping with the well-established link between cancer and genomic rearrangements.

ATM Gene.

ATM Protein

Yosef Shiloh
Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel

Synonyms

Ataxia-telangiectasia mutated (ATM)

Definition

ATM is a large protein kinase that is the primary activator of the cellular responses to double strand breaks (DSBs) in the DNA – a complex network of signaling pathways. ATM is activated in response to DSB induction and in turn phosphorylates a multitude of substrates, each of which is a key player in a DNA damage response pathway. ATM is missing or inactive in patients with the multisystem genetic disorder ataxia telangiectasia (A-T), characterized by neurodegeneration, immune deficiency, genomic instability, sensitivity to ionizing radiation, and cancer predisposition. The cellular phenotype of cells from A-T patients includes premature senescence, chromosomal breakage, extreme sensitivity to ionizing radiation and radiomimetic chemicals, and defective activation of the extensive array of DSB responses, most notably the activation of the cell-cycle checkpoints, which temporarily halt the cell cycle at specific stages while the DNA damage is assessed. The complex and broad manifestations of ATM deficiency demonstrate the importance of the DNA damage response in maintaining cellular homeostasis.

Characteristics

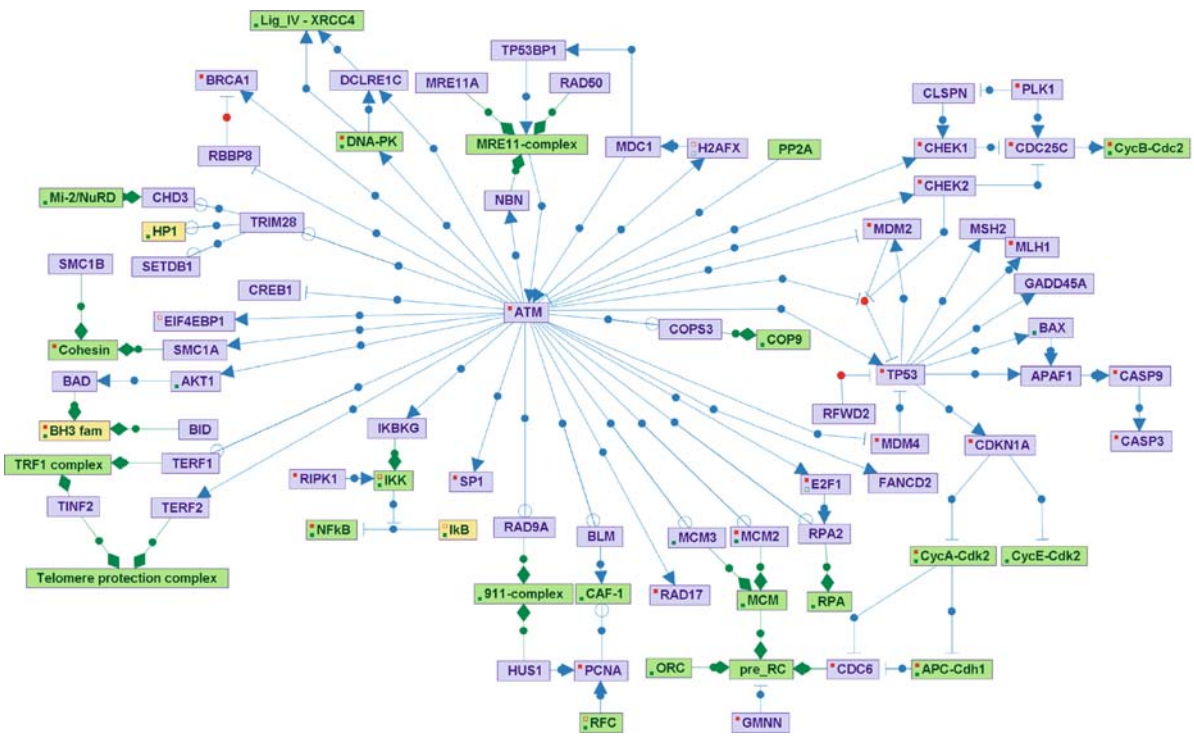
ATM is a large, heavily phosphorylated protein of 370 kDa containing 3,056 amino acids. Its most prominent motif is a carboxy-terminal region of about 350 amino acids that is similar to the catalytic subunit of phosphatidylinositol 3-kinases (PI3-kinases). The large size and PI 3-kinase-related region are common to a family of proteins identified in organisms ranging from yeast to mammals, which are involved in maintaining genomic stability, cell cycle control and responses to genotoxic stress. Most members of this protein family were found to have a serine/threonine protein kinase

activity, i.e., they phosphorylate other proteins on specific serine or threonine residues. A notable member of this group is the catalytic subunit of the DNA-dependent protein kinase (DNA-PKcs), which is activated by DNA ends. The mammalian PI3-kinase-like protein kinase most closely related to ATM is the ATR protein, which responds primarily to UV damage and stalled replication forks, but in response to DSBs phosphorylates many of ATM substrates, albeit at later time points and slower pace compared to ATM.

Cellular Functions and Molecular Regulation

ATM is primarily a nuclear protein, with a possible minute cytoplasmic fraction. In unprovoked cells, ATM exists as dormant homodimers. Following DSB induction, ATM is rapidly activated in a process that involves its autophosphorylation, followed by release of highly active ATM monomers. ATM activation may be mediated by chromatin reorganization following DNA damage, and requires the activity of several DSB sensors such as the trimolecular complex MRN (Mre11-Rad50-Nbs1). The number of ATM downstream effectors is currently estimated at several hundred. Some of them are shown in Fig. 1. Among them are the tumor suppressor proteins p53 and BRCA1.

Mouse strains lacking the Atm protein were generated by targeted inactivation of their *Atm* gene, the murine *ATM* homolog. These animals recapitulate the human disease, with radiosensitivity and a striking propensity to thymic lymphomas, but they do not show the profound cerebellar degeneration typical of human patients. ATM-deficient mice, like A-T patients, are sterile as a result of extensive chromosomal fragmentation during meiotic recombination. Indeed, in normal mice, the ATM protein is associated with the synapsed chromosomal axes during normal meiosis, pointing to its involvement in meiotic recombination. This indicates that ATM is involved not only in damage responses, but also in responding to DNA breaks that take place during normal physiological processes. Another such process is the maturation of the immune system genes by somatic recombination. The marked immunodeficiency of A-T patients, as well as the appearance of chromosomal translocations involving these genes in



ATM Protein. Figure 1 A partial map of the ATM-mediated network. The map was drawn using a computational software. It contain nodes representing three biological entities: gene/proteins (violet nodes); protein complexes (green nodes, e.g., the MRN complex); and gene families (yellow nodes, e.g., the IκB family of NF-κB inhibitors). The map contains two types of edges: ►Blue edges represent regulations and interactions between genes/proteins. Arrowheads (→) correspond to activation, T-shaped edges (—|) represent inhibition, and open circle edges (—○) denote regulations with yet unknown effect. Blue lines with no head represent physical interactions between proteins. ►Green edges represent containment relations between nodes (e.g., the relationships between a complex and its components). Red and green dots within a node indicate that not all the regulation and containment relations stored in the database of ATM functions for that node are shown on the map.

patient lymphocytes, points to the possible involvement of ATM in this process as well.

Many of the numerous stress responses controlled by ATM end up in activation or down-regulation of gene expression. A global look at gene expression profiles in the cell can be obtained using ►microarray (cDNA) technology, a tool that measures the extent of expression of thousands of genes at the same time. This technique disclosed that ATM is involved in the majority of alterations in gene expression that follow treatments with ionizing radiation or radiomimetic chemicals. This finding further underscores the central role of ATM as a master controller of the DNA damage response.

Clinical Relevance

The clinical manifestation of ATM inactivation is A-T, a genetic disease characterized by a perplexing array of clinical symptoms and cellular defects. The phenotype attests to the centrality of ATM-controlled cellular pathways to the development and proper function of many tissues. The striking predisposition of A-T patients to lymphoid cancers (►lymphoma) clearly shows that ATM controls an important intersection of functions necessary to prevent the development of malignancy in these cells. It is a common notion that the genomic instability in A-T is a major cause of cancer in A-T patients, in keeping with the well-established link between cancer and genomic rearrangements.

It has long been suspected that carriers of A-T mutations bear a certain degree of predisposition to malignancies, primarily breast cancer. This notion stemmed primarily from epidemiological observations and is continuously being re-examined using molecular assays for the detection of carriers of ATM mutations. Evidence is accumulating that some degree of cancer predisposition may be conferred by heterozygosity for specific types of ATM mutations. Since cells from A-T carriers exhibit a moderate degree of radiation sensitivity, heterozygosity for ATM mutations might also lead to adverse side-effects of radiotherapy, such as severe local responses to treatment or radiation-induced secondary cancers.

A further link between ATM sequence alterations and cancer comes from another line of research: In certain hematopoietic malignancies, most notably T-prolymphocytic leukemia, both copies of the ATM gene are inactivated due to somatic mutations and rearrangements. This phenomenon is typical of tumor suppressor genes and points to the role of ATM-dependent processes in guarding mammalian cells from malignant transformation.

Genomic instability is at the heart of cancer development, and inherited genomic instability is directly associated with predisposition to various forms of cancer. On the other hand, because many radiotherapy and chemotherapy agents for cancer induce DNA damage, understanding the DNA damage response also impacts on the refinement of those therapies and may eventually lead to novel treatment modalities for cancer.

Atypical Mole Syndrome

Definition

Synonym dysplastic nevus syndrome; is a disorder of the skin characterized by the presence of many mole-like tumors (nevi). Most people have 10–20 moles over their bodies. People with atypical mole syndrome often have more than 100 moles, at least some of which are unusual (atypical) in size and structure. These moles vary in size, location, and coloring. They are usually larger than normal moles (5 mm or more in diameter) and have irregular borders. Changes in the appearance of these moles must be taken seriously by patients since such changes may foreshadow the onset of cancerous disease. Individuals with atypical mole syndrome are at greater than others for developing cancer of the skin in the form of malignant ►melanoma. Atypical mole syndrome is thought by some clinicians to be a precursor or forerunner of malignant melanoma. This type of cancer may spread to adjacent parts of the skin or, through the blood and lymph circulation, to other organs.

Atypical Neurocytoma

►Neurocytoma

Atypical Nevi (dysplastic nevi)

Definition

Atypical nevi may be distinguished by their asymmetry, border (indistinct irregular margins), color (presence of unevenness of pigmentation, red-brown color), and diameter ≥5 mm. The presence of multiple nevi of atypical appearance is called the Dysplastic Nevus Syndrome (DNS), the ►Atypical Mole Syndrome (AMS) or, if present with familial clustering of both nevi and melanoma, the Familial Atypical Multiple Mole-Melanoma (FAMMM) Syndrome. Atypical nevi may be found on non-sun-exposed areas, the genitalia, and the iris. Whether familial or not, the presence of multiple atypical nevi constitutes and increased risk for melanoma.

Definition
Aurora kinases are mitotic serine/threonine kinases, which regulate mitotic events.

A

Characteristics

Aurora is a subfamily of serine/threonine protein kinase and is conserved from yeast, *Drosophila*, to humans. In mammals, this subfamily of serine/threonine kinases comprises three members: Aurora-A, -B, and -C. *Drosophila* and *C. elegans* also express Aurora-A and -B kinases, whereas *S. cerevisiae* and *S. pombe* have only one Aurora kinase gene, *Ipl1* (Fig. 1a), suggesting that the functions of Auroras have diverged throughout evolution. All Aurora kinases share similar structures, with their catalytic domains flanked by very short C-terminal tails (15–20 residues) and variable lengths of N-terminal domains (39–129 residues). The overall homology between these three members in human is about 60% at amino acid level. The C-terminal domain of human Aurora-B shares 53 and 73% sequence similarity to human Auroras A and C, respectively. The N-terminal domain of Aurora kinases are less conserved, which may determine selectivity of protein–protein interactions (Fig. 1b).

Despite these similarities, the three mammalian Aurora family members differ in their expression patterns, subcellular localization, and timing of activity. Aurora-A is upregulated at the onset of mitosis. It localizes to centrosomes during interphase and to both spindle poles and spindle microtubules during early mitosis. However, it is noted that immunostaining studies show that Aurora-A distributes not only to centrosome but also to cytoplasm and/or nucleus. Aurora-B, whose activity appears to reach maximal levels later in mitosis, displays the dynamic properties of a chromosomal passenger protein. It first associates with centromeres/kinetochores – the sites on chromosomes where microtubules attach – then relocalizes to the midzone of the central spindle, and finally concentrates at the midbody between dividing cells. In line with these distinct localizations, Aurora-A is implicated primarily in centrosome maturation and spindle assembly, whereas Aurora-B is proposed to regulate chromosome condensation and cohesion, kinetochore assembly and bipolar chromosome attachment, the spindle checkpoint and the coordination between chromosome segregation and cytokinesis. Aurora-C has been described only in mammals, where it is expressed in testis and certain tumor cell lines and, like Aurora-B, functions as a chromosomal passenger, which localizes first to centromeres and then to the midzone of mitotic cells. It has been shown that Aurora-C cooperates with Aurora-B to regulate mitotic chromosome segregation and cytokinesis.

Aurora-A is located on chromosome 20q13.2, a region commonly amplified in malignancies, such as melanoma and cancers of the breast, colon, pancreas, ovary, bladder, liver, and stomach. Interest in Aurora has intensified since the discovery that transfection of rodent Rat1 and NIH3T3 fibroblast cell lines with Aurora-A is sufficient to induce colony formation in culture and tumors in nude mice, thus establishing Aurora-A as a bona fide oncogene. Moreover, we and another group have recently shown that overexpression of wild-type Aurora-A induces breast cancer in vivo. *Aurora-B* is located on chromosome 17p13.1, a region not typically amplified in human malignancies. Despite

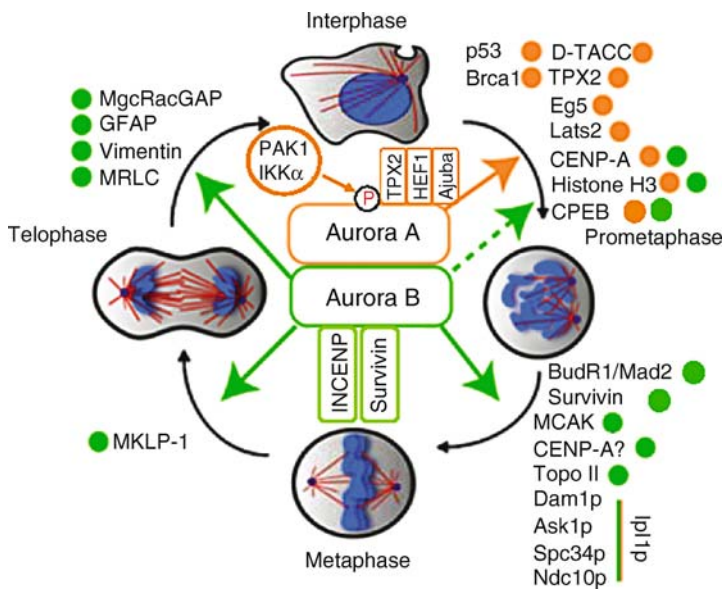
lack of amplification at the gene level, mRNA and protein levels of Aurora-B are frequently increased in human tumors.

Mechanisms

Aurora-A was shown to be activated by autophosphorylation of Thr-288 during G2/M phase upon interacting with TPX, Ajuba, and HEF1 (Fig. 2). However, recent studies have demonstrated that PAK1 and IKKα bind to and phosphorylate Aurora-A on Thr288 and Ser342, which are key sites for kinase activation in mitosis. In vivo PAK activation causes an accumulation of activated Aurora-A. Aurora-A phosphorylates several proteins which are important in mitosis, including histone H3 on Ser10, a key molecule in conversion of the relaxed interphase chromatin to mitotic condensed chromosomes; CPEB (cytoplasmic polyadenylation element-binding protein), best known for its role in promoting polyadenylation of cyclin B and cdc2 mRNA; TACC3, a protein required for stabilization and organization of microtubules; Eg5, a kinesin-like protein involved in both centrosome separation and spindle assembly and stability, TPX2, which is required to generate stable bipolar spindle, and two tumor-suppressor proteins, Lats2 and BRCA1. Further, TPX2, Ajuba, and HEF1 have been shown to interact and activate Aurora-A. The crystal structure of activated Aurora-A in complex with a TPX2 fragment showed that TPX2 binding is sufficient to allow autophosphorylation of the activatory T-loop Thr-288, allowing Aurora-A to adopt a conformation similar to the "active" conformation of other Ser/Thr kinases. With regard to mechanism of Aurora-A regulation of cell survival and proliferation, we have recently demonstrated Aurora-A upregulation of c-Myc to induce telomerase activity. Moreover, we and others have also documented that Auraro-A abrogates p53 DNA-binding activity and induces p53 degradation by direct phosphorylation of p53 at Ser215 and Ser315, respectively. Aurora-B activation is triggered by autophosphorylation after association with its substrates INCENP and survivin, with peak activity in metaphase and telophase (Fig. 2). Key substrates of activated Aurora-B include the centromeric proteins centromere protein A, INCENP, survivin, Borealin; microtubule-destabilizing kinesin mitotic centromere-associated kinesin; the mitotic checkpoint proteins BubR1 and Mad2; the cytoskeletal proteins myosin II regulatory light chain, vimentin, desmin, and glial fibrillary acidic protein; and histone H3. Following mitosis, the D-box region of Aurora-B is recognized by the anaphase-promoting complex/cyclosome, leading to Aurora-B ubiquitination and degradation.

Aurora Kinase as Target for Cancer Intervention

Frequent deregulation of Aurora kinase in human cancer prompted to develop Aurora kinase inhibitors as novel anticancer drugs. A half of dozen of such inhibitors have



Aurora Kinases. Figure 2 Activation, cell cycle execution points and substrates of Aurora-A and Aurora-B kinases. Schematic diagram illustrating (i) the activation of Aurora-A through phosphorylation of Thr288 by PAK1 and IKKα as well as via the interaction with TPX2, HEF1, and Ajuba, (ii) activation of Aurora-B by binding to INCENP and survivin, and (iii) known execution points and substrates of Aurora-A and -B across the cell cycle. The substrates phosphorylated in each phase of the cell cycle are color coded: orange circles indicate Aurora-A substrates and green circles indicate Aurora-B substrates. Ipl1p substrates are indicated as a double green and orange line.

been reported and a few of them are in clinic trails, which include VX-680 (Merck), AZD1152 (AstraZeneca), MLN8054 (Millenium), and PHA-739358 (Nerviano). However, VX-680 and PHA-739358 are pan-Aurora kinase inhibitors. AZD1152 and MLN8054 also inhibit three members of Aurora kinase, however, AZD1152 preferentially inhibits Aurora-B, whereas MLN8054 is more potent toward Aurora-A. Further investigations are required to identify more potent and selective Aurora kinase inhibitor for cancer intervention.

Autoantibodies

Félix Fernández Madrid
Department of Internal Medicine, Karmanos Cancer Institute and Center for Molecular Medicine and Genetics, Wayne State University, Detroit, MI, USA

Definition

Autoantibodies are those antibodies that recognize proteins, nucleic acids, or carbohydrates derived from the cells of the organism in which they were formed as nonself. Cancer-associated autoantibodies are potential reagents for the early diagnosis and prognosis of cancer. Autoantibodies target molecules involved in signal transduction, cell cycle regulation, cell proliferation, and apoptosis, all of them key processes in carcinogenesis. Molecular studies of antigen–antibody systems in cancer can also yield valuable information on the carcinogenic process. The study of autoantibodies in cancer has broad implications for the discovery of molecular targets for drug therapy and for cancer biomarkers in general. Cancer-associated autoantibodies can be invaluable reagents in the selection of naturally immunogenic molecules as key targets for cancer immunotherapy.

Characteristics

Available serologic markers for the diagnosis of cancer exhibit limited specificity and sensitivity. Thus, there is need to develop biomarkers with high accuracy, which alone or in combination with other screening methods such as ►mammography ►prostate specific antigen, might significantly improve the likelihood of diagnosing cancer at an earlier stage. There is ample evidence that malignant tumors can induce T-cell-mediated as well as humoral responses. For decades, autoantibodies reported in cancer sera have been considered to represent epiphenomena and only recently have autoantibodies emerged as promising biomarkers for the diagnosis and prognosis of cancer. Autoimmunity in the systemic autoimmune diseases constitutes a useful model to look at mechanisms by which autoantibodies arise in cancer patients. The autoantibody response observed in both, the systemic autoimmune diseases and in cancer is antigen-driven. It has been determined in ►medullary breast carcinoma that tumor infiltrating B-cells differentiate into plasma cells in situ and that their IgG genes exhibit patterns of mutations that are consistent with antigenic selection and affinity maturation, suggesting a tumor antigen-driven ►humoral immune response. Although it is not known whether these findings apply to solid tumors in general, other data suggest that the autoantibody response in cancer is driven by antigen. The autoantibodies observed in cancer sera are predominantly of the IgG, and the IgM class of immunoglobulins. IgG antibodies may predict the coexistence of helper T-cell activity. In each of the systemic autoimmune diseases, the autoantibody profile has diagnostic and prognostic significance. Likewise, the picture is emerging pointing to a characteristic autoantibody profile in many types of cancer, expanding the opportunities for serologic diagnosis. Several studies have shown that autoantibodies appear in cancer sera before the disease becomes clinically evident, suggesting that they have the potential of detecting early disease, i.e., when the treatment has the best chance to influence tumor behavior and ideally to achieve a cure. In agreement with this possibility, immunopathological studies of premalignant disease have shown molecular alterations that have been associated with autoreactivity to cancer-associated proteins. Also, studies on breast tumor-infiltrating B-cells suggest that antitumor antibodies are commonly produced in response to solid tumors and that ►B-cell responses occur early in tumor development.

As to the origin of autoantibodies, it has been shown that increased proteolytic cleavage of tumor-associated autoantigens in the process of apoptosis may increase their immunogenicity. Apoptosis is a process which

can make cancer-associated antigens or fragments of cytosolic or nuclear proteins accessible to cell surfaces and may expose cryptic peptides for ►MHC I ►MHC II display by ►antigen-presenting cells. The immunogenicity of many or even most tumor-associated antigens is not due to mutations but appears to be the result of overexpression in tumor or of other tumor factors. From the many tumor-associated antigens reported using autoantibodies as reagents for ►immunoscreening cDNA expression libraries or using proteomics, relatively few are membrane-associated or nuclear antigens, while the majority of the autoantigens identified by these methods are cytosolic proteins.

Autontibodies recognizing cancer-associated autoantigens can also be detected in a small proportion of healthy individuals. This is to be expected since antibodies recognizing cancer-associated autoantigens develop months or years before the clinical diagnosis of cancer. It is clear that the larger the pool of "normal" sera, the more likely will be the presence of tumor-associated clones.

Autoantibodies Can Produce Tissue Injury and May Influence Tumor Behavior

Autoantibodies in the ►paraneoplastic syndromes are markers of cancer, and can also result in tissue injury in regions remote from the tumor. Several neurologic syndromes have been described in association with small cell lung cancer and breast cancer. Although neurologic autoimmune syndromes have not been reported in vaccine trials, the presence of cancer-associated autoantibodies cross-reacting with brain antigens and potentially causing neurologic disease should be considered in the design of anticancer vaccines. Although the paraneoplastic syndromes are rare, studies on the specificity of the autoantibodies suggest that they may be able to influence cellular functions.

It has been presumed that spontaneous regressions rarely occurring in cancer patients have an immunological basis. Although there is ample evidence that autoantibodies can function as effectors of the immune system in the systemic autoimmune diseases, whether autoantibodies can in any way influence tumor behavior in cancer patients is unclear.

Studies of the lymphoplasmacytic cell infiltrate observed in medullary carcinoma of the breast have demonstrated its importance to the improved prognosis of this form of breast cancer, suggesting that the host immune response – most likely the autoantibody response to cancer-associated antigens – is involved in restraining tumor growth. Associations with improved prognosis as well as with poor prognosis have been reported for several naturally occurring humoral responses.

The factors underlying the poor effectiveness of naturally occurring antibody responses against cancer are complex. It has been suggested that ►tolerance, an important obstacle to cellular and vaccine-based immunotherapy of cancer, may constitute a similar obstacle to naturally occurring responses i.e., the decreased response to tumor antigens may not be a function of systemic immunodeficiency, but at least to some extent may be due to specific tolerance to tumor-associated antigens. It is also likely, that at least for some antigens, spontaneous autoantibody responses may be subtherapeutic.

Other possibilities exist to explain why naturally occurring autoantibodies are not more effective against cancer. It has been shown that the collaboration of both humoral and cellular immune responses is required for the complete eradication of antigen-expressing tumors. It is likely that this type of cooperation between humoral and cell-mediated response is necessary for an effective spontaneous antitumor immune response. Another possibility that may negate the beneficial effect of a cancer-associated immune response is that autoantibodies against some tumor antigens may actually stimulate uncontrolled cell proliferation and tumor progression. Indeed, some autoantibody responses may be stimulatory of tumor growth in vivo. In addition antibodies against shed tumor cell surface antigens can also promote tumor invasion and metastases through ►FcR-induced release of angiogenic cytokines in the tumor microenvironment. It seems likely that the ►affinity-matured IgG responses observed in draining nodes in breast cancer represents a mixture of protective and harmful autoantibodies. Thus, it is possible that in addition to T-cell reactivity, the balance of the antagonic effect of the autoantibodies produced in a particular patient will contribute to determine whether the immune response may be protective or harmful.

Autoantibodies as Diagnostic and Prognostic Serologic Biomarkers of Cancer

In 1995 Sahin et al. described ►SEREX technology, in which recombinant tumor cDNA expression libraries were screened with cancer sera. Since then hundreds of autoantigens have been identified using SEREX and its modifications in cancer sera. Proteomics technology has also been successfully used for the identification of tumor-associated antigens. Proteomics is a versatile approach which has generated considerable interest in the field of biomarker discovery for its capability of uncovering antigen–antibody systems in serum and other biological fluids. One advantage of this approach over genomics is its ability to assess the contribution of posttranslational modifications of the autoantigens. Once an autoantigen has been identified in cancer sera, it is essential to establish that it is not only patient-associated but also tumor-related, i.e., recognized by multiple sera from patients with cancer and not by control sera. However, these two conditions may not be sufficient for a potential biomarker to become a

reagent useful for the early diagnosis of cancer. Some studies using genomics or proteomics have reported the association of reactivity of individual IgG autoantibodies or of panels of autoantibodies with the diagnosis of solid tumors, while other studies have reported correlations between autoantibody reactivity and patient survival. Despite the abundance of potential biomarkers, efforts to consistently predict malignant disease based on autoimmunity to individual antigens has not resulted thus far in serologic markers with sufficiently high predicting specificity and sensitivity to merit adoption in a clinical setting. However, it has been shown that the use of panels of autoantigens rather than individual antigens in breast, prostate, and ovarian cancers enhances the likelihood of detecting cancer-associated antigens with potential diagnostic value. High-throughput methodology, genomics using phage display and proteomics are being increasingly used in the identification of biomarkers useful for the diagnosis of solid tumors and hematological malignancies. For all the multiple autoantibodies presently being studied as diagnostic instruments, the appropriate validation rout must be followed.

A factor that should be considered when evaluating the predictive value of autoantibodies as biomarkers for the early diagnosis of cancer is the stage of the tumor of patients donating their sera to probe the antigen collection. Although advanced stage cancer patients have normal cellular and humoral responses to recall antigens, they do not generate effective responses against tumor antigens. In addition, a large proportion of patients with early stages of malignancy have serum antibodies reactive with autologous tumor, while a significantly smaller proportion of patients with metastatic disease have tumor-reactive antibodies. These findings suggest that a decrease in antibody response against tumor-associated antigens may be the result of tumor/autoantigen-specific tolerance mechanisms rather than generalized disease-related immune dysfunction. Not only there may be less autoantibody reactivity in advanced stages of cancer, but also there may be a change in the specificity of the autoantibodies. These considerations are relevant to the design of studies proposing to demonstrate the ability of autoantibodies to contribute to the early diagnosis of cancer, since lumping data from all stages of cancer, and particularly the inclusion of patients with advanced stages of the disease in the assessment of sensitivity and specificity, may dilute the predicting ability of a biomarker for the early diagnosis of cancer. Existing data support the view that serum antibodies may be prevalent in premalignant disease, thus supporting the likelihood that autoantibodies may show significant predicting ability for the diagnosis of early disease.

The field of diagnostic biomarkers is still in the discovery phase, but is rapidly approaching testing in the real world. The use of genomics, proteomics and high throughput technology has led to the identification of a large group of cancer-associated autoantigens. These studies strongly suggest that autoantibodies have potential as biomarkers and may facilitate the early diagnosis of malignancies. It has been suggested that proposed markers for classifying or predicting risk in individual subjects must be held to a much higher standard than merely being associated with outcome, and that their sensitivities and specificities must be shown to be adequate through appropriate statistical evaluations. Validation of the most promising of the proposed biomarkers for diagnosis and prognosis of cancer requires the application of these high evaluative standards in prospective studies of large cohorts of patients with cancer against the present diagnostic standards.

The goal of most of these studies is to develop accurate and reliable serologic tests useful to diagnose cancer early. While the biodiscovery and validation phases are supported by the Early Diagnosis Research Network of NIH in the US, the National Institute of Standards and Technology, also a branch of NIH, directs the efforts of the scientific community in bringing metrology to serology. Indeed, after the usefulness of the autoantibody or of a panel of autoantibodies is established, the gap between the discovery phase and the real world should be bridged by developing new standards for autoantibody measurement with participation of industry, academia, physicians, and patients.

Autoantigens

Definition

Self antigens to which the immune system makes a response are called autoantigens.

►Sjögren Syndrome

Autocrine

Definition

Autocrine is a factor acting on the same cells that produce it. Following interaction with the endogenous receptor(s), an autocrine activation (autocrine loop) is obtained. Self-stimulation by a cell that expresses both the receptor for a particular hormone or growth factor and secretes the ligand. Autocrine one of three fundamental types (with ►paracrine and ►endocrine) of cellular regulation by intercellular diffusible factors, where the diffusible factor exerts a regulatory influence primarily on the same cell that secreted it.

►Scatter Factor
►Receptor Tyrosine Kinases

Autocrine Growth Factors

Definition

Are multifunctional peptides that are extremely potent for the growth of cancer cells and they can also act on the cell in which they are produced. Growth factors that function via an autocrine mechanism in cancer cells include transforming growth factor α (TGF-α), ►transforming growth factor β (TGF-β), ►platelet-derived growth factor (PDGF), bambesine, and interleukins; each with its own membrane receptor on the cells that produce them.

►Sivelestat

Autocrine Signaling

Definition

Is a form of local area signaling in which a cell secretes a chemical messenger (►autocrine agent) that signals the same cell. In contrast, in the ►paracrine signaling, the signal of the chemical messenger (paracrine agent) is limited to other cells also in the local area.

►Chemoattraction

Autocrine Stimulation

Definition

Production of a factor that stimulates the producer cell itself.

►Platelet-Derived Growth Factor

Autografts

Definition

The engraftment of organs, cells or tissues from one individual to themselves.

►Graft Acceptance and Rejection

Autoimmune Diseases

Definition

Diseases in which the pathology is caused by adaptive immune responses to self antigens are called autoimmune diseases.

►Sjögren Syndrome

Autoimmune Hemolytic Anemia

Definition

Anemia that results from an abnormality of the immune system that attacks and destroys red blood cells. Antibodies and associated complement system components adhere to the red blood cell surface.

►Rituximab

Autoimmune Lymphoproliferative Syndrome

Definition

Synonym: Canale-Smith Syndrome, is a childhood syndrome of autoimmunity with a phenotype of hemolytic anemia and thrombocytopenia with massive lymphadenopathy and splenomegaly within first 2 years of life. Lymphadenopathy is associated with mutations of the FAS gene, and the accumulation of lymphocytes is mainly the result of failure of FAS-mediated apoptosis. Autoimmune manifestations, such as hemolytic anemia and thrombocytopenia, which result from the production of autoantibodies against red blood cells and platelets, can persist into adolescence, and the FAS mutations are compatible with long-term survival. Patients have been detected lacking mutation in the FAS gene, and it is thought that in these cases the impaired apoptosis results from other defects of the FAS pathway (Ref.: Vaishnaw AK, Orlinick JR, Chu J-L, Krammer PH, Chao MV, Elkton KB. (1999) The molecular basis for apoptotic defects in patients with CD95 (Fas/Apo-1) mutations. J Clin Invest 103:355–363).

►Apoptosis
►Sjögren syndrome

Autoimmune Response

Definition

An adaptive immune response directed at self antigens is called an autoimmune response; likewise, adaptive immunity specific for self antigens is called autoimmunity.

►Sjögren Syndrome

Autoimmune Thyroid Disease

Definition

A disease that results from an aberrant immune response directed against its own cells and tissues. The most common autoimmune thyroid diseases are Graves disease and Hashimoto disease.

►Graves Disease
►Hashimoto Disease
►Follicular Thyroid Tumors

Autoimmunity

Definition

Refers to the ability of the host immune system to make a response to self, i.e. to components of the host's own tissues or cells. Autoimmunity includes antibody responses (autoantibodies) or cellular responses mediated by T lymphocytes specific for self components (autoantigens). Healthy individuals do not make such responses, because tolerance to self exists and guards against the development of autoimmunity. In disease or when tissue destruction occurs, tolerance to self may be broken and autoimmunity induced. Uncontrolled chronic immune activation may lead to the development of an autoimmune disease, such as rheumatoid arthritis, systemic lupus erythematosus, scleroderma and others.

Immune responses to autoantigens; Antibodies to self antigens; T-cells recognizing autoantigens; Immunoregulatory aberrations in cancer

Definition

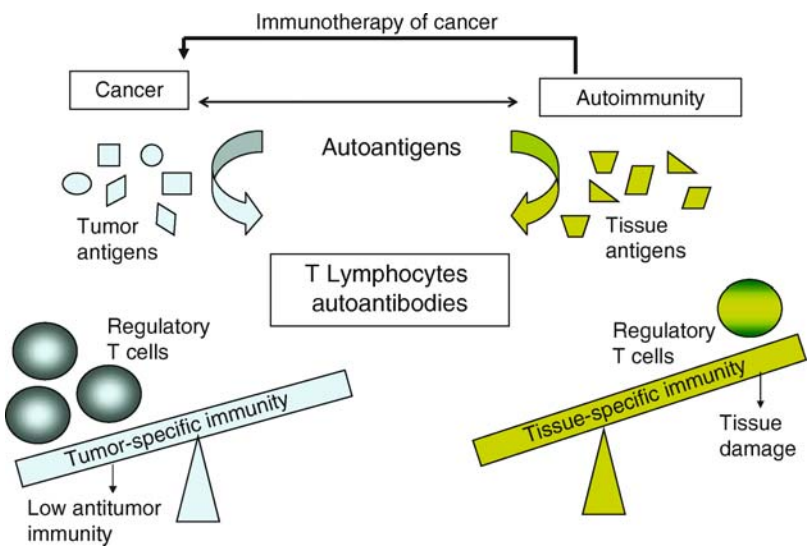
Characteristics

It has often been said that cancer and ►autoimmunity represent "two sides of the same coin." Links between these two disease states have been identified many years ago. However, this relationship has been receiving increased attention recently, largely due to emerging evidence that antitumor immunotherapies, especially ►antitumor vaccines, are often associated with the

manifestation of autoimmunity in cancer patients. Apparently, the most successful vaccinations in terms of their ability to induce immune activation in cancer patients are also most likely to induce autoimmune sequelae. These may be mild or severe and may result in substantial pathology. Immune therapies could also induce autoantibody or self antigen-specific T cell responses without associated clinical symptoms in some patients. It has been well documented that the development of cancer and autoimmune disease is accompanied by aberrations in immune regulation. The crucial role of immune regulation in disease development and progression has been intensively studied in various animal models and, to a lesser extent, in humans with the result that at least some mechanisms responsible for immune dysfunction in autoimmunity and cancer are now defined. The interesting point to consider is that in cancer and autoimmune disease, these mechanisms seem to involve the same immune cell subsets behaving in a diametrically opposite way in response to similar antigenic stimuli. Thus, excessive activation of the immune system to autoantigens is a hallmark of autoimmunity, while in cancer, a down-regulation of autoantigen-specific immune functions allows for cancer development, progression and metastasis.

Evidence for Autoreactivity in Patients with Cancer

In patients with cancer or autoimmune diseases, the presence of circulating antibodies to self antigens is a common finding, and one that has been helpful in diagnosis and management of patients with autoimmune conditions. The development of antibodies to autologous cellular antigens (autoantibodies) in cancer occurs spontaneously, presumably as a result of a tissue damage or trauma in the past, or in response to therapeutic intervention and may or may not be prognostically useful. The types of cellular proteins which induce autoantibody response in malignancy are quite varied and include cellular antigens encoded by mutated normal genes such as p53, cellular proteins that are aberrantly expressed in tumor cells (e.g. alpha-fetoprotein or carcinoembryonic antigen), mucins (e.g. MUC1), inhibitors of apoptosis (e.g. survivin), surface receptors of apoptosis (e.g. CD95) or nuclear antigens such as double-stranded or single-stranded DNA. In recent years the list of the so-called "cancer-related antigens" which initiate humoral immune responses in the host has considerably expanded, and the presence of some of these antibodies has been taken as evidence that the host is not ignorant of the tumor. In patients with melanoma, the appearance of autoantibodies, e.g. anti-nuclear antibodies (ANA), anti-DNA antibodies, anti-thyroid antibodies or of clinical manifestations of autoimmunity or both during immunotherapy with interferon α-2b was associated with good prognosis and significantly improved survival. In many other studies, the presence of autoantibodies against tumor antigens was considered as evidence that tumor-specific immune



Autoimmunity and Prognosis in Cancer. Figure 1 Immunotherapy of cancer can shift the balance of autoantigen-driven immune responses. In cancer, T lymphocytes and /or antibodies specific for tumor-derived antigens, which are self, are generated. However, in the presence of an excess of regulatory Tcells (Treg) these immune responses are suppressed, and tumor-specific immunity is low (*left*). In autoimmuine disease, autoantigens derived from tissues similarly stimulate T-cell and antibody responses. However, because Treg are few or are not functional, tissue-specific immune responses are strongly increased, resulting in immune-mediated tissue damage (*right*). Successful immunotherapy of cancer leads to up-regulation of immune responses to self, similar to what happens in autoimmunity, and to improved antitumor immunity. This may be brought about by a decrease in Treg numbers or function. The ultimate result may be a better prognosis for cancer patients who are predisposed to making immune responses to autoantigens.

responses can be made and could potentially contribute to improved survival of patients with cancer. In reality, these antibodies with specificity for tumor-associated proteins are targeting self antigens and therefore, they represent an autoimmune response. Immune therapies further enhance the host capability to mount these responses, thereby breaking the tolerance to self and contributing to the development of antitumor immunity.

Cellular responses mediated by T cells specific for self antigens are also observed in patients with cancer as well as autoimmune diseases. The self-antigen specific T cells are detectable in the peripheral circulation of patients with cancer and are present at the tumor site. Using MHC tetramers, it has been possible to quantify the frequency of epitope-specific CD8+ T cells in the circulation of normal donors and patients with cancer or autoimmune disease. ►Cancer immunotherapies often increase the frequency and activation levels of such effector T cells, creating an opportunity for autoimmune tissue destruction. There is a valid concern that this type of therapy could potentially result in activation of auto-reactive T cells capable of killing tissue cells, similar to what happens in autoimmune diseases.

Regulation of Autoreactivity

Given that both autoantibodies and self-reactive T cells are present in patients with autoimmune disease and cancer, the question arises as to how immune responses are regulated in these diverse pathologic situations. Presumably, mechanisms allowing for expansion of immune responses to self antigens in autoimmunity and their suppression in cancer are involved. Indeed, recent evidence suggests that a subset of T lymphocytes named ►regulatory T cells (Treg) and able to suppress responses of effector T cells, represents one mechanism that may be relevant to both autoimmunity and cancer. Normally, T reg defined as CD4+CD25+FoxP3+ cells are responsible for maintaining tolerance to self and preventing autoimmunity. Their numbers and functional competence in the local microenvironment determine the nature and magnitude of immune responses. Treg depletion or functional deficiency results in development of autoimmunity. In contrast, Treg accumulations at tumor sites and in the peripheral circulation have been observed in patients with cancer. Further, their presence and suppressive activity in the ►tumor microenvironment have been linked to poor survival in patients with cancer. Therefore, Treg represent a common regulatory mechanism that could account for immune aberrations seen in cancer as well as autoimmunity.

The concept that the same regulatory T-cell subset patrolling responses to self is involved in seemingly opposite functions, i.e. a lack of suppression vs. an excess of suppression, in autoimmunity and cancer, respectively, seems reasonable when it is remembered that the vast majority of non-mutated tumor antigens are seen by the immune system as self. The Janus face presented by Treg in cancer and autoimmunity is a result of biological economy, whereby the same cell subset is differently regulated, depending on the environmental context. Under normal conditions, the immune system maintains tolerance to self by utilizing Treg. In disease, pathologic events accompanied by danger signals trigger inflammatory cascades, which shift the immune balance and activate or down-regulate Treg, depending on the nature of triggering signals. Molecular mechanisms responsible for down- or up-regulation of immunity by Tregs in disease are being intensely investigated at present, and the critical unanswered issues concern their origin, the factors that contribute to Treg generation, the nature of Treg activation stimuli and pathways used for suppression/activation of immune responses. Treg are a heterogenous population encompassing several types of regulatory cells, including natural or nTreg, antigen-dependent Tr1 cells, and perhaps other suppressor cells induced by ►IL-10 or ►TGF-β in the tissue microenvironment. It is unclear whether all or only some of these regulatory cell subsets participate in suppressing antitumor responses and thus, in promoting tumor growth and its escape from immune surveillance. In animals with autoimmune diseases, selective depletion of partially overlapping CD4+ T cell subsets or their adoptive transfers identified the existence of phenotypically distinct Treg which mediate distinct clinical manifestations of disease. The critical role of a cytokine/chemokine milieu, unique cytokine dependency of various Treg subsets and the ability of these subsets to produce distinct cytokines all contribute to tremendous pliability of Treg and suggest organ-restricted regulation of autoimmunity as well as anti-tumor responses. ►Cytokines, especially TNF-α, are implicated in the development of autoimmunity as well as cancer, and their pluripotent activities represent another example of biologic redundancy.

In addition to Treg and cytokines, other links between cancer and autoimmunity have been identified. The role ►dendritic cells (DC) play in regulating T-cell activation is well known. It now appears that DC not only elicit potent effector cell responses but may also cross-talk with Treg. Evidence indicates that DC have the ability to induce and expand subsets of CD4+ Treg cells, with antigen-targeted immature DC promoting induction of Tr1 cells and antigen-loaded mature DC stimulating CD4+CD25+ nTreg. Silencing of cytokine signaling inhibitor SOCS1 in murine DC has been shown to induce unbridled IL-12 signaling and a down-stream cytokine cascade resulting in a breakdown of tolerance and the development of autoimmune responses against normal tissues as well as tumor. Signaling via toll-like receptors (TLR), which are expressed on DC and recognize a set of conserved pathogen-associated molecular structures (PAMPS), may also be involved in regulation of Treg functions.

Thus, molecular signals that DC experience in the tissue microenvironment determine their cross-talk with other immune cells. This cross-talk is most likely driven by cytokines produced by immune and/or tissue cells, and it controls the magnitude of responses mediated by effector cells responsible for antigen-specific or innate immunity. It may well be that the requirements for autoreactive cytolytic T lymphocyte (CTL) responses are defined and regulated at the level of DC-T cell interactions. The outcome could be critical for either cancer progression or development of autoimmunity.

Immunotherapy May Induce Autoimmunity

The mechanisms for breaking tolerance to self and simultaneously up-regulating anti-tumor immunity may operate at the cellular level (e.g. Treg, Treg-DC, DC) or may involve cytokine networks or signaling pathways, such as the NFκB pathway known to regulate pro-inflammatory cytokine responses and recently identified as a potential molecular link between inflammation and cancer. To what extent the same mechanisms are potentially involved in the development of autoimmune disease and cancer is critical to unravel. For many years, reports have been suggesting increased cancer risk among patients with autoimmune diseases. Conversely, the presence of autoimmune disease has been noted in patients with cancer. More recently, the onset of autoimmune diseases among cancer patients immunologically responding to biologic therapies has been observed. In particular, immune therapy of patients with metastatic melanoma using a combination of a peptide vaccine and antibody to cytotoxic T lymphocyte antigen-4 (CTLA-4) was reported to cause durable objective responses, which correlated with the induction of symptomatic autoimmunity. The ability of interferon α-2b to induce autoimmunity in patients with metastatic melanoma and correlations observed by Gogas et al [3], between the development of autoimmunity and the reduced risk of melanoma recurrence convincingly suggest that benefits of immune therapies are restricted to cancer patients in whom evidence of autoimmunity exists or appears in response to therapy. In another interesting report, a patient with melanoma who was treated with anti-CTLA-4 monoclonal antibody in combination with a vaccine containing autologous tumor cells engineered to secrete granulocyte-macrophage colony stimulating factor (GMCSF) developed high titer antibodies against MHC class I chain-related protein A (MICA), while favorably responding to this therapy. These results highlight the therapeutic potential of anti-MICA antibodies, which were shown to be able to opsonize tumor cells for efficient cross-presentation to DC and to lyse tumor cells via complement fixation. In aggregate, clinical and immunologic results of antitumor vaccination trials strongly suggest that cancer patients in whom breaking of tolerance to self can be induced by immunopotentiating therapies are most likely to become clinical responders to the treatment. Seen from this perspective, the reports correlating the presence of autoimmunity to improved prognosis and survival in cancer have important implications for diagnosis, patient selection, immune monitoring and immunotherapy of cancer.

Autoantigens as a Link Between Cancer and Autoimmunity

The above described development of autoimmunity and associated benefits in prognosis or survival of cancer patients treated with immunotherapies, underscores a potential mechanistic link between cancer and autoimmunity. Accumulated data suggest that autoantigens drive the autoimmune response in both instances and are the key factor in pathogenesis. However, it is necessary to distinguish two alternatives. In the first instance, the patient has pre-existing autoimmunity, as indicated by low but detectable titers of pre-existing autoantibodies and/or autoreactive T cells. Such patients with a strong propensity toward autoimmunity might be a group for whom immune therapy should be considered, because memory responses to autoantigens are present. In the second instance, no pre-existing autoimmunity is evident prior to treatment, but immune therapy induces the appearance of autoantibodies and symptoms of autoimmunity that correlate with a favorable clinical response. In such cancer patients autoimmunity develops during effective immunotherapy, perhaps because the tolerance threshold to autoantigens is lowered by therapy, with the result that robust antitumor responses can be generated. The prospective identification of such patients could help clinicians in selecting patients for immunotherapy and lead to improved treatment strategies.

Multiple strategies have been used to optimize immune therapy of cancer and to improve prognosis. It now appears that therapies capable of effectively breaking tolerance in patients who are pre-disposed to autoimmunity are among the most promising. As the cellular and molecular mechanisms of immune regulation become better defined, new opportunities arise for changing the balance in favor of autoimmunity, with a proviso that it can be adequately clinically managed in patients with a malignant disease. The discovery that excess of Treg can be at least transiently decreased with anti-CD25 antibodies, cyclophosphamide or interleukin-2-diphtheria recombinant fusion protein (DAB_{389}IL-2) offers a window of opportunity for delivery of tumor-specific vaccines. It is also now feasible to expand Treg many folds in the presence of

rapamycin (1nM), presenting us with a potentially useful therapeutic tool for ameliorating autoimmune disease. In cancer patients undergoing hematopoietic stem cell transplantation, the post-transplant delivery of expanded, strongly suppressive Treg might help in the control of graft versus host disease (GVHD). These and other strategies targeting regulatory cells or molecular pathways involved in immune regulation are likely to clarify the complex interactions between immune cell subsets mediating autoimmune responses to autoantigens and to provide new insights into more effective approaches to improving prognosis in patients with malignancies.

Definition

Autophagy is intracellular uptake of cytoplasm (proteins, nucleic acids, small molecules, whole organelles, etc.) into the ►lysosome and its subsequent degradation. Autophagy is a constitutive as well as a stress-inducible process responsible for the degradation of the majority of cellular proteins.

Characteristics

Lysosomal uptake and degradation of proteins by autophagy can be found in virtually all eukaryotic cells. Autophagy is a way of degrading and recycling long-lived cytosolic proteins and complexes (like ribosomes) and the only way of degrading whole organelles. Autophagy is regarded to be a largely non-selective bulk process, but it also serves more specialized roles in biogenesis of the lysosome (import of lysosomal hydrolases), cellular differentiation and cell death, and in the elimination of mitochondria and ►peroxisomes, organelles which can be degraded with high selectivity by autophagy-related pathways. Autophagy of peroxisomes is referred to as pexophagy. Recently, the autophagic removal of endoplasmic reticulum (ER) has been described.

Autophagy is upregulated as a response to starvation, growth factor withdrawal, during stress response (oxidative stress, chemotherapy, protein aggregation), developmental differentiation, and tumor suppression. An excess of autophagy is involved in diseases like myopathies and neurodegenerative disorders.

Autophagy is highly conserved in evolution. Autophagic degradation is being studied in model organisms like *Dictyostelium discoideum*, *Arabidopsis thaliana*, *Caenorhabditis elegans*, *Drosophila*, and mice. Most of the autophagy genes (ATG genes) have been discovered in the yeast *Saccharomyces cerevisiae*. Many of them are conserved in higher eukaryotes including mammals.

Cell Biology of Autophagy

There are three morphologically distinct forms of autophagy (Fig. 1): (i) Carrier-mediated uptake involves the recognition of cytosolic proteins by a ►chaperone-related receptor and its subsequent direct translocation through the lysosomal membrane. (ii) In ►microautophagy cytosolic material is sequestered through invaginations of the lysosome. (iii) In macroautophagy, cytosol is engulfed by double membranes thereby forming ►autophagosomes. These autophagosomes fuse with lysosomes, thereby delivering the inner vesicle (►Autophagic body) of the autophagosomes into the lysosome. In subsequent steps, the vesicle membrane and the autophagic cargo are degraded and amino acids and other small molecules are recycled. Macroautophagy is the most prominent form of autophagy, therefore these terms are often used synonymously.

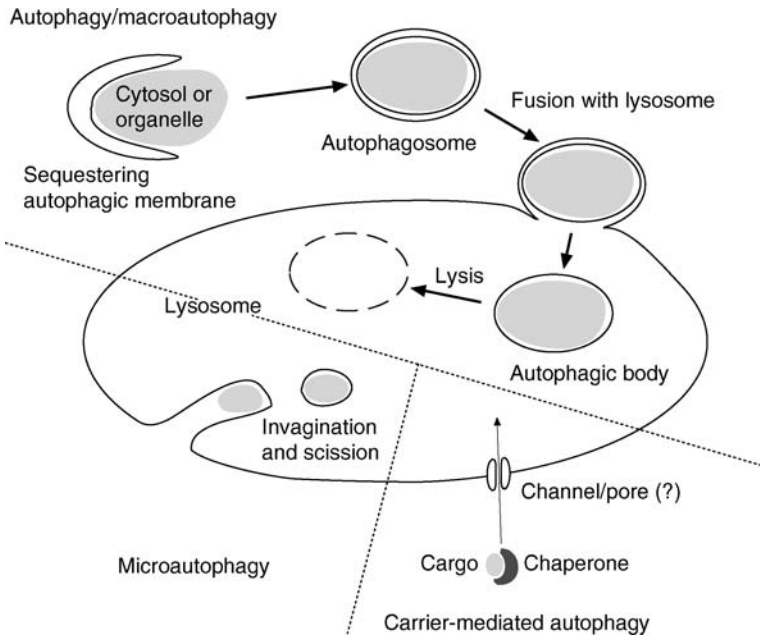
Signal Transduction

When nutrients, amino acids in particular, are abundant, autophagic activity is reduced to basal levels. Concomitantly, active growth factor signaling downregulates autophagy to basal levels. The serine/threonine kinase ►TOR (target of rapamycin) signaling pathway is regarded as a core component in the regulation of autophagy in response to there signals. The TOR pathway transduces extracellular growth factor or hormone signals (e.g. insulin) through receptor tyrosine kinases, phosphatidyl inositol 3-kinase (►PI3K), ►AKT/PKB, TOR, and ►p70S6 kinase, to ultimately regulate cell growth by translational and transcriptional mechanisms (Fig. 2). TOR is thus a nutrient sensor together with the AMP-activated protein kinase (►AMPK) which is responsible to low ATP to AMP ratios.

A number of autophagy protein complexes (mostly Atg proteins) are involved in regulating and executing autophagy: (i) the serine/threonine kinase Atg1 complex that responds to TOR and other upstream signals; (ii) a lipid kinase complex that is involved in vesicle formation in the cytosol; (iii) two ►ubiquitin-like conjugation pathways mediate vesicle expansion; and (iv) a protein recycling pathway is involved in the maturation of autophagosomes.

Autophagy and Programmed Cell Death

Induction of autophagy beyond the constitutive level can be associated with a non-apoptotic form of programmed cell death (PCD), referred to as type II PCD or autophagic



Autophagy. Figure 1 Cell biology of three forms of autophagy. In ►macroautophagy (for short: autophagy) intracellular membranes form in the process of sequestering cytosolic material. The edges of these membranes fuse to form double (or multiple) membrane structures (autophagosomes). The outer membranes of the autophagosomes fuse with the lysosome. Delivery of the inner sequestered material leads to the appearance of autophagic bodies within the lysosome. Phospholipases, proteases and other hydrolases degrade intralysosomal membranes and their content for re-use. Constitutive autophagy replenishes the cellular storages of energy and building blocks. Microautophagy involves the direct uptake of cytosol through membrane invaginations of the lysosome. Microautophagy might be required for membrane homeostasis of the lysosome and might therefore be linked to macroautophagy. In chaperone- or ►carrier-mediated autophagy, the autophagic cargo is recognized in the cytosol by a carrier chaperone and is guided to/though the lysosomal membrane by an unknown mechanism. Drawing Sven Thoms 2007.

cell death. In contrast to classical apoptotic type I cell death, organelle degradation precedes the collapse of cytoskeletal elements in type II PCD. Likewise, ►caspase activation and DNA fragmentation occur at later stages (if at all) in type II PCD. Both, apoptotic and autophagic cell death differ from necrosis by the lack of a tissue inflammatory response.

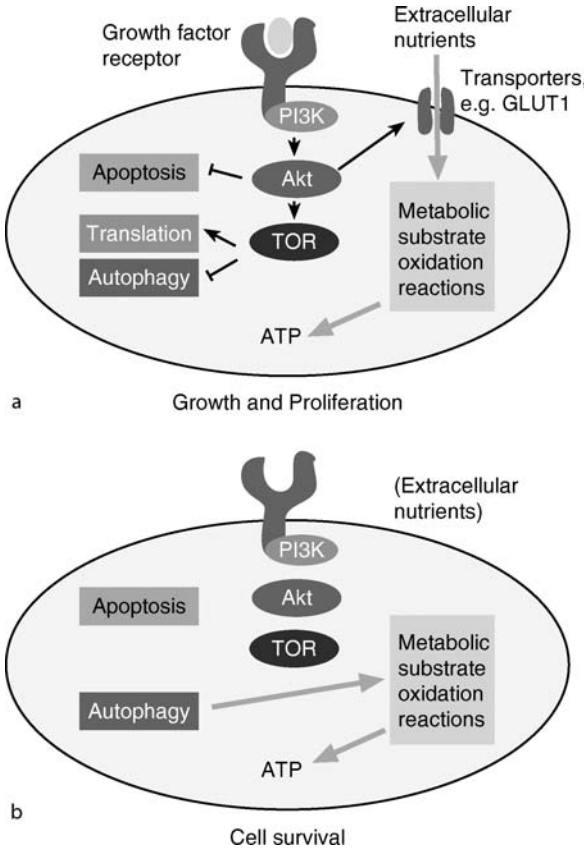
Autophagic cell death is associated with cell reduction in development (e.g. insect metamorphosis or postlactational mammary gland involution). Autophagic cell death is also observed in mammalian tissue treated with chemotherapeutics like ►tamoxifen. The association of cell death with increased autophagy is often only correlative and based on morphological features like the appearance of autophagic vacuoles. Recently it could be shown that in developmental embryonic apoptosis, autophagy is necessary to produce the signals that induce removal of apoptotic cells.

A positive correlation between cell death and autophagy is supported by studies showing that pharmacological inhibition of autophagy can prevent cell death. 3-Methyladenine (3-MA) blocks autophagy by acting on class II PI3K. 3-MA delays or inhibits cell death in various cancer cell lines.

The cell death and survival functions of autophagy do not exclude each other and it is clear from morphological and genetic data that a complex interplay exists between autophagy and apoptosis. Cell death can arise from high levels of autophagy though self-digestion. Low levels of autophagy might contribute to cell death by making the cell more susceptible to environmental stressors that are otherwise eliminated by autophagy.

Autophagy and Cancer

Autophagy is likely to play a role in the development and in treatment of cancer. In the development of cancer, those functions of autophagy that are associated with the restriction of cell growth and proliferation might be more important than the pro-survival functions. It has been speculated that a reduced level of intracellular protein degradation confers a selective advantage to malignant cells over normal cells. Accordingly, the inactivation of autophagy genes promotes tumor development in mice and overexpression of some autophagy genes inhibits formation of breast tumors in mice models. ►Beclin 1, the mammalian homologue of the yeast autophagy protein Atg6/Vps30



Autophagy. Figure 2 Regulation of autophagy in response to growth factor signaling and nutrient availability. (a) In the presence of growth factors and nutrients, TOR kinase is activated through PI3K and AKT and by amino acids. TOR inhibits autophagy and induces translation of household genes. AKT ensures expression of nutrient transporters including ►GLUT1, which in turn contributes to nutrient uptake and ATP production from external sources. Under these conditions, anabolic processes like translation and cell growth are induced, whereas β-oxidation and autophagic turnover are repressed. Not shown: the small GTPase ►Rheb and its GTPase activators, the tuberous sclerosis complex (TSC) proteins are involved upstream in TOR signaling. (b) In the absence of growth factor signaling and under conditions of nutrient deprivation, cell survival is ensured by autophagy. Cell surface nutrient expression is shut down and TOR kinase is inactive. Autophagy provides energy from within the cell by recycling as an alternative to external sources. Excess autophagy can also lead to cell death rather than survival. Redrawn from Nat Rev Mol Cell Biol 6, 442.

is monoallelically deleted in a number of human breast, ovarian, and prostrate cancers. Certain forms of cancer are associated with decreased autophagic activity. In line with these observations, tumor-suppressors like ►p53 or ►PTEN have a positive effect on autophagy, whereas proto-oncogenes like class I PI3K and AKT negatively affect autophagy. Consequently, inhibitors of autophagy have been suggested as anti-cancer drugs.

In cancer treatment, the survival supporting functions of autophagy are in conflict with its role in cell-death. Autophagy might help a cancer cell to survive during nutrient-limitation or to resist chemotherapy or radiation treatment. But autophagy might also support cancer treatment by promoting tumour cell death or the removal of apoptotic cells.

To find out whether the anticancer activity of drugs like tamoxifen, ►rapamycin or ►temozolomide can be (partially) attributed to their autophagy-inducing activity will remain an important area of research.

It is now clear that autophagy and cancer are intimately linked. But it is also becoming evident that autophagy, being a homeostatic as well as a stress-inducible cellular process, is regulated in a complex way in health and disease.

5-Azacytidine

Definition
5-Azacytidine represents an analogue of the cytosine nucleoside. It is incorporated into the DNA during replication. Inclusion of 5-azacytidine inhibits DNA methylation by the DNA methyl-transferase and results in the demethylation of the 5-Azacytidine containing sequence. DNA methylation controls gene transcription by regulating transcription factor binding.

►5-aza-2″-deoxycytidine
►Melanoma Antigens

5Y-Aza-2Y-Deoxycytidine

Definition
A nucleotide that can substitute for cytosine in DNA during replication but cannot be methylated as cytosine residues can; it is thus used as a drug in cells, animals or humans to cause demethylation of hypermethylated regions of genes.

►Methylation

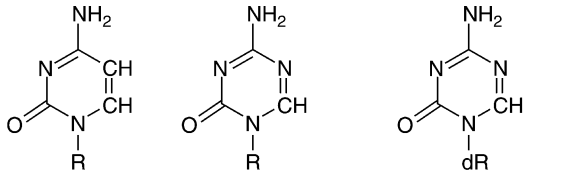
Definition
Sorm and Vesely first described the pyrimidine analogs 5-aza-2′-deoxycytidine and 5-azacytidine in the mid-1960. They were generally considered to be in the antimetabolite class of anticancer agents; however, unique actions of 5-aza-2′-deoxycytidine clearly extend these molecules beyond the realm of most other anti-metabolites. 5-aza-2′-deoxycytidine and 5-azacytidine may be better considered as the prototypical agents of an emergent class of therapeutic agents, epigenetic modifiers (►Epigenetics, epigenetic therapy). The most notable epigenetic effect of these 5-aza-pyrimidines is their ability to demethylate the DNA of proliferating cells, and these drugs are now classified as DNA demethylating agents (►methylation). To attain therapeutic efficacy, enzymatic activation of 5-aza-2′-deoxycytidine to its triphosphate form and incorporation into replicating DNA must occur.

Characteristics
History
Following its synthesis in the early 1960s, 5-aza-2′-deoxycytidine and its close relative 5-azacytidine went through extensive laboratory characterization (Fig. 1). 5-aza-2′-deoxycytidine and 5-azacytidine were shown to be bacterio- and viriostatic, mutagenic, immunosuppressive, antimitotic, and antineoplastic. At the cytotoxic doses examined in the early studies, 5-aza-2′-deoxycytidine and 5-azacytidine altered the activity of multiple enzymes involved in nucleic acid metabolism, and inhibited DNA, RNA, and protein synthesis. 5-aza-2′-deoxycytidine only incorporates into DNA, while



Cytidine 5-azacytidine 5-aza-2′-deoxycytidine

5-aza-2′ Deoxycytidine. Figure 1 Chemical structures of cytidine and two therapeutic analogs, 5-azacytidine and 5-aza-2′deoxycytidine. R: ribose, dR: deoxyribose.

5-azacytidine incorporates into DNA and RNA. 5-aza-2′-deoxycytidine is approximately 10 times more potent than 5-azacytidine, reaffirming that DNA is a critical site of drug action.

Clinical studies to determine the potential role of 5-aza-2′-deoxycytidine and 5-azacytidine as cancer chemotherapeutic agents quickly followed, and their efficacy assessed in various human malignancies. Results from these early clinical studies indicated that these drugs had activity in acute myelogenous leukemia (AML); however, the significant toxicities encountered coupled with the emergence of 1-beta-D-arabinofuranosylcytosine (cytosine arabinoside, araC) for the treatment of AML limited the widespread use of these 5-aza-pyrimidines.

Contemporary Research

Later, investigations found that 5-aza-2′-deoxycytidine and 5-azacytidine had distinctive properties. One example was the striking observation that treatment with 5-azacytidine was able to generate functional striated muscle cells from non-myoblast precursors in a process that resembled a phenotypic conversion. Jones and Taylor shortly thereafter linked this 5-azacytidine-induced phenotypic conversion with inhibition of DNA methylation. Specifically, drug treatment at minimally- or non-cytotoxic doses caused a decrease in genomic levels of 5-methylcytosine. These changes in 5-methylcytosine levels were subsequently shown to induce changes in gene expression. Thus, 5-azacytidine possesses unique properties that produce a transcriptional reprogramming of the cell resulting in significant changes in cell phenotype. This transcriptional reprogramming activity resides in the ability of 5-azacytidine to directly affect the epigenetic landscape of cells. The discovery of these properties has contributed greatly to understanding the therapeutic mechanism of action of these drugs, and has led to a reinvigoration of basic and clinical research on 5-aza-2′-deoxycytidine and 5-azacytidine.

The work by Jones and Taylor also showed that some, but not all, pyrimidine analogs were capable of inhibiting DNA methylation. The few pyrimidine analogs that could inhibit DNA methylation each had modifications at the 5C position of the pyrimidine ring (pseudoisocytidine, 5-fluoro-2′deoxycytidine, and of course, 5-aza-2′-deoxycytidine). Pyrimidine analogs not capable of inhibiting methylation included 6-azacytidine and the clinically active drug, 1-beta-D-arabinofuranosylcytosine. Importantly, the pyrimidine analogs that did not inhibit DNA methylation also did not induce a phenotypic switch. Taken together this work indicated that drug-induced epigenetic changes were not a general effect of pyrimidine analogs, but instead novel mechanisms of action unique to specific compounds.

The primary mechanism by which 5-aza-2′-deoxycytidine and 5-azacytidine decreases 5-methylcytosine levels in mammalian cells is by inhibition of the enzyme responsible for the faithful maintenance and transmission of DNA methylation patterns from one cell generation to the next, DNA methyltransferase I (DNMT1). The DNA methylation maintenance activity of DNMT1 is S-phase specific as is incorporation of 5-aza-2′-deoxycytidine into DNA. Following incorporation into DNA, the 5-aza-pyrimidines act as irreversible inhibitors of DNMT1 and rapidly deplete the cell of this enzymatic activity. The inhibition of this enzyme results in the inability to maintain faithfully DNA methylation levels and patterns in subsequent cell generations. This information indicates that actively proliferating cells are likely to be the most sensitive to the effects of these compounds on epigenetic control systems.

There are additional DNA methyltransferase found in mammalian cells, such as DNMT3a and DNMT3b. These DNMT enzymes appear to be largely responsible for *de novo* methylation of DNA and not maintenance methylation. Although the data is not yet as decisive as it is for DNMT1, it appears that these enzymes are also inhibited by 5-aza-2′-deoxycytidine. Additionally, considering that the enzymatic mechanism of action for DNMT3a and 3b is very similar DNMT1, it is likely that these DNA methyltransferases are also targets of 5-aza-2′-deoxycytidine and 5-azacytidine. What role the inhibition of these enzymes plays in the therapeutic efficacy of the 5-aza-pyrimidines is yet unclear.

5-methylcytosine, in collaboration with other epigenetic marks, serves as a part of an epigenetic switch involved in the control of genome function. The precise control of these epigenetic switches are crucial to normal cellular differentiation and proper organism development, since they play functional roles in X chromosome inactivation, the regulation of tissue-restricted genes, gene imprinting, and chromosomal stability. Disruption of the epigenetic switches, reflected in changes to the normal levels and patterns of 5-methylcytosine, are mechanistically linked to human cancer, and have now been implicated in a number of other complex human diseases including diabetes, cardiovascular disease, autoimmune syndromes, and psychiatric and behavioral disorders.

The normal levels and patterns of 5-methylcytosine is non-random in the mammalian genome. In mammalian cells, 5-methylcytosine occurs only in cytosines found in the nucleotide doublet, 5′-CpG-3′. In general, normal levels and patterns of DNA methylation can be viewed as follows. It is estimated that 60–80% of CpG cytosines are methylated. High copy satellite sequences in pericentromeric heterochromatin are heavily or completely methylated. Other mid to high copy sequences such as ALU sequences, on average, are also heavily methylated. In most single copy genic and intergenic regions of the genome, CpG cytosines are variably methylated. Regions in which CpG cytosines are not methylated in normal genomes are ►CpG islands. CpG islands are areas of the genome that are relatively CpG-rich, having about a threefold overrepresentation of CpG dinucleotides when compared to the genome overall. CpG islands average about 1 kb in size, but can range from 200bp to greater than 10kb. CpG islands are often found in the 5′ end of genes and overlapping the transcription start site, and therefore are coincident with gene regulatory sequences. It has been estimated that 50% of human genes have CpG islands at their 5′ ends.

In cancer, the normal levels and patterns of DNA methylation are disrupted. Overall, there is a generalized DNA ►hypomethylation of the cancer genome when compared to its healthy counterpart. The relative hypomethyaltion is largely driven by a decrease in the levels of DNA methylation seen in high copy elements, such as satellite sequences. While the overall cancer genome becomes hypomethylated, some areas of the genome become aberrantly methylated or hypermethylated. The genomic targets of hypermethylation are frequently CpG islands, and thousands of these CpG islands can become hypermethylated during ►carcinogenesis. The aberrant methylation of these CpG islands is linked to the acquisition of a repressive chromatin state and the inappropriate silencing of the associated gene. Common and important CpG island targets of aberrant DNA methylation are those associated with genes that have tumor suppressor functions, including those involved in cell cycle control, DNA repair, invasion and metastasis, and apoptosis (►tumor suppressor genes). As such, aberrant DNA methylation of CpG islands is an epigenetic mechanism involved in gene inactivation, in much the same way that mutation and deletion are genetic mechanisms involved in gene inactivation in cancer, except that epigenetic inactivation can be a reversible process (►Epigenetic gene silencing).

The therapeutic activity of 5-aza-2′-deoxycytidine and 5-azacytidine is thought to involve their ability to reactivate these critical genes and restore their function. In support of this idea are a variety of studies that show genes associated with aberrantly methylated CpG islands do reactivate following treatment with the 5-aza-pyrimidines, albeit often not to gene expression levels seen in normal tissue counterparts. This gene reactivation is often linked to a demethylation of the associated CpG island, providing further support for an epigenetic mechanism of action of the 5-aza-pyrimidines. Indeed, successful clinical trials that tested 5-aza-2′-deoxycytidine and 5-azacytidine in patients with myelodysplastic syndrome also monitored and detected changes in the DNA methylation state of the CpG island promoter associated with the p15 tumor suppressor gene. Thus, basic epigenetic mechanisms of action operative *in vitro* now extend to the *in vivo* situation, as well.

While 5-aza-2′-deoxycytidine and 5-azacytidine have clear effects on DNA methylation, they may very well have multiple mechanisms of action, and there is experimental evidence to support this possibility. For example, 5-aza-2′-deoxycytidine can induce expression of genes lacking CpG methylation, such as p21WAF1, CDKN2D and APAF-1 and 5-azacytidine has also been shown to activate gene expression in an organism lacking DNA methylation). One alternative mechanism of action is reactivation of the tumor suppressor genes maspin and desmocollin-3 in breast cancer cell lines. In this case, gene reactivation was directly linked to significant decreases in a different repressive epigenetic modification – di-methylation of the K9 residue of histone H3. Indeed, not only did 5-aza-2′-deoxycytidine reduce H3 K9 di-methylation levels in the CpG island promoters of maspin and desmocollin-3, drug treatment also led to global decreases in H3 K9 di-methylation, as well as in the key enzyme responsible for this H3 K9 di-methylation, G9A (EHMT2).

In summary, contemporary research on 5-aza-2′-deoxycytidine and 5-azacytidine demonstrates that the future clinical utility of these compounds likely resides in their ability to alter the epigenetic landscape of diseased cells. This drug-induced change in the epigenetic landscape produces a transcriptional reprogramming of cells, and results in a variety of potential phenotypic outcomes that include, differentiation, loss of malignant properties, or even programmed cell death. Reversal of aberrant DNA methylation is clearly one epigenetic mechanism by which these 5-aza-pyrimidines produce this effect; however, recent work suggests that the reversal of other aberrant epigenetic marks may also participate in the cellular response.

Clinical Research

Renewed clinical interest in 5-aza-2′-deoxycytidine and 5-azacytidine grew out of results from phase I/II, II and III clinical trials in patients with myelodysplastic syndrome (MDS). These studies, conducted in the 1990s and early 2000s, emphasized low dose approaches that would more selectively target the epigenetic mechanisms of actions of 5-aza-2′-deoxycytidine

and 5-azacytidine, and are in stark contrast to the high dose approaches taken in the clinical trials of the 1970s that focused on standard cytotoxic activity. Using the low dose approach, multiple independent clinical groups largely obtained similar positive clinical results.

The common conclusions drawn from these clinical trials were that treatment of MDS patients with low doses of 5-aza-2′-deoxycytidine or 5-azacytidine resulted in significantly higher response rates, an improved quality of life for the patient, a decrease in leukemic transformation, and improved survival compared with the standard intervention, supportive care. Analysis of molecular markers of patients before and after treatment indicated that 5-aza-2′-deoxycytidine and 5-azacytidine could induce DNA demethylation both globally as well as at target loci. Clinical data also suggested that patients with "high risk" chromosomal abnormalities, in particular, might benefit from this treatment strategy.

There has been clear progress in the clinical use of 5-aza-2′-deoxycytidine and 5-azacytidine. Their use in MDS produces hematologic improvement in about 50% of patients and results in an improvement in the quality of life. Unfortunately, complete and partial responses occur in only about 20% of patients and the duration of response remains under two years. Taken together these results indicate the clinical story of 5-aza-2′-deoxycytidine and 5-azacytidine is incomplete. Current efforts to improve their therapeutic efficacy include dose optimization based on their ability to modulate epigenetic markers of disease; identification of patients who may be more likely to benefit due to their molecular profile; and combining 5-aza-2′-deoxycytidine and 5-azacytidine with other epigenetic modifiers, such as histone deacetylase inhibitors (►histone deacetylases). Other strategies considered involve a general debulking of the tumor with cytotoxic agents followed by low dose 5-aza-2′-deoxycytidine or 5-azacytidine in an effort to drive differentiation of the remaining tumor cells to a nonmalignant state. It is likely that an increasingly detailed molecular dissection of clinical responders and non-responders will help investigators better understand the mechanisms governing response, and aid in the further development of therapeutic agents that target the epigenetic landscape.

Aza-epothilone B

►Epothilone B Analogue

Azathioprine

Definition

Is a potent immunosuppressive drug that is converted to its active form in vivo and then kills rapidly proliferating cells, including lymphocytes responding to grafted tissues.

►Sjögren Syndrome

Aziridine

Definition

Reactive three sided organic molecule (C_2H_5N).

►Mitomycin C

Azoxymethane

Definition

A widely used synthetic carcinogen for inducing colon cancer in laboratory animals.

►Sulforaphane
►Conjugated Linolenic Acids

B Cell

Definition

A B cell, or B lymphocyte, is one of the two major types of lymphocytes. The antigen receptor on B lymphocytes, usually called the B-cell receptor, is a cell-surface immunoglobulin. On activation by antigen, B-cells differentiate into cells producing antibody molecules of the same antigen specificity as this receptor. B Cells play a major role in the body's response to foreign materials (viruses, bacteria, parasites, etc) by generating antibodies to fight these intruders.

►Fluoxetine

B-1 Cells

Definition

B-1 cells, also known as CD5 B cells, are a class of atypical, self-renewing B cells found mainly in the peritoneal and pleural cavities in adults. They have a far less diverse repertoire of receptors than do B-2 cells (also known as conventional B cells), which are generated in the bone marrow throughout life, emerging to populate the blood and lymphoid tissues.

►Sjögren Syndrome
►Omental Immune Aggregates

B7 Molecules

Definition

The major T-cell costimulatory molecules are the B7 molecules, B7.1 (CD80) and B7.2 (CD86). They are closely related members of the immunoglobulin gene superfamily and both bind to the CD28 molecule on T cells. They are expressed differentially on various antigen-presenting cell types.

►Sjögren Syndrome

B Symptoms

Definition

Constitutional symptoms consisting of fever >38°C, night sweats and/or unintentional weight loss of >10% the body weight over a period of up to 6 months. B symptoms are relevant in non-Hodgkin lymphoma and Hodgkin lymphoma staging and are related to tumor burden and prognosis.

►Diffuse Large B-Cell Lymphoma

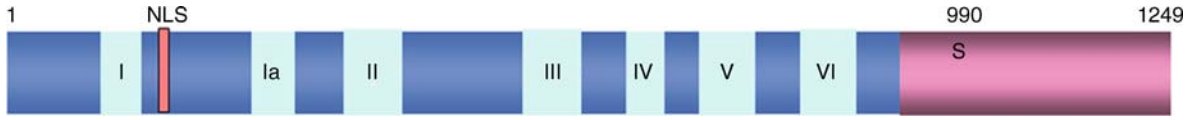
BACH1 Helicase

Sharon Cantor, Jenny Xie
Cancer Biology, UMASS Medical School, Worcester, MA, USA

Synonyms

BRIP1; FANCJ



BACH1 Helicase. Figure 1 Schematic representation of BACH1. BACH1 is composed of 7 helicase domains (light blue) which is characteristic of the DEAH helicase, and its interaction with BRCA1 depends on the ►phosphorylation status of a serine residue (S) situated at the carboxy-terminal 990 position.

Definition

The ►BRCA1 associated Carboxy (C)-terminal helicase (BACH1) (Fig. 1) gene encodes a 1249 amino acid nuclear protein that is characteristic of the DEAH family of DNA helicases. BACH1 is an ATP dependent DNA helicase that catalyzes the destabilization of hydrogen bonds between complementary nucleic acids. The C-terminal region of BACH1, including a phosphorylated serine 990 residue, interacts directly with the C-terminal BRCT repeats of BRCA1. In addition, BACH1 also participates in the ►Fanconi anemia (FA) ►DNA damage response pathway as it was identified as the FA gene product, FANCJ.

Characteristics

BACH1 and Hereditary Breast Cancer

Breast cancer afflicts over 200,000 individuals each year, and is the leading cause of cancer death among US women with cumulative lifetime risk of one in nine. Hereditary breast cancer account for approximately 10% of all breast cancer, making it the most commonly inherited cancer in the US. Germline mutations in the Breast Cancer Associated genes *BRCA1* and *BRCA2* account for ~30–40% of these cases. Thus, research has focused on understanding how the BRCA gene products function to support normal cell growth and ultimately suppress tumor formation.

BACH1 was Identified by its Direct Interaction with BRCA1

BRCA1 is a nuclear phosphoprotein with an amino (N)-terminal zinc finger domain and C-terminal BRCT (*BR*CA1 *C*-Terminal) repeats. The integrity of the BRCT repeats is critical for BRCA1-mediated DNA damage response. BRCT region missense and deletion mutations disrupt the BRCA1 DNA damage repair function and are also associated with cancer predisposition. Thus, the integrity of the BRCT region is linked to BRCA1 tumor suppression. Consistent with this role, the BRCA1-BRCT repeats are highly conserved and are also present in other proteins involved in the DNA damage response. The BRCT repeats in BRCA1 and other proteins have been shown to bind phosphopeptides. In fact, the BRCA1-BRCT repeats bind directly to BACH1 when a phosphoserine residue (pSer990) at the C-terminal of BACH1 is phosphorylated.

