Hyperthermia can augment the body's innate immunity as well as increase immune activity specifically towards tumors. In general, the body increases in temperature as a response to infection; many bacterial or viral pathogens are heat sensitive and thus an elevation in body temperature serves as a primary method of defense against invading agents. Furthermore, as body temperature rises, cellular metabolism does as well, which can aid in accelerating immunologic responses.

With regards to immune response towards tumor, hyperthermia can induce maturation of ►dendritic cells, cause increased lymphocyte trafficking, and engage in ►heat shock protein 70 (HSP70) mediated immune response, which in turn increases T-cell specific antitumor activity and further stimulates dendritic cells. These physiologic responses augment the body's natural immune response against tumors.

Hyperthermia Physics

Delivery Modalities

Hyperthermia may be delivered using either invasive or non-invasive sources. Non-invasive techniques are generally preferred, and consist of two main methods of delivering heat to tissues: ►electromagnetic (EM) heating or ►ultrasound. While the underlying physics principles of heat deposition differ between EM and ultrasound modalities, they are similar in a variety of ways. Both are sensitive to tissue heterogeneity as well as blood flow geometry, and are susceptible to difficulties of energy coupling into tumor tissue.

Materials with finite electrical conductivity experience energy dissipation with the flow of electric current; this is the principle behind ohmic, or resistance electromagnetic heating. Delivery of EM heating is dependent on both frequency and wavelength. As EM frequency increases over the radio frequency (RF) and microwave (MW) range, electrical conductivity also increases. Since energy deposition in tissue is proportional to the local tissue conductivity and the magnitude of the electric field, these higher frequencies result in greater energy deposition and shorter penetration depths. Additionally, in the design of antennae or electrodes to deliver the EM field, there is a general constraint that limits the ability to localize heating at depths greater than 2–5 cm. This arises from the relation between EM frequency and wavelength to the physical size of the antenna or electrode source. Longer wavelengths will penetrate deeper into tissue, but require physically larger heating antennae, thus preventing localization of the EM field. This tradeoff between localization and penetration yields a critical limitation in electromagnetic heating: localized heating is limited to depths less than 2–5 cm. At depths greater than 2–5 cm EM heating will result in regional energy deposition, potentially involving large volumes of normal tissue.

In accordance with these depth limitations, electromagnetic heating devices are typically divided into two categories: superficial applicators which provide focused heating at depths less than 2–5 cm and deep heating devices which distribute heat to a deeper penetration but over a broader range. Superficial devices consist of waveguides and microstrip or patch antennas which operate in typical microwave band frequencies (433, 915, or 2,450 MHz) and usually require a water bolus to couple energy into the tissue. The deep heating devices typically used are magnetic induction, capacitive coupling, and phased array fields. These devices operate at lower frequencies, between 5 MHz and 200 MHz. A schematic illustration of a phased array device for deep heating is shown in Fig. 1.

Similarly to electromagnetic heating, ultrasound also experiences decreased penetration with increasing frequency. As an advantage over EM, however, ultrasound operates with much lower wavelengths and consequently avoids the severity of problems associated with focusing at greater depths. Unfortunately, ultrasound is limited by resolution, since it is particularly sensitive to the reflective and absorptive effects of air and bone, respectively. This imposes severe limitations of ultrasound heating in regions of tissue heterogeneity and changing geometry.