BACH1 is Mutated in Hereditary Breast Cancer Patients

Due to the direct interaction between BRCA1 and BACH1, it was hypothesized that, like BRCA1, BACH1 may also function to suppress breast cancer development. Consistent with this hypothesis, early genetic screens identified two early-onset breast cancer patients with BACH1 germline mutations. Further analysis of these mutations *in vitro*, revealed that these sequence changes resulted in defective BACH1 protein disrupting the helicase activity. Recently BACH1 truncating mutations were identified in 9 out of 1212 breast cancer patients, whereas, similar mutations were only presented in 2 out of 2018 healthy individuals. Overall, these data suggested that BACH1 mutations conferred a two-fold risk in the development of breast cancer.

BACH1 is Important for Mediating the DNA Damage Response

The BRCA1/BACH1 interaction suggests that BACH1 likely contributes to BRCA1 DNA repair functions. BACH1 similar to BRCA1, following DNA damage is modified by phosphorylation, displays a BRCA1-like nuclear foci pattern and co-localizes with ►gamma (γ)-H2AX. The BACH1/BRCA1 complex is unaltered by DNA damage, but both proteins contribute to the localization of each other to DNA damage foci. In the absence of BRCA1, BACH1 fails to localize to site of DNA damage. While BACH1 is not required for BRCA1 localization to sites of DNA damage, the intensity of BRCA1 foci is diminished in BACH1 deficient cells. Furthermore, this interaction has been shown to be required for activation of the ionizing radiation (IR)–induced ►G2/M checkpoint. Cell cycle analysis revealed a G2/M checkpoint defect in BACH1 siRNA expressing HeLa cells that was corrected by expression of wild-type BACH1, but not with the S990A version of BACH1 disrupted for BRCA1 binding. BACH1 depleted cells also exhibit an elevated S-phase accumulation compared to control cells after treatment with low dose of aphidicolin, which is known to activate the intra ►S-phase checkpoint. BACH1's role in intra S-phase checkpoint was further validated when BACH1-deficient cells showed ►radioresistant DNA synthesis (RDS).

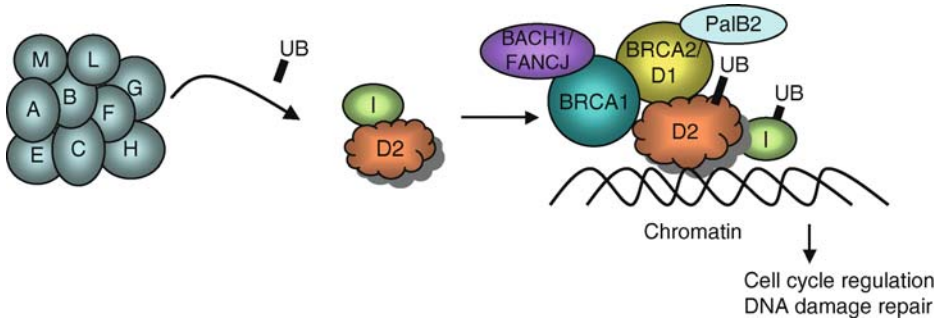
BACH1 is Required for DSBR

As part of the DNA damage response, BACH1 is required for the repair of ►DNA double strand breaks (DSBs). The contribution of BACH1 to double stranded break repair (DSBR) was first apparent through the observation that BRCA1 clinical mutations that disrupted its interaction with BACH1 also resulted in defective DNA damage repair. In addition, overexpression of a helicase inactive version of BACH1 (K52R) displayed a marked delay in repair, as shown by an increase in the level of unrepaired breaks detectable after IR. This repair delay was dependent on BACH1 binding to BRCA1 suggesting that the K52R BACH1 functions as a dominant negative to perturb DSBR in a BRCA1 dependent manner.

Moreover, similar to BRCA1, BACH1 promotes the repair of DSBs by promoting ►Rad51-dependent ►homologous recombination (HR). Specifically, BACH1's role in HR was examined using mammalian cell based homology directed repair assay, where it was found that suppression of either BRCA1 or BACH1 disrupted HR to a similar degree. In support of a role for BACH1 in HR, BACH1 is able to unwind D-loop recombination intermediates in vitro. Since BACH1 does not unwind holiday junction intermediates similar to other DNA repair helicases, such as Bloom syndrome (BLM) and Werner syndrome (WRN), BACH1 most likely has a distinct HR function. The D-loop is the initial structure formed in recombination when the Rad51 nucleoprotein filament invades the duplex DNA in search of homologous repair-template. Thus, Rad51 focal accumulation has been speculated to represent the development of these HR intermediates. Although suppression of either BRCA1 or BACH1 protein results in defective HR, one difference observed between BRCA1 and BACH1 deficient cells was the visualization of Rad51 foci following DNA damage. Rad51 foci formation in BRCA1 suppressed cells is dramatically reduced compares to control cells. However, BACH1 suppressed cells retain robust Rad51 foci. The unaltered presence of Rad51 foci, but reduced HR in BACH1-deficient cells suggests that some form of Rad51 based recombination is active. One possibility is that BRCA1 functions upstream of Rad51 and BACH1 functions downstream of BRCA1. Alternatively, it was proposed that BRCA1 regulates BACH1 helicase activity in a manner that regulates Rad51 foci formation. In this model, it was proposed that in the absence of BRCA1, BACH1 helicase activity would be unregulated and disrupting of Rad51 foci due to perpetual unwinding of recombination intermediates.

BACH1 and Fanconi Anemia

FA is a recessive disorder, in which, FA patients are characterized by congenital abnormalities, bone marrow failure, and predisposition to leukemia and solid tumors. FA is a multigenic disorder and to date, there are 12 FA complementation groups FA-A, -B, -C, -D1, -D2, -E, -F, -G, -I, -J, -L, -M (Fig. 2). Germline mutations in the BACH1 gene were identified in patients from the FA-J complementation group. FA-J cells, similar to other FA cells, exhibit chromosome abnormality and hypersensitivity to DNA interstrand crosslinking agents such as mitomycin C and cisplatin. Most likely FA proteins are critical for processing crosslinked DNA. In the absence of processing, ►interstrand cross links (ICLs) are extremely deleterious because DNA strands are covalently tethered, which can block DNA replication and compromise cell viability. Consistent with a role for the FA proteins in this process, cellular exposure to ICLs activates the FA core complex (FANCA, -B, -C, -E, -F, -G, -L and -M) and promotes the ►monoubiquitination of the effector protein, FANCD2. Activated FANCD2 translocates into chromatin and forms nuclear foci that co-localizes with BRCA1, BRCA2/FANCD1 and BACH1/FANCJ. Activation of the FA pathway through monoubiquitination of FANCD2 and FA protein relocalization are essential for coordinating the



BACH1 Helicase. Figure 2 The FA pathway is composed of 12 FA complementation groups, with the central feature being the monoubiquitination of FANCD2 in response to DNA damage. Activated FANCD2 translocates to chromatin associated foci where it localizes with BACH1/FANCJ, BRCA1 and BRCA2/FANCD1 to promote cell cycle regulation and DNA damage repair.

ICL repair response. BACH1/FANCJ is considered downstream of the FANCD2, since it is not required for FANCD2 monoubiquitination. The FA proteins, BRCA2/FANCD1 and the newly identified PALB2 proteins are also downstream of FANCD2. While the role of BACH1/FANCJ in the FA pathway is not yet clear, its helicase activity, but not BRCA1 binding activity appears to be essential to correct the ICL-response in chicken and patient cells.

Bacillus Calmette-Guérin

Sven Brandau
Department of Otorhinolaryngology, University Duisburg-Essen, Essen, Germany

Synonyms

Mycobacterium bovis BCG; BCG

Definition

Bacillus Calmette-Guérin (►BCG) is a ►mycobacterium belonging to the Mycobacterium tuberculosis complex. It is a live attenuated organism and generally nonpathogenic for healthy human subjects. Originally developed as a vaccine against tuberculosis, since the mid 1970's it is increasingly used as a successful active immunotherapeutic agent in the treatment of nonmuscle invasive ►bladder cancer.

Characteristics

Microbiological Background on BCG and Tuberculosis Vaccination

BCG is an attenuated derivative of virulent *Mycobacterium bovis* (*M. bovis*), the causative pathogen of bovine tuberculosis. The name of BCG acknowledges the contributions of two French researchers Albert Calmette, a microbiologist, and Jean-Marie Camille Guérin, a veterinarian. Those two, between 1908 and 1921, passaged a virulent strain of *M. bovis* in an attempt to generate a vaccine against tuberculosis in humans. By using a continuous in vitro passage and a special bile-glycero-potato culture medium they succeeded in generating a nonvirulent mycobacterial strain that did no longer cause disease in experimental rodent animals. Shortly after these observations the vaccine was first applied to human subjects as a vaccine against tuberculosis. Although controversial since its first use, the vaccine has now been administered to over 3 billion people world-wide with an excellent safety profile. In spite of BCG's efficacy as a preventive vaccine in general, its highly variable efficacy in preventing pulmonary tuberculosis in adults (with some studies showing no protection at all) remains a major challenge.

The original live BCG vaccine required continuous culture and was spread over various continents for clinical application. By the time lyophilization was available as a method to preserve viable mycobacteria, several substrains of the original strain were created which are collectively known as BCG. Characteristic for BCG is its relatively slow growth in in vitro culture with doubling times between 8 and 36 h depending on the strain and the respective culture conditions. Modern molecular biological analyses are now used to follow the "in vitro evolution" of BCG vaccines. Although the genetic basis for BCGs attenuation has not yet been fully elucidated, several regions of genetic difference between virulent *M. tuberculosis* and BCG have been identified and characterized.

Today, for use in cancer ►immunotherapy, several substrains of BCG mycobacteria are available as freeze-dried lyophilisates with a guaranteed amount of viable bacilli at the end of the shelf-live, which usually exceeds 1 year. Easy clinical use is facilitated by the availability of aliquots pretitrated for one single instillation and delivered together with the respective dilution buffer.

BCG in Cancer Immunotherapy

At the end of the nineteenth century, the American Surgeon W. E. Coley observed occasional remissions of lymphosarcomas following local and/or systemic bacterial infections. Based on these observations, he used bacterial extracts for the adjuvant treatment of cancers of the head and neck which have become known as Coley toxin. Furthermore, it was noted that patients with tuberculosis rarely developed malignant neoplasms. These observations stimulated investigators to further explore the potential use of BCG for various anticancer applications.

In 1976, Morales et al. combined this experience and investigated a new form of application for BCG. They developed a schedule for the effective adjuvant intravesical treatment of nonmuscle invasive bladder tumors following transurethral resection (TUR) with BCG. Since that time, adjuvant BCG-immunotherapy for bladder cancer has remained largely unmodified. Additionally, a large number of prospective controlled phase III trials were published confirming the efficacy of BCG and strengthening its role in uro-oncology. Today, an estimated number of 1 million annual BCG treatments are given to cancer patients.

According to recent metaanalyses of published randomized clinical trials, the following conclusions can be drawn from these trials: (i) patients after TUR in combination with adjuvant BCG will suffer from less recurrences as compared to TUR alone, (ii) BCG-immunotherapy is superior to intravesical chemotherapy for the reduction of bladder cancer recurrences, and (iii) BCG is the only treatment option for preventing and/or delaying bladder cancer progression to muscle invasive disease.

BCG-immunotherapy is first applied at 1–3 weeks following complete TUR of the primary tumors. It consists of a 6-week induction cycle including weekly intravesical instillations of about 81 mg BCG reconstituted in 50 ml saline corresponding to $1–5 \times 10^8$ ►colony-forming unit (►CFU) viable mycobacteria. Retention of the BCG mycobacteria in the urinary bladder for not less than 2 h is recommended to ensure sufficient immunostimulation. While the efficacy of various BCG strains has never been compared in prospective trials, data from a recent metaanalysis suggest that at least the five most commonly used strains Tice, Pasteur, Connaught, RIVM and A. Frappier do not differ in terms of preventing tumor progression. Contraindications against the intravesical use of BCG are given in patients with a compromised immune status, active tuberculosis, acute urinary tract infections, lesions in the lower urinary tract, fever of unknown origin, a history of radiotherapy to the bladder and/or pelvis, and during pregnancy or active nursing.

Recent clinical approaches aimed at improving BCG efficacy by addition of a so-called maintenance therapy schedule. BCG maintenance consists of three intravesical instillations given in weekly intervals at 3, 6, 12, 18, 24, 30, and 36 months after initiation of the induction cycle. Initial data suggest that this modified treatment protocol provides additional benefit for preventing tumor recurrence and progression.

In addition to the current success in bladder cancer, historically, BCG has been used as an anticancer agent in a variety of other cancer types including ►melanoma and lung cancer among many others. However, in most cases these treatment regimens have not become standard clinical practice. With the identification of ►toll-like receptor agonist structures present on the BCG surface, an immunological rationale for the well known ►adjuvant effect of BCG has now emerged. Currently, a variety of approaches are trying to utilize the immunostimulatory effect of BCG and its subcomponents as additives in autologous tumor vaccines.

Mode of Action in Antitumor Activity

When BCG was first used in clinical practice more than 30 years ago, its mode of action has been far from understood. Progress in the fields of infection biology, ►innate immunity, and tumor immunology has set the stage for a better understanding of the mechanism of BCG's antitumor activity. Mechanistic and descriptive studies in vitro, in rodent bladder cancer models and with patient material have provided a clear picture of the processes leading from instillation of mycobacteria into the bladder lumen to antitumor effects.

Based on in vitro studies initial data have suggested a direct antiproliferative, cytotoxic, or proapoptotic effect of BCG on tumor cells. While this effect can certainly be demonstrated in vitro, mechanistic studies in rodent models now provide convinving evidence that a functional immune system of the tumor-bearing host is absolutely essential for most of BCGs antitumor activity in vivo.

BCG mycobacteria have a characteristic outer cell-wall consisting of various complex structural biomolecules. Microbiologists, biochemists, and immunologists have identified and characterized the interaction of a variety of those biomolecules with their respective-receptors on target cells of the host. Collectively, immunologically active parts of those molecules are today referred to as ►pathogen-associated molecular patterns (PAMP). Those PAMPs on the mycobacterial surface are biochemically quite diverse and, for example, include peptidoglycan, mycolic acids, lipomannan, and lipoarabinomannan. Although the role of the mycobacterial surface molecules is better defined in infection biology, it can be assumed that initial contact to primary host target cells in physiologic mycobacterial infection and in instillation immunotherapy is mediated by similar mechanisms.

In BCG-immunotherapy of bladder cancer the vast majority of the original instillation dose of several hundred million of mycobacteria will be washed out with the first postoperative micturition. The remaining mycobacteria will adhere to the bladder wall. This contact will lead to an activation of epithelial cells in the bladder, which can respond with the release of immunologically active mediators such as ►cytokines-like interleukin-(IL-)8, IL-6, and IL-1. Within days after instillation BCG initiates a complex inflammatory cascade in the bladder wall resulting in the enhanced production of a vast array of cytokines and ►chemokines. Most of these cytokines and chemokines

are proinflammatory or promoting a so-called ►T-helper 1 (Th1) response associated with the induction of cell-mediated immunity. Animal experiments have shown that this Th1 response is essential for induction of protective antitumor immunity. The local inflammatory response (►inflammation) in the bladder tissue consists of different phases and changes in the cellular composition of the bladder wall become apparent already a few hours after instillation and can last for up to several month in human patients. A large number of studies have analyzed the cellular immune response (►Th1 response) induced by BCG in immunotherapy of bladder cancer. Collectively, these studies suggest the following scenario: In an immediate and early inflammatory phase, the cellular infiltration of the bladder wall is dominated by ►neutrophil granulocytes (Neutrophils) known to the immunologist as prototypic inflammatory cells. This neutrophilic infiltration is characteristic for the early postinstillation urine and the cellular composition of the urine early after instillation is dominated by more than 90% granulocytes. Polymorphonuclear neutrophil granulocytes (PNG; PMN) then direct in a second phase the subsequent influx of mononuclear cells including macrophages, T cells, and NK cells by mechanisms which are only beginning to emerge. The complex interplay of these immunocompetent cells mediates potent antitumor effects and mechanistic studies have shown that concurrent activation of different effector cell populations is required for full therapeutic efficacy. In a third chronic inflammatory phase, granuloma-like structures of cellular infiltration can persist for up to several month possibly representing a long-lasting immunostimulatory event.

Inspired by the plethora of immune mediators induced during BCG–immunotherapy, researchers have tried to identify a prognostic immunologic marker which could be used to predict a clinical response to this type of immunotherapy. However, until now no definite prognostic immunologic marker has been identified, although certain good candidates (e.g., IL-2) do exist and will be further explored in the future.

Bacteriophage

Definition

A bacteriophage is a virus that infects bacteria.

►Phage Display

Bacteriophage Display

►Phage Display

Baculoviral IAP-repeat Containing Protein 5

►Survivin

Baculovirus

Definition

Is a pathogen that attacks insects and other arthropods. Like some human viruses, they are usually extremely small (less than a thousandth of a millimeter across), and are composed primarily of double-stranded DNA that codes for genes needed for virus establishment and reproduction.

BAD

Definition

Is a Bcl-2 antagonist of ►apoptosis/death, a pro-apoptotic member of the Bcl-2 family of proteins. It is a 18 kD protein that binds to Bcl-xL and Bcl-2. It competes out the binding of Bcl-xL and Bcl-2 to Bax, thus promoting apoptosis.

BAF47

►hSNF5/INI1/SMARCB1 Tumor Suppressor Gene

Bak

Definition

Bcl2-antagonist/killer 1, a member of Bcl-2 protein family. Bak functions in a similar manner as Bax to induce ►apoptosis.

►PUMA (p53 Upregulated Modulator of Apoptosis)

BAK1

Definition

synonym: Bak-1, Is a Bcl-2 antagonist/killer-1, a pro-apoptotic member of the Bcl-2 family of proteins. It is a 23 kD protein that binds to and antagonizes Bcl-2. It also forms heterodimers with anti-apoptotic Bcl-xL and binds to adenovirus E1b19k.

►Apoptosis

BALT

Definition

The lymphoid cells and organized lymphoid tissue in the respiratory tract are termed the bronchial-associated lymphoid tissues (BALT). These tissues are very important in the induction of immune responses to inhaled antigens and to respiratory infection.

►Sjögren Syndrome

Bannayan-Riley-Ruvalcaba Syndrome

Definition

Is a rare inherited disorder characterized by excessive growth before and after birth; an abnormally large head (macrocephaly) that is often long and narrow (scaphocephaly); normal intelligence or mild mental retardation; and/or benign tumor-like growths (hamartomas) that, in most cases, occur below the surface of the skin (subcutaneously). The symptoms of this disorder vary greatly from case to case. Additional abnormalities associated with this disorder may include abnormal skin coloration (pigmentation) such as areas of skin that may appear "marbled" (cutis marmorata) and/or the development of freckle-like spots (pigmented macules) on the penis in males or the vulva in females. In some cases, affected individuals may also have skeletal abnormalities and/or abnormalities affecting the muscles (myopathy). Bannayan-Riley-Ruvalcaba syndrome is inherited as an autosomal dominant genetic trait. Bannayan-Riley-Ruvalcaba is the name used to denote the combination of three conditions formerly recognized as separate disorders. These disorders are Bannayan-Zonana syndrome, Riley-Smith syndrome, and Ruvalcaba-Myhre-Smith syndrome.

BAR Domain

Definition

Banana-shaped domain seen in adapter proteins that bind and tubulate cellular membranes during the dynamic processes of endocytosis, vesicle trafficking, organelle fission, and specialized membrane formation events (e.g. muscle T tubules). BAR domains also bind small GTPases and their regulators as well as phosphatidylinositol lipid binding proteins.

►Bin1

BARD1

Irmgard Irminger-Finger
Molecular Gynecology and Obstetrics Laboratory, Department of Gynecology and Obstetrics, Geneva University Hospitals, Geneva, Switzerland

Synonyms

BRCA1-associated Ring domain (gene/protein) 1

Definition

BARD1 codes for a protein that forms a functional heterodimer with the breast cancer predisposition gene product ►BRCA1. This BRCA1–BARD1 complex has ►ubiquitin ligase activity, but not the respective monomers. The specific targets of the BRCA1–BARD1 ubiquitin ligase relate to the tumor suppressor functions of BARD1 and BRCA1. ►BRCA1-independent functions are attributed to BARD1, based on its role as inducer of ►p53-dependent apoptosis.

Characteristics

The tumor suppressor BARD1 was originally identified as a protein binding to the BRCA1 gene product, BRCA1. BRCA1 depends on binding to BARD1 for most of its tumor suppressor functions mostly through the ubiquitin ligase activity of the BRCA1–BARD1 heterodimer. This is presumably due to the fact that the stability of both proteins depends on their interaction via their N-terminal ►RING finger domains.

BARD1 Structure, Conservation, and Expression

BARD1 is a RING finger protein, like BRCA1, and both have ►BRCT domains at their C-terminus. *BARD1* genes have been found in several species: mouse, rat, *Xenopus*, *C. elegans*, and a database entry is found for the tropical fish *Takifugu rubripes*. While the N-terminal RING finger and the BRCT domains of BARD1 are evolutionary conserved with at least 90% identity of amino acids, the regions between these structures show only little conservation (Fig. 1). In addition to these two conserved domains, BARD1 possesses ►ankyrin (ANK) repeats that are found in proteins of diverse functions. Besides similar structure, BARD1 has several features in common with BRCA1: embryonic lethality of knock out in animal models, and genetic instability in cellular model systems of BARD1 or BRCA1 depletion.

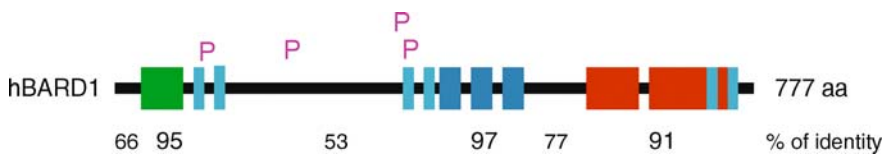
BARD1 is composed of 11 exons. First observation of ►alternate splice variants was BARD1β in pre-leptotene ►spermatocytes, while the wild-type form of BARD1 was expressed in ►spermatogonia. An isoform BARD1δ, derived form ►differential splicing, was found in a rat ovarian cancer cell line and in HeLa cells.

BARD1 mRNA expression was found in most proliferative tissues, mostly parallel with the expression pattern of BRCA1. However, in hormonally regulated tissues BARD1 expression was different from BRCA1. Further evidence for hormonally controlled expression of BARD1 was found in ►spermatogenesis. BARD1 expression is also induced by hypoxia.

Functions of the BARD1–BRCA1 Heterodimer

BARD1 and BRCA1 interact with a number of proteins involved in various functions, most cited are ►homologous repair and ubiquitin ligase activity. Dissection of repair pathways showed that the BRCA1–BARD1 heterodimer has a role in homologous repair before the branch point of HDR (homology derived repair) and SSA (single strand annealing).

The RING finger domains of BARD1 and BRCA1 are required for ubiquitin ligase functions, and missense mutations in the BRCA1 RING finger that abrogate this ubiquitin E3 ligase function, are found in breast and ovarian cancer, suggesting that the ubiquitin ligase activity is linked to tumor suppressor functions. Specifically, BARD1 protein residues 8-142 could enhance ubiquitin ligase activity of BRCA1. The results of mutagenesis studies indicate that the enhancement of BRCA1 E3 ligase activity by BARD1 depends on direct interaction between BARD1 and BRCA1. Across its ubiquitin ligase activity, the BRCA1–BARD1 heterodimer controls cell cycle progression and exerts tumor suppressor functions. BARD1–BRCA1 might also regulate cell cycle progression by interacting with another potential target for ubiquitinations, PolI, or the ►nucleolar protein nucleophosmin/B23 (NMP).



BARD1. Figure 1 Human BARD1 domain structure. RING (green), ANK (blue), and BRCT (red) domains are indicated and location of potential NLS (light blue) and phosphorylation sites (P). Evolutionary conservation is indicated as percentage of identical amino acids between human and mouse BARD1 sequences within distinct regions.

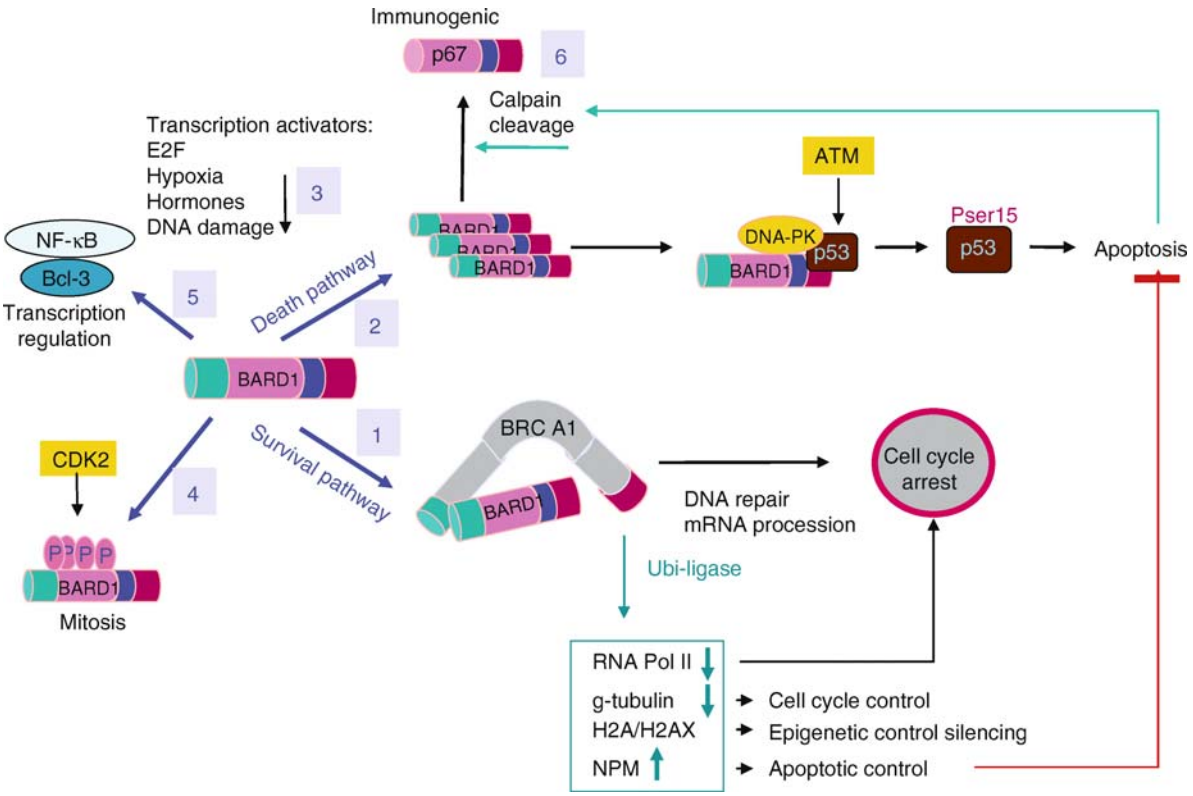
A function in regulation of transcription is exerted via BARD1 binding to the ►Bcl-3 oncoprotein, which acts as a bridging factor between ►NF-κB/Rel and nuclear coregulators. The functional interaction of BARD1 with polyadenylation factor ►CstF-50, provides another possible regulatory mechanism by linking ►mRNA 3′ end formation to DNA damage and tumor suppression.

BRCA1-Indendent Tumor Suppressor Function of BARD1

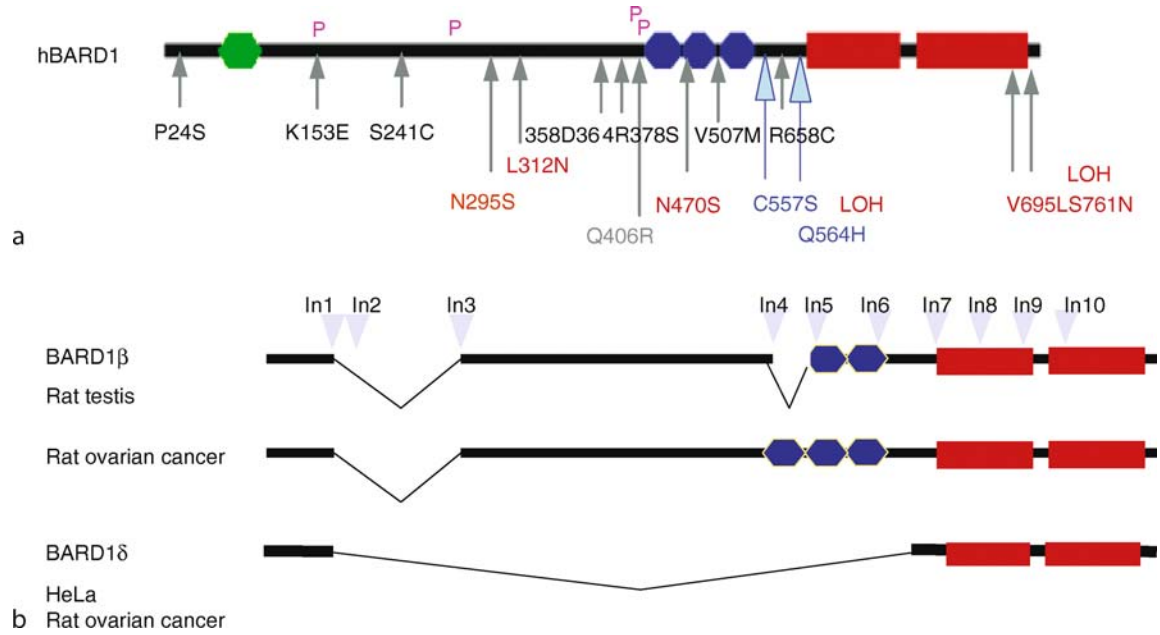
Independently of BRCA1, BARD1 acts in an ►apoptosis pathway by binding and stabilizing ►p53. The mechanism of p53-dependent apoptosis, induced by BARD1, is based on BARD1 binding to the ►Ku-70 subunit of ►DNA-PK and to p53 thus facilitating or catalyzing the phosphorylation of p53 on serine 15. This phosphorylation is required for stabilization of p53 and for initiation of apoptosis. An excess of BARD1 over BRCA1 can induce apoptosis and binding to BRCA1 inhibits BARD1 apoptotic function. Upregulation of BARD1 expression can be induced by various types of cellular stress.

BARD1 deletions that lack the RING finger domain are stable, suggesting that the RING finger is targeting BARD1 for degradation, and proteolytic cleavage of the RING finger leads to the apoptosis pathway. During apoptosis BARD1 (97 kDa) translocates to the cytoplasm where it is cleaved to become the more stable p67, and consistently the apoptotic function of BARD1 was mapped to a region within p67, including ANK, the regions between ANK and BRCT, and part of BRCT.

Therefore BARD1 acts as a cellular switch from repair mode with BRCA1 and moderate BARD1 levels to apoptosis without BRCA1 and excessive BARD1 levels (Fig. 2).



BARD1. Figure 2 Major BARD1 and BRCA1–BARD1 pathways and functions. BARD1 participates in several pathways: (1) survival pathway as BRCA1BARD1 heterodimer and (2) death pathway in a BRCA1-independent function in apoptosis. BRCA1–BARD1 acts in survival pathway. BRCA1–BARD1 ubiquitin ligase activity leads to RNAPolII degradation and cell cycle arrest, to γ-tubulin degradation and regulation of centromere duplication, to H2A/H2AX ubiquitylation and epigenetic control, and to NPB ubiquitylation. Upregulated NPB is a known inhibitor of apoptosis, it causes centromere amplification and genetic instability; hence NPM antagonizes BARD1 functions. (3) BARD1 is transcriptionally upregulated by different conditions, (4) is modified upon apoptosis by phosphorylation, (5) and can modulate NF-kb function. The proteolytic cleavage product p67 is immunogenic and has antitumorigenic properties (6).



BARD1. Figure 3 BARD1 mutations and isoforms. (a) Schematic drawing of BARD1 protein structure with RING (green), ANK (blue), BRCT (red) motifs indicated. Phosphorylation sites are marked with P. Mutations are marked in red and polymorphisms in black underneath. The Q406R mutation was found recently in ovarian cancer. (b) Splice variants found for *BARD1*: BARD1β in preleptotene spermatocytes, BARD1δ in ovarian cancer cell line and in HeLa cells. The N-terminal exons 1–5 were frequently lost in ovarian and ovarian cancer cells cancer, as shown by immunohistochemistry and RT-PCR.

BARD1 in Mitosis

A role of BARD1 in mitosis was suspected, since BARD1 protein levels are increased in mitosis. Mice deficient for BARD1 are embryonic lethal, and embryos die at day 8 of embryonic development due to deficient proliferation. A novel function of BARD1–BRCA1 in mitosis implies interaction with the ►Ran-GTPase and provides an explanation for the genetic instability and lethality observed in BARD1 repressed cells and embryos.

Clinical Relevance

BARD1 Mutations in Cancer

Interestingly, mutations in *BRCA1* occur all over the protein-coding region, leading to truncated presumably unstable proteins. Missense mutations are mostly found in the RING finger and disrupt the BRCA1–BARD1 interaction, suggesting that the BRCA1 function is linked to the function of the BARD1–BRCA1 heterodimer. On the contrary, mutations in BARD1 are found mostly around the ANK repeats, the BRCT domains and the region in between these domains (Fig. 3). This C-terminal region has been shown to be stable in the absence of BRCA1 and to play a role in apoptosis, which suggests that BARD1 has tumor suppressor functions independently of BRCA1.

Considering the multiple functions of *BARD1* as tumor suppressor, it is expected that its functions might be lost or abrogated in cancer cells. Surprisingly, in human breast and ovarian tumors, elevated expression and mislocalization to the cytoplasm of BARD1 was found, as compared to the healthy tissue. Most samples showed 5′ truncations and the upregulation of BARD1 isoform expression in cancer was correlated with poor prognosis.

Basal Cell Carcinoma

Jorge R. Toro[1], Rasha S. Hamouda[2], Sherri Bale[2]
[1]National Institutes of Health, Bethesda, MD, USA
[2]GeneDx, Rockville, MD, USA

Definition

Non-melanoma skin cancers are the most common malignant neoplasms in the United States, representing one third of all cancers diagnosed every year. Basal cell carcinoma (BCC) represents 75% of non-melanoma skin cancers and has an estimated annual incidence of more than 700,000 cases in the United States outnumbering ►squamous cell carcinoma (SCC) 4–1. Over half a million BCCs are diagnosed in the United States annually, outnumbering squamous cell carcinoma (SCC) 4–1. The US average annual incidence of BCC in whites is currently 191 per 100,000 and is increasing at a rate of 3–7% per year. The peak incidence of BCC occurs in the seventh decade of life and is rare in children.

Characteristics

Basal cell carcinoma has multiple distinctive clinical forms, and these clinical subtypes can often be correlated with histologic subtypes. BCC is protean in its manifestations. For this reason, biopsy for histologic confirmation is necessary. The various clinical forms of BCC include nodular, morpheaform and superficial. Nodular BCC is the most frequent form of BCC. It usually presents as a waxy, pearly or translucent papule/nodule with overlying fine telangiectasias, with frequent ulceration or erosion of the surface. BCCs may occasionally be pigmented to varying degrees. Superficial BCCs most commonly arise on the trunk and extremities, but may be seen anywhere on the body. The tumors are characterized by an erythematous macule or patch, which may be variably pigmented. There may also be an overlying fine scale, a superficial erosion or hemorrhagic scale crust. Superficial BCC is the variant most frequently seen in chronic arsenism and as late sequelae of radiation therapy. Individuals may have broad areas of superficial BCC that are multiple and disconnected. Morpheaform or sclerosing has a scar-like appearance. It consists of a dermal plaque with overlying epidermal atrophy in a sun-exposed distribution. As with infiltrative BCC, subclinical extension is often great and treatment failures frequent.

Risk Factors and Therapy

Location, histologic subtype, clinical characteristics and size are predictive factors for the biologic behavior of BCCs. The typically indolent growth pattern of BCC accounts for the resistance and fusion planes of the central facial zone being a more significant determinant of subclinical extension. Size is also a good predictor of high risk BCCs. Cure rates with ►Mohs micrographic surgery (MMS) decreases as tumor size increases. A cure rate of 99.8% for tumors less than 2 cm in diameter, 98.6% for tumors between 2 and 3 cm and 90.5% for tumors greater than 3 cm has been reported.

Micronodular, infiltrative and ►morpheaform BCCs have a much higher incidence of positive surgical margins after surgical excision (18.6–33.3%) as compared with tumors with a nodular or superficial histologic pattern. Morpheaform BCCs may have significant subclinical extent, with the average subclinical extension being 7.2 mm. Similarly, significant subclinical extension in infiltrative BCC has been noted. BCC with marked squamous differentiation has been determined to be a more virulent tumor (a local recurrence rate of 45.7% and metastatic incidence 8.6% of 35 such tumors as compared to rates of 24.2%/0.09% for BCC). As with SCC, the perineural space can serve as a conduit for significant subclinical tumor extension.

Although BCC is rarely life threatening its capacity for local tissue destruction can result in significant functional or cosmetic morbidity. Untreated or inadequately treated BCCs have an insidious growth pattern and may result in death. ►Metastasis from BCC is a rare event, with estimates of metastatic incidence ranging from 0.0028% to 0.1%. Metastasis is associated with the metatypical (basosquamous) BCC and with duration and size of the lesion. The most frequent site of

metastasis is the lungs, followed by bone, lymph nodes, and liver. For these reasons, great importance is attached to the early diagnosis and treatment of this malignancy.

BCC is related to chronic ultraviolet radiation (►UV radiation) exposure. UVR exposure is partly responsible for both BCC and SCC, as evidenced by the preponderance of these lesions on sun-damaged skin after chronic exposure to sunlight. More than 99% of individuals developing BCC are Caucasians, and 85% of these tumors arise on the head and neck. The nose is most common of all sites, accounting for 25–30% of all tumors. Individuals of Scottish, Celtic, or Scandinavian ancestry are at higher risk. Affected persons usually have a history of significant occupational and/or recreational sun exposure. There is evidence that BCC arising before the age of 40 years corresponds with childhood or recreational sun exposure but does not correlate directly with cumulative sun damage. Thus, in areas of the world where the UV radiation is most intense, such as the sun belt in the United States, childhood sun exposure is at a maximum and younger patients are at a higher risk of developing BCC.

It is debatable whether BCC is more aggressive in children. As total incidence rates of BCC continue to rise, childhood cases may become more common. This increase in pediatric BCC may be especially true in areas of high UV radiation exposure. The percentage of sunny days during the year, higher altitude, and location closer to the equator may place children in these areas at increased risk. There exist other significant risk factors for the development of BCC: Prior injury such as trauma, burns, or vaccinations at the tumor site is frequently noted by persons with BCC. Carcinomas arising as a late sequelae of radiation therapy most frequently takes the form of BCC on the head, neck, and trunk, and SCC on the hands. Prior exposure to inorganic arsenic can also lead to the formation of BCC. In this setting, tumors are often multiple, truncal, and superficial lesions. Immunosuppressed individuals are also prone to the development of BCC, although their risk is greater for SCC than for BCC.

Basal cell ►nevus syndrome (BCNS), ►xeroderma pigmentosum (XP), Baze syndrome and albinism represent inherited genetic disorders that predispose those affects to BCC and SCC. Patients with basal cell nevus syndrome are found to have a germline mutation in ►PCTH, a ►tumor suppressor gene located on 9q22.3. PTCH is the human homolog of Drosophila patched. Approximately 1/3 of cases result from a new germline mutation. Approximately 80% of PTCH mutations result in premature truncation of the patched protein. Inactivation of this gene was found in tumor tissue in 68% of BCCs examined and did not correlate directly with sun exposure or age. Typically, multiple BCCs develop at a young age in ►BCNS. Multiple BCCs, odontogenic keratocysts and palmo-plantar pits constitute the primary features of BCNS. Approximately 5% of infants with BCNS develop ►medulloblastoma. ►Radiation therapy for the medulloblastoma can result in a crop of BCCs in the radiation port.

Xeroderma pigmentosum (XP) is due to a genetic defect in the biochemical pathway to eliminate the carcinogenic potential caused by the damage of ►ultravilet light B (UVB) to DNA. Several genes, those for XP groups B, D, and G and ►Cockayne syndrome groups B code for components of transcription factors, the protein complexes that bind the promoter regions and control gene transcription. BCCs and SCCs occur at a much higher rate and a much earlier age. Keratoacanthomans, fibrosarcomas and melanomas are also common in patients with XP.

BCC can be treated with multiple modalities providing 90% cure rates for primary disease in most cases. Cure rates for ablative surgery and excisional surgery vary with a number of factors including the clinical size of the tumor, the location, the histological subtype and whether or not it is recurrent. Cure rates for ablative surgery are less than 90% for BCC exceeding 0.5 cm in diameter on the face and over 2.0 cm in diameter on the trunk and extremities. In these instances, consideration should be given for excisional surgery with adequate margin control. BCCs exceeding 0.5 mm in diameter of the central facial zone and aggressive growth pattern tumors with sclerosing stromas are best treated with Mohs micrographic surgery. The histologic subtype or growth pattern is a good predictor of cure rate. These tumors do not respond well to superficial or ablative surgery. Nodular and superficial BCC respond well to curettage and electrodesiccation, cryotherapy or shave excision can result in less morbidity than full-thickness excisional surgery. For adequate cure rates morpheaform or sclerosing, micronodular or infiltrative variants of BCC require excisional surgery with histologic margin control.

Squamous Cell Carcinoma

SCC is the second most common skin cancer, representing 20% of cutaneous malignancies. Over 100,000 cases of SCC are diagnosed annually in the United States, accounting for an incidence of 41.4 per 100,000. SCC of the skin is the fifth most common cancer among men and the sixth most common cancer among women in Sweden. SCC in situ or ►Bowen disease is the most common benign/precancerous tumor among men, while among women, it is second only to in situ cervical cancer. It most commonly affects individuals in mid to late life. SCC usually cause local tissue destruction and in advanced cases it may cause cosmetic and functional morbidity.

Clinically, typical SCC is a hyperkeratotic papule, nodule or plaque with variable ►erythema. Associated pain may suggest perineural extension. The central part

of the face is the area at highest risk for recurrence. Tumors in this region tend to grow down or extend at various resistance planes such as the perichondrium of auricular and nasal cartilages. The tarsal plates of the eyelids or embryonic fusion planes at the junction of the nasal and nasolabial folds, and along the nasal columella or in the periauricular region. The size of the tumor also affects risk for recurrence. Tumors less than 1 cm have a 99.5% cure rate by Mohs micrographic surgery, compared with 82.3% for tumors 2–3 cm and 58.9% for tumors greater than 3 cm. Tumors under 2 cm of diameter have a local recurrence rate of 7.4% in contrast to a 15.2% recurrence rate for tumors greater than 2 cm. Therefore, margins of excision are adjusted according to size, with a 4 mm margin recommended for tumors less than 2 cm and 6 mm for tumors of 2 cm or greater.

Deeply invasive tumors have a greater tendency for local recurrence and metastases. Tumors with less than 4 mm in depth have a local recurrence rate of 5.3% compared with a rate of 17.2% for tumors 4 mm or greater. SCCs that penetrate though the dermis to the subcutaneous tissue have a recurrence rate of 19.8%. Tumors greater than 1 cm in diameter or a histologic grade 2 or higher are more likely to extend to subcutaneous tissue. The degree of histologic differentiation has a propensity for aggressive disease. SCC Broder grades 2 or higher usually require larger resections and has greater risk of local recurrence. Well differentiated SCC have a 13.6% recurrence rate in contrast to a 28.6% recurrence rate for poorly differentiated SCC. SCC with neurotropic growth pattern, which invade the perineural space, have a greater risk for local recurrence.

SCC usually have a low metastasis rates ranging from 0.3 to 3.7%. SCC arising in the lip, ear, penis, scrotum and anus have a higher risk for metastases. There is a greater risk of metastases for SCC more than 2 cm in size, with depth of invasion to at least 4 mm, ►Broader histologic classification of 2 or greater and perineural extension. SCC usually metastasis to the regional lymph nodes. The 5 year survival rates for patients with regional lymph node metastases is 26%, and 23% in patients with distant metastases.

Risk Factors and Therapy

The risk factors for SCC include exposure to UV light and ►arsenic compounds, immunosuppression and underlying genetic predisposition. Cellular atypia is often equally high among those with in situ SCC or invasive SCC, and it is difficult to use cytological criteria to define in situ SCC as a benign lesion, in spite of an intact basement membrane in histological specimens. Even when using molecular markers such as the expression of p53 gene, in situ and invasive SCC are indistinguishable. The incidence of invasive SCC is two times higher for men, whereas in situ SCC is more common among women. It is possible that there are close etiological links between in situ and invasive SCC, and in situ appears to be as important a marker for subsequent cancer risk as invasive SCC.

SCC can also be treated satisfactorily with different modalities. Histologic growth pattern is less important in SCC than clinical size and depth of invasion, with the exception of rare histologic subtypes such as adenosquamous cell carcinoma. SCC exceeding 1 cm in diameter and tumors that invade into the mid-dermis or deeper, particularly those involving cartilage and bone, are high-risk tumors. SCC on the lip, ear, temple, genitalia and those associated with preexistent conditions such as radiation or burn scars are all higher risk tumors. In these instances excisional surgery with careful margin control should be the treatment of choice. Postoperative radiation therapy may also be considered for these aggressive high-risk tumors on a case-by-case basis. Superficial or ablative procedures such as curettage and electrodesiccation, cryotherapy and shave excision should be reserved for SCC in situ (►Bowen disease) or SCC that invades only the superficial dermis. The depth of the invasion can be measured with an adequate preoperative biopsy. Indurated tumors with an undermining infiltrative border are often deeply invasive and should be treated with excisional surgery.

Basal Cell Nevus Syndrome (BCNS)

Definition

Is a heritable autosomal dominant tumor syndrome, characterized by a multitude of developmental abnormalities including basal cell carcinomas of the skin, keratocysts of the jaw, palmar and plantar pits, fibromas of the ovaries and heart, medulloblastomas, and less

commonly polydactyly, syndactyly, and spina bifida. Approximately 2% of patients with BCNS develop medulloblastomas. The disease results from germline mutations in the *PTCH1* gene in chromosome 9q22.3.

[3]Department of Medicine, Feinberg School of Medicine, Northwesten University, Chicago, IL, USA

Synonyms

Basal phenotype breast cancer; Basal-subtype breast cancer; Basal-type breast cancer

Definition

Basal-like breast cancer is an aggressive type of breast cancer that expresses genes characteristic of epithelial cells in the outer or basal layer of the normal breast, including the basal ►cytokeratins. These tumors are usually ►hormone receptor negative and have a poor prognosis.

Characteristics

The normal adult breast is a glandular tissue organized into ducts and lobules that are made up of an inner layer of ►luminal epithelial cells, which surround the lumen of these structures and produce milk, and an outer or basal layer of ►myoepithelial cells (basal epithelial cells), which are surrounded by a basement membrane, separating them from the adjacent connective tissue. Luminal and basal epithelial cells can be distinguished by their expression patterns of the cytokeratins (CK), a family of cytoskeletal proteins. To understand the basis for nomenclature, it should be noted that the name "basal cytokeratin" was originally given to those (namely CK5/14/17) expressed in the basal cells of the stratified epithelium of the skin. Cytokeratins 8, 18, and 19 were named as "luminal" according to their strong expression in luminal epithelial cells. The basal or suprabasal layer of the breast also contains a population of multipotent CK5-positive ►progenitor or adult stem cells (►breast stem cells) that are capable of generating both epithelial cell types and likely play an important role in regenerating the gland after pregnancy and lactation.

Intriguingly, human breast tumors have distinctive ►gene expression profiles or "molecular portraits" that likely reflect the contribution of luminal epithelial cells, myoepithelial cells and/or breast stem cells. These gene signatures have recently been used to classify breast cancer into several molecular types, including ER-positive luminal groups, which expresses genes characteristic of luminal epithelial cells (ER, PR, and the luminal cytokeratins 8 and 18), and two major ER-negative groups, the HER2 group, characterized by amplification and overexpression of the proto-oncogene HER2, and the basal-like group, which express genes characteristic of myoepithelial cells (basal cytokeratins 5 and 17 and HER1/EGFR). The vast majority of basal-like breast tumors are negative for ER and PR and lack amplification of HER2. Hence, basal-like tumors are sometimes referred to as ►triple negative breast cancer, although not all basal-like tumors are triple negative and vice versa (see comments below). Other genes expressed in basal-like breast cancer have been implicated in apoptosis-resistance (e.g., α6 and β4 integrins, the molecular chaperone αB-crystallin, and pleiotrophin) and multiple molecular events in metastasis, including epithelial-to-mesenchymal transition (EMT), cell migration, and invasion (e.g., TGFβ2, the chemokine CXCL1, and the matrix metalloproteinase MMP14). These genes may contribute to the aggressive nature of basal-like breast cancer, which has a poor prognosis due in large part to its tendency to metastasize to distant organs. Basal-like tumors also express genes characteristic of breast stem cells, such as c-kit, vimentin and α6 integrin, suggesting that these tumors may have their origin in primitive breast stem/progenitor cells rather than in differentiated myoepithelial cells.

Basal-like breast tumors have also been identified by their expression of basal cytokeratins. In general, all or nearly all sporadic breast carcinomas show strong expression of luminal cytokeratins CK8, CK18 and CK19. The tumors expressing only luminal CK8, CK18 and CK19 are called "luminal" or "non-basal." A small fraction (~10%) of breast cancers also express CK5 together with its major partners CK14 and CK17, which are normally found in the basal layer of the breast, leading to their designation as "basal" or "basal phenotype" tumors. Tumor classification into the basal-like

subtype by cytokeratin immunohistochemistry and gene expression microarrays is very similar, but not completely identical. Some breast tumors lacking immunohistochemically detectable CK5 and CK14 may display a typical basal-like gene expression profile, and vice versa.

Basal cytokeratin expression can be seen in the tumor either uniformly in almost every carcinoma cell or strikingly heterogeneously in a checker-board manner. This feature can be used to further classify basal phenotype tumors as "basal" and "basoluminal" subtypes. All tumors in both subtypes show strong expression for luminal cytokeratins. Thus, in heterogeneously CK5/14-positive tumors, a large number of tumor cells express luminal cytokeratins only. Based on this observation, these tumors were called "basoluminal," in contrast to the uniformly CK5/14-positive "basal" tumors. Basoluminal tumors are also characterized by higher rates of HER2 amplification and a poorer prognosis than "basal" tumors.

Molecular Etiology

Despite the distinctive gene expression profile of basal-like breast cancer, which has been validated in multiple studies, the specific role of individual basal-like genes in the etiology of these tumors is poorly understood at the present time. Nevertheless, the gene signature of basal-like tumors has provided invaluable insights into potential pathogenic mechanisms. Indeed, the observation that the gene expression profiles of breast tumors in women who have inherited a mutation in the *BRCA1* tumor suppressor gene are largely basal-like strongly suggests that defects in BRCA1 function may play an important role in the etiology of non-hereditary basal-like breast cancer. BRCA1 normally functions to protect the genome through its actions in DNA damage repair and cell cycle checkpoint activation. Although mutations in *BRCA1* do not occur in non-hereditary breast cancer, basal-like tumors often have diminished expression of BRCA1 mRNA and protein due to promoter methylation and other mechanisms. Similar to basal-like tumors, hereditary *BRCA1*-related breast tumors are typically triple negative. Moreover, mutations in the *TP53* tumor suppressor gene and overexpression of the cell cycle regulator cyclin E occur commonly in both hereditary *BRCA1*-related breast tumors and non-hereditary basal-like tumors and may contribute to the genomic instability and the rapid proliferation rates of these tumors. Defective X chromosome inactivation is also a hallmark of both tumor types (and BRCA1 dysfunction), although the role of this abnormality in their pathogenesis is unclear. Taken together, these findings suggest that BRCA1 dysfunction and resultant defects in DNA damage repair may play a key role in the etiology of basal-like breast cancer and provide a molecular target for therapy.

Diagnosis

The highly reproducible gene expression profile of basal-like breast cancer remains the definitive method for diagnosing basal-like tumors. However, gene expression profiling is not routinely available in the clinic. Consequently, basal-like tumors can be identified by basal cytokeratin expression by immunohistochemistry or by double negative (ER and HER2 negative) status combined with positive immunostaining for either CK 5/6 or HER1/EGFR. As noted, these methods identify similar, but not identical, subsets of breast tumors given the likely heterogeneity of the basal-like group, an important caveat for clinical studies. In the near future, it may become possible to diagnose basal-like tumors using gene signatures of a subset of basal-like genes (20–50 genes) determined by ►reverse transcription-polymerase chain reaction (RT-PCR) methods on clinical specimens.

Clinical Features

The unfavorable prognosis of basal cytokeratin expressing breast cancer was first described in 1987. Thereafter, it has been shown in many immunohistochemical studies that basal cytokeratin expressing tumors associate with poor survival and early relapse. More recently, the molecular classification of breast cancer by gene expression profiling has been shown to provide important prognostic information for patients. Indeed, patients with basal-like and HER2 tumors have the shortest overall and relapse-free survival of all the molecular types. When basal-like tumors are further subclassified into basoluminal and basal subgroups, as described earlier, the basoluminal tumors show shorter survival estimates than the basal tumors. This difference is not due to more frequent amplification of HER-2 in the basoluminal subgroup.

Consistent with their aggressive behavior, basal-like tumors are poorly differentiated, highly proliferative with high mitotic counts, and are characterized by genomic or chromosomal instability, resulting in numerous chromosome abnormalities, including gains and losses. In addition to these properties, basal-like tumors often show aggressive morphological features like pushing borders, lymphocyte infiltration, tumor necrosis, central scarring, and the presence of spindle cells. Many of these features are typical for medullary and/or metaplastic carcinomas, rare histologic types of breast cancer, which express basal cytokeratins and have a basal-like gene expression profile. Moreover,

basal-like breast cancer tends to metastasize via the blood stream ("hematogenous" route) to distant organs such as the brain and lung, rather than spreading through the lymphatic system to adjacent lymph nodes. These metastases are particularly prevalent during the first five years after diagnosis and are largely responsible for the poor survival of patients with basal-like breast cancer. Intriguingly, hereditary *BRCA1*-related breast tumors are also characterized by early metastases to distant organs that account for their poor prognosis. Approximately 10–20% of all breast cancer cases are basal-like. However, basal-like tumors appear to be more prevalent in younger women, particularly African American women. Hence, the clinical impact of these poor prognosis tumors is compounded by their tendency to strike younger woman.

Treatment

Unlike the other molecular types of breast cancer, there are no currently available, targeted therapies for basal-like breast cancer. For instance, most basal-like breast tumors do not respond to endocrine therapy such as tamoxifen or aromatase inhibitors because they are ER-negative. Similarly, trastuzumab (Herceptin), a therapeutic antibody targeting HER2, is of little benefit against most basal-like tumors because they lack amplification of HER2. Although our understanding of the molecular etiology of basal-like tumors is limited, several candidate drug targets have been identified by gene profiling, including the receptor tyrosine kinases HER1/EGFR and c-Kit, the MEK-ERK MAP kinase pathway (activated by HER1/EGFR and c-Kit), and the cell cycle regulator cyclin E. Importantly, drugs targeting several of these molecules have already been developed and may prove to be useful in treating basal-like tumors. Another potential therapeutic target is the likely BRCA1 dysfunction in basal-like tumors. Recent studies indicate that breast cancer cells expressing mutant *BRCA1* are highly sensitive to chemotherapy drugs which cause DNA double-strand breaks (e.g., topoisomerase II inhibitors) or cross-link DNA (e.g., cisplatin), consistent with the established role of BRCA1 in repairing DNA damage. Hence, these agents may be effective against basal-like tumors, particularly those with reduced *BRCA1* expression. Moreover, inhibition of *BRCA1* expression by RNA interference sensitizes cancer cells to apoptosis by inhibitors of the DNA repair enzyme poly(ADP-ribose) polymerase (PARP), which catalyzes poly(ADP-ribosyl)ation of target proteins. These findings suggest that PARP inhibitors may be of benefit in basal-like tumors. Given the aggressive nature of basal-like tumors and the lack of targeted therapies at present, there is a clearly a pressing need for carefully designed clinical trials to evaluate these and other agents in basal-like breast cancer.

Basal Phenotype Breast Cancer

►Basal-like Breast Cancer

Basal-subtype Breast Cancer

►Basal-like Breast Cancer

Basal-type Breast Cancer

►Basal-like Breast Cancer

Basalioma

Definition

Refers to a skin cancer with extended growth, but no metastasis; develops in skin areas exposed to sun, such as face, nose, or ears.

Base Excision Repair (BER)

Definition

Is a DNA repair pathway that repairs mainly non-bulky adducts that causes only minor disturbances in the helical structure of DNA, such as oxidized, alkylated, or even absent bases.

►Mutagen Sensitivity
►Nucleotide Excision Repair

Basement Membrane

Definition

The basement membrane (BM) is a thin mat of extracellular matrix that separates epithelial sheets and many types of cells, such as muscle cells and fat cells, from connective tissue. The characteristic components of BMs are laminin, collagen type IV and heparan sulfate proteoglycan.

Basic FGF

Definition

►Fibroblast Growth Factor 2.

Basic Fibroblast Growth Factor (bFGF)

Is a cytokine that belongs to a homologous family of at least 18 proteins. Basic FGF binds FGF receptors 1 and 2, acts as a potent mitogen for endothelial cells, and is expressed in many benign and malignant tumors.

►Antiangiogenesis

Basic Helix-Loop-Helix Domain

Definition

A phylogenetically conserved domain that defines a class of transcription factors. The basic region, rich in positively charged amino acids, mediates interactions with DNA while two amphipathic alpha helices separated by a flexible, unstructured loop mediate hetero- or homodimeric interactions with other bHLH-containing transcription factors.

►E2A-PBX1
►Myc Oncogene

Basolateral Surface

Definition

As applied to the gastrointestinal tract wall refers to the wall surface on the outside (the side exposed to the bodies blood flow) of the GI tract or in Caco-2 cell culture the cell surface that mimics the outside of the GI tract. In Caco-2 cultures this is the cell surface that grows on the semi-permeable support membrane.

►ADMET Screen

Basophil

Definition

A white blood cell that contributes to inflammatory reactions. Along with mast cells, basophils are responsible for the symptoms of allergy.

BAX

Definition

Bax is a Bcl-2-associated X protein of 192 aa and 21 kD that is membrane-bound and expressed widely in different tissues. It has proapoptotic activity, by binding

and antagonizing the antiapoptotic Bcl-2, thereby accelerating apoptosis. The gene maps to 19q13.

B-Cell Response

Definition

Response of B-1 and B-2 cells to antigen stimulation. B-1 cells bear high levels of surface IgM, lower levels of surface IgD, and most express the cell surface antigen CD5, they frequently secrete high levels of polyspecific antibody with relatively low affinity. The majority of B-cells are B-2 cells which express low levels of surface IgM, do not express CD5 and secrete highly specific antibody. While B-1 cells are $CD43^+$ and $CD23^-$, B-2 cells are $CD43^-$ and $CD23^+$.

Definition

B-cell lymphomas are malignant tumors of B-lymphocytes. They arise at all stages of B-cell differentiation, from immature B-lymphocytes in the bone-marrow through to terminally differentiated plasma cells (Fig. 1). It is now possible to use immunogenetic analyses to define more clearly the cell origin and clonal history of B-cell tumors.

Characteristics

What is a B-lymphocyte?

B-lymphocytes are cells of the immune system that are destined to express immunoglobulins (antibody molecules). These immunoglobulins (Igs) play a central role in the recognition of foreign antigens like infectious organisms, which could threaten the integrity of the individual.

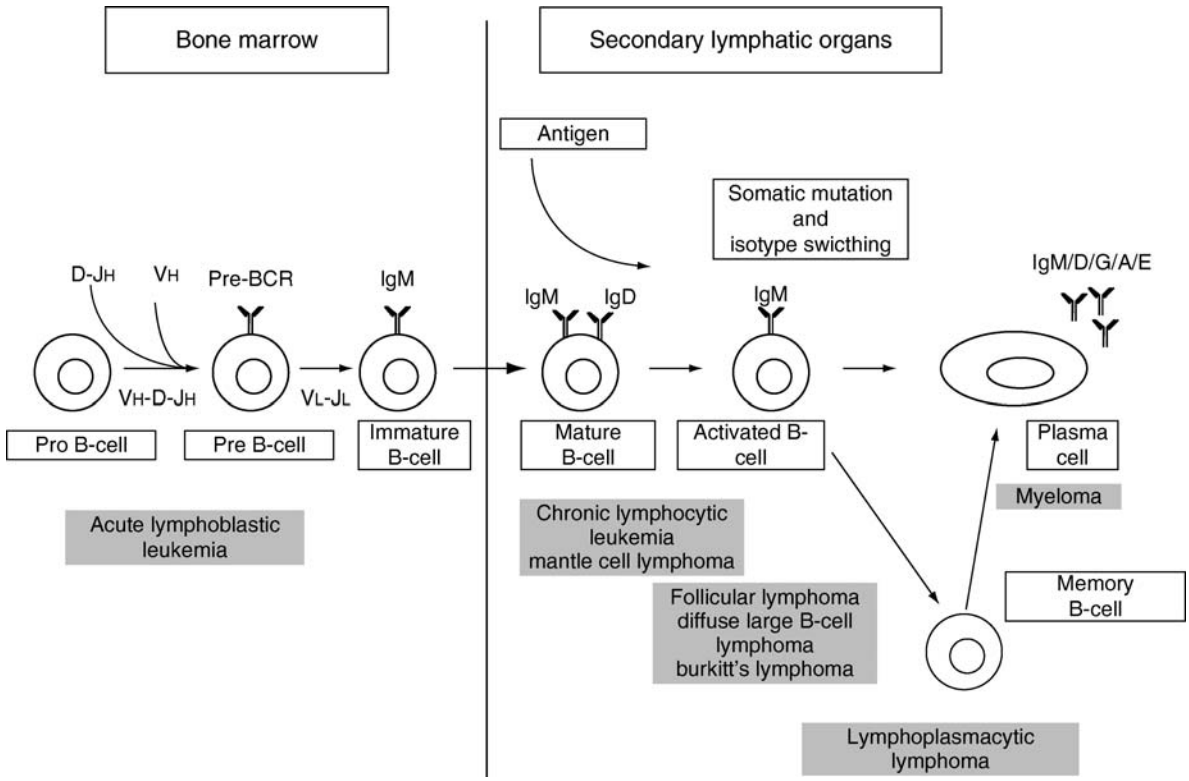
Igs are glycoproteins that can exist either as membrane-bound molecules on the cell surface or as secreted molecules in the serum. There are five classes of Ig with different size, structure and function; IgM, IgD, IgG, IgA and IgE. Each basic Ig molecule contains two identical heavy chains (μ, δ, γ, α or ε) and two identical light chains (κ or λ). A mature B-cell carries about 105–106 identical Igs on its cell surface. Both light chains and heavy chains can be subdivided into distinct regions. The N-terminal variable (V-) regions mediate antigen contact and their amino acid sequence is specific to each B-cell. The C-terminal constant regions are common to all antibodies of the same class.

The sequence variability, which is necessary to recognize the vast number of different antigens present in the environment, is created by two processes. The first is ►immunoglobulin gene rearrangement and the second is somatic mutation. ►Class switching changes Ig effector function.

Immunoglobulin Gene Rearrangement

During this remarkable process, double-stranded DNA breaks are created and repaired in a tightly controlled fashion. Rearrangement brings together one representative from different gene families: variable region (VH) genes, diversity region (D) genes and joining region (JH) genes for the Ig heavy chain, VL and JL for the Ig light chain (Fig. 1). The process of VH-D-JH and VL-JL joining is imprecise; non-templated nucleotides (N-additions) can be inserted and the ends of the joined segments can be trimmed back. Thus the final products of rearrangement, the VH-D-JH and VL-JL, will have a unique nucleotide sequence V(D)J Recombination.

The heavy chain variable (VH) region is about 120 amino acids (aa) long and can be subdivided into discrete structural sections. Three complementarity determining regions form the classical antigen binding site; CDR1, CDR2 and CDR3. While CDR1 and CDR2 are encoded in the germline, CDR3 is created de novo in each B cell by VH-D-JH rearrangement. In the antibody molecule this sequence corresponds to the central part of the antigen recognition site. The CDRs alternate with four framework regions (FR1–4). Light chain variable



B-cell Tumors. Figure 1 In the bone marrow first the D-JH then VH-D-JH recombination takes place. This heavy chain is expressed on the cell surface with the surrogate light chain to form the pre-B-cell receptor (pre-BCR). Next the light chain genes are rearranged. The B-cell now expresses surface Ig and leaves the bone marrow. Mature B-cells encounter antigen, and are stimulated to somatically mutate their V genes. Additionally class switching is initiated. Some B-cells then leave the germinal centre to become plasma cells, some become memory cells. The grey blocks illustrate, at which stage of B-cell differentiation some B-cell tumors are thought to originate.

regions (VL) regions are about ten aa shorter, but contain similar structural motifs.

In the bone marrow the Ig heavy chain genes are rearranged first followed by the light chain genes (Fig. 1). Ultimately a B-cell that successfully completes this process will have a unique immunoglobulin heavy and light chain gene sequence for antigen recognition. The nucleotide sequence in CDR3 can be viewed as its molecular marker or "fingerprint."

Somatic Mutation and Class Switching

Following antigen encounter, further variability is introduced into the rearranged variable region genes by somatic mutation that occurs in secondary lymphatic organs. Somatic mutation can change the amino acid sequence of variable region genes and may therefore impact on the antigen binding of the resulting protein.

The process of class switching changes the effector function of the antibody molecule (complement activation, binding to Fc receptors or uptake by phagocytic cells). During class switching the DNA segment of one constant region (e.g. IgM) is deleted and the variable region of the heavy chain brought into the vicinity of another constant region gene (e.g. IgG or IgA). This process conserves the unique variable region.

What is a B-cell Tumor?

In the broadest sense ►B-cell tumors are malignancies in which tumor cells have undergone rearrangements of their ►immunoglobulin genes. Analysis of the status of these genes provides information that defines origin and clonal history of the tumor cell. Figure 1 shows key steps in normal B-cell development, and gives examples of B-cell malignancies that may arise at a particular stage. Within each cancer, the tumor cells are clonally related, as revealed by the common CDR3 sequence in the tumor cell population.

In some lymphomas the tumor clone has non-functionally rearranged VH genes, as appears to be the case in Hodgkin lymphoma (►Hodgkin disease). This sets these lymphomas apart from normal B-cells, which can only survive if they express immunoglobulins. The antigenic determinants, derived from the variable regions of the immunoglobulin molecule, provide us with a

unique tumor antigen called ►idiotype. This tumor antigen is now being exploited in new immunotherapeutic strategies.

Characteristics of B-cell Tumors

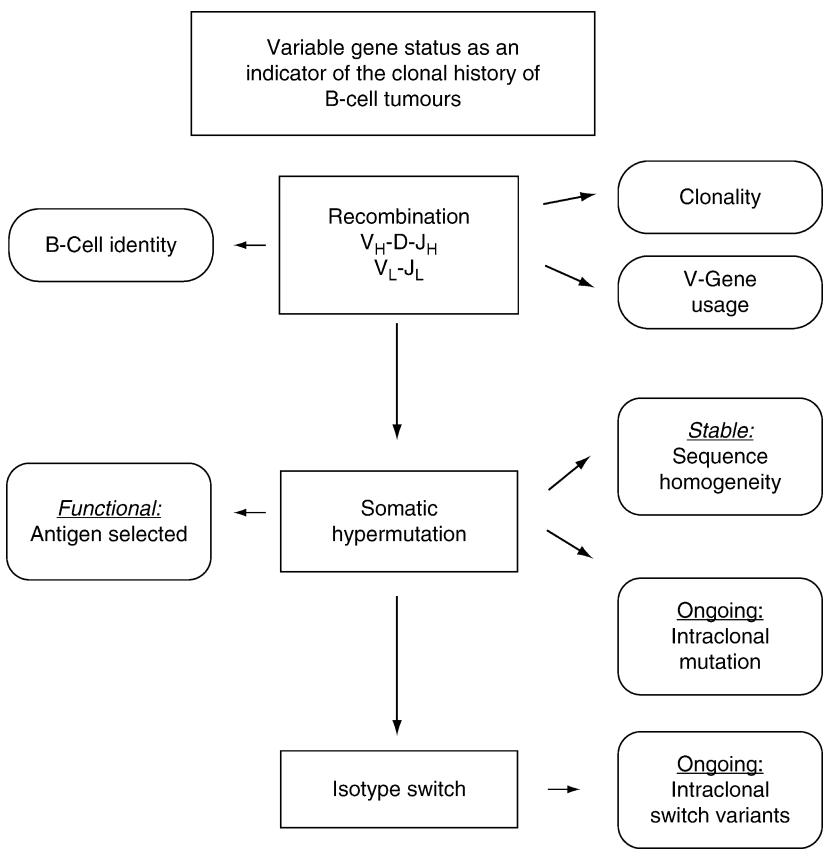
B-cell tumors account for about 3% of all cancers. For unknown reasons their incidence is rising steadily at about 6% per year world-wide. B-cell tumors are the most common malignancies in childhood. In adults, the frequency of B-cell tumors increases steadily with age, with a median of 50–60 years. They occur more frequently in men than women.

The presentation of B-cell tumors at the clinical and morphological level can vary widely. Aggressive malignancies are at the one end of the spectrum, which if untreated will cause death in weeks but are frequently curable with combination chemotherapy. Indolent malignancies are at the other end of the spectrum, which are usually incurable but can remain untreated for decades. The diagnosis of B-cell malignancies relies on the clinical picture, histological analysis and immunophenotype of the tumor. Increasingly, hallmark genetic abnormalities are being defined in individual entities. They frequently involve translocations into the immunoglobulin loci of the heavy chain genes on chromosome 14 or the κ or λ light chain loci on chromosomes 2 and 22.

Different ways of grouping lymphoid malignancies in a logical fashion have been applied. They were based on the need of clinicians to determine a suitable course of treatment as well as the desire of pathologists to distinguish morphological similarities. Although these classifications were used in parallel, they are difficult to compare since similar entities were often attributed to different categories. In 1994, an attempt was made to divide lymphoid malignancies taking into account the combined available information from clinical patterns, morphology, immunophentoype and genetic characteristics. Also, as far as possible, the normal counterparts were attributed to each malignancy. This led to the "Revised European-American Classification of Lymphoid Neoplasms" (REAL). This REAL classification provides the first truly international view of lymphomas and has been developed further in the form of the recently proposed WHO classification.

Immunogenetics of B-cell Lymphomas

Genetic analysis of B-cell lymphomas has aided our understanding of malignant lymphoma. Specific chromosomal rearrangements in many of the lymphoma



B-cell Tumors. Figure 2

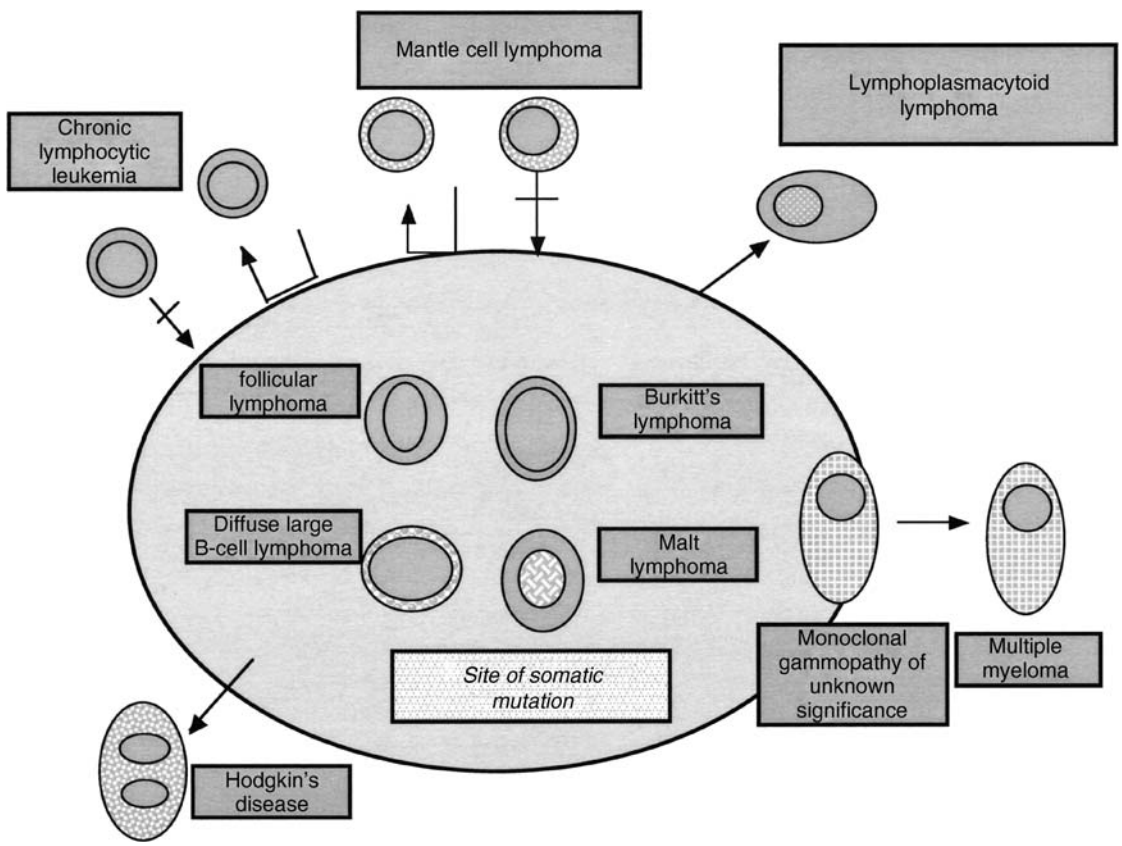
entities indicate that a particular type of genetic damage in the precursor cell is important for the development of the lymphoma. For example t(14;18) translocation is characteristic of ►follicular lymphoma. The isolation of the same translocation in cells from healthy individuals suggests that this genetic change may be a necessary but insufficient condition for the development of follicular lymphoma.

More recently, the analysis of the status of the immunoglobulin genes in B-cell tumors has shed new light on the events which shape the malignant cell. Figure 2 summarizes the information that V-gene analysis of B-cell tumors can reveal. The presence of rearranged immunoglobulin genes defines the cells under investigation as being of B-cell origin (Fig. 2). In this way it could finally be established that in the majority of cases Hodgkin lymphoma is a B-cell tumor.

Sometimes it can be very difficult to assess if an abnormal population of B-cells represents a true malignancy. Examples include low grade ►MALT lymphomas in the stomach or lymphoproliferations after organ transplants. Here the analysis of the Ig genes can help to separate a poly- or oligo-clonal and pre-malignant lesion from a truly clonal and cancerous one (Fig. 2).

In some B-cell lymphomas (follicular lymphoma, diffuse large B-cell lymphomas) the observed VH gene usage is similar to that of normal B-cells. In other tumor types, however, a marked over- or under-representation of certain VH genes has been detected. For example, a member of the VH4 gene family, called V4–34, is used by about 6% of normal cells. In contrast, all known cases of ►Waldenstrom macroglobulinemia with cold agglutinins of anti-I activity use the V4–34 gene. This suggests that B-cell superantigens may play a role in the pathogenesis of cancer in these B-cell lymphomas.

Since gene rearrangement, somatic mutation and class switching all leave their traces in the Ig-genotype of a B-cell, Ig analysis can provide important information about the clonal history of the malignant B-cell. V-gene analysis allows us to determine which processes the



B-cell Tumors. Figure 3 Origin and development of B-cell tumors in relation to the site of somatic mutation in the germinal centre (GC). V-gene mutational patterns can be used to classify tumors as follows: (i) not entering the GC (*blocked arrows*); (ii) passing through the GC (*arrows out*); (iii) remaining in the GC (*no arrows*). Monoclonal gammopathy of unknown significance may in some cases remain in the GC. CLL has subgroups, with different patterns of mutations, which thus possibly arise from different stages of B cell development.

B-cell has been exposed to and also suggests which 'normal' counterpart the tumor cell may be related to.

The majority of B-cells in the periphery will have been exposed to somatic mutation in the germinal centre of the secondary lymphatic organs. Figure 3 relates the origin and development of B-cell tumors relative to the germinal centre. The analysis of the tumor related VH-D-JH genes in tumors can reveal evidence that the tumor cell clone has entered this site, if somatic mutations are found in the VH-D-JH gene. Within the same tumor type some cases may show somatic mutation, while others do not. ►Chronic lymphocytic leukemia (CLL) segregates into two categories; patients with unmutated (pre-germinal centre) CLL have a significantly worse prognosis than those with mutated VH-D-JH genes.

Evidence for ongoing mutation can be identified by detecting micro-heterogeneity in clonally-related sequences from the tumor. While the clonal fingerprint of the tumor is shared between all cells, some cells have acquired additional mutations that are not shared by other cells. This type of pattern is found in follicular lymphoma, ►Burkitt lymphoma and diffuse large B-cell lymphomas (DLBCL) (Fig. 3). The tumor cells of DLBCL and hairy cell leukemias are also able to produce transcripts for more than one Ig isotype. This provides additional evidence that the malignant tumor cells are less frozen in their development than previously thought.

Malignancies like multiple myeloma (MM) have mutated VH-D-JH genes, but all sequences are identical (they are "stable"). This suggests that MM has undergone somatic mutation but that the tumor cells have then left the site of somatic mutation (post germinal centre tumors). ►Monoclonal gammopathy of undetermined significance (MGUS) can show or lack intraclonal heterogeneity.

The available data now allow us a detailed description of human B-cell tumors. Immunogenetics has contributed to the classification by providing information that is independent of the morphology and clarifies the developmental stage at which the final transforming event occurred.

It is likely that in the future new methods like the gene ►microarray technology will help us understand which disease entities should be further subdivided. Additionally, we are likely to predict better within lymphoma entities and tailor treatment according to more accurate prognostic factors.

Definition

The Bcl2 family of proteins belong to a peculiar class of proteins regulating ►apoptosis, ►cell cycle, ►differentiation, and ►autophagy; in oncology, the genes

coding for these proteins could not be defined neither as dominant transforming ►oncogenes (such as ►*myc*), nor ►tumor suppressor genes (such as ►*p53*). They could be best defined as apoptosis-related genes, a definition that stresses the importance of apoptosis (and of its dysregulation) in the genesis and development of cancer in humans and other species. Dysregulation of apoptosis is involved also in the development of diseases other that cancer, such as autoimmune diseases, AIDS and various degenerative pathologies.