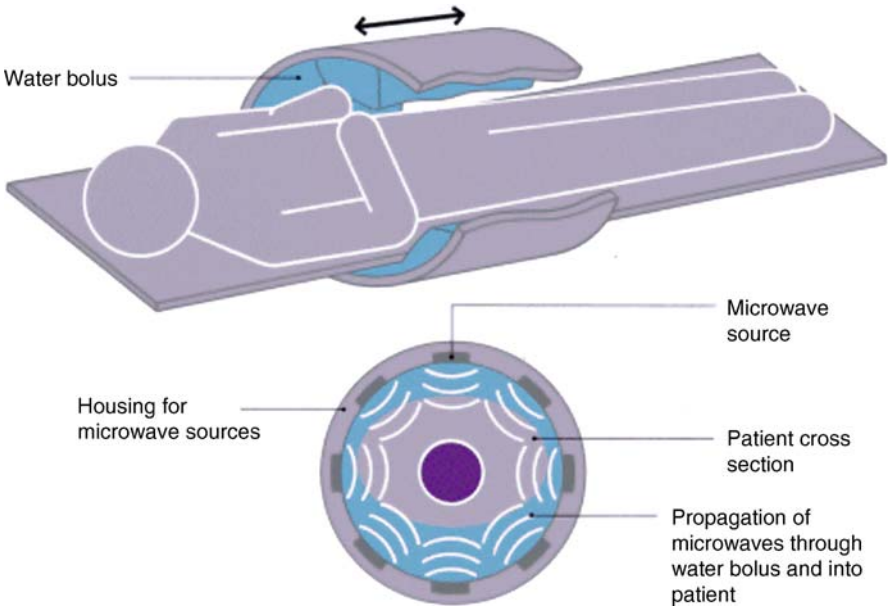
Ultrasound devices are also separated into categories of superficial and deep heating. Single and multiple transducer plane wave devices operating with frequencies between 1 MHz and 3 MHz have been designed for superficial tumors, while at depths greater than 2–5 cm scanned focused transducers, phased arrays, or multiple scanned focused transducers in the 0.5–2 MHz range are used. Ultrasound devices require a temperature controlled water bolus for energy coupling.

Thermometry

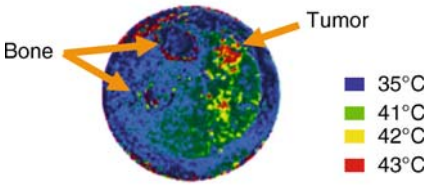
One of the greatest challenges facing clinical hyperthermia is the difficulty in obtaining accurate and noninvasive thermometry. Currently, most thermometry is performed through placement of ►catheters into the tumor via ultrasound or CT guidance; thermometers are then placed within the catheters. Temperature readings are attained statically with multipoint thermometers or dynamically by moving a single point thermometer through the catheter during heating.

There are many disadvantages to the common method of invasive thermometry. For one, there is a greater risk to the patient. Invasive methods are uncomfortable and present a risk for infection and hemorrhage. Additionally, the procedure is lengthy, requiring image registration and extra time of the physician. Perhaps most crucially, the data obtained from invasive methods is limited and often does not provide much spatial data, which in turn limits the control and uniformity of the hyperthermic treatment.

In an attempt to gain better uniformity of treatment, noninvasive thermometry methods have been developed; these methods rely mostly on ►Magnetic Resonance Imaging (MRI) techniques, although a variety of technologies are being pursued. MR imaging has many temperature sensitive parameters that can be exploited for thermometry purposes, including relaxation times T_1 and T_2, bulk magnetization, and proton resonance frequency. Of these four parameters, the proton resonance frequency is the most commonly



Hyperthermia. Figure 1 Illustration of an annular phased microwave array for heating deep situated tumors.



Hyperthermia. Figure 2 Example of noninvasive thermometry data acquired with phase difference (chemical shift) MRI in a sarcoma of the lower leg. This method can yield temperature data with a resolution of 1.0°C.

used, and has demonstrated superior temperature sensitivity and resolution. Clinical studies have illustrated resolutions of 0.5–1°C with MRI thermometry. Figure 2 shows a temperature distribution image obtained from an MRI of a sarcoma in the lower leg.

Despite the many advantages hyperthermia affords, clinical implementation has proved challenging. As mentioned above, hyperthermia heating regimens can be difficult to reproduce, utilizing invasive thermometry methods that have limited spatial coverage. Additionally, the definition and calculation of thermal dose used in hyperthermia is not well defined, making clinical trial comparisons between institutions difficult. However, the technology associated with clinical hyperthermia continues to improve, and many of these challenges are being addressed in ongoing research.

Thermal Dosimetry

The Arrhenius relationship is used to describe the rate of cell kill for a given temperature over time, and provides the basis for thermal dosimetry. Hyperthermia cell survival curves decrease exponentially, with higher rates of cell kill at increased temperatures. Arrhenius plots can be determined from in vitro data by taking the log of the slope of cell survival curves as a function of temperature. A typical graph of surviving fraction with temperature and its resulting Arrhenius plot is given in Fig. 3.

Arrhenius plots are characterized by their biphasic nature, with the temperature at which the slope changes commonly referred to as the "breakpoint;" this phenomenon is derived from tissues developing thermal tolerance. For human tissue, the "breakpoint" occurs at ~43.5°C. Below the breakpoint, the rate of cell kill decreases twofold to fourfold for each 1.0°C decline in temperature. Above the breakpoint, the rate of cell kill doubles for each 1.0°C elevation of temperature.

Achieving constant temperatures over time is difficult in tumor tissue, leading to non-uniformity in hyperthermia delivery between patients. Since the in vivo slopes of the Arrhenius plots are practically identical to the in vitro slopes, and they provide a correlation between rate of cell kill and temperature, the Arrhenius relationship is used as a method for normalizing thermal data between different patients or treatments. This is expressed as Cumulative Equivalent Minutes at 43°C (CEM 43°C) and is given by the equation:

$$\text{CEM } 43^{\circ}\text{C} = \text{tR}^{(43-\text{T})}$$

Where t = time of treatment in minutes, T = average temperature in Celsius during treatment, and R is a constant, equal to 0.5 above the breakpoint and 0.25 below. In more complex situations with large temperature variations, the thermal data may be broken into shorter time intervals of 1–2 min where the temperature remains relatively constant. In these instances the total CEM 43°C for the treatment is attained through summation of CEM 43°Cs for each interval period. Also referred to as the thermal isoeffect dose, the CEM 43°C has been a valuable predictor of treatment efficacy and standardization of heat treatment in clinical trials.

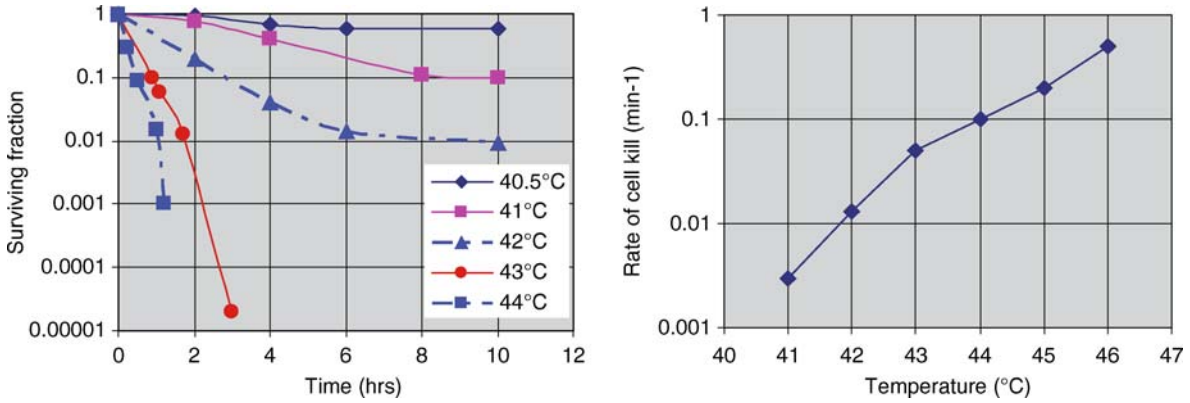
Clinical Hyperthermia

Hyperthermia has been used to treat superficial tumors as a lone method of treatment. However, while the occasional response is observed, in general heat treatment alone is not associated with long term tumor control. While the practice of using solely hyperthermia is still performed in some clinics, this use is not supported by peer-reviewed published scientific data. Instead, hyperthermia is best utilized as a synergistic adjunct modality to oncology treatments, including radiation and chemotherapy. Figure 4 underscores the important physiological processes of hyperthermia in augmenting radiation and chemotherapy efficacy.