Characteristics

The Bcl2 family encompasses several members divided in antiapoptotic and proapoptotic proteins; among the antiapoptotic are Bcl2 and BclXL, whereas among the proapoptotic are Bax, Bak, ►Bid, and Bad. These proteins contain conserved Bcl2 homology (BH) domains (termed BH1, BH2, BH3, and BH4), together with a transmembrane domain, all being identified as crucial for the regulation of apoptosis. In addition, based on functional studies and the conservation of BH domains, the Bcl2 family can be further divided into three subgroups. The Bcl2 subgroup includes all antiapoptotic proteins, such as Bcl2 and BclXL. The Bax subgroup consists of proapoptotic members, such as Bax, Bak, and Bad. Both groups contain more than one BH domain. The third subgroup contains BH3-only proteins, such as Bid and Bim, which can interact with either antiapoptotic proteins or proapoptosis members. The observation that inhibitors and inducers of cell death interact with each other by forming homodimers or heterodimers suggests that apoptosis is regulated, at least in part, by protein–protein interaction. By means of two alternative transcripts (a and b), Bcl2 codes for a protein of 205 amino acids (Bcl2b), or 239 amino acids (Bcl2a); both proteins contain BH domains for homo/heterodimerization with members of the Bcl2 family of proteins. The BH4 domain is required for antiapoptotic activity and also for interaction with the serine/threonine kinase encoded by ►Raf-1, an oncogene homologous to ►protein kinase C, that is the target of several tumor promoters. The hydrophobic carboxyl terminus of the protein determines association with cellular membranes; also this tail seems necessary for the antiapoptotic function. Proteins of the *Bcl2* gene family are evolutionarily conserved from the Sponges to man.

Functions

The main biological function of Bcl2 is to inhibit apoptosis or, conversely, to promote cell survival. Other related biological functions concern the control of cell cycle. In fact, Bcl2, as well as the antiapoptotic members of this family of proteins, are antiproliferative by facilitating G0, thus suggesting that cell survival is maintained at the expense of proliferation. In hematopoietic cell lines, these functions are crucial for differentiation, and Bcl2 might also have a direct role in cell fate decision beyond strict cell survival. In addition, Bcl2 family members are involved in the control of autophagy. As far as cell survival is concerned, it appears that the cell fate is dependent on the amount of intracellular Bcl2 protein; an increase (overexpression) of Bcl2 protein is associated with prolonged survival and apoptotic protection, whereas its decrease is associated with apoptosis or enhanced sensitivity to apoptosis-inducing agents. For example, HIV-specific CD8 + T-cells show a significantly reduced expression of Bcl2, potentially priming them to apoptosis. Conversely, in the development of cancer, Bcl2 overexpression inhibits the apoptosis of cancer cells bearing mutations, thus being a key determinant of neoplastic cell expansion and resistance to anticancer treatments. As a consequence, cancer cell death is delayed, and cancer cell accumulation occurs.

At the molecular level, inhibition of apoptosis as well as control of cell cycle, differentiation, and autophagy occur through a complex process of protein–protein interaction. In the inhibition of apoptosis this process involves heterodimerization, especially with the proapoptotic member of the Bcl2 family. In addition to homo/heterodimerization within the Bcl2 family members, the antiapoptotic members of the Bcl2 family also interact with other proteins regulating apoptosis, such as ►caspases and ►APAF1. Formation of complexes with these proteins involved in the actuation of apoptosis prevent them to initiate the protease cascade eventually leading to cell death.

The multiple independent functions of Bcl2 proteins are mediated by the BH domains and the hydrophobic helices. These functions can be grouped in two main categories: (i) A function as membrane channels for ions and proteins and (ii) A function as membrane adaptor/docking proteins. The first hint about Bcl2 function came from studies on the three-dimensional structure of the Bcl2 analog, antiapoptotic Bcl-XL. It showed a surprising similarity to the pore-forming domains of some bacterial toxins that cause the formation of channels for ions, proteins, or both. It was observed that Bcl2 and its homologues are localized to intracellular membranes, in particular, the outer ►mitochondrial membrane, the endoplasmic reticulum and the intracellular membrane of the nuclear envelope. In these areas they have a membrane transport function for calcium ions and proteins. The channels created by Bcl2 insertion into membranes resemble the pores formed by certain bacterial toxins. Thus, the two long hydrophobic helices of the protein core insert deeply through the phospholipid bilayer,

perpendicular to the membrane surface, and the rest of the protein undergoes conformational changes resembling the opening of an umbrella with the five surrounding amphipathic helices resting on the top of the membrane. The ability to form channels, by insertion of the two hydrophobic helices, is essential for Bcl2 antiapoptotic function. However, by analogy with other channel-forming proteins, the Bcl2 channels are formed by two or more proteins of the Bcl2 family. Thus, there is the possibility that anti- and proapoptotic members of the Bcl2 family form homo- or heterodimers. In fact, the proapoptotic members of the family also have channel forming activity, although the channels formed by these proteins might have different transport selectivity or subcellular localization. Heterodimerization of anti- and proapoptotic Bcl2 family proteins might lead to the formation of different channels or, alternatively, the heterodimers might be unable to form channels at all. Schematically, the channels formed by Bcl2 and the other antiapoptotic members prevent apoptosis, possibly transporting back, and thus antagonizing, the proapoptotic factors that outflow through the channels formed by the proapoptotic members of the Bcl2 family. For example, Fas ligand, a well characterized inducer of apoptosis, activates a member of the caspase family (caspase 8) that cleaves proapoptotic Bid. Once truncated, Bid translocates to mitochondria where it might function as a channel protein to release cytochrome *c*, thus activating cytosolic caspases which are the terminal effectors of apoptosis. Bcl2 inhibits the release of cytochrome *c* either by plugging the channels opened by Bid, or by transporting cytochrome *c* back to the mitochondria. Also in this case, the level of expression and the ratio between antiapoptotic and proapoptotic Bcl2 family proteins is critical in deciding cell death or survival.

In addition to the channel forming properties, Bcl2 family proteins interact with a number of signal transducing proteins involved in apoptosis and other crucial cellular processes. These include the protein kinase C homologue Raf-1, the ►G-proteins H-Ras and R-Ras, the p53-binding protein p53-BP2, the proapoptotic protein CED-4, (homologue to APAF1), and the protein phosphatase calcineurin. These interactions are mediated by specific BH domains; for example, the BH4 domain has been reported to bind with calcineurin, Raf-1, and CED-4. The association between Bcl2 and these proteins might be responsible for their translocation to intracellular membranes where Bcl2 is anchored. This may lead to changes of their activity, such that they might be sequestered and inactivated, or targeted for interaction with other membrane-associated proteins. For example, Raf-1 is a serine/threonine kinase which transduces mitogenic signals from membrane receptors to the nucleus. Association between Raf-1 and Bcl2 causes translocation of the protein kinase to the mitochondrial membrane where Bcl2 is located. Once there, Raf-1 phosphorylates and inactivates Bad, one of the proapoptotic members of the Bcl2 family. Phosphorylated Bad is sequestered in the cytosol, encaged by an adaptor protein termed 14-3-3, and thus unable induce apoptosis. In the absence of growth/survival factors (such as in IL-3 deprivation of IL-3-dependent hematopoietic cell lines), Raf-1 is not activated and the unphosphorylated Bad is able to induce apoptosis. Protein–protein interaction is also responsible for Bcl2 biological functions other than control of apoptosis. In fact, interaction between the catalytic domain of Raf-1 and the BH4 domain of Bcl2 in multipotent hematopoietic progenitor cells is critical in determining the erythroid/myeloid fate of differentiating cells. Another protein originally isolated as a Bcl2-interacting protein, is Beclin 1, the first identified mammalian autophagy gene product. Bcl2 negatively regulates Beclin 1-dependent autophagy and Beclin 1-dependent autophagic cell death, thus raising the possibility that Bcl2 family members also regulate autophagy.

Regulation

The first association between Bcl2 and human cancer was observed in follicular lymphomas bearing the t(14;18) chromosomal translocation by which the gene was cloned. This translocation brings the *Bcl2* gene to chromosomal location 18q21 into juxtaposition with the immunoglobulin heavy-chain locus at 14q32, resulting in transcriptional deregulation of the *Bcl2* gene. This event does not involve alterations of the coding regions of the gene. Subsequently, *Bcl2* overexpression was recognized as a general feature of various types of hematological and solid malignancies. Thus, many members of the Bcl2 family have been found to be differentially expressed in various malignancies, and some are useful prognostic cancer biomarkers. Whether through its function as a channel protein or as an adaptor/docking protein, the final result on cell fate, however, depends upon the level of expression of *Bcl2*. Therefore, the control of Bcl2 expression has been the object of numerous studies of transcriptional, translational, and posttranslational regulation. Overexpression of Bcl2 has been associated with hypomethylation in the promoter region. In normal cells, once apoptosis is initiated, Bcl2 is proteolytically cleaved by caspases. Interestingly, the cleaved protein, lacking the BH4 domain, has proapoptotic activity, and causes the release of cytochrome *c* into the cytosol thus promoting further caspase activity. Bcl2 family proteins are also regulated by phosphorylation that affects their activity and conformation. The structural

analysis of antiapoptotic members of Bcl2 family led to the discovery of an unstructured "loop region" near the N-terminus exposed to the cytoplasm. The antiapoptotic members of Bcl2 family such as Bcl2 and Bcl-XL are phosphorylated on specific serine/threonine residues within this unstructured loop in response to diverse stimuli including treatment with chemotherapeutic or chemopreventive agents. In most instances, such phosphorylation has been associated with the loss of their biological (antiapoptotic) function. The chemoresistant tumors often overexpress Bcl2/Bcl-XL. In these instances, the apoptosis yielding effect due to phosphorylation of antiapoptotic Bcl2 family members is quite interesting because phosphorylation–dephosphorylation pathway of these antiapoptotic proteins could be an ideal molecular target for therapy of subpopulation of cancer in which these cell death repressors are essential prognostic markers. Thus, further gaining the knowledge on the mechanism of inactivation of Bcl2/Bcl-XL by phosphorylation might be of significant importance to therapy for human malignancies in which overexpression of these antiapoptotic proteins is recognized.

Bioactivity

Oncogenes and tumor suppressor genes modulate *Bcl2* expression with profound results on death or survival of cancer cells. The tumor suppressor gene *p53* can induce apoptotic cell death by downregulation of Bcl2 and upregulation of Bax. The p53-dependent negative response element on Bcl2 has the features of a transcriptional silencer, mediating inhibition of transcription in an orientation-dependent manner. In a variety of tumors, p53 expression is associated with apoptosis and with sensitivity to DNA damaging agents (anticancer drugs and ►ionizing radiations), by enhancing the transcription of a gene that favors apoptosis (Bax), at the same time blocking the transcription of a gene that would protect cancer cells from apoptosis (i.e., *Bcl2*). *Bcl2* overexpression is able to hinder p53-induced apoptosis, but it is ineffective against p53-dependent growth arrest. However, when Bcl2 is expressed together with the proto-oncogene *c-myc*, both p53-induced growth arrest and apoptosis are counteracted. In recent years, however, the role of mutations of single genes in the genesis of cancer has been questioned, and it was proposed instead that cancer is a chromosomal disease. According to this hypothesis, carcinogens initiate chromosomal evolutions via unspecific aneuploidies. By unbalancing thousands of genes, ►aneuploidy corrupts teams of proteins that segregate, synthesize, and repair chromosomes. Aneuploidy is thus considered a steady source of karyotypic–phenotypic variations from which selection of further cancer-specific aneuploidies encourages the evolution and subsequent malignant progression of cancer cells. The rates of these variations are proportional to the degrees of aneuploidy, and can exceed conventional mutation by 4–7 orders of magnitude. In this scenario, the role of antiapoptotic genes, such as *Bcl2*, is even more paramount as they provide the opportunity for cancer cells to survive despite gross aneuploidy and to accumulate complex, malignant phenotypes.

Bcl-2 Binding Component 3

►PUMA

Bcl-2 Family Proteins

Definition

These molecules can regulate apoptosis positively or negatively at the site of mitochondria. The prototype is ►Bcl-2, which is originally isolated at the t(14, 18) breakpoint from the follicular lymphoma. All members share the Bcl-2 homology (BH) domain. Three subgroups have been defined. The anti-death members include Bcl-2, Bcl-x_L, Mcl-1 and Ced-9. They possess the BH1, BH2, BH3 and BH4 domains. The multi-domain pro-death members include ►Bax, ►Bak and Bok, which have the BH1, BH2 and BH3 domains. The BH3-only pro-death members consist of Bad, Bik/Nbk/Blk, Bid, Bim, Bmf, Hrk/DP5, EGL-1, Noxa and ►PUMA, which all contain the BH3 domain only.

BCL3

Katja Brocke-Heidrich
Institute of Clinical Immunology and Transfusion Medicine, University Hospital of Leipzig, Leipzig, Germany

Definition

BCL3 stands for B-cell leukemia/►lymphoma 3. The BCL3 gene is a proto-oncogene mapping to chromosomal band 19q13. It encodes a phosphoprotein of 446 amino acids exhibiting an apparent molecular weight between 47 and 60 kDa. BCL3 is an ►IκB-like protein that primarily functions as a transcriptional cofactor, especially in cooperation with ►NF-κB (nuclear factor κB).

Characteristics

Structure and Molecular Function

As its main structural feature, BCL3 protein exhibits seven so-called ankyrin repeat elements in its central domain. This structure is characteristic of the IκB family of proteins. Ankyrin repeats are tandemly arranged modules of about 33 amino acids. Through these motifs, IκB proteins interact with, and modulate the activity of NF-κB transcription factors. The NF-κB family consists of five members called RelA, RelB, c-Rel, p50 and p52. These subunits form various homo- and heterodimers that regulate the transcription of target genes by binding to specific (κB) sites present in promoter or enhancer elements. Unlike the other NF-κB subunits, p50 and p52 contain a DNA-binding domain but lack a transactivation domain. Thus, DNA-bound p50 and p52 homodimers inhibit gene transcription.

BCL3 differs from classical IκB family members by acting as a transcriptional cofactor. Hence, in many cells BCL3 is primarily located in the nucleus. Its proline-rich amino terminus and proline/serine-rich carboxyl terminus appear to function as transactivation domains. BCL3 preferentially binds to NF-κB p50 and p52 homodimers. These complexes can either activate or repress transcription of target genes. Two mechanisms of transcriptional activation by BCL3 have been described. It can either directly activate transcription by providing its transactivation activity to p50 and p52 homodimers, or cause de-repression by removing these inhibitory subunits from κB sites. Alternatively, BCL3 can also enhance binding of p50 and p52 to DNA, thereby inducing transcriptional repression. The circumstances leading to either effect are not well understood. The dual role of BCL3 in transcriptional regulation is reflected by its interaction with the basal transcription machinery and coactivators such as ►p300/CBP, SRC-1, and the ►histone acetyltransferase Tip60 and with corepressors such as ►histone deacetylases (HDACs). In addition to its role in NF-κB-dependent transcription, BCL3 has been described to function as a coactivator in complex with transcription factors ►AP-1 and ►retinoid X receptor by potentiating their activities.

Additionally, apart from its role in transcriptional regulation, BCL3 seems to exert a function in intracellular signaling. This conclusion results from the observation of BCL3 expression in thrombin-activated platelets. These cells are anuclear and incapable of gene transcription. Here, BCL3 has been found to associate with the ►Src-related protein kinase Fyn. The molecular relevance of this interaction is not known.

Regulation

BCL3 protein is modified by phosphorylation and polyubiquitination (►Ubiquitination). Phosphorylation occurs extensively and constitutively, predominantly at the serine-rich C-terminal domain. BCL3 exhibits several protein forms differing in their phosphorylation state. A major protein kinase shown to act on BCL3 is ►glycogen synthase kinase-3 (GSK3) that constitutively phosphorylates BCL3 at serines 394 and 398. This modification is followed by polyubiquitin linkage on N-terminal lysine residues of BCL3 and its subsequent degradation through the proteasome pathway. Therefore, this mechanism regulates BCL3 turnover. In addition, GSK3-mediated phosphorylation also influences the transcriptional function of BCL3 by modulating its interaction with HDAC transcriptional repressors, and attenuates its oncogenicity. Independent of these findings, the extent of BCL3 phosphorylation has been shown to affect its interaction with both NF-κB p50 and p52. Further information on signaling pathways leading to BCL3 phosphorylation is missing.

In addition, polyubiquitination has also been shown to regulate BCL3 entry into the nucleus. In B and T-cells, BCL3 exhibits a predominantly nuclear localization, while in several other cell types (e.g. erythroblasts, hepatocytes, keratinocytes) BCL3 resides in the cytoplasm and needs activation prior to nuclear translocation. Current data reveal that BCL3 requires a lysine 63-linked polyubiquitin chain in order to enter the nucleus and regulate gene transcription. This polyubiquitin modification acts as a "molecular ticket," probably by facilitating the interaction with nuclear transport receptors (called importins) and mediating transport through the nuclear core complex. Nuclear translocation of BCL3 is prevented by the de-ubiquitinating enzyme ►CYLD, which was identified as a tumor suppressor. Loss of CYLD results in de-ubiquitinylation of BCL3, which in turn facilitates nuclear accumulation of BCL3 and transcription of target genes which are able to promote cellular transformation.

Expression

The BCL3 gene is composed of nine exons, spanning 11.5 kb. Its transcript shows a broad expression pattern in multiple cells types. It is highly expressed in spleen and liver, with no apparent expression in brain. Transcription of BCL3 is regulated through several signaling pathways. In addition to regulatory elements in the promoter, two enhancer regions have been identified within the second intron.

BCL3 itself is an NF-κB target gene whose expression is initiated by a number of classic NF-κB-inducing stimuli (e.g. TNF-α, interleukin-1) but also upon activation of the T cell receptor. The corresponding κB sites have been found in the promoter and first intronic enhancer. BCL3 transcription is further induced by the Jak/Stat pathway (►Signal transducers and activators of transcription in oncogenesis). Stat3-activating cytokines (e.g., ►interleukin-6, -9 and -10) initiate BCL3 transcription primarily via Stat binding sites in the second enhancer. In mice, an AP1-dependent mechanism of BCL3 gene expression was found in T cells upon ►interleukin-4 stimulation. Moreover, BCL3 autoregulates its own transcription in a repressive manner. The negative feedback is mediated via the κB motifs.

In platelets, which lack nuclei and cannot synthesize mRNA, BCL3 expression is regulated on the translational level. In resting platelets, a preformed BCL3 mRNA pool exists whose translation is constitutively repressed. Upon activation, an ►mTOR-dependent rapid increase of BCL3 protein synthesis takes place. This specialized translational control pathway is mediated by a cascade also involving PI3K (►PI3K signaling) and PDK1 protein kinases and culminates in phosphorylation of the translation repressor ►4EBP-1, causing its dissociation from eukaryotic translation initiation factor 4E and allowing translation to proceed.

Physiological Function

Knockout mouse studies provide some information on the physiological function of BCL3. Although BCL3 is widely expressed, it seems to play its primary role in the immune system. BCL3 knockout mice appear developmentally normal, but are susceptible to certain kinds of pathogens. They are severely impaired in producing antigen-specific T and B cell responses. The altered microarchitecture in the spleen and lymph nodes, including the lack of ►germinal center formation, is thought to underlie the immunological defects.

In accordance with its observed role in immune responses, BCL3 functions have been found in immunologically relevant cells. BCL3 is selectively up-regulated in mature dendritic cells, and its absence results in failure of normal follicular dendritic cell differentiation. This finding might be the main reason for the observed defects in the microarchitecture of secondary ►lymphoid organs and T cell responses in BCL3-deficient mice. BCL3 was further shown to be required for the survival of activated T cells as well as for the attenuation of the pro-inflammatory (►inflammation) action of activated macrophages.

Moreover, BCL3 has been found to be transiently upregulated by DNA damage and to suppress p53 activation (see below). The data suggest a physiological role of BCL3 in B cell development. According to this hypothesis, BCL3 expression allows germinal center B cells to tolerate the DNA damage required for immunoglobulin ►class switch recombination and ►somatic hypermutation without mounting an apoptotic (►apoptosis) response.

BCL3 expression is highly upregulated in thrombin-activated platelets. In these activated platelets, BCL3 is required for retraction of fibrin clots, which is an important step in wound healing.

Oncological Relevance

The BCL3 gene was initially identified through its involvement in a t(14;19)(q32;q13) chromosomal translocation found in some patients with chronic lymphocytic leukemia (B-CLL) or other B-cell neoplasms. This translocation leads to juxtaposition of the BCL3 locus at chromosome 19q13 to the enhancer of the immunoglobulin heavy chain gene on chromosome 14q32, resulting in high-level expression of the BCL3 transcript. Recent studies have shown that elevated BCL3 expression is not limited to the rare cases of CLL or lymphomas with this translocation. High BCL3 expression has also been reported in subsets of ►diffuse large B-cell lymphomas, T-cell lymphomas (especially ►anaplastic large cell lymphoma), and (►Hodgkin disease). Furthermore, increased nuclear levels of BCL3 have been demonstrated in a growing number of non-lymphoid tumors such as breast cancer and nasopharyngeal carcinomas. Oncogenically activating mutations within the coding region of BCL3 have not been found so far. Consequently, elevated expression of BCL3 is hypothesized to contribute to oncogenesis by dysregulating target genes involved in cell proliferation, apoptosis and differentiation.

Consistent with a direct oncogenic function, BCL3 overexpression has been shown to lead to transformation of murine fibroblasts and induction of tumor growth *in vivo*. In contrast, transgenic mice expressing BCL3 in both B and T cells develop a lymphoproliferative disorder but no lymphoid neoplasms, indicating that BCL3 overexpression alone is not sufficient for the direct transformation of lymphoid cells.

A few target genes potentially involved in the oncogenic potential of BCL3 have been identified

so far. Transcription of the cyclin D1 (►cyclin D) gene, whose product acts as a key factor in driving cell cycle progression, is activated by BCL3 through its cooperation with p52 homodimers bound to an NF-κB motif in the cyclin D1 promoter. Concerted elevation of BCL3, p52 and cyclin D1 levels have been found in breast cancer cells. In these cells, *in vitro* studies also suggested a BCL3-mediated activation of the anti-apoptotic ►BCL-2 gene.

BCL3 can suppress the activation of tumor suppressor protein p53 (►p53 protein, Biological and Clinical Aspects), which is a crucial guardian of genomic integrity. Normally, p53 is kept at low levels mainly by its interaction with the Mdm2 protein, which mediates the proteosomal degradation of p53. When cells are exposed to genotoxic stress, this interaction is disrupted, and p53 accumulation results in either cell-cycle arrest or apoptosis. One proposed mechanism in this regulatory circuit is the ability of BCL3 to induce the expression of the p53 inhibitor Mdm2 via its recruitment to κB sites in the promoter occupied by p50 or p52. A more complete understanding of the role of BCL3 in human cancers is still lacking.

BCL-6

Definition

B-cell CLL/lymphoma 6, also known as Bcl-6, BCL5, LAZ3, and zinc finger protein 51 (ZNF51) is a zinc-finger protein of 706 amino acids and 78 kD. The human BCL6 locus maps to 3q27 and the mouse bcl-6 gene locus to chromosome 16 (13.90 cM). BCL6 is a transcriptional regulator that probably plays an important role in lymphomagenesis. It is involved in a form of B-cell non-Hodgkin lymphoma characterized by chromosomal translocation t(3;14)(q27;q32) and t(3;22)(q27;q11) that involves BCL6 and immunoglobulin gene regions, and also in a t(3;4)(q27;p11) chromosomal translocation with Arhh (Ttf).

►BCL6 Translocations in B-Cell Tumor

BCL6 Translocations in B-cell Tumors

Hitoshi Ohno
Department of Internal Medicine, Faculty of Medicine, Kyoto University, Kyoto, Japan

Synonyms

BCL6 translocations in B-cell tumors are chromosomic translocations involving the 3q27 chromosome band

Definition

Mature B-cell tumors are often associated with chromosomal translocations that lead to the juxtaposition of cellular oncogenes with the ►immunoglobulin gene (IG) loci. The 3q27 translocation is unique, fusing the BCL6 gene on 3q27 to either one of the three IGs but also another non-IG partner. Cytogenetic and molecular analyses have demonstrated that alteration of 3q27 and/or BCL6 is one of the most common genetic abnormalities in B-cell tumors.

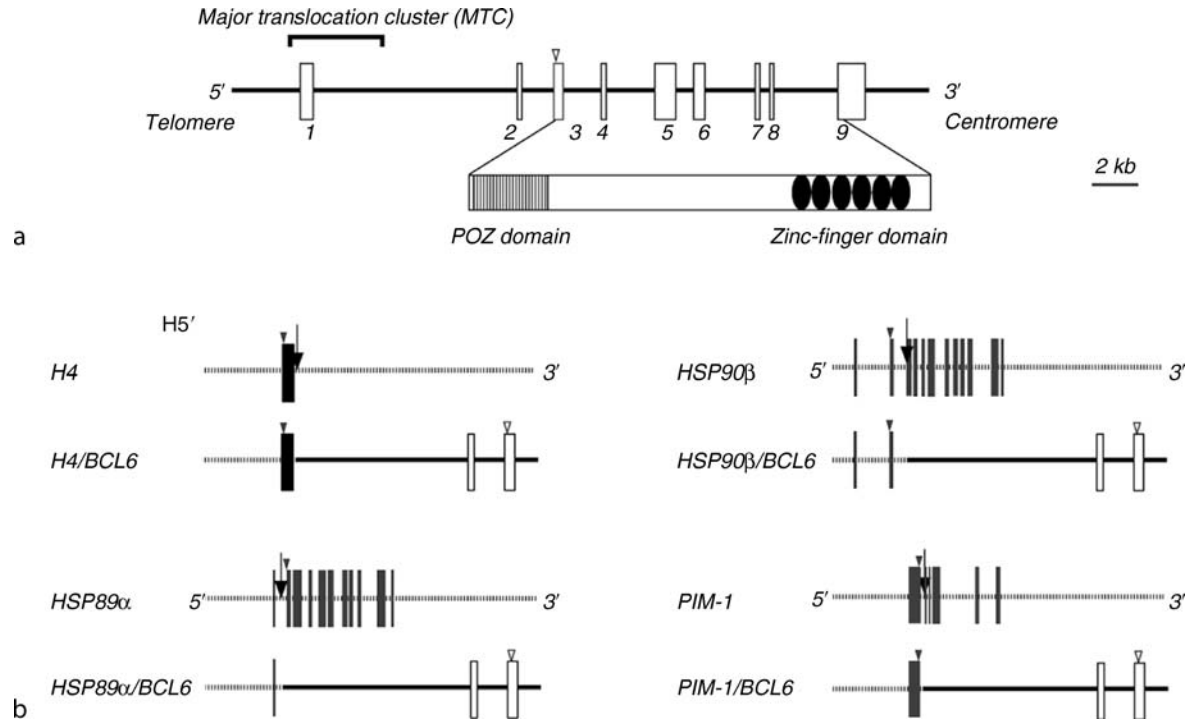
Characteristics

The BCL6 Gene and Gene Product

The BCL6 gene spans 26-kb and contains nine exons (Fig. 1a). At least two types of mRNA are produced by ►alternative splicing that may or may not contain exon 2. The ATG signal for initiation of protein synthesis is within exon 3 and is followed by an open reading frame, which encodes the Bcl-6 protein consisting of 706 amino acids with a calculated molecular weight of 79 kD. The Bcl-6 protein is a sequence-specific transcriptional repressor that contains two identified functional domains (Fig. 1a). The C-terminal region comprises six ►Cys2-His2 zinc finger motifs, each separated by a conserved stretch of seven amino acids. Hence, the Bcl-6 protein was classified as belonging to the Krüppel-like subfamily of ►zinc finger proteins. The N-terminal region contains a conserved protein-protein interaction motif, the POZ domain, which plays a role in homodimerization and heterodimerization. It has been shown that the repressing activity of Bcl-6 protein is exerted by the recruitment of both the ►SMRT co-repressor and a SMRT/mSin3A/HDAC-containing complex. Targeted inactivation of BCL6 in the mouse germline prevents germinal center formation in the lymphoid tissues and alters Th2-mediated immune responses, indicating that BCL6 is an important regulator of lymphoid development and function.

BCL6 Translocation Affecting the IG Loci

The most common type of 3q27/IG translocation is t(3;14)(q27;q32) involving IG heavy chain gene (IGH) on 14q32 [2, 3]. The breakpoints on IGH are within



BCL6 Translocations in B-cell Tumors. Figure 1 (a) Schematic presentation of the BCL6 gene and its protein product. (b) Non-IG/BCL6 translocations involving ►histone H4 gene, HSP89α heat shock protein gene, HSP90β gene [see ►HSP] and ►PIM-1 proto-oncogene. Open (BCL6) and closed (partner genes) boxes indicate the exons, and arrowheads indicate the translation initiation sites of each gene. Arrows indicate breakpoints of each translocation. All the translocations occurred with the same transcriptional orientation.

the switch regions of IGH, and the IGH upstream sequences are juxtaposed to BCL6 in the same transcriptional orientation. The breakpoints on BCL6 are clustered within a 4 kb region spanning the non-coding exon 1 and intron 1 (major translocation cluster; MTC; Fig. 1a); in the majority of cases, breakpoints are localized immediately 3′ of exon 1 (hyper-cluster) [2]. Thus, the coding regions of BCL6 remain intact. On the reciprocal junction, the 5′-BCL6 sequences are fused to downstream sequences of IGH. t(3;14) generates chimeric IGH/BCL6 transcripts that initiate from the IGH germline transcript promoters (Iμ and Iγ), and are followed by the BCL6 coding sequences [3].

Forms of the second, "variant" type of translocation are t(3;22)(q27;q11), involving IGλ light chain (IGLλ) on 22q11 and t(2;3)(p12:q27), involving IGLκ on 2p12 [2]. The last two "variant" translocations lead to juxtaposition of the 3′ sequences of IGLs to the BCL6 in divergent orientation. The breakpoints within the two IGLs are varied; 5′ of V genes, 5′ of Vλ/Jλ complex, at a point between the Vλ2–1, which is the most 3′ V gene of IGLλ, and the Jλ1 segment, and between the Jλ and Cλ segments [2]. Thus, the positions of breakpoints on the IGLs are not related to the regions in which V/J recombination normally occurs. Since IG translocations presumably occur as the result of errors in the recombination process, the positions of breakpoints on IGs can reflect the B cell stage where the translocation develops. While IGH/BCL6 translocations are most likely associated with the isotype class switching process following completion of V/D/J recombination, this "mis-class switch" mechanism may not be applicable to the variant IGL/BCL6 translocations.

BCL6 Translocations Affecting Non-IG Loci

Non-IG partners have been cloned by 5′-rapid amplification of cDNA ends (5′-►RACE) strategy. Another method to obtain a sequence of non-IG partner is long-distance ►inverse PCR. The Table 1 lists non-IG partners that have been identified using these two PCR-based approaches. These non-IG partners are not random but recurrently identified.

TTF is the first identified non-IG partner, which has been renamed RhoH (►Rho family proteins). The RhoH/TTF product possesses many Rho-hallmarks and defines a new group within the Rho subfamily. Other non-IG partners were registered in the GenBank database, and the exon-intron structure as well as the sequence of the regulatory region was studied. Figure 1b shows the representative organization of der(3) chromosome affected by BCL6 translocation.

BCL6 Translocations in B-cell Tumors. Table 1 Diverse partner genes of *BCL6* translocation in B-cell tumors

Genes		Gene product	Chromosomal locus
IG genes	*IGH*	Immunoglobulin heavy chain	14q32
	*IGL*κ	Immunoglobulin κ light chain	2p12
	*IGL*λ	Immunoglobulin λ light chain	22q11
Non-*IG* genes	*RhoH/TTF*	Rho GTP-binding protein	4p13
	BOB1/OBF1	B cell-specific transcriptional coactivator	11q23.1
	H4	H4 histone	6p21.3
	*HSP89*α	Heat shock protein 89α	14q32
	*HSP90*β	Heat shock protein 90β	6p12
	CIITA	MHC class II transactivator	16p13
	PIM-1	Pim-1 proto-oncogene product	6p21.2
	eif4AII	Eukaryotic initiation factor 4AII	18p11.2
	TFRR	Transferrin receptor	3q29
	Ikaros	Ikaros	7p12
	LCP1	L-plastin	13q14
	α-*NAC*	α Chain of the nascent polypeptide-associated complex	12q23–q24.1

The common molecular features of non-IG/BCL6 translocations include:

- The gene fusion occurs in the same transcriptional orientation
- The breakpoint on the partner gene is localized in close proximity to its promoter sequence
- The complete set of the promoter is fused upstream to the coding region of BCL6 on the der(3) chromosome

As the result of the translocation, many types of regulatory sequences on each partner locus substitute for the 5′ untranslated region of the BCL6 gene, and the rearranged BCL6 gene is presumed to be under the control of the replaced promoter activity (promoter substitution). Partner genes are transcriptionally activated by a variety of stimuli, including cell-cycle control, changes in the physical environment and response to cytokines. As ►germinal center (GC) B-cells proliferate rapidly in response to antigen stimulation, it is likely that the BCL6 gene affected by the translocation is inappropriately expressed during B-cell proliferation. A key experiment to establish the role of non-IG/BCL6 translocation would be the creation of a transgenic mouse model, in which the translocation is re-created by placing BCL6 under the control of these diverse promoters.

The 5′ Non-coding Region of BCL6 Undergoes Somatic Hypermutation

Somatic mutations within the 5′ non-coding region of BCL6 have been described in a significant proportion of ►GC/post-GC type B-cell tumors. The majority of the mutations cluster around the 3′ of exon 1, which has been referred to as the Major Mutation Cluster (MMC). These mutations are often multiple, are frequently biallelic and are independent of BCL6 translocation or linkage to IGs. Somatic mutations within the MMC were observed in a large proportion of memory B-cells isolated from normal individuals as well as GC B-cells from a reactive tonsil. The presence of cis-acting elements in BCL6, which are shared with IG and essential for targeting the mutation, has been suggested. Although the MTC and MMC apparently overlap, possible linkage between the two genetic alterations remains to be determined.

Clinical Relevance

Large numbers of B-cell tumors with 3q27 translocation in association with the IG gene loci were first described in 1989. 3q27/IG Translocations were identified in 20 of 318 (6.3%) cases of B-cell ►non-Hodgkin lymphoma (B-NHL) with clonal chromosomal abnormalities. There are nearly 20 cytogenetically identifiable non-IG chromosomal sites, some of which have been reported by several independent laboratories. The overall incidence of 3q27 abnormalities in NHL has been estimated to be 15.9% of all NHL types and 23.1% of ►DLBCL.

An initial study of BCL6 rearrangement, using Southern blot analysis with a probe for MTC, indicated a specific correlation of the rearrangement with diffuse large B-cell lymphoma (DLBCL). However, later studies of panels of many NHL types invariably showed that a significant number of cases with ►follicular lymphoma (FL) carried such rearrangements. The range of BCL6 rearrangements in B-NHL subtypes are 5–15% in FL, 20–40% in DLBCL and its variants, and 20% in ►acquired immunodeficiency syndrome (AIDS)-associated DLBCL.

The 3q27 translocation and/or BCL6 rearrangement sometimes coexist with other IG translocations associated with B-cell tumors, i.e. t(8;14)(q24;q32) and t(14;18)(q32;q21) and their variants. In some cases, alteration of the BCL6 locus was not a primary genetic abnormality but may have occurred at the time of transformation from low- to high-grade disease.

IG translocations sometimes correlate with clinical features of B-cell tumors. For instance, B-NHL associated with t(8;14) and/or its molecular equivalent shows aggressive clinical behavior even though the translocation can occur not only in ►Burkitt lymphoma but also in other types of B-cell tumors. An earlier study showed that BCL6 rearrangement more frequently occurs in extranodal DLBCL than in node-based disease and is correlated with a favorable clinical outcome. However, later studies failed to confirm these observations. Another interesting issue is whether the diverse partner genes can affect the clinical features of NHL carrying a particular BCL6 translocation. It has been observed that the overall survival of DLBCL with non-IG/BCL6 translocation was significantly inferior to that of those with IG/BCL6 translocation. Although the total number of patients analyzed is quite small, additional studies of larger cohorts are warranted.

BCL-x

Definition

Bcl-x belongs to the ►BCL-2 family of proteins and is associated with cell survival.

►Signal Transducers and Activators of Transcription in Oncogenesis

Bcl-X_L

Definition

Is a member of the pro-survival subfamily ►(Bcl-2, Bcl-xL, Bcl-w, Mcl-1, A1 and also Bcl-B in humans) that protects cells exposed to diverse cytotoxic conditions by promoting cell survival. It is a member of an evolutionarily conserved 'stress' pathway, which is triggered by developmental cues and diverse intracellular stresses that activate caspase-9 on a scaffold formed by Apaf-1 in response to cytochrome *c* released from damaged mitochondria. This pathway, also termed 'mitochondrial' or 'intrinsic', is primarily regulated by the Bcl-2 family.

Basal Cell Nevus Syndrome; synonym ►Gorlin Syndrome, nevoid basal cell carcinoma syndrome (NBCCS).

BCR-ABL1

Christine M. Morris, Suzanne M. Benjes
Cancer Genetics Research Group, University of Otago at Christchurch, Christchurch, New Zealand

Definition

BCR-ABL1 is a hybrid (fusion or chimaeric) gene that arises when genomic ►DNA of the *BCR* gene on chromosome 22 and of the *ABL1* gene on chromosome 9 breaks and recombines. The *BCR-ABL1* hybrid gene is transcribed to produce a hybrid mRNA that is subsequently translated into a functional BCR-ABL1 protein. The *BCR-ABL1* mutation causes and is diagnostic of human ►chronic myeloid leukemia (CML) and some acute leukemias including particularly ►acute lymphoblastic leukemia (ALL).

Characteristics

A Somatic Mutation of Bone Marrow Progenitor Cells

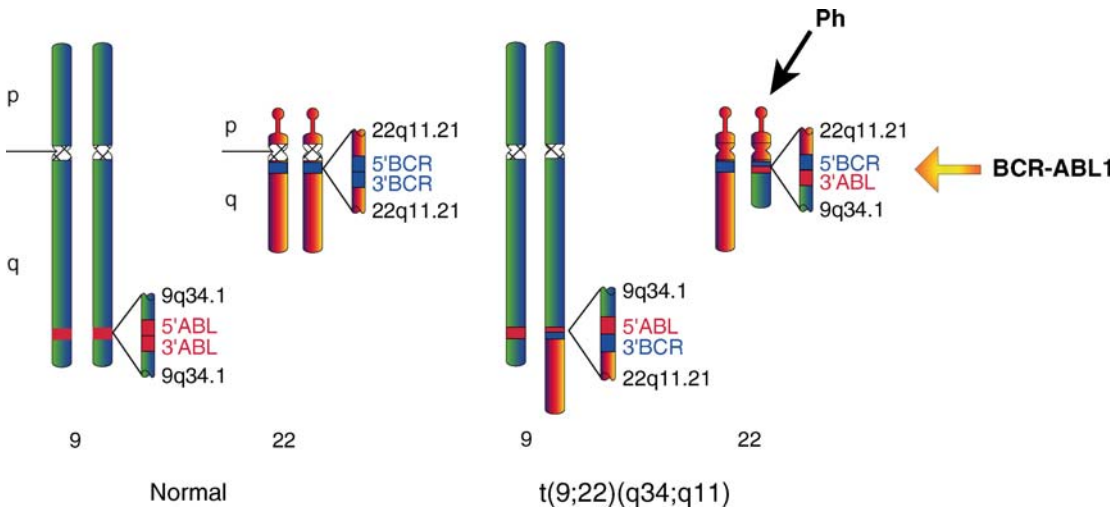
The *BCR-ABL1* mutation is somatically acquired. ►Recombination between the *BCR* and *ABL1* genes

occurs in an early progenitor or stem cell of the bone marrow, and usually results in the microscopically visible ►chromosome translocation t(9;22)(q34;q11) (Fig. 1).

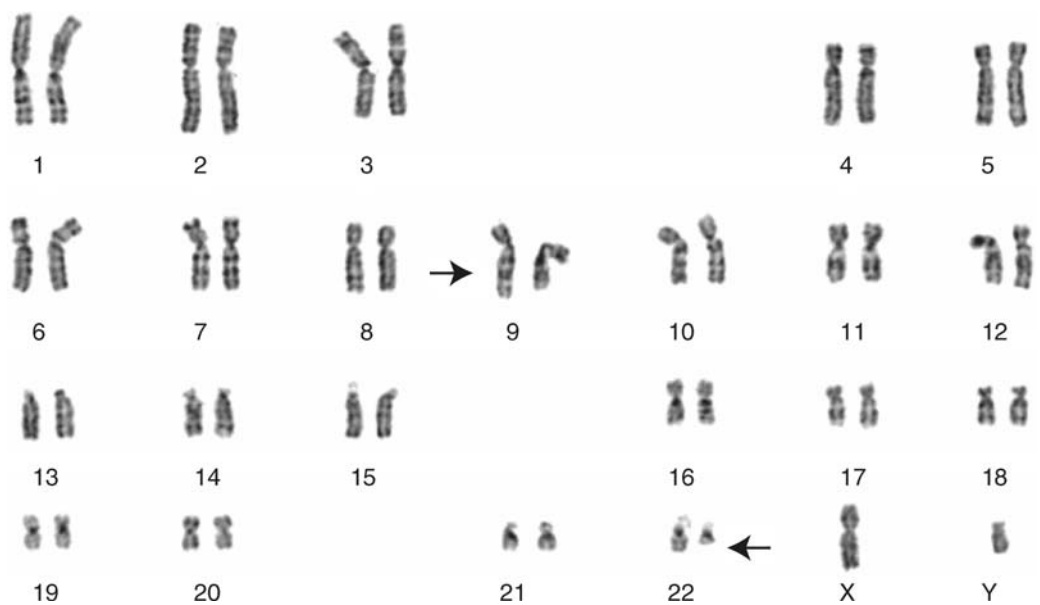
One product of this translocation is the well known Philadelphia (Ph) chromosome (Fig. 2) a shortened chromosome 22 identifiable in leukemic metaphase cells of ~90% of patients with CML. The Ph and associated *BCR-ABL1* hybrid gene are also found recurrently in ALL, although with higher frequency in adult (15–20%) compared with childhood ALL (5%). The discovery of the Ph chromosome in 1960 was a milestone for cancer research, providing the first clear indication that specific cancer types were characterized by recurrent genetic changes with potential proliferative advantage.

Molecular Features of BCR-ABL1 Recombination

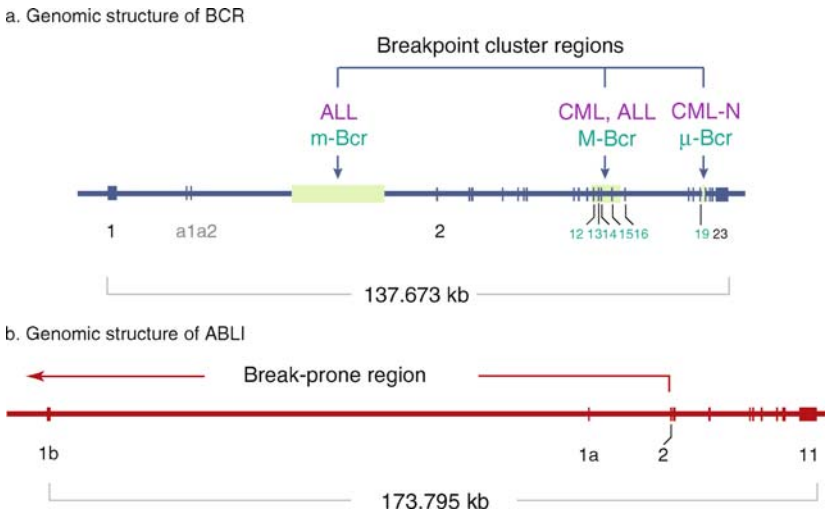
Recombination between the *BCR* and *ABL1* genes usually generates two products: a *5′ABL1–3′BCR* hybrid gene on the derivative 9q + chromosome that is in some cases transcribed but not apparently



BCR-ABL1. Figure 1 Ideogrammatic representation of chromosomes 9 and 22 before (left) and after (right) recombination between the *BCR* and *ABL1* genes to form the leukemia-initiating hybrid *BCR-ABL1* gene.



BCR-ABL1. Figure 2 Karyotype of a leukemic metaphase cell showing the standard Ph translocation, 46,XY,t(9;22)(q34;q11).



BCR-ABL1. Figure 3 Genomic structure and features of the human *BCR* and *ABL1* genes. (a) Exons 1–23 of *BCR* and alternatives (a) are indicated as blue boxes; The minor breakpoint cluster region (m-Bcr), major ▶breakpoint cluster region (M-Bcr) and micro breakpoint cluster region (μ-Bcr) are shaded in green. Disease subtypes associated with the different regions are shown as ALL, acute lymphoblastic leukemia; CML, chronic myeloid leukemia and CML-N, neutrophilic chronic myeloid leukaemia; (b) Genomic structure of the human *ABL1* gene. Exons 1–11 and alternatives (a) are indicated as red boxed regions.

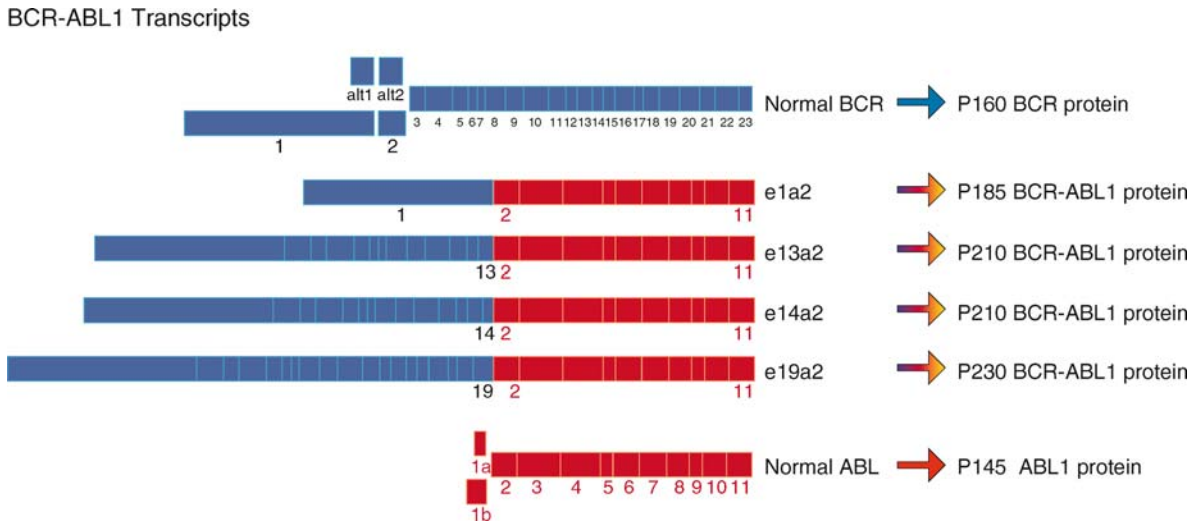
translated, and a *5′BCR-3′ABL1* product on the derivative 22q- or Ph chromosome that is both transcribed and translated. The leukemia-causing properties of the 5′BCR-3′ABL1 protein have been proven in a variety of animal models, and it is to this product that the BCR-ABL1 acronym usually refers.

Both *BCR* and *ABL1* are large genes, at ~138 and 174 kb, respectively (Fig. 3). Several viable in-frame *BCR-ABL1* fusions have been reported or predicted. However, depending on the location of the breakpoint site within *BCR*, those associated with leukemia generally differ according to the number of *BCR* exons that link with the constant *ABL1* exons 2–11 (Fig. 4).

- p210 BCR-ABL1: Breaks occur within the 5-kb major breakpoint cluster region (M-Bcr) of BCR in most cases of CML, and in about 50% of BCR-ABL1 rearrangement-positive cases of ALL. In these cases, the *BCR-ABL1* fusion gene is transcribed as a large chimaeric mRNA that is spliced into an 8-kb mRNA with BCR exon 13:ABL1 exon 2 (e13a2) and/or BCR exon 14:ABL1 exon 2 (e14a2) junctions. This hybrid mRNA is in turn translated to form a 210-kD BCR-ABL1 fusion protein.
- P230 BCR-ABL1: A larger 230-kD protein identifies a subgroup of patients with neutrophilic CML (CML-N) that present with a lower white cell count than usual and for whom progression to blast crisis is slow. In these cases, a breakpoint occurs in a region more 3′ in *BCR* (m-Bcr) to form a BCR exon 19: ABL1 exon 2 (e19a2) mRNA transcript in which almost the entire BCR gene is joined with ABL1.
- P190 BCR-ABL1: For the remaining 50% of BCR-ABL1 positive ALL cases, breakpoints usually occur at different sites across a wider ~35-kb region designated m-Bcr (minor breakpoint cluster region), which maps ~46-kb upstream of M-Bcr. A BCR exon 1:ABL1 exon 2 (e1a2) transcript is expressed in these cases, which is translated into a smaller 185-kD BCR-ABL1 protein. The e1a2 transcript is occasionally found in CML patients when it may be associated with a more aggressive clinical course.
- For all BCR-ABL1 leukemias, although sites of preferential breakage in the *ABL1* gene have been identified, breakpoint locations overall are more variable than those in *BCR*, and may occur at different sites within a >200-kb region extending from a point 9-kb 5′ of the entire gene to exon 2.

Complex BCR-ABL1 Rearrangements

About 10% of CML cases show more complex *BCR-ABL1* rearrangements that involve other chromosomal sites, and which may be camouflaged by a normal karyotype. In all of these cases, the 5′ part of *BCR* is fused with the 3′ part of *ABL1* to form the characteristic *BCR-ABL1* fusion gene essential for the development of CML. However, the 3′ part of *BCR*, which unites with the 5′ *ABL1* remnant in the standard t(9;22)(q34;q11), usually recombines with one of the additional chromosomes in the complex translocations or with a part of chromosome 9 outside of the *ABL1* gene. Although patients present with clinical features typical of BCR-ABL1



BCR-ABL1. Figure 4 Normal BCR and ABL1 transcripts and the most frequently detected variant BCR-ABL1 fusion transcripts. Corresponding protein products are shown to the right. Alternative (alt) exons are marked above the normal transcript for BCR and as 1a or 1b for ABL1.

leukemia, the biological and pathological consequences of complex recombination variants to treatment response and disease course is still unresolved.

Translocation-Associated Genomic Deletions

Another level of complexity in *BCR-ABL1* rearrangement is found in the form of translocation-associated deletions. These genomic deletions, either proximal to the 5′ *ABL1* breakpoint or distal to the 3′ *BCR* breakpoint are associated with the derivative 9q + of the standard t(9;22) or with sites of recombination on additional partner chromosomes in complex variant *BCR-ABL1* rearrangements. The deletions, which were initially identified fortuitously after development of new fluorescent *in situ* hybridization (►FISH) probe systems for detecting ►minimal residual disease in interphase cells of CML patients, are found in ~10–15% of all CML patients, with an increased frequency reportedly associated with complex *BCR-ABL1* rearrangements. The deletions can be large, with variable proximal and distal breakpoints located up to 8 Mb from *ABL1* and 4 Mb from *BCR* on the derivative 9q + or derivative additional partner chromosome. They can occur simultaneously during the *BCR-ABL1* recombination translocation-forming process or occasionally as a subsequent step after the initial translocation. Patients having translocation-associated deletions tend to have a considerably worse prognosis and survival than patients without deletions. The biological basis for the survival disadvantage associated with positive deletion status is presently not known, but may possibly be due to loss of tumor suppressor genes within the deleted region.

Detection of BCR-ABL1

The *BCR-ABL1* fusion gene may be detected in leukemic cells by one or more of the following molecular procedures:

- Amplification of predicted e1a2, e13a2, e14a2, e19a2 or variant splice junctions using polymerase chain reaction (►PCR) after reverse transcription of leukemic cell mRNA (RT-PCR)
- FISH on single cells (metaphase or interphase) using a combination of large insert *BCR* and *ABL1* probes
- ►Southern blotting using leukemic DNA digested with appropriate restriction enzymes and one or more probes from within M-Bcr or other relevant regions of *BCR*
- By immunoprecipitation and Western blot analysis of the chimaeric protein

What Causes BCR-ABL1?

The mechanism that underlies *BCR-ABL1* gene rearrangement in most leukemias is unknown, but new and relevant clues are gradually emerging. For example, there is a clear association, both epidemiologically and in the laboratory, between exposure to ionizing radiation and the development of BCR-ABL1 leukemia. This increased risk is reflected in the increased incidence of CML in atomic bomb survivors compared to the general population, and in the increased occurrence of *BCR-ABL1* mutations in cultured cells subjected to high-dose gamma-irradiation and X-irradiation. Recent findings suggest that ionizing radiation can influence the generation of leukemia-specific fusion genes by juxtaposing genes normally

distanced in the interphase cell nucleus, and that certain cell types with a lineage-specific 3-D chromatin distribution may be more or less susceptible to a particular fusion gene rearrangement than others.

BCR-ABL1 in Healthy Individuals

BCR-ABL1 transcripts have been identified, using RT-PCR, at very low levels in circulating peripheral blood granulocytes of more than two thirds of healthy adults. The identification of other leukemia-associated fusion transcripts in different studies provides good evidence that aberrant recombination occurs ubiquitously at a baseline level in somatic cells of normal individuals. These findings also suggest that additional selective processes, such as immunological tolerance or cell type origin and stage of differentiation, are required to provide BCR-ABL1 cells with a proliferative advantage and produce the leukemic phenotype.

Why Breakpoint Cluster Regions?

The molecular factors that determine preferential breakage sites in *BCR*, and precipitate *BCR-ABL1* recombination are presently unknown, but the ►Alu element is a strong candidate to facilitate this process. Sequence analysis of M-Bcr has identified a single Alu element central within an ~3-kb region where more than 70% of the breakpoints occur. In addition, analysis of reciprocal *BCR-ABL1* and *ABL1-BCR* breakpoint junctions from several cases of CML and ALL has identified sequence homology to Alu elements at, or close to, the sites of recombination. M-Bcr also recombines preferentially with Alu elements at chromosomal sites outside of *ABL1* in complex *BCR-ABL1* rearrangements, and in these cases an association with gene coding domains and ►translin-specific binding motifs was also suggested. Further research is needed to clarify the significance of these findings.

Molecular Consequences of BCR-ABL1

The leukemia-causing properties of the BCR-ABL1 protein have been demonstrated in a range of *in vivo* and *in vitro* laboratory models, including mice made transgenic for different forms of the hybrid oncogene or transplanted with BCR-ABL1 transfected stem cells. BCR-ABL1 cells are more proliferatively active, differentiate abnormally, show an increased resistance to ►apoptosis and have altered adhesion properties compared with their normal counterparts. Much recent work has sought to understand the mechanisms that precipitate these features and precisely how the BCR-ABL1 mutation activates cell transformation in vivo.

Normal BCR proteins are found in the cytoplasm and have at least two enzymatic activities, serine/threonine kinase at the N-terminal, and GAP activity at the C-terminal. The normal ABL1 protein is a non-receptor protein tyrosine kinase that is localized to the cytoplasm, where it is weakly associated with actin filaments, and the nucleus, where it is associated with chromatin. In BCR-ABL1 hybrid proteins, the fused BCR sequences block nuclear translocation and activate the actin binding function that is required for BCR-ABL1 to efficiently transform cells. Because of its heightened ►tyrosine kinase activity, the *BCR-ABL1* protein can phosphorylate a range of different substrates, so activating multiple different cytoplasmic and nuclear signal-transduction pathways relevant to hematopoietic cell growth and differentiation. Examples of signaling cascades activated by BCR-ABL1 include the ►Ras pathway, the Jun-kinase pathway, the phosphatidylinositol-3 kinase pathway, a variety of CRKL-linked signaling processes, the Jak-STAT (►Signal transducers and activators of transcription in oncogenesis) pathway and the Src pathway.

Clinical Relevance

- Chronic myeloid leukemia (CML) is a myeloproliferative disorder that develops after the BCR-ABL1 mutation occurs in a pluripotent bone marrow stem cell. The affected stem cell gains a proliferative advantage and a malignant leukemic clone becomes established. CML, characterized by overproduction of granulocytes in the bone marrow and peripheral blood, accounts for about 25% of all human leukemias, with an incidence of ~1 in 100,000 per year. CML affects both sexes and all age groups, but occurs most commonly at 40–50 years. Patients typically present with symptoms of fatigue, bleeding, moderate weight loss, an enlarged palpable spleen, and a high white blood cell count.
- ►Blast crisis CML: CML is a biphasic disease, and without effective treatment usually progresses within 3–5 years of diagnosis to an aggressive and terminal acute phase or blast crisis. The precise molecular events that determine blast crisis are still unknown, although there is much evidence from cytogenetic and molecular studies that non-random and lineage-specific accumulation of gene mutations may be important.
- BCR-ABL1 is also found in leukemic cells of patients with adult (10–20%) or childhood (5%) acute lymphoblastic leukemia (ALL L1 or L2), and in rare cases (~3%) of acute myeloid leukemia (AML, mostly M1 or M2).

Anti-BCR-ABL1 Therapies

Bone marrow transplantation and/or alpha-interferon therapy have been the treatments of choice for BCR-ABL1 leukemias. But the introduction of ►imatinib mesylate, a synthetic tyrosine kinase inhibitor designed to specifically impede BCR-ABL1 fusion protein activity, has significantly improved the overall outlook and prognosis for the majority of CML patients and

this drug is now considered standard therapy for CML. New anti-BCR-ABL1 therapies are additionally being developed to improve outlook for the proportion of patients who do not respond or to help overcome leukemic cell resistance developed in some cases to imatinib.

Beckwith-Wiedemann Syndrome Associated Childhood Tumors

Marcel Mannens
Academic Medical Centre, University of Amsterdam, Amsterdam, The Netherlands

Definition

Beckwith-Wiedemann syndrome (BWS) is a complex overgrowth disorder caused by a number of genes that are subject to genomic imprinting. A high incidence of solid childhood tumors is seen in patients that present with BWS.

Characteristics

Diagnostic Criteria

Beckwith-Wiedemann syndrome is a disorder first described by Beckwith in 1963 at the 11th annual meeting of the Western Society for Pediatric Research. Later, Wiedemann and Beckwith described the syndrome in more detail [1, 2]. BWS is characterized by a great variety of clinical features, among which are abdominal wall defects, macroglossia, pre- and post-natal gigantism, earlobe pits or creases, facial nevus flammeus, hypoglycemia, renal abnormalities and hemihypertrophy. BWS patients have a 7.5% risk of developing (mostly intra-abdominal) childhood tumors. Tumors most frequently found are ►Wilms tumor (WT), adrenocortical carcinoma (ACC), rhabdomyosarcoma (RMS) and hepatoblastoma (HB). Patients can be classified as having BWS according to the clinical criteria proposed by Elliot or DeBaun, although cases of BWS are known that do not comply with either set of criteria.

(Epi)-Genetics

The syndrome occurs with an estimated incidence of 1:13,700 and most cases are sporadic (85%). The genetic predisposition for BWS lies on chromosome 11p15 (linkage analysis, chromosome abnormalities, loss of imprinting (LOI), gene mutations). The syndrome is

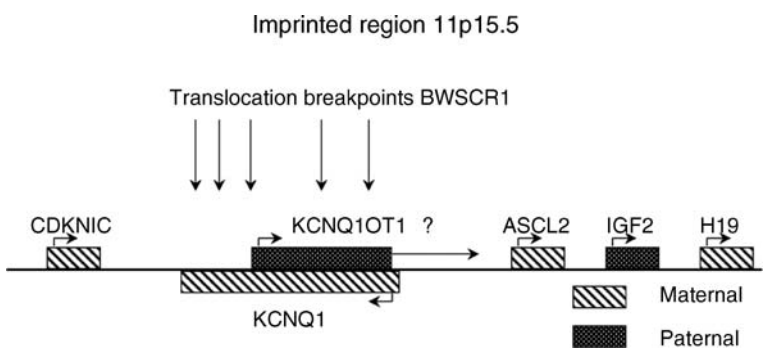
subject to genomic imprinting since maternal transmission seems to be predominant. In addition chromosomal translocations are of maternal origin, duplications and uniparental disomies (UPD) of paternal origin. All hitherto known causative genes are imprinted. The translocation breakpoints on chromosome 11 map to three distinct regions within 11p15.3-pter. Beckwith-Wiedemann syndrome chromosome region 1 (BWSCR1) near INS/IGF2, BWSCR2 5-Mb proximal to BWSCR1 and BWSCR3 2-Mb even more proximal. This already points to genetic heterogeneity, but also at the clinical level there seems to be heterogeneity. Chromosomal translocations in BWSCR1 and BWSCR3 are associated with the classical BWS phenotype, and BWSCR2 with minor BWS features but pronounced hemihypertrophy. BWSCR 1 and BWSCR2 have been cloned, and genes isolated from this region were shown to be involved in the development of this disorder. All genes involved are subject to genomic ►imprinting.

BWSCR1

This region consists of a number of imprinted genes (Fig. 1). All known translocation breakpoints disrupt KCNQ1, a gene coding for a potassium channel involved in the Romano-Ward en Jervell-Lange-Nielsen cardiac arrhythmias syndromes. However, this imprinted gene is most likely not directly involved in BWS, but a gene transcribed in the antisense orientation of KCNQ1 clearly is. This gene, KCNQ1OT1, shows aberrant methylation in 50–80% of BWS cases. It does not code for a protein and functions through its RNA. CDKN1C is an inhibitor of cyclin-dependent kinases. Heterozygous mutations have been identified in about 20% of BWS patients in two studies. Others, however, have not been able to confirm this mutation frequency. The gene is not a major cause of BWS. It is, however, possible that in certain countries the mutation frequency is elevated (e.g. Asia). In addition, it has been reported that this gene is more frequently involved in familial cases of BWS. CDKN1C mouse models revealed some of the clinical BWS features such as omphalocele and renal adrenal cortex anomalies. In humans, CDKN1C also seems to be more frequently associated with abdominal wall defects. Another strong candidate for involvement in the aetiology of BWS is the embryonic growth factor IGF2. Mouse models overexpressing IGF2 displayed a phenotype overlapping with the BWS phenotype. Loss of IGF2 imprinting is often seen in BWS patients. H19, another non-coding gene, lies downstream of IGF2 and the expression of IGF2 and H19 seems to be linked. H19 is important for the maintenance of the imprinting status of IGF2. Mouse studies underline the link between IGF2 and H19 expression and overgrowth phenotypes were found. H19 loss of imprinting (silencing of the gene) is frequently seen in BWS cases although not always in combination with IGF2 loss of imprinting (LOI). Interestingly, overexpression of H19 seems to lead to the Silver Russell Syndrome (SRS), characterized by intrauterine growth retardation, poor postnatal growth, asymmetry a classic facial phenotype and no increased risk for childhood tumors. Finally a gene called ASCL2 is localized to the 11p15-imprinted region. Although no direct involvement in the BWS aetiology is known, this gene might account for the fact that most, if not all, BWS cases with uniparental disomy (UPD) present in a mosaic form. The mouse homologue codes for a transcription factor, which is expressed during early mouse development and is essential for the development of the placenta. Therefore, also in humans, complete lack of expression might be lethal.

BWSCR2

Two patients with balanced chromosomal translocations define this second chromosomal region, one of which developed a Wilms tumor. Both translocations in 11p15.4 disrupt a paternally imprinted zinc-binding finger gene ZNF215. Parts of the 3′ end of this gene are transcribed from the antisense strand of a second zinc-finger gene, ZNF214. Although putative mutations in



Beckwith-Wiedemann Syndrome Associated Childhood Tumors. Figure 1 Imprinted genes on 11p15 involved in BWS. The parental expression (imprinting) of these genes is indicated.

these genes in other sporadic BWS cases were found, their involvement in BWS needs to be further elucidated by functional studies.

Diagnostics

BWS can be diagnosed in the laboratory with cytogenetics (<5%) or DNA-diagnostics. The current major test involves methylation assays or LOI studies at the RNA level. The majority of cases (50–80%) exhibit aberrant methylation of KCNQ1OT1 with or without aberrant methylation of IGF2/H19. These former cases often show UPD for 11p15 (in a mosaic form) which explains this aberrant methylation for multiple genes. However, the majority of cases with KCNQ1OT1 defects and some cases with H19/IGF2 defects have no UPD 11p15. Therefore, an imprinting switch can be assumed, involving an imprinting centre analogous to the Prader-Willi and Angelman syndromes. The current data are most compatible with two distinct imprinting centers for either KCNQ1OT1 or IGF2/H19. CDKN1C mutation analyses might be considered, especially in familial cases of BWS. The increased tumor risk for BWS patients seems to be associated with UPD in general and H19 methylation defects in particular. KCNQOT1 methylation defects only seem to be a reliable prognostic factor since tumors are seldomly associated with this group of patients. Recurrence risks for a second pregnancy can be assessed with UPD studies. In cases of a UPD in a mosaic form, there is no increased recurrence risk for BWS in a second pregnancy since the genetic defect occurred post-fertilization.

BWS Associated Tumors

Although childhood solid tumors associated with BWS share some common genetic features, the spectrum of genetic changes found in these tumors is diverse and complicated with many genetic alterations seen.

Wilms Tumor

The tumor most often found to be associated with BWS is Wilms tumor (WT) or nephroblastoma (59% of the tumors found in BWS patients). Overall it occurs with a frequency of 1 in 10,000 children, mostly in children under the age of 5 years. In patients suffering from BWS the incidence is 800–1000 times increased. A high percentage (38%) show loss of heterozygosity (LOH) of chromosome 11p. This region can be subdivided roughly into two parts: LOH of markers on 11p13 and LOH of markers on 11p15. The region on 11p13 has been shown to be deleted in patients affected by WAGR. WAGR stands for the combined occurrence of sporadic aniridia, WT, genitourinary abnormalities and mental retardation. A gene in the candidate region (WT1) has been cloned. Mutations of this gene occur in only 10–15% of sporadic Wilms tumors, suggesting the existence of additional genes involved in the development of this tumor. The Denys-Drash syndrome, another syndrome associated with Wilms tumor, shows constitutional mutations of the WT1. The region on 11p15 showing LOH in WTs can be subdivided into two regions: An 800 kb region containing the WT2 locus near IGF2 and an additional locus of 336 kb proximal to WT2. WT can also be found in association with other syndromes, like the trisomy 18 syndrome, the Perlman syndrome and the Simpson-Golabi-Behmel, the Sotos syndrome and the Klippel-Trenaunay syndrome. The ►Li-Fraumeni syndrome is a rare familial tumor syndrome and patients suffering from this disease contain germline point mutations in the ►p53 tumor suppressor gene. The tumors that develop in these patients show a deletion of the wild type p53 allele. Although WT is not considered to be part of the Li-Fraumeni syndrome there have been few reports of the occurrence of WT in families affected by this syndrome. Mutations in the tumor suppressor gene p53 have been found in sporadic WTs and seem to be associated with a histological subtype. In a series of 140 WTs, mutations were restricted to tumors of the anaplastic subtype, showing aberrations in 8/11 samples. This subtype is linked to a poor prognosis. In 10–25% of the Wilms tumors, LOH of 16q markers is found. It has been suggested that LOH of 16q is associated with an adverse prognosis. Another genetic abnormality, which seems to confer an adverse outcome, is LOH of 1p. This abnormality was found in 12 and 18% of the cases respectively. Chromosome 7 also seems to be involved in Wilms tumor. According to the literature in 23% of the cases chromosome 7 is rearranged. Another region found to be frequently involved in LOH (14%) is on chromosome 22q. In a study which quantified chromosome 12 allelic imbalance in a series of 28 Wilms tumors, duplications were detected in 18%. An inventory of all quantitative chromosome aberrations occurring in a series of 46 WTs was made using comparative genomic hybridization analysis (CGH). Chromosome regions showing loss of DNA in three or more samples included 1p (11%), 11p (9%), 16q (13%) and 17p (7%). Regions showing gain of DNA in three or more samples included 1q (20%), 7q (9%), 8 (7%), 12q (17%), 17q (7%) and 18 (7%). In 2007, it became clear that a somatic deletion of an X-linked gene (WTX) is found in 1/3 Wilms tumors.

As expected, imprinting seems to play a major role in WT development since 11p15 LOH is always of maternal origin. This resulted in the hypothesis that a paternally imprinted tumor suppressor gene is involved in Wilms tumorigenesis. Alternatively, a maternally imprinted gene involved in stimulation of cell growth could be involved in the cases showing paternal UPD of (part of) chromosome 11. At present there are three

candidate genes on 11p15 that show parent-of-origin-dependent monoallelic expression and belong to one of these two categories: the tumor suppressor genes H19 and CDKN1C which are maternally expressed and the paternally expressed growth-promoting gene IGF2. Evidence for the involvement of these genes has been found i.e. loss of imprinting, or increased expression of IGF2 or reduced expression of CDKN1C or H19.

Adrenocortical Carcinoma

The second most common tumor found in BWS-patients is adrenocortical carcinoma (ACC). It is found in 15% of patients that develop a tumor. In the general population ACC is found to be an extremely rare tumor with an incidence of 1.7 new cases per 1,000,000 per year. As in BWS, IGF2 seems to be involved in sporadic ACC-tumorigenesis. A considerable proportion of the malignant tumors (~60%) display LOH of the 11p15.5 region, presumably all representing uniparental disomies. This is seen in both adult and childhood ACCs. In these cases a good correlation was found with over-expression of the IGF2 gene. These phenomena were found in a much smaller percentage in the benign adenomas. It has been hypothesized that adrenocortical tumorigenesis is a multistep process with sequential progression from the normal to the adenomatous and then to the malignant cell. If this is the case then IGF2 could be involved in the transition from adenoma to carcinoma. ACC is also found in association with other syndromes. One of these is the Li-Fraumeni syndrome, which is associated with mutations of the p53 gene on chromosome 17p. In one study, in which sporadic ACC's were analyzed for the presence of LOH at three different chromosome regions, chromosome 17p (containing the p53 gene) had become homozygous in all informative samples. LOH of 17p was not found in adrenocortical adenoma, the benign counterpart of ACC. Again, if the hypothesis that adrenocortical tumors develop from normal tissue to adenomas to carcinomas is correct, this would mean that LOH of 17p could be a late event in ACC tumorigenesis. Two other groups identified mutations in the p53 gene in ~30% of sporadic ACC's. In addition, CGH analysis showed loss of 17p in 50% of the (sporadic) cases. Another hereditary tumour syndrome associated with adrenocortical tumors is ►multiple endocrine neoplasia type 1 (MEN1). In most cases associated with MEN1 adrenocortical adenomas are found. The disease is caused by mutation of the menin tumor suppressor gene (MEN1), located at 11q13.

Other regions found to be lost in ACC's include chromosome 13q, which was shown to have lost heterozygosity in 50% of informative patients, and chromosome 2. Genetic aberrations that were found in 38% of the tumors in this study were gains of chromosomes 12, 15q, 16q and 19p and losses of chromosomes 3p, 6q, 8p, 9p, 11p, 17q, 18q and 22q. There are numerous differences between the genetic aberrations found in adrenocortical adenomas and adrenocortical carcinomas. These differences may reflect various stages along the carcinogenic pathway.

Evidence for an involvement of imprinting in ACC again comes from LOH 11p15 studies (maternal loss) and LOI and expression studies for IGF2 and H19. It should be noted that LOI of IGF2 was associated with the malignant phenotype, since it was not detected in the adenomas but only in the carcinomas.

Rhabdomyosarcoma

Although rare, rhabdomyosarcoma (RMS) represents the most common soft-tissue sarcoma in children under the age of 15 years. It occurs with a frequency of 1.3–4.5 cases per million children per year. Based on their histology, rhabdomyosarcomas can be subdivided into three major subtypes: embryonal (E-RMS), alveolar (A-RMS) and pleomorphic (P-RMS) rhabdomyosarcoma, of which E-RMS is the subtype associated with BWS. Of all newly diagnosed cases 60% are E-RMS and 20% are A-RMS. Patients with E-RMS have a better prognosis than patients with A-RMS. LOH of chromosome 11p is an abnormality found frequently in RMS. In one study it was found in 72% of primary E-RMS and 20% of primary A-RMS. A gene located in this region, GOK (gene on chromosome 11) or STIM1 (stromal interaction molecule 1) was postulated to be a candidate tumor suppressor gene in RMS. No expression was found in seven RMS cell lines, and transfection of the gene into the RMS cell line RD was followed by growth arrest of the cells. LOH of 16q was also found in both types (in 55% of E-RMS and 40% of A-RMS). In total, LOH of 6p was found in 28% and LOH of 18p in 32% of the cases. Studies of A-RMS have shown that they often (~90%) contain a specific translocation. In most of these cases (68%) a t(2;13)(q35;q14) is found. In a smaller subset of A-RMS (14%) a variant translocation of t(1;13)(p36;q14) has been detected. Both these translocations cause the formation of a chimeric protein. In the case of the t(2;13) a PAX3-FKHR fusion product is expressed and in tumors with the t(1;13) a PAX7-►FOXO1A product is detected. PAX3 and PAX7 are both transcription factors involved in embryonal myogenesis. In the chimeric proteins the DNA binding domains of the PAX genes are retained and fused to the C-terminal region of the FKHR gene containing a strong transactivation domain. It has therefore been proposed that both fusion proteins function as transcription factors that aberrantly regulate transcription of genes, controlled by PAX3 or PAX7 binding sites. The PAX3-FOXO1A fusion protein has been shown to be a strong transcriptional activator. In addition both PAX3-FOXO1A and PAX7-FOXO1A

are over-expressed in A-RMS either by increased transcription (PAX3-FOXO1A) or by gene amplification (PAX7-FOXO1A). Although the presence of either translocation is considered to be a characteristic of A-RMS, some cases with the t(1;13) show mixed histology of both the embryonal and the alveolar type, and a case of E-RMS containing the t(2;13) has been described. In addition the age at diagnosis in patients with the t(1;13) is more consistent with E-RMS. Cytogenetic analysis of RMS showed a high incidence of trisomy 2 (in 9/9 E-RMS samples) and a high incidence of structural rearrangements of chromosomes 1 and 3 (both in 4/5 RMS samples). The alterations on chromosome 3 seem to cluster within 3p14–21. The presence of a der(16)t(1;16)(q21;q13) is also noted in both RMS types and has been categorized as a secondary structural abnormality. RMS was one of the first tumors found to be associated with the Li-Fraumeni syndrome. DNA amplifications have been identified for regions on chromosome 2p and 12q. Both A-RMS and E-RMS have been studied by CGH and the results showed clear differences between the two RMS subtypes. Aberrations found in E-RMS concerned gains and losses of whole chromosomes or large parts of chromosomes: Gains were most frequently found for chromosomes 2, 8, 12, 13 (in 6/10 cases), chromosome 7 (in 5/10 cases), and chromosomes 17, 18 and 19 (in 4/10 cases). Losses were identified most often for chromosome 16 (in 4/10 cases), chromosome 10 (in 3/10 cases) and chromosomes 14 and 15 (in 2/10 cases). One tumor showed an amplification of 12q13-q15. In the A-RMS samples whole (or part of) chromosome gains and losses were found to a much smaller extent. In ten tumors and four cell lines gain of chromosome 17q was found in four cases. However, in a high percentage amplifications were present. Chromosome regions most often involved were 12q13-q15 (in seven cases) and 2p25 (in five cases). The latter region contains the N-MYC gene which is known to be amplified in A-RMS. The regions containing the PAX7 and FKHR genes on 1p36 and 13q14 were found to be amplified in two cases.

As for Wilms tumor, abnormal genomic imprinting of chromosome region 11p15 appears to play a role in the development of RMS (paternal LOH, LOI of IGF2). Increased expression of IGF2 in tumors with monoallelic expression of the gene confirm the important role postulated for IGF2 in the development of this tumor. The imprinting status of H19 has also been examined in RMS and was found to be normal in both subtypes. However, the expression was reduced significantly in 13/15 E-RMS and 2/11 A-RMS. This phenomenon was associated with either loss of the maternal (expressed) allele or LOI of IGF2. In contrast to the situation for Wilms tumor, reduced expression of H19 was not seen in all cases with LOI of IGF2.

Hepatoblastoma

Hepatoblastoma (HB) is a rare malignant epithelial tumor of the liver with an incidence of one case per million children. However, it is the most common malignant hepatic neoplasm of childhood, and occurs with a predominance in males. Although most cases are sporadic, some HBs are associated with either BWS or familial adenomatous polyposis coli (FAP; ►APC gene in Familial Adenomatous Polyposis). Since FAP patients carry mutations in the adenomatous polyposis coli (APC) gene, sporadic HBs have also been analyzed for the presence of mutations in this gene. Indeed, alterations of the APC gene were found in 69% of the sporadic cases. When FAP occurs in combination with extracolonic symptoms it is commonly referred to as Gardner syndrome. Patients suffering from this disease also have an increased risk for the development of HB. The trisomy 18 syndrome can also be associated with HB, as has been found in four patients. One of the phenotypic features of trisomy 18 syndrome is the presence of an omphalocele (also found in BWS patients). It has been suggested that this feature may be one of the factors important in the development of HB in cases in which part of the liver has herniated into the omphalocele. As was found for the other BWS associated tumors, LOH of 11p15 has also been found independently by several researchers for HB (up to 33%). An LOH study of chromosome 1 showed frequent loss of alleles in HBs. In 32 cases 34% had lost heterozygosity for (a part of) chromosome 1, of which 22% were homozygous for markers on the (distal) short arm. There has been a report of the occurrence of HB in the Li-Fraumeni syndrome, and in addition one study showed mutation of the p53 gene in 1/3 sporadic HB samples. Cytogenetic analysis of HB revealed certain consistent chromosome anomalies. Extra copies of chromosomes 2q and 20 are most frequently found. There has also been a report about a recurring translocation: t(1;4)(q12;q34) that results in partial trisomy of most of chromosome arm 1q and partial monosomy of distal 4q. CGH analysis identified mostly gain of DNA. Chromosomes affected in more than 30% of the cases included 1, 2, 7, 8 and 17. When determining the parental origin of 11p alleles lost in HBs it became clear that in this BWS-associated tumor LOH of 11p15.5 was exclusively of maternal origin. When looking directly at the imprinting status of the IGF2 and H19 genes biallelic expression was detected. Two studies showed LOI of IGF2 with normal imprinting of H19 in 1/3 HBs and in 1/5 HBs. A third study showed LOI of both genes in 1/5 cases.