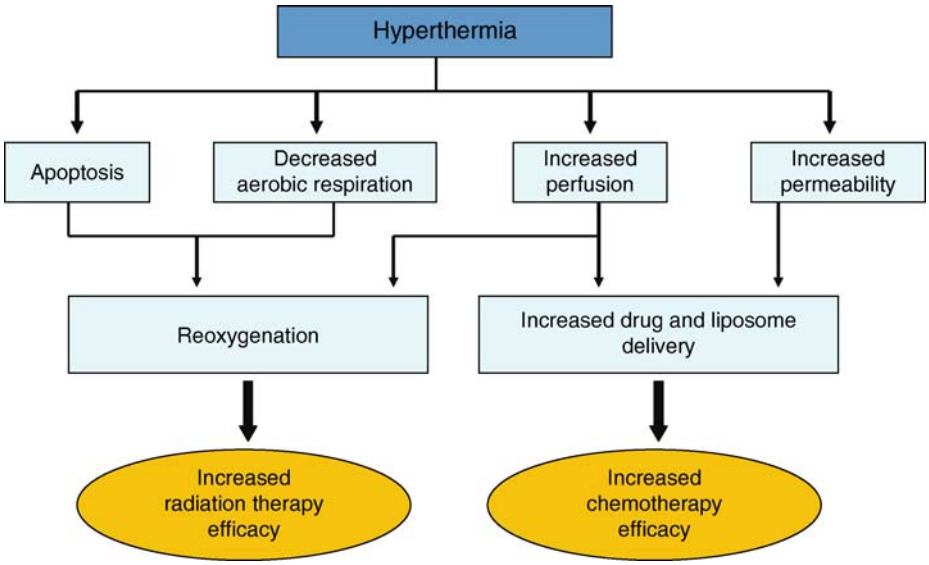
Radiation Therapy and Hyperthermia

The rationale for combining hyperthermia with radiation therapy is based on a variety of synergistic effects. For one, the areas of radiation resistivity and heat sensitivity are complimentary. While cells in ▶S-phase are typically radioresistant, this is the most heat sensitive phase of the cell cycle. Also, hypoxic cells are typically three times more resistant to radiation than normoxic cells, whereas there is no difference in thermal sensitivity based on cellular oxygenation status. Furthermore, hyperthermia can augment radiation response by causing reoxygenation of tumor tissue and inhibiting sublethal repair through inactivation of critical DNA repair pathways.

Clinically, the therapeutic gain of combining radiation therapy and hyperthermia is determined by the Thermal Enhancement Ratio, or TER. The TER is defined as the ratio of radiation dose to achieve an isoeffect for radiation divided by the radiation dose to achieve the same effect with combined radiation and hyperthermia. Typical TER values for local tumor control are greater than one, and are typically smaller



Hyperthermia. Figure 3 Example of thermal cell survival curves (on the left), plotted as surviving fraction over time at a specific temperature. On the right, the Arrhenius plot is shown for the data. The breakpoint is observed at 43°C.



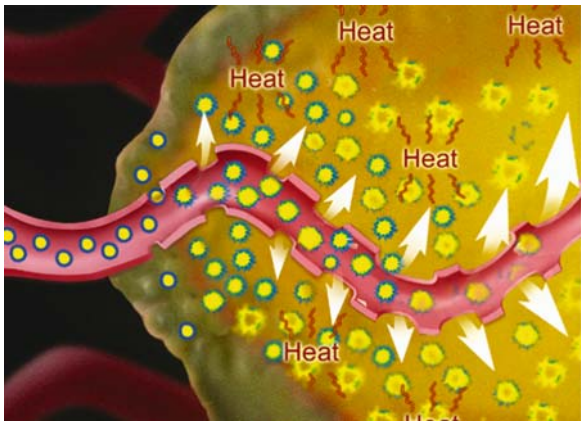
Hyperthermia. Figure 4 Physiologic benefits of low temperature (40–43°C) hyperthermia and the rationale behind synergistic radiation and chemotherapy uses.

for normal tissue damage, suggesting therapeutic gain for a combined hyperthermia and radiation course over radiation alone.