Common Genetic Pathways

When reviewing all genetic and epigenetic data it becomes clear that the most evident abnormality found in all BWS-associated tumors affects chromosome

region 11p15. This is the region to which the syndrome has been linked. All four tumor types show LOH of markers in this region. To date, data has been published for all except ACC showing LOH affecting the maternal allele, with retention of the paternal allele (one ACC with paternal UPD has been described). This suggests the involvement of genomic imprinting. Indeed, abnormal imprinting was found for these tumors, as it was for BWS: They display LOI of the maternally imprinted IGF2 gene. Therefore, this growth factor may play a central role in the development of the overgrowth syndrome and its associated tumors. Increased expression has been noted for WT, ACC and E-RMS, and LOI of IGF2 has been associated with decreased expression of the supposed tumor suppressor gene H19. There is an additional genetic abnormality common between all four types of neoplasms. They all show mutations in the p53 gene. However, this is found in a large proportion of all cancers and therefore is considered not to be specific for the development of tumors associated with the BWS.

Besides genetic evidence there are also pathological data indicating an association between these tumors. Both WT and HB may contain rhabdomyomatous tissue, whereas primary tumors of the liver have been shown to consist of ACC and RMS.

There are also several chromosome aberrations found in a subset of these tumours. When considering abnormalities found in three of the four tumor-types there seems to be a strong connection between WT, E-RMS and HB. They share seven common genetic abnormalities. Besides the abnormalities already mentioned above, they all might contain extra copies of chromosomes 7q, 8 and 17q. Therefore, these chromosome regions may contain genes that play a role in the normal embryonic development of the affected tissues. Since these affected regions are large it would be very difficult to identify the genes involved. More interesting therefore is the abnormality of chromosome 1p that was found in these tumors. This presented either as LOH or structural abnormality of the short arm of chromosome 1. Since these aberrations affect small(er) regions of the chromosome they may be very helpful in the identification of genes. This applies especially to the analysis of translocation breakpoint regions, as has been shown for the regions involved in BWS. Extra copies of chromosome 12 have been identified in the subset consisting of WT, ACC and E-RMS. These tumours are also characterized by increased expression of IGF2.

When analyzing the published data, it becomes clear that WT and E-RMS share most genetic aberrations, with a total of 12. Therefore, the genetic relationship is most evident between these two tumor-types. In addition to the abnormalities already mentioned they have both been shown to contain extra copies of chromosome 18, and in both tumor types decreased expression of H19 has been found. Further elucidation of the common genetic pathways involved in the aetiology of the BWS associated tumors awaits identification of the genes involved.

Beclin 1

Definition

Mammalian homologue of the yeast autophagy protein Atg6/Vps30. Found in an inhibitory complex with Bcl-2. After release of ►Bcl-2, beclin 1 can associate with class III PI3K and stimulate ►autophagy. Beclin 1 is monoallelically deleted in some human cancers.

Becquerel

Definition

A Becquerel (Bq) is a measure for the disintegration per second. A disintegration of 1 nucleus per second equals 1 Bq.

►Radon

Behcet Disease (BD)

Definition

Synonym Behcet syndrome; was named in 1937 after the Turkish dermatologist Hulusi Behçet, who first

described the triple-symptom complex of recurrent oral aphthous ulcers, genital ulcers, and uveitis. This complex, multisystemic disease includes involvement of the mucocutaneous, ocular, cardiovascular, renal, gastrointestinal, pulmonary, urologic, and central nervous systems and the joints, blood vessels, and lungs. It is characterized by oral aphthae and by at least two of the following: (i) genital aphthae, (ii) synovitis, (iii) posterior uveitis, (iv) cutaneous pustular vasculitis, (v) meningoencephalitis, (vi) recurrent genital ulcers, and (vii) uveitis in the absence of inflammatory bowel disease or collagen vascular disease. The cause of BD is not known; however, immunogenetics, immune regulation, vascular abnormalities, or bacterial and viral infection may have a role in its development.

Benign Tumor

Definition

A tumor that remains confined to its site of origin and neither invades surrounding tissue nor spreads to other organ sites.

Benzene and Leukemia

Definition

Benzene and Leukemia addresses leukemogenic effect of benzene, representing a complex model of chemical carcinogenesis in humans.

Characteristics

The relationship between benzene, the smallest and most stable ►aromatic hydrocarbon, and leukemia has been reported in the past for workers with high exposures, when benzene in the commercial form (►Benzol) was used largely as a solvent, especially in the shoe industry and in rotogravure printing. Today, occupational exposures are controlled by law and are at most reserved to workers in the petrochemical industry, workers exposed to automobile emissions such as urban officers or gas station attendants, firefighters, and vehicle mechanics. Currently most European countries and the USA have fixed the threshold of acceptable occupational exposure at 1.63–3.25 mg/m^3 (0.5–1 ►ppm). Benzene, even at much lower concentrations, is also a pollutant of the general environment. Among major sources of benzene for the general population (usually below 50 μg/m^3, 15 ►ppb) are traffic exhaust fumes, since benzene is still a typical component of gasoline (1%), and cigarette smoking, which remains a significant source of exposure in both occupationally and nonoccupationally exposed individuals.

Benzene Toxicity and Carcinogenicity

Since the nineteenth century benzene has been recognized as the cause of hematotoxicity of various degrees, up to aplastic anemia, in workers chronically exposed to high concentrations. However, high-dose benzene leukemogenicity was first reported only in 1928 by Delore and Borgomano in a subject showing benzene intoxication. Subsequent studies confirmed an increased risk of leukemia in different occupational settings characterized by high exposure. In Italy, outbreaks of severe benzene poisoning and leukemia have been observed from the thirties to the early sixties, when benzene as a solvent was prohibited by law. Similar findings were reported in the seventies in Turkey and more recently in China. In Italy, most cases of fatal aplastic anemia and leukemia occurred in shoe manufacturing and in rotogravure printing where commercial benzene was used as a solvent of glues and inks respectively. The estimated or measured exposures were in the order of hundreds ppm. Less severe cases of benzene toxicity were observed in subjects exposed to several tens ppm. The acceptable threshold in the 1960s (25 ppm) was later reduced in many countries after the confirmation of benzene leukemogenic activity at lower exposures, claimed on the basis of some epidemiologic studies in chemical and rubber workers, in USA.

Benzene was recognized as a group A carcinogen ("a known carcinogen") by ►EPA in 1979 and as a group 1 human carcinogen ("known to be carcinogenic to humans") by ►IARC in 1982. Based on the general assumption that no threshold might exist for carcinogenic substances and the fact that benzene exposures in certain industries cannot be avoided, the threshold has been lowered to less than 1 ppm, anyway the lowest technically possible threshold.

Conflicting results, however, have been reported in low-level exposure populations such as drivers, police

traffic officers, and gasoline station attendants. Concerns about health effects of benzene at very low doses have been raised recently by results of a study showing a reduction of white blood cells and platelets also in subjects chronically exposed to less than 1 ppm in air, but the values reported were anyway within normal ranges.

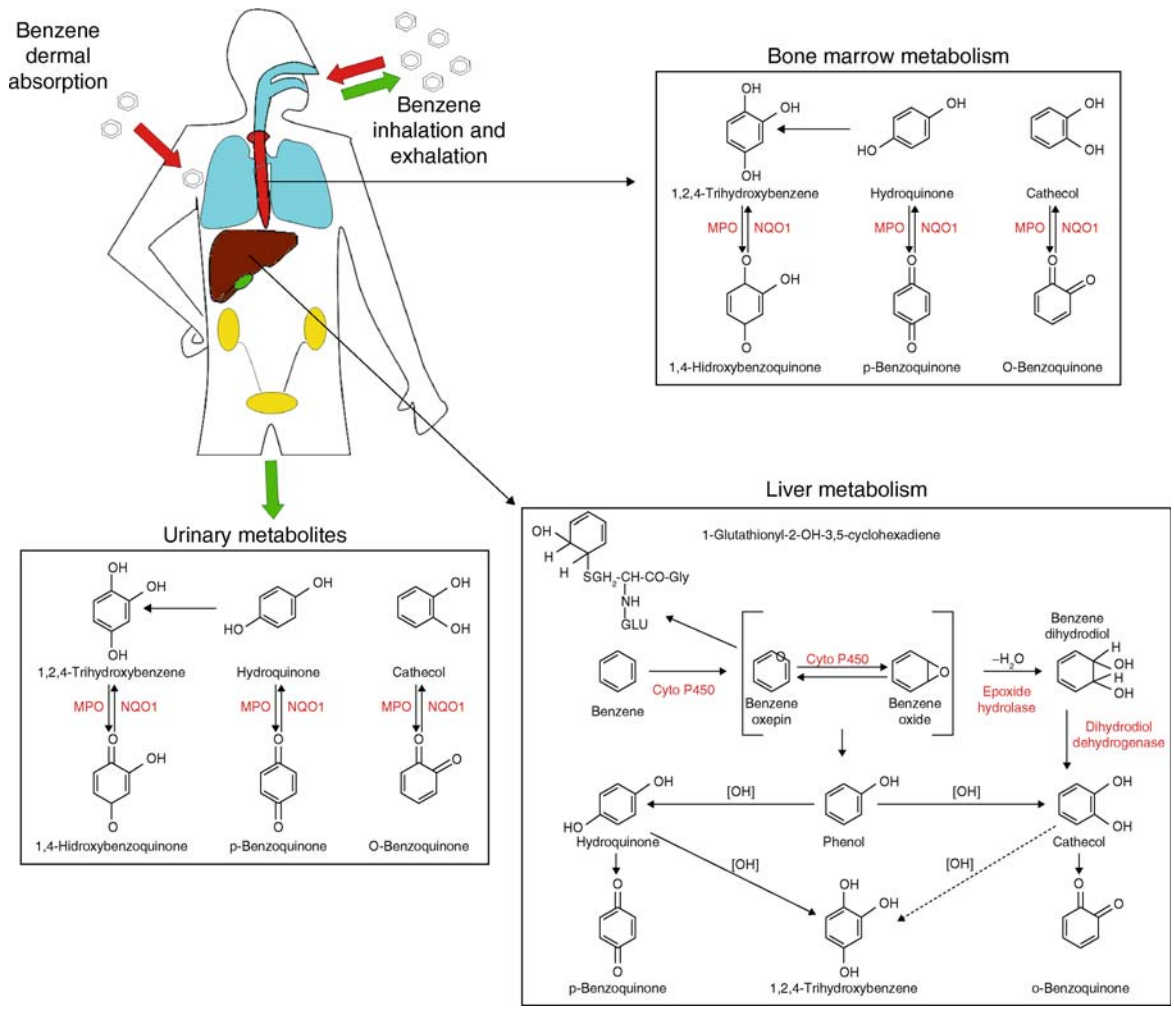
The bone marrow depression of chronic benzene poisoning, resulting in hyporegenerative anemia, leukopenia and thrombocytopenia of varying degree, may slowly recover after removal from exposure, but sometimes persists and evolves into fatal aplastic anemia or into ►acute myeloid leukemia (AML). AML may be preceded by a myelodysplastic syndrome (or preleukemic syndrome), consisting in abnormalities of bone marrow cells surviving ►apoptosis and of blood precursor cells differentiation.

The majority of benzene AMLs are myeloblastic, but other rarer subtypes (e.g., erythroleukemia) have been reported. Many cases of benzene leukemia have low white cell counts, or show only a moderate leukocytosis with a small percentage of immature cells, except in the terminal stage.

Aplastic anemia may occur in subjects while they are still exposed to high concentration of benzene. Leukemia may occur at the same time, or more or less shortly after cessation of exposure. In a few cases a long latency period between the end of work with benzene and occurrence of leukemia has been reported.

Benzene Metabolism and Toxicity

Benzene is not toxic and carcinogenic per se, but rather its toxicity is through its metabolites. Experimental evidences indicate that reactive intermediates are necessary for benzene carcinogenicity and toxicity, but the metabolite(s) responsible are still not fully identified. Inhaled benzene is partly eliminated in the exhaled air. The remaining is rapidly distributed, crosses blood–brain, placental, and gonadal barriers, and is found in



Benzene and Leukemia. Figure 1 Benzene metabolism in humans.

several organs including the bone marrow. Benzene is transformed in the liver to benzene oxide, phenol, cathecol, hydroquinone, and 1,2,4-trihydroxybenzene by the microsomal ►cytochrome P-450 monooxygenase system (►CYP2E1). Cathecol and hydroquinone oxidation results into the reactive intermediates *ortho*-benzoquinone and *para*-hydroquinone. Hydroquinones may also be produced from benzene derived ►quinones via ►NAD(P)H:quinone oxidoreductase (►NQO1) (Fig. 1). Benzene metabolites such as hydroquinone and cathecol, reach the bone marrow and can be further activated by ►myeloperoxidase (►MPO), present at high levels in stromal ►macrophages, resulting in the production of quinones and ►reactive oxygen species, which bind covalently to biological macromolecules. Unmetabolized benzene and several metabolites are eliminated through the kidney and some of them can be measured to assess benzene exposure.

In order to explain the different susceptibility to benzene poisoning in workers with similar levels of exposure, some ►metabolic polymorphisms have been examined in benzene-exposed subjects. A rapid CYP2E1 activity and a loss of NQO1 function polymorphism were found to be associated with increased benzene toxicity in workers exposed to high levels of benzene (>10 ppm) in Shanghai (China). More recent results highlighted the role of MPO and NQO1 polymorphisms even at exposures lower than 1 ppm. CYP2E1 and NQO1 are polymorphically distributed in human populations: in Caucasians, the estimated frequency of CYP2E1 rapid metabolizers is around 10% and a loss-function NQO1 polymorphism has been identified with a 40% frequency.

Benzene, Chromosome Changes and Leukemia

Benzene metabolites are not mutagenic, but are able to generate oxygen reactive species, which might be responsible for DNA damage, both by genetic and ►epigenetic mechanisms.

In the 1960s, the possibility of studying human chromosomes in lymphocytes, stimulated to divide in culture, and in direct preparations of bone marrow cells, raised the interest for cytogenetic studies in benzene-exposed workers with or without signs of benzene toxicity and in cases of benzene leukemia. Exposure to high concentrations of benzene was demonstrated to induce structural (►Chromosome translocations, breaks, deletions) and/or numerical chromosome changes, persisting in lymphocytes also for decades after cessation of exposure and in bone marrow cells at the time of benzene poisoning or during persisting myelodysplastic syndrome.

Structural chromosome changes in benzene-exposed workers were studied more recently with special techniques and resulted to be nonrandom, involving specific chromosomes, both for breaks and for translocations.

In vitro studies of hematopoietic progenitor cells from human bone marrow or umbilical cord blood, cultured in the presence of hydroquinone, showed specific deletions and/or numerical changes in chromosomes more frequently involved in benzene-induced myelodysplastic syndrome and leukemia.

On the basis of some clinical reports, the hypothesis is suggested that myeloid precursor cells with different chromosome changes either die by apoptosis or necrosis, or survive giving rise to atypical cell clones. One clone with selective advantage might proliferate and be responsible for the evolution into leukemia. This mechanism might be enhanced by the bone marrow microenvironment conditions and be favored by benzene-induced immunodepression.

Benzpyrene

Definition

Member of he group of ►polycyclic aromatic hydrocarbons. Benzpyrenes are present in coal tar at low levels and are considered carcinogenic (cancer-inducing). Traces of benzpyrenes are present in wood smoke, and this has given rise to some concern about the safety of naturally smoked foods.

Berlin Breakage Syndrome

►Nijmegen Breakage Syndrome

Beta-2 Microglobulin (β2 Microglobulin)

Definition

Component of MHC class I molecules present on virtually all cells except red blood cells. β2 microglobulin has no trans-membrane region.

►Plasmacytoma

Beta-glucosidase

A glycoside hydrolase enzyme that cleaves sugar residues from compounds.

►Genistein

Beta Subunit of Human Chorionic Gonadotropin (β-hCG)

Definition

β-hCG is normally produced by the placenta and human fetal tissue. Elevated serum β-hCG is most commonly associated with pregnancy, gestational trophoblastic

disease and germ cell tumors. It can also be found in hypogonadal states and with marijuana use.

►Serum Biomarkers

Betacellulin (BTC)

Definition

Has been isolated from conditioned media from a pancreatic β cell tumor cell line. BTC is also expressed in a variety of mesynchymal and epithelial cell lines and in many tissue including pancreas, liver, kidney and small intestine. Membrane-bound proBTC is processed by ADAM10 to release soluble BTC. Transgenic chicken actin promoter-driven BTC over-expression in mice causes bony deformations of the skull, pulmonary hemorrhage syndrome, and complex eye pathology. Transgenic animals showed decrease in the weight of pancreas and increase weight of the eye, lung and spleen.

A triterpenol from birch bark.

►Urothelial Carcinoma

Betulinic Acid

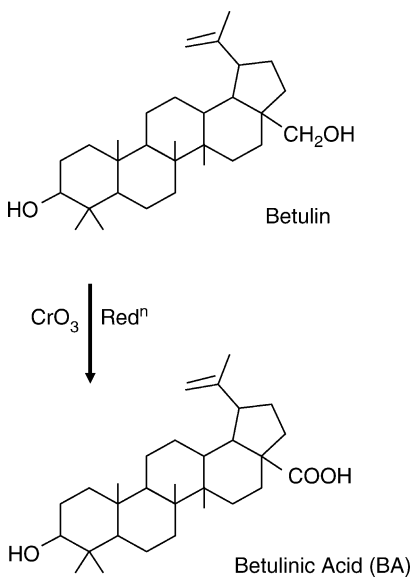
Stephen Safe, Sabitha Papineni, Sudhakar Chintharlapalli
Department of Veterinary Physiology and Pharmacology, Texas A&M University, College Station, TX, USA

Definition

►Betulinic acid is a naturally occurring triterpenoid acid and a potent anticancer drug.

Characteristics

►Betulin is a pentacyclic triterpenol natural product that is found in tree bark and this compound may constitute up to 30% of the bark from birch trees. Betulinic acid (BA) is a minor bark constituent but is readily synthesized from betulin by oxidation to betulonic acid followed by reduction to betulinic acid (Fig. 1). Birch bark extracts containing betulin and BA have been used in traditional folk medicines; however, in recent years, BA alone or some of its derivatives have been developed as pharmacological agents for treating multiple diseases. For example, these compounds are antiviral agents that inhibit HIV-1 replication and exhibit antimalarial, antihelmintic, and antibacterial activity as well as antiinflammatory and analgesic effects. Many of these responses induced by BA and its



Betulinic Acid. Figure 1 Betulin, a major component of birch bark is readily oxidized by chromic acid to betulonic acid which is reduced with sodium borohydride to betulinic acid.

derivatives are structure-dependent and involve changes in structure of one or more regions in the molecule.

Many of the naturally occurring triterpenoid acids, such as ►ursolic acid, ►glycyrrhetinic acid, ►oleanolic acid and ►betulinic acids, exhibit some cytotoxicity to various cancer cell lines; however, among these natural products, BA is by far the most potent anticancer agent. Initial studies by Pisha et al. showed that BA was a highly potent drug for treatment of melanoma in mouse xenograft model. In this study, athymic mice were injected with melanoma cells (MEL-2 or MEL-1) and treated with BA at doses of 50, 250, or 500 mg/kg every third day and this resulted in significant tumor growth inhibition. Moreover, BA also decreased tumor volume in mice already bearing relatively large tumors. It was also reported that tumor growth inhibition could be observed at doses of BA as low as 5 mg/kg (X 6), whereas at doses as high as 500 mg/kg, minimal toxic side-effects were observed in the animals. It was also reported that BA induced ►apoptosis in melanoma cell lines and the high cytotoxocity of BA was observed in melanoma cells but not in squamous, breast, colon, sarcoma, prostate, lung, neuroblastoma, and glioma cancer cell lines.

Subsequent studies on the cytotoxicity of BA in cancer cell lines demonstrated that comparable effects were observed in cells derived from multiple tumor types. BA alone inhibited proliferation of various cancer cell lines, and several reports show the potential chemotherapeutic advantages of using BA in combination with other anticancer drugs such as vincristine, tumor necrosis factor (TNF)-related apoptosis inducing ligand (TRAIL), doxorubicin, taxol, and irradiation. Interactions of these anticancer drugs with BA generally enhance the overall cytotoxicity of the combination compared to the treatments alone; however, these interactions are highly cell context-dependent. Recombinant TRAIL is now being investigated in clinical trials and the protein is a ligand for cell membrane death receptors and activates the extrinsic apoptosis pathway characterized by caspase-8-dependent PARP cleavage. Treatment of neuroblastoma cells with TRAIL plus BA (combination) clearly enhanced apoptosis compared to treatment with the individual agents. TRAIL and BA alone tend to activate the extrinsic and intrinsic apoptosis pathways and the combination of these drugs results in mutual enhancement of both pathways. Since many tumor types are highly resistant to cell death, the combination of BA and other proapoptotic agents may offer many advantages for clinical treatment of some tumors.

Although BA induces apoptosis in most cancer cell lines, there is also evidence that activation of other responses may also contribute to the anticancer activity of this drug. In human melanoma cells, BA induces reactive oxygen species (ROS) and this is accompanied by time-dependent and persistent activation of p38 and c-Jun NH_2-terminal kinase (JNK). ROS acts upstream of these mitogen-activated protein kinases; however, both p38 and JNK can be involved in apoptotic pathways induced by BA in melanoma cells. Interestingly, studies in other melanoma cell lines showed that BA-induced effects on some cell cycle proteins and apoptosis (PARP cleavage and DNA laddering) were dependent on persistent activation of MAPK, since all of these responses were inhibited by the MAPK inhibitor U0126. Thus, BA-induced apoptosis is linked to activation of multiple kinases and differences in their action are highly dependent on cell context. The anticancer activity of BA may also be associated with other effects including the inhibition of topoisomerase 1 and antiangiogenic activity. This latter response was determined in ECV 304 endothelial cells in a Matrigel tube formation assay where BA and three substituted analogs exhibited angiogenic activity.

The mechanism of the anticarcinogenic activity of BA is complex and cell context-dependent and may include contributions from the direct effects of this compound on mitochondria and activation of kinase pathways. Research in our laboratory has focused on studying some of the underlying mechanisms of cancer cell and tumor growth, survival and angiogenesis. Using RNA interference, we have shown that specificity protein (►Sp) transcription factors are responsible, in part, for the growth and survival of cancer cells and their ability to metastasize and grow at distal sites. Sp1, Sp3, and Sp4 are overexpressed in colon and pancreatic cancer cells and tumors, and play a key role in overexpression of the ►angiogenic factors vascular endothelial growth factor (►VEGF), VEGF receptor 1 (VEGFR1) and VEGFR2, the survival gene survivin, and Sp3-dependent suppression of the cyclin-dependent kinase inhibitor p27. These results directly link overexpression of Sp proteins to the enhanced growth and survival and potential for metastasis/angiogenesis of cancer cells and tumors, and also suggest that inhibiting Sp protein-dependent gene expression or by inducing ►Sp protein degradation may be an important strategy for developing effective anticancer drugs. The first example of this approach was the identification and application of ►tolfenamic acid, a nonsteroidal antiinflammatory drug, which inhibited pancreatic cell growth through activation of proteasome-dependent degradation of Sp1, Sp3, and Sp4. Moreover, in an orthotopic model for pancreatic cancer, we also observed that tolfenamic acid inhibited tumor growth and metastasis and this was accompanied by degradation of Sp proteins in pancreatic tumors. Based on the reported proapoptotic/antiangiogenic effects of BA in cancer cell lines, we hypothesized that this compound

may also act, in part, through Sp protein degradation. In LNCaP prostate cancer cells, we have shown that BA induced proteasome-dependent degradation of Sp1, Sp3, and Sp4 and we have observed similar responses in cell lines derived from other tumor types. Moreover, in in vivo studies in athymic nude mice bearing human LNCaP cells as xenografts, BA also inhibited tumor growth and this was accompanied by decreased Sp1, Sp3, and Sp4 expression in the tumors. These results demonstrate that some of the anticancer activities BA in multiple cell lines may be partially due to degradation of Sp proteins and we have observed that this process is due to the activation of both proteasome-dependent and -independent pathways. Thus, betulinic acid and some of its derivatives are part of a new class of anticancer drugs that work through targeting Sp proteins and Sp-dependent genes involved in cancer cell survival, growth, and angiogenesis.

Bid

Xiao-Ming Yin
Department of Pathology, University of Pittsburgh School of Medicine, Pittsburgh, PA, USA

Synonyms

BH3-interacting domain death agonist

Definition

Bid is a pro-death ►Bcl-2 family protein. Structurally, it contains only one Bcl-2 homology domain, the BH3 domain. Thus it belongs to the BH3-only subfamily, which also includes Bad, Bik/Nbk/Blk, Bim, Bmf, Hrk/DP5, EGL-1, Noxa and PUMA.

Characteristics

The Bid Molecule

Bid was first cloned in 1996 from an expression cDNA library screened with recombinant Bcl-2 and Bax. Its ability to interact with both the anti-death and the pro-death Bcl-2 family proteins is a distinguished feature of this molecule among the BH3-only members. Bid was re-cloned in 1998 by two other laboratories. In both cases, Bid was identified as a substrate of ►caspase-8.

Bid is phylogenetically conserved. The mouse Bid gene is located at chromosome 6 (6 F1; 6 54.0 cM), while the human Bid is localized in a syntenic region, chromosome 22q11.2. The major protein product is derived from the originally defined five exons with 195 amino acids (about 22Kd) in both human and mouse. The Bid molecule is widely expressed. At the protein level, the full length Bid is a long lived protein, but caspase-8 cleaved truncated Bid (tBid) is degraded through the ubiquitination proteasome system and has a half-life of less than 1.5 h.

The structure of Bid has been resolved with NMR. It is the only structure resolved for a BH3-only molecule. Bid is composed of eight alpha helices. The central hydrophobic helices (alpha 6 and alpha 7) are surrounded by the amphipathic helices. Such an arrangement is conserved among other Bcl-2 family proteins, such as Bcl-2, Bcl-x_L and Bax. There is a non-structural loop between alpha 2 and alpha 3, which is subjected to regulatory modifications by protease cleavage or phosphorylation. Similar loops are present in Bcl-x_L, Bcl-2 and Bax, which play the same regulatory role.

Bid does not have a transmembrane domain. It shares sequence homology with other Bcl-2 family proteins in the BH3 domain, which is important for its interaction with other family members and for its pro-apoptotic activity. Interaction of Bcl-2 or Bcl-x_L suppresses Bid by preventing it from interacting with the pro-death Bax or Bak.

Bid is a Pro-Death Sensor for Specific Protease Activation

Early studies based on transient transfection or an inducible system demonstrated that over-expression of full length Bid could induce ►apoptosis. However, in most cases it seems that Bid may function in a truncated form. Bid was initially found to be cleaved and activated by caspase-8 following death receptor activation and thus considered to be specific to the death receptor pathway. However, studies in recent years indicate that Bid can be cleaved in a specific and limited way by several other proteases such as Granzyme B, calpains and cathepsins. These proteases are first activated in response to a plethora of stimuli, including death receptor activation, cytotoxic T cell attack, ischemia/reperfusion injury and lysosome damage. These observations indicate that Bid is in general a sentinel to protease activation resulted from various injury stimuli. As such Bid serves a critical role in connecting these stimuli to the ►mitochondria, allowing the death process to be advanced or amplified.

The cellular death receptor pathway is activated when the death receptors, Fas, TNF-R1 or ►TRAIL-R1, are engaged by their ligands or agonistic antibodies. Both in vitro cell lines and in vivo animal models have been used to study the signaling events. In a murine model of anti-Fas antibody-induced liver injury, Bid has been found to play a significant role in Fas-mediated apoptosis. Normal wild type mice are particularly susceptible to the administration of a Fas agnostic monoclonal antibody (clone Jo2), which induces significant hepatocyte apoptosis and severe liver injury. However, *bid*-deficient mice are resistant to such a treatment with minimal hepatocyte apoptosis and liver injury. In these mice, while caspase-8 is appropriately activated, the downstream effector caspase-3 is not. Caspase-3 activation is arrested in *bid*-deficient hepatocytes in a pattern consistent with being suppressed by XIAP, the X-linked inhibitor of apoptosis protein. In the wild type mice, Bid is cleaved by caspase-8 and the truncated Bid is translocated to the mitochondria to induce the release of cytochrome c and Smac. While cytochrome c could activate Apaf-1 and therefore caspase-9, Smac is able to bind to XIAP to release its suppression on caspase-3 activation. In this scenario, Bid connects the death receptor pathway to the ►mitochondria pathway, which is necessary for the prompt activation of effector caspases and subsequent apoptosis in hepatocytes.

Activation of Mitochondria by Bid

The ability of Bid to activate the mitochondria pathway is related to its ability to interact with the mitochondria and to permeabilize the mitochondrial outer membranes. Bid is able to induce the release of multiple mitochondrial inter-membrane space proteins,

including cytochrome c and Smac/DIABLO. Full length Bid is usually much weaker than truncated Bid in this capability. Bid is also able to induce several other prominent mitochondria dysfunctions, including mitochondrial permeability transition, mitochondrial depolarization, mitochondrial cristae reorganization and the generation of mitochondrial ▶reactive oxygen species. While the mechanisms for some of the phenomena are better understood, others are not.

In the case of cytochrome c release, it seems that Bid could activate at least two different mechanisms. One is based on protein interactions and the other is based on lipid interactions. Bid can interact with either Bax or Bak, the multi-domain pro-death Bcl-2 family proteins, via its BH3 domain, to promote their oligomerization on the mitochondrial outer membranes. Indeed, mice deficient in both Bax and Bak are much like *bid*-deficient mice and are resistant to anti-Fas induced hepatocyte apoptosis in vivo. The other important mechanism is based on the interaction of Bid with cardiolipin at the mitochondrial contact site. This interaction promotes mitochondrial cristae reorganization, which contributes to the mobilization of stored cytochrome c and its subsequent release. As the majority of cytochrome c is tightly bound to cardiolipin, a full release of this molecule would require its dissociation from cardiolipin, which is facilitated by Bid-cardiolipin interactions.

The two mechanisms activated by Bid, involving proteins and lipids, respectively, seem to be well coordinated. Bid interaction with Bak or Bax is the primary mechanism, which initiates mitochondrial leakage. This requires the BH3 domain and can be blocked by Bcl-2 or Bcl-x_L. On the other hand, the serial events of Bid-cardiolipin interaction and cristae reorganization do not require the BH3 domain of Bid and could not be suppressed by Bcl-2/Bcl-x_L. The mobilized cytochrome c is released through the mechanism enforced by Bid-Bak or Bid-Bax interactions.

Bid as a Pro-Life Sensor for Cell Cycle Progression and DNA Damage

Although Bid was initially defined as a pro-death molecule, recent studies have shown that Bid can possess functions important to the life of a cell. Bid has a pro-proliferation activity and can also serve as a DNA damage sensor to participate in cell cycle arrest. Other Bcl-2 family proteins, such as Bcl-2, Bcl-x_L, Bax and Bad have also been shown to possess the function of regulating cell cycle progression. From a broad point of view, it seems that Bcl-2 family proteins do not just simply regulate cell death, but also affect other key cellular events.

Bid seems to be able to regulate the G0-G1/S transition, as shown in several types of cells entering cell cycle from the resting stage. As a result, *bid*-deficient cells are often delayed in entering S phase upon mitogen stimulation. How Bid may promote cell proliferation is not clear at the moment. Regulation at the cyclin and cyclin-dependent kinase could be a key mechanism, although this has yet to be determined.

Another function of Bid in cell cycle regulation relates to S/G2 transition in cells with DNA damage or under replication stress. Thus *bid*-deficient cells fail to be arrested at S/G2 boundary in these conditions. Further studies showed that Bid can be a phosphorylation substrate of ATM/ATR. Mutagenesis studies indicate that Bid phosphorylation by ATM/ATR is required for the S phase arrest following DNA damage. However, it is not clear how Bid may then contribute to the S phase arrest. It seems that this function of Bid is beneficial to cells so that they would not have to go into mitosis in the presence of DNA damage. Thus the protective effect of Bid phosphorylation in this case could be largely due to its effect in inducing S phase arrest. Finally, this ability of Bid is not dependent on its BH3 domain.

Role of Bid in Oncogenesis

In general, neoplasia could be resulted from an uncontrolled cell proliferation owing to the activation of oncogenes, or from deregulated cell survival owing to the over-expression of anti-death molecules or the loss of pro-death molecules. For the Bcl-2 family proteins, it is generally assumed that their role in tumorigenesis is related to their ability to regulate cell death. However, other functions of the Bcl-2 family proteins can be equally important in tumorigenesis.

Bid-deficient mice develop spontaneous chronic myelomonocytic leukemia when they become aged. This may be explained by the loss of the pro-death activity of Bid. However, *bid*-deficient mice do not have an enhanced development of liver cancers following the administration of a chemical carcinogen, diethylnitrosamine (DEN). In contrast, they manifest a delayed development of tumors despite that there is a reduced cell death in the affected livers. These observations could be better explained by the role of Bid in promoting cell proliferation. Indeed, Bid was subsequently found to have such a function. Since this ability to regulate cell cycle progression is also possessed by other Bcl-2 family proteins, it is possible that Bcl-2 family proteins can in general affect tumorigenesis via both of their functions in cell death and cell proliferation. The net effects could be specific to the affected tissue or the etiology of the tumor.

In addition, as far as Bid is concerned, one may have to also consider whether the regulation of mitosis checkpoint by Bid following DNA damage can be another key factor in affecting tumorigenesis. There

is a significant presence of genomic instability in *bid*-deficient myeloid cells. It is possible that the myeloid cells are prone to DNA damage, which in the absence of Bid would lead to an accumulation of DNA abnormalities and subsequent leukemogenesis.

Summary

Bid is a versatile multi-function BH3-only molecule. While its function was initially defined to be pro-apoptosis, it is now clear that it can also regulate cell proliferation and genomic stability. These functions could be intimately connected and are overall responsible for the role of Bid in cell death, tissue injury, cell proliferation and oncogenesis. Future studies would be devoted to understand how these functions are integrated and regulated, and what the underlining mechanisms are.

BIK Proapoptotic Protein

Toshi Shioda
Massachusetts General Hospital Center for Cancer Research, Charlestown, MA, USA

Synonyms

BIK (BCL-2 Interacting Killer); Bp4; NBK (Natural Born Killer)

Definition

BIK is a ►BH3-only protein localized exclusively on the cytosolic surface of the endoplasmic reticulum (ER) membrane. Although the amino acid sequence of mouse Blk (BIK-like killer; also known as Biklk for Bik-like) has only 43% identity to that of human BIK, Blk is usually considered mouse ortholog of BIK due to their functional similarities. The official gene symbol of Blk is *bik*. Blk should not be confused with *B lymphoid tyrosine kinase*, a member of the SRC family non-receptor protein tyrosine kinase and whose official gene symbol is *BLK*.

Characteristics

Discovery

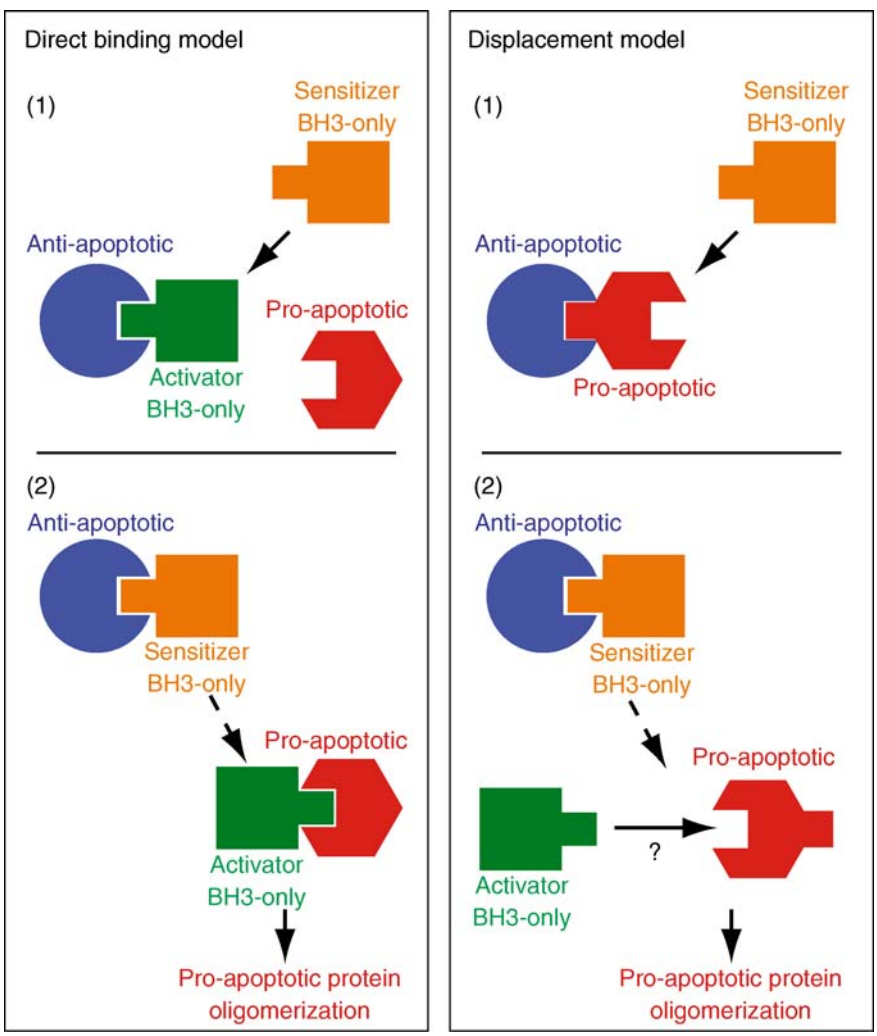
BIK was originally cloned in a two-hybrid screening as a protein that interacts with cellular antiapoptotic proteins ►BCL-2 and BCL-xL as well as viral antiapoptotic proteins ►Epstein-Barr virus BHRF1 and the ►19-kDa adenovirus E1B protein, both of which were viral homologues of human ►BCL-2. In an independently performed two-hybrid screening using the 19-kDa adenovirus E1B protein as bait, BIK was isolated as an E1B-binding protein and described as cDNA clone Bp4, which was later renamed NBK. These early studies characterized BIK/NBK as an apoptosis-inducing protein. Later, a DNA microarray study performed by an independent investigator identified BIK as a protein induced by the ►Adenovirus E1A protein in human KB epithelial cells.

Protein Structure and Molecular Functions

Human BIK consists of 160 amino acids, and its ►BH3 domain spans from amino acid 57(Leu) to 71(Ser). The strongly hydrophobic, leucine-rich C-terminal transmembrane domain (amino acids 136–159) selectively anchors BIK to the ER membrane, thus almost entire BIK protein including its N-terminus is exposed to cytosol. In human cells, BIK is phosphorylated at 33(Thr) and 35(Ser) by an unidentified, casein kinase II-like enzyme. Substitutions of these amino acids with alanines reduce the proapoptotic activity of BIK without significantly affecting its protein stability or ability to heterodimerize with BCL-2. Conversely,

substitutions of these amino acids with aspartic acids enhance the proapoptotic activity.

When expressed in mammalian cells, either endogenously or from exogenous vectors, BIK potently induces apoptosis. This activity involves the release of cytochrome c from mitochondria and is entirely dependent on BAX, a ►proapoptotic member of the BCL-2 family. However, BIK does not directly bind to BAX, nor affect mitochondrial membrane potential or voltage-dependent anion channel activity. Instead, BIK directly binds to BCL-2, BCL-xL, and BCL-w ►antiapoptotic members of the BCL-2 family. Therefore, BIK is a typical ►sensitizer-type BH3-only protein. In contrast, the ►activator-type BH3-only proteins bind directly to BAX or BAK, the proapoptotic members of the BCL-2 family that possess multiple BCL-2 homology (BH) domains and oligomerize on the mitochondrial outer membrane to form a channel that release cytochrome c to the cytosol. The antiapoptotic members of the BCL-2 family bind to the activator-type BH3-only proteins and thus sequester them from interacting with BAX or BAK (Fig. 1). Since each sensitizer and activator BH3-only protein has discrete binding specificity and affinity to the antiapoptotic members of the BCL-2 family, the apoptotic signal is activated only when correct combinations of these three groups of proteins are expressed (Table 1). Reflecting its weak affinity to MCL-1, an antiapoptotic member of the BCL-2 family, BIK cannot kill cells in the presence of sufficient expression of MCL-1. When MCL-1 expression is weak and BCL-2/BCL-xL/BCL-w expression is high, BIK can kill cells in the presence of ►tBID as an activator BH3-only protein, showing specificity similar to that of BMF. However, BIK also has to cooperate with another, weak BH3-only protein such as NOXA to cause rapid release of mobilized cytochrome c and subsequent activation of caspases.



BIK Proapoptotic Protein. Figure 1 Mechanism of the proapoptotic actions of the BH3-only proteins.

BIK Proapoptotic Protein. Table 1 Effects of combinations of anti-apoptotic, sensitizer BH3-only, and activator BH3-only proteins on induction of cell apoptosis

Anti-apoptotic BCL-2 family	Activator BH3-only	Sensitizer/Inactivator BH3-only Proteins				
		None	BAD	NOXA	BMF	BIK
BCL-2 BCL-xL	tBID	n	Y	n	Y	Y
	BIM	n	Y	n	n	n
	PUMA	n	Y	n	n	n
MCL-1	tBID	n	n	Y	n	n
	BIM	n	n	Y	n	n
	PUMA	n	n	Y	n	n

n, no apoptosis; Y, apoptosis. Modified from Kim et al. [2].

The activator BH3-only proteins such as tBID or BIM directly bind to BAK or BAX, the proapoptotic multi-BH domain members of the BCL-2 family. These activator BH3-only proteins are sequestered by the antiapoptotic members of the BCL-2 family proteins BCL-2, BCL-xL, BCL-w, and/or MCL-1. When the sensitizer BH3-only proteins bind to the antiapoptotic members, the activator BH3-only proteins are released from them and instead bind to BAK or BAX, which then oligomerizes to form channels through the outer membrane of mitochondria to release cytochrome c to the cytosol. Thus, the sensitizer and activator BH3-only proteins compete for binding to the antiapoptotic proteins.

At the ER, BIK can initiate early release of Ca^{2+} from the ER lumen to cytosol in response to apoptotic stimuli. This BIK-activated Ca^{2+} release requires BAK recruitment to the ER membrane. The reuptake of cytosolic Ca^{2+} by mitochondria causes recruitment and activation of the fission enzyme ►DRP1 at discrete sites on the mitochondrial tubular network, resulting in mitochondrial fragmentation and cristae opening but minimal release of cytochrome c. Since loss of the GTPase activity of DRP1 results in suppression of mitochondrial fission and cytochrome c release during apoptosis, the BIK-dependent early morphological changes in mitochondria may enhance cytochrome c release, which is later induced by activation of BAX/BAK in the presence of both BIK and NOXA.

Gene Structure, Expression, and Phenotypes

The *BIK* gene is found in human, bovine, rat, and mouse genomes but not in frog or fish. Therefore, among the BH3-only proteins, BIK seems a relatively new, mammalian-specific member. The human *BIK* gene is localized to chromosome 22q13.3 and is comprised of five exons spanning in about a 19-kb region. The minimal BIK promoter is localized to a region between −211 bp and +153 bp relative to its transcription initiation site. Although it was originally reported as a TATA-less promoter, a later study and the EST data suggest possible involvement of a TATA-like sequence in its transcriptional activity. No evidence of alternative promoters or splicing has been found in the EST database or literature.

The BIK mRNA transcripts are strongly expressed in lymphatic tissues and endothelial cells of the venous (but not arterial) lineages. Normal adult mammary and prostate glands also express significant amounts of BIK mRNA. C57BL/6 mice express Bik mRNA in the liver, lung, heart, and kidneys; weaker expression was also detected in spleen, skeletal muscle, and salivary gland. Mechanisms of the BIK tissue-specific distribution are unknown. At least one strain of *bik* gene knockout mice was generated, but no significant phenotype has been observed with them. However, simultaneous knockdown of *bik* and *bim* genes causes male infertility with severely perturbed spermatogenesis. Bik and Bim may share the role of eliminating supernumerary germ cells during the first wave of the permatogenesis, a process critical for normal testicular development.

The A/WySnJ mice, which have 90% fewer peripheral B cells than normal animals and fail to make significant immunoglobulin memory response, overexpress the Bik mRNA transcripts, and their transitional B cells rapidly succumb to apoptosis in vitro. During the transition from naïve B cell to centroblast B cell, expression of the BIK mRNA transcripts increase by about 8.5-fold, and the high level of BIK mRNA expression is maintained in memory B cells. These observations suggest possible roles of BIK during B-cell maturation.

Expression of the BIK mRNA transcripts and protein is inducible in human cells by overexpression of wild type ►p53 protein. Adenovirus E1A protein also induces BIK in a manner dependent on p53 protein. Apoptosis-inducing stimuli that involve p53 protein activation, such as doxorubicin or gamma-irradiation, induce BIK expression as well. Doxorubicin may be able to activate *BIK* gene transcription by a mechanism independent of

p53 protein but involving the E2F transcription factors. In MCF-7 human ►breast cancer cells, antiestrogens such as ►tamoxifen and ►fulvestrant induce BIK expression in a manner dependent on p53 protein, but its mechanism may be independent of the transcription factor activity of p53 protein.

Relevance to Cancer Genetics and Therapy

Significant frequency of missense mutations in the *BIK* gene was observed in peripheral B-cell lymphomas. Chromosomal deletions causing loss of heterozygosity (LOH) of the *BIK* locus has been reported for head and neck tumors, colorectal cancers, glioblastomas, and clear-cell renal cell carcinomas. Epigenetic silencing of BIK mRNA expression was reported for the KAS-6/1 multiple myeloma cell line and in a number of cell lines of renal cell carcinoma. Although these data suggests possible roles of *BIK* in human carcinogenesis, this remains to be established by further studies.

Since the strong proapoptotic activity of BIK potently induces ►apoptosis even in malignant cells, a number of studies reported the possible application of BIK-expressing vectors in the context of ►gene therapy. A chimeric protein consisting of gonadotropin releasing hormone (GnRH) and BIK specifically killed adnocarcinoma cell lines expressing plasma membrane GnRH receptor in vitro. In vivo growth of a human melanoma cell line stably transfected with a doxycycline-inducible expression plasmid for BIK as nude mice xenograft was strongly inhibited by doxycycline administration in drinking water. When administered systematically by intravenous injection, a cationic liposome-based gene delivery system of a BIK expression plasmid effectively suppressed growth of human breast cancer xenografts in nude mice. An adenoviral expression system of BIK induced apoptosis in glioma cell lines, and intratumoral injection of an ►adenovirus vector expressing BIK significantly suppressed growth of prostate (PC-3) and colon (HT-29) tumor xenografts in nude mice. A liposome-based, systematic intravenous delivery of a plasmid that expressed BIK using the pancreatic cancer-specific, cholecystokinin type A receptor promoter completely suppressed growth of human PANC-1 cells as xenograft in nude mice. These results suggest promise for BIK as a cytotoxic protein agent in gene therapy.

Because of the apoptosis sensitizing activity of BIK, low-level expression of exogenously introduced BIK that cannot induce apoptosis by itself may still be able to enhance cellular sensitivity to apoptotic stimuli. Thus, BIK-enhanced sensitivity of the H9 human T-cell leukemia cell line to chemotherapeutic agents increased apoptosis by 10- to 39-fold. Breast cancer cell lines selected for doxorubicin resistance were also effectively sensitized by expression of exogenously introduced BIK. These results suggest possible use of BIK in adjuvant gene therapy in combination with apoptosis-inducing chemotherapy.

The intracellular half-life of BIK protein is very short because of its rapid degradation by a proteasome-dependent mechanism. Therefore, when cells are exposed to proteasome inhibitors such as lactacystin, MG-132, or ►bortezomib, strong intracellular accumulation of BIK protein is often observed. Bortezomib does not cause significant accumulation of other BCL-2 family proteins except for NOXA. The bortezomib effect to resensitize malignant cells resistant to the death receptor ligand ►TRAIL is dependent on BIK protein accumulation. Bortezomib-induced ZR75–1 breast cancer cell apoptosis is also largely dependent on the accumulated BIK protein. Thus, proteasome inhibitors might be useful as adjuvant therapy agents for the purpose of increasing expression of the endogenous BIK protein in malignant cells to enhance their sensitivity to apoptosis-inducing chemotherapy.

Bilateral Acoustic Neurofibromatosis

►Neurofibromatosis 2

Bile

Definition

Bile is a yellow, green digestive juice produced by the liver and stored in the gallbladder. It is passes through the bile ducts into the duodenum where it aids in digestion and absorption of dietary fat. Bile is

predominately composed of bile salts, cholesterol, phospholipids, bicarbonate and waste products such as bilirubin. The electrolytes present in bile especially bicarbonate which neutralize acid secretions from the stomach as they enter the duodenum.

Bile Acids

Toshiya Soma, Yutaka Shimada
Department of Surgery, Graduate School of Medicine, Kyoto University, Kyoto, Japan

Definition

Bile acids are complex physiological molecules that are essential for solubilization, absorption, and transport of dietary lipids in the intestine. On the other hand, bile acids are potentially toxic to cells.

Characteristics

Primary bile acids such as cholic acid and chenodeoxycholic acid are derived from cholesterol in the liver and are secreted and stored in the gallbladder as glycine or taurine conjugates. For example, cholic acid is stored as either glycocholic acid or taurocholic acid, and chenodeoxycholic acid is stored as either glycodeoxycholic acids or taurodeoxycholic acids. Bile acids are then released into the intestinal tract when fat enters the proximal portion of the intestine. About 90–95% of released bile acids are absorbed in the terminal ileum. Bile acids are transported via the portal vein to the liver and extracted for re-use in the so-called "enterohepatic circulation." However, about 5–10% of secreted bile acids reach the colon, where conjugated cholic acid and chenodeoxycholic acid undergo deconjugation and 7α-dehydroxylation by the anaerobic bacterial flora, forming the secondary bile acids deoxycholic acid and lithocholic acid, respectively. The tertiary bile acid ursodeoxycholic acid is subsequently formed by epimerization of chenodeoxycholic acid. In the colon, deoxycholic acid is partly absorbed and enters the enterohepatic circulation. Consequently, about 2–5% of secreted bile acids, consisting mainly of lithocholic acid, are excreted in the stool.

Toxicity of Bile Acids

Bile acids are probably not genotoxic but may be cytotoxic. ►(Toxicological carcinogenesis) Specifically, unconjugated bile acids are known to be toxic. Conjugation reduces the pKa of bile acids, thereby increasing solubility at low pH. Thus, at a pH lower than the physiological value, unconjugated bile acids precipitate easily, whereas conjugated bile acids remain soluble. Taurine conjugates are especially soluble even at more acidic pH. Hence, at physiological pH, bile acids usually remain as ionized forms and may be termed bile salts, which cannot pass through the cell membrane. However, at acidic pH, unconjugated bile acids are nonionized and can accumulate inside mucosal cells and potentially cause damage. An acidic pH thus does not affect the toxicity of conjugated bile acids, but may potentiate the toxicity of unconjugated bile acids. On the other hand, both conjugated and unconjugated bile acids reduce the pH sensitivity of cells. Decreased pH sensitivity results in the induction of cyclooxygenase-2, which is rapidly induced in response to tumor promoters, cytokines, and growth factors. Furthermore, cholic acid and chenodeoxycholic acid are considered to be tumor promoters and increase the incidence of benign adenomas and malignant adenocarcinomas when administered after carcinogens. It is thus likely that pH and bile acids are dual drivers of metaplasia, acting in combination to fuel inflammation and mediate cellular change.

Effects of Bile Acids on Organs

Upper Gastrointestinal Tract

Several studies indicate that duodenogastroesophageal reflux leads to esophagitis or Barrett esophagus and may be related to esophageal adenocarcinoma. Although the pathogenesis of ►esophageal cancer remains to be fully elucidated, bile acids are somehow involved, probably by being cytotoxic rather than genotoxic. As such, bile acids stimulate the development of esophageal squamous cell carcinoma, not to mention esophageal adenocarcinoma or ►gastric cancer, by promoting ►angiogenesis via the cyclooxygenase-2 pathway. ►(Arachidonic acid-pathway and cancer) In contrast, unconjugated bile acids, which are more toxic than conjugated forms, appear more frequently in the bile acid profiles of patients with severe esophagitis. Although reflux of unconjugated bile acids has not been demonstrated in patients with an intact stomach, such reflux has been found in the stomach after partial gastrectomy and in the esophagus after total gastrectomy. However, further studies are required to establish whether bile acids have a role in gastric cancer.

Lower Gastrointestinal Tract

Several studies indicate that ►colorectal cancer is associated with higher fecal levels of secondary bile acids. Deoxycholic acid and lithocholic acid appear to promote carcinogenesis and tumorigenesis by activating multiple oncogenic signaling pathways. ►(Cycloxygenase-2 in colorectal cancer) Furthermore, a high fat diet and cholesterol are implicated in the

pathogenesis of human colorectal cancer, presumably because both of these factors promote the synthesis and secretion of bile acids. Carcinogenesis is also associated with conditions such as ileal resection, cholecystectomy, or ileal inflammation such as that accompanying ►Crohn's disease, which can alter intestinal exposure to bile. These conditions can result in incomplete active reabsorption of bile acids from the distal ileum and interrupt the enterohepatic circulation of bile acids. In addition, increased colonic concentrations of bile acids are also associated with diarrhea, which may respond to bile acid sequestrants.

Liver, Gallbladder, and Bile Ducts

Several etiological studies indicate that bile acids might induce carcinogenesis in the gallbladder. ►(Gallbladder cancer) The gallbladder and bile ducts are exposed to high concentrations of bile acids, most of which are unconjugated. If retained for a long time in the gallbladder and bile ducts, bile acids may induce carcinogenesis in the biliary tree, although the mechanism remains unclear. Furthermore, numerous studies have shown that elevated concentrations of bile acids in the liver induce hepatocyte apoptosis. Some evidence suggests a relation between the hydrophobicity of bile acids and the induction of apoptosis. Thus, the degree of hepatocellular damage may be related to bile acid hydrophobicity, and lithocholic acid, the major constituent of hydrophobic bile acids, is the most hepatotoxic. These findings suggest a possible mechanism for bile-acid-mediated liver injury, but since most hepatic bile acids are in conjugated form, the hydrophobicity of bile acid is reduced, thereby decreasing its entry into cells. Moreover, the hepatotoxicity of chenodeoxycholic acid treatment in patients with cholelithiasis appears to be caused by secondary increases in lithocholic acid production.

Pancreas

Epidemiological studies have demonstrated a positive correlation between the incidence of pancreatic cancer and a high fat diet in association with the secretion of bile acids. ►(Pancreas cancer, clinical oncology) Pancreatic adenocarcinoma tends to develop in the head of the gland, which is more exposed to bile. These findings suggest that bile acids participate in carcinogenesis of the pancreas, although underlying mechanisms remain to be clarified.

Bile Duct

Definition

Bile ducts are long tube-like structures lined by epithelial cells that carry bile (originating from the bile canaliculus) from the liver to the hepatic duct, which joins with the cystic duct to form the common bile duct opening into the duodenum. Bile ducts within the tissue of the liver are termed intrahepatic, whereas those outside the liver are termed extrahepatic.

Synonyms

Bile duct adenoma; Bile duct hamartoma; Biliary cystadenoma; Carcinoid; Cholangiocarcinoma Cholangiosarcoma; Intraductal papillary mucinous tumors

Definition

Bile duct neoplasms are classified as benign and malignant tumors of the cells comprising the bile ducts of the liver, which include the bile duct epithelial cells and the connective tissues supporting the bile duct structure.

Characteristics

The biliary system is comprised of intra- and extrahepatic ►bile ducts. The function of this system is to transport ►bile from the liver to the duodenum where bile aids in the digestion of dietary fats. Bile ducts have a tube or vessel-like appearance. The interior of the ducts is lined with columnar epithelial cells, which have been termed ►cholangiocytes. Cholangiocytes are surrounded by a subepithelial layer of tough connective tissue, which contains a scant number of smooth muscle cells. Also, within this connective tissue layer, resides a population of mucous cells. The biliary system is surrounded by a network of nerves, blood vessels and lymphatics. Bile duct neoplasms are an extremely rare condition that includes both benign and malignant growth of cholangiocytes and the surrounding supporting tissues of the bile duct.

Benign Bile Duct Neoplasms

Benign tumors of the intrahepatic and extrahepatic biliary system are exceedingly rare as the large majority of bile duct neoplasms are malignant. These benign tumors include adenomas and papillomas and neoplasms of the supporting structure of the bile duct, such as bile duct hamartomas, carcinoids, leiomyomas, and fibromas. Some benign biliary lesions, such as papillomas, adenomas carcinoids and cystadenomas result in biliary obstruction and symptoms of ►cholestasis and ►jaundice. The most commonly diagnosed benign neoplasms are bile duct hamartomas (von Meyenburg complexes), carcinoids, and cystoadenomas.

Bile duct hamartomas are characterized by the growth of many tiny noncancerous nodules in the intrahepatic bile ducts, which are the result of the malformation of the ductal plates of the liver during embryonic development. Pathologically hamartomas are characterized by cysts dilated embedded in a fibrous, collagenous ►stroma. Hamartomas have for the large part been defined to be innocuous. Hamartomas have been associated with increased neoplastic transformation resulting in biliary adenocarcinoma (i.e., ►cholangiocarcinoma). Biliary cystoadenomas arise from von Meyenburg complexes and are also a rare neoplasm of the bile duct that is difficult to diagnose preoperatively. Biliary cystoadenomas occur more often in females. The predominant treatment for cystoadenoma is surgical ablation due to the high potential for malignant transformation.

Benign carcinoid tumors are also extremely uncommon. These neoplasms arise from enterochromaffin cells of the biliary tract. Due to the rarity of this type of tumor, carcinoids have been poorly characterized. Biliary carcinoids have not been associated with the production of functional hormones that has been reported for carcinoids in other areas of the gastrointestinal tract. Patients with carcinoids often present with symptoms mimicking cholangiocarcinoma and/or choledocholithiasis. Biliary carcinoids are slow growing and thus, have a low potential for malignant transformation. The predominant treatment for carcinoids is surgical removal.

Diagnostically, benign bile duct neoplasms are virtually impossible to differentiate from malignant neoplasms. Since these neoplasms are extremely rare, there is a lack of understanding of the potential for these tumors to become malignant. In certain cases, benign neoplasms are thought to contribute to ►inflammation of the liver from damage due to cholestasis. Therefore, surgical resection is the current and predominant treatment course.

Malignant Bile Duct Neoplasms

Over 95% of bile duct neoplasms are malignant. Recent reports indicate that there is an increase in global incidence of malignant bile duct tumors. These malignant tumors include cholangiocarcinoma (an ►adenocarcinoma), cholangiosarcoma, malignant carcinoids, and intraductal papillary mucinous adenocarcinoma.

Cholangiocarcinoma is the predominant cancer of the bile ducts. Cholangiocarcinoma results from the malignant transformation of cholangiocytes, which are epithelial cells that line the biliary system. Cholangiocarcinoma occurs in ~2 per 100,000 people. Approximately 13% of primary ►liver cancers are cholangiocarcinomas. Cholangiocarcinoma is divided

into two types: (i) intrahepatic that occurs in the bile ducts residing within the liver; and (ii) extrahepatic that arises in the right and left hepatic ducts, common hepatic and common bile duct. Risk factors for this cancer share long-standing inflammation of the liver and chronic damage of the biliary epithelium. Increased proliferation of biliary epithelium due to chronic damage of the liver is thought to play a key role in the pathogenesis of malignant bile duct neoplasms. The list of risk factors includes: ►gallstones or gallbladder inflammation, ►chronic ulcerative colitis, or chronic infection of the parasitic worm, ►*Clonorchis sinensis*, and ►primary sclerosing cholangitis (PSC). The prognosis for cholangiocarcinoma is grim due to lack of early diagnostic modalities and effective treatment paradigms. Cholangiocarcinomas are slow growing, metastasize late during the cancer's progression, and present with symptoms of cholestasis due to the blockage of the bile duct by tumor growth. In most cases, the tumors are well advanced at the time of diagnosis, which results in limited treatment options. Many of these tumors are too advanced to be removed surgically and chemotherapy and radiation therapy usually are not effective. In addition to cholangiocarcinoma, cholangiosarcoma is a tumor arising from the cells constituting the connective tissue layer of the bile ducts. Cholangiosarcoma is rarely reported and information is lacking on prevalence.

A subset of cholangiocarcinoma tumors have been defined as papillary cholangiocarcinoma or interductal papillary mucinous neoplasms. These tumors are characterized by frondlike, papillary projects that occasionally produce large amounts of mucous. The excessive mucous secretions may disturb bile flow and cause dilation of the bile ducts, which results in symptoms of obstructive cholestasis or bile duct stones. Interductal papillary tumors have low-grade malignancy penetrating the bile duct wall in the late stages of pathogenesis. Diagnostically, these tumors are often confused with bile duct stones due to the constant sloughing of tumor debris into the bile. The predominant treatment is surgical removal.

Malignant carcinoids are also extremely rare neoplasms. Similar to benign carcinoids, the treatment of choice is surgical removal with chemotherapy used when the tumors are metastatic.

Biliary Glycoprotein

Definition

A member of the ►CEA gene family first found in bile. The BGP group of molecules consists of seven members formed by alternative splicing. There are differences in the number of Ig domains and there are two types of cytoplasmic domains present. The forms will longer cytoplasmic domains can participate in signaling.

►CEA

Bin1

George C. Prendergast
Department of Pathology, Anatomy and Cell Biology, Jefferson Medical School, Lankenau Institute for Medical Research, Wynnewood, PA, USA

Synonyms

Amphiphysin II; Amph II; Amphiphysin-like; AMPL; SH3P9

Definition

Bin1 is a cancer suppression gene that functions in membrane dynamics, ►vesicle trafficking, and nucleocytosolic signaling processes. The Bin1 gene maps to human chromosome 2q14–2q21.

Characteristics

Bin1 encodes a set of BAR adapter proteins that bind and tubulate curved membranes in the cytosol and that can restrict gene expression in the nucleus. Bin1 protein structure is varied by alternate RNA splicing events that determine its cancer suppression activity. All Bin1 proteins include an N-terminal ►BAR domain and a C-terminal ►SH3 domain. Two isoforms found in all

cells localize to the nucleus and cytoplasm and both display cancer suppression activity. Several other tissue-specific isoforms found mainly in neurons include specialized membrane targeting sequences that prevent nuclear entry. These isoforms lack cancer suppression activity. In fact, Bin1 suppression activity is often inactivated in cancer cells by a specific RNA missplicing event that adds a neuron-specific exon (12a) preventing nuclear entry by the aberrant Bin1 protein generated. Studies of RNA splicing patterns in cancer cells indicate that this aberrant event is among the most common missplicing events occurring in human cancer.

Loss of heterozygosity at the Bin1 locus occurs with some frequency in ►prostate cancer, but in general deletions of Bin1 seem to be rare in human cancer. In contrast, Bin1 is often attenuated at the level of missplicing or loss of expression, including in breast (►Breast Cancer), prostate, lung (►Lung Cancer), and ►colon cancer and in ►astrocytoma, ►neuroblastoma, and malignant ►melanoma. In breast cancer, loss of nuclear Bin1 protein may predict poor prognosis. Restoring normal expression in cancer cells can restrict cell proliferation and/or survival, including by eliciting a caspase-independent mechanism of cell suicide. Thus, attenuation of the nuclear function (s) of Bin1 is important during cancer development or progression.

Genetic and cell biological studies in animal model systems indicate that Bin1 acts at several levels to suppress cancer, including by blocking cell proliferation, survival, motility, and ►immune escape. Bin1 was initially identified through its ability to interact with and inhibit the transcriptional and oncogenic activity of the ►Myc oncogene. There is also some evidence that Bin1 may also facilitate Myc-mediated ►apoptosis in certain settings. Furthermore, genetic ablation of Bin1 in the mouse mammary gland drives the progression of lesions initiated by activation of the Ras pathway, which cooperates with Myc in triggering neoplastic cell transformation. Thus, Bin1 may act in part to suppress cancer by restraining the oncogenic activity of Myc. In animals where Bin1 is more widely ablated, inflammation (►Inflammation), premalignant lesions, and tumors occur with a markedly increased incidence during aging. In particular, lung or liver tumors occur within 18 months in most animals where Bin1 is ablated. Mouse model studies further indicate that Bin1 acts to restrict immune escape, an important trait of cancer which is highly relevant to the emergence of clinical disease. At this level, Bin1 acts by restricting expression of ►indoleamine 2,3-dioxygenase, an important modulator of T cell immunity in cancer. Thus, Bin1 loss during tumor development influences the immune ►microenvironment as well as the cancer cell itself.

Bioactivation

Definition

Is the transformation of a compound within an organism into a more biochemically active metabolite.

►Arylamine *N*-Acetyltransferases (NAT)

Bioactive Lipids

►Lipid Mediators

Bioavailability

Definition

Bioavailability of nutrients: Refers to the fraction of a mineral nutrient intake that is biologically available to

meet the essential metabolic and/or structural functions associated with that mineral nutrient in the body. Bioavailability incorporates the concepts of absorption, distribution, metabolic transformation (where necessary to meet biological function) and excretion. In some circumstances the main component of bioavailability is absorption across the gastrointestinal wall, so that sometimes the term bioavailability may be used interchangeably with absorption.

Bioavailability of drugs: Refers to the percentage of drug that is detected in the systemic circulation after its administration. Losses can be attributed to an inherent lack of absorption/passage into the systemic circulation and/or to metabolic clearance. Detection of drug can be accomplished ►pharmacodynamically or ►pharmacokinetically. Oral bioavailability is associated with orally administered drugs.

Biochip

►Proteinchip

Bioconjugate

Definition

A covalent or non-covalent coupling two or more distinct molecules together to confer a specific functionality. For example, the coupling of a aptamer targeting molecules to drug encapsulated nanoparticles can result in a nanoparticle drug delivery bioconjuate that is targeted to specific cells or tissues.

►Aptamer Bioconjugates for Cancer Therapy

Biodribin

►Cladribine

Biogenic Amines

Definition

A group of naturally occurring, biologically active amines, such as monoamines (norepinephrine, histamine, tyramine, dopamine, and serotonin) and polyamines (putrescine, spermidine, spermine).

►Amine Oxidases

Bioinformatics

Definition

Is a discipline covering all aspects of biological information acquisition, processing, storage, visualization, distribution, as well as analysis and interpretation that combines the tools of mathematics, computer science, and biology to advance the scientific understanding of the biological significance of huge amount of data. It involves the creation and advancement of algorithms, computational and statistical techniques, as well as the theories to solve formal and practical problems inspired from the management and analysis of biological data. Genomics and proteomics analyses generate expression information from tremendous amount of genes or proteins, which have to be organized, stored, and analyzed with the aid of bioinformatics.

►Drug Design
►Personalized Cancer Medicine

Biologic Therapy

Definition

Treatments for autoimmune disease or cancer that comprise proteins such as antibodies and cytokines or fragments of proteins or synthetic peptides are called biologic therapy. The term also encompasses the use of cells such as bone marrow-derived cells for treatment.

►Sjögren Syndrome

Biological Clock

Definition
The mechanism within an organism that generates repeated cycles (rhythms, oscillations) in behavioral, biochemical, metabolic and/or physiological activity that can be synchronized by environmental stimuli, primarily light.

►Melatonin

Biological Markers

►Clinical Cancer Biomarkers

Biological Monitoring

►Biomonitoring

Biological Response Modifiers

Definition
Substances, either natural or synthesized, that boost, direct, or restore normal immune defenses, BRMs include interferones, interleukins, thymus hormones, and monoclonal antibodies.

Biological Therapy

►Immunotherapy

Biologically Effective Dose (BED)

Definition
The quantity of a drug that results in a therapeutic benefit. The accurate measurement of the BED is essential for the clinical evaluation of cytostatic molecularly-targeted drugs.

►Drug Design

Biologicals

Definition
Biologicals are large drug compounds with atomic mass units typically in the tens of thousands, e.g. vaccines, monoclonal antibodies, fusion proteins, peglated proteins (proteins chemically modified with long chains of polyethylenglycol).

►ADMET Screen

Bioluminescence Imaging

Scott K. Lyons
Molecular Imaging Group, CRUK Cambridge Research Institute, Li Ka Shing Centre, Cambridge, UK

Synonyms
BLI

Definition
A non-invasive imaging approach that relies upon the detection of light resulting from the oxidation of a specific substrate by luciferase enzyme expressing cells.

Characteristics
Bioluminescence imaging (BLI) comprises a relatively new preclinical imaging modality that has become popular with researchers across a broad range of biological disciplines. From an oncology perspective, the high sensitivity, versatility and speed afforded by BLI has made it a particularly attractive modality

for measuring many aspects of *in vivo* tumor biology within cohorts of animals.

In general terms and in comparison to the other non-invasive imaging modalities, the hardware and consumable reagents needed for BLI are relatively cheap and safe (i.e. non-radioactive). *In vivo* images of multiple subjects can be acquired quickly (typically ranging between 1 and 180 s) so throughput is high. Moreover, when used in conjunction with small animal models of disease, where tissue depths seldom exceed 1–2 cm, BLI can exhibit sensitivity limits that compare very favorably with ►PET (►Positron emission tomography) (currently deemed the most sensitive non-invasive imaging approach). Unlike ►CT (►Computed tomography) or ►MRI (►Magnetic resonance imaging), BLI does not generate images with a high degree of anatomical detail. The wavelengths of light generated in this approach are prone to scattering and absorption as they pass through tissue, resulting in an imaging resolution of approximately 1 mm. As BLI is reliant on the expression of a luciferase transgene, it is also a highly versatile technique that can be used to non-invasively determine diverse aspects of *in vivo* tumor biology, ranging from the relative quantification of tumor burden to measuring the activation states of various cellular processes or detecting specific protein: protein interactions. In addition, as only viable labeled cells generate bioluminescence in the vast majority of cases, BLI has proven particularly useful for testing the *in vivo* efficacy of experimental cancer treatments using tumor cell lines and small animal models of cancer.

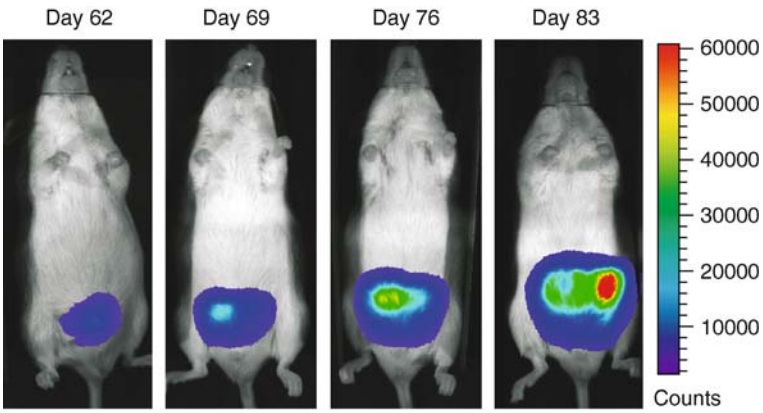
About Luciferases

As stated in the definition, BLI relies upon the external detection of light produced by cells that express a luciferase enzyme. These are not endogenously expressed by mammalian cells, therefore, luciferase transgene expression must first be introduced prior to the direct imaging of tumor cells by this method. The most commonly used luciferase enzymes for such purposes have been the ►codon-optimized (Codon-optimization) forms of firefly luciferase (derived from the North American firefly, *Photinus pyralis*) and renilla luciferase (derived from the sea pansy, *Renilla reniformis*). Also validated for expression in mammalian cells are the click beetle luciferases (green or red; derived from the Jamaican click beetle *Pyrophorus plagiophthalamus*) and gaussia luciferase (derived from a copepod called *Gaussia princeps* and unique amongst the enzymes mentioned in that it is naturally secreted by expressing cells).

These individual luciferase enzymes share little homology and vary in the efficiency that they produce light. To generate bioluminescence, firefly and click beetle luciferases specifically catalyze the oxidation of D-luciferin in the presence of O_2, ATP and Mg^{2+}. Renilla and gaussia luciferases, however, specifically catalyze the oxidation of a different substrate, coelenterazine, in the presence of O_2 and independently of ATP. Neither of these substrates are produced endogenously by mammalian cells and so must be administered either to tissue culture medium or by injection/►osmotic pump to enable *in vitro* or *in vivo* bioluminescence imaging respectively. Both substrates are relatively small molecules that are broadly taken up by cells throughout the body and can be administered repeatedly without eliciting an immune reaction. The *in vivo* use of coelenterazine is slightly more complicated than luciferin, however, as it is less soluble and prone to auto-oxidation (resulting in bioluminescent "noise") and deactivation in serum. It has also been shown that coelenterazine is actively pumped out of cells that express high levels of ►P-glycoprotein. Therefore, renilla or gaussia luciferases are likely not ideal reporters to directly image multi-drug resistant (i.e. P-glycoprotein over-expressing) tumor cells *in vivo*. The emission spectra produced by these luciferases are also characteristically broad (spanning >100 nm) and differ. For example, the peak emission of renilla luciferase is 480 nm, whereas firefly luciferase is 610 nm. Collectively, these factors ensure that bioluminescent signals from selected pairs of luciferase enzyme can be discerned upon the basis of substrate exclusivity as well as their spectral signature. This is highly useful as it enables the employment of powerful dual-labeled BLI studies, where the light generated by different luciferase enzymes can be detected sequentially to measure multiple parameters within the same cell or individual animal (e.g. viable tumor burden measured by renilla luciferase and the activation of a cellular process by firefly luciferase). The development of increasingly sophisticated ►spectral unmixing image analysis techniques should soon make it possible to routinely discern the optical spectra from two different luciferases when both substrates are administered simultaneously.

How is In Vivo Bioluminescence Detected?

The intensity of light generated by luciferase labeled cells in a typical bioluminescence imaging experiment is sufficiently low that a highly sensitive light detector is needed to measure it. Such detectors are commercially available and typically comprise a cryogenically cooled CCD camera (Charge-Coupled Device; cooled to $\leq -90°C$ to reduce thermal noise and increase light sensitivity) that is housed behind a lens within a completely light tight box. The non-visible levels of light associated with bioluminescence imaging can be detected by the pixels of the cold CCD, which results in a fully digitized and quantifiable 2-D map of light intensity across the field of view. An image of this light intensity map is then superimposed over a digital



Bioluminescence Imaging. Figure 1 The above figure shows a series of bioluminescent images of an individual mouse taken at weekly intervals and shows the development of a spontaneous and bioluminescent prostate tumor. Note that the colors associated with these images and accompanying scale bar correspond to light intensity and do not reflect the color of detected light. This figure is reproduced with modification from Fig. 4A (Lyons SK, Lim E, Clermont AO et al (2006) Noninvasive bioluminescence imaging of normal and spontaneously transformed prostate tissue in mice. Cancer Res 66(9):4701–4707) by copyright permission of the AACR.

photograph of the subject (taken in normal light conditions immediately prior to bioluminescence acquisition) to indicate the regions of the subject where labeled cells reside (Fig. 1).

In a manner analogous to conventional photography, the exposure time and aperture settings of the CCD camera can be adjusted to modify the sensitivity of bioluminescence acquisitions. This ensures that CCD pixels do not become saturated when imaging relatively bright subjects and maximizes sensitivity when imaging relatively dim subjects. Computer software can be used to add together (or "bin") the signals detected by adjacent CCD pixels to further increase imaging sensitivity, but this gain is made at a cost to image resolution. Software tools are also used to create "regions of interest" to quantitatively measure light emission from any area of the image in fully calibrated physical units (i.e. photons/s/cm^2/►steradian).

Considerations to Maximize In Vivo Imaging Sensitivity

Currently BLI is considered one of the most sensitive non-invasive preclinical imaging modalities when used in conjunction with small animal models of disease. There are, however, several important factors that will affect the sensitivity of any *in vivo* BLI approach and so influence the minimum number of cells that can be detected or the ability to visualize the activity levels of a cellular process above noise.

One obvious issue relates to the extent of luciferase enzyme expression in the target cell; labeled cells that express relatively low levels of luciferase will be harder to detect than an equivalent number of labeled cells that express greater amounts of luciferase.

Another key issue is the depth of signal, as the wavelengths of light produced by the commonly employed luciferases are prone to scatter and absorption as they pass through mammalian tissue. Red wavelengths of light (>600 nm) pass through tissue with greater efficiency than relatively bluer wavelengths (<500 nm). Therefore, in principal, luciferases that produce light with the highest proportion of red light should be better-suited for *in vivo* imaging. The quantum yield or relative brightness of the different luciferases also varies however, and can compensate for issues relating to the colour of emitted light. For example, even though gaussia luciferase generates predominantly blue/green light, imaging sensitivity has been reported to be roughly comparable to that associated with firefly luciferase as the relative efficiency of light production is sufficiently high. The absorbance of *in vivo* bioluminescence is increased when overlying tissues, skin or fur are darkly pigmented. Indeed, whenever BLI sensitivity issues become prevalent for any given *in vivo* application, the use of albino mouse strain variants or the local removal of pigmented fur is highly recommended.

The fact that different colors of light have inherently different tissue transmission properties has led to the development of algorithms that can predict the depth of firefly luciferase expressing cells in tissue. As red light passes through tissue with greater efficiency than green, the ratio of red to green light on the surface of the animal is proportional to tissue depth (i.e. the presence or absence of green light in relation to the amount of measured red light is indicative of a shallow or deep bioluminescent origin respectively).

Another key factor that influences the sensitivity of BLI is the extent of bioluminescent background. In terms of imaging labeled tumor ►xenograft models, this is not a serious issue as non-labeled host tissue does not emit light at appreciable levels. This issue does become pertinent when working with luciferase labeled transgenic mice (as certain lines may express significant levels of luciferase in a non-specific manner) or when attempting to detect micro-metastases that reside near to the primary tumor. Attempts to image the activation of a molecular pathway in a population of cells can also prove challenging in transgenic mice, if basal levels of luciferase expression are already high.

Oncology Model Applications

A tremendous degree of versatility is afforded by the fact that the direct imaging of mammalian cells by BLI relies upon the expression of a luciferase transgene. A wide range of validated transgenic strategies currently exist to control transgene expression at the transcriptional level or reporter gene functionality following translation. As a consequence, a diverse range of tumor biology related parameters can be imaged *in vivo* using BLI.

One of the most common applications of BLI in cancer research is the detection and repeated measurement of *in vivo* tumor burden within the same subject over time.

For tumor xenograft based studies, this can be achieved by introducing stable constitutive luciferase expression into the cell line of choice prior to implantation. Derivatives of strong viral promoters such as CMV or SV40 have been frequently employed for such purposes, but promoter sequences from eukaryotic house-keeping genes (e.g. β-actin or GAPDH) can also be used and may be preferable for ensuring robust luciferase expression in certain cell types.

It is now well established that when luciferases are constitutively expressed in tumor cells (with the exception of secreted gaussia luciferase), overall light emission is proportional to tumor cell viability. At the early to mid stages of tumor development, this is typically reflected by a strong correlation between measured bioluminescence and tumor volume. This correlation becomes less pronounced when tumors near end-stage, as extensive regions of tumor necrosis (which contribute to tumor volume but not bioluminescence), variable tissue-depth and tumor perfusion/substrate bioavailability (affecting measured bioluminescence but not volume) become more prevalent.

BLI can also measure spontaneously arisen tumor burden in transgenic mice. Imaging such tumors is more complicated than xenograft models as, in order to maintain sensitivity, strategies must be implemented to ensure that luciferase expression is maximized in the tumor, yet kept to a minimum in proximal non-transformed tissues. Tissue specific promoters can be useful when tumorigenesis occurs in a target organ or cell type population that is relatively small (tumors arising spontaneously in the pituitary and prostate glands have been successfully imaged in this way). The growth dynamics of spontaneous tumors arising in other more elaborate conditional (►Cre/loxP dependent) tumor models can also be measured using a generally expressed but conditional (Cre/loxP dependent) luciferase allele.

Constitutive promoter strategies can also be used to detect the appearance of tumor ►metastases *in vivo*. As the primary tumor may be relatively large (and consequently bright) at the time that metastases appear, imaging sensitivity is maximal when metastases develop at sites that are spatially distinct from the primary tumor. Tissue depth will also vary between the metastatic sites within a cohort of subjects. Therefore, longitudinal BLI measurements indicate only the presence and relative growth dynamics of each metastatic lesion as opposed to the absolute quantification of tumor burden at every location. BLI can also be performed on freshly excised organs at necropsy (i.e. *ex vivo* BLI) to quickly validate the presence of metastases at the end of an experiment.

The sensitivity of BLI is such that many other tumor associated processes (and the effects of drug treatment upon them) can also be imaged non-invasively when luciferase expression or functionality is regulated in different ways. For example, the relative levels of tumor cell proliferation can be imaged before and after drug treatment using a luciferase allele that is only expressed at the onset of ►S-phase in replicating cells. Tumor cell ►apoptosis has also been imaged *in vivo* by employing engineered luciferase alleles that have extra peptide domains fused to them that cause either reporter instability or impair function in normal cells. The activation of specific ►caspase enzymes, which mark the onset of apoptosis, specifically cleave this interfering peptide domain from the reporter, resulting in reporter functionality and the generation of bioluminescence. Several approaches have also been devised to image specific protein:protein interactions in tumor cells *in vivo*. One involves the splitting of firefly or renilla luciferase into two separate but complementary domains. When these intrinsically inactive N- and C-terminal reporter fragments are fused to two different proteins, bioluminescent activity is only reconstituted when the proteins that they are fused to bind each other. Again, the ability to garner this type of information non-invasively *in vivo* is incredibly useful for characterizing fundamental aspects of tumor biology or examining the effects of experimental therapeutics.

Biomarkers

Beatrice L. Pool-Zobel
Nutritional Toxicology, Friedrich-Schiller-University of Jena, Jena, Germany

Definition

Biomarkers are parameters that provide information on exposure to xenobiotics and to chemopreventive compounds, or on the effects of that exposure in an individual or in a group.

Characteristics

Biomarkers used for the detection of cancer risk factors and in studies of chemoprevention can reveal an overall body load of genotoxins (which should be avoided) or of chemoprotective components (which should be enhanced).

Background

Most forms of cancer are due to somatic alterations (mutation, amplification, recombination) in proto-oncogenes, in tumor suppressor genes or in DNA repair genes. These are acquired in the tumor target tissues during life time, accumulate and produce a clonal selection of cells with aggressive and invasive growth properties. Only ~1% of all cancers are due to inheritance of these types of genetic alterations. Most other cancers are dietary related, are due to inhalation of tobacco smoke, or may be a consequence of inflammation or viral infections. Therefore the majority of all human tumors are considered to be preventable by avoiding exposure to risk factors. Biomarkers may be used in human trials and in studies of ►molecular cancer epidemiology to study these types of exposures and to identify measures to reduce cancer risks.

Types of Biomarkers

The most straight forward determination of risk is to identify people already carrying the disease on account of having tumor cells in their body. These markers are of diagnostic value. In the context of exposure and health, however, other parameters that can be detected prior to manifestation of tumors are considered more feasible. These include:

- Susceptibility biomarkers (predetermining damage) to identify people at high risk, since they carry cancer prone genetic alterations (mutations, gene amplifications, or recombination) in cancer target genes (e.g. ►APC deletions; hMSH mutations, K-►ras amplification).
- Susceptibility biomarkers (predisposing alterations) to identify people at different degrees of risk because they carry frequent alterations in genes that are more indirectly related to the process of carcinogenesis. These indirect mechanisms include features of carcinogen metabolism (►metabolic polymorphisms) or pharmacological variations (e.g. receptors for micronutrients, sensory dispositions). There is some evidence available that single genetic polymorphisms, or a combination of these, can be associated with cancer risk.
- Biomarkers of early effects in cells and tissues to identify past exposure to risk factors by determining genetic damage (►DNA adducts, DNA breaks, ►oxidative DNA damage, genome instability) in somatic cells. This is based on the assumption that increased DNA damage is the result of a higher load of genotoxic agents that will cause the complex process of carcinogenesis. Additional cellular processes that may serve as biomarkers are cell proliferation or ►apoptosis (intermediate endpoints). These may also be decreased on account of exposure to protective factors. Furthermore, the modulation of gene expression, such as induction of phase II enzymes may render the cell less vulnerable and more resistant to risk factors, and the measurement of these effects are thus novel biomarkers of chemoprevention.
- Biomarkers of exposure (risk and protective factors) to identify current exposure to risk compounds (e.g. carcinogens from tobacco (►tobacco carcinogenesis) or food, reactive oxygen species, products of lipid

peroxidation) or protective compounds (e.g. antioxidants, metabolites of chemopreventive agents, ►fermentation products of the gut flora) by measuring their concentrations in urine or blood. For complex associations such as ►diet and cancer, the shift of these groups of substances relative to each other can then be evaluated as contributing to an increase or to a decrease of risk.

Biomarker Techniques and Fields of Application

Depending on the source of body fluid or cells analyzed, the biomarkers will reveal systemic or tissue specific exposures. Specific endpoints will be more suited for molecular cancer epidemiology studies, whereas non-specific end points are also of value for occupational types of exposure assessment or for dietary intervention studies. Non-invasive methods should be better suited for large scale studies, whereas invasive methods will be employed more selectively. In this context, largely depending on the degree of invasiveness, biomarkers may be categorized as follows:

- Non-invasive methods using body fluids or exfoliated cells include techniques such as the analytical detection of single compounds or of their metabolites. The methods are indicators of exposure. Also, a functional determination of mutagenic or genotoxic effects of body fluids using cultured cells as target organisms (e.g. determination of fecal water genotoxicity) are biomarkers for determining exposure. Other non-invasive methods are directed at analyzing genetic alterations in isolated exfoliated cells from these body fluids. Examples are the analysis of micronuclei e.g. in sputum or urinary and buccal cells.
- Relatively non-invasive methods using cells of the peripheral blood stream are aimed at detecting exposure-related genotoxic damage. The endpoints include DNA-strand breaks, oxidized DNA bases (using the single cell microgel electrophoresis assay, also referred to as the ►comet assay), DNA adducts (detected with ►32P-postlabeling) and cytogenetic endpoints (micronuclei, sister chromatid exchanges, chromosomal aberrations). The development of the techniques for genetic damage has been largely based on their utilization as methods to assess exposure in occupational, environmental settings or subsequent to tobacco smoke inhalation. They have only sporadically been used to study associations of diet and cancer.
- Invasive methods using cells from tumor target tissues make use of cells from biopsies (e.g. colon, breast, kidney) to determine functional parameters in potential tumor target tissues. The parameters indicate cellular responses and genetic alterations (proliferation, K-ras-, p53-mutations, APC-alterations and DNA damage). The end points are indicators of very early response to risk factors and are biomarkers of effect. However, they are invasive, and thus may be limited to studies on special exposures or in specific groups of patients. In any case, their utilization and development will serve as basis for the refinement of non-invasive methods with exfoliated cells as outlined above (Fig. 1).

In conclusion, a variety of biomarkers to assess the impact of risk and of protective factors is available. Already research has provided evidence that biomarkers can measure the efficacy of exposure as well as of exposure reduction. Many of the techniques, however, need to be further validated for their applicability, reliability and predictivity of potential tumor risks in human studies. Another set of techniques is available that can serve as a meaningful basis for the development of potentially new biomarkers. Altogether these methods are of value to serve as indicators of effects and indicators of exposure by risk and protective compounds. Depending on the specificity of the end point or on the technical feasibility, individual methods will be more or less suited for use in dietary intervention studies, in occupational exposure settings and/or in larger scale trials of molecular epidemiology.

Biological monitoring

Definition

Biological monitoring (i.e., biomonitoring) has conventionally been defined as "the periodic measurement of ►xenobiotic(s) or their ►metabolite(s) in accessible biological media for the comparison with an appropriate reference." At present, a broader definition could be used that included effect ►biomarkers and biologically relevant dose, as well as biomarkers of susceptibility.

Characteristics

Biomonitoring is mainly aimed at (i) defining the existence of an occupational or environmental exposure; (ii) quantifying the ►internal dose; and (iii) verifying that exposure limits are respected. The most commonly used matrices for biomonitoring are blood (and its components, e.g., serum and plasma) and urine.

Biological monitoring is complementary to the two other monitoring programs that are carried out to evaluate the health risk associated with exposure to pollutants, i.e., ambient monitoring and health surveillance. The basis of these monitoring programs is defined by following up the fate of a chemical from the environment to the target molecules in the organism. The main characteristics of biological and ambient monitoring are summarized in Table 1.

Once absorbed and present in the circulation, the chemical may be eliminated unchanged, mainly in urine or in expired air, or distributed to different compartments of the body. Organic chemicals usually undergo a ►biotransformation to more water-soluble compounds that are more easily excreted via urine or bile than the parent compound. If not excreted, the chemical or its ►metabolites may bind to different sites on the target molecules. Binding on critical sites may give rise to adverse health effects at least when the amount bound has reached a certain level and the protective mechanisms are inadequate or insufficient.

Biological monitoring may offer several advantages over environmental monitoring to evaluate the internal dose and hence to estimate the health risk. One of the main advantages is that biological monitoring takes into consideration all routes of absorption (inhalation, skin, ingestion) in both occupational and leisure activities, accounting for individual differences in absorption rate due variations in, e.g., work load or coexposure to additional components of complex mixtures. It also takes into account the variations in individual

Biomonitoring. Table 1 Main characteristics of biomonitoring and ambient monitoring

	Biomonitoring	Ambient monitoring
Quantifies	Dose	External exposure
Routes of absorption	All routes	Inhalation
Measurement	Biomarkers	Direct
Interpretation	Complicated	Easy
Variability	High	Usually low
Confounding	Metabolic ►phenotype	Protection devices
Cost	Usually high	Usually low

►metabolic capability, due to either genetically determined or acquired changes in gene expression and enzyme activity. The greatest advantage of biomonitoring, however, is the fact that the biological parameter of exposure is more directly related to the adverse health effects that one attempts to prevent than any environmental measurement.

On the other hand, biomonitoring is more complex in terms of ►standardization and interpretative efforts as compared with ambient monitoring. Since biomonitoring rely on the use of biomarkers, rational biological monitoring is only possible when sufficient ►toxicological information has been gathered on the mechanism of action and/or the metabolism (absorption, biotransformation, distribution, excretion) of ►xenobiotics to which people may be exposed. When a biomonitoring method is based on the determination of chemical or its metabolite in biological media, it is essential to know how the substance is absorbed via the lung, the gastrointestinal tract, and the skin, and subsequently how it is distributed to the different compartments of the body, ►biotransformed, and finally eliminated. It is also important to know whether the chemical can accumulate to the body.

According to the National Research Council (NRC), biomarkers can be classified as (i) biomarkers of exposure; (ii) biomarkers of effect; and (iii) biomarkers of susceptibility. The use of biomarkers rather than their intrinsic properties may define their classification.

Biomarkers of Exposure

Exposure biomarkers are widely used, e.g., in occupational ►toxicology for a more accurate risk assessment. In workers exposed to similar air concentrations of chemical pollutants, various factors can determine the actual absorbed dose, including physical workload, additional skin absorbance due to bad working practice or, on the contrary, the use of personal protection devices, and differences in individual uptake and metabolism.

The meaning of the marker may depend on the sampling time. Therefore, the choice of the biomarker should rely on a number of considerations, but mainly on ►kinetic parameters and on the knowledge of the mechanistic basis of adverse effects. An ideal biomarker of exposure should be (i) specific for the exposure of interest; (ii) detectable in small quantities; (iii) measurable by noninvasive techniques; (iv) inexpensive; (v) associated with prior exposure; and (vi) able to provide an excellent positive predictive value to a specific health status. Several biomarkers of exposure are often available for the same chemical, e.g., the parent compound itself, a metabolite, or a macromolecular ►adduct (to DNA or protein).

A great majority of the currently available biomonitoring tests are based on determination of the chemical or its metabolite in a biological media. According to their selectivity, these tests can be classified into two subgroups: (i) the selective tests based on the direct measurement of the unchanged chemicals or their metabolites in biological media; (ii) the nonselective tests used as nonspecific indicators of exposure to a group of chemicals.

DNA and protein ►adducts are primary measures of exposure to carcinogenic compounds. DNA adducts are mechanistically linked to cancer formation, as they may cause gene mutations and chromosomal alterations in growth controlling genes. Measurement of DNA adduct levels allows insight into the impact of metabolic variations, the interactions between components of complex mixtures, and coexposure to compounds that enhance the effect of carcinogens. In human studies, DNA adduct levels in the target organ are consistent with the excess risk noted for populations with specific exposures. For instance, significant differences in DNA adduct levels have been detected in persons exposed to passive tobacco smoke in the face of only modest differences in exposures. Moreover, simple interventions have been shown to reduce DNA adduct levels in the target organ of an exposed population. So, while analysis of carcinogen DNA adducts remains primarily a research tool, these research studies have begun to validate its wider use in biological monitoring of exposed human.

Biotransformation is obviously a central issue for any biomarker used in biomonitoring of xenobiotic exposure. Variation in individual metabolism is expected to be an important contributor to variation in biomarker levels. Metabolic differences among individuals can stem from acquired factors, such as enzyme induction or inhibition, or from inherited polymorphisms of xenobiotic-metabolizing enzymes (XMEs).

Most absorbed xenobiotic chemicals undergo biotransformation that eventually aims at disposal of the chemical with as little harm as possible. For indirectly toxic chemicals, phase I reactions mediated by cytochrome P-450 (CYP)-dependent monooxygenases usually comprise metabolic activation, while phase II conjugation reactions are part of detoxification and lead to excretion. In many cases, the metabolism is, however, complicated, and metabolic activation and detoxification does not follow this simple model.

During last decade many of the XME-genes have been shown to be polymorphic, resulting in individual differences in the metabolic capability related to these enzymes. For some enzymes, the polymorphism involves ►genotypes that are associated with no enzyme activity, while in other cases ►phenotypic differences between the genotypes are subtler. The phenotypic consequences of many metabolic polymorphisms are, however, inadequately known. Accordingly, we are just beginning to understand the possible toxicological

impacts of genetic polymorphisms in environmental exposures.

Biomarkers of Effect

Biomarker of effect has been defined as "any measurable biochemical, physiological, or other alteration within an organism that, depending on the magnitude, can be recognized as an established or potential health impairment or disease." Research on biomarkers of effect is rapidly generating a large amount of data measuring intermediate end-points occurring probably after exposure and possibly before illness. Such biomarkers are expected to reflect early modifications preceding progressive structural or functional damage at the molecular, cellular, and tissue level. A wide spectrum of biomarkers may be used for this purpose. Cytogenetic (►Cytogenetics) tests involving scoring of microscopic chromosomal damage are the oldest of biomarkers used and are still applied in a wide variety of exposures.

The main conceptual basis for using cytogenetic assays for biological monitoring is that genetic damage in a nontarget tissue, most often peripheral blood lymphocytes, reflects similar events in cells involved in carcinogenic process. The conventional chromosomal damage assessments include determination of (i) structural chromosomal aberrations (CAs); (ii) sister chromatid exchanges (SCEs); and (iii) micronuclei (MN). Recently, in situ fluorescence techniques (FISH) have been used in order to score specific chromosomes and chromosomal loci. Rigorous study design is necessary in all cytogenetic biomonitoring methods, since many interindividual factors that are not related to the specific chemical exposure(s) of interest may affect the parameters studied. Experimental confirmation of the chromosome damaging potential of the test agent(s) is therefore a prerequisite in performing human cytogenetic studies.

A good example of the potential applicability of chromosomal damage as surrogate for disease comes from recent prospective studies on cytogenetic biomarkers and cancer risk that followed several European cohorts; subjects in the group of highest frequency of CAs were at a more than doubled overall risk for cancer with comparison to the lowest frequency group. The use of MN as a measure of chromosomal damage, on the other hand, has become a widely used assay in both genetic toxicology testing and human biomonitoring studies. Analysis of results from European cohorts indicated that subjects with cancer had a significant increase in MN frequency.

Biomarkers of Susceptibility

The concatenation of environmental exposure, genetic effect, and ►individual susceptibility is a key issue in assessment of risks for populations exposed to environmental pollutants. In view of the interindividual differences in susceptibility to xenobiotics, one might consider the detection of increased susceptibility to a chemical hazard. A biomarker of susceptibility is defined as an indicator of an inherent or acquired ability of an organism to respond to the challenge of exposure to a specific xenobiotic substance. For instance, the ability to acetylate aromatic amines has been shown to be genetically determined and it has been suggested that carriers of allelic variants of the *N*-acetyltransferase (NAT2) gene that result in decreased *N*-acetylation capacity are at increased risk for colorectal cancer when exposed to carcinogenic aromatic amines.

Genetic polymorphisms in the activity of the aryl hydrocarbon hydroxylase (AHH) has also been suggested as an example of the relationship of metabolic variation to individual susceptibility to develop lung cancer in case of exposure to polycyclic aromatic hydrocarbons (PAHs).

The genetic polymorphisms potentially important for a particular biomarker largely depend on the exposing agent and biological material examined. As ►genotype effects have only occasionally been considered in ►biomarker studies, much basic research is needed, and no general conclusions can yet be drawn on their real importance. It is, however, expected that genotype differences exist in biomarker response to many exposures. In such cases, information on this effect will be very valuable for correct assessment of exposure and effect biomarkers. If genotyping can be shown to markedly improve routine biomarker reliability, the ethical question whether this tool should be utilized only in setting standards or incorporated as part of the analysis must be addressed.

Ethical and Social Implications

Biological monitoring has been a major tool of medical health surveillance in most EU member states already for several decades. Biomonitoring data can also be used to fine tune or even launch environment and health policies; it allows policy makers to identify priorities and provides early warning on potential threats and enables them to assess how effective the strategies are (time trends analysis).

For many pollutants, however, interpretation of health significance is still hampered by the lack of toxicological and medical information. Moreover, ►internal doses cannot be directly linked to the external exposure source. And because human biomonitoring has to do with people, an ethical and communication framework has to be further developed in order to ensure that the biological monitoring surveys respect ethical and privacy considerations.

Much work has therefore still to be done, especially with respect to proper interpretation of human biomonitoring data and its translation into policy actions.

In line with this, developing a coherent approach to human biomonitoring is one of the main priorities of the European Union Environment and Health Action Plan 2004–2010.

Biopsy

Definition

Sample of tissue obtained for diagnostic examination by a special surgical intervention.

►Exfoliation of Cells

Bioreductive Drug

Definition

Is an agent that is reduced in the state of oxygen deficiency, usually to produce a more active metabolite that can be cytotoxic or that can be used for the detection of O_2-depleted tissue areas.

►Oxygenation of Tumors

Biosensor

Definition

A sensor to detect a biological component or a sensor that provides bioanalytical information by mean of applying biological molecules such as nucleic acids, enzymes, or antibodies which functions as biological recognition element.

►Surface Plasmon Resonance

Biosynthesis

Definition

Is the production (usually enzymatic) of components in living cells

►Estrogenic Hormones

Biotechnology

Definition

The use of living organisms or their products to make or modify a substance. Biotechnology includes recombinant DNA techniques (genetic engineering) and hybridoma technology.

Biotechnology Derived Therapeutic Proteins

►Recombinant Therapeutics

Biotin

Definition

(vitamin H or B7) A water-soluble B-complex vitamin which is composed of an ureido (tetrahydroimidizalone) ring fused with a tetrahydrothiophene ring. Biotin

is important in the catalysis of essential metabolic reactions to synthesize fatty acids, in gluconeogenesis, and to metabolize leucine.

►Anti-HER2/Neu Peptide Mimetic (AHNP)

Biotransformation

Definition

Chemical conversion of substances by living organisms or enzyme preparations.

►Biomonitoring

BiP/GRp78

Definition

BiP (Binding protein for immunoglobulins)/GRp78 (Glucose-regulated protein of 78 kDa) is a molecular chaperone of the Hsp70 family, and expressed in the endoplasmic reticulum. It recognizes non-native folding intermediates through hydrophobic amino acids in proteins.

►Calreticulin

BIR Domain

Definition

►Baculovirus IAP Repeat Domain; Is an approximately 70 amino acid zinc-binding domain, first identified by sequence homology among proteins belonging to the ►Inhibitors of Apoptosis (IAP) family. Present in one to three tandem copies per protein, the BIR domain has been identified in over 80 different proteins in eukaryotic organisms. Most of what is known about BIR domains come from their role in IAP proteins. IAPs bind to and inhibit caspases, a class of cysteine proteases involved in propagating ►apoptosis signals within the cell.

BIRADS

Definition

Acronym for ►Breast Imaging Reporting and Data System.

Birbeck Granule

Definition

Is a Langerhans' cell specific rod-shaped or tennis racquet-shaped organelle detected by electron microscopy, whose function is unknown.

►Langerhans Cell Histiocytosis

BIRC5

►Survivin

Birt–Hogg–Dubé Syndrome

Shree Ram Singh
Mouse Cancer Genetics Program, National Cancer Institute at Frederick, Frederick, MD, USA

Synonyms

BHD syndrome; Folliculin (FLCN); Fibrofolliculomas with trichodiscomas and acrochordons; Hornstein–Knickenberg syndrome

Definition

Birt–Hogg–Dubé syndrome is a rare, autosomal dominantly inherited genodermatosis characterized by multiple, benign cutaneous hair follicle tumors (fibrofolliculomas), trichodiscomas, and acrochordons (skin tags), lung cysts, spontaneous pneumothorax (lung wall collapse), colon polyps and colon carcinoma, lipomas, angiolipomas, parathyroid adenomas, parotid oncocytomas, and an increased risk for developing kidney

tumors such as oncocytomas, chromophobe, papillary, and clear renal cell carcinoma (RCC).

Characteristics

BHD syndrome was originally described in 1977 by Birt, Hogg, and Dubé as a rare form of inherited ►autosomal dominant syndrome in large kindred, wherein 15 of 37 members were older than 25 years of age. Originally, it was characterized as a triad of multiple, skin hamartomatous lesions (fibrofolliculomas, trichodiscomas, and acrochordon). The fibrofolliculomas and trichodiscomas appear as multiple, small, dome-shaped, smooth, 2–4 mm, yellowish or skin-colored papules, scattered over the forehead, face, neck, nose, chest, scalp, and upper trunk. The onset of skin lesions typically begins during the third or fourth decade of life. Skin lesions tend to increase in size and number with age. The acrochordons appear as small and soft skin tags (furrowed, 1–2 mm soft papules) composed of loose connective tissues. Histogenesis of skin lesions confirmed that trichodiscomas originated from the mesenchymal component of the pilar complex, acrochordons from epithelial components, and fibrofolliculomas from both epithelial and mesenchymal proliferation. Since its initial description, more than 60 families have been identified with BHD syndrome and a number of other features of BHD have been recognized, including an increased incidence of ►renal carcinoma, most commonly, chromophobe and hybrid oncocytic/chromophobe ►renal cell carcinomas (RCCs), lung cysts, pleural blebs, spontaneous pneumothorax, developing colonic adenomas and carcinoma, neurothekeomas, meningiomas, flecked chorioretinopathy, parathyroid adenomas, multiple lipomas, intraoral papules, parotid oncocytoma, and other cutaneous tumors such as, collagenomas, perivascular fibromas, angiofibromas, and ►melanomas.

Individuals with BHD syndrome were found to have sevenfold higher risk of developing kidney neoplasm, 50-fold higher risk of developing spontaneous pneumothorax, and 80-fold higher risk of developing pulmonary cysts over the general population. The first report of BHD syndrome with renal pathology when examined showed bilateral kidney tumors with a one clear RCC and one chromophobe RCC. Further, in a study of 13 patients with BHD syndrome, seven had renal neoplasms, including renal oncocytomas and papillary RCCs. BHD patients with renal ►neoplasia display multifocal, bilateral tumors of several histopathological variants including chromophobe RCC (34%), oncocytic hybrid (50%) with features of chromophobe RCC and renal oncocytoma, and less frequently, clear cell RCC (9%), renal oncocytoma (5%), and papillary RCC (2%). Oncocytoma and chromophobe RCC originate from the intercalated cells of renal collecting tubules and share overlapping histologic features. A study on 98 patients with BHD syndrome described the occurrence of both oncocytoma and chromophobe RCC with predominancy of chromophobe RCC in renal cancer, found in 7 of 14 histologically examined tumors. Chromophobe RCCs are slowly progressive, locally invasive, and average 7–9 cm in diameter but rarely metastasize. Mean age at diagnosis of kidney tumors is 50.7 years. Recent findings suggest that microscopic oncocytic lesions may be precursors of hybrid oncocytic tumors, chromophobe RCCs, and perhaps clear cell RCCs in patients with BHD syndrome. Strong associations between renal neoplasms and pulmonary cysts and spontaneous pneumothorax have been observed in BHD families. The lung cysts in BHD affected individual are mostly bilateral and multifocal and have a high risk of developing spontaneous pneumothorax. Pneumothorax likely occurs in younger individuals with BHD syndrome. Male gender and older age has been associated with increased risk of renal tumors, whereas the risk of spontaneous pneumothorax is inversely associated with age. Based on these clinical manifestations, penetrance of BHD syndrome is considered to be very high. Thus, the BHD syndrome conferred an increased risk for the development of renal tumors, spontaneous pneumothorax, and lung cysts.

Diagnostic Criteria

The following diagnostic features may be considered in a patient with BHD syndrome: the presence of 10–100 cream to flesh-colored, smooth, firm skin papules on the face, neck, or upper torso, with at least one histologically confirmed fibrofolliculoma with or without family history of BHD or a single renal tumor or history of spontaneous pneumothorax; a patient with multiple and bilateral chromophobe, oncocytic, and/or oncocytic hybrid renal tumors; single oncocytic, chromophobe, or oncocytic-hybrid tumor and a family history of renal cancer with any of above renal cell tumor types; and a family history of autosomal dominant primary spontaneous pneumothorax without a history of chronic obstructive pulmonary disease.

BHD Gene Mutations

The genetic defect responsible for BHD syndrome has been mapped to the pericentromeric region of chromosome 17p11.2 by linkage analysis and the gene in this region has been cloned and is believed to be responsible for the BHD syndrome. This region is interesting because of the presence of low copy number repeat elements, unstable, and associated with a number of diseases. Several heterozygous ►germline mutations have been identified in a novel gene, *BHD*, in BHD families. The human *BHD* gene encodes a tumor-suppressor protein, folliculin (*FLCN*), a cytoplasmic protein with an open reading frame of 579 amino acids,

64-kDa protein. Human *FLCN* consists of 14 exons. Folliculin contains a glutamic acid rich, coiled-coil domain with no significant homology to any known human protein. Folliculin homologs have been identified in many species, including *Drosophila*, *Caenorhabditis elegans*, mouse, dog, and rat, implying a critical biological role for folliculin. Although the function of the *BHD* gene is unknown, germline mutations in *FLCN*, with somatic mutations and loss of heterozygosity in tumor tissue, suggest that loss of function of the folliculin protein is the basis of tumor formation in BHD syndrome. Recently, it has been shown that *FLCN* binds with *FNIP1* (folliculin interacting protein 1) and may be involved in energy and/or nutrient sensing through AMPK and mTOR signaling pathways. Further, a recent study demonstrates that the *Drosophila* homolog of gene BHD regulates male germline stem cell maintenance and functions downstream of the JAK/STAT (janus kinease/signal transducer and activator of transcription) and Dpp (decapentaplegic) signal transduction pathways. This study suggests that the BHD may regulate tumor formation through modulating stem cells in human.

The germline mutations identified in BHD families so far are frameshift or nonsense mutations, predicted to truncate folliculin, including insertions or deletions (44%) of a hypermutable tract of eight cytosines (C8) in exon 11. Initially, the distinct germline mutations on exon 11 of the folliculin gene (c.1733insC and c.1733delC) in three of four families with BHD syndrome, was identified. Later, mutations along the entire length of the coding region of the folliculin gene has been identified, including 16 insertion/deletion, 3 nonsense, and 3 splice site mutations in 51 of 61 families with BHD syndrome. Interestingly, among patients with a mutation in the exon 11 hot spot, significantly fewer renal tumors were observed in patients with the C-deletion than those with the C-insertion mutation. Two unique features of renal tumors in patients with BHD syndrome are the variable expression of the phenotype among members of a given family who carry the same germline mutation, and between families who carry the "hot spot" mutation in exon 11. Mutational hot spot is also reported to be a target of mutation in ►microsatellite instability (MSI) sporadic colorectal cancer. Five of 32 (16%) sporadic colorectal cancers with MSI were found to have insertion/deletion mutations in the poly(C)8 tract of the *BHD* exon 11. In addition, mutations truncating folliculin have been described in patients with 4-bp deletions in *BHD* exon 4, dominantly inherited lung cysts and/or spontaneous pneumothorax without skin lesions or kidney tumors. Moreover, germline mutation in the rat and dog homologs of the *BHD* gene also resulted in inherited kidney tumors, suggesting that the *BHD* gene has a tumor suppressor function. Furthermore, recent evidence of somatic second "hit" mutations in renal tumors from BHD patients in which 53% showed a second somatic mutation and 17% showed loss of ►heterozygosity (LOH) of the wild type allele, strongly supports the Knudson "two-hit" tumor suppressor model for *BHD* and suggesting that BHD is a new ►tumor suppressor gene with roles in both human and animal carcinogenesis.

BHD mRNA is expressed in a wide variety of normal tissues including the differentiated epidermal layers of the skin, the outer and inner root sheath supporting structures of the hair follicle, lung, and kidney and also expressed in a variety of secretory cell types, including acinar cells of the parotid gland and pancreas, brain, lymphocytes and ductal cells of the breast and prostate. Tissues with reduced expression of folliculin mRNA included heart, muscle, and liver. Folliculin immunoreactivity also occurred in the nucleolus of normal cells and was associated with mitosis. In addition, folliculin mRNA was expressed strongly in fibrofolliculomas but loss of folliculin expression was seen in oncocytoma (3.3%), chromophobe RCC (60.7%), papillary RCC (36.4%), and clear cell RCC (21.1%). Abnormal accumulation in the cytoplasm was also observed in oncocytoma (76.7%), chromophobe RCC (3.6%), and clear cell RCC (14.7%). Thus, the protein may have important biological functions in a variety of tissues and organisms. Furthermore, the defective protein in BHD patients may affect the cell's cytoskeleton, disrupting the extracellular matrix and affecting the regulation of cellular proliferation.

Screening and Possible Treatment for BHD

BHD syndrome is inherited in an autosomal dominant manner. A child having a parent with mutation on *BHD* has a 50% chance of inheriting that mutation. No specific screening guidelines for BHD syndrome have been described. However, due to the risk of kidney cancer and other associated abnormalities, it has been suggested that individuals with BHD syndrome or a family history of BHD syndrome should have yearly ultrasounds of their kidneys from the age of 25 and abdominal computerized tomography (CT) scan or magnetic resonance imaging (MRI) every 2 years. Further, BHD syndrome can be identified by skin biopsies to confirm the fibrofolliculomas and X-rays to look for lung cysts and previous spontaneous pneumothorax. Individuals with BHD syndrome should avoid smoking because of increased risk of kidney cancer associated with smoking. No curative medical treatment is currently available for the cutaneous lesions associated with BHD syndrome. However, surgery and electrodesiccation have provided definitive treatment of solitary perifollicular fibromas and multiple lesions, respectively. Treatment of folliculoma/trichodiscoma shows substantial improvement after laser ablation but

can be reverted. Renal tumors can be treated with nephron sparing surgical approaches, depending on the size and location of the tumors. Individuals with spontaneous pneumothorax may avoid high ambient pressures, which can precipitate spontaneous pneumothorax. Consider colonoscopy for colonic polyps and colonic adenocarcinoma. Genetic testing for BHD syndrome is also available. Use of molecular genetic testing for early identification of at-risk family members before disease causing mutations are manifested, may improve diagnostic certainty and reduce costly screening procedures. Methods of using BHD encoding sequence also allow for a differential genetic diagnosis of spontaneous pneumothorax, or collapsed lung.

Bispecific Antibodies

Roland E. Kontermann
Institute of Cell Biology and Immunology, University of Stuttgart, Germany

Definition

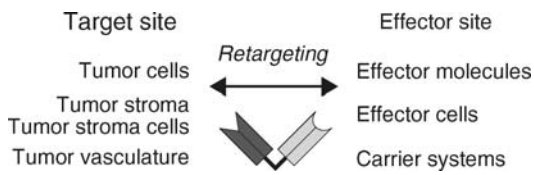
Bispecific antibodies are ►antibodies possessing antigen-binding sites with specificity for two different structures (dual specificity).

Characteristics

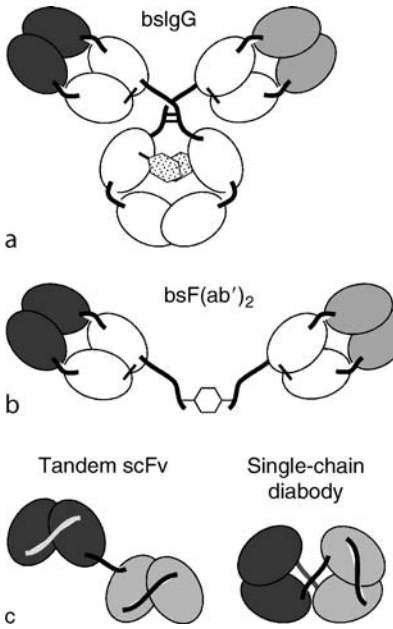
Bispecific antibodies are molecules able to simultaneously bind to two different ►epitopes on the same or different antigens. Bispecific antibodies act as mediators or adaptors bringing two different structures into close contact. In cancer therapy, possible applications include the retargeting of effector molecules (e.g. radionuclides, drugs, enzymes, ►cytokines), effector cells (e.g. cytotoxic T lymphocytes, ►natural killer cells), or carrier systems (e.g. drug-loaded liposomes, genetic vehicles) to tumor-associated target sites, such as tumor cells, tumor stroma cells and extracellular components as well as cells and structures associated with the tumor vasculature. Thus, potential applications of bispecific antibodies cover the areas of immunotherapy, ►chemotherapy, radiotherapy (►radioimmunotherapy) and ►gene therapy. Bispecific antibodies can lead to increased selectivity and improved efficacy of natural effector functions and are able to expand therapeutic effects to those not exerted by normal immunoglobulins used in the clinic (e.g. IgG molecules) (Fig. 1).

Generation of Bispecific Antibodies

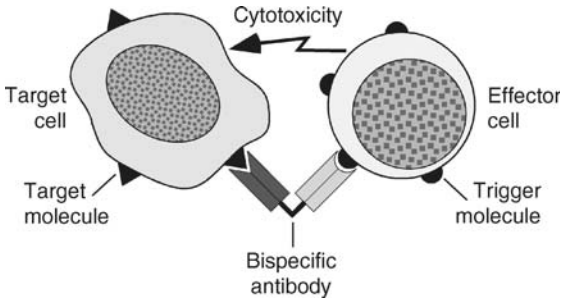
Bispecific antibodies are not found in nature and hence have to be generated in vitro. Various methods have been established including somatic hybridization of two antigen-producing cells, chemical cross-linking of two Fab′ fragments derived from different antibodies, and genetic approaches leading to recombinant antibody molecules. Somatic hybridization, e.g. of two ►hybridoma cells, leads to hybrid-hybridomas or quadromas. These quadromas produce light and heavy chains of both antibodies within one cell, which assemble into bispecific antibodies. However, also nonfunctional or monospecific antibodies are produced due to random association of light and heavy chains. Thus, this approach results in a heterogeneous population of antibodies. Alternatively, Fab′ fragments produced by proteolytic cleavage of two antibody molecules with different specificity can be chemically conjugated to form bispecific $F(ab')_2$ fragments. More recent approaches utilize genetic engineering to combine two different antigen-binding sites within one molecule. A large variety of different formats have been developed. Currently, the most widely used formats are



Bispecific Antibodies. Figure 1 Possible applications of bispecific antibodies in cancer therapy. Bispecific antibodies can act as mediators to retarget effector molecules, effector cells or carrier systems to tumor-associated target sites.



Bispecific Antibodies. Figure 2 Various forms of bispecific antibodies. Bispecific antibodies can be generated by (a) somatic hybridization of two antibody-producing cells, (b) by chemical cross-linking of two Fab′ fragments, or (c) by genetically combining two different antigen-binding sites, e.g. as tandem scFv or as single-chain diabody format.



Bispecific Antibodies. Figure 3 Bispecific antibodies for the retargeting of effector cells. Bispecific antibodies are able to retarget effector cells such as cytotoxic T lymphocytes or natural killer cells to target cells by simultaneous binding to a target molecule on the target cell and a trigger molecule on the effector cell leading to killing of the target cell.

Bispecific Antibodies. Table 1 Effector cells and trigger molecules

Effector cell	Main trigger molecule	Costimulus	Activating cytokine
Cytotoxic T lymphocytes (CTL)	TCR/CD3	B7, anti-CD28	IL-2
Natural killer cells (NK)	CD16	–	IL-2
Macrophages	CD64, CD16, CD89	–	GM-CSF, IFN-γ
Neutrophils	CD89, CD64	–	G-CSF, GM-CSF, IFN-γ

tandem scFv molecules linking two ►single-chain Fv fragments (scFv) by a flexible linker and diabodies or single-chain diabodies with a more rigid structure. Compared to whole antibodies or $F(ab')_2$ fragments these recombinant formats are much smaller with a molecular weight of 50–60 kDa (Fig. 2).

Effector Cell Retargeting

Preclinical and clinical developments of bispecific antibodies for cancer therapy have a strong focus on the retargeting of effector cells of the immune system to tumor cells. Suitable effector cells of the immune system include cytotoxic T lymphocytes (CTL); Natural killer cells (NK), macrophages and neutrophils, which can efficiently kill target cells by antibody-independent or ►antibody-dependent cellular cytotoxicity (ADCC). Retargeting of these effector cells to target cells requires binding of the bispecific antibody to one or more trigger molecules on the effector cell (Fig. 3).

Cytotoxic T cells are among the most potent effector cells of the immune system. Trigger molecules on CTLs are molecules associated with the T cell receptor (TCR) such as CD3. Bispecific antibodies thus bypass normal ►MHC-mediated T cell activation. This is of special interest since many tumor cells escape from a T cell response by down-regulation or loss of MHC expression during tumorigenesis. T cell activation, however, depends on a costimulatory signal, e.g. through binding of B7 to CD28 on CTLs. In a therapeutic setting this costimulatory signal can be provided by anti-CD28 monoclonal antibodies or by bispecific or bifunctional antibodies (Table 1). Interestingly, some anti-CD3 antibodies are able to activate T cells without the need for costimulation. One recombinant bispecific antibody (MT103) directed against CD19 and CD3 is based on such a costimulation independent anti-CD3 antibody. This antibody is currently in a phase I trial for the treatment of non-Hodgkin lymphoma (NHL).

Fc receptors are the trigger molecules employed for retargeting of NK cells, macrophages, and neutrophils. Fcγ receptor III (CD16) represents the main trigger

molecule on NK cells, while Fcγ receptor I (CD64) or the Fcα receptor (CD89) have been utilized for retargeting of macrophages and neutrophils, respectively. The expression of these trigger molecules on effector cells can be increased by activating cytokines such as interleukin-2 (IL-2), granulocyte/macrophage-colony stimulating factor (GM-CSF), or ►interferon-γ (INF-γ) (Table 1).

Clinical Experience with Bispecific Antibodies

Various bispecific antibodies have entered clinical trials. However, as to yet none has been approved for therapeutic applications. Initial problems were associated with the use of whole bispecific immunoglobulins derived from murine hybridomas, especially Fc-mediated toxicity due to the release of inflammatory cytokines (cytokine storm) and a neutralizing immune response against the murine antibodies (human–anti-mouse antibodies, HAMA). Further studies using bispecific $F(ab')_2$ fragments in combination with activating cytokines such as GM-CSF could demonstrate some biological effects, however, clinical responses remained vague. Current research focuses on the development of novel antibody formats including costimulation-independent bispecific tandem scFv molecules for the retargeting of CTLs, the retargeting and activation of CTLs as well as Fcγ receptor expressing effector cells by combination therapy with two bispecific antibody molecules or trispecific antibodies, but also on bispecific antibody molecules with improved pharmacokinetic properties.

Bisphosphonates

Valentina Guarneri
Department of Oncology and Hematology, University of Modena and Reggio Emilia, Policlinico, via del Pozzo, Modena, Italy

Definition

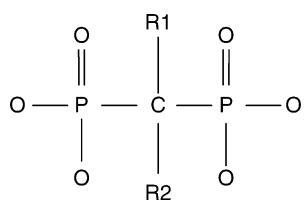
Bisphosphonates are potent inhibitors of ►osteoclast mediated ►bone resorption. These compounds are stable analogues of the inorganic pyrophosphate (PPi), which is an endogenous regulator of bone mineralization.

Characteristics

Bisphosphonates were developed in the nineteenth century for industrial use, in particular as "water softeners." The first clinical use of bisphosphonates in humans was in the 1960s for the treatment of ►Paget disease, a focal disorder of bone remodeling due to abnormally increased osteoclast-mediated bone resorption. So far, bisphosphonates have been successfully studied in several clinical disorders characterized by an alteration in bone resorption, such as metastatic and osteolytic bone diseases, hypercalcemia of malignancy and ►osteoporosis.

All bisphosphonates share a common structure which consists of two phosphate groups attached to a single carbon atom (P-C-P) (See Fig. 1).

The P-C-P group is responsible for the affinity of these drugs for the bone, since it is essential for binding to ►hydroxyapatite or hydroxylapatite. The substitution in the R1 and R2 side chains give rise to a variety of compounds with different potency and biological effects. For instance, the presence of a ►hydroxyl group in the R1 side chain confers a higher affinity for the bone mineral. The R2 side chains directly influence the potency of bisphosphonates for inhibiting osteoclast-mediated bone resorption. In particular, the bisphosphonates containing a basic primary nitrogen atom in an ►alkyl chain (such as pamidronate and alendronate) are 10–100 times more potent than non



Bisphosphonates. Figure 1 Generic structure of bisphosphonates.

nitrogen bisphosphonates. Indeed, the higher antiresorptive potency is obtained when the R2 side chain contains a nitrogen atom within a heterocyclic ring (as in risendronate and zoledronate).

Thus, according to the chemical structure of the R2 side chain, bisphosphonates are generally classified as follows:

- Non nitrogen containing bisphosphonates:
  - Etidronate (Didronel®)
  - Clodronate (Bonefos®, Loron®)
  - Tiludronate (Skelid®)
- Nitrogen containing bisphosphonates
  - Pamidronate (Aredia®)
  - Neridronate
  - Olpandronate
  - Alendronate (Fosamax®)
  - Ibandronate (Bondronat®)
  - Risendronate (Actonel®)
  - Zoledronate (Zometa®)

Mechanism of Action

Bisphosphonates bind to the bone mineral in particular at sites of active bone metabolism, where they achieve therapeutic concentration. During the process of bone resorption, since the acid environment osteoclasts causes dissolution of the hydoxyapatite bone mineral, bisphosphonates are released in this sub-cellular space, and are internalized by osteoclasts. At this point, osteoclasts lose the ruffled border and show cytoskeleton alterations, and eventually become apoptotic.

The toxic effect of bisphosphonates on osteoclasts can be explained in at least two different ways, according to their chemical structure.

First-generation, non nitrogen containing bisphosphonates, such as clodronate and etidronate, are metabolized by osteoclasts to nonhydrolyzable adenosine triphosphate (ATP) analogues, with subsequent inhibition of ATP-dependent intracellular enzymes. The intracellular accumulation of these metabolites inhibits osteoclast function and can induce apoptosis. On the other hand, aminobisphosphonates, following internalization in the osteoclasts, inhibit the farnesyl diphosphonate (FPP) synthase, affecting the biosynthetic mevalonate pathway. This pathway is involved in the production of sterols such as cholesterol, and isoprenoid lipids such as isopentenyldiphosphate, farnesyldiphosphate (FPP) and geranylgeranyldiphosphate (GGPP). FPP and GGPP are essential for the post-translational modification of small ►GTPases (Ras, Rab, Rho and Rac). These signaling proteins are involved in the regulation of cell proliferation, cytoskeletal organization, membrane ruffling, intracellular vesicle transport, and apoptosis. In addition, aminobisphosphonates can also induce the formation of intracellular ATP analogues which may directly induce osteoclast apoptosis.

More recently, a growing number of preclinical data have consistently demonstrated the direct antitumor effect of bisphosphonates. The mechanisms responsible for this effect are not still fully elucidated. However, it has been shown that bisphosphonates can inhibit angiogenesis, cell proliferation and adhesion. Moreover, the effects of bisphosphonates on osteoclasts result in an inhibited release of growth factors in the bone microenvironment, thus rendering the bone less hospitable to cancer cell homing.

Pharmacokinetic

Bisphosphonates are characterized by very low absorption from the gastrointestinal tract (less than 6% for clodronate and etidronate). The plasma half-life ranges between 20 min and 2–3 h, depending on the type of bisphosphonates and the individual rate of clearance. However, because of the high affinity for the bone matrix, half-life in bone is very long, ranging from months to years.

Clinical Use

Hypercalcemia of Malignancy (HCM)

HCM is a severe clinical condition that can occur in up to 20% of patients with advanced cancer, in the presence or absence of bone metastases. HCM is a consequence of osteoclast activation due to the presence of cancer cells in the bone (metastatic bone disease), or the production by cancer cells of parathyroid hormone-related protein (humoral hypercalcemia). Tumors more frequently inducing episodes of HCM include non Hodgkin lymphomas, myeloma, lung cancer, breast cancer, ►renal cancer and ►prostate cancer.

HCM occurs when total serum calcium is above 10.2 mg/dl (2.55 mmol/l), and causes a variety of symptoms including gastrointestinal manifestations (anorexia, vomiting, constipation), renal function deterioration, alteration of cardiac rhythm (EKG abnormalities and arrhythmias), and neurological disorders (from asthenia to lethargy and coma).

Treatment of HCM includes iv hydration and diuretics to facilitate renal calcium excretion, and bisphosphonates to inhibit calcium resorption from the bone. A single bisphosphonate iv infusion can obtain a sustained serum calcium normalization in about 80% of the patients.

Treatment of Bone Metastases

Bone metastases represent a major health problem and can occur in a significant proportion of patients with solid tumors. Bone metastases are frequent (up to 70–80% of the patients) in common tumor types such as prostate cancer, breast cancer and lung cancer. Bone metastases develop when circulating tumor cells home in the bone marrow and stimulate the activation of osteoclasts that eventually initiate bone matrix resorption. Bone metastases can be lytic, sclerotic, or mixed,

depending on the balance between bone resorption induced by osteoclasts and new bone formation by ►osteoblasts.

Metastatic bone disease causes considerable morbidity, leading to several complications including pain, pathologic fractures, spinal cord compression, ineffective hematopoiesis, and HCM. In addition to the specific anticancer therapy (e.g. chemotherapy, hormonal therapy, or biologic agents), the current options to treat bone metastases are radiation therapy, orthopedic surgery, radiopharmaceuticals and bisphosphonates. Currently, bisphosphonates are considered the mainstay of the treatment for metastatic bone disease from myeloma, breast cancer, prostate cancer and other solid tumors including lung and renal cancer.

In clinical trials, the efficacy of bisphosphonates has been measured on the basis of their capacity to reduce or delay the skeletal related events (SRE). An SRE is defined as the occurrence of pathologic fractures, radiation therapy for bone pain or to treat/prevent a fracture, surgery to stabilize bone fractures, hypercalcemia of malignancy, or spinal-cord compression.

The following sections will briefly summarize the clinical experience with different bisphosphonates according to tumor types.

Multiple Myeloma

►Multiple myeloma (MM) is associated with relevant skeleton morbidity, since lytic lesions are present in more than 90% of the patients. The lytic process in MM is different from bone metastases from other cancers, where bone destruction is generally followed by new bone formation. Several bisphosphonates including clodronate, pamidronate and ►zoledronic acid, are effective in preventing or delaying skeletal complications. Oral clodronate have shown a significant reduction in non-vertebral and vertebral fracture rates over a placebo. Again compared to placebo, intravenous pamidronate significantly reduce the proportion of patients with any SRE. It was also associated with significant decrease of bone pain. More recently, zoledronic acid was shown not only to be as effective as iv pamidronate, but to also produce an additional 16% risk reduction of skeletal complication as measured by multiple event analysis.

Bone Metastases from Breast Cancer

Several bisphosphonates have been approved in the United States and Europe for the treatment of skeletal metastases from breast cancer.

The efficacy of pamidronate has been known since the early 1990s. In two pivotal, phase III randomized trials, pamidronate significantly reduced the incidence and delayed the onset of SREs as compared to placebo. It was also effective in the reduction of pain scores.

The more potent bisphosphonate zoledronic acid has been directly compared to pamidronate. The pivotal trial, including breast cancer and multiple myeloma patients, was designed as a non inferiority trial, the primary end point being the percentage of patients with at least 1 SRE at 25 months. Zoledronic acid was at least as effective as pamidronate according to the primary end point. Furthermore, the multiple events analysis demonstrated that zoledronic acid was significantly more effective in reducing the risk of SREs in the subset of breast cancer patients.

Zoledronic acid was also compared to placebo in a trial conducted in Japan, where pamidronate is not approved for the treatment of bone metastases from breast cancer, showing a clear superiority in reducing the SRE rate ratio, the percentage of patients with at least 1 SRE, and in delaying the time to first SRE. The multiple event analysis showed a 44% reduction in the risk of developing an SRE, and significantly reduced mean pain scores from baseline over 12 months.

Ibandronate is a single-nitrogen bisphosphonate available in both intravenous and oral formulations. In terms of reduction of SREs and pain control, the efficacy of iv and oral ibandronate has been confirmed in three placebo-controlled phase III randomized trials. Ibandronate is currently approved in more than 40 non-US countries for the treatment of patients with breast cancer and bone metastases. The approval of the US Food and Drug Administration is still pending. A direct comparison between ibandronate and zoledronic acid is ongoing. Recently, in a review of 21 randomized controlled trials of bisphosphonates in breast cancer by the Cochrane Collaboration, it has been shown that zoledronic acid reduces the risk of SRE by 41%, compared with 33% by pamidronate, 18% by iv ibandronate, 14% by oral ibandronate, and 16% by oral clodronate.

Bone Metastases from Prostate Cancer

Bisphosphonates have also been studied in patients with prostate cancer and bone metastases. In patients with symptomatic bone disease, pamidronate failed to show any advantage over placebo in pain scores, analgesic use, and SREs. On the contrary, as compared to placebo, zoledronic acid significantly reduced the proportion of patients with an SRE over 2 years and delayed the time to first SRE by approximately 6 months. Therefore, zoledronic acid was approved for the treatment of patients with prostate cancer metastatic to bone and progression of disease despite first line hormonal therapy.

More recently, ibandronate has shown some palliative benefit in a small open-label study, but its efficacy over placebo in a randomized trial is still to be demonstrated.

Bone Metastases from Lung Cancer and Other Solid Tumors

The first bisphosphonate with proven efficacy in the treatment of bone metastases from lung cancer and solid tumors is zoledronic acid. In a placebo-controlled randomized trial in more than 700 patients, zoledronic acid significantly reduced the proportion of patients experiencing at least one SRE, and delayed the median time to first SRE as well. Currently, zoledronic acid is the only bisphosphonate approved for the treatment of metastatic bone disease from solid tumors other than breast cancer.

Prevention of Bone Metastases

Because of their mechanism of action, bisphosphonates have the potential to prevent cancer cells homing in the bone, thus changing the entire process of metastatic spread. The data from the earlier, weaker generation of bisphosphonates are conflicting, and to date bisphosphonates are not recommended for the prevention of bone metastases. However, ongoing studies with the newer, more potent intravenous bisphosphonates will establish the role of these compounds in the prevention of bone metastases in several tumor types such as breast, prostate and lung cancer.

Osteoporosis

In both men and women, bone mass decreases with age. In men, this process is constant over time while women usually experience a significant increase in the rate of bone loss after menopause. The most standardized method to evaluate the bone mineral density (BMD) is the dual energy X-ray absorptiometry (DXA) at the recommended site of the proximal femur. Patients are classified as osteoporotic when the BMD (as expressed as T-score) is 2.5 standard deviation (SD) or more below the average value for premenopausal women. When the T-score is between −1 and −2.5 SD patients are classified as osteopenic. For each SD reduction in BMD there is a doubling in the risk of fracture.

Bisphosphonates have been successfully used to treat osteoporosis. In particular, alendronate and etidronate can increase the BMD and almost halve the fracture rates in postmenopausal women, representing the most frequent agents used worldwide in this setting.

Besides the risk of bone metastatization, the bone health of cancer patients can be further affected by cancer therapies. This particular condition, known as cancer-treatment-induced bone loss (CTIBL), reflects the effects of cancer therapy (both chemotherapy and endocrine therapy) on bone mineralization. In brief, all cancer therapies that directly or indirectly antagonize the effect of estrogen or androgen significantly enhance the loss in bone mineral density, thus dramatically increasing the risk of fractures. Because of the higher severity of CTIBL, the common strategies to treat benign osteoporosis, such as oral bisphosphonates, calcium/vitamin D supplements, and calcitonin, might not be sufficient. In early breast cancer, both daily oral clodronate and intermittent oral risendronate have shown superiority over placebo, although clodronate was unable to completely prevent bone loss in patients with chemotherapy-induced ovarian dysfunction. The use of more potent intravenous bisphosphonates is under investigation in three large trials. In prostate cancer patients receiving androgen deprivation therapy, zoledronic acid was able to reverse CTIBL, and even increase bone density at multiple sites. Several trials in prostate cancer are under way to confirm these results. With these potent agents, a less frequent schedule (every 3 or 6 months) seems to be effective, while the monthly dose is used for metastatic bone disease.

Side Effects

The safety profile of bisphosphonates varies depending on the route of administration. Treatment with intravenous bisphosphonates is usually well tolerated, with transient side effects such as mild to moderate flu-like symptoms following initial infusions, generally self-limited. However, iv bisphosphonates have the potential to adversely affect renal function, and sporadic episodes of both acute and chronic renal failure have been described. The risk of renal failure is directly related to dose and to the drug infusion time: when bisphosphonates are administered at the recommended doses and infusion rates, the incidence of elevated serum creatinine is generally low (<10%), and severe adverse renal events are rare. Nevertheless, accurate renal-function monitoring is recommended in the use of iv pamidronate and zoledronic acid. In breast cancer patients, iv ibandronate has shown a renal safety profile similar to a placebo, and because no case of renal failure has been described at the time of writing this, the monitoring of serum creatinine prior to each ibandronate administration is not mandatory.

Oral administration of bisphosphonates can cause esophagitis and other gastrointestinal side effects such as mucositis, nausea, vomiting, and diarrhea.

In the past few years, a growing number of cases of ►jaw osteonecrosis have been associated with the use of aminobisphosphonates, prompting labeling changes for pamidonate and zoledronic acid. Several reports have described a frequency of jaw osteonecrosis ranging from 0.6 to 4.3% for patients with breast cancer and from 3 to 9.9% for those with multiple myeloma. The exact mechanism underlying jaw osteonecrosis has not yet been fully elucidated. Dental disease, dental surgery, periodontal disease, trauma and poor oral hygiene are the most often reported precipitating factors. Several reports

have also identified a relationship between dose and duration of treatment and the development of this complication. Because jaw osteonecrosis is not reversible in the majority of the cases, physicians should focus on the prevention of this complication. It is therefore recommended to assess the dental status of patients before starting bisphosphonates, and avoid invasive dental procedures while on bisphosphonate therapy.

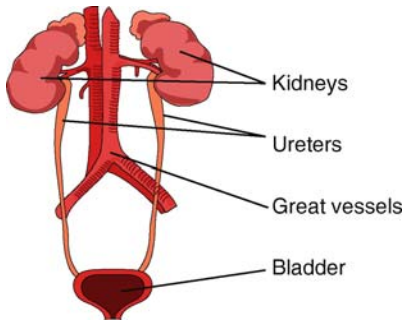
Bladder Cancer

Dan Theodorescu, Behfar Ehdaie
Department of Urology, University of Virginia, Charlottesville, VA, USA

Definition

Bladder cancer is a malignant neoplasm which arises from the epithelial lining of the bladder (Fig. 1). Several histological forms have been identified. Cancers with urothelial histology (UC) comprises more than 90% of the neoplasms, while ►squamous cell carcinoma (SCC) and adenocarcinoma account for 5% and 2%, respectively. In areas with endemic schistosomiasis, SCC is the predominant histological form. It is also not uncommon for urothelial cell malignancies to have minor elements of adenomatous or squamous cell histology. However, from the clinical management standpoint, urinary neoplasms with minor components of these two histologic types are treated for their primary component. The clinical relevance of these minor components or the percentage at which a minor component becomes significant is unclear. An important prognostic criteria in urothelial cell carcinoma is tumor grade. Tumor grading most commonly follows World Health Organization (WHO) guidelines in which malignant tumors are classified as papillary urothelial neoplasm of low malignant potential (PUNLMP), low grade or high grade, regardless of invasion status.



Bladder Cancer. Figure 1 Anatomy of the urinary tract.

Characteristics

Clinical Epidemiology and Risk Factors

Carcinoma of the urinary bladder is the second most common urologic malignancy. The worldwide incidence of bladder cancer is approximately 200,000 patients per year with 120,000 annual deaths, accounting for 3.2% of all malignancies. It affects more males than females by a 3:1 ratio. In the United States, the incidence is higher in Whites than Blacks, although survival is longer in Whites and men than in Blacks and women. The disease can affect all ages (even children) but the median age at presentation is 70 years. It is rarely found as an incidental finding at autopsy suggesting that these cancers do not have a long latent or subclinical course. Bladder cancer incidence has increased 50% between 1985 and 2005; however the mortality rate has decreased by 33% in the past four decades.

Environmental risk factors for ►urothelial cell carcinoma include cigarette smoking, aniline dyes, pelvic radiation, benzidine, 2-naphthylamine, and other aromatic amines. Acrolein, a metabolic product of cyclophosphamide, can increase the risk of bladder cancer ninefold. Smoking increases the risk of bladder cancer fourfold, and at least one quarter of cases

can be attributed to smoking. Chronic cystitis and long-term bladder catheters increase the risk of squamous cell carcinoma. *Schistosoma haematobium* infection not only increases the risk of SCC significantly, but also increases the risk of urothelial cell carcinoma. Epidemiologic evidence does not exist for a hereditary etiology for bladder cancer.

Tumor Biology and Genetics

Urothelial cell carcinoma is a field change disease rendering the entire urothelium susceptible to malignant transformation. Polychronotopicity refers to the propensity of tumors to arise at different times and sites in the urothelium. Both the ►TP53 and ►RAS genes are known targets of chemical carcinogens. The most frequent genetic alterations in urothelial cell carcinoma are monosomies of chromosome 9 (57%), and losses on chromosome arms 11p (32%), 17p (32%), 8p (23%), 4p (22%), and 13q (15%). Deletions specifically associated with higher grades and stages of cancer, indicative of tumor progression to muscle invasive disease, have been identified at 3p, 4q, 8p, 10, 15, 17p, 18q among many others. Other studies utilizing immunohistochemical techniques have suggested that overexpression of p21Ras protein, mutated TP53, and the epidermal growth factor receptor (EGFR) in bladder tumors are related to bladder tumor progression. In addition, loss of RB1, DCC, and ►E-cadherin (CDH1) expression has also been related to this transition. Tumors with p53 mutations tend to exhibit more aggressive behavior when present in both noninvasive and invasive disease, while chromosome 9 alterations and ►fibroblast growth factor receptor 3 (FGFR3) mutations are associated with low grade noninvasive disease. In fact, FGFR3 mutations are found in up to 90% of non-muscle invasive cancers while only found in 10% of muscle invasive or metastatic cancers.

Characteristics of Nonurothelial Cell Carcinomas

SCC comprises only 1–3% of bladder tumors in the U.S. and Britain but represents 75% of tumors in Egypt. Most of the SCCs found in Egypt are due to *S. haematobium* ("bilharzial" bladder cancer) and are well differentiated with lower risk of metastases than urothelial cell carcinoma. Non-bilharzial squamous cell tumors are caused by chronic inflammation from infection, stones, indwelling catheters, or bladder diverticuli. Although these tumors' prognosis is similar to urothelial cell carcinoma by stage, non-bilharzial tumors tend to present with late-stage disease. Primary bladder adenocarcinomas represent approximately two percent of bladder tumors and are more common in extrophic bladders, urachi and intestinal conduits or augmentations. They may produce mucin and can be associated with cystitis glandularis. Most are poorly differentiated and present with advanced disease.

Clinical Presentation

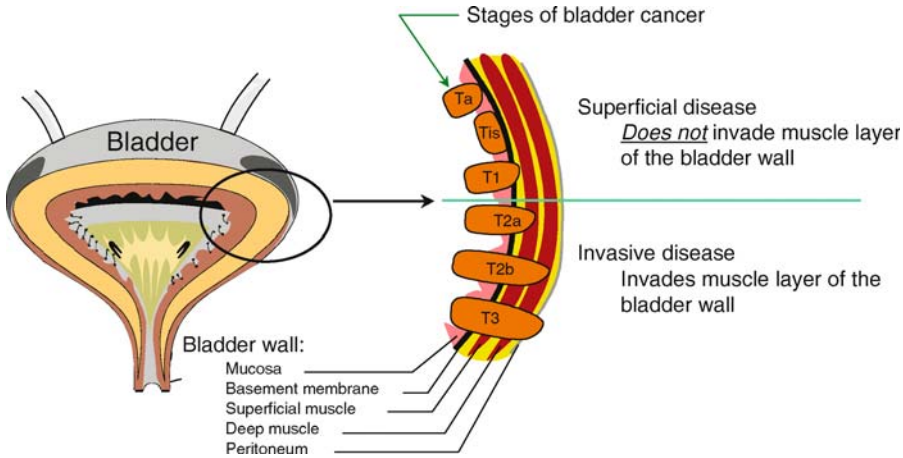
Bladder cancer frequently presents with painless hematuria, although urinary frequency, urgency, and dysuria can occur as well. Gross hematuria is common, and bladder cancer is rarely diagnosed in the absence of at least microscopic hematuria although this can be intermittent. Bladder cancer can also present with flank pain and hydronephrosis if the tumor obstructs the ureteral orifice.

Diagnosis and Staging

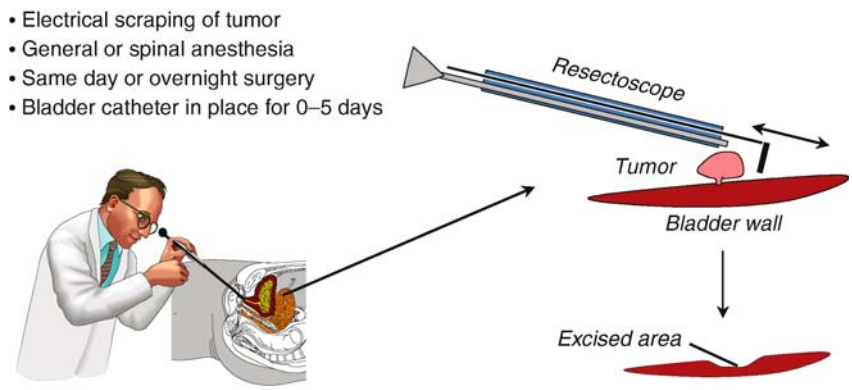
The diagnostic evaluation of bladder cancer begins with a history and physical examination including bimanual pelvic exam, urinalysis, cytology, and cystoscopy. In the past, intravenous urography (IVU) was indicated in all patients with bladder tumors to evaluate the upper urinary tracts. Retrograde ureteropyelograms (IVP) can also be performed at the time of cystoscopy if IVU does not provide an adequate view of the upper tracts. Currently, IVP has been replaced by CT scanning of the abdomen and pelvis with 3-D reconstructions allowing for both the assessments of extravesical spread (contiguous and metastatic) and urography (CT urogram). This is discussed in more detail later. Cytologic examination of bladder cells that slough off into urine is useful in the diagnosis of carcinoma in situ (CIS) or high grade tumors, but low grade tumors are more difficult to detect by cytology. Cytology is primarily used in the diagnosis and follow up of patients at risk for recurrent disease. Novel ►biomarkers such as the nuclear matrix protein (NMP-22) assay, ►survivin, BLCA4, and FISH analysis (UroVysion) offer promise for enhanced detection of symptomatic patients, screening of high risk populations, and treatment follow up and monitoring.

At presentation, 85% of patients with urothelial cell carcinoma of the bladder have disease limited to the organ, while 10% have regional disease and 5% have metastatic disease. Of the 85% with localized disease, 80% have non-muscle invasive disease (stages Tis/CIS, Ta, T1) and 20% have muscle invasive disease (stages T2–T4) (Fig. 2). These stages are according to the UICC/AJCC system, the most common staging system in use today. Urothelial cell carcinoma may grow in papillary, sessile, nodular, or flat (Tis) forms. Papillary tumors with orderly cellular arrangement and minimal nuclear atypia are designated PUNLMP. Such tumors rarely progress to invasive disease and are considered benign. Tis/CIS is sessile, poorly differentiated urothelial cell carcinoma involving only the urothelium. Although CIS can cause irritative voiding, it is often asymptomatic. Cystoscopy may be normal or exhibit erythematous patches, and urine cytology is 80–90% sensitive.

Transurethral resection (TUR) of bladder tumors not only provides tissue for pathologic diagnosis, but can



Bladder Cancer. Figure 2 Stages of bladder cancer.



Bladder Cancer. Figure 3 The trans urethral resection (TUR).

represent definitive therapy in the most clinical stage Ta and T1 tumors as long as the whole tumor is resected (Fig. 3). After the intraluminal portions of the tumor are resected, the tumor base is frequently resected as a separate pathologic specimen to ensure complete resection and accurate staging. T1 tumors undergo a second resection 3–6 weeks later to reduce the risk of understaging. It is critical that muscularis propria is included in the specimen to exclude the presence of muscle invasion by the tumor. Routine performance of random biopsies of the bladder or prosatic fossa mucosa remain controversial. However, these may be indicated to evaluate for CIS in patients with positive cytology or in patients that are candidates for orthotopic neobladder or partial cystectomy. If the tumor appears invasive (i.e., sessile, solid configuration), the resection is tailored so as to accurately determine clinical stage and to optimize subsequent definitive therapy. For example, if the patient is likely to choose radical cystectomy as the treatment of choice then complete TUR is not necessary. Conversely, if the patient is likely to select bladder sparing therapy with radiation and chemotherapy, then resection of as much tumor as safely possible should be carried out.

As alluded to earlier, the staging of bladder cancer is based primarily on the specimen generated by the TUR and is classified according to the 1997 UICC/AJCC system (Table 1) and revised by the World Health Organization/International Society of Urological Pathology WHO/ISUP Consensus Classification (Table 2). In 1998, the WHO/ISUP Consensus Classification of urothelial neoplasms of the urinary bladder was developed to unify the numerous diverse grading schemes for noninvasive bladder cancer and provide detailed histological criteria for papillary urothelial lesions. In addition, the new classification system allows for designation of a lesion papillary urothelial neoplasm of low malignant potential, which biologically has a very low risk of progression, but is not entirely benign. Therefore an intermediate classification enables these patients to avoid the label of having cancer with its psychosocial and financial implications and prevent them

Bladder Cancer. Table 1 UICC/AJCC consensus classification

UICC/AJCC 1997	Description
Ta[1]	Papillary tumor, epithelium confined
Tis	Carcinoma in situ: "flat tumor"
T1	Lamina propria invasion
T2a	Tumor invades non-muscle invasive muscle (inner half)
T2b	Tumor invades deep muscle (outer half)
T3a	Tumor invades perivesical fat microscopically
T3b	Tumor invades perivesical fat macroscopically (extravesical mass)
T4a	Tumor invades prostate or uterus or vagina
T4b	Tumor invades pelvic wall or abdominal wall
N1[2]	Single node <2 cm
N2	Single node >2–5 cm or multiple nodes <5 cm
N3	Any node >5 cm
M1	Nodal meets above bifurcation of common iliac vessels
M1	Metastasis

[1]Suffix "*m*" after T stage to indicate multiple tumors.
[2]Nodes of "true pelvis" (i.e., below bifurcation of common iliac vessels).

Bladder Cancer. Table 2 WHO/ISUP Consensus Classification

World Health Organization/International Society of Urological Pathology Classification
Hyperplasia
Flat hyperplasia
Papillary hyperplasia
Flat lesions with atypia
Reactive (inflammatory) atypia
Dysplasia
Carcinoma in situ (CIS)
Papillary neoplasms
Papilloma
Papillary neoplasm of low malignant potential (PUNLMP)
Papillary carcinoma, low grade
Apillary carcinoma, high grade

from being diagnosed as having a benign lesion, whereby they might not be followed as closely.

The pathologic exam of bladder specimens may be complicated by difficulty in differentiating muscularis propria from the more non-muscle invasive and thin muscularis mucosa, the latter which does not represent "true muscle" invasion and thus direct communication between urologist and pathologist is essential. If pathologic examination reveals tumor invasion into muscularis propria, CT or MRI of the abdomen pelvis is used to evaluate for gross extravesical spread, lymphadenopathy, or hepatic metastases. In general, these methods fail to detect lymph node spread in as many as 30% of patients. A radionucleotide bone scan can be obtained to evaluate for bony metastases, but the yield of a bone scan in the face of a normal alkaline phosphatase is low. Chest X-ray or CT scan is obtained to rule out pulmonary metastases.

Management of Noninvasive Disease

The therapy of noninvasive (Ta/T1) bladder cancer consists of TUR and fulguration. Because approximately 30% of these tumors tend to recur and 10% may progress to muscle invasion, follow up cystoscopy at regular intervals is mandatory. Tumors that invade the lamina propria (T1) should be considered potentially more aggressive, particularly if high grade. Argon and Nd:Yag lasers have also been used successfully for ablation of noninvasive bladder tumors especially those that are multifocal or difficult to access via the resectoscope used for TUR. The disadvantage of these techniques is the lack of tumor specimen to be analyzed by pathology and thus only lesions with a high likelihood of being noninvasive should be treated in this way.

Patients with recurrent, high grade Ta, T1 tumors or CIS may benefit from intravesical therapy with ►Bacillus Calmette–Guerin (BCG) or ►mitomycin C. These treatments can be given in two clinical contexts. They can be given for the treatment of residual disease which could not to be removed at TUR. Alternatively, they can be used to reduce the incidence of recurrence and progression in patients that have completely resected tumors. Furthermore, Mitomycin C delivered perioperatively in one dose has successfully reduced the incidence of tumor recurrence following TUR. BCG

is a live attenuated strain of *Mycobacterium bovis*, which stimulates a local and possibly systemic immune response. BCG can often delay recurrence and progression of high grade noninvasive disease and CIS. Side effects of BCG include bladder irritability, granulomatous prostatitis, systemic disseminated infection requiring antitubercular agents, and rarely death. Contraindications for intravesical delivery include: active tuberculosis, immunosuppression, traumatic catheterization, gross hematuria, and prior severe reaction to BCG. Mitomycin C is an alkylating chemotherapeutic agent that inhibits DNA synthesis. BCG is superior to Mitomycin C in reducing the risk of progression in high grade tumors in some but not all studies. BCG can also be used for maintenance therapy where it has been shown to reduce recurrence even further. Other intravesical compounds include interferon, keyhole-limpet hemocyanin, bropirimine, mycobacterial cell wall DNA extract, doxorubicin and its derivatives, thiotepa, and ►gemcitabine. The effectiveness of these agents compared with the two mentioned earlier in delaying progression and recurrence in initially treated patients is generally less and thus their use has been reserved for the salvage setting. Similarly, the addition of interferon gamma to BCG has been used to treat patients who have recurred after initial BCG therapy. Among patients with Ta, T1, or CIS, radical cystectomy is reserved for diffuse, symptomatic, recurrent high grade or unresectable papillary tumors unresponsive to intravesical therapy.

Recurrence polychronotropism (multiple reoccurrences in space and time) in noninvasive bladder tumors is uniquely elevated when compared to other organ sites. 20–70% of patients suffer disease recurrence. While in the absence of progression recurrence per se is not life threatening, this phenomenon nonetheless constitutes a cause of significant morbidity and treatment expense. While less common, the progression of noninvasive tumors to muscle invasion is associated with a marked decrease in 5-year disease-specific survival. Progression risks vary widely by stage and grade, ranging from less than 5% for low grade papillary tumors and greater than 50% for T1 lesions with associated CIS.

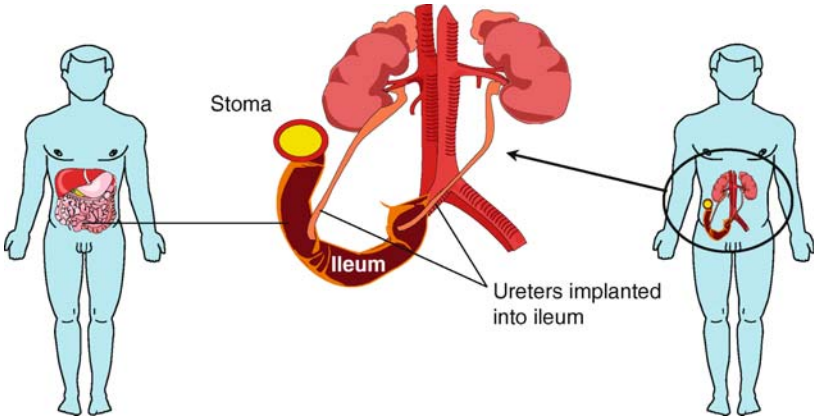
Management of Invasive and Metastatic Disease

Radical cystectomy with urinary diversion or bladder sparing protocols, using a combination of radiation and chemotherapy, are the treatments of choice for patients who have resectable muscle invasive bladder cancer. Radical cystectomy includes wide excision of bladder and prostate in male patients and typically bladder, uterus, ovaries and anterior vaginal wall in females. Perioperative mortality from cystectomy is approximately 1% in most centers. The 5-year disease-free survival is 65–80% for pT2 tumors and 37–61% for pT3 tumors. Microscopic involvement of local lymph nodes decreases 5-year survival to approximately 5–20% depending on the number and extent of nodal involvement. Pelvic recurrence rates after cystectomy range from 2 to10% and depends on the stage of the primary tumor as well as the presence of pelvic nodal involvement. In addition, an interval longer than 12 weeks between the diagnosis of muscle invasive bladder cancer and radical cystectomy is associated with decreased survival. Recently, the use of ►neoadjuvant therapy consisting of a four drug regimen MVAC (methotrexate, vinblastine, doxorubicin, and ►cisplatin) has demonstrated a survival advantage for patients with localized bladder cancer undergoing cystectomy. The use of ►adjuvant therapy has been suggested by some authors however there is limited evidence of benefit of this approach. Ongoing clinical trials are addressing this question.

Recurrence or persistence rates after bladder sparing protocols approach 50%. By careful patient selection these latter protocols can achieve comparable disease specific survival rates to those obtained by radical cystectomy. Large tumors that are only minimally resectable by TUR and those causing hydronephrosis have a significantly worse response rate with such bladder sparing protocols. Complications of radiotherapy include dysuria, frequency, or diarrhea in up to 70% of patients.

Following cystectomy, multiple options in urinary diversion exist, most of which utilize intestinal segments. An ileal conduit using a short portion of the terminal ileum to carry urine from the ureters to the anterior abdominal wall is the simplest most commonly performed diversion and the one associated with the least number of complications. Patients wear an external appliance on the stoma. Possible complications include parastomal hernia, stomal stenosis, or stricture at the ureteroileal anastomosis. A cutaneous continent urinary diversion such as the indiana (ileocecum) pouch forms an internal reservoir which can then be intermittently catheterized via a small cutaneous stoma (Fig. 4). In selected patients, such continent reservoirs can be anastomosed to the native urethra and in this setting are called “orthotopic neobladders” Such continent diversions are technically more difficult and require motivated patients to manage the postoperative care required. Ureterosigmoidostomies are now rarely performed because of difficulties with reflux, urolithiasis, electrolyte imbalance, and increased risk of adenocarcinoma of the colon.

Recent advances in laparoscopic and robotic surgery have enabled minimally invasive techniques to be applied for treatment of various benign and malignant conditions of the urinary bladder. Multiple centers worldwide are reporting their initial experience with



Bladder Cancer. Figure 4 The ileal conduit urinary diversion.

laparoscopic radical cystectomy and urinary diversion. The majority of centers perform an intracorporeal laparoscopic cystoprostatectomy and complete the urinary diversion extracorporeally through a mini-laparotomy incision.

Metastatic urothelial cell carcinoma has traditionally been treated with MVAC with a response rate of 15–35%. Complete remission is seen in approximately 13% of patients and mean survival can be improved from 8 to 12 months. However, MVAC is associated with significant toxicity, as 20% experience neutropenic fever and sepsis associated mortality approaches 3–4%. Newer agents have recently been used with a significantly lower morbidity and mortality than MVAC. Gemcitabine is an antimetabolite chemotherapeutic agent. The combination of gemcitabine and cisplatin has demonstrated similar effectiveness to that of MVAC with a better safety profile and tolerability. However, larger randomized trials are needed to conclusively prove this point.

Blast Crisis

Christine M. Morris
Cancer Genetics Research Group, University of Otago at Christchurch, Christchurch, New Zealand

Definition

Blast crisis is the aggressive and rapidly fatal terminal phase of ►BCR-ABL1 positive ►chronic myeloid leukemia (CML). This phase of the disease is characterized by accumulation of immature myeloblasts or lymphoblasts similar to those found in patients with acute leukemia.