Chemotherapy and Hyperthermia

Hyperthermia also exhibits synergism with some chemotherapeutic agents, through increasing cellular uptake, oxygen radical production, and DNA damage, while inhibiting DNA repair. Chemotherapeutic drugs that have been shown to have heightened efficacy when combined with hyperthermia include ►cisplatin, ►nitrogen mustards, doxorubicin (►Adriamycin), ►nitrosoureas, ►bleomycin, ►mitomycin C, and hypoxic cell sensitizers. While this list of drugs that are synergistic with hyperthermia are many, there are also those that have not shown interaction when combined with heat, such as ►etoposide and the ►vinca alkaloids.

In addition to showing additive effects with traditional chemotherapeutic agents, hyperthermia also offers an avenue for exploitation of innovative drug delivery strategies. Liposomes (►Liposomal Chemotherapy) are nanoparticle lipid vesicles that can be loaded with a variety of high concentration chemotherapeutics. These liposomes show enhanced extravasation following hyperthermia due to increased permeability of the vasculature. Furthermore, this enhanced accumulation is tumor specific, due to the discrepancy in degree of permeability increase between



Hyperthermia. Figure 5 Illustration of the principles underlying thermosensitive liposome efficacy. Thermosensitive liposomes release their contents upon heating to a desired temperature, and release drug both within the tumor vasculature and after extravasation into tumor tissue.

tumor and normal blood vessels. Not only does hyperthermia increase overall liposomal extravasation, but novel thermosensitive liposomes have been developed with lipid bilayers that degrade upon reaching a thermal transition temperature, typically designed to release in a range of 40–43°C. This allows for both targeted and triggered drug release into tumor tissue. Figure 5 shows an illustration of thermosensitive liposomes extravasating into tumor tissue and releasing their contents upon heating.

There are a variety of factors that should be considered when combining hyperthermia and chemotherapy. For one, response may vary based on the hypoxic and pH parameters of the tumor. Additionally, a very notable effect of hyperthermia is its influence on tumor resistivity to certain drugs; hyperthermia can induce at least partial reversal of drug resistance with a variety of drugs, most notably cisplatin, ►melphalan, nitrosoureas, and doxorubicin. Finally, sequencing of hyperthermia and drug delivery may greatly influence efficacy of treatment. Most drugs exhibit optimal results when heat and drug are delivered concomitantly, or when drug is given immediately prior to heating; some exceptions include 5-FU (►Fluorouracil) and a few other antimetabolites.

Clinical Trials

Phase III clinical trials, particularly those comparing radiotherapy (RT) alone to RT + HT, have yielded significant positive results for a variety of cancers. Both superficial and deep tumor sites have been investigated, as well as both palliative and curative treatment goals. Statistically significant improvement in complete response (CR) rates with HT + RT versus RT alone have been demonstrated with many cancers, most notably chest wall recurrences of breast cancer, stage III and IV head and neck, metastatic melanoma, bladder, and cervical carcinoma. Most importantly, improvements in survival have also been shown in cervix, head and neck, glioblastoma, esophageal cancers.

While many trials have been performed validating the use of hyperthermia with radiotherapy, fewer exist for chemotherapy (CT) and hyperthermia. However, phase II trials have illustrated improved treatment efficacy of CT + HT in sarcomas and breast carcinomas, compared with historical controls. Additionally, the use of tri-modality (CT, RT, and HT) treatments are being investigated, with encouraging results in phase II trials of locally advanced rectal and cervical cancers and a phase III trial for esophageal cancer.

Hypertrophy

Definition

Increase in size of an organ or tissue due to an increase in the size of cells while the number stays the same.

►Peroxisome Proliferator-Activated Receptor

Hypertrophy of Male Breast

►Gynecomastia

Hypervariable Region

Definition
Regions of the heavy or light chains of ►immunoglobulins in which there is considerable sequence diversity within that set of immunoglobulins in a single individual. These regions specify the antigen affinity of each antibody.

Hypodiploidy

Definition
Having a chromosome number that is less than the normal diploid number.

►Acute Lymphoblastic Leukemia

Hypoechoic

Definition
The echo of the tissue is low compared to the adjacent area.

►Hepatic Epithelioid Hemangioendothelioma

Hypogammaglobulinemia

Definition
Abnormally low levels of immunoglobulins.