Characteristics

Clinical Features

When left untreated, CML is a biphasic disease. Patients typically present in a relatively benign chronic phase which is characterized by symptoms of fatigue and lethargy, bleeding, moderate weight loss, an enlarged palpable spleen, and a high white blood cell (WBC) count. The increased WBC population in large part constitutes cells of the myeloid compartment, with over-representation of the granulocyte series. Within a

period of 3–5 years, the natural course of the disease is to accelerate, then to transform to an aggressive and rapidly terminal acute phase or blast crisis of 4–6 months duration. Features associated with this transformation include an increasing number of leukocytes, particularly immature blasts, in the blood and bone marrow, progressive anemia, thrombocytopenia and lack of response to therapy. In a small proportion of patients, the blast transformation may occur outside the bone marrow (extramedullary) in sites such as the lymph nodes, spleen, skin or meninges. There is no known cure for blast crisis CML. However, transition to accelerated disease may be postponed for several years or prevented by treatment early during chronic phase CML with the BCR-ABL1 tyrosine kinase inhibitor ►imatinib mesylate or allogeneic bone marrow transplant.

Blast crisis can be divided into two general forms: lymphoid and myeloid. Lymphoid blast crisis develops in about 30% of patients, and the blast cells are phenotypically similar to the common form of ►acute lymphoblastic leukemia (ALL). In rare cases, T-cell morphology has been described. Myeloid transformation is heterogeneous, where myeloblasts are the usual blast cell type, but megakaryoblasts or erythroblasts have been frequently identified. Occasional patients show blasts with myelomonocytic, monocytic or very rarely, basophilic blast differentiation. It is important to differentiate between myeloid and lymphoid blast cells, as patients in lymphoid blast crisis respond better to treatment.

Biological Basis

The precise molecular events that determine blast crisis are still poorly understood. However, the destabilized proliferation status that is imposed by expression of the BCR-ABL1 fusion gene in a self-renewing leukemic stem cell is a likely mitigating influence. Much evidence has shown that there is lineage-specific selection for, and accumulation of, cytogenetic and molecular gene rearrangements in the affected myeloid or lymphoid cell compartments. Cytogenetic evolution of the BCR-ABL1 fusion gene positive clone occurs in ~80% of cases with CML that transform to blast crisis, and a change in karyotype is considered to be a poor prognostic sign, heralding or accompanying the acute transition. Diverse karyotype abnormalities are observed, both structural and numerical, either singly or in combination, and there is marked non-random involvement of certain chromosomes. Duplication of the Ph chromosome (and therefore the BCR-ABL1 fusion gene), i(17q), +8 or +19 are observed alone or in various combinations in 60–80% of cases having additional abnormalities. Recurring molecular changes have also been identified at transformation in some cases, and include mutation of the ►TP53 and ►retinoblastoma 1 (RB1) genes, activation of ►RAS, and, in lymphoid blast crisis cells, homozygous loss of the tumor suppressor gene ►CDKN2A (p16). These and other studies suggest that BCR-ABL1 cells are genetically unstable, and preferentially accumulate non-random genomic mutations that are compatible with the BCR-ABL1 oncogene product and provide a proliferative advantage. Similar non-random accumulation of genomic aberrations is also observed in advanced leukemias of BCR-ABL1 transgenic mice. New evidence suggests that the biological characteristics of blast crisis CML will alter in the post-imatinib mesylate era.

Blood–Brain Barrier

Shalom Avraham, Tzong-Shi Lu,
Hava Karsenty Avraham
Division of Experimental Medicine, Beth Israel Deaconess Medical Center, Harvard Institutes of Medicine, Boston, MA, USA

Synonyms

Blood–brain barrier; Brain microvascular endothelial cells; Brain capillaries

Definition

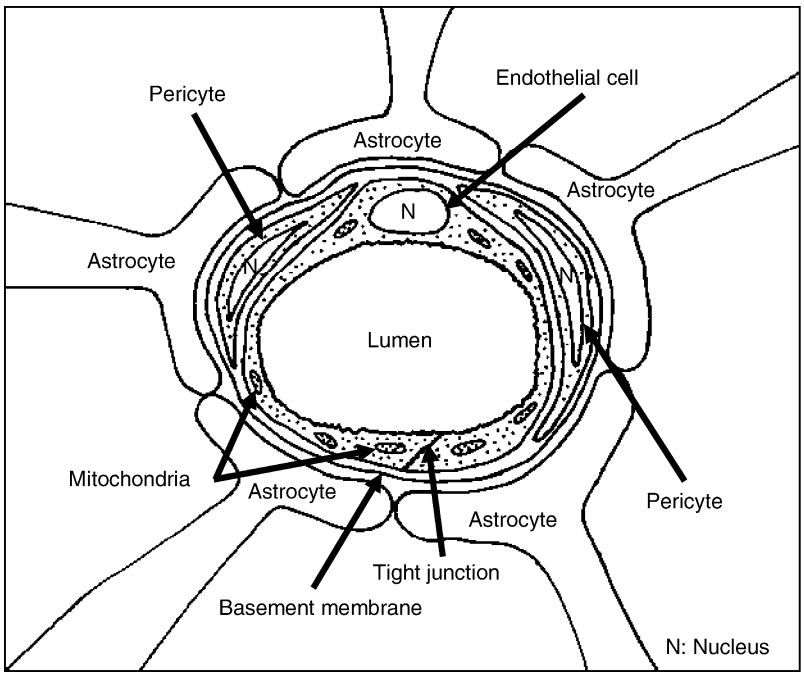
The blood–brain barrier (BBB) is formed by brain capillary endothelial cells. The BBB is composed of cerebral endothelial cells, astrocyte end-feet, and pericytes and regulates the homeostasis of the central nervous system (CNS).

Characteristics

The BBB was identified by Paul Ehrlich in 1885 [1–2]. However, the biology of the BBB, its importance in health and disease, and its anatomical definition were mostly revealed over the last 30 years. The BBB is a well-differentiated network of brain microvessels that maintains the homeostasis of the brain microenvironment. The BBB regulates the interface between the peripheral circulation and the CNS. It restricts the nonspecific flux of ions, proteins, and other substances into the CNS environment, thereby protecting neurons from harmful components of the blood, and also allows the uptake of essential molecules from the blood to the CNS. The BBB is a selective diffusion barrier at the level of the cerebral microvascular endothelium. The anatomy of the brain microvascular endothelial cells (BMEC) of the BBB, which are a major component of the BBB, are distinguished from other types of endothelial cells in the periphery by increased mitochondrial content, a lack of fenestration, minimal pinocytotic activity, and the presence of ►tight junctions (TJs). The tight junctions create a barrier in the BBB that helps to maintain brain homeostasis and provide high transendothelial electrical resistance (100–2000 ohm/cm^2), resulting in decreased paracellular permeability. BMEC are surrounded with pericytes, often divided into granular and filamentous subtypes, and astrocytic end-feet, which play an essential role in maintaining the structure of the BBB (Fig. 1). Astrocytes confer protection to the BBB against hypoxia and aglycemia.

The development of the BBB involves brain angiogenesis and BBB differentiation. First, brain endothelial cells derived from permeable vessels invade the vascular neuroectoderm and form intraneural vessels. Next, during the late embryonic and early postnatal periods, brain capillaries, in concert with astrocytes, differentiate, gradually mature, and are remodeled into the BBB, with impermeable properties.

Failure to maintain BBB integrity can have profound effects on the CNS. The disruption of the BBB may result in many brain disorders, including brain tumors. Changes in BBB function are associated with several neurological disorders, including stroke, multiple sclerosis, and Alzheimer's disease as well as inflammatory diseases such as chronic relapsing multiple sclerosis. Many of these changes have been linked to alterations in the tight junctions of the BBB.



Blood–Brain Barrier. Figure 1 Anatomical view of major components of the blood–brain barrier (BBB). The BBB is formed by endothelial cells, pericytes, basement membrane, and astrocytes. The BBB forms a highly restricted barrier that controls the exchange of materials between brain tissue and the circulatory system to maintain brain homeostasis. Tight junctions are more abundant than in other vessel systems and play a major role in regulating the permeability changes of the BBB. N: nucleus.

The BBB Junctional Complexes

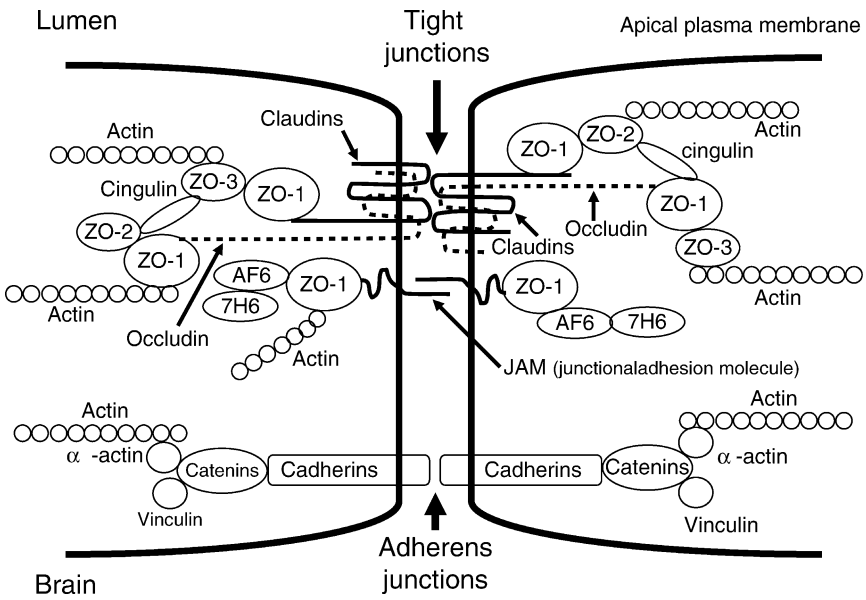
The interendothelial space of the cerebral microvasculature is characterized by the presence of a junctional complex that includes adherens junctions (AJs), tight junctions (TJs), and ►gap junctions (Fig. 2) [3]. While the gap junctions mediate intercellular communications, both AJs and TJs act to restrict permeability across the endothelium.

The TJs are dynamic structures. The physiological and pathological conditions of the BBB affect TJ organization and function in the BBB. Disruption of the TJs by disease or drugs can lead to impaired BBB function and thus compromise the CNS microenvironment. Changes in TJ expression, subcellular localization, and/or posttranslational modification or changes in the protein–protein interactions of TJs can lead to alterations in BBB permeability and integrity.

AJs are ubiquitous in the vasculature and mediate the following functions: (i) adhesion of endothelial cells to each other; (ii) contact inhibition during vascular growth and remodeling; (iii) initiation of cell polarity; and (iv) partial regulation of paracellular permeability. The components of AJs include VE-cadherin, alpha-actinin, and vinculin which all link to the actin cytoskeleton, thus stabilizing the AJ complex.

The TJs form a continuous network of parallel, interconnected, intramembrane strands of protein arranged as a series of multiple barriers. It is the TJs that confer the low paracellular permeability and the high electrical resistance. The TJs are composed of transmembrane proteins that form a primary seal linked via accessory proteins to the actin cytoskeleton. The proteins of the tight junctions include: junctional adhesion molecule (JAM-1), occludin, and the claudins.

1. JAM-1 is a 40-kDa member of the IgG superfamily and is believed to mediate the early attachment of adjacent cell membranes via homophilic interactions. JAM-1 is composed of a single membrane-spanning chain with a large extracellular domain.
2. Occludin is a 60–65-kDa protein that has four transmembrane domains with the carboxyl and amino terminals oriented to the cytoplasm and two extracellular loops which span the intercellular cleft. It is highly expressed along the cell margins in the cerebral endothelium. Occludin increases electrical resistance in TJ-containing tissues, and has multiple sites for phosphorylation on serine and threonine residues. In addition, the cytoplasmic C-terminal domain is likely involved in the association of occludin with the cytoskeleton via accessory proteins, such as the ►zonula occludens ZO-1 and ZO-2.
3. Claudins are a family of 20–24-kDa membrane proteins that includes 24 members. The assumption



Blood–Brain Barrier. Figure 2 Major tight junction and adherens junction proteins in the blood–brain barrier (BBB). Three transmembrane proteins, claudin, occludin, and junctional ►adhesion molecule (JAM), form integral tight junctions between adjacent endothelial cells. They provide the primary seal and regulate the paracellular permeability of the BBB. Other accessory proteins, such as zonula occludens (ZO-1, ZO-2, and ZO-3), AF6, 7H6, and cingulin, are involved in structure support, regulation, location recognition, and signal transduction for the tight junctions. Adherens junctions consist of one transmembrane protein, cadherin, and three structure support proteins, catenin, α-actinin, and vinculin, that link to the major cytoskeletal protein, actin.

is that claudins form the primary seal of the TJs and that occludin acts as an additional support structure. In the brain endothelium, claudin-5 is the most critical for BBB permeability.

4. In addition to the transmembrane components of the TJs, there are several accessory proteins that associate with them in the cytoplasm. These include members of the membrane-associated guanylate kinase-like (MAGUK) homolog family. MAGUK proteins are involved in the coordination and clustering of protein complexes to the cell membrane and in the establishment of specialized domains within the membrane. Three MAGUK proteins have been identified at the TJs: ZO-1, ZO-2, and ZO-3. ZO-1, which is abundantly expressed in BMEC, is a 220-kDa protein that links transmembrane proteins of the TJs to the actin cytoskeleton. This interaction is critical to the stability and function of the TJs and is important for the integrity and permeability of the BBB.
5. Additional accessory proteins of the BBB include cingulin, AF6, and 7H6.

Permeability Properties of the BBB

The BBB significantly impedes entry from the blood into the brain of virtually all molecules, except those that are small and lipophilic. However, there are sets of small and large hydrophilic molecules that can enter the brain, and they do so by active transport. One of the important transporters is P-glycoprotein (Pgp), which is present in relatively high concentrations in brain capillaries and is also part of the barrier. Pgp is associated with multidrug resistance (MDR) in numerous tumors. The discovery of Pgp on the BBB has contributed to an understanding of the penetration of various drugs into the brain.

Net fluid influx and brain extracellular fluid homeostasis are regulated by hormones produced in the CNS that affect blood–brain transport. Transcytosis of insulin and transferrin has been well-defined and these pathways have been utilized for targeted delivery to the brain and brain tumors. The presence of active efflux transporters in the BBB prevents many systemically administered drugs from entering the brain and is a major obstacle in designing drugs to treat neurological disorders.

In Vitro BBB Models

Research on BBB functionality has been facilitated by the availability of in vitro BBB culture systems [4]. Culturing of the in vitro BBB involves the isolation of capillaries and culture of BMEC alone or in combination with astrocytes or astrocyte-conditioned medium.

BBB in Disease

The BBB is sensitive to the pharmacodynamic effects of compounds and disease mediators that may result in

changes in BBB integrity and function [5]. Alterations of the barrier tight junctions are a hallmark of many CNS pathologies, including tumor, stroke, HIV, encephalitis, and bacterial meningitis. BBB breakdown or TJ protein rearrangement seems to be involved in both the direct and indirect effects of stress responses and inflammatory mediators. Traumatic brain injury leads to an upregulation of ►vascular endothelial growth factor (VEGF) and the VEGF receptors, VEGFR-1 and VEGFR-2. Although a compromised BBB has been reported under some pathologic conditions, the precise role of a disrupted BBB in the pathogenesis of neurological diseases is not well-defined.

In addition, the BBB presents a major obstacle to the treatment of malignant brain tumors and other CNS diseases. Delivery of therapeutics to the CNS is critical for the successful treatment of brain tumors and other neurological diseases. In this context, the current view is that the BBB, BMEC along with glia cells, pericytes, and neurons, should be viewed as a neurovascular unit for drug delivery.

Future studies should be aimed at understanding BBB dysfunction and the factors that regulate its recovery as well as at designing new approaches for the prevention and treatment of neurological diseases including brain tumors.

Blood Stasis due to Vital Energy Stagnancy

Definition

Is a pathogenesis and syndrome in Chinese medicine. Various pathogenic factors such as emotional depression, unhealthy diet, infection, and injury obstruct the circulation of vital energy and result in vital energy stagnancy. Chronic or severe stagnation of vital energy may lead to blood stasis, with syndrome characterized by distention, pain, ecchymosis, and even mass formation. The principle of its treatment is to supplement vital energy, promote blood circulation, and resolve blood stasis.

Bloom Syndrome

Mounira Amor-Guéret
Institut Curie – UMR 2027 CNRS, Orsay Cedex, France

Synonyms

Bloom-Torre-Mackacek syndrome; Congenital telangiectatic erythema

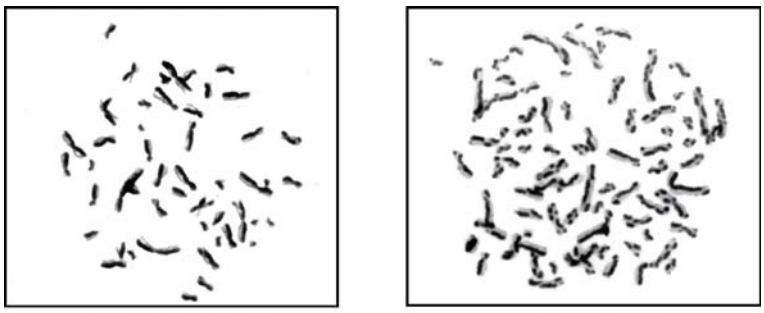
Definition

Bloom syndrome (BS) is a rare human autosomal recessive disorder that belongs to the group of "►chromosomal breakage syndromes," and is characterized by marked ►chromosomal instability associated with a greatly increased predisposition to a wide range of ►cancers commonly affecting the general population. BS was first described by David Bloom in 1954 as "congenital telangiectatic erythema resembling lupus erythematosus in dwarfs." The predominant and constant clinical feature of BS is proportionate pre- and postnatal growth retardation. Additional clinical features are described below. The hallmark of BS cells is an approximately tenfold increase in the rate of ►sister chromatid exchanges (SCEs) compared to normal cells. This increased level of SCE is the only objective criteria for BS diagnosis (Fig. 1). SCEs frequency averages 0.24 per chromosome in normal cells and 2.12 per chromosome in BS cells.

Characteristics

Clinical Description

A surveillance program, the Bloom Syndrome Registry, was established in 1960 by James German and Eberhard Passarge, in which the follow-up of 168 BS patients (93 males, 75 females) was reported until 1991. From the data in this Registry, it appears that the two constant clinical features associated with BS are growth retardation starting *in utero* and persisting throughout life with normal proportioning and accompanied by



Bloom Syndrome. Figure 1 Increased sister chromatid exchange in Bloom Syndrome cells. The sister chromatids in the images are differentially labelled so that regions of chromatid exchange can be seen as regions of light and dark staining. Little chromatid exchange is seen in normal cell metaphase (left panel), whereas most of the chromosomes in a Bloom Syndrome cell metaphase (right panel) show chromatid exchange.

dolichocephaly, and predisposition to all types of cancers. The mean adult height for men is 147.5 cm (range 130–162), and for women is 138.6 cm (range 122–151). Eleven additional clinical features that are not constant and that vary in severity among BS patients were also reported by James German: (i) a "bird-like" facies with a narrow face and prominent nose, and malar and mandibular hypoplasia, (ii) sun-sensitive erythema affecting the butterfly area of the face (similar to that caused by lupus erythematosis), and sometimes affecting the dorsa of the hands and forearms, (iii) spots of hyper- and hypopigmentation of the skin ("café au lait" spots), (iv) a high-pitched voice (Mickey Mouse voice), (v) a variable degree of "vomiting and diarrhea" during infancy, (vi) diabetes mellitus (diagnosed at a mean age of 24.9 years in 20 of the 168 BS patients in the Registry), (vii) small testes accompanied by a total failure of spermatogenesis in men and early cessation of menstruation accompanied by reduced fertility in women, (viii) immunodeficiency manifested by recurrent respiratory tract infections complicated by otitis media and pneumonia (life-threatening ear and lung infections are common), and manifested by the gastrointestinal problems mentioned in (v), (ix) some minor anatomic abnormalities such as obstructing anomalies of the urethra, which were of major clinical importance in several cases, (x) average intelligence (sometimes mental deficiency), (xi) clinical features that occurred in only one or a few BS patients and that are not to be considered part of BS itself, such as congenital thrombocytopenia, mild anemia, asthma, or psoriatic arthritis.

The 100 cancers that arose in 71 of the 168 BS patients recorded in the Bloom Syndrome Registry have been reported, and the distribution of the sites and types of these cancers is similar to that found in the general population. The main conclusions of this report are that nearly half of the registered BS (71/168) patients have had at least one cancer by the mean age of 24.7, and of those patients, 40% have had more than one primary cancer (29/71). ►Acute leukemias (21% of cancers), lymphomas (23%) and rare tumors (5% including ►medulloblastoma, ►Wilms tumor, osteogenic sarcoma) predominate in the first two decades of life, whereas carcinomas (51%) start to appear late in the second decade of life.

BLM-Deficient Cells

BS cells display an increase in chromosome breaks, a spontaneous ►mutation rate ten times higher than that in normal cells, an increased frequency of spontaneous ►symmetric quadriradial interchanges and sister chromatid exchanges, and increased ►loss of heterozygosity (LOH). BS cells also display replication abnormalities, including retarded replication-fork elongation and abnormal replication intermediates, and a general delay in the timing of replication associated with an increased level of constitutive ►DNA damage in mid- to late-S-phase. BS cells bud out large number of micronuclei during S phase and have constitutively high levels of RAD51-containing nuclear foci. Chronic overproduction of the superoxide-free radical O_2^- (►Reactive oxygen species) has also been reported in BS cells.

BLM Gene

BS arises through mutations in both copies of the BLM gene, which is located on chromosome 15 at 15q26.1. Nonsense or frameshift mutations leading to a premature termination codon, and missense mutations have been found in BLM gene from BS patients. One particular BLM gene mutation corresponding to a 6-bp deletion and a 7-bp insertion at nucleotide position 2207, referred to as the blm^{Ash} mutation, is homozygous in nearly all BS patients with Ashkenazi Jewish ancestry and is due to a founder effect. Screening for

BLM gene mutations can be done by analyzing the 21 coding exons (4,437 bp total length).

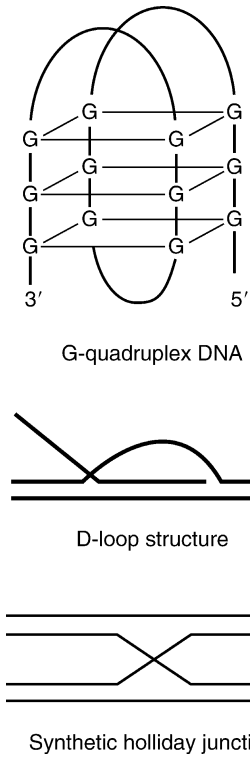
Frequency

BS affects all human populations, and its reported frequency is 1 in 10,836,000 in Japan, 1 in 3,331,000 in the United States, 1 in 5,590,000 in West Germany, and 1 in 2,395,000 in the Netherlands. In the Ashkenazi Jewish population, the frequency of BS is ~1 in 48,000. This is due to a founder effect, and ~1% of the Ashkenazi Jewish population are heterozygous carriers for the blm^{Ash} mutation.

BLM Protein

The BLM gene codes for the BLM protein, which is 1417 amino acids in length with a predicted molecular mass of 159 kDa, and it belongs to the DExH box-containing ►RecQ helicase subfamily. BLM displays an ATP- and Mg^{2+} dependent 3′-5′-DNA helicase activity that separates the complementary strands of DNA in a 3′-5′ direction. However, the exact function of BLM is still unclear. BLM protein accumulates in S and ►G2/M phases of the cell cycle, and localizes in two distinct nuclear structures, PML nuclear bodies (also called ND10) and the nucleolus. The preferred substrates for BLM are ►G-quadruplex DNA (G4 DNA), ►D-loop structures and ►X-junctions (Fig. 2). BLM promotes branch migration of RecA-generated Holliday junctions and effects, with topoisomerase IIIα, the resolution of a recombination intermediate containing a double Holliday junction with no flanking sequence exchanges (►Reverse branch migration activity). BLM also catalyzes the annealing of complementary single-stranded DNA molecules (DNA strand annealing activity). BLM interacts with several proteins involved in the maintenance of genome integrity. It participates in a super complex of ►BRCA1-associated proteins called BASC (BRCA1-associated genome surveillance complex) which includes BRCA1 (mutated in some familial breast cancers) ►ATM defective in Ataxia Telangectasia, AT, NBS1 (defective in ►Nijmegen Breakage syndrome) and MRE11 (defective in ataxia-telangiectasia-like disorder), MLH1, MSH2 and MSH6 (involved in Human Non-Polyposis Colorectal Cancer, HNPCC syndrome or ►Lynch syndrome), and several other proteins known to be involved in replicational and/or post-replicational ►repair processes. BLM also participates in a complex called BRAFT (BLM, RPA, FA, Topoisomerase IIIα), which contains five of the ►Fanconi anemia (FA) complementation group proteins (FANCA, FANCG, FANCC, FANCE and FANCF), RPA and topoisomerase IIIα (which are also known to interact independently with BLM), and a newly identified factor called BLAP75. Among the other proteins known to co-localize and/or to interact physically and/or functionally with BLM in undamaged cells and/or in cells submitted to ►genotoxic stresses, are the tumor suppressor protein ►p53, WRN protein (a RecQ helicase defective in the Werner syndrome), RAD51 (a key protein in ►homologous recombination), RAD51L3 (a RAD51 paralog), ATR (ataxia telangiectasia and rad^{3+} related kinase), TRF2 (a double-stranded telomeric DNA binding protein), Mus81 (a DNA-structure specific endonuclease), γ-H2AX (►GammaH2AX; histone H2AX phosphorylated on Ser 139 in response to DNA double-strand breaks), hp150 (the largest subunit of chromatin assembly factor 1, CAF1), FEN1, (flap endonuclease 1, involved in the removal of RNA primers of Okazaki fragments), FANCD2 (Fanconi anemia complementation group D2 protein), and the Chk1 kinase (a serine/threonine protein kinase that is a key mediator in DNA damage-induced cell cycle checkpoints).

Altogether, these data support a major role for BLM in maintaining genomic stability during DNA replication, homologous recombination and repair. Several models for the role of BLM have been proposed and suggest that BLM acts as a "roadblock" remover during DNA replication by disrupting complex structures such



Bloom Syndrome. Figure 2 Preferred substrates of the BLM helicase. The recombinant BLM protein efficiently unwinds DNA structures such as G-quadruplex, D-loop and synthetic holiday junctions.

as G-quadruplexes or DNA hairpins. BLM may also restart replication after the fork stalls and/or resolve recombination intermediates during DNA double-strand break repair through its ►reverse branch migration and DNA strand annealing activities.

Mouse Models

Among the five BS knockout alleles that have been generated, four led to embryonic lethality when the targeted allele was homozygous, and only one resulted in viable "BS" mice through a complex rearrangement of the targeted region. By 20 months of age, 29% of these Blm-deficient mice had developed a wide spectrum of cancer, similar to human BS patients.

Genetic Counseling

Due to the autosomal recessive transmission of BS, sibs of two heterozygous carriers are at 25% risk of having BS and at 50% risk of being carriers. When the risk of BS transmission has been well evaluated, prenatal diagnosis can be proposed (SCE analysis of fetal cells or detection of a specific *BLM* gene mutation when causative mutations are identified).

Therapy

There is no curative treatment for BS. However, a physician should carefully follow BS patients to ensure early cancer diagnosis.

Definition

Metastasis describes the spread of cancer from its site of origin (the "primary site") to another location in the body (the "secondary site"). Bone is the most frequent site affected by metastatic cancer. While any type of cancer can spread to bone, metastatic bone disease is most commonly associated with cancers whose primary origin is the breast, prostate or lung. Although less common, bone metastases are also associated with cancers arising in the thyroid, kidney stomach, uterus, colon, bladder and rectum (Table 1). Metastasis of cancer to bone often results in significant skeletal morbidity which manifests as severe bone pain, pathologic fractures, spinal cord compression and life threatening ►hypercalcemia.

Bone Loss, Cancer Mediated. Table 1 Incidence of primary tumors which metastasis to bone as a percentage of all bone metastases

Primary tumor	As a percentage of all bone metastases
Breast	35
Prostate	30
Lung	10
Kidney	5
Thyroid	2
Others	18

Characteristics

Types of Bone Metastasis

Bone metastases are classified as osteolytic, osteoblastic, or mixed, based on their radiographic appearance. Patients can present with either osteolytic or ►osteoblastic metastasis, or mixed lesions containing both elements. Bone metastases from prostate cancer are predominantly osteoblastic, whereas bone lesions from breast cancer can be osteoblastic, osteolytic, or mixed. Only in multiple myeloma do purely lytic bone lesions develop. Regardless of the mechanisms involved in the formation of osteolytic or osteoblastic metastases, the end result is a change to the bone architecture which predisposes the patient to a variety of skeletal co-morbidities.

Bone Physiology: Control of Normal Bone Remodeling

Healthy bone is a dynamic organ which is constantly rejuvenated by the coordinated activity of two cells types; namely the bone resorbing ►osteoclasts and the bone forming ►osteoblasts. Osteoblasts are responsible for the synthesis of collagen and non-collagenous bone proteins which are involved in the mineralization of the bone matrix. Normal bone remodeling (or turnover) is initiated by osteoclasts which degrade the bone matrix, creating cavities or lacunae. Once resorption is complete, osteoblasts synthesize a new osteoid matrix which is then mineralized. Under normal physiological conditions, the amount of newly formed calcified matrix is equal to the amount of bone resorbed by the osteoclast, thereby maintaining bone mass and skeletal integrity.

The bone resorbing osteoclasts are derived from hematopoietic stem cells. Osteoclast formation and activity is regulated by systemic hormones and growth factors which are synthesized in the bone microenvironment, including macrophage colony stimulating factor (M-CSF) and *r*eceptor *a*ctivator of *n*uclear *f*actor κB (RANK) ligand (RANKL). RANKL, a member of the tumor necrosis factor family, is expressed on the surface of stromal cells and osteoblasts. RANKL binds the RANK receptor on the osteoclast precursor cell surface and induces the formation of osteoclasts by signaling through the nuclear factor κB and Jun N-terminal kinase pathways. A number of osteotropic factors, such as parathyroid hormone, 1,25-dihydroxyvitamin D3, and prostaglandins, induce the formation of osteoclasts by increasing the expression of RANKL on marrow stromal cells and osteoblasts rather than by acting directly on osteoclast precursors. The activities of RANKL are further regulated by the decoy receptor, ►osteoprotegerin (OPG) which is synthesized by numerous cells including

marrow stromal cells and osteoblasts. The binding of OPG to RANKL precludes RANKL from binding to RANK, thereby inhibiting the differentiation and activity of osteoclasts. The ratio of RANKL to OPG will ultimately determine whether osteoclast formation will occur. Osteoclasts resorb bone by forming a tight seal between the ruffled border of the plasma membrane and the bone surface and secreting proteases and acid which dissolves the bone matrix.

Bone-forming osteoblasts are derived from mesenchymal stem cells. The transcription factor, Runx-2, (also termed core-binding factor α 1; CBFA1), is critical for the differentiation of osteoblasts by activating the expression of numerous genes which "drive" osteoblast differentiation. Many factors can enhance the growth and differentiation of osteoblasts, including platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), transforming growth factor (TGF)-β and the bone morphogenetic proteins (BMP).

Bone is a Unique Environment for Metastasis

In 1889, Stephan Paget proffered the "seed-and-soil hypothesis" to explain why primary cancer cells selectively colonize distant organs. Paget suggested that cancer metastasis is reliant upon multiple interactions ("cross-talk") between cancer cells (the "seeds") and certain organ environments ("the soil") which provide a favorable environment for tumor localization and growth. To this day, this hypothesis still holds true. Metastasis to bone is a complex multi-step event which involves a bidirectional interaction of the tumor cells with cellular elements in three different microenvironments: (i) the site of primary tumor, (ii) the circulation and (iii) the bone microenvironment. The metastatic tumor cells must first break away from the primary tumor and move into the circulation and reach various skeletal sites, where they colonize, proliferate, and induce metastatic lesions. The preferential skeletal localization of tumor cells is attributed to the biologic and molecular characteristics of tumor cells as well as that of the bone microenvironment. For example, while unable to confer a bone metastatic potential individually, over-expression of an array of proteins, including the chemokine receptor, (CXCR)-4, interleukin (IL)-11, connective tissue growth factor (CTGF), and matrix metalloproteinase, (MMP)-1, along with the osteopontin, enhance the metastatic potential of breast cancer cells to bone. These proteins participate in one or more of the steps involved in the homing, invasion, angiogenesis, and proliferation of tumor cells in the bone microenvironment.

The multi-focal nature and predilection of tumor cells for the hematopoietic marrow sites in the proximal long bones and axial skeleton (vertebrae, pelvis, ribs, and cranium) can be attributed to the continuous and dynamic turnover of the bone matrix and bone marrow which provides a fertile ground for tumor cells to utilize resources (cells, growth factors, cytokines, and receptors) for their homing and growth. The anatomical and molecular characteristics of bone also make it a favorable site for metastasis, with the slow-moving but copious metaphyseal blood flow assisting intimate interactions between endothelium and tumor cells, a process necessary for the initial colonization of tumor cells within the bone marrow. In addition, various growth factors and cytokines in the bone marrow such as endothelin (ET)-1, basic fibroblast growth factor (bFGF), TGF-β, IL-6 and IL-8 serve as paracrine regulators of the initial growth of metastatic tumor cells. The interaction of chemotactic extracellular matrix and stromal cell expressed proteins (stromal cell derived factor-1, vascular cell adhesion molecule-1, fibronectin, type I collagen, type IV collagen, vitronectin, osteopontin, osteocalcin, bone sialoprotein and osteonectin) with ligands that are over-expressed on tumor cells (integrins α4β1 and α5β1, CTGF and CXCR4) promote tumor colonization within the bone marrow. Moreover, the bone matrix is a large repository of latent growth factors such as insulin-like growth factor (IGF), TGF-β, BMPs, PDGF and vascular endothelial growth factor (VEGF), which are released during the formation of both osteolytic and osteoblastic lesions and serve to stimulate the "vicious cycle" of tumor growth and progression of bone lesions.

The Vicious Cycle of Osteolytic Metastasis

The most common manifestation of bone metastasis is osteolysis (osteolytic metastasis). Osteolytic bone metastases are common in solid tumour metastases of lung, renal, breast cancer and the hematological malignancy, multiple myeloma. In osteolytic metastases, skeletal destruction is mediated primarily by osteoclasts rather than the tumor cells. However, the factors responsible for the activation of osteoclasts vary depending on the tumor type. The pathogenesis and progression of osteolytic metastases are often the result of a complex "vicious cycle" which involves the interactions between tumor cells, bone cells (osteoclasts and osteoblasts), and the bone matrix. The tumor cells secrete various soluble factors including IL-6, IL-8, IL-11, TNF-α, M-CSF, prostaglandin E2 (PGE2) and parathyroid related protein (PTHrP) that directly or indirectly promote osteoclast differentiation, proliferation, and activation leading to increased osteolysis. Furthermore, the process of bone resorption itself results in the release of growth factors, including TGF-β, IGF, bFGF and BMP, from the bone matrix which support the growth and survival of the tumor cells. In turn, the growing tumor secretes more pro-osteolytic factors, which results in further osteolysis and perpetuation of the vicious cycle.

The Vicious Cycle of Osteoblastic Metastases

Osteoblastic bone metastases are characterized by an increase in woven bone formation which radiographically appear as sclerotic lesions, and are most commonly seen in patients with prostate cancer. Tumor cells forming osteoblastic metastases secrete numerous pro-osteoblastic factors that drive bone remodeling toward a predominant bone-forming state. Furthermore, activated osteoblasts secrete numerous growth factors during woven bone formation, including TGF-β, BMP and VEGF, which further stimulate tumor survival and growth and perpetuate the vicious cycle. In addition, the Wnt (wingless int) pathway, the ET axis, and the BMP pathway have emerged as key regulators in the establishment of osteoblastic skeletal metastasis. Wnt proteins are soluble glycoproteins that promote embryonic and postnatal bone formation by binding to a membrane receptor complex comprised of frizzled (FZD) G-protein-coupled receptor and a low-density lipoprotein receptor-related protein. The formation of this ligand-receptor complex initiates a number of intracellular signaling cascades that modulate differentiation, survival, and activity of the osteoblasts. ET-1 promotes osteogenic differentiation, stimulates bone matrix formation, and inhibits osteoclast formation and motility. BMPs (BMP-2, BMP-6 and BMP-7) play a central role in skeletal development and postnatal bone repair, and are implicated in metastatic bone formation due to their osteoinductive properties.

Osteolytic Multiple Myeloma

Multiple myeloma is a hematological malignancy characterized by the "homing" of a clonal population of neoplastic plasma cells from secondary lymphoid organs to sites within the bone marrow, close to the bone surface. Here, multiple myeloma plasma cells recruit and activate the bone resorbing activities of osteclasts. Lytic lesions are observed in more than 80% of patients afflicted with multiple myeloma. Several osteoclastogenic factors have been implicated in the increased activity of osteoclasts in myeloma, including macrophage inflammatory protein (MIP)-1α, SDF-1 and RANKL. RANKL is produced by both the myeloma cells and marrow stromal cells in response to factors secreted by the myeloma cells themselves. In the bone microenvironment of myeloma patients, RANKL production is increased and ►osteoprotegerin is markedly decreased. MIP-1α is a potent inducer of osteoclast formation and enhances both RANKL- and IL-6–stimulated osteoclast formation. MIP-1α also stimulates integrin-mediated adhesion of myeloma cells to stromal cells resulting in an increased production of IL-6, RANKL and MIP-1α, which in turn further stimulates bone destruction. MIP-1α levels in myeloma patient serum correlate strongly with the presence of osteolytic lesions. Similarly, levels of the CXC chemokine, SDF-1, are elevated in myeloma patients which exhibit radiographically detectable bone lesions. While incapable of stimulating osteoclast formation in the absence of RANKL, myeloma cell-derived SDF-1 serves to hyper-activate the resorptive activity of osteoclasts leading to bone loss.

Bone lesions in myeloma are purely lytic and are not accompanied by an osteoblastic response. While the basis for the lack of an osteoblastic response in myeloma remains to be determined, recent studies suggest roles for the soluble Wnt-signaling antagonists, dickkopf 1 (DKK1) and soluble frizzled related protein, sFRP-2 (Fig. 1). High serum levels of soluble DKK1 and sFRP2 have been correlated with myeloma-induced focal bone lesions.

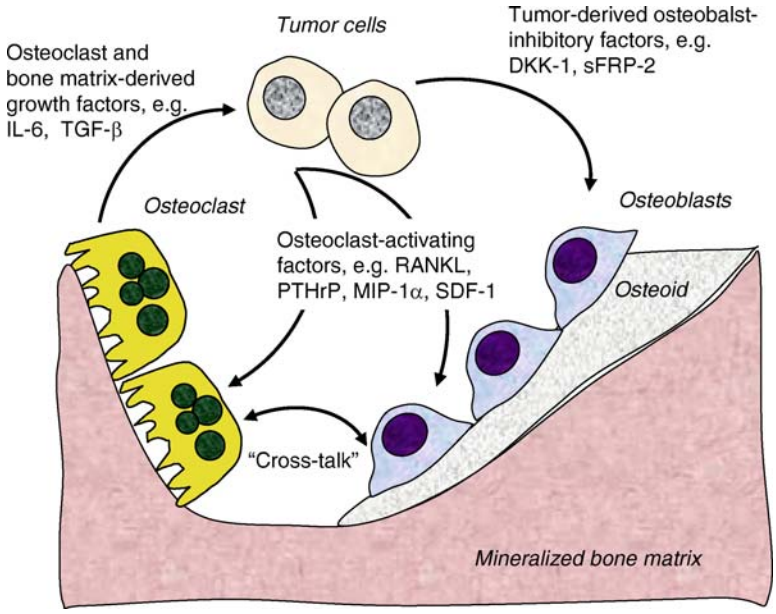
Myeloma tumor cells secrete numerous factors (RANKL, MIP-1a, SDF-1 and PTHrP) which directly or indirectly (via the osteoblast) stimulate osteoclast formation and activity. Myeloma tumor cells also express factors which suppress normal osteoblast function, including the Wnt signaling pathway antagonists DKK-1 and sFRP-1.

Osteolytic Metastasis from Breast Cancer

Breast cancer commonly metastasizes to and destroys bone, causing pain and fracture, and the median survival of patients with bone metastases is only 19–25 months. Almost one third of patients present with radiographically detectable mixed osteoblastic and osteolytic lesions. Tumor cells in breast cancer produce factors that directly or indirectly induce the formation of osteoclasts, including parathyroid hormone-related protein (PTHrP), interleukin (IL)-6, IL-8, IL-11, M-CSF, PGE-2, TNF-α, and RANKL. The resultant osteoclastic bone resorption releases growth factors from the bone matrix which further stimulate tumor growth and bone destruction. In particular, PTHrP functions by inducing the expression of RANKL on marrow stromal cells which further stimulates osteoclast formation and activity. The resultant osteoclastic resorption releases growth factors such as TGF-β from the bone matrix, with TGF-β in turn stimulating PTHrP production by tumor cells, and perpetuating the vicious cycle of breast-cancer metastases.

Osteoblastic Metastasis in Prostate Cancer

Prostate cancer is the most prevalent non-dermatologic cancer in males, and the clinical course of patients with metastatic prostate cancer can be relatively long with a median survival measured in years not months. At presentation, 10% of patients have bone metastases, and almost all patients who die of prostate cancer have skeletal involvement. Based on radiographic



Bone Loss, Cancer Mediated. Figure 1 The formation of lytic bone disease in myeloma.

appearance, prostate metastases are classified as osteoblastic, however studies have show that both bone resorption and bone formation are dysregulated in this disease. Although the mechanisms and factors involved in osteoblastic metastasis are unknown, a number of factors have been implicated, including ET-1, PDGF, urokinase-type plasminogen activator (u-PA), and prostate specific antigen (PSA). ET-1 stimulates the formation of bone and the proliferation of osteoblasts in bone organ cultures, and serum endothelin-1 levels are increased in patients with osteoblastic prostate metastases. Overproduction of u-PA by prostate-cancer cells imparts an enhanced capacity to initiate osteoblastic metastases. Prostate-cancer cells also release PSA, a kallikrein serine protease, which can cleave and inactivate parathyroid hormone–related peptide which can block tumor induced bone resorption. It may also activate osteoblastic growth factors released in the bone microenvironment during the development of bone metastases, such as IGF-I and -II or TGF-β. These data suggest that a vicious cycle may also be responsible for osteoblastic metastasis. While markers of bone resorption are also increased in prostate cancer patients with metastasis, there is usually no histologic evidence of increased numbers of osteoclasts. Studies show that blocking osteoclastic bone resorption in patients with prostate cancer decreases the number of skeletal-related events suggesting that bone resorption may precede bone formation in the development of osteoblastic metastases.

Bone Marrow

Definition

Is the site of hematopoiesis, the generation of the cellular elements of blood, including red blood cells, monocytes, polymorphonuclear leukocytes, and platelets. The bone marrow is also the site of B-cell development in mammals and the source of stem cells that give rise to T cells upon migration to the thymus. Thus, bone marrow transplantation can restore all the cellular elements of the blood, including the cells required for adaptive immunity.

Bone Marrow-Derived Mesenchymal Stem Cells (MSC)

Definition

Synonym marrow stromal cells; these bone marrow fibroblasts act as a supportive framework within bone marrow and support hematopoiesis (i.e., blood cell development). MSC are also an adult stem cell population. The have the ability to self-renew, and they can give rise to osteoblasts (bone), adipocytes (fat), and cartilage.

Bone Tropism

Alessandro Fatatis
Department of Pharmacology and Physiology, Drexel University College of Medicine, Philadelphia, PA, USA

Synonyms

Skeletal secondary tumors; Bone-seeking malignant phenotypes

Definition

Bone tropism is the propensity of certain tumors to spread from the organ(s) in which they initially originated and target preferentially the skeleton, in which they may eventually grow into secondary tumors or ►metastasis.

Characteristics

Solid tumors at their initial stage present unique challenges for the selection of the appropriate treatment. Several considerations come into play, including the feasibility of their surgical ablation, the age of the patient and the histological grade of the neoplasia, among others. However, the risk of metastatic spread is indeed one of the most critical factors in deciding the therapeutic strategy to adopt. It is also widely recognized that the detection of secondary tumors at

the time of the initial diagnosis poses additional and most often prohibitive hurdles to a positive clinical outcome. This is because after secondary tumors become clinically evident there is no turning back and, despite slight individual differences in disease progression, both the prognosis and the quality of life dramatically worsen.

Although primitive tumors may be rapidly lethal or are defeated before a significant metastatic disease delineates itself, a defined group of solid tumors including prostate and breast adenocarcinomas consistently spread to the skeleton. Major complications caused by the growth of cancer cells in the skeleton include pathological fractures, spinal cord compression and an overall organ impairment affecting both mielogenic and immunological properties of the bone marrow. For several forms of neoplasia, skeletal metastases are the sole site of spread in ≥80% of patients; their distribution overlaps that of bone marrow in the adult and they represent the major cause of death. In fact, patients may succumb to the metastatic disease years after their primitive tumors were surgically removed.

Bone secondary tumors are extremely difficult to treat; since surgical procedures are commonly limited to mere ►palliative therapy, the treatments of choice are either ►chemoradiotherapy or immunotherapy. However, cancer cells located in the bone marrow benefit from the "sanctuary" characteristics of this tissue. Small foci of cancer cells can grow almost undisturbed because of the restricted access to the site combined to the high availability of nutrients and growth factors, which are constantly produced locally or delivered by the blood circulation.

There are several postulated mechanisms that could explain the bone tropism of cancer cells:

Blood Circulation Patterns

The anatomical description of the Paravertebral Venous Plexus, made by Batson in 1940, led to postulate that retrograde blood flow would deliver cells from tumors such as prostate and colon carcinomas preferentially to the spine, thereby determining the occurrence of secondary tumors at the vertebral level. Based on this paradigm, migrating cancer cells would not specifically arrest to the vertebrae but rather be passively forced by blood-flow patterns to settle in the first capillary bed they encounter. Their lodging into the bone would then occur by size restriction arrest, with capillaries progressively smaller in diameter trapping the traveling cancer cells.

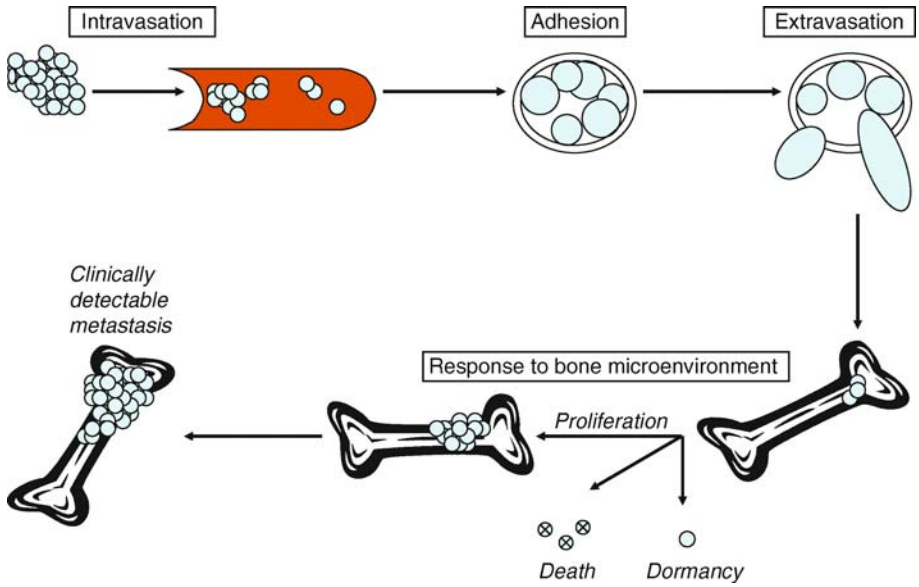
The role of blood flow and circulatory patterns in hematogenous skeletal metastases is obviously fundamental; however, a large body of evidence discounts mechanical entrapment as the exclusive factor and points toward additional mechanisms underlining the bone tropism of tumors. For example, certain tumors, such as prostate cancer, affect the skeleton both at the pelvic and the upper torso regions, an unlikely scenario for mechanical trapping by simple blood-flow distribution; in addition, several studies have shown that cancer cells can bypass more than one capillary bed and lodge in selected distant organs.

Cellular Adhesive Interactions

When cancer cells reach the marrow of different bones through blood circulation, they encounter the vascular wall of the bone sinusoids and interact with the endothelial cells which are lining it. The times required for adhesion of cancer cells to the endothelium by simple vicinity of cellular surfaces are in fact considerably in excess of their luminal transit times, suggesting the formation of adhesive bridges. Therefore, unique characteristics of bone marrow endothelial cells could promote the specific adhesion of cancer cells (Fig. 1).

This scenario is compatible with the trafficking of immuno-competent cells and their adhesion to different types of endothelia, including that of bone marrow sinusoids. For instance, the recruitment of leukocytes into sites of inflammation requires the sequential execution of events such as *capture* and subsequent firm *adhesion* to endothelial cells. The capture of leukocytes from the lumen of blood vessels involves the intervention of specific ►cell adhesion molecules (CAMs) exposed on the surface of leukocytes and endothelial cells. These molecules – including ►integrins and ►selectins among others – need to establish firm interactions with their respective substrates, such as ►fibronectin, to resist the shear force exerted by the blood flow while arresting the cells traveling through the lumen of the vessel. Similar mechanisms are in place to ensure the trafficking of hematopoietic progenitor cells from the bone marrow to the peripheral blood and vice versa.

It has been proposed that adhesive mechanisms involving CAMs could be usurped by cancer cells, allowing them to colonize the skeleton, among other organs. The activation of selected CAMs can be induced by molecules involved in the inflammatory response, named chemotactic cytokines or ►chemokines, through their interaction with specific receptors located on the surface of leukocytes and other cell types. During the last few years, a large number of studies have shown that different types of cancer cells express receptors for chemokines that are produced in organs which are common sites of metastasis. For example, breast cancer cells express the ►CXCR4 receptor for the chemokine CXCL12/SDF-1, which is detected in the bone marrow. Similarly, prostate cancer cells express the ►CX3CR1 receptor for the chemokine ►CX3CL1/fractalkine, which is constitutively anchored to the surface of the bone marrow endothelium, whereas



Bone Tropism. Figure 1 Bone tropism. Schematic representation of the sequential steps of skeletal metastasis that can be determinant in conferring bone tropism to cancer cells (Artwork by Whitney Jamieson).

other endothelia need inflammatory conditions to express it. Comparable chemokine/receptor interactions have been reported for different types of cancer targeting the skeleton, suggesting that chemokine-induced adhesive interactions might promote the preferential, albeit not exclusive, arrest of cancer cells into a specific tissue and indeed represent a crucial determinant of bone tropism.

Chemoattraction of Cancer Cells

Cancer cells can proliferate and grow within the blood vessels at their primary site of attachment to the endothelium, as shown by studies conducted by Dr. Muschel and co-workers, among others. However, particularly for skeletal metastases, simply adhering to the bone marrow endothelial wall may not suffice to invade the bone. Similarly to leukocytes, cancer cells need to migrate from the luminal side of the endothelial cells into the surrounding bone marrow stroma. This process, named ►extravasation, is comparable to the diapedesis observed for leukocytes and can be similarly regulated by chemokines. Thus, the mutual interactions between chemokines present in the bone tissue and their receptors expressed by bone-seeking cancer cells could exert an attractive force and induce migratory events involved in the skeletal secondary location of specific tumors. In support of this hypothesis, numerous studies have found CXCL12/SDF-1, CX3CL1/fractalkine and other chemokines being produced at high levels by the cells of the bone marrow.

However, bone marrow-produced chemokines are also abundant in other organs – for example the optic nerve and cardiac muscle for CXCL12/SDF-1 – which are seldom sites of metastasis from breast cancer cells, which express the compatible receptor CXCR4. Therefore, bone tropism likely depends on multiple factors; the idea of favorable conditions for cancer cell growth offered only by selected organs is epitomized by the ►seed and soil hypothesis.

Tissue Conditions Supporting the Growth of Cancer Cells

Once cancer cells have migrated into a foreign tissue, they will need to find favorable conditions to survive and proliferate. The seed and soil hypothesis – originally conceived by the English surgeon Stephen Paget in 1889 – emphasizes the importance of appropriate local trophic factors (the soil) in determining the growth of disseminated cancer cells (the seeds) into secondary tumors. Thus, cancer cells targeting distinct organs would differ in their responsiveness to molecules produced by different tissues; this idea could also explain the discrepancy between the relatively high blood supply of certain organs and their relatively low frequency of metastatic growth.

The seed and soil hypothesis might imply that tumor cells leave the blood and lymphatic circulation to the same degree at all organs, but survive and proliferate only in those organs producing congenial growth factors. However, it is highly plausible that selective adhesion/extravasation as well as trophic interactions between cancer cells and skeletal tissue are not mutually exclusive phenomena and they all play a crucial role in determining the bone tropism of tumors.

The bone is composed of different cell types and is characterized by sustained levels of metabolic activity due to bone remodeling or repair, inflammation and reactive hematopoiesis, throughout the entire life of the individual. Thus, bone tissue homeostasis is orchestrated by a plethora of trophic molecules to which cancer cells might also be sensitive. In fact, an important role for bone turnover in the preferential location of prostate cancer cells to the skeleton has been recently reported.

The quest to identify factors produced by the bone microenvironment that could support the growth of cancer cells has led to implicate several molecules, including ►transforming growth factor, ►osteopontin, ►platelet derived growth factor, among others.

The disruption of the trophic interactions between cancer cells and bone, for example by using inhibitors of growth factor receptors such as ►imatinib, has been recently attempted. In general, the identification of crucial molecules supporting the survival of cancer cells in the bone will provide novel targets for the treatment or prevention of skeletal tumors by pharmacological, immunological or gene therapy approaches.

Cancer cells may leave the primitive tumors and enter the blood circulation in large numbers, a process called ►intravasation. However, the metastatic process is highly inefficient and it has been shown that the vast majority of disseminated cancer cells fail to produce secondary tumors. Using animal models, only a very small fraction of cells delivered into the blood stream were seen reaching peripheral organs; of those that located to secondary organs some would proliferate while others would remain dormant. Thus, growth factors produced by the bone tissue can be determinant for supporting the small foci of cancer cells immediately after their arrival and their successful lodging in the skeleton.

Alteration of Bone Microenvironment by Cancer Cells

The small number of cancer cells reaching the skeleton are probably unable to immediately affect the surrounding cells and stroma and will depend on growth factors already present in the microenvironment to sustain their survival and growth. However, it is conceivable that once the initially small foci of malignant cells have reached significant size, functional cross-talking with the bone resident cells is established. This phenomenon has been shown to regulate phenotype and genotype of tumor as well as bone stromal cells and ultimately modify the microenvironment in a fashion that can potentially benefit metastatic growth.

An intriguing hypothesis is that cancer cells, in order to survive in the bone, need to acquire bone-like properties. This phenomenon – defined ►osteomimicry – is characterized by the expression of bone cell-related genes and is regulated by the interaction with bone resident cells, which can occur through either physical contacts or released factors. Some bone cell-related genes are those for osteopontin, osteocalcin and bone sialoprotein. A soluble factor, ►osteoprotegerin, a member of the ►tumor necrosis factor superfamily, can be detected in high levels in the serum of patients affected by advanced prostate cancer, which is almost invariably associated with skeletal metastasis. Osteoprotegerin acts as a ►decoy receptor and blocks ►TRAIL/Apo 2L, a cytokine that can trigger cancer cell death by interacting with death-receptors. Interestingly, osteoprotegerin is overexpressed by cancer cells as a consequence of osteomimicry. However, as bone marrow stromal cells also produce this protein during bone remodeling, the bone microenvironment could independently protect cancer cells from the TRAIL-induced death. Thus, the production of osteoprotegerin by cancer cells upon osteomimicry would essentially amplify this phenomenon.

Because of the obvious problems posed by bone secondary tumors for prognosis and quality of life, therapies to successfully counteract malignant cells growing at the skeletal level are of utmost importance for the management of cancer.

Bone Tumors

Michael J. Klein
Center for Metabolic Bone Disease, The University of Alabama at Birmingham, Birmingham, AL, USA

Synonyms

Bone neoplasms; Bone sarcomas

Definition

Bone tumors are space-occupying lesions arising in bone that are usually derived from primitive connective tissue elements.

They constitute a diverse group of neoplasms that are collectively less common than those of almost all other body sites. Malignant primary bone tumors have an approximate incidence one new malignant bone tumor per 100,000 individuals per year. Since the incidence of benign bone tumors is about half that of malignant tumors, the average aggregate incidence of all bone tumors is about one in 67,000 persons per year.

With a few notable exceptions, bone tumors have a predilection for individuals in the second and third decade; there is a second, smaller peak of incidence in the sixth and seventh decade. In most large series of bone tumors there is a slight male predominance. Each tumor type has a characteristic range age, skeletal distribution, and sometimes sex and racial predilection.

Characteristics

Etiology

While the link between bone tumors and a predisposing cause is not demonstrable in most cases, there are conditions in which the incidence of bone tumors is increased. The presence of pre-existing ►Paget disease of bone, ►idiopathic bone infarctions, and ►fibrous dysplasia are all associated with increased frequency of bone sarcomas. Ionizing radiation, whether given for therapeutic purposes or accidentally acquired through external exposure or ingestion also predisposes to the development of bone sarcomas. Ollier's disease, a congenital but non-hereditary disorder characterized by multiple ►enchondromas predisposes to malignant cartilage tumors in 10–20% of cases. About half of all patients with Maffucci syndrome, which is characterized by multiple soft tissue ►hemangiomas in patients with Ollier's disease, develop malignant cartilage tumors. Multiple hereditary exostoses, an autosomal dominant disorder, is associated with a specific genetic abnormality, usually at the EXT-1 or EXT-2 chromosomal loci. In this disorder, which is characterized by the development of multiple ►osteochondromas, resulting in bone modeling abnormalities, the incidence of malignant cartilage tumors is in about 10% of patients.

Other familial disorders having an increased incidence of other malignant neoplasms also have an increased predisposition for ►osteosarcomas. Chief amongst these are the Li–Fraumeni Syndrome, in which mutations in the p53 gene causes an increased incidence of many tumors (►p53 gene family). Patients with familial retinoblastoma gene mutations (Rb) have a high risk for the development of osteosarcoma. Two other autosomally recessive disorders that usually present with skin abnormalities, the ►Rothmund–Thomson syndrome and ►Bloom syndrome, have associated specific chromosomal mutations that result in an increased association with osteosarcomas. A specific and reproducible chromosomal abnormality, namely, a fixed reciprocal translocation between chromosomes 11 and 22 and, less frequently, between chromosomes 7 or 21 and 22 results in a chimeric gene product that encodes for the proliferation protein promoter found in the cells of more that 90% of patients with ►Ewing sarcoma.

Diagnosis

Bone tumors present with fairly non-specific symptoms, the most common of which is pain that is noticed at rest or is severe enough to wake a patient from sleep. Interference with normal limb function or the presence of a mass may also be present, but these usually occur later in disease evolution. A specific diagnosis is made by biopsy, which may be as simple as a fine needle aspiration or as extensive as a complete excision. Since the overlying soft tissues and skin cover the bones, bone tumors are essentially invisible without clinical imaging studies. The most important of these are routine radiographic studies done using multiple views. Imaging studies should always be reviewed in tandem with the histology prior to rendering a diagnosis, because not only do they provide information regarding the location, extent and aggressiveness of the disease, but also correlative information on the likelihood that the biopsy is representative of the process.

Primary bone tumors are classified into their various histologic subtypes on the basis of their histologic grade, their anatomic location, and especially by the kinds of extracellular connective tissue (e.g. bone, cartilage, fibrous tissue) produced by each or whether there is differentiation into any other types of soft tissue elements (Table 1). For example, osteosarcoma is a malignant tumor in which the cells have the capacity to produce bone. While the diagnosis is usually made from the histologic features, some bone tumors that look deceptively benign histologically may actually be diagnosed as malignant tumors when the imaging and histologic features are correlated. In addition, a very few varieties of tumor are characteristically unpredictable in biologic potential. A few primary bone tumors may behave in a locally destructive fashion but have an unpredictable propensity for metastatic behavior. The most important examples include ►giant cell tumors of bone and ►hemangioendotheliomas.

Because they often produce so large a quantity of extracellular matrix, the volume of primary bone tumors tend to be comprised more of extracellular connective tissue elements rather than by tumor cells. This relationship is the exact opposite of what is observed in carcinomas. With the notable exception of chordoma, adamantinoma, and neural tumors, it is

Bone Tumors. Table 1 Bone tumor classification

Myeloid		Myeloma
Histiocytic	Giant cell tumor	

believed that almost all primary bone tumors are derived from embryonic ►mesoderm. This is again in contrast to adenomas and carcinomas, which are derived from ►ectodermal or ►endodermal precursors.

Staging and Prognosis

Benign tumors of bone are almost always of a limited growth potential and their morbidity is confined to interference with local anatomy or function. They are usually controlled or cured by limited surgery such as curettage or simple excision. Locally aggressive bone tumors may require more aggressive surgery depending upon their size, location, and whether there has been previous treatment. Most malignant bone tumors are high-grade lesions and are usually treated as systemic diseases even if they seem localized at the time of diagnosis. With the exception of ►chondrosarcoma, malignant tumors are now treated with systemic chemotherapy (►neoadjuvant Therapy). A few tumors, notably lymphoma and myeloma, may also be treated with local radiation therapy, but most other bone tumors are no longer irradiated. Most malignant bone tumors spread systemically to the lungs though other bones and sometimes other parenchymal organs may be affected. In general, regional lymph nodes are not affected, so the most meaningful staging schemas of bone tumors does not necessarily include the presence of nodal disease. The musculoskeletal tumor society staging system first proposed by Enneking takes into account only whether a malignant tumor is high grade or low grade, confined to one or more compartments, or is metastatic. This system both summarizes tumor biology and helps to clarify the treatment regimen required for a particular patient.

In general, patients with low-grade malignant bone tumors have a good prognosis so long as their initial surgery is adequate. If surgery is not adequate, malignant tumors recur locally. The longer a low-grade tumor persists locally or the more times it recurs, the greater is the likelihood for systemic spread by the tumor. Certain low-grade tumors such as central chondrosarcoma and low-grade osteosarcomas are notorious for undergoing ►dedifferentiation, with greatly increased likelihood for metastasis. The prognosis of patients with high-grade bone sarcomas has improved with the advent of present-day chemotherapy. For example, the 5-year survival for patients with osteosarcomas was in the range of 20% but is now better than 70% in some series.

[2]Department of Biological Sciences, University of Essex, Colchester, Essex, UK

Synonyms

Brother of the regulator of imprinted sites; CTCFL (stands for CTCF-like); CTCF-T (stands for CTCF-testis specific)

Definition

BORIS (acronym for *B*rother of the *R*egulator of *I*mprinted *S*ites) is a member of Cancer–Testis Antigen (CTA) family and a mammalian paralogue of ►CTCF, with the suggested role in the regulation of epigenetic reprogramming.

Characteristics

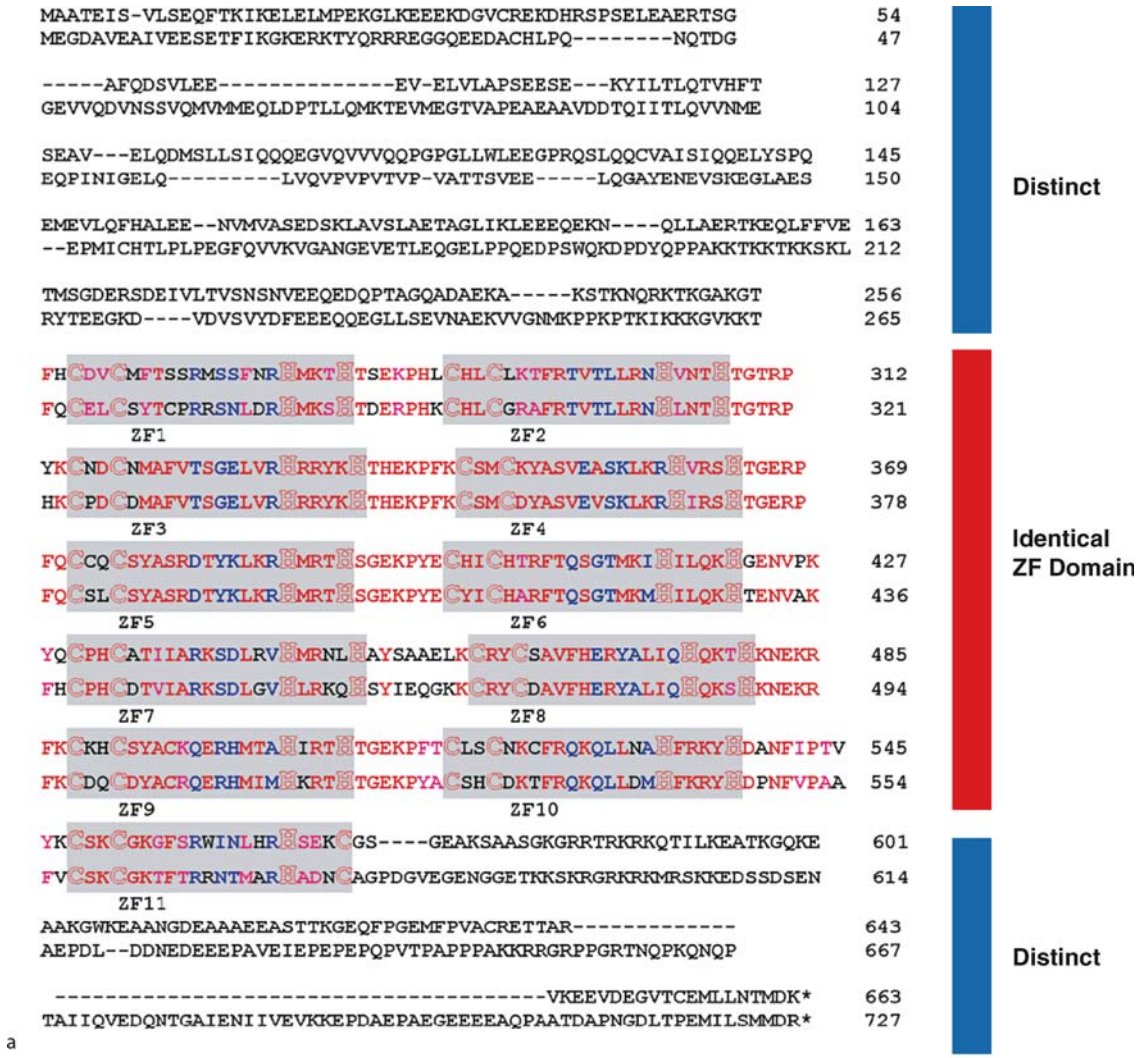
Studies on a transcription factor CTCF, a candidate ►tumor suppressor gene (TSG) involved in transcriptional regulation, control of imprinted genes, and insulators, led to a discovery of its paralogue, termed BORIS. The rationale behind the discovery of BORIS was to explain the process of resetting of ►imprinting marks in testis, in other words, how methylation-sensitive CTCF binding sites can be established in germ cells de novo. The existence of a protein with certain characteristics in these cells was therefore postulated. On one hand, such a hypothetic protein needed to recognize the same DNA sequences as CTCF to modify CTCF binding sites. On the other hand, this protein should be associated with a different biochemical machinery to erase and/or establish the methylation marks in germ cells that will later be read by CTCF in somatic cells. This hypothesis of the existence of germ cell specific molecule was later confirmed by the identification of BORIS, which was the ideal candidate for the role.

Firstly, in contrast to the ubiquitous CTCF, BORIS was only expressed in germ cells (spermatocytes) in testis; other testicular cells (Sertoli, Leydig, and the somatic cells) were BORIS negative. It is worth noting that, contrary to BORIS, CTCF was significantly down-regulated in the spermatocytes. Secondly, BORIS had the DNA binding domain identical to CTCF (74% identity), whereas the flanking N- and C-terminal domains were dissimilar (Fig. 1a). These structural features indicated that BORIS could recognize the same set of DNA targets as CTCF, while the dissimilar flanking domains could bring different interacting partners to the sequences to perform epigenetic modifications. The ability of BORIS to bind to a variety of DNA targets of CTCF was tested experimentally. In this study, all CTCF DNA targets inspected formed complexes with BORIS. This implies that evolutionary pressure maintained the same specificity of the DNA binding domain in CTCF and BORIS, thus suggesting important functions for both proteins; these functions are discussed in this and CTCF essays in the Encyclopedia.

BORIS is a 85 kDa protein; it can be detected both in the nucleus and in the cytoplasm, which is not common for transcription factors. This is in contrast to CTCF, which has strictly nuclear localization. The cytoplasmic form of BORIS may represent the inactive, sequestered protein, although the precise function(s) of the cytoplasmic BORIS remains to be investigated.

The human BORIS gene is mapped to chromosome 20q13 (Fig. 1b), whereas its mouse counterpart is mapped to chromosome 2, bands H3-4. Of note, the mouse chromosome 2 has significant homology to the human chromosome 20q. Surprisingly, BORIS not only possesses the DNA binding domain similar to CTCF, but its gene also preserved similar exon/intron structure, with identical splice sites for each exon–exon junctions in the ZF domain as the mammalian CTCF (Fig. 1c). It is worth noting that the exon/intron structure of

B



a

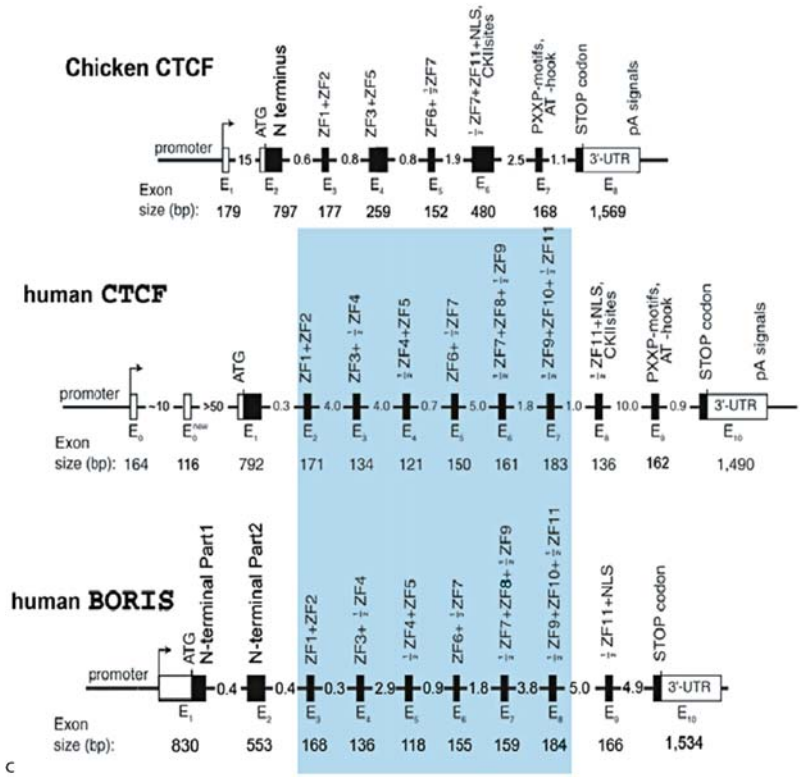
BORIS. Figure 1 Continued



BORIS. Figure 1 Comparative amino acid alignment of human CTCF and BORIS. Identical and homologous residues in the ZF domain are shown in red, homologous in magenta, nonhomologous in black. Residues responsible to form DNA contacts in Zn-fingers are shown in blue. Residues chelating Zn ion are shown in larger font sizes. (b) Both BORIS and CTCF map to cancer-associated "hot spots": on 20q13 and 16q22, respectively. According to the modified "two hit" hypothesis, two hits occur on different chromosomes – first in the region of frequent LOH at 16q22 where CTCF is localized and second in a region of 20q13 frequently amplified in multiple human cancers, where BORIS is localized. BORIS in this context can be regarded as a dominant-negative mutant of CTCF. (c) Comparison of the overall exon/intron structures of CTCF and BORIS genes. The region of homology over the exons encoding the ZF domain is highlighted. BORIS contains duplicated ZF-coding exons of mammalian, but not chicken, CTCF.

chicken CTCF is very different from that of the mammalian CTCF suggesting that BORIS gene most likely appeared in the evolution after the separation of mammals and birds possibly due to the duplication and translocation of the CTCF DNA-binding domain (Fig. 1c).

So far, the human and mouse BORIS genes have been cloned, while the rat, dog, and chimpanzee homologues of BORIS can be easily found using bioinformatics approaches, such as a homology search of the Genbank.

BORIS Functions

Although indirect evidence indicates that BORIS plays important functional roles in the cells where it is expressed, there are only a few published reports investigating BORIS functions. The fact that CTCF and BORIS are expressed in a mutually exclusive manner during male germline development led to the hypothesis that BORIS may be important for epigenetic reprogramming occurring in these cells during development. Indeed, BORIS has been implicated into the initiation of a series of methylation events at the imprinting control regions (ICR), in the vicinity of the CTCF/BORIS binding sites. In this model, BORIS interaction with a protein arginine methyltransferase PRMT7 leads to methylation of histones, followed by methylation of DNA by the de novo methyltransferase Dnmt3b and the establishment of a heterochromatic (silent) configuration of chromatin in this locus. However, the exact role that BORIS plays during spermatogenesis needs to be further investigated using knock-out and/or knock-in models.

When BORIS is introduced into cells that do not normally express this molecule, for example, into somatic cells such as normal human dermal fibroblasts, it activates a group of members of CTA family (MAGE-A1, MAGE-A2, MAGE-B1, MAGE-B4,

GAGE-3-8, RAGE-2, NY-ESO-1 (CTAG1B), LAGE-1 (CTAG2)) and also transcription factors playing a role in maintaining germ/stem cells phenotype (Oct-3/4, or POU5F1). The molecular events underlying this function of BORIS involve demethylation of the promoters of the genes in question, followed by activation of these genes. This implies the involvement of different biochemical machinery recruited by BORIS to the DNA targets in these cells. Interaction between BORIS and a transcription factor, SP1, facilitates derepression of *NY-ESO-1* gene in lung cancer cells. These findings further signify the importance of protein partners interacting with BORIS; the identification of such proteins will be instrumental in the understanding of the exact molecular mechanisms of BORIS functions in the processes of DNA methylation and demethylation.

Some of the CTAs (for instance MAGE-A1 and NY-ESO) are considered to be potential clinical targets for cancer immunotherapy. Therefore the investigations into how these genes may be regulated by BORIS are very important as they may provide the means to increase the expression from the relevant genes and enhance the response from the patients' immune system.

BORIS is capable to compete with CTCF on different targets both in vitro and in vivo. Taking into account the same DNA binding specificity, it is conceivable that the aberrantly expressed BORIS can act as an interfering mutation to CTCF. As CTCF regulates several genes implicated in cancer development (►*c-Myc*, *hTERT*, ►*BRCA1*, *IGF2*, ►*p53*, ►*p27*, ►*p21*, ►*ARF* etc. – see the essay on CTCF in this Encyclopedia), aberrantly expressed BORIS can compete with CTCF for binding thus ultimately leading to deregulation of those genes.

BORIS in Cancers

Some of BORIS features indicate that BORIS can be classified as an ►oncogene. It is located at the 20q13, together with Aurora kinase; this small 20q amplicon is a hotspot for chromosomal amplification in many human cancers (Fig. 1b). BORIS proximity to Aurora and their frequent coamplification raises an interesting possibility of potential cooperation of those two potential oncogenes in the process of cell transformation.

Normal BORIS expression is restricted to adult testis while abnormal expression is detected in a wide variety of cancers including breast, prostate, colon, melanomas, testicular, endometrial, and others. This expression pattern and the ability to induce immune response in patients, both antibody and cellular, place BORIS into a category of CTAs. The CTAs include around 14 families of tumor antigens. The function of the majority of the CTAs is still unknown, although some CTAs are though to be implicated in the regulation of gene expression and others may control gametogenesis. As a member of the CTA family, BORIS is now seen as an attractive target for both diagnostics and therapy of many human tumors (see below).

Although the mechanisms of BORIS activation in cancers are not yet known, the consequences of such an event can be dramatic. For example, BORIS can reverse the function of CTCF as a TSG by binding to CTCF targets and deregulating them. The possibility of such a "two chromosome hit" scenario, when a TSG is inactivated by the events occurring on two different chromosomes, creates a necessity to revise Knudsen's "two hit" theory, suggesting that while one copy of a TSG can be eliminated by loss of heterozygosity (LOH), the other copy can be either inactivated by epigenetic means or by somatic mutations. For the CTCF/BORIS pair, the second hit can occur at a different chromosome (20q13) by activation and subsequent chromosomal amplification of a gene with the same DNA binding specificity but different regulatory domains. This activation of a different gene on a different chromosome but capable of interfering with a tumor suppressor can be considered as analogous to the action of a dominant negative mutant (Fig. 1b). The aberrantly expressed BORIS is likely to interfere with the CTCF regulatory pathways that include a number of cancer-related genes, thus leading to deregulation of these genes and contributing to transformed phenotype.

BORIS interaction with the protein arginine methyl transferase PRMT7 that can result in DNA methylation and formation of heterochromatin may be responsible for silencing of some tumor suppressor genes that are inactivated in cancers due to aberrant methylation of the promoter regions. Finally, BORIS appears to be capable of the reversing the epigenetically silenced multiple CTAs, which results in activation of these genes and may contribute to tumor development.

Clinical Aspects

BORIS as a Cancer Biomarker

The identification of new markers to discriminate tumorigenic from normal cells, as well as the different stages of tumor pathology, has now become of critical importance for cancer diagnosis, prognosis, and monitoring. All currently available tumor markers are not ideal as in most cases they lack of sensitivity for early cancer and specificity for malignancy. Therefore, the quest to identify additional "cancer genes" implicated in breast tumorigenesis, along with delineation of prognostic biomarkers, has now become the most important step towards developing better diagnostic tools and a possibility of curing the disease. The finding that, similar to other CTAs, BORIS is aberrantly expressed in a wide variety of cancers points to important practical applications, namely, using BORIS as a molecular ►biomarker of cancer, especially for early diagnostics of the disease.