Hypomethylation

Definition
A reduced level of CpG island ►methylation relative to the normal tissue specific pattern.

►Methylation-Controlled J Protein (MCJ)
►CpG Islands

Hypomethylation of DNA

Miguel A. Peinado
Institute of Predictive and Personalized Medicine of Cancer (IMPPC), Badalona, Barcelona, Spain

Synonyms
DNA demethylation; DNA undermethylation

Definition
DNA hypomethylation refers to the loss of the methyl group in the 5-methylcytosine nucleotide. Methylation is a natural modification of DNA, and mainly affects the cytosine base (C) when it is followed by a guanosine (G) in mammals ►(Methylation). The term hypomethylation can be applied to describe the unmethylated state of most CpG sites in a specific sequence that is normally methylated, or as a general phenomenon affecting the bulk of the genome; this is a decrease in the proportion of methylated versus unmethylated cytosines.

Characteristics
In human, DNA methylation mainly occurs at CpG sites. Up to 80% of all CpG sites in human DNA are methylated. However, this methylation occurs primarily in areas where CpG density is low, or at repeat DNA sites, such as Alu elements. CpG islands are regions where CpG density is high and most of them are unmethylated. Patterns of DNA methylation have been linked to control of gene expression, maintenance of chromosomal integrity, and in regulation of DNA recombination in mammals. Methylation in a gene promoter region is generally associated with gene silencing. Heavily methylated DNA replicates later than nonmethylated DNA, and late replication is associated with the formation of inactive chromatin, which facilitates transcriptional silencing of noncoding regions.

Global hypomethylation is typical in aging cells, as well as in neoplasia, where it is an early event. Early studies in the eighties already identified a depletion of the methyl-cytosine content as a landmark in colorectal cancer and other types of tumors. DNA hypomethylation has been shown to promote tumorigenesis in murine colon and liver and was included as an early event in a genetic model for colorectal tumorigenesis. Different investigations sustain a causal link between DNA hypomethylation and genetic instability, reporting an association between defects in DNA methylation and aneuploidy in human colorectal cancer cell lines, increased chromosomal rearrangements in hypomethylated centromeric regions in mitogen-stimulated cells from individuals affected with immunodeficiency, centromere instability and facial anomalies (ICF

syndrome), and an increased mutation rate owing to DNMT1 deficiency in murine embryonic stem cells and in murine somatic cells. Moreover, DNMT1 deficiency also results in constitutive chromosomal instability in a human colon cancer cell line. Decreased methylation levels in LINE sequences correlate with losses of heterozygosity on discrete chromosomal loci in colorectal carcinomas and other studies have demonstrated that DNA hypomethylation precedes genomic damage in human gastrointestinal cancer.

Definition

Being oxygen deprived.

Characteristics

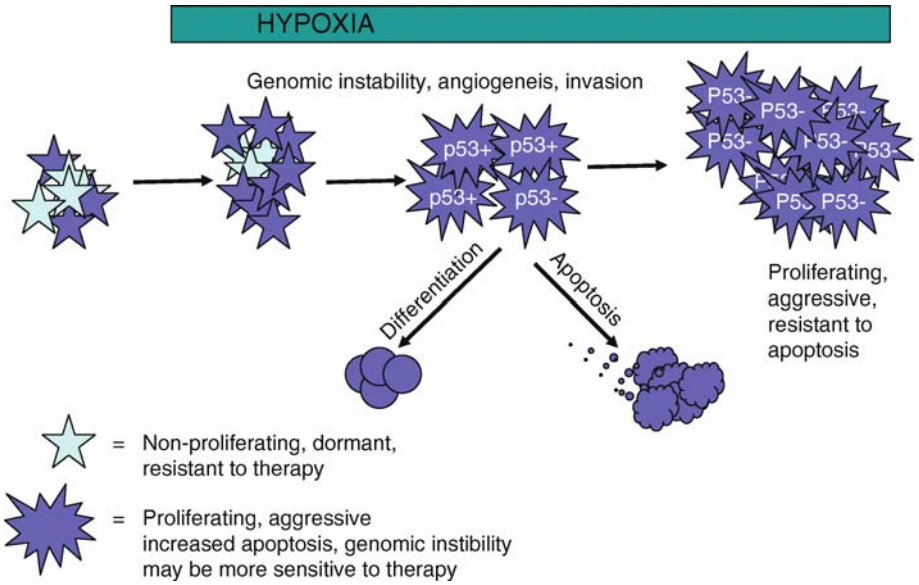
Cellular hypoxia is a common stress in normal development and numerous pathological conditions, including cancer. By the time a tumor has grown to a detectable size, poor and disordered ►angiogenesis, leaky vessels, and high interstitial tumor pressure all result in significant tumor hypoxia. Studies in human tumor ►xenografts reveal a mean pO_2 of <5 mmHg 70–80 μm from a vessel wall. Both non-invasive measurements and direct assessment of tumor oxygenation in patients have demonstrated the presence of profound hypoxia in a marked variety of solid tumors, including, ►melanoma, ►prostate cancer, head and neck, and ►cervical cancer as well as in ►hematological malignancies including myeloma. In one study, using oxygen electrodes to assess breast cancer oxygenation in 36 patients and controls, the average pO_2 was 30 mmHg in tumors as compared to 65 mmHg in normal breast tissue and 67 mmHg in benign fibrocystic breast disease. Areas of severe hypoxia or ►anoxia (<5.0 mmHg) were noted in >30% of the measurements. There was no correlation between tumor hypoxia and tumor size or stage.

For over 30 years, hypoxic tumors have been known to be relatively chemo-resistant and radio-resistant. More recently, tumor hypoxia has been correlated with poor clinical response to radiation in cervical and breast cancer, chemo-radiation in patients with head and neck cancer, and chemotherapy in myeloma. Proteins up-regulated in hypoxic cells predict a poor prognosis when identified in a resected tumor or, in some cases, in patient serum. Intriguingly, prospective studies of head and neck and cervical cancer patients show that tumor hypoxia correlates with local/regional progression irrespective of whether surgery or radiation is applied as primary treatment. This suggests that while hypoxic tumors are less responsive to cytotoxic therapy, potentially due to drug delivery issues, they are also *inherently* more aggressive than non-hypoxic tumors.

Phenotypes of Hypoxic Cells

Several hypotheses could explain why hypoxic tumors may be less responsive to therapy and inherently more aggressive than non-hypoxic tumors (Fig. 1). These hypotheses are based primarily on the phenotypes of hypoxic neoplastic cells, for the most part studied *in vitro*. One hypothesis of why hypoxic tumors are more aggressive than non-hypoxic tumors is that hypoxia selects against cells with a pro-apoptotic phenotype. Hypoxia is a potent stimulus for apoptosis in a variety of tumor cell lines. Hypoxia-induced ►apoptosis can be blocked by ►Bcl-2 over-expression or a variety of other mutations (including, in some

H



Hypoxia. Figure 1 A model of how tumor hypoxia may affect the aggressiveness of these tumors. Hypoxia may promote de-regulated proliferation and apoptosis, genomic instability and differentiation, and thus select for aggressive tumors.

cases, ►p53 mutations). Thus, only hypoxic cells with a strong anti-apoptotic advantage survive, resulting in the selection of cells that are less responsive to therapy and a more aggressive tumor.

A second hypothesis for the aggressiveness of hypoxic tumors is that hypoxic cells are more prone to ►genomic instability, which may lead to inactivation of tumor suppressor genes or conversely, to activation of ►oncogenes. Several studies have suggested that hypoxia down-regulates several ►mismatch repair genes, and that some hypoxic cells have an increased rate of mutagenesis. Genomic instability appears to be increased in cells that are rendered hypoxic and then re-exposed to oxygen, perhaps due to DNA damage from the generation of ►reactive oxygen species. This hypoxia-reoxygenation pattern is known to occur in stroke and myocardial infarctions (i.e. re-perfusion damage) but may also play an important role in the dynamic tissue bed of tumors.