BORIS has the potential to be an early circulating marker, the detection of which may indicate the existence of a cancerous condition in the patient or of a predisposition of the patient to such a condition. In these investigations, BORIS was found to be present in the white blood cells (or leukocytes) in patients with breast cancer, but not in healthy donors. The type of the leukocytes was determined as the neutrophil polymorphonuclear granulocytes (PMNs). These findings place BORIS in a new category of cancer biomarkers, different from those currently used in medical practice.

The molecular mechanisms of BORIS activation and the functions in PMNs of breast cancer patients remain to be established. However, it is acknowledged that this is a tumor-related occurrence because BORIS was not detected in PMNs in donors with injuries, immune, and inflammatory diseases. This opens the perspective to utilize BORIS as a valuable blood marker for early detection of breast cancer (and may be other types of tumors), as well as the attractive target for early intervention and prevention of the disease.

This discovery is of great importance in the context of an ongoing quest to identify accurate circulating markers as far there are no established ►circulating tumor markers available for clinical use in the determination of cancer susceptibility, screening, diagnosis, and prognosis. The presence in such markers in blood makes them particularly useful since clinical analysis will involve relatively noninvasive procedures.

BORIS as a Target for Cancer Immunotherapy

Multiple CTAs are promising candidates for immunotherapeutic approach to treat cancer, although they have limitations. One of the main disadvantages for using these targets is their relatively narrow expression patterns. Another problem lies in the fact that sometimes during the treatment of the cancerous condition, the expression of the target antigen ceases without affecting the tumor growth, thus allowing tumor cells to escape from the immune response directed against them.

The fact that BORIS belongs to cancer–testis gene family as well as its wide expression in multiple cancers suggests that BORIS can be a good candidate for cancer immunotherapy. Using a mouse model, it was recently demonstrated that immune response to BORIS can be developed in the organism and, furthermore, such immune response has protective effects against several mouse tumors of different origin. Importantly, this immune reaction seems to be of a MHC class I-restricted response of cytotoxic T lymphocytes (CTLs) against histologically diverse tumor cells expressing only endogenous BORIS.

As BORIS seems to reverse tumor suppressor functions of CTCF in cancer, it is likely that BORIS is important to sustain the transformed phenotype. Therefore, if some tumor cells escape the anti-BORIS immune cells following the cessation of BORIS production in these cells, such BORIS-negative cells are expected to have much weaker growth/tumorigenic potential than BORIS-positive cells. This means that even if complete elimination of tumor can not be achieved, the patient still might benefit from anti-BORIS therapy.

In summary, BORIS has an excellent potential for immunotherapy and even preventive vaccination against cancers, although more research is required to advance BORIS to clinical trials.

Bortezomib

Jochen Lorch
Dana Farlur Cancer Institute, Boston, MA, USA

Synonyms

PS 341; Velcade®

Definition

An antineoplastic agent targeting the proteasome.

Characteristics

Mechanism of Action

Bortezomib is a proteasome inhibitor and the first drug to emerge from a new class of therapeutic agents

targeting the ubiquitin–proteasome pathway. This pathway mediates the degradation of polyubiquitinated proteins and accounts for 80% of the protein degradation in eukaryotic cells. Proteins that are marked for degradation undergo conjugation of polyubiquitin chains to lysine residues in a process called ubiquitination. The proteasome is an enzymatic complex that recognizes ubiquitin-tagged proteins and catalyzes their proteolytic breakdown in an ATP-dependent fashion. Bortezomib is a reversible inhibitor of the chymotrypsin-like activity of the 26S proteasome in mammalian cells. It has been approved in the United States and Europe for the treatment of ►multiple myeloma and has recently been approved in the US for the treatment of relapsed ►mantle cell lymphoma. In addition, it has also shown significant antitumor activity in many other types of cancer. Due to the wide range of proteins that are subject to ubiquitination and subsequent proteasomal degradation, bortezomib interferes with multiple pathways ultimately leading to ►apoptosis. Proposed mechanism of action includes NF-κB inhibition trough reduced Iκα degradation, leading to reduced NF-κB-dependent synthesis of antiapoptotic factors such as c-Flip. Other mechanisms include inhibition of apoptosis (IAP)1/2 and ►BCL-2, stabilization of ►p53, deregulation of cyclin turnover, and subsequently ►cyclin-dependent kinases activity as well as effects on stability of cdc25 family proteins, ►KIP1 and WAF1 during cell cycle. In addition, it has been shown to influence the balance between pro- and antiapoptotic Bcl-2-family proteins, stabilizes JNK, as well as increases c-Jun phosphorylation and AP-1 DNA-binding activity with subsequent Fas upregulation. Other pathways include deregulated proapoptotic signaling via ►tumor necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL) and disruption of the unfolded protein response with endoplasmic reticulum (ER) stress induction. Increased intracellular reactive oxygen species and oxidative stress may also contribute to its antitumor activity. Preclinical data suggests that bortezomib reverses the antiapoptotic effects of ►interleukin (IL)-6 and ►insulin growth factor (IGF)-1. It also reduces tumor cell migration in multiple myeloma cells and squamous cell cancer cells due to its effects on ►VEGF and dysregulation of focal ►adhesion assembly. Furthermore, it may affect the tumor ►microenvironment thus exerting an anti-angiogenic effect. As a result, bortezomib ultimately triggers an apoptotic cascade mediated by ►caspases. The number of proposed mechanisms is likely to grow in the future as none of these pathways can fully explain the clinical effectiveness of bortezomib in malignancy, and research is under way to fill these gaps. Depending on the tumor cell type, one or a combination of several pathways may be responsible for the clinical effects and different cell types may therefore be more or less sensitive to the effects of bortezomib. For example, terminally differentiated immumoglobulin-secreting plasma cells have impaired proteasome activity, which could explain bortezomib's activity against malignant plasma cells in multiple myeloma.

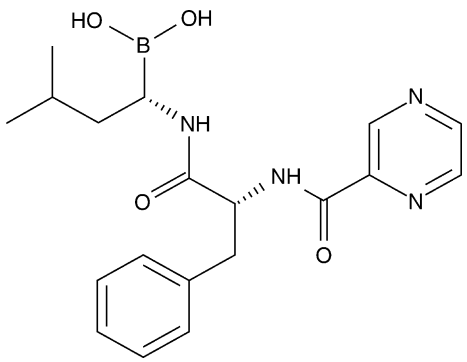
Pharmacology

The chemical formula for bortezomib is [3-methyl-1-(3-phenyl-2-pyrazin-2-ylcarbonylamino-propanoyl)amino-butyl] boronic acid. The chemical structure is shown in Fig. 1. Bortezomib is administered intravenously and weekly once and twice dosing schedules have been tested. The mean elimination half-life of bortezomib after first dose ranges from 9 to 15 h at doses ranging from 1.45 to 2.00 mg/m^2 in patients with advanced malignancies. In vitro studies with human liver microsomes and human cDNA-expressed cytochrome P450 isozymes indicate that bortezomib is oxidatively metabolized primarily via cytochrome P450 enzymes 3A4, 2C19, and 1A2, while bortezomib metabolism by CYP 2D6 and 2C9 enzymes is minor. The major metabolic pathway is deboronation to form two deboronated metabolites that subsequently undergo hydroxylation to several metabolites, which are inactive as 26S proteasome inhibitors. The most common side effects include asthenia, nausea, diarrhea, anorrhexia, constipation, ►thrombocytopenia, peripheral neuropathy, and pyrexia.

Clinical Aspects

In Cancer

The effectiveness of bortezomib is based on response rates which led to the accelerated approval of bortezomib by the Food and Drug Administration (FDA) and the European Medicines Agency (EMEA). The approval of bortezomib was based on an open-label, single-arm, multicenter study of 202 subjects with multiple myeloma who had received at least two prior therapies. An IV bolus



Bortezomib. Figure 1 Chemical structure of bortezomib.

injection of bortezomib (1.3 mg/m2/dose) was administered twice a week for 2 weeks, followed by a 10-day rest period (21-day treatment cycle) for a maximum of eight treatment cycles. Subjects who experienced a response to bortezomib treatment were allowed to continue treatment in an extension study. Results showed 52 (27.7%) subjects achieved an overall response rate, 5 (2.7%) achieved a complete response, 47 (25%) achieved a partial response, and 33 (17.6%) demonstrated a clinical remission. The ►Kaplan–Meier estimated median duration of response was 1 year. In another trial, bortezomib was compared with high-dose ►dexamethasone in 669 patients with relapsed multiple myeloma, which confirmed superior activity of bortezomib over dexamethasone resulting in a higher response rate, a longer time to progression (the primary end point), and a longer survival than patients treated with dexamethasone. The combined complete and partial response rates were significantly longer for the group receiving bortezomib (38% vs. 18%), and the complete response rates were 6% and less than 1%, respectively. Median times of progression in the bortezomib and dexamethasone groups were 6.22 months (189 days) and 3.49 months (106 days), respectively. The 1-year survival rate was 80% among patients treated with bortezomib and 66% among patients treated with dexamethasone, and the hazard ratio for overall survival with bortezomib was 0.57. Since then, more data from phase 2 and 3 trials have emerged and have confirmed the activity of bortezomib in relapsed and newly diagnosed multiple myeloma. Trials evaluating the combination of bortezomib and other drugs such as ►thalidomide and its analog lenalidomide are ongoing and the results will be available in the near future. Bortezomib has recently been approved for the treatment of relapsed and refractory mantle cell lymphoma. The approval was based on data from an open-label, single-group, multicenter phase 2 clinical trial of 155 patients with relapsed or refractory mantle cell lymphoma who had received at least one prior therapy. Participants received single-agent bortezomib (1.3 mg/m^2 twice a week for 2 weeks every 21 days) for up to a year. Results showed that 31% of patients achieved overall response to bortezomib, with 8% demonstrating a complete response, and 23% a partial response, as determined by computed tomography scan reviews. The median number of cycles in responding patients was eight, and the median time to response was 40 days. The median duration of response was 9.3 months overall and longer for those achieving complete response compared with those with partial response to bortezomib. The median time to progression of disease was 6.2 months.

Trials are also investigating thalidomide in combination with bortezomib in patients with ►myelodysplastic syndromes. Phase 2 studies on bortezomib in other types of lymphoma are ongoing and interesting results have been presented as abstracts which indicate that bortezomib may be useful in the treatment of these diseases with high response rates and substantial number of complete remissions in pretreated patients.

Early data is also emerging showing that bortezomib has activity in various solid tumors such as lung, head and neck, prostate cancer. Preclinical and early clinical data suggests that bortezomib may enhance the activity of EGF-R inhibitors through the upregulation of the EGF-receptor. As trials are under way to evaluate the use of bortezomib alone and in combination with other agents, other indications for bortezomib in solid tumors are likely to emerge.

In Graft Versus Host Disease and Immune Disorders

The use of bortezomib in graft versus host disease (GVHD) is based on bortezomib's effect on antigen procesing, apoptosis, cell-cycle onco-stimulation, and chemotaxis. The ability of proteasome inhibitors to prevent NF-κB activation has made proteasome inhibitors attractive candidates for the treatment of immune-mediated disorders. Preclinical and early clinical data suggests that proteasome inhibitors may be effective in the treatment of osteoarthritis, psoriasis, and a spectrum of other autoimmune conditions. In preclinical models, GVHD was effectively prevented without affecting the beneficial graft versus tumor effects. At this point it is unknown whether this will be reproducible in humans. It appears that bortezomib has direct proapoptotic effects on human T-lymphocytes which has been shown in vitro which may explain the clinical observation of lymphopenia in some patients undergoing treatment with bortezomib.

Other Uses

Preclinical models suggest that bortezomib may also be useful in the treatment of cardiovascular disease and ischemic strokes. It is unclear whether these effects may be related to its effects on the NF-κB inactivation; cytokine secretion and modulation of cell adhesion may also play an important role.

Future Directions

Other compounds that target the proteasome are in preclinical and clinical development. NPI-0052, a compound derived from the marine actinomycete *Salinospora tropica*, an inhibitor of the 20S subunit of the proteasome, is currently undergoing early phase clinical testing. It has shown significant activity in multiple myeloma.

Bovine Papillomavirus

Giuseppe Borzacchiello
Department of Pathology and Animal health, University of Naples "Federico II", Naples, Italy

Definition

Oncogenic DNA viruses causing both benign and malignant epithelial and mesenchymal tumors in cows and equids.

Characteristics

Bovine papillomaviruses (BPV) belong to the Papillomaviruses (PV) family. BPV are small oncogenic DNA viruses strictly specie-specific and, even in experimental conditions, do not infect any other host than the natural one. The only known case of cross-species infection is the infection of horses and other equids by BPV type 1 (BPV-1) or BPV type-2 (BPV-2). Papillomavirus infections usually regress, but occasionally they develop to cancer.

Ten BPV types (BPV 1–10) have been characterized associated with different histopathological lesions. The different genotypes have been classified into three genera. Two noval BPV were characterised further and the phylogenetic analysis showed that both viruses were new BPV types: one was designated as BPV-7 and classified as a member of a new PV genus, and the other was designated as BPV-8 and classified as a member of the *Epsilonpapillomavirus* genus.

Recently, two new BPV types belonging to the genus *Xipapillomavirus* have been characterised and designed as BPV-9 and BPV-10.

Xi-papillomaviruses encompassing the pure epitheliotropic BPV-3; BPV-4 and BPV-6; Delta-papillomaviruses encompassing BPV-1 and BPV-2 associated to fibropapillomas (i.e., benign tumors of both epithelium and underlying derma) and Epsilon papillomavirus comprising the BPV-5 whose genome seems to share similarities with the former two BPV groups.

The BPV virion is a nonenveloped structure of 55–60 nm diameter containing a double-stranded covalently closed circular DNA. Three different regions compose the genome: the long control region (LCR) and two regions encoding for early and late genes.

The LCR is the genome region containing signals for both viral DNA replication and transcription. E2 regulates BPV transcription at LCR level; the LCR of BPV-4 contains different E2 binding sites; depending on the sites involved the transcription may be repressed or activated. The E2 sites are also bound by different cellular transcription factors and the E2 can also bind to mitotic chromosomes resulting in efficient distribution of the BPV genome into daughter cells.

BPV Gene Products

E5

The papillomavirus ►E5 proteins are short hydrophobic polypeptides [from 83 amino acid residues in ►human papillomavirus type 16 (HPV-16) to 42 residues in BPV-4], many of which have transforming activity. *BPV-1 E5* oncogene encodes for a 44 amino acid protein that is the major BPV transforming oncoprotein. It is a type II transmembrane protein which is expressed in the deep layers of the infected epithelia and is largely localized to the membranes of the endoplasmic reticulum (ER) and Golgi apparatus (GA) of the host cells. BPV E5 is expressed in the cytoplasm of both basal and suprabasal transformed epithelial cells with a typical juxtanuclear pattern due to its localization in the GA. It may also be expressed in neoplastic cells of mesenchymal origin such those of endothelial origin.

Due to its relative small size BPV E5 has no intrinsic enzymatic activity and its transformation activity is related to the activation of several kinases, from growth factor receptor to cdk cyclins. E5 interacts with the 16-K subunit c protein, a component of the vacuolar H^+-ATPase pump. This proton pump acidify the lumen of intracellular compartments, (endosomes, lysosomes, and GA) that process growth factors so that E5 binding may result in alteration of this processing. Another consequence of E5-mediated impaired acidification is the downregulation (both in vivo and in vitro) of the major histocompatibility complex class I (►MHC-I) expression, representing one of the mechanisms by which the BPV evade the immunoresponse by the host.

The mechanism by which BPV-1 E5 induces cell transformation is its binding to and activation of the cellular β receptor for the ►platelet-derived growth factor (PDGFβ). The activation of endogenous PDGFβ receptors is characterized by the formation of stable E5-receptor complexes, persistent tyrosine phosphorilation of the receptor, its dimerization and cellular transformation. This interaction takes place also in naturally occurring BPV-2 associated bovine urinary bladder cancer.

E6

The *BPV-1 E6* gene of Xi BPV encodes an oncoprotein of 137 amino acids. It binds to paxillin blocking its

interaction with vinculin and the focal adhesion kinase. It also binds to several others cellular proteins such as ERC-55, the E3 ubiquitin ligase E6AP, and with the AP-1. Finally, it has been demonstrated that E6 interacts with the CBP/p300 inhibiting the p53.

E7

The *BPV E7* gene encodes a 127 amino acids zinc binding protein which cooperates with E5 and E6 in inducing cell transformation. Once ►E7 is coexpressed with E5 and E6 its transformation capacity increases many folds, and such coexpression may also occur in tumors of mesenchymal origin. BPV-1 E7 transformation function correlates with its binding to a cellular target p-600, which is a shared transformation pathway of HPV-16 E7.

The BPV-4 E7 can also cooperate with E8 in inducing cellular transformation and the activation of the ►ras oncogene is responsible for morphological changes of primary bovine fibroblasts (PalF). Like other E7 PV, BPV-4 E7 has a p105Rb-binding domain whose mutation may reduce or abolish its transforming activity,

BPV E7 localizes in the cytoplasm and nucleoli of basal and lower spinous epithelial cells. It may also be found in mesenchymal neoplastic cells.

L1 and L2

The BPV late proteins L1 and L2 are expressed into the more differentiated epithelial cells. The former mediates virus interaction with cellular receptor, the latter induces virion assembly by binding to viral DNA.

Infection by delta-PVs leads to transformation of subepithelial fibroblasts followed by epithelial acanthosis and then papillomatosis, while infection by Xi-PVs induces transformation only of the epithelial component. Virus replication can take place only in keratinocytes undergoing terminal differentiation to squamous epithelium, so it is seen only in the epithelial component of the tumors and only at certain stages of its development. Virus replication has never found in fibroblasts where the BPV genome is present in a nonintegrated episomal form, although *BPV* viral gene expression has been recently found in tumors of mesenchymal origin such those arising from blood vessels (hemangioma and ►hemangiosarcoma) suggesting a role of the virus even in neoplastic transformation other than epithelial.

BPV and Papillomas

►Papillomas and fibropapillomas may occur in different organs in cattle and different BPV genotypes are found. BPV-1, BPV-5, and BPV-6 are associated to papillomas of the teats and udders in cows. This can become a great economic problem once the papillomas spread around the primary tumors and the cows cannot be milked, veals are unable to suckle properly and the site may become infected inducing mastitis. Occasionally, the herds should be culled if the papillomatosis progress.

Epithelia of both prepuce and penis may be infected by BPV-1 resulting in fibropapillomas. The tumors can spread along the perineum and even up toward the back; they can become necrotic and cause loss of reproductive functions.

BPV-4 induces fibropapillomas of the upper gastrointestinal (GI) tract. All sites form the tongue to stomach can be affected. Healthy cattles normally recover from papillomatosis in approximately one year time, but if the animals are not able to reject the tumors they are at high risk to develop cancer such as squamous cell carcinoma.

Normally, these benign lesions (papillomas and fibropapillomas) regress but some animals may even die due to widespread cutaneous or mucosal papillomatosis if they are not able to reject the infection. Progression of benign persistent lesions to cancer occur once cofactors synergize with the virus.

BPV and Cancer

One of the major environmental cofactor involved in BPV-associated carcinogenesis is the ►bracken fern (genus *Pteridium*), the only higher plant proven to cause cancer naturally in animals.

Bracken eating animals may develop cancer since the plant contains immunosuppressants as well as a number of mutagens and oncogenic principles such as ►ptaquiloside. Bracken-fed cows become chronically immunosuppressed and the latent BPV is activated. Full malignant transformation depends on others mutagens that are believed to trigger *BPV* gene expression leading to initiation and development of cancer.

Additionally, bracken eating animals develop a clinical syndrome known as chronic enzootic hematuria and chromosomal abnormalities.

Field cases of urinary bladder and GI cancers in cattle occur wherever the plant is spread. The disease is known to occur in continental Europe, Azores Islands, in some regions of Kenya, Brasil, New Zealand, India, and in China. Human exposure to bracken fern directly or indirectly through milk from bracken eating cattle has been linked to human GI cancer.

Cows affected by BPV-4-associated papillomas of the upper GI tract and naturally exposed to bracken fern are at high risk of developing carcinoma. The fern induces immunosuppression and the fibropapillomas spread, additionally the mutagens from the plant such as ►quercetin and ptaquiloside act synergistically with

the virus in the carcinogenic process. The BPV-4 E7 oncoprotein cooperates with quercetin for neoplastic transformation, in so doing the ras oncogene is activated, the p53 is mutated and the number of the cellular receptors for epidermal growth factors is increased. From a comparative point of view it is worth noting that some human GI cancer may have the same etiology: papillomavirus and bracken suggesting that similar molecular mechanisms underlying bovine cancer may even occur in humans.

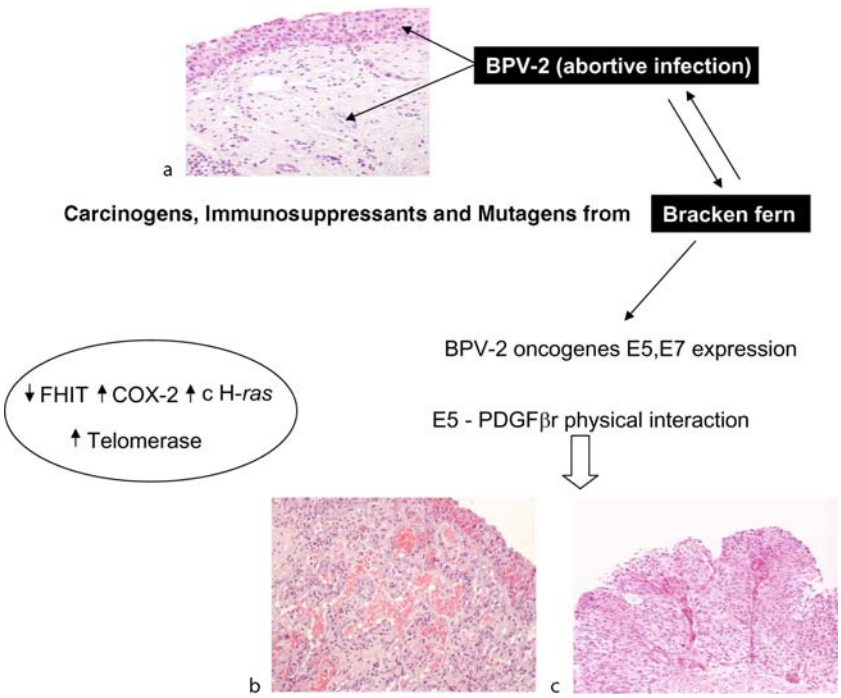
At the same time cows suffering from chronic enzootic haematuria may develop urinary ►bladder cancer. The cancer are of both epithelial and mesenchymal origin with ►hemangiosarcomas being the most frequent histotype. In both cases the BPV-2 is involved testifying that the virus is not a pure epitheliotropic agent in its natural host. The BPV-2 infects the urinary bladder mucosa inducing an abortive and latent infection with no production of virions. The exposure to immunosuppressants, mutagenic and carcinogenic principles from bracken triggers viral gene expression leading to cell transformation. In both cancers of epithelial and mesenchymal origin the BPV-2 E5 oncoprotein is expressed and is in complex with the activated form of the PDGFβ receptor. Additionally, in ►urothelial cancers the ►telomerase activity is upregulated, expression of ras and ►cyclooxygenase-2 (COX-2) is increased and, as already observed in HPV-associated ►cervical cancer, the ►fragile sites are disrupted and the expression of the tumor suppressor fragile histidine tetrads (►FHIT) is downregulated (Fig. 1).

BPV and Equine Sarcoids

The ►sarcoids are benign tumors of fibroblastic skin origin affecting horses, mules, and donkeys. They are locally invasive often occurring at sites of previous injury or scarring. Tumors can exist as single or multiple lesions in different forms. Clinically, five different types of sarcoids can be distinguished: Occult sarcoid: is an hairless circular area of the skin; Verrucous: tumors with wart-like appearance; Fibroblastic sarcoids present as a fleshy mass; Nodular sarcoids consist of firm masses lying under the skin and mixed sarcoid show a combination of features of verrucous, fibroblastic, and nodular types.

It is the most common dermatological neoplasm reported in horses. The most common sites of appearance is the skin of the head, ventral abdomen, legs, and the paragenital region.

Despite the failure to isolate any papillomavirus from the sarcoids, a large body of evidence strongly support the hypothesis that BPV is the etiological agent of this tumor.



Bovine Papillomavirus. Figure 1 Schematic representation of the multi-step carcinogenesis of bovine urinary bladder tumors. Histological sections of (a) normal bladder mucosa; (b) hemangiosarcoma; (c) papillary urothelial carcinoma.

Both BPV-1 and BPV-2 have been detected in sarcoid tumors with the BPV-1 being the predominant type. The BPV exsists as episomally and its major oncoprotein E5 is expressed, thus suggesting the viral genes are expressed.

Equine sarcoids is a biologically attractive tumor since it is the only known case of natural cross-species PV infection. Moreover, while BPV infection in cattle produce benign lesions that may regress, the sarcoids are nonpermissive for virus production, locally aggressive and nonregressing.

Cell cycle regulatory proteins are involved in the pathogenesis of equine sarcoids. P53 is stabilized in sarcoid cells being expressed in the nuclei as well as in perinuclear region, however its transactivation function is abrogated. Low levels of cell proliferation are characteristic of sarcoids with no overexpression neither of cyclin A, $p27^{kip1}$ nor of CDK-2.

The loss of p53 function and the low levels of cell proliferation indicate that sarcoid cellular and molecular pathology may not be associated with abnormal cell cycle control mechanisms.

Bowen Disease

Definition

A red patch on the mucosa that is not attributable to any obvious cause. Generally, these lesions have a well-defined border and a soft, velvet-like appearance. Their atrophic nature contributes to the red coloration, as underlying vasculature is more prominent. Around 90% show signs of severe dysplasia or carcinoma-in-situ and may progress to invasive squamous cell carcinoma.

►Squamous Cell Carcinoma

Bowman-Birk Inhibitor (BBI)

Definition

Serine protease inhibitor consisting of a single chain of 71 amino acid residues cross-linked by seven pairs of disulfide bonds and a well characterized ability to inhibit trypsin and chymotrypsin. It has been shown to be capable of preventing or suppressing carcinogenic processes in a wide variety of *in vitro* and *in vivo* animal model systems.

►Lunasin

Boyden Chambers

Definition

A hollow plastic chamber sealed at one end with a porous membrane and suspended in a well containing chemoattractants. Cells are placed inside the chamber and allowed to migrate through the pores to the other side of the membrane.

53BP

Definition

p53 Binding Protein 1, a checkpoint molecule that acts as a mediator for transducing DNA damage signals, especially following detection of DNA double-stranded breaks

Synonyms

Endocurietherapy; Radioactive seed therapy

Definition

Brachytherapy treatments deliver radiation dose using radioactive isotopes placed via applicator devices or catheters directly into tumors or into cavities in close approximation to the tumor.

Characteristics

Radiation therapy is the treatment of cancer with radiation. Radiation targets the DNA in cells and causes DNA strand breaks. Normal cells have the ability to repair the DNA damage, whereas cancer cells lack such repair mechanisms.

Brachytherapy is one method of delivering radiation. The word "brachy" is derived from Greek meaning "short." The radiation from the radioactive isotopes penetrates a short distance, allowing for conformity to a target volume or tumor while sparing the normal structures in the vicinity. The ►dose fall-off for brachytherapy sources follows the inverse square law, in that the distance traveled by the radiation is inversely proportional to the square of the radius of distance ($d = 1/r^2$).

Historically, the isotopes used for brachytherapy were radium, radon and its derivatives, and gold. In modern times, isotopes must be non-gaseous, have effective energies for treatments, be able to be encapsulated in a size that is clinically useful, and have a ►half-life either suitable for permanent implants or temporary implants (Table 1).

Dose Rate

Brachytherapy treatments can utilize different ►dose rates to treat cancer. The definitions for dose rates were defined by the International Commission on Radiation Units and Measurements Report #38. Low dose rate (LDR) is defined as a range of 0.4–2 ►Gray (Gy)/h. Medium dose rate (MDR) is a range of 2–12 Gy/h, and high dose rate (HDR) is defined as >12 Gy/h. VLDR (very low dose rate) radiation is used in permanent radioactive seed implants, at a dose rate of less than 40 cGy/h. Temporary implants are placed into the tumor/adjacent tissues in order to deliver LDR, MDR, or HDR treatments. VLDR implants typically reside permanently in the tissue implanted, but decay over the course of a few months. In the delivery of LDR or MDR radiation, the temporary implant stays in place over several hours, whereas HDR treatments usually last only a few minutes.

LDR techniques involve the static placement of radiation isotopes within the applicators for a period of time. ^{137}Cesium (^{137}Cs) for gynecologic brachytherapy or ^{192}Iridium (^{192}Ir) for ►gynecologic cancers or sarcomas are most commonly used. The radiation is either manually afterloaded by a physician or can be remotely afterloaded if a cesium selectron afterloader (for gynecologic brachytherapy) is available. HDR treatments involve a single ^{192}Ir source fixed to a wire that is guided remotely by a computer. The HDR afterloader attaches to individual applicators by transfer tubes. Computer programming determines the position of the radiation isotope within the applicator, and calculates a radiation ►isodose curve that may be manipulated by altering the dwell times. ►Dwell positions are defined along the applicators every

Brachytherapy. Table 1 Characteristics of some commonly used radioisotopes in the United States

Isotope	Half-life	Energy (MeV)
^{137}Cesium	30 years	0.66
^{192}Iridium	74 days	0.29–0.6
^{125}Iodine	60 days	0.028
^{103}Paladium	17 days	0.023

2.5–10 mm, and the isotope remains at designated dwell positions for a preset time as determined by the optimized plan. LDR radiation may have a ►radiobiological advantage over HDR radiation, as the normal tissue is more likely to be able to repair sublethal damage. Additionally, the continuous dose may prevent repopulation of the tumor cells, and the longer period of time that the cells are exposed to radiation allows the cell cycle to move through radio-resistant and radiosensitive phases. HDR radiation may lead to an increase in normal tissue toxicity if the total dose delivered compared to LDR is not decreased. It is important to fractionate the HDR radiation sufficiently and deliver as small a fraction size as feasible depending on the tissue treated, the indications for treatments and the amount of normal tissue in proximity to the source. In ►cervical cancer brachytherapy, packing the vagina can reduce the amount of normal tissue exposed to radiation.

Pulsed dose rate (PDR) brachytherapy uses an HDR afterloader and source but attempts to mimic the radiobiologic effect of LDR by giving a large number of very small fractions over a longer period of time than HDR.

Dose Calculations

Historically, the dose delivered to a treatment volume was hand-calculated, based on one of three methods of implantation. The Paris and Quimby systems place parallel sources with uniform spacing and source activity, to give a higher central dose compared with the periphery. The Paterson–Parker method utilizes higher peripheral radioactivity compared with the centers resulting in increased ►dose homogeneity throughout the implant. These methods have been replaced in several radiation oncology clinics by computer programs that utilize information gathered from imaging techniques such as CT scans to define the target volume and identify the implant geometry within that volume to calculate the dose.

Implantation Techniques

The placement of the radiation source in relation to the treatment volume is the most important determinant in the effectiveness of brachytherapy. Therefore the techniques used depend on the location of the tissue being targeted.

Surface applicators involve sculpting a radiotherapy delivery system on or around the target surface area. A superficial dose may be delivered to lesions of the skin or intraoperatively to exposed tumor beds.

Intracavitary radiation utilizes orifices within the human body to introduce applicators in close proximity to the tumor. Common examples of intracavitary radiation include gynecologic malignancies, in which the vagina, cervical os, and uterine cavity allow for the relatively easy placement of applicators. Other intracavitary treatments include the bronchus, esophagus, and rectum.

Interstitial radiation entails passing catheters through normal tissue to reach the target volume or placing tubes within a surgical bed at the time of operation.

Clinical Applications of Brachytherapy

Brachytherapy may be administered alone or in combination with external beam radiation, chemotherapy, or surgery to provide either cure or palliation for the patient. The most common uses of brachytherapy are discussed below.

Gynecologic Malignancies

The most common gynecologic malignancy treated with brachytherapy in the United States is ►endometrial cancer. Intracavitary radiation targets the vaginal vault in women thought to be at high risk of local recurrence to the vagina following definitive surgery. This treatment involves the insertion of a cylinder into the vagina (Fig. 1). LDR or HDR radiation may be used. The dose and fractionation of the radiation depend on both the dose rate and the patient's history of prior external beam radiation therapy. The dose may be prescribed at either the surface of the applicator or at a depth, typically 5 mm, from the applicator.

Cervical cancer is treated using a combination of external beam radiation with or without chemotherapy and brachytherapy, commonly referred to as a tandem and ovoid application. A central uterine tandem is placed through the cervical os into the uterine cavity. Vaginal ovoids or a vaginal ring or cylinder are secured to the central tandem (Fig. 2). Historically, cervical cancer brachytherapy was administered using LDR radiation, most commonly using tandem and ovoids placed twice with one week between treatments. In most centers, plain films assess the location of normal tissue structures; however, several radiation oncology clinics have acquired CT imaging capability, allowing for 3D imaging of the normal tissues and more accurate dose calculation. In more recent times, several centers have incorporated HDR radiation into the management of cervical cancer. HDR tandem and ovoid dose is delivered in minutes, and most commonly requires four or five separate insertions, with each treatment lasting several minutes. The HDR isodose curve approximates a standard LDR loading (Fig. 3).

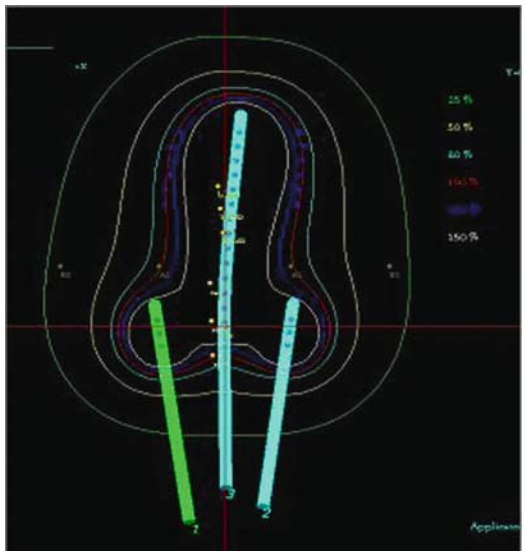
Vulvar and vaginal cancers are rare, but their treatment may involve interstitial or intracavitary radiation after external beam radiation.

Brachytherapy. Figure 1 A high dose rate vaginal cylinder is inserted into the vagina to treat the vaginal surface for patients who have had a hysterectomy for uterine or cervical cancer. The applicator is attached to a brachytherapy board for stabilization.

Brachytherapy. Figure 2 Low dose rate Fletcher–Suit–Delclos tandem and ovoid applicator will be loaded with ^{137}Cs. The central tandem is inserted into the uterus. The ovoids may have plastic caps placed over them in order to fill the vaginal fornices. A flange rests outside the external os of the cervix. The apparatus is held in place by vaginal packing.

►Prostate Cancer

Brachytherapy in prostate cancer may be the sole treatment for low-risk disease or in combination with external beam radiation as a form of dose escalation. VLDR brachytherapy places permanent radioactive seeds of either ^{125}I or ^{103}Pd into the prostate through the perineal skin, under image guidance and using catheters. The seeds remain permanently within the prostate and deliver a low dose of radiation continuously until they have decayed. HDR brachytherapy for prostate cancer is currently being investigated in research protocols.



Brachytherapy. Figure 3 High dose rate tandem and ovoid isodose curve demonstrates the 100% isodose line optimized to point A, a point 2 cm above and lateral to the cervical os.

Other

Other cancers that can be treated with brachytherapy as part of combined care include head and neck cancers, including nasopharynx and tongue, breast cancers, sarcomas, thoracics and some gastrointestinal cancers.

Definition

B-Raf signaling comprises the activation of the proto-oncogene product B-Raf and its downstream effectors and represents a key regulatory step in the activation of the canonical ►MAP kinase pathway by various extracellular stimuli and oncogene products such as ►RAS and activated receptor tyrosine kinases like ►NTRK and ►RET. Aberrant B-Raf activity as a result of somatic mutations is observed in 8% of human cancers.

Characteristics

Physiological Aspects of B-Raf Signaling

B-Raf is a member of the ►Raf kinase family and represents an important component of the Ras/Raf/MEK/ERK MAP kinase signal transduction pathway, which plays a pivotal role in growth control and differentiation. Dysregulation of this pathway is observed in about 30% of human tumors and represents an established mechanism for tumorigenesis. In their role as gatekeepers of this pathway, Raf-kinases appear as attractive targets for therapeutic intervention. The Raf-family contains three genes in vertebrates, A-Raf, B-Raf and Raf-1 as well as D-Raf and LIN-45 in *Drosophila* und *Caenorhabditis*, respectively. While the *RAF1* gene displays a ubiquitous and prominent expression pattern, B-Raf is predominantly expressed in neuro-ectoderm derived tissues, placenta, the hematopoietic system and the testis. However, gene targeting experiments in mice and ►DT40 B cells revealed that B-Raf represents the major ERK activator, even if it is expressed at barely detectable levels, whereas Raf-1 serves as an accessory ERK activator. Among the three mammalian isoforms, B-Raf displays the highest affinity towards its substrate MEK and has the highest activities in biological and ►*in vitro* kinase assays. In many cell types, B-Raf plays a non-redundant role in the maintenance of ERK signaling induced by various extracellular signals and thereby regulates directly, or in concert with other signaling pathways, the expression of important target gene products such as growth factors and cytokines. The importance of B-Raf for the efficient expression of ERK-regulated target gene products is most likely

explained by the fact that ERK activation is not only required for the induction of ►immediate early genes transcription, but also for the stabilization of the resulting proteins by phosphorylation through sustained ERK signaling. The correlation between B-Raf expression and sustained ERK signaling has been implicated in various physiological processes such as lymphocyte activation, myelopoiesis, angiogenesis, development of extra-embryonic tissues as well as for the growth-factor-mediated survival of neurons and their effector functions. The discovery of germ-line mutations with mostly slight to moderate gain-of-function character in the *SOS*, *KRAS*, *HRAS*, *SHP2/PTPN11*, *BRAF* and *MEK1/2* genes in patients suffering from the various ►neuro-cardio-facial-cutaneous syndromes illustrates that tight control of this pathway upstream or at the level of the B-Raf/MEK interface is key to the normal development and homeostasis of many organs.

B-Raf Signaling and Tumor Development

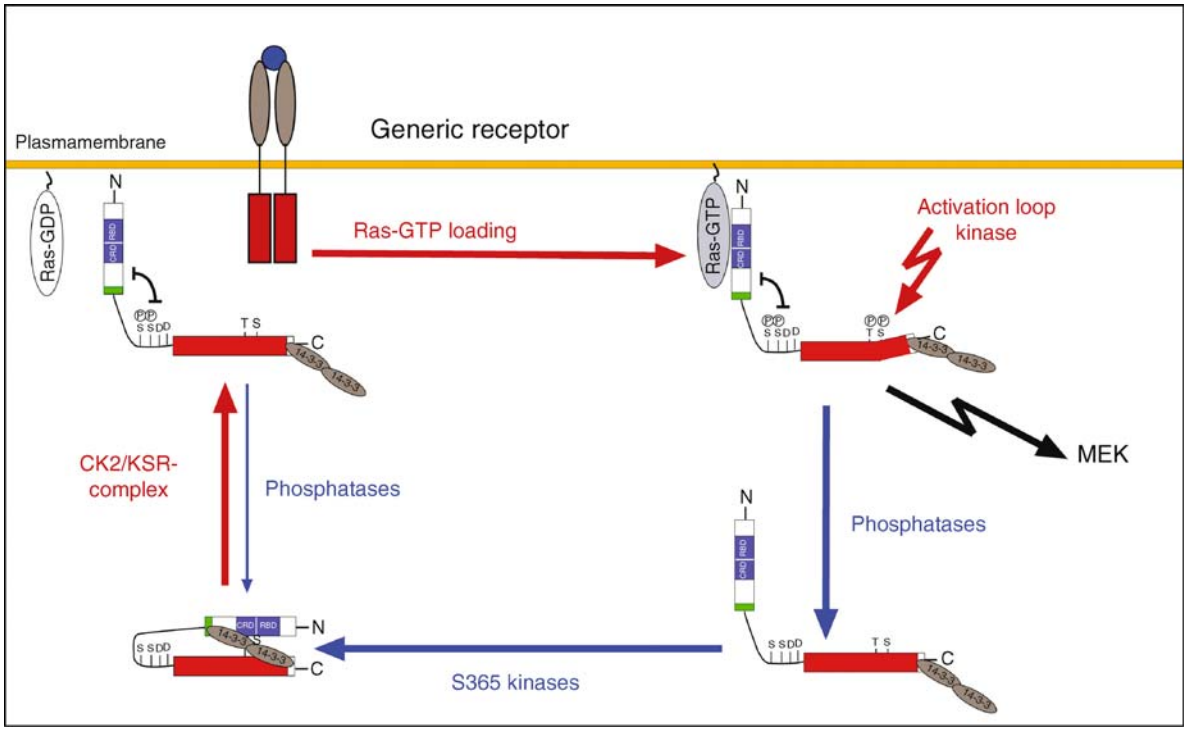
The high biological relevance of B-Raf is also reflected in the discovery that ►somatic alterations of the *BRAF* gene occur in about 8% of all human tumors with particular high frequencies in ►melanoma (70%), ovarian (30%), thyroid (27%), colorectal and biliary tract carcinoma (both 15%). Many of the resulting mutant B-Raf proteins cause chronic ERK activation and transform a variety of cell types *in vitro*. Furthermore, the B-Raf^{V600E} oncoprotein, which is the most frequently found mutant and occurs in 7% of human tumors, induces neoplasms in transgenic mice and zebrafish. Apart from their established role as ERK activators, B-Raf^{V600E} and other oncogenic mutants have been shown to activate the ►NF-κB pathway, although the exact mechanism for this oncologically relevant aspect of B-Raf sigaling remains elusive.

Dysregulated B-Raf signaling in the absence of any *BRAF* mutations has been also implicated in various neoplastic diseases. For example, hyper-activation of wild type B-Raf has been observed in ►Polycystic Kidney Disease. Similarly, over-expression and de-regulation of B-Raf have been implicated in ►Kaposi Sarcoma. Likewise, amplification and/or overexpression of the *BRAF* gene were described as alternative events to *BRAF* mutations in melanoma. Furthermore, B-Raf serves as an important signal transducer of upstream oncogene products such as RAS or activated receptor tyrosine kinases (RTKs) such as ►RET, ►NTRK, ►Epidermal Growth Factor Receptor family members or the ►Kit/Stem cell factor receptor. In many cell types where the chronic activation of the RAF/MEK/ERK effector arm by these oncoproteins represents a major mechanism of cellular transformation, a mutual exclusivity is observed between mutations in *BRAF* or genes encoding its upstream activators. For example, gain-of-function mutations in either the ►*RET*, ►NTRK, ►*RAS* or *BRAF* proto-oncogenes account for 70% of papillary thyroid carcinoma and provoke similar transformed phenotypes indicating that the activation of B-Raf effectors such as ERK and NF-κB is a major driving force in thyrocyte transformation. Similar constellations have been described for *RAS* and *BRAF* in melanoma, colorectal and ovarian carcinoma. However, Ras and B-Raf transformed cells differ in their responsiveness to MEK-inhibitors showing that both oncoproteins, while having a large group of effectors in common, also trigger ►oncogene addiction through distinct mechanisms. Oncogenic B-Raf not only mimics growth factor signaling, but also induces a variety of auto- and paracrine acting growth factors itself, e.g. ►Heparin-Binding Epidermal Growth factor (EGF)-Like Growth Factor, chemokines and pro-inflammatory and angiogenic cytokines like ►Vascular Endothelial Growth Factor A. Apart from tumor initiation, tissue culture experiments suggest that oncogenic B-Raf also contributes to tumor progression by inducing two additional key events in metastasis: the ►Epithelial to Mesenchymal Transition of the oncogene-bearing cell and the ►angiogenic switch in its environment through the aforementioned growth factors and cytokines.

Aberrant B-Raf activity does not necessarily result in tumorigenesis unless profound changes in the regulatory network underlying cell cycle control have occurred. Through the ERK and NF-κB pathways, oncogenic B-Raf stimulates not only the production of positive cell cycle regulators such as Cyclin D1, but also induces negative regulators such as cyclin-dependent kinase inhibitors like p16^{INK4A}. Consequently, chronic B-Raf/ERK signaling ultimately results in cell cycle arrest and cellular ►senescence. For example, melanocytes with an intact cell cycle control program become growth arrested by chronic B-Raf signaling and develop only into benign nevi. However, if important negative cell cycle regulators and tumor suppressor genes like ►INK4A or ►p53 are lost, oncogenic B-Raf signaling will trigger cell cycle progression and drive tumor development.

B-Raf Structure and Regulation

Like many other protein kinases, B-Raf is part of a large multi-protein complex or ►signalosome in which the individual components regulate B-Raf conformation and activity through various protein-protein interactions in a dynamic spatio-temporal manner. Key to the understanding of the (dys-)regulation of B-Raf is the knowledge of its modular structure. B-Raf shares three highly conserved regions (CR) with the other members of the Raf-family (Fig. 1): the N-terminal CR1 contains the Ras-GTP binding domain, which initiates the interaction with activated Ras, and the Cystein-rich domain involved in the stabilization of



B-Raf Signaling. Figure 1 Model of the B-Raf activation cycle. B-Raf contains three conserved regions: CR1 (blue) consisting of the Ras-binding domain (RBD) and the Cystein-rich domain (CRD), CR2 (green) and the kinase domain CR3 (blue). Inactive B-Raf resides in the cytoplasm in a closed, inactive conformation stabilized by 14-3-3. Interaction of B-Raf with a complex consisting of CK2 and the scaffold protein KSR results in phosphorylation of S446 (and perhaps S447) in the N-region thereby transferring B-Raf into a more open conformation. The constitutive basal phosphorylation of B-Raf at S446 suggests that a large fraction of B-Raf resides in this primed state. Interaction with activated Ras (Ras-GTP) leads to phosphorylation of T599 and S602 within the activation loop, which induces a conformational change within the CR3 and renders B-Raf active. B-Raf is supposedly inactivated by phosphatases, re-phosphorylation of the inhibitory residue S365 and transition into the closed conformation.

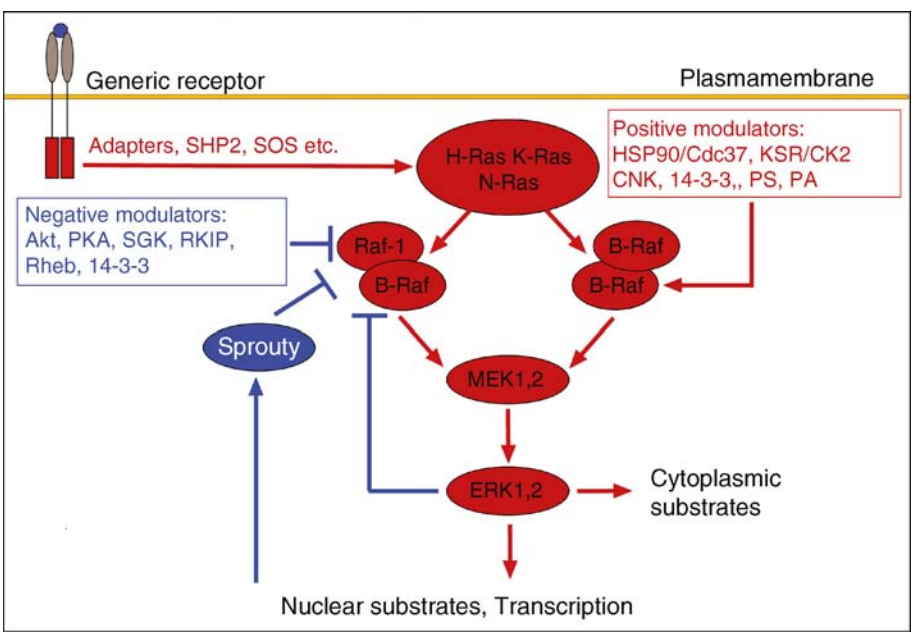
Ras/Raf interaction. The CR2 contains a negative regulatory serine residue (S365) that serves as a binding site for ►14-3-3 proteins upon phosphorylation by ►Akt and other kinases. The catalytic domain (CR3) harbors phosphorylation sites for Raf-regulating enzymes within two segments, the N-region and the ►activation loop. B-Raf carries a second 14-3-3 binding motif around S729 at the C-terminal end of the CR3 domain, which is essential to couple B-Raf to its downstream effector MEK.

Similar to the better-characterized Raf-1 isoform, B-Raf is activated by its interaction with small GTPases of the RAS family. Although no crystal structure for any of the full-length Raf-proteins is available, various experimental approaches imply that Raf activation is accompanied by a transition from a closed, auto-inhibited into an open, active conformation in which the N-terminal lobe consisting of the CR1 and CR2 domains is displaced from the C-terminal lobe encompassing the CR3 (Fig. 1). The degree of auto-inhibition of B-Raf is influenced by the inclusion/exclusion of amino acid sequences within the linker region between N- and C-terminal lobe, which are encoded by alternatively spliced, tissue-specific exons and various phosphorylation events. Among the latter, two phosphorylation sites within the CR3, the N-region and the activation loop, are of particular importance (Fig. 1). The introduction of negative charges into the N-region, which is located at the N-terminal end of the CR3 domain, plays a critical, multi-faceted role in Raf activation. While the N-region of Raf-1 is charged through phosphorylation of its $S^{338}SYY^{341}$-sequence in a RAS-dependent manner by Ser/Thr- and Tyr-kinases, the equivalent serine residues within the N-region of B-Raf ($S^{446}SDD^{449}$-motif) are phosphorylated in a constitutive and RAS-independent manner (Fig. 1). Although structural data are still missing, several lines of evidence propose that N-region phosphorylation primes B-Raf for activation at the membrane by reducing the affinity between N-terminal and C-terminal lobe. The significance of the aspartate residues, which are the functional equivalents of the phosphotyrosine residues in the SSYY-sequence of Raf-1, is

twofold: firstly the negative charge of the aspartate residues are supposed to prime B-Raf for N-region phosphorylation by Casein Kinase 2 (CK2). Secondly, the D448 residue stabilizes the conformation of activated B-Raf through the formation of a salt-bridge with R506 within the αC-helix of the CR3. The important role of the SSDD-sequence is highlighted by the fact that mutation of the serine and/or aspartate residues results in drastic reduction of the basal *in vitro* kinase and biological activities. Furthermore, it has been suggested that the different mechanisms that supply the N-region of B-Raf and Raf-1 with negative charges, account not only for the aforementioned isoform-specific differences in the enzymatic, biological and transforming activities, but also predispose the *BRAF* gene for oncogenic hits. However, while tissue culture experiments demonstrated that the rare B-Raf^{E586K} mutant indeed requires an intact SSDD-sequence to induce MEK/ERK activation and oncogenic transformation, the biological activity of the most frequently found mutant, B-Raf^{V600E}, is not affected by N-region neutralization, at least not in experimental approaches involving the ectopic expression of this oncoprotein.

The interaction with Ras recruits B-Raf to the plasma membrane followed by the phosphorylation of the activation loop residues T599 and S602 (Fig. 2). This phosphorylation event presumably leads to the dislocation of the activation loop relative to the overall catalytic domain thereby resulting in full B-Raf activity. The importance of the activation segment phosphorylation is established by the fact that mutation of these phosphorylation sites to alanine residues renders B-Raf resistant to extracellular signals and even to strong activators like oncogenic Ras^{G12V}. Conversely, mutations that mimic the phosphorylation-induced dislocation of the activation segment, such as *BRAF*^{V600E}, lock B-Raf in an active conformation and confer high constitutive enzymatic and transforming activities to B-Raf independent of RAS. Consequently, these activation loop mutations are frequently found as somatic alterations of the *BRAF* gene in human tumors.

Intracellular B-Raf activity is also regulated by the phosphorylation-dependent recruitment of ▶14-3-3 proteins in an opposing manner (Fig. 1). Binding of 14-3-3 proteins to phospho-S729 at the C-Terminus of B-Raf is essential to couple B-Raf to the MEK/ERK pathway. In contrast, phosphorylation of S365 within the CR2 by Protein kinases A, Akt or Serum-and-Glucocorticoid-induced kinase (SGK) generates a second binding site for 14-3-3 proteins, which negatively regulates B-Raf activity, most likely through the



B-Raf Signaling. Figure 2 Modulation of B-Raf signaling. Extracellular signals received by various receptor classes trigger the activation of Ras-GTPases by stimulating their loading with GTP. Activated Ras not only recruits B-Raf and promotes its phosphorylation by unknown activation loop kinases, but also stimulates its homo- and hetero-dimerisation. The activity of B-Raf (and Raf-1) is fine tuned by a multitude of positive and negative modulators. The longevity of B-Raf/Raf-1 heterodimers is determined by a rapid negative feedback loop from ERK. In a delayed negative feedback loop, sustained B-Raf/ERK signaling also induces the transcription of Sprouty-2, a negative regulator of B-Raf.

stabilization of the auto-inhibited conformation through the simultaneous binding of the 14-3-3 dimer to S365 and S729 (Figs. 1 and 2). 14-3-3 proteins are also involved in the RAS-stimulated formation of homo-dimers of B-Raf and its hetero-dimerisation with Raf-1 (Fig. 2). Indeed, B-Raf/Raf-1 hetero-dimers represent the most potent form of Raf-activity within the cell. Activated ERK limits the longevity of these dimers by targeting an evolutionary conserved phosphorylation motif at the C-terminus of B-Raf (Fig. 2). In addition, B-Raf activity is modulated by other components of the signalosome such as the ►HSP90/Cdc37 chaperone complex and ►scaffold proteins like Kinase-suppressor-of-Ras (KSR) and Connector-and-enhancer-of-KSR (CNK). Membrane phospholipids such as phosphatidylserine (PS) and phosphatidic acid (PA) are also discussed as important regulators of Raf activation. B-Raf is also negatively regulated by Sprouty-2 and Raf-kinase-inhibitory protein (RKIP), two proteins, which are both often down-regulated in human cancer raising the possibility that their epigenetic silencing represents an alternative mechanism to gain-of-function mutations in genes linked to the Ras/Raf/MEK/ERK pathway in human cancer. Similarly, B-Raf^{V600E} and other activation loop mutants are incapable of interacting with Sprouty demonstrating that the V600E mutation not only uncouples B-Raf from positive (interaction with Ras, N-region and activation loop phosphorylation) but also negative regulatory mechanisms.

B-Raf as a Therapeutic Target

The growing importance of B-Raf in tumor biology has fostered the development of therapeutic strategies aiming at either reducing the expression or activity of B-Raf or its downstream effector MEK. Various MEK inhibitors are currently in clinical trials and experiments in tissue culture and xenograft models indicate that tumor cells harboring the *BRAF*^{V600E} mutation, but not those with RAS mutations, are highly "addicted" to ERK activity and are consequently particularly sensitive towards MEK inhibition. Similar results have been obtained in experiments in which the expression of B-Raf^{V600E} but not of wild type B-Raf was specifically abolished by allele-specific ►RNA interference illustrating the importance of this oncoprotein for the maintenance of the tumor phenotype. Recent strategies also target B-Raf directly. The orally available multi-kinase inhibitor BAY 43-9006 (also known as Sorafenib or Nexavar), which was originally designed to block Raf-1, inhibits B-Raf as well as several receptor tyrosine kinases (RTKs) involved in neo-angiogenesis and tumor progression. However, it is assumed that the inhibition of the latter kinase class or the simultaneous inhibition of several kinases, rather than the inhibition of Raf itself, is responsible for the anti-tumor activity of BAY 43-9006, in particular in renal cell carcinoma. A third approach employs the requirement of the HSP90/Cdc37 chaperone complex for the stability of B-Raf. In this regard, the HSP90 inhibitor ►Geldanamycin was shown to trigger the degradation of B-Raf by disrupting its association with the HSP90/Cdc37 chaperone complex. The stability of most activated B-Raf mutants, including B-Raf^{V600E}, appears to be more reliant on the chaperone complex than those of wild type B-Raf suggesting that tumor cells driven by *BRAF* mutations will be particularly sensitive to Geldanamycin.

B-Raf Somatic Alterations

Tilman Brummer
Cancer Research Program, Garvan Institute of Medical Research, Sydney, NSW, Australia

Definition

Somatic alterations of the *BRAF* gene in cancer, either caused by point mutation or genomic rearrangement of the *BRAF* proto-oncogene.

Characteristics

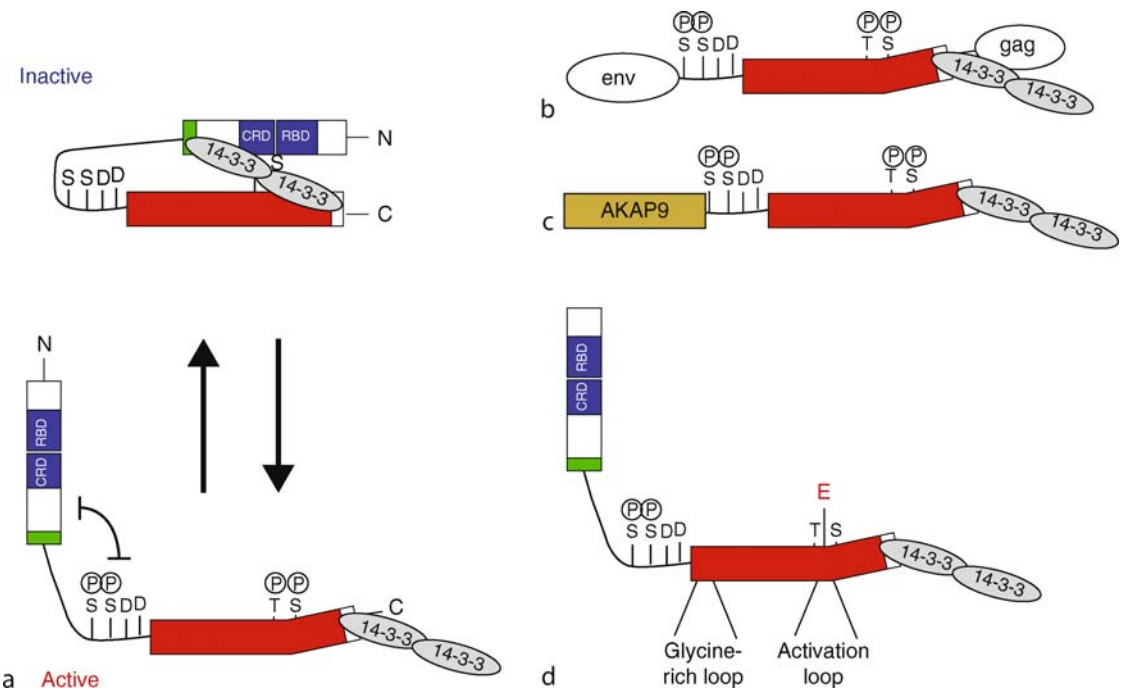
The Ser/Thr-kinase B-Raf, a product of the human *BRAF* proto-oncogene, plays a pivotal role in the activation of the classical ►ERK/MAP kinase pathway that is involved in the control of proliferation and differentiation of various tissues. Consequently, alterations of the expression level or the activity of B-Raf are associated with malignancies like ►polycystic kidney disease and various cancers. Proto-oncogenes can be converted into oncogenes by point mutations, amplifications, genomic rearrangement, e.g. translocation or inversion, or by retroviral transduction. Interestingly, all four mechanisms of oncogene activation have

been documented for the *BRAF* genes in human and/or animal tumors.

History of the *BRAF* Proto-Oncogene

The discovery of the *raf*-oncogenes originates back to the isolation of the chicken Mill Hill 2 (MH2) retrovirus by Begg in 1927. Genetic studies in the 1980s demonstrated that MH2 contains two unrelated retroviral oncogenes that were designated as v-*myc* and v-*mil*. Subsequent analysis of v-*mil* revealed a high sequence homology to the v-*raf* oncogene of the murine sarcoma retrovirus 3611. Further analyses showed that both v-*mil* and v-*raf* arose independently by retroviral transduction from the chicken c-*mil* and mammalian *raf*-1 genes, respectively. In 1988, a v-*mil* related oncogene was discovered in ►transforming retroviruses that were generated by passaging the non-oncogenic Rous-associated virus type 1 (RAV-1) on embryonic chicken neuroretina cells. Due to its origin in retinal cultures, this relative of v-*mil* was designated as v-R*mil*. Subsequent studies showed that v-R*mil* was generated by retroviral transduction from the proto-oncogene c-R*mil*, which is related but distinct to the c-*mil*/*raf*-1 proto-oncogenes and represents the avian ►orthologue of *BRAF*. Similar to the avian c-R*mil*/B-*raf* gene, the *BRAF* genes of other vertebrates display a conserved exon/intron structure with 18–20 coding exons, in which the first eight exons encode the N-terminal autoinhibitory region (Fig. 1a).

At the same time as v-R*mil* was discovered, the human *BRAF* oncogene was identified in a ►NIH3T3 transformation assay using ►Ewing sarcoma DNA. Importantly and in striking analogy to v-Mil and v-Raf, both the v-Rmil and the B-Raf oncoprotein from the Ewing sarcoma isolate represent N-terminally truncated B-Raf proteins (Fig. 1b), which have lost the N-terminal regulatory lobe and consequently the ability for auto-inhibition (►B-Raf signaling). Therefore, all these Raf-oncoproteins display constitutive activity and induce chronic activation of the ERK pathway. Thus, loss of exons encoding for the auto-inhibitory N-terminal moiety is a common mechanism of oncogenic activation of *raf* proto-oncogenes. This notion is further supported by recent experiments showing that the



B-Raf Somatic Alterations. Figure 1 B-Raf oncoproteins. (a) Situation for wildtype B-Raf. In its inactive state, the *BRAF* proto-oncogene product resides in a closed conformation stabilized by 14-3-3 proteins. Activation of B-Raf by activated RAS results in a displacement of the N-terminal auto-inhibitory region (Conserved region (CR) 1 in blue, CR2 in green) from the CR3 or kinase domain (red) allowing access of the activation loop kinase to the the TVKS-motif. Phosphorylation of T599 and S602 within this motif renders B-Raf active. (►B-Raf signaling). (b) Schematic representation of v-Rmil. Due to the retroviral transduction event, the genome of RAV encodes for a fusion protein flanking the B-Raf (CR3) kinase domain with an N-terminal portion encoded by the *env* gene and a C-terminal moiety encoded by a portion of the *gag* gene. Both the *env* and *gag* genes are integral components of retroviral genomes. (c) Schematic representation of AKAP9-B-Raf. (d) Schematic representation of B-Raf proteins with point mutations as exemplified for the activation loop mutant B-Raf^{V600E}.

murine *Braf* gene represents a frequent integration point for the *Sleeping Beauty* transposon. All transposon integrations were observed between exons 9 and 10 resulting in a disruption of the coding sequence of full-length B-Raf and expression of an N-terminally truncated B-Raf protein with an intact kinase domain and structural similarity to v-Rmil and v-Raf. However, it should be mentioned that neither retroviral B-Raf oncogenes nor transposon-mediated oncogenic activation of the *BRAF* gene have been observed in human beings. Likewise N-terminal truncations of B-Raf like those found in the original publication on the human B-Raf gene, which most likely represents a transfection artifact, have not been found in human tumors until recently. Nevertheless, the human *BRAF* proto-oncogene is affected by somatic alteration in about 7% of human tumors. The following alterations are observed in human tumors:

Chromosomal Aberrations

A recent study has identified an oncogenic BRAF allele in about 11% of papillary thyroid carcinomas (PTC) in children and adolescents that had been exposed to radiation following the Chernobyl nuclear power plant station accident in 1986. This oncogene was generated *via* a paracentric inversion of the *BRAF* locus on chromosome 7q34 resulting in an in-frame fusion with exons 1–8 of the *A-kinase anchor protein* 9 (*AKAP*9) gene on 7q21-22. The resulting AKAP9-B-Raf fusion protein is made up by exons 1–8 of *AKAP*9 and exons 9–18 of *BRAF*. Thus, this AKAP9-B-Raf protein contains an intact kinase domain, but the auto-inhibitory N-terminal regulatory domain of B-Raf is replaced by the AKAP9 moiety, which cannot confer autoinhibition (Fig. 1c). Consequently, the activity of this fusion protein is, similar to the situation in v-Rmil, unrestrained and able to transform NIH3T3 cells. Interestingly these mutations were only found in tumors that had developed within a short latency period suggesting that this chromosomal aberration is a driver of radiation induced PTC rather than being a secondary event.

Another recent study has reported the occurrence of chromosomal translocations involving the human *BRAF* gene in two cases of large congenital melanocytic nevi, which can progress into malignant melanoma. In both cases and similar to the situation of the AKAP9-B-Raf fusion protein, these translocations give rise to fusion proteins, which lack the exons encoding the auto-inhibitory N-terminal regulatory domain, but again contain an intact B-Raf kinase domain.

Somatic and Germ-Line Point Mutations

Although Raf proteins were implicated early on as important effectors of human oncoproteins, e.g. Ras, they were not considered as frequent mutational targets in cancer. In 2002, however, the ►cancer genome project (CGP) reported a high frequency of somatic point mutations in the human *BRAF* gene in malignant melanoma (27–70%). Subsequent studies also revealed high point mutation frequencies in thyroid (36–53%), ovarian (30%), biliary (14%) and colorectal cancer (522%) and lower frequencies in a wide range of other human tumors. It is estimated that the human *BRAF* gene bears somatic mutations in about 7% of all human cancers. In contrast to the aforementioned alterations of the *BRAF* gene, these point mutations do not affect the overall primary structure of B-Raf (Fig. 1d), but mostly bypass critical regulatory events required for the activation of wildtype B-Raf (►B-Raf signaling).

While mutations in the human *CRAF* gene are still considered as a very rare event, over 40 different somatic mutations, involving 24 different codons, have been identified in *BRAF* since 2002. Most alterations represent point mutations, however, codon deletions or in-frame insertions have been occasionally identified as well. A detailed overview on these mutations can be found on the CGP homepage (http://www.sanger.ac.uk/perl/genetics/CGP/cgp_viewer?action =gene&ln=BRAF). Most mutations cluster within the activation loop codons and, to a lesser extent, within the nucleotide sequence encoding the glycine-rich loop (also known as P-loop; Fig. 1d). Among the activation segment mutations, the thymidine to adenine transversion at nucleotide 1799, which results in the substitution of valine 600 within the $T^{599}V^{600}KS^{602}$-motif in the activation segment by glutamate, represents the most common mutation and is found in 6% of human cancers. Structural analysis of the B-Raf kinase domain suggests that the inactive conformation of B-Raf is stabilized by a hydrophobic interaction between the activation loop residues with the glycine rich loop, with V600 and F467 playing key roles in this process. Upon activation of wildtype B-Raf by activated Ras, T599 and S602 in the activation loop become phosphorylated by an unknown kinase resulting in the disruption of the inhibitory hydrophobic interaction between the activation and glycine rich loop and consequently full activation of B-Raf (Fig. 1a). In a similar way, any mutation in either the activation or glycine-rich loop mutation that disrupts this hydrophobic interaction, e.g. replacement of V600 by bulky and/or charged amino acids like glutamate, mimics the activated state and confers constitutive activity to B-Raf. As described in ►B-Raf signaling, the current model of B-Raf activation proposes a sequence of positive regulatory events leading to a relief of auto-inhibition by the N-terminal lobe followed by activation loop phosphorylation and full B-Raf activation. According to this sequential model of B-Raf activation, the V600E mutation not only bypasses these events, but is also

able to counteract auto-inhibition, which would explain why this mutation is so frequently found in tumors driven by chronic ►B-Raf signaling. However, why the V600E mutation occurs more frequently than any other activation loop or glycine-rich loop mutations that would also disrupt the inactive conformation, remains controversial. The V600E codon might represent a mutational "hotspot" or, due to still unknown details of B-Raf activation, might be an extremely efficient oncogene that subjects B-Raf^{V600E} expressing cells to a particularly strong positive selection. It should be also mentioned that the occurrence of the *BRAF*^{V600E} allele in colorectal cancer is correlated with ►microsatellite instability (MSI) and widespread methylation of CpG islands in a highly statistically significant manner. However, it remains to be clarified as to whether the MSI phenotype that is caused by absence or hypo-activity of DNA mismatch repair genes and is characterized by a widespread methylation of CpG islands, reflects a cause or a consequence of dysregulated B-Raf signaling.

In 2006, germ-line mutations in the human *BRAF* gene were found in patients suffering from the ►cardio-facial-cutaneous (CFC) syndrome. Some of these mostly gain-of-function mutations in CFC patients are also found in cancer, however, mutations conferring high activity to B-Raf such as *BRAF*^{V600E} have not been found. Indeed, *knock-in* experiments in mice have shown that ubiquitous expression of B-Raf^{V600E} confers early embryonic lethality suggesting that high levels of chronic B-Raf activity would not be tolerated during human development as well.

However, it should be noted that not all of the point mutations found in cancer or CFC patients represent obvious gain-of-function mutations as some of them actually display impaired *in vitro* kinase activity. Nevertheless, these impaired activity mutants still appear to activate the ERK pathway within the cell, either through stimulating the activity of Raf-1 in Raf-1/B-Raf heterodimers or, potentially, by acting as a buffer against negative regulators, e.g. RKIP, or negative feedback loops controlling ►B-Raf signaling.

Amplification

Amplification of the *BRAF* locus is another mechanism contributing to elevated B-Raf protein expression and activity. Studies in malignant melanoma have described the amplification of *BRAF* alleles with point mutations such as V600E at the expense of the wildtype *BRAF* allele.

Genetic experiments have identified B-Raf as an important factor for ERK activation under basal and steady state conditions (►B-Raf signaling). Experiments in various cell types have shown that increasing levels of wildtype B-Raf enhanced basal and steady state ERK signaling suggesting that over-expression of endogenous wildtype B-Raf might contribute to tumorigenesis. Indeed, amplification of the *BRAF* locus in the absence of any mutations in exon11 (Gly-rich loop) and exon 15 (activation loop) was described as an important contributor to the proliferation of malignant melanoma cell lines.

Definition

Primary ►brain tumors present most commonly as ►meningioma or various grades of ►astrocytoma. ►Gliomas constitute 78% of all malignant brain and central nervous system tumors. It is estimated that ~20,500 individuals will be diagnosed with cancer of the brain and nervous system in 2007, or about 1.4% of all newly occurring malignancies. Of those diagnosed, there will be 10% more men than women. Primary brain and nervous system cancers will account for 2.3% of the estimated 560,000 cancer deaths in 2007. Based on the most recent report of the Central Brain Tumor Registry of the United States, benign tumors of the CNS arise in numbers comparable to malignant brain tumors. In children and young adults, brain tumors are responsible for 25% of all cancer-related deaths, second only to leukemia in this age group. The estimated 5-year relative survival rate for malignant brain tumors is 29%, but there is much variation in survival, depending on tumor histology. The 5-year survival rate exceeds 91% for pilocytic astrocytomas, but is less than 4% for glioblastomas. Generally, survival decreases with increasing age at diagnosis.

Characteristics

Classification and Pathology

The cell of origin of commonly occurring brain tumors is not known, although recent evidence suggests that these tumors arise either from ►neural stem cells or from other cells that take on many characteristics of neural stem cells as a result of malignant transformation caused by the activation of oncogenes and the inactivation of ►tumor suppressor genes within the cells. Pathologically, these tumors are classified according to the World Health Organization (WHO) nomenclature and grading criteria. Tumors that share cytologic and histologic evidence of astrocytic differentiation are known as ►astrocytoma and are the most frequent primary intracranial neoplasms. Their neuropathological appearance is highly variable. Tumors with evidence of oligodendroglial differentiation are known as ►oligodendroglioma. Some tumors that have cells reminiscent of both lineages are known as ►mixed oligo-astrocytomas. Each of these tumor types can be graded histologically according to a four-tiered system of increasing malignancy from Grades I through IV. Grade I, for example, has an excellent prognosis following surgical excision, and Grade IV, ►glioblastoma multiforme, has multiple features of clinical aggressiveness and is typically incurable. Hypercellularity with evidence of high mitotic activity, nuclear and cytoplasmic atypia, endothelial proliferation, and necrosis correspond closely to tumor virulence and are most characteristically present in Grade IV tumors. The overwhelming majority of gliomas arising in adults are high-grade and arise in a supratentorial location. High-grade tumors do not have a clear margin separating neoplastic and normal tissue. This finding is consistent with the observation that tumor cells usually have infiltrated adjacent normal brain by the time of diagnosis, when complete resection is oftentimes not possible. Tumor cells capable of initiating new tumor foci can now be recognized as tumor stem cells.

Cytogenetic examination of chromosomes within the cells of a ►brain tumor has revealed characteristic regions that tend to be altered in specific tumor types (Table 1). Frequent sites for chromosomal DNA loss in astrocytic tumors include chromosomes 17p, 13q, and 9. In oligodendroglioma, DNA from 1p and 19q is frequently lost, and in ►meningiomas, 22q is often lost. Molecular genetic analysis can also reveal evidence of tumor-specific genetic alterations at sites where chromosomes appear normal upon cytogenetic

Brain Tumors. Table 1 Cytogenetic and genetic alterations in brain tumors

Tumor type	Chromosomal alteration	Genetic changes	
		Oncogene	Tumor suppressor gene
Astrocytoma	$1p^{-}$, 7^{+}, $9p^{-}$, de110, $11p^{-}$, $12q^{-}$, $12q^{+}$, $13q^{-}$, $13q^{+}$, $18p^{+}$, $17p^{-}$, $17q^{-}$, $19p^{-}$, $19q^{-}$, $22q^{-}$, DMs[a]	*EGFR, PDGFRA, KIT, CROS, MET, CDK4, NEU, RAS, MDM2, GLI, CMYC*	*P53, RB1, NF1, PTEN, DMBT, CDKN2A, CDKN2D, RASSF1A*

analysis. Using a variety of molecular technologies, it has been possible to document the alteration of many different genes in brain tumors, particularly astrocytic tumors (Table 1).

While the particular constellation of genetic alterations that activate oncogenes and inactivate tumor suppressor genes varies among individual brain tumors that appear to be histologically indistinguishable, an accumulation of mutations is typically associated with increasingly aggressive malignant behavior. Glioblastoma multiforme (►GBM) typically presents without evidence of a precursor lesion, referred to as de novo or primary GBM. These tumors typically have evidence for chromosome 10 deletions in the region where the tumor suppressor ►*PTEN* is known to be located, and activation of the ►epidermal growth factor receptor (►*EGFR*) gene either by amplification or deletion of ~275 amino acids from the extracellular domain of the receptor. This and closely related mutations occur in ~60% of GBM. *EGFR* is the gene most frequently activated in malignant astrocytomas. *EGFR* amplification and activation by mutation occurs in ~5% of low-grade astrocytomas and about 30% of GBM, indicating that this molecular change is principally associated with the progression from low- or intermediate-grade neoplasia to high-grade astrocytic neoplasia. In fewer than 20% of cases, GBM arises in association with progressive genetic alterations after the diagnosis of a lower-grade astrocytoma. These tumors are referred to as secondary GBMs. The most widely described alterations are amplification or overexpression of the ►*PDGF* receptor, mutations of ►*p53* or ►*MDM2* and ►*INK4a*, and loss of *PTEN* (Table 1). Deletion of the ►*CDKN2* gene, which encodes the cyclin-dependent kinase inhibitor *p16*, has been reported to occur in ~40–70% of glioblastoma. The ►*RB1* tumor suppressor gene is homozygously deleted or mutated in about 30% of high-grade gliomas.

The protein products of tumor suppressor genes are proteins that act to regulate or suppress cell growth or promote cell death. These genes are inactivated during tumorigenesis, and several such genes have been implicated in the development of astrocytoma. Occasionally, inactivation of one of these alleles in the germline can occur without disturbing development, and patients who carry germline mutations of some tumor suppressor genes can be predisposed to the development of cancer. Several inherited cancer-predisposition syndromes are known to be associated with the development of different brain tumors. Patients with ►Li-Fraumeni syndrome, caused by an inherited constitutional *p53* mutation, have a predisposition for the development of brain tumors. The *p53* gene, located on chromosome *17p*, has been found to influence multiple cellular functions thought to be important in tumorigenesis. *p53* mutations have been reported in sporadically arising astrocytic tumors of all grades, occurring in ~40% of astrocytomas, in 30% of ►anaplastic astrocytomas, and in a slightly smaller fraction of GBM. Other brain tumor predisposition syndromes associated with the inactivation of one copy of a particular gene in the germline include ►neurofibromatosis type 1 (*NF1* gene), which is associated with meningioma and optic glioma; ►neurofibromatosis type 2 (*NF2* gene), which is associated with acoustic neuroma and glioma; familial ►retinoblastoma (►*Rb* gene), which is associated with retinoblastoma and pinealoblastoma; ►von Hippel-Lindau syndrome (*VHL* gene), which is associated with cerebellar hemangioblastoma; ►tuberous sclerosis (*TSC1* and *TSC2* genes), which is associated with subependymal giant cell astrocytoma; ►Turcot syndrome (►*APC* gene), which is associated with astrocytoma and ►medulloblastoma; and Gorlin's syndrome (*PTCH* gene), which is associated with desmoplastic medulloblastoma.

The second most common primary brain tumor is oligodendroglioma, which has a more benign course than astrocytoma. Many ►gliomas have mixtures of cells with astrocytic and oligodendroglial features. If this mixed histology is prominent, the tumor is termed a mixed glioma or an ►oligoastrocytoma. Many investigators believe that the greater the oligodendroglial component, the more benign the clinical course. The presence of such histologic characteristics as mitosis, necrosis, and nuclear atypia generally is associated with a more aggressive clinical course. If these features are prominent, the tumor is termed a malignant oligodendroglioma. The highest grade oligodendroglioma are indistinguishable from glioblastoma multiforme.

Other malignant primary brain tumors include ►primitive neuroectodermal tumors (►PNET) such as ►medulloblastoma, ►ependymoma, and ►atypical teratoid/►rhabdoid tumors; ►germinomas; and CNS ►lymphoma. Cerebral PNETs and medulloblastoma, a PNET that arises in the posterior fossa, are highly cellular malignant tumors thought to arise in neural precursor cells. These tumors are difficult to distinguish from one another and typically appear histologically as sheets of small round malignant cells. Germline mutation of *PTCH* and *SUFU* in rare patients has called attention to the importance of sonic hedgehog signaling in medulloblastoma. Similarly, *APC* germline mutations in rare patients implicate *WNT* signaling as well. These tumors most commonly occur in children. Ependymomas are rare tumors, and when these occur in children, they typically are within the fourth ventricle, where they are thought to arise from cells lining the fourth ventricle. In adults, they arise more frequently in the spinal cord. Patients with neurofibromatosis type 2 are at increased risk of developing ependymoma, and 30% of sporadically occurring tumors exhibit deletion of Ch22q where the *NF2* gene is located. Histologically, these tumors exhibit diagnostic ependymal rosettes.

Atypical teratoid/rhabdoid tumors histologically appear as fields of undifferentiated malignant neuroectodermal cells that are indistinguishable from PNET, except for infrequent cells that exhibit evidence of rhabdoid differentiation and the presence of mesenchymal and epithelial elements. Germinomas arise most commonly during the second decade of life at midline locations. Both malignant and benign variants occur frequently. These tumors present with hypothalamic–pituitary dysfunction and visual field deficits.

Primary CNS lymphomas are most commonly seen in immunocompromised patients, and have a clinical presentation similar to other primary brain tumors with signs and symptoms referable to cerebral and cranial nerve involvement. Imaging studies typically demonstrate a uniformly enhancing mass lesion. Secondary CNS lymphoma almost always occurs in association with the progression of systemic disease. Several kinds of tumors that are most often benign also occur in the nervous system. ►Meningiomas are derived from cells of the arachnoid membranes. They are more frequent in women than in men, with a peak incidence in middle age. Meningiomas rarely have histological evidence of malignancy. Other tumors that have a benign clinical course include giant cell astrocytomas, pleomorphic xanthroastrocytomas, neurocytomas, and gangliogliomas. Colloid cysts, dermoid cysts, and epidermoid cysts also occur in the brain.

Clinical Presentation of Brain Tumor Patients

The most common symptoms that bring patients with a tumor arising in the brain to their physician include a slow progressive focal neurological disability, or a nonfocal neurological syndrome such as headache, dementia, gait disorder, or seizure. Other systemic symptoms suggest a tumor from some other location that may have metastasized to the brain, since patients with primary brain tumors typically do not exhibit systemic symptoms. Patients with primary brain tumors rarely have any biochemical abnormalities; thus CT (Computerized Tomography) and MR (Magnetic Resonance) imaging are key diagnostic modalities for the identification of brain tumors. The characteristic imaging features of brain tumors are mass effect, edema, and contrast media enhancement. Positron emission tomography (PET) scanning and single photon emission computed tomography (SPECT) have ancillary roles in the imaging of brain tumors. Meningiomas and other slow-growing tumors may be found incidentally on a CT or MRI scan or they may present with a focal seizure, a slow progressive focal deficit, or symptoms of increased intracranial pressure. As described above, brain tumors are also recognizable in many inherited syndromes including von Recklinghausen syndrome (neurofibromatosis type 1), neurofibromatosis type 2, Li-Fraumeni syndrome, ►Multiple endocrine neoplasia type 1, tuberous sclerosis, Turcot syndrome, and Gorlin syndrome.

Clinical Management of Brain Tumor Patients and Prognosis

Stereotaxic needle biopsy may establish the histological diagnosis of primary brain tumor, although open biopsy is also often utilized to establish the diagnosis. The primary modality of treatment for most primary brain tumors is surgery. The goals of surgery are to obtain tissue for pathological examination, to remove tumor, and to control mass effect. In the case of low-grade and benign tumors, the removal of tumor tissue can be curative or contribute substantially to extending the time to symptomatic progression. In higher-grade tumors, the role of surgery in contributing to curative therapy is less clearly defined, but in younger patients most surgeons aggressively pursue the removal of as much tumor as possible. Following total excision of an ependymoma, the prognosis is excellent. However, many ependymomas cannot be totally excised. Following surgery, ►radiation therapy has been shown to prolong survival and improve the quality of life of patients with high-grade glioma, PNET, ependymoma, or meningioma when malignant histologic elements can be pathologically identified within the tumor.

The medical management of most brain tumors is symptomatic, although a role for chemotherapy is clearly defined in oligodendroglioma and medulloblastoma. In patients with oligodendroglioma, a combination of procarbazine, lomustine, and vincristine has been shown to be most effective in patients with a deletion of Ch1p. Various combination therapies have been shown to contribute to the treatment of medulloblastoma, which has a propensity to spread throughout the neuroaxis. If medulloblastoma is limited to the posterior fossa and completely resected, this tumor has a good prognosis. Temozolomide given during radiation therapy for glioblastoma has been shown to contribute to longer overall survival time. Chemotherapy and radiation typically play a central role in the treatment of germinomas, although there is a role for surgery as well. Patients whose brain tumors are associated with surrounding edema benefit symptomatically from the administration of high doses of glucocorticoids. Anticonvulsants are useful in the control of seizures. Some glioma patients receive anticoagulation therapy to avoid complications of venous thrombosis that occurs in these patients.

The prognosis for patients with primary brain tumors varies greatly as a function of the histology and location of the tumor. Benign tumors are often cured by surgery alone. ►Germinomas and medulloblastomas are more sensitive to cytotoxic therapies than are other brain tumors, and the prognosis for patients with these tumors is generally better than for patients with high-grade

glioma. In modern studies, the median survival of patients with high-grade glioma is ~1–2 years.

Complications of Therapy

Neurological damage associated with surgical intervention presents a key challenge in the management of brain tumors. Furthermore, the nervous system is vulnerable to injury by therapeutic radiation, and this is frequently manifested by neuropsychological compromise and disability, particularly in very young children who have been treated with high doses of radiation. Pathologically, there is demyelination, hyaline degeneration of small arterioles, and eventually brain infarction and necrosis. Endocrine dysfunction is also commonly seen when the hypothalamus or pituitary gland has been exposed to therapeutic radiation. Depending on the radiated field, secondary tumors such as glioma, meningioma, sarcoma, and thyroid cancer occur following radiation therapy. Toxicities associated with chemotherapy can be significant, but they are not usually different from the toxicities associated with comparable treatments for tumors arising elsewhere in the body.

Brain-Derived Neurotrophic Factor

Definition

BDNF; Is a neurotrophin in the central nervous system (CNS), predominantly in the brain and the periphery. This is in contrast to ►NGF acting predominantly in the peripheral nervous system. It acts on certain neurons of the CNS and the peripheral nervous system that helps to support the survival of existing neurons and encourage the growth and differentiation of new neurons and synapses. In the brain, it is active in the hippocampus, cortex, and basal forebrain—areas vital to learning, memory, and higher thinking. BDNF was the second neurotrophic factor to be characterized after NGF.

Branching Morphogenesis

Definition

Branching morphogenesis refers to the formation of tree-like networks of epithelial tubes through reiterated cycles of branch initiation, branch outgrowth and branch arrest. This process relies on the precise spatio-temporal control of gene expression, cell proliferation and migration, and is essential for the physiological function of many organs including the lung, the vascular system and the kidney.

BRCA1/BRCA2 Germline Mutations and Breast Cancer Risk

Peter Devilee
Leiden University Medical Center, Leiden, The Netherlands

Definition

Mutations in the ►breast cancer genes BRCA1 and BRCA2 cause elevated risks to breast and ovarian cancer. BRCA1 maps to chromosome 17 (band q21), BRCA2 maps to chromosome 13 (band q12).

At the genetic level there are interesting analogies between the two genes, even though they are not detectably related by sequence. Both genes are large (coding regions of 5.6 and 10.2 kb, respectively),

complex (22 and 26 coding exons, respectively), and span about 80 kb of genomic DNA. Both have extremely large central exons encoding >50% of the protein. The majority of the mutations in both genes detected to date lead to premature termination of protein translation, presumably resulting in an inactive truncated protein. Gene changes are distributed nearly ubiquitously over the coding exons and immediate flanking introns. Even though more than half of all mutations are found only once, many mutations have been detected repeatedly in certain populations. For most of these, this has been shown to be the result of a founder effect: these mutations arose a long time ago, and have since spread in the population. Typical founder mutations are the 1185delAG and 15382insC in BRCA1 and 26174delT in BRCA2 that have a joint frequency of about 2.5% among individuals of Ashkenazi Jewish descent.

Characteristics

Clinical Characteristics

Female carriers of a deleterious BRCA1 mutation were estimated by the Breast Cancer Linkage Consortium (BCLC) to have an 87% cumulative risk to develop breast cancer before the age of 70, and 40–63% risk to develop ovarian cancer before that age (Fig. 1). The gene frequency of BRCA1 was estimated at 1 in 833 women, implying that 1.7% of all breast cancer patients diagnosed between the ages of 20 and 70 are carrier of such a mutation. The estimated cumulative risk of breast cancer conferred by BRCA2 reached 84% by age 70 years. The corresponding ovarian cancer risk was 27% (Fig. 1). These estimates imply that BRCA2 mutations are about as prevalent as BRCA1 mutations. It has been suggested that the ovarian cancer risks are dependent on the position of the mutation in the gene, for BRCA1 as well as BRCA2 mutations. There is also some evidence that cancer risks can be modified by other factors. For example, a strong variability in phenotype can be seen among families segregating the same mutation. This can range from early-onset breast cancer and ovarian cancer, to late-onset breast cancer without ovarian cancer. Even within a single pedigree, ages of onset of cancer can vary substantially. It seems likely that environmental and hormonally related factors (smoking, oral contraceptives) importantly co-determine disease outcome in carriers.

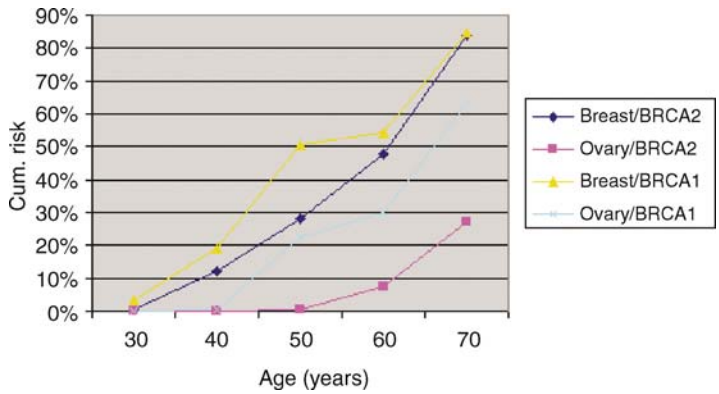
Molecular and Cellular Characteristics

Tumor Suppressor Genes

The first clues to the roles of BRCA1 and BRCA2 in tumorigenesis were genetic. The fact that most germline mutations are predicted to inactivate the protein, and the observed loss of the wild type allele in almost all breast and ovarian cancers arising in mutation carriers, are strong indicators that BRCA1 and BRCA2 proteins act as tumor suppressors. This is supported by the finding that induced overexpression of wild type but not mutant BRCA1 in MCF-7 breast cancer cells leads to growth inhibition and inhibited tumor growth in nude mice.

Expression of BRCA1 and BRCA2

In normal cells, BRCA1 and BRCA2 encode nuclear proteins, preferentially expressed during the late-G1/early-S phase of the cell cycle, but down-regulated in quiescent cells. While apparently at odds with the



BRCA1/BRCA2 Germline Mutations and Breast Cancer Risk. Figure 1 Overall penetrances of BRCA1 and BRCA2 for breast and ovarian cancer. Estimates were obtained by maximizing the LOD score with respect to all the different penetrance functions in those families with strong evidence of the breast and ovarian cancers being caused by the gene (done by linkage analysis). This is equivalent to maximizing the likelihood of the marker data, which is determined only by disease phenotype data. This will give an unbiased estimation of the penetrance irrespective of ascertainment of families on the basis of multiple affected individuals. Data were compiled from Ford et al. (1994) Lancet 343:692–695 and Ford et al (1998) Am J Hum Genet 62:676–689. The graphs can be read in such a way that, for example, an unaffected carrier of a BRCA1 mutation has a 50% risk to develop breast cancer before age 50.

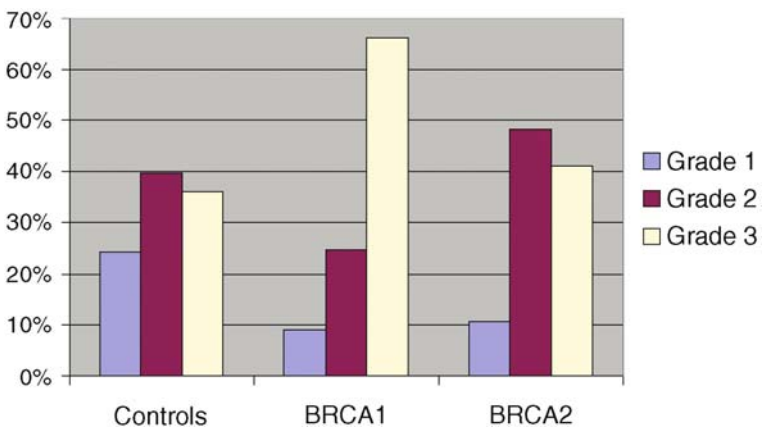
above-mentioned observations that BRCA1 expression inhibits cellular proliferation, the proliferation-induced expression could represent a negative feedback loop tending to decrease breast cancer risk. However, BRCA1 expression can also be up-regulated in a proliferation-independent way in mammary epithelial cells induced to differentiate into lactating cells by glucocorticoids. Hence, BRCA1 might also play a role in controlling mammary gland development. In mice, expression of BRCA1 and BRCA2 is coordinately up-regulated with proliferation of breast epithelial cells during puberty, pregnancy and lactation. Intriguingly, BRCA1 might suppress estrogen-dependent mammary epithelial proliferation by inhibiting ER-α mediated transcriptional pathways related to cell proliferation. Whatever the cellular function of BRCA1, it appears to be regulated by phosphorylation: it becomes hyperphosphorylated at G1/S with dephosphorylation occurring at M phase. BRCA1 might regulate the G1/S checkpoint by binding hypophosphorylated retinoblastoma protein. BRCA1 and BRCA2 have also been suggested to regulate the G2/M checkpoint by controlling the assembly of mitotic spindles and the appropriate segregation of chromosomes to daughter cells.

BRCA1- and BRCA2-Related Breast Cancer

A close examination of the pathology of BRCA1- and BRCA2-related breast cancers has defined a typical pathology for each category, differing from that in sporadic cases. In general, cancers in carriers are of higher grade than age-matched controls (Fig. 2), and the BRCA1-cancers more frequently display a "medullary"-like appearance. This is due to a higher mitotic count and lymphocytic infiltrate. BRCA2-related breast cancers generally show fewer mitoses and less tubule formation. For both BRCA1- and BRCA2-related cancers, greater proportions of the tumor show continuous pushing margins. Although a role for BRCA1 and BRCA2 in non-inherited sporadic breast cancer is unclear, protein expression of BRCA1 was found to be reduced in most sporadic advanced (grade III) ductal breast carcinomas.

BRCA1 and BRCA2 as Caretakers of the Genome

To date, several biological roles for BRCA1 and BRCA2 have been demonstrated, and a number of observations indicate that they function in a similar pathway. Both maintain genomic stability through their involvement in homologous recombination, transcription-coupled repair of oxidative DNA damage and double-strand break repair. These roles are suggested by interactions of the Brca1 and/or Brca2 proteins with proteins known to be involved in DNA damage repair, most notably RAD50 and RAD51. Murine embryonic stem cells and mice in which both copies of BRCA1 or BRCA2 have been mutated show a repair deficiency and defects in cell-cycle checkpoints. BRCA1 and BRCA2 play a role in transcriptional regulation, through interactions or complex formation with RNA polymerase II and various transcriptional regulators, although this is presently more firmly established for BRCA1 than for BRCA2. A transcriptional response to DNA damage is well-documented,



BRCA1/BRCA2 Germline Mutations and Breast Cancer Risk. Figure 2 BRCA1- and BRCA2-related breast cancers are generally of higher grade than age-matched controls. Histological sections from 118 breast tumors attributable to BRCA1, and 78 attributable to BRCA2, were evaluated by five histopathologists, all experts in breast disease. Every slide was seen by two pathologists. An age-matched group of 547 apparently sporadic female breast cancer cases served as control. The overall grade of both BRCA1 and BRCA2 breast cancers was significantly higher than that of controls ($p < 0.0001$ and $p < 0.04$, respectively). For BRCA1 breast cancers this was due to higher scores for all three grade indices, whereas for BRCA2 breast cancers the grade was only significantly higher for tubule formation. Data taken from The Breast Cancer Linkage Consortium (1997) Lancet 349:1505–1510.

and identification of downstream targets of BRCA1/2-mediated transcription regulation might help to further understand how BRCA1 and BRCA2 suppress tumor formation. Microarray-based screening of genes regulated by BRCA1 were recently found to fall into two categories, cell-cycle control genes and DNA damage response genes.

Clinical Relevance

When to Take the DNA-test?

Diagnosis of gene defects became possible after the identification of BRCA1 and BRCA2 in 1994 and 1995, respectively. In many countries, testing for mutations is being offered to women with a high priori familial risk in Clinical Genetic Centres or multidisciplinary Cancer Family Clinics. A few studies have presented models to determine the prior probability that the counselee is a BRCA mutation carrier, by combining breast and ovarian cancer family history data with results from comprehensive mutation-testing. These models enable the genetic counselor to decide when a DNA-test is indicated.

Why Take the DNA-test?

A clear positive result of the DNA-test, i.e. the presence of a deleterious mutation, is being used to enter these women into early-detection cancer screening programs or in the decision for or against prophylactic surgery. A woman in which breast cancer has just been diagnosed can benefit from knowledge about gene carrier status, since the risks to the contralateral breast and ovaria must be considered. The treatment of such cancer by lumpectomy will not reduce recurrence risks dramatically, as opposed to complete mastectomy. Healthy women who test positive can take action to prevent cancer developing, although the efficacy of the preventive options currently offered to a woman remains without formal supporting evidence. Chemoprevention is still controversial, and good prospective data on BRCA carriers will probably never become available, given the ethical and clinical difficulties surrounding randomization. Prophylactic surgery, intuitively the most secure way to reduce breast cancer risk to below population levels, is socially ill-accepted in many parts of the world, and formal proof of its preventive effect in BRCA carriers is also lacking. Clearly, this area is fraught with clinical dilemmas.

Interpreting a Negative Test Result

Paradoxically, a negative test result (the absence of a deleterious mutation) presently still has limited power in excluding the presence of a strong susceptibility allele. A negative test result is presently being found in 70–80% of all probands tested in most non-Ashkenazi Jewish populations. Among probands with a family history for ovarian cancer, a negative test result is found less frequently (although still in 40–60% of the cases). There are several levels of uncertainty.

- The first is technical: no single mutation-detection method is 100% sensitive, and therefore only exhaustive testing, using a range of different methodologies sensitive to various types of mutation-mechanisms,

BRCA1/BRCA2 Germline Mutations and Breast Cancer Risk. Table 1 Mutation types in BRCA1 and BRCA2 and their predicted effects

	BRCA1		BRCA2	
	% of Total	% of Distinct	% of Total	% of Distinct
Mutation type				
Frameshifting	47.1	38.7	33.7	36.5
Nonsense	11.3	11.1	11.5	10.2
Splice-site	4.4	7.9	2.2	3.6
In-frame del/ins	0.6	1.8	0.4	1.0
Missense	28.4	28.4	44.3	35.4
Neutral	3.5	3.9	3.1	5.5
Intronic change	4.7	8.3	4.9	7.8
Mutation effect				
Protein truncating	62.6	56.9	41.4	47.9
Missense	2.2	1.5	0.7	1.9
Neutral polymorphism	11.0	7.2	14.4	13.7
Unclassified variant	24.2	34.4	43.4	36.4

The entire Breast Cancer Information Core (BIC) database was down-loaded on March 1, 2000 from http://www.nhgri.nih.gov/Intramural_research/Lab_transfer/Bic. There were 3,086 *BRCA1* mutations and 1,892 *BRCA2* mutations. The total numbers of distinct changes were 724 and 670, respectively.

and investigating the entire coding regions and regulatory domains, can detect any changes. This is obviously very cost- and labor-intensive.

- The second level of uncertainty relates to the interpretation of sequence changes that do not predict a truncated protein. Of the almost 5,000 BRCA1 and BRCA2 mutations submitted to the Breast Cancer Information Core (BIC) database, about one-third are either missense, in-frame deletions or insertions, base-substitutions not leading to an amino acid change (neutral changes) or intronic changes with unknown effect on mRNA-processing (Table 1). Only a small proportion of these have been unmasked as polymorphisms unrelated to disease outcome. They include missense changes and intronic variants, but, intriguingly, also a nonsense mutation in BRCA2. The K3326X mutation was found in 2.2% of over 400 controls tested. Only a few missense changes (e.g., BRCA1C61G) have been called a deleterious disease-related mutation, mainly because they reside in a validated functional domain of the protein or affect an evolutionary conserved residue. As a result, about 35% of all the distinct gene changes detected to date are lumped into the "unclassified variant" category, meaning that their relevance to disease outcome is uncertain. Almost certainly, a substantial proportion of these represent rare polymorphisms but equally certainly, a number of them will turn out to be true deleterious mutations.
- A third reason for a negative test result is that the familial clustering of breast cancer in a family is due to an unknown gene or in fact is a non-genetic chance event. The proportion of truly missed, deleterious mutations is therefore difficult to gauge. A study by the BCLC has suggested that a combination of incomplete testing and missed or misinterpreted gene changes, causes false-negative test results in over 30% of all family types with some evidence of being linked to BRCA1. This proportion was independent of the mutation-screening methodology used.

BRCT Domain

Definition

Named after BRCA1 c-terminal repeat. The domain consists of a 90–100 amino acid unit that occurs as a single element or as multiple repeats in several proteins involved in the DNA-damage response. Heterodimerization between BRCT repeats promotes protein-protein interactions. A subset of tandem BRCT repeats adopt a conserved head-to-tail structure. Such tandem repeats can function as a phospho-peptide binding module that binds proteins with specific phosphorylation motifs.

Breast Cancer

Bill Gullick
Department of Biosciences, University of Kent at Canterbury, Canterbury, Kent, UK

Definition

Breast cancer may originate from more than one cell type in the breast as a result of different subsets of molecular changes. It is therefore a collection of diseases with different characteristics, different risks and different treatments. It occurs predominantly in women but it may also occur in men (0.5% of cases). In addition to invasive disease, several benign pre-malignant and non-invasive forms exist. Although the broad pathological categories are generally accepted there are several alternative systems of sub-categorization.

- Benign conditions: include sclerosing conditions and obliterative mastitis; mild moderate and severe hyperplasias and atypical hyperplasias; fibrocystic conditions, fibroadenomas and related conditions (note that the Oxford Textbook of Pathology presents a "simplified nomenclature" of 50 subtypes of benign breast disease).
- Non-invasive carcinoma: generally divided into Lobular Carcinoma in situ (LCIS) and Ductal Carcinoma in situ (DCIS). DCIS was originally sub-divided into comedo, cribriform, papillary, solid and clinging but has more recently been categorized as well, moderately and poorly differentiated.
- Invasive carcinoma: broadly defined as of "special type" (30% of cases) and "no special type" (70% of cases).

Characteristics

Epidemiology

Breast cancer is the most common fatal malignancy in women in the Western world representing about 10% of all cancer deaths. It is however much less common in other countries probably as a result of environmental rather than genetic factors. Behavioral risk factors have been identified. Early pregnancy to term and multiple pregnancy are protective for breast cancer incidence probably due to a reduced exposure to estrogens. There are several reports of weak associations with diet and use of oral contraceptives.

Screening

In some countries mammographic screening is available to women to detect early disease, as it is likely that earlier treatment is beneficial for survival. Educational programs are also active, for instance in promoting self-examination as a method of early detection. The value of these approaches for improving patient survival is not yet fully established.

Genetics

About 5–10% of breast cancer cases are associated with a genetic predisposition to the disease. Recently three genes have been identified where the inheritance of variants is associated with a very high incidence (penetrance) of the disease. The ►BRCA1 gene was the first to be identified, and gene carriers are thought to have as much as a 70–80% chance of developing the disease, generally at an earlier age than women with "sporadic" (not genetically predisposed) disease. Subsequently a second gene called ►BRCA2 was also found in other families that predisposes to breast and ovarian cancers. The particular risk in an individual gene carrier may be determined by the nature of the particular gene defect and by environmental and hormonal factors and by their background genetic makeup (►breast cancer genes BRCA1 and BRCA2). A further inherited condition, called ►Li-Fraumeni syndrome is associated with increased risk to breast and many other types of cancers. This is due to the inheritance of a rare mutant copy of the ►p53 gene.

Molecular Biology

Breast cancer is the most studied form of human cancer, due to its common occurrence and to the availability of many immortal breast cancer derived cell lines that can be grown in tissue culture (in contrast to prostate cancer for instance). About 60% of breast cancers at diagnosis express the estrogen receptor. Several genes have been found to be altered by mutation or amplification in invasive cancer and in DCIS. The ►HER-2 or ERBB2 gene (also known as c-erbB-2 and neu) is amplified in about 25% of invasive breast cancers leading to overexpression of the growth factor receptor which it encodes. The c-myc gene is similarly found to be amplified in about 20% of breast cancer also resulting in overexpression of the c-myc protein. The ►cyclin D gene, which specifies a protein important in regulating the cell cycle, is also amplified in a proportion of breast cancers. The p53 gene has been found to be point mutated in ~20% of invasive breast cancers and to be overexpressed in about 50% of cases. Other point mutations have been found in E-cadherin gene, which encodes a cell adhesion molecule. In this case the mutations are most common in lobular cancers. More subtle changes occur in the expression of apparently normal proteins including growth factors such as those in the epidermal growth factor (EGF) family and the FGF family of proteins, the receptor tyrosine kinase c-erbB-3 and the Src tyrosine kinase. Some of these altered proteins represent targets for new forms of treatments.

Treatment

Three methods of treatment are available, surgery, radiotherapy and chemotherapy/hormonal therapy. Benign disease and lobular carcinoma in situ are rarely treated but are observed, as they are associated with an increased risk of developing breast cancer. DCIS of the breast has often been treated by mastectomy as it is frequently quite widespread within the breast but may also be treated by local surgery. It is possible that the different pathologically defined forms of DCIS may be associated with different relative risks of recurrence and recurrence as invasive disease. Invasive disease is generally first treated by surgery, and lymph nodes are sampled to determine, by pathological diagnosis, if there is evidence of tumor spread. This procedure may be limited to a single node (called the sentinel node) or may involve a greater degree of surgery. Patients with invasive breast cancer are often treated with radiotherapy to the breast to reduce the chances of local recurrence. Even if the cancer has not apparently spread, patients are sometimes offered preventative or "adjuvant" therapy using drugs, as this helps to prevent recurrence of the disease. Chemotherapy or hormonal therapy are generally offered to patients where metastatic spread of the disease has occurred. Hormonal therapy is frequently offered to women whose tumors express the estrogen receptor. Specific methods of treatment still vary depending on the patient and the institution where it is given, although more generally agreed protocols are becoming accepted.

New Treatments

Breast cancer is frequently a hormonally dependent disease. Thus treatments with drugs such as tamoxifen, which binds to the estrogen receptor and reduces its activity, or other drugs that suppress the production of estrogen, such as aromatase inhibitors, are frequently employed. However, new drugs directed to known molecular changes in the cancer cells are under development. These include signal transduction inhibitors directed to molecules such as the epidermal growth factor receptor, monoclonal antibodies to the c-erbB-2 receptor and drugs which inhibit proteolytic enzymes thought to be involved in the process of metastasis. Several of these are now in clinical trials that will determine their usefulness for the treatment of the disease.

Breast Cancer Genes BRCA1 and BRCA2

Ashok R. Venkitaraman
Hutchison/MRC Research Centre,
Cambridge, UK

Definition

►*BRCA1* and ►*BRCA2* are cancer-predisposition genes, germline mutations in which are associated with a high risk of developing breast, ovarian and other cancers. Much information has been accumulated on the function of their large, nuclear-localized protein products, which implicates them in the cellular response to DNA damage, the control of mitotic cell division, and the regulation of gene transcription. BRCA1 and BRCA2 are very distinct genes, despite the similarity in their acronyms.

Characteristics

Roughly one-tenth of all ►breast cancer cases exhibit a familial pattern of inheritance. Of these familial cases, germline mutations in either one of two genes, *BRCA1* or *BRCA2*, occur in 20–60% (that is, in 2–6% of all cases). Somatic mutations in *BRCA1* or *BRCA2* do not appear to be a feature of non-familial (that is, sporadic) breast cancer, but there is evidence that epigenetic suppression of *BRCA* gene expression, or genetic alterations affecting the biological pathways in which they participate, can occur in sporadic breast cancer.

BRCA1 and *BRCA2* were first identified in 1994–1995 through the analysis of families exhibiting a predisposition to early-onset breast cancer. Founder mutations affecting these genes occur in Iceland and amongst the Ashkenazim, where they confer a highly penetrant risk of breast, ovarian and other cancers (including cancers of the male breast, pancreas and prostate). In other populations, germline *BRCA1* or *BRCA2* mutations are found in the great majority (up to 80%) of families that suffer from multiple occurrences of breast plus ovarian cancer. Germline *BRCA2*

mutations affecting both alleles also occur in the rare D1 complementation group of Fanconi anaemia.

The *BRCA1* and *BRCA2* genes have been assigned to human chromosomes 17q and 13q, respectively. In both genes, exon 11 (~3.4 kb in *BRCA1*, or 5 kb in *BRCA2*) encodes a large portion of the protein. Overall, the murine and human genes are no more than 60% identical at the amino acid level, although small regions exhibit a much higher degree of conservation. Proteins encoded in alternative splice products, such as the IRIS protein encoded by the *BRCA1* gene, also exist.

Protein

BRCA1 and *BRCA2* encode large proteins (human BRCA1 is 1,863 amino acids long; and human BRCA2 is 3,418 amino acids) that localise to the nucleus in mitotic and meiotic cells (Fig. 1). They bear little resemblance to proteins of known function. At its N-terminus BRCA1 protein contains a RING-domain known to mediate hetero-dimerization with the RING domain of BARD1, forming an active E3 ubiquitin ligase. At its C-terminus, BRCA1 includes two copies of a ~95 amino acid motif (the BRCT domain, for BRCA1 C-terminal) later detected in a number of different proteins implicated in DNA repair and cell cycle checkpoint control. This domain, whose atomic structure has been elucidated, mediates a number of protein-protein interactions with phosphorylated targets by serving as a phosphopeptide-binding module.

Eight repeated sequences (the BRC repeats), each of about 30 amino acids, are encoded in *BRCA2* exon 11. The BRC repeats, but not their intervening sequences, are conserved between several mammalian species suggestive of a conserved function. Indeed, the interaction of BRCA2 protein with RAD51, a mammalian homologue of bacterial RecA essential for genetic recombination, occurs through the BRC repeats. There is good evidence from genetic, structural and biochemical studies that the BRC repeats regulate the activity of RAD51 in reactions that lead to DNA repair by recombination. Two other regions of BRCA2 have been implicated in the control of recombination. A domain carboxyl-terminal to the BRC repeats interacts with the small protein Dss1 to form a structure capable of binding junctions between single-stranded and double-stranded DNA, which can displace the ssDNA-binding protein RPA from recombination substrates, whereas an additional RAD51-binding region of uncertain function is located near the extreme C-terminus of BRCA2.

Cellular and Molecular Regulation

The transcripts and protein products encoded by BRCA1 and BRCA2 are expressed in dividing cells of many types. Expression is also high in meiotic cells. These expression patterns speak to the possible functions of BRCA1 and BRCA2 proteins.

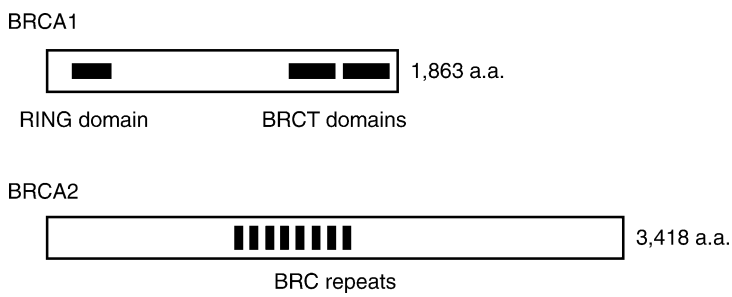
Role in the Cellular Response to DNA Damage

Both BRCA1 and BRCA2 proteins localize to the nucleus. In meiotic cells, co-localisation has been reported to the synaptonemal complexes of developing axial elements. This is suggestive of a role in meiotic recombination, a process that is initiated by DNA double-strand DNA breakage. Similarly, there is good evidence that BRCA1 and BRCA2 are essential in mitotic cells for the repair of DNA double-strand breaks by homologous recombination.

Several lines of evidence are indicative of such a role:

- Cells in which BRCA1 or BRCA2 or their homologues in other species have been inactivated exhibit genotoxin hypersensitivity and chromosomal instability suggestive of defects in DNA double-strand break repair.
- Second, homology-directed repair of double-strand DNA breaks introduced into chromosomal substrates is impaired by the disruption of BRCA1 or BRCA2, although pathways for non-homologous end joining remain largely unaffected.
- Finally, BRCA1 and BRCA2 localize after DNA damage to nuclear foci where they interact with molecules implicated in DNA recombination, including RAD51, and the Fanconi anemia proteins.

The precise mechanisms that may underlie such a function remain to be determined. BRCA2 interacts directly, and at a relatively high stoichiometry, with



Breast Cancer Genes BRCA1 and BRCA2. Figure 1 Structural features of the BRCA1 and BRCA2 proteins (not drawn to scale).

RAD51, a protein essential for DNA repair by recombination, to modulate RAD51 activity or availability. The interaction of BRCA1 with RAD51 is less well defined, although both proteins co-localize – along with BRCA2 – to discrete nuclear foci following DNA damage. BRCA1 may participate in the cellular mechanisms that sense and signal DNA damage, culminating in the activation of cell-cycle checkpoints and the machinery for DNA repair. The protein kinases ATM (encoded by the gene mutated in Ataxia telangiectasia), ATR, chk1 and chk2 (mutated in ►Li-Fraumeni syndrome) are proximal components of these sensing/signaling mechanisms. ATM, chk1 and probably the other checkpoint kinases, phosphorylate BRCA1 following DNA damage, a modification essential for its proper function. These observations are important because they place BRCA1 – and by extension, possibly BRCA2 – in the same pathway as genes such as ATM (►ATM protein), germline mutations in which are also associated with an increased risk of breast and other cancers. Thus, a common DNA damage response pathway may be defective in a significant fraction of breast cancers.

BRCA1 and BRCA2 have also been implicated in the enforcement of cell cycle checkpoints during the G2 and M phases, and in the regulation of centrosome number. Additional functions have recently been described in the control of mitosis. BRCA1 regulates proteins such as MAD2 that act in the mitotic spindle assembly checkpoint, and has an essential function in directing the correct formation and function of the mitotic spindle, whereas BRCA2-deficient cells exhibit defects in the completion of cell division by cytokinesis. Thus, BRCA1 and BRCA2 appear to work in multiple processes responsible for maintaining the integrity of chromosome number as well as structure in dividing cells, which may help to explain why they are potent tumor suppressors.

Other Functions

It is difficult to reconcile the disparate nature and severity of the cellular and developmental defects induced by the disruption of murine homologues of BRCA1 and BRCA2, with functions exclusively in the response to DNA damage. Indeed, evidence is accumulating that BRCA1, in particular, can control gene transcription. Several proteins that interact with BRCA1 are known to regulate transcription or mRNA processing. Moreover, at least a fraction of the total intracellular pool of BRCA1 is linked to the general transcription machinery – the RNA polymerase II holoenzyme – through its RNA helicase subunit.

Intriguingly, BRCA1 has been implicated in the control of X-inactivation in female cells, a process whose dysregulation is associated with breast cancer predisposition. How this function may be exerted is not clear, but it may work through the control of localization of the Xist product.

In addition, roles for BRCA1 and possibly BRCA2 have been reported in the control of oestrogen receptor expression and signaling.

Tumor Suppression by BRCA1 and BRCA2

Inheritance of a single defective copy of *BRCA1* or *BRCA2* confers cancer predisposition in humans. However, the second allele is almost invariably lost in the cancers that arise in predisposed individuals, indicating that *BRCA1* and *BRCA2* behave in some respects as ►tumor suppressor genes.

Abnormalities in growth or in DNA repair have not yet been reliably detected in murine or human cells heterozygous for *BRCA1* or *BRCA2* mutations. Thus, there is currently little to suggest that cancer predisposition arises solely from haplo-insufficiency, or a trans-dominant deleterious effect induced by a single mutant *BRCA1* or *BRCA2* allele. Rather, as has been proposed for other tumor suppressor genes, germline mutations in one allele may simply increase the likelihood that the gene is wholly inactivated by loss of the second allele through somatic mutation. However, aneuploidy as a consequence of abnormal cytokinesis has been reported in cells and tissues heterozygous for *BRCA2* mutations, and the possibility that this effect of haplo-insufficiency contributes to carcinogenesis remains to be determined.

Whatever the events that lead to loss-of-heterozygosity, inactivation of BRCA1 or BRCA2 would initiate genetic instability by destabilizing chromosome structure and number, allowing the rapid evolution of tumors due to increased somatic alterations in genes that control cell division, death or lifespan. Thus, *BRCA* genes are proposed to work as "caretakers" of genetic stability. This "caretaker" role is most likely to arise through the function of the BRCA proteins in DNA repair and mitosis. Cells that harbor disruptions in BRCA1 or BRCA2 accumulate aberrations in chromosome structure, reminiscent of diseases like Bloom syndrome or ►Fanconi anemia, where chromosomal instability is associated with cancer predisposition. They also exhibit aneuploidy and defects in cell division. These defects could together elevate the rate of genomic instability, leading to somatic mutations or alterations in gene copy number that promote carcinogenesis.

It is unclear why carcinogenesis accompanied by loss of the second *BRCA* gene allele in individuals who inherit one mutant allele should occur preferentially in tissues such as the breast or ovaries. Both BRCA1 and BRCA2 are widely expressed and appear to perform functions essential to all tissues. Currently there is little evidence to help distinguish between the several possible explanations that can be advanced.

The chronology of the molecular events during carcinogenesis in *BRCA* gene mutation carriers is not known. Loss of the second allele is clearly very frequent, but it is unclear at what stage in tumor

evolution this may occur. However, the catastrophic cellular consequences of homozygous inactivation of *BRCA1* or *BRCA2*, which quickly lead to cell death, does emphasize that other genetic alterations will be necessary. Current evidence favors the notion that the inactivation of cell-cycle checkpoint genes, particularly those that enforce mitotic checkpoints, is an important additional step during carcinogenesis in *BRCA* gene mutation carriers.

Viewed in this way, it is conceivable that the tissue specificity of carcinogenesis represents differences in the ability of cells which have lost both alleles of *BRCA1* or *BRCA2* to survive for long enough to acquire these additional genetic alterations. For instance, BRCA-deficient cells in epithelial tissues such as the breast and ovary may take advantage of hormonal or local inter-cellular interactions to support survival until the accumulation of additional genetic alterations allows outgrowth. By contrast, BRCA-deficient cells in non-target tissues may quickly be eliminated.

Clinical Relevance

Germline mutations in *BRCA1* or *BRCA2* are frequently associated with familial, early-onset, breast and ovarian cancer, particularly in those families that suffer from multiple cases of cancer in both sites. This has obvious important implications for genetic testing and counselling in the clinic. The mutations have been estimated to carry a cumulative life-time cancer risk of between 40–70%.

There is some evidence that the pathological features of breast and ovarian cancers associated with *BRCA1* or *BRCA2* mutations differ from those of sporadic tumors. So far, these differences seem to be insufficiently well-marked to be of diagnostic significance. One notable association is that BRCA1-deficient cancers often exhibit a "basal-like" phenotype usually characterized by the expression of specific markers, and negativity for oestrogen receptor expression.

It is also unclear if the prognosis of breast and ovarian cancers associated with *BRCA1* or *BRCA2* mutations will differ significantly from that of sporadic cases. Conflicting results have been reported in the literature, their interpretation made difficult by the varied study designs and by the relatively small numbers of cases that have been compared. Similarly, the value of prophylactic interventions, whether surgical or drug-based, in *BRCA* gene mutation carriers awaits evaluation.

Emerging evidence suggests that the DNA repair defect inherent in *BRCA*-mutant tumors can be exploited in cancer therapy. Thus, both BRCA1 and BRCA2-deficient cancers appear to be hypersensitive to the effect of DNA cross-linking agents such as carboplatin, and also to novel chemical inhibitors of the PARP1 enzyme.

Breast Cancer Resistance Protein

Definition

The breast cancer resistance protein is a plasma membrane transporter and member 2 of the subfamily G of ATP-binding cassette transporters. It is predominantly localized in the epithelium of small and large intestine, in hepatocyte canalicular membranes, in ducts and lobules of the breast, on the placental syncytiotrophoblast, and in the plasma membrane of stem cells. Physiological substrates include sulfated steroids. Transported xenobiotics are e.g., several dietary carcinogens, the chlorophyll breakdown product pheophorbide, and the receptor tyrosine kinase inhibitor imatinib. The breast cancer resistance protein is involved in conferring multidrug resistance.

Synonyms

Microcephalin; MCPH1

Definition

BRCT-repeat inhibitor of hTERT expression.

Characteristics

Significance of BRIT1 in the Development of Cancer

►BRIT1 was first described through a genetic screen for transcriptional repressors of the catalytic subunit of ►human telomerase, (hTERT). This catalytic subunit, hTERT, is the rate-limiting determinant of and is necessary for telomerase activity and thus is highly significant for cellular immortalization by preventing natural cellular senescence. Therefore, molecules that negatively control hTERT activity, such as BRIT1, directly influence the development of pre-cancerous and cancerous cells.

The BRIT1 amino acid sequence matched a previously identified gene, ►Microcephalin (►MCPH1) that is implicated as one of the contributing factors in the autosomal recessive neuro-develomental disorder, primary microcephaly. Additional biological roles for BRIT1 in the DNA damage response pathway were suggested by the protein structure. The presence of three ►BRCA1 carboxy-terminal (BRCT) domains within its structure connected BRIT1 with a group of proteins involved in DNA damage repair and checkpoint control such as ►53BP1, ►MDC1 and BRCA1. Proper cellular response to DNA damage is essential for the maintenance of genomic stability and is consequently crucial in prevention of neoplastic transformation. Depletion of BRIT1 by experimental manipulation abolishes normal DNA damage response and introduces chromosomal and centrosomal abnormalities. The reduction of BRIT1 expression in normal human mammary epithelial cells by experimental RNA interference generated chromosomal breaks, dicentric chromosomes and telomeric fusions. Additional chromosomal aberrations were introduced when BRIT-deficient cells were submitted to genotoxic insult. The resultant genomic instability generated from the loss of an appropriate BRIT1-mediated checkpoint and DNA repair mechanism may contribute to tumor formation. Functional impairment or loss of proteins, such as BRIT1, may significantly contribute to tumorigenic development by allowing the perpetuation of damaged or mutated genes within a cell, resulting in the inappropriate expression and control of the affected genes.

In addition to the influence on hTERT expression, BRIT1 appears to control the expression of two vital checkpoint-regulating proteins; BRCA1 and Chk1. BRCA1 and Chk1 protein levels are dramatically reduced in cells where BRIT1 has been experimentally reduced by RNA interference. A concurrent reduction in mRNA levels of BRCA1 and Chk1 were observed in BRIT1 knockdown cells suggesting that BRIT1 exercises an influence on the transcription of these genes. The significance of BRCA1 in breast cancer has been previously established. Whether BRIT1 functions directly as a specific transcription factor or as a chromatin modifying factor is unclear at this time, however, as a controller of these key players in the DNA damage checkpoint control network, BRIT1 is extremely important to the maintenance of normal cell function and thus in the prevention of tumorigenesis.

Aberrations of BRIT1 have been identified in various different human cancers. BRIT1 mRNA and protein expression is aberrantly reduced in several breast cancer cell lines and is reduced in some human ovarian and prostate epithelial tumors as compared to the corresponding normal tissue. Reduction of BRIT1 gene copy number significantly correlated with genomic instability found in the specimens. Additionally, reduced BRIT1 expression correlated with the duration of the relapse-free intervals and with the occurrence of metastases in some breast cancer patients suggesting that BRIT1 deficiency may contribute to the aggressive nature of breast tumors. A mutant form of BRIT1, isolated from one human breast tumor specimen, lacked two C-terminal BRCT-domains of the protein. This shorter form of BRIT1 resulted in a loss-of-function with respect to DNA damage response when tested experimentally. Therefore, significant evidence exists to directly link defective or reduced BRIT1 protein expression to several forms of cancer and to implicate BRIT1 as a novel tumor suppressor gene.

BRIT1 Function in DNA Damage Response

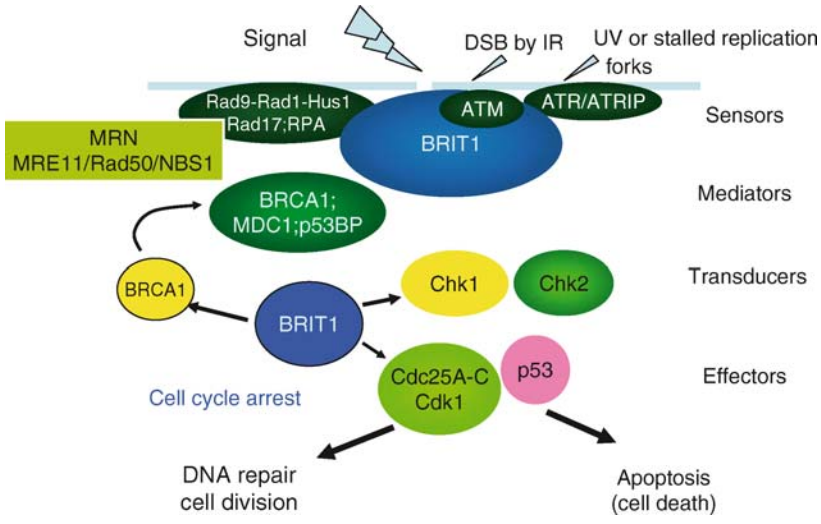
In the normal course of events, cellular DNA is subjected to a variety of endogenous and environmental factors that induce damage within its structure. In response to these insults, normal cells activate complex mechanisms to detect, signal the presence of and subsequently repair DNA damage when possible. Propagation of the DNA damage alarm progresses

through a complex signal transduction network that includes the BRIT1 protein. Initially, sensor proteins recognize the location of damaged or altered DNA structure and transmit a signal through mediator molecules to transducer proteins. The transducer proteins transmit the signal to numerous downstream effectors involved in specific pathways (Fig. 1). Two distinct DNA damage repair networks, both requiring BRIT1 activity, have been described. The ►ATM (ataxia telangiectasia mutated) pathway is activated by double-stranded breaks in the DNA observed after exposure to ionizing radiation while the ►ATR (ATM and Rad3-related) pathway is activated by prolonged presence of single-stranded DNA induced by either ultraviolet radiation or stalled DNA replication. ATM and ATR are essential kinases that are responsible for phosphorylating numerous transducer and effector proteins in the DNA damage network. BRIT1 co-localizes with numerous molecules associated with these two signaling networks including ►γH2AX, MDC1, 53BP, ►NBS1, p-ATM, ATR, p-RAD17 and p-RPA34 after DNA damage is induced. In the absence of functional BRIT1, all of these molecules with the exception of γH2AX, fail to localize to sites of DNA damage strongly suggesting that the BRIT1 molecule is an essential mediator for the subsequent repair processes. However, BRIT1 expression does not influence the chromatin binding of proteins unrelated to DNA damage such as Orc-2 indicating that the BRIT1 function is highly specific. The depletion of BRIT1 inhibits the recruitment of phosphorylated ATM to double-stranded DNA broken ends and subsequently blocks the phosphorylation of multiple down-stream members of the ATM repair pathway including Chk2 and NBS1. Depletion of BRIT1 also abolishes the UV-induced phosphorylation of RPA34 and reduces the levels of phosphorylated RAD17 indicating the importance of BRIT1 in the ATR signaling pathway. Based on these observations, it has been determined that BRIT1 is a pivotal protein in both of the DNA damage signaling networks and for this reason has great significance in the prevention neoplastic transformations of cells.

Figure 1 illustrates a simple model for the function of BRIT1 based on current experimental evidence. After exposure to ionizing radiation, double-stranded breaks in DNA occur resulting in the recruitment the MRE11/RAD50/NBS1 (MRN) complex and MDC1 to the damaged site thus facilitating the recruitment and kinase activity of ATM. Activated p-ATM phosphorylates NBS1, H2AX and BRCA1 which localize to sites of DNA damage. Increased single-stranded DNA by exposure to ultraviolet radiation induces the coating of RPA on DNA leading to the recruitment of ATRIP and ATR to the sites of DNA damage. Activated ATR then phosphorylates critical downstream molecules such as Rad17 and Chk1 further propagating the DNA damage signal in the cell. BRIT1 appears to regulate the recruitment of NBS1, MDC1 and thus the MRN complex in the ATM pathway. BRIT1 also regulates the recruitment of RPA, which in turn recruits ATRIP/ATR complex initiating the ATR signaling cascade.

BRIT1 Function in Cell Cycle Control

Normally, the progression of a cell through the cell division cycle is stalled to allow for its DNA repair and if the damage cannot be repaired, the cell enters programmed cell death (apoptosis). This retardation or cell cycle checkpoint is essential to maintain the



BRIT1 Gene. Figure 1 BRIT1 Function in DNA Damage and Cell Cycle Control.

integrity of cellular DNA that insures normalcy in consecutive descendant cells. Key molecules involved in cell cycle arrest, (p53, chk1 and chk2), are all activated when phosphorylated by ATM or ATR. BRIT1 clearly impacts the activity of both ATM and ATR by affecting the association of these molecules to damaged DNA. Activated p53 induces cell cycle arrest at G1 while p-Chk1 and p-Chk2 negatively regulate Cdc25 phosphatases that promote transition through the cell cycle thereby inducing the execution of G1/S, G2/M and intra-S checkpoints of the cell cycle. BRIT1 is required for the activation of intra-S and G2/M cell cycle checkpoints after cellular exposure to ionizing radiation. The influence of BRIT1 on control of these cell cycle checkpoints may result from BRIT1's regulation of three checkpoint regulator proteins, Chk1, BRCA1 and NBS1. In the absence of BRIT1, BRCA1 and Chk1 expression is significantly reduced and NBS1 fails to be phosphorylated. BRCA1 plays a significant role in homologous recombination DNA repair and possibly serves as a scaffold for ATM and ATR thus affecting phosphorylation of many downstream effectors proteins. Therefore the regulation of BRCA1 by BRIT1 dramatically affects multiple aspects of cell cycle control and DNA damage repair.

The normal cellular response to ionizing radiation is to arrest the cell cycle also at G2, allowing for the initiation of DNA repair, however, BRIT1-depleted cells continue to progress through G2 indicating that BRIT1 is essential in the activation of this important cell cycle checkpoint. Additionally, BRIT1-depleted cells continue to synthesize DNA and proceed through mitosis unlike normal cells exposed to ionizing radiation. Replication of DNA damaged by ionizing radiation could easily result in the propagation of mutated or disrupted genes and contribute to tumorigenesis.

BRIT1 also controls the cell's entry into mitosis by affecting the stabilization of the cdc25A, a key phosphatase in cell cycle control. Cells derived from a microcephaly patient (BRIT1 defective) maintained a persistent level of the phosphatase, cdc25A following UV treatment. Cdc25A is targeted for degradation when phosphorylated by Chk1 kinase during normal cell division and its degradation is usually amplified by UV exposure. Degradation of cdc25A abolishes the activation of the Cdk2-cyclin complex inhibiting DNA synthesis. Conversely, inappropriate persistence of cdc25A allows for the continued DNA synthesis despite aberrations or damage in the structure. These BRIT1 mutant cells also harbor reduced levels of phosphorylated Cdk1-cyclin B complex that is essential for mitotic entry. It was proposed that the regulation of mitosis by BRIT1 is both ATR dependent through regulation of cdc25A stability and ATR independent through regulation of Cdk1-cyclin B phosphorylation.

The affect of BRIT1 on cell cycle control is therefore multi-faceted (Fig. 1). Complete loss of the BRIT protein results in reduced protein levels of BRCA1 and Chk1 and impairs the activity of a multitude of vital proteins through their diminished phosphorylation. Presence of a mutated BRIT1 protein allows for expression of BRCA1 and Chk1 but still blocks proper signal transduction by inhibiting the activities of both ATM and ATR kinases.

Biological response modifier.

BRMS1

Alexandra C. Silveira, Danny R. Welch
Department of Pathology and Comprehensive Cancer Center, University of Alabama at Birmingham, Birmingham, AL, USA

Definition

BRMS1 (Breast Metastasis Suppressor 1) is a human ►metastasis suppressor gene that, when re-expressed, suppresses metastasis of human breast carcinoma, ovarian, and melanoma cell lines in immunocompromised mouse models.

Characteristics

The *BRMS1* gene is located on chromosome 11q13.1-q13.2. It spans over 8.5 kb and is comprised of ten exons, the first exon being untranslated. *BRMS1* cDNA is 1485 base pairs and encodes a 246 amino acid protein (MW ~28.5 kD, although it runs more slowly (~35 kDa) by SDS-PAGE). It is highly conserved with the mouse ortholog (*Brms1*) having 95% homology at the amino acid level. Like human *BRMS1*, the mouse ortholog has suppresses metastasis in murine models of breast cancer.

BRMS1 protein contains two nuclear localization sequences, two coiled-coil motifs and imperfect leucine zippers. It also contains a glutamic acid rich N-terminus and a potential endoplasmic retention signal. *BRMS1* shows almost ubiquitous expression in human tissues; highest expression is in kidney, placenta, peripheral blood lymphocytes and testis and lowest expression in brain and lung. Subcellular fractionation and immunofluorescence studies have determined that *BRMS1* protein is predominantly (>90%) nuclear. *BRMS1* protein is stabilized by interaction with the chaperone protein, Hsp90, and is further regulated by proteasomal degradation.

Cellular and Functional Characteristics

BRMS1 re-establishes gap junctional cell-cell communication in human breast cancer cell lines. Studies using MDA-MB-435, MDA-MB-231, and the ovarian cancer cell line HO-8910PM show an inverse effect of *BRMS1* expression on cell motility. Further, over-expression of *BRMS1* in H1299 human lung carcinoma cells and MDA-MB-435 cells results in suppressed growth in soft agar. Additionally, *BRMS1* transfection increases apoptosis in suspended non-small cell lung carcinoma.

The exact mechanism by which *BRMS1* affects these phenotypes is as yet unknown. However, it is known that *BRMS1* interacts with several different proteins and large (megadalton) protein complexes, most notably with class I and class II histone deacetylases (HDACs) and the transcription factor NFκB. *BRMS1* is specifically a core member of mSin3-HDAC chromatin remodeling/transcriptional repression complexes but its involvement is implicated in other HDAC complexes. Additionally, *BRMS1* and HDAC1 function as NFκB co-repressors; chromatin bound *BRMS1* facilitates HDAC-1-mediated deacetylation and inactivation of NFκB. Studies also suggest that direct interaction of *BRMS1* and the RelA/p65 subunit of NFκB represses the transactivation potential of NFκB. Further, *BRMS1* leads to a reduction in NFκB translocation by inhibiting the phosphorylation and degradation of the NFκB inhibitor, IκB.

Studies show reduced phosphoinositide signaling in *BRMS1* transfected cells. Decreased phosphoinositide signaling results in decreased mobilization of intracellular calcium, a known regulator of metastasis. *BRMS1* expression also downregulates fascin, an actin-bundling protein associated with cell motility. Further, repression of NFκB results in decreased expression of anti-apoptotic genes and two tumor-metastasis activators, osteopontin and urokinase-type plasminogen activator.

Clinical Relevance

BRMS1 is regulated at both the RNA and protein levels. To date, only a single study has examined levels of *BRMS1* protein in patient samples to find a loss of *BRMS1* in nearly 25% of 238 breast cancer cases. Further, the study showed loss of *BRMS1* correlated with disease-free survival when stratified by loss of estrogen receptor, progesterone receptor, or Her2 over-expression. Other clinical studies have studied *BRMS1* mRNA expression in human cancers compared to adjacent non-cancerous tissues or regional lymph nodes. Since *BRMS1* is regulated at the protein level, looking exclusively at mRNA may be misleading. Nonetheless, the majority of studies show high levels of *BRMS1* correlates with increased disease-free survival and diminished progression.

Bryostatin-1

Bassel El-Rayes
Karmanos Cancer Institute, Wayne State University, Detroit, MI, USA

Definition

Bryostatins are a class of macrocyclic lactones. Bryostatins are potent modulators of ►Protein Kinase C (PKC). Bryostatin-1 was isolated from the marine invertebrate *Bugula neritina*. Bryostatin-1 is currently not available for commercial use.

Characteristics

Rationale for Targeting the PKC

PKC is a family of homologous serine/threonine protein ►kinases that transduce signals linked to diverse cellular processes including proliferation, differentiation, angiogenesis, and ►apoptosis. The PKC family includes 12 isoforms subdivided into three major classes based on their co-factor requirements for activation. Aberrant regulation of the PKC enzymes activity has been demonstrated in a number of malignancies including: breast, colorectal, pancreatic and non-small cell lung cancer.

Preclinical Activity of Bryostatin-1

Treatment of cancer cell lines with bryostatin-1 results in the activation of PKC. However, prolonged exposure to bryostatin-1 induces PKC inhibition most probably through ubiquitin-mediated degradation. Inhibition of PKC activity results in cell cycle arrest, apoptosis, cell differentiation and modulation of chemoresistance.

Bryostatin-1 has been shown to potentiate the effects of several classes of cytotoxic agents including: vincristine in diffuse large cell lymphoma, melphalan in Waldenstrom's macroglobulinemia, gemcitabine in pancreatic and breast cancer, paclitaxel and mitomycin C in gastric cancer cell lines. The synergism between bryostatin and cytotoxic agents is sequence dependent.

Single Agent Activity of Bryostatin-1

Phase I trials of bryostatin-1 used two different schedules. The maximal tolerated doses were 25 μg/m^2 when infused over 24 h and 120 μg/m^2 when infused over 72 h. The most common side effects included ►myalgia. Other observed toxicities included headache, phlebitis, and transient ►thrombocytopenia.

Single agent bryostatin-1 has been studied in phase II trials for lymphoma, renal, colorectal, head and neck, sarcoma, and melanoma. Bryostatin-1 did not demonstrate single agent activity in any of these diseases.

Bryostatin-Based Combinations

Since PKC activation contributes to chemoresistance the combinations of bryostatin-1 and cytotoxic agents were tested. In Chronic Lymphocytic Leukemia (CLL) and indolent Non-Hodgkin Lymphoma, bryostatin-1 was evaluated in combination with fludarabine. Patients received fludarabine daily for 5 days and bryostatin-1 over 24 h infusion either before or after fludarabine. The combination was well tolerated. Partial and complete responses were observed in 6 and 2 patients (total number 27), respectively. Bryostatin-1 and vincristine was evaluated in patients with refractory B-cell lymphoma. Twenty four patients were enrolled on the study. The bryostatin-1 was well tolerated at a dose of 50 μg/m^2 over 24 h infusion. The regimen had activity with five patients having objective response and five having stable disease.

Bryostatin-1 was also evaluated in combination with cisplatin in two phase I trials. In the first trial, bryostatin-1 (30 μg/m^2 over 24 h infusion), had no significant activity. In the second trial bryostatin-1 was administered at a dose of 15–55 μg/m^2 over 72 h. In this study, three responses were reported. A phase I trial of gemcitabine and bryostatin-1 (25–35 μg/m^2 over 24 h) revealed that the regimen was well tolerated and resulted in stable disease in 8 out of 36 patients. Bryostatin-1 (15–50 μg/m^2 infused over 24 h) was evaluated in combination with paclitaxel. Partial responses were observed in patients with pancreatic and gastroesophageal cancer. The common finding in these trials is that bryostatin-1 can be combined safely with cytotoxic chemotherapy agents.

Phase II trials evaluating the activity of bryostatin-1 with cisplatin in cervical cancer had disappointing results. Fourteen patients were enrolled on the trial and there were no treatment responses. Ajani et al. reported on thirty seven patients with gastroesophageal and gastric cancer treated with bryostatin-1 (40 μg/m^2 infused over 24 h) and weekly paclitaxel (80 mg/m^2). The response rate was 29% which is higher than the previously reported response rates with paclitaxel. In a phase II trial, bryostatin-1 (50 μg/m^2 infused over 24 h) and weekly paclitaxel (90 mg/m^2) were evaluated in patients with non-small cell lung cancer. Of eleven response evaluable patients, stable disease was seen in five patients. Therefore, the bryostatin-1 and paclitaxel combination did not demonstrate significant activity in lung cancer.

Future Directions

Mixed results have been observed in the trials evaluating bryostatin-1 and cytotoxic chemotherapy agents. The future challenges in the development of bryostatin-1 include, the identification of biomarkers that can predict activity and the development of combination therapy with other targeted agents. Another approach for the development of bryostatins is through the modification of the chemical structure in order to identify analogues with better safety or efficacy profiles than bryostatin-1.

BSA

Definition

Body surface area; The current practice of using body-surface area (calculated using a formula derived from height and weight) in dosing anticancer agents has been implemented in clinical oncology about half a century ago. By correcting for BSA, it was generally assumed that the interindividual variation in the pharmacokinetics of the drug administered would be reduced which would lower the risk of serious adverse effects without reducing the agent's therapeutic effect. Recently, doubt has arisen to this hypothesis, and for many anticancer drugs the rationale for individualization of dosage based on BSA is lacking.

CA19-9

Definition

Carbohydrate antigen 19-9 is used as a tumor-marker when measured in serum. It is thought to be a sialylated Lewis blood group antigen. CA19-9 levels are elevated in many gastrointestinal malignancies including cholangiocarcinoma and pancreatic cancer, as well as some non-malignant conditions such as cholangitis and peritoneal ►inflammation/infection. Patients who have a genetic deficiency in a fucosyltransferase specified by the Le gene are Lewis^{a-b-} and are unable to make this antigen; thus CA19-9 testing in Lewis^{a-b-} patients can be falsely negative.

►Cholangiocarcinoma
►Fucosylation

CA125

Definition

CA125 (cancer antigen 125) is a mucin-like protein of high molecular mass estimated at 200–20,000 kDA. CA125 cell surface expression is upregulated when cells undergo metaplastic differentiation into a Müllerian-type epithelium. CA125 is the most extensively studied biomarker for possible use in ovarian carcinoma early detection. It is elevated in some cases of ►endometriosis.

Cachexia

Chen Bing
Division of Cellular and Metabolic Medicine, School of Clinical Sciences, University of Liverpool, Liverpool, UK

Definition

Cachexia came from the Greek "kakos" and "hexis" meaning "bad conditions." Cachexia is a complex metabolic syndrome characterized by progressive weight loss with extensive loss of skeletal muscle and adipose tissue, which is secondary to the growing malignancy.

Characteristics

Most cancer patients develop cachexia at some point during the course of their disease, and nearly one-half of all cancer patients have weight loss at diagnosis. Cachexia prevents effective treatments for cancer and predicts a poor prognosis because the severity of wasting inversely correlates with survival. The consequences of cachexia are detrimental and cachexia is considered to be the direct cause of about 20% of cancer deaths. The pathogenesis of cancer cachexia remains to be fully understood, but it is evidently multifactorial.

Weight Loss

Clinically, cachexia should be suspected if involuntary weight loss of more than five percent of premorbid weight occurs within a six-month period. Weight loss is not simply caused by competition for nutrients between tumor and host as the tumor burden may be only 1–2% of total body weight. The frequency of weight loss varies with the type of malignancy, being more common and severe in patients with cancers of gastrointestinal tract (►gastrointestinal tumors) and lung (►lung cancer). Gastric and pancreatic cancer patients may lose large amounts of weight, up to 25% of initial body weight. Over 15% of weight loss in patients is likely to cause significant impairment of respiratory muscle function, which probably contributes to premature death. Weight loss can arise from several metabolic changes that take place during malignancy, for example, reduced food intake, increased energy expenditure, and tissue breakdown.

Poor Appetite

Loss of the desire to eat or lack of hunger is common in cancer patients. It can be related to the mechanical effect of the tumor such as obstructions (especially of the upper gastrointestinal tract), side-effects of chemotherapy or radiotherapy (►chemoradiotherapy), and emotional distress. Some tumors may secrete products which act on the brain to inhibit appetite. Regulation of food intake involves the integration of the peripheral and neural signals in the hypothalamus and other brain regions. In the hypothalamus, the orexigenic signals such as ►neuropeptide Y (NPY), the most potent appetite stimulant, increase food intake, and the anorexigenic signals including the pro-opiomelanocortin/cocaine and amphetamine regulated transcript (POMC/CART) inhibit appetite. Dysregulation of NPY in the hypothalamic pathway can lead to decreased energy intake but higher metabolic demand for nutrients. It has been demonstrated that NPY-immunoreactive neurons in the hypothalamus are decreased in experimental model of cancer anorexia. In contrast, reduced food consumption can be restored to normal levels by blocking the POMC/CART pathway in tumor-bearing animals.

High level of leptin, a hormone primarily secreted by adipocytes, inhibits the release of hypothalamic NPY. In cancer cachexia the leptin feedback loop appears to be deranged, altering the signaling pathway of NPY. Cytokines such as interleukin 1β (IL-1β), interleukin-6 (IL-6) and tumor necrosis factor α (TNFα) are implicated to be involved in cancer anorexia, possibly by stimulating corticotrophin-releasing factor, a neurotransmitter which suppresses food intake at least in rodents, and/or by inhibiting neurons that produce NPY in the hypothalamus.

Increased Metabolism and Energy Expenditure

Maintaining normal body weight requires energy intake to equal energy expenditure. In some patients with cancer cachexia, energy balance becomes negative as reduced food intake is not accompanied by a parallel decrease in energy expenditure. For example, patients with lung and pancreatic cancers generally have higher ►resting energy expenditure (REE) compared with normal control subjects; however, REE is usually normal in patients with colorectal cancer. The mechanisms of increased energy expenditure are not clear although studies suggest that it might be through the upregulation of uncoupling proteins, a family of mitochondrial membrane proteins, which are proposed to be involved in the control of energy metabolism. ►Uncoupling protein-1 (UCP-1), which decreases the coupling of respiration to ADP phosphorylation thereby generating heat instead of ATP, is only expressed in ►brown adipose tissue (BAT). UCP-1 mRNA levels in BAT are increased in mice bearing the MAC16 colon adenocarcinoma. Although BAT is uncommon in adults, the prevalence of BAT has been found to be higher in cancer cachectic patients than the age-matched control subjects. mRNA levels of UCP-2 (expressed ubiquitously) and UCP-3 (expressed in skeletal muscle and BAT) in skeletal muscle are upregulated in rodent models of cancer cachexia. In humans, skeletal muscle UCP-3 mRNA levels are over fivefold higher in cachectic cancer patients compared with patients without weight loss and health controls. Elevated expression of UCP-2 and -3 has been suggested to contribute to lipid utilization rather than whole-body energy expenditure. Cytokines such as TNFα and/or other tumor products may be responsible for the changes in UCP expression at least in rodents. Additional energy consumption could arise from the metabolism of tumor-derived lactate via "futile cycles" between the tumor and the host. The main energy source for many solid tumors is glucose, which is converted to lactate and transferred to the liver to convert back into glucose. This "futile cycle" requires large amount of ATP, resulting in an extra loss of energy in cancer patients.

Loss of Adipose Tissue

Fat constitutes 90% of normal adult fuel reserves and depletion of adipose tissue together with ►hyperlipidemia becomes a hallmark of cancer cachexia. Computed tomography (CT) scanning has revealed that cachectic cancer patients with gastrointestinal carcinoma had significantly smaller visceral adipose tissue area than control subjects. Increased lipolysis is implicated in cancer-associated adipose atrophy. The activity of hormone-sensitive lipase, a rate-limiting enzyme of the lipolytic pathway, is increased in cancer cachectic patients, which causes elevated plasma levels of free fatty acids and triglycerides. Meanwhile, there is a fall in lipoprotein lipase (LPL) activity in white adipose tissue, thus inhibiting cleavage of triglycerides from plasma lipoproteins into glycerol and free fatty acids for storage, causing a net flux of lipid into the circulation. Finally, glucose transport and de novo ►lipogenesis in the tissue are reduced in tumor-bearing state, leading to a decrease in lipid deposition. There is also evidence that loss of adipose tissue in cancer cachexia could be the result of impairment in the formation and development of adipose tissue. The expression of several key adipogenic transcription factors including CCAAT/enhancer binding protein alpha, CCAAT/enhancer binding protein beta, peroxisome proliferator-activated receptor gamma, and sterol regulatory element binding protein-1c are markedly reduced in adipose tissue of cancer cachectic mice.

Various factors produced by tumors or the host's immune cells, responding to the tumor can disturb lipid metabolism. TNFα has been shown to affect adipose tissue formation by inhibiting the differentiation of new adipocytes, causing dedifferentiation of mature fat cells and suppressing the expression of genes encoding key lipogenic enzymes. TNFα has also been associated with increased lipolysis probably through suppression of LPL activity in adipocytes. In addition, both TNFα and IL-1 are able to inhibit glucose transport in adipocytes and consequently decrease the availability of substrates for lipogenesis. Certain prostate, gut and pancreatic tumors secrete a lipid-mobilizing factor (LMF), also produced by a mouse adenocarcinoma model. LMF has been shown to be identical to the plasma protein zinc-α2-glycoprotein (ZAG). It is recently found to be secreted by human adipocytes and upregulated in adipose tissue of mice with cancer cachexia. ZAG causes rapid lipolysis in vitro and in vivo, possibly through activation of intracellular cyclic AMP. ZAG also stimulates expression of UCPs in brown fat of mice, which may contribute to increased energy expenditure as well as lipid catabolism during cachexia. Moreover, ZAG has been shown to reduce glucose metabolic rate in adipose tissue, consistent with a decrease in glucose transportor-4 transcript in white fat of mice bearing a ZAG-producing tumor.

Loss of Muscle Protein

Weakness, commonly seen in cancer cachectic patients, is directly related to wasting of muscle that accounts for almost half the body's total protein and bears the brunt of enhanced protein destruction. Reduced protein synthesis together with enhanced proteolysis have been observed in experimental animal models and in muscle biopsies from cancer patients with cachexia, and whole-body protein turnover can be markedly increased in cachectic cancer patients.

Some mediators and pathways of excessive protein breakdown have been incriminated in cancer cachexia. TNFα appears to be involved, as treatment with recombinant TNFα enhances proteolysis in rat skeletal muscle and activates the ubiquitin–proteasome system. Ubiquitin, an 8.6 kD peptide, is crucially involved in targeting of proteins undergoing cytosolic ATP-dependent proteolysis. There is an increase in ubiquitin gene expression in rat skeletal muscle after incubation with TNFα in vitro. Tumors also produce cachectic factors such as proteolysis-inducing factor (PIF), a 24 kD glycoprotein initially isolated from a cachexia-inducing tumor (MAC16) and the urine of cachectic cancer patients. PIF induces muscle protein breakdown by stimulation of the ubiquitin–proteasome proteolytic pathway.

There is increasing evidence that both cytokines and PIF cause protein degradation by activation of ►nuclear factor kappa B (NFκB), a transcription factor that regulates the expression of a number of proinflammatory cytokines. TNFα and PIF can upregulate components of the ubiquitin–proteasome pathway in an NFκB-dependent manner. Activation of NFκB by TNFα in murine muscle cells suppresses mRNA of the transcription factor ►MyoD, inhibiting skeletal muscle cell differentiation as well as preventing the repair of damaged skeletal muscle fibers.

Treatment

Current treatment designed to ameliorate cancer cachexia has limited benefit. Nutritional supplementation (oral or parenteral) alone has little effect and, critically, does not restore muscle mass, improve quality of life or prognosis in cancer patients. Appetite stimulants such as megestrol acetate and medroxyprogesterone acetate are commonly used at present in the treatment of anorexia and cachexia. These agents are believed to stimulate orexigenic peptide NPY in the hypothalamus, and inhibit the synthesis and release of proinflammatory cytokines. Their effects on appetite and well being are short-termed and they do not influence lean body mass and survival. Cannabinoids (►cannabinoids and cancer) have also been studied as potential appetite stimulants. However, dronabinol has failed to prevent progressive weight loss in patients with advanced cancer.

Therapeutic interventions include anticytokines such as thalidomide (►thalidomide and its analogs) with multiple immunomodulatory properties. It suppresses the production of TNFα, IL-1β, IL-12, and cyclooxygenase-2, which is probably through inhibiting NFκB activity. Thalidomide has been shown to attenuate total weight loss and loss of lean body mass in cachectic patients with advanced pancreatic cancer.

►Eicosapentaenoic acid (EPA), a polyunsaturated fatty acid from fish oil, has attracted attention as a potential anticachectic agent. EPA has been shown to attenuate the increased expression of the components of the ubiquitin–proteasome proteolytic pathway in skeletal muscle of mice with cancer cachexia, and EPA can block PIF-induced protein degradation in vitro. In randomized clinical trials, cachectic patients with unresectable pancreatic cancer receiving EPA have shown a stabilization in the rate of weight loss, fat and muscle mass as well as the REE. Recent data from animal studies suggest that EPA combined with the leucine metabolite beta-hydroxy-betamethylbutyrate seems to be more effective in the reverse of muscle-protein wasting.

CDH1; synonyms Epithelial cadherin, Uvomorulin.

►E-Cadherin

Cadherins

Definition

Cadherins are a family of cell adhesion receptor glycoproteins that are involved in the calcium-dependent cell-to-cell adhesion. E-, V-, and N-cadherins are distinct in immunological specificity and tissue distribution. They promote cell adhesion via their homophilic binding interactions. Class of type-1 transmembrane proteins important in cell adhesion. They are dependent on calcium (Ca^{2+}) ions to function, hence their name. Cadherins play an important role in regulation of morphogenesis. Cadherins inhibit invasiveness of tumor cells.

Cafe Au Lait Spots

Definition

Synonym Cafe-au-lait Macule; Coffee-with-milk-colored spots on the skin that are seen characteristically in the neurofibromatosis type 1 (NF1) syndrome.

Cajal Bodies

Vincenzo de Laurenzi
Department of Experimental Medicine and Biochemical Sciences, University of Tor Vergata, Rome, Italy

Synonyms

Coiled bodies

Definition

Small nuclear organelles (0.1–2.0 μM in diameter), present in all eukaryotic cells, involved in a number of different nuclear functions.

Characteristics

The nucleus of eukaryotic cells contains a number of different highly specialized organelles. Unlike cytoplasmic organelles these nuclear structures are not delimited by a membrane but are by all means compartments that contain a number of specific proteins. Most of the organelles can be clearly identified trough immuno-staining using antibodies directed against specific marker proteins; however, it should be kept in mind that these organelles are highly dynamic structures that often exchange components and therefore many proteins can be found in more than one organelle.

Among these organelles are Cajal Bodies (CBs), described over a century ago by Ramon y Cajal. CBs were originally described in neuronal cells but have since been described in a variety of cell types, both in animals and in plants, suggesting that they are involved in some fundamental cellular process. Due to their characteristic ultra-structural appearance as a tangle of coiled fibrillar strands they have also been called coiled bodies. They usually vary in size from 0.2 μM to 2 μM, but can be occasionally larger. The number of CBs is usually between 0 and4 in normal diploid cells; however, many more can be found in some cancer cells. The number of CBs per cell is regulated during the cell cycle. Indeed, CBs disappear in prophase nuclei, to reappear in G1 at the same time of the nucleolus. Their number is then doubled, usually reaching the number of four, in the S phase. It has been suggested that in these cells the number of CBs depends on the ploidy of the cells or more specifically on the number of chromosomes 1 and 6. CBs can be found associated with specific gene loci such as snoRNA, snRNA and histone gene clusters. In addition, CBs can also be found in association with other nuclear bodies such as cleavage bodies and ►PML bodies, suggesting that there is an exchange of components between the different nuclear organelles.

CBs have a heterogeneous composition, containing different Small Nuclear Ribonucleoproteins (snRNPs), Small Nucleolar Ribonucleoproteins (snoRNPs), cell cycle regulating proteins, and transcription factors, as well as other proteins, whose function still needs to be determined.

The generally recognized marker of CBs is p80 coilin. The function of this protein is still unknown, its deletion in mice results in reduced coilin –/– animal litters, suggesting a developmental defect; however surviving animals appear normal. Deletion of coilin results in residual bodies that still contain some components such as fibrillarin, Nopp140 and FLASH, but not others like splicing snRNPs.

While their function is still in part elusive, recent work suggests that they are involved in several nuclear functions. CBs are supposed to be the site of assembly of the three eukaryotic RNA polymerases (pol I, pol II and pol III) with their respective transcription and processing factors that are then transported as multiprotein complexes to the sites of transcription.They are also involved in the modification of Small Nuclear RNAs (snRNAs) and Small Nuclear Ribonucleoproteins (snRNPs), which are important for spliceosome formation. Indeed CBs contain newly assembled snRNPs and snoRNPs that later accumulate in speckles and nucleoli and it has recently been suggested that CBs are sites of modification for snRNPs and particularly sites where 2′-O-methylation and pseudouridine formation occur. This process requires a novel class of CB specific small RNAs (scaRNAs) that pair with the snRNAs and function as guides for 2′-O-methylation. The reaction is probably mediated by the fibrillarin, a CB and nucleolar associated protein with methyl transferase activity. CBs have also been implicated in ►replication dependent histone gene transcription, and a subset of CBs is physically associated with histone gene clusters on chromosomes 1 and 6. Phosphorylation of a CB component p220/NPAT by cyclinE/Cdk2 is required for activation of histone transcription, exit from G1 and progression through S phase of the cell cycle. Moreover it has been shown that another CBs component FLASH is essential for this function. Downregulation of FLASH results in structural alteration of CBs, reduction of replication dependent histone gene transcription, and block of cells in the S phase (►S-phase damage-sensing checkpoints) of the cell cycle. In addition, CBs are involved in U7 snRNA dependent cleavage of the 3′ end of histone pre-mRNA before the mature mRNA can be exported to the cytoplasm.

Finally, a role for CBs in regulating ►telomerase function has been proposed. Based on the presence of the RNA component of telomerase (hRT) in CBs of cancer cells, it has been suggested that CBs play a role in the maturation of hRT or in the assembly of the telomerase complex. However, CBs might represent only a site of accumulation of hRT; alternatively, this could be an altered localization only present in cancer cells; therefore further studies are required to clarify this potential CB function.

Alteration of CB structure, as well as other nuclear structure alterations, has been observed in various diseases; however, in most cases it is not clear if these defects are a consequence of altered nuclear functions or play a role in the disease pathogenesis.