An additional hypothesis of why hypoxic tumors are more aggressive than non-hypoxic tumors is based on *in vivo* and *in vitro* data demonstrating that while most non-transformed, differentiated cells do not proliferate when hypoxic, a variety of tumor cells can proliferate in these conditions. While hypoxia-induced growth arrest has been noted in several transformed, neoplastic cell lines, hypoxic proliferation can occur in some cervical cancer, osteosarcoma, and transformed rodent cell lines. ►p53 status does not affect proliferation of hypoxic cells, but other mutations in the ►Retinoblastoma (Rb) axis allow cells to proliferate when moderately hypoxic (~1% environmental oxygen); these mutations are well documented in a majority of tumors and include elevated CDK2 activity (due to cyclin E over-expression in breast cancer, increased cyclin D activity in lymphoma, and decreased p27 found in many cancers) and mutations in Rb. Thus it is conceivable that hypoxic cells which can proliferate have ►cell cycle checkpoint abnormalities, and these abnormalities render these tumors more aggressive.

A lack of differentiation is a hallmark of cancer, and hypoxia has also been demonstrated to regulate differentiation. These effects vary, as do proliferation and apoptosis, depending on the cell type. Some hypoxic cells, including some hematopoietic stem cells, are resistant to pharmacologically-induced differentiation. Other cells undergo increased differentiation when hypoxic. Therefore, it is plausible that hypoxia correlates with absence of differentiation, hence aggressive tumorigenesis. A final hypothesis to explain the aggressiveness of hypoxia is that hypoxic tumors, through up-regulation of ►vascular endothelial growth factor (VEGF) and other pro-►angiogenic factors, are able to metastasize more rapidly than non-hypoxic tumors. Indeed, studies in cervical cancer have shown more metastatic disease in those patients with resected hypoxic tumors. Hypoxic cells have also been shown to up-regulate genes that may play an important role in digesting the extracellular matrix and tumor cell invasion.

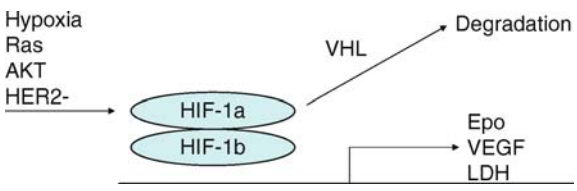
Gene Regulation in Hypoxic Cells: Implications for Tumorigenesis

In an attempt to better understand the biology of hypoxic cells and hypoxic tumors, much work has

focused into the delineation of the mechanisms by which cell signaling and gene regulation are altered in hypoxic cells, and whether this may be extrapolated to hypoxic tumors. Several signaling events and ►transcription factors are generated in hypoxic cells, including ►NFκB, activation of p38, and fluxes in reactive oxygen species. However, the best studied regulator of hypoxia-induced genes is the transcription factor ►Hypoxia Inducible Factor 1 (HIF-1), a heterodimer HIF-1α and HIF-1β. HIF-1β may also heterodimerize with the HIF-1α-related proteins HIF-2α and HIF-3α, and while the individual roles of each of these are still being evaluated, HIF-2 may play an important role in tumorigenesis. HIF-1 was first characterized as the transcription factor responsible for up-regulating erythropotietin, a growth factor for red blood cells that is induced during periods of anemia (and thus systemic hypoxia).

Under normoxic conditions, HIF-1α is hydroxylated by a prolyl hydroxylase, ubiquitinated, and degraded by the ►proteasome. In hypoxic cells, prolyl hydroxylases are inactive, and HIF-1α is stabilized. HIF-1α is over-expressed in renal cancer when the ►E3 ubiquitin ligase responsible for its degradation, the ►Von-Hippel-Lindau protein VHL, is absent. In fact, renal cell cancers are often characterized by increased vasculature and associated with erythrocytosis, both features of HIF-1 target gene activation. HIF-1α is also stabilized by ras, AKT, Her-2 over-expression and other oncogenic alterations often found in cancer (Fig. 2). Over-expression of HIF-1 is an independent indicator of poor prognosis in many malignancies.

Complete ►knockout of HIF-1α is embryonic lethal in mice. Original experiments done on embryonic stem cells suggested that apoptosis may be increased in hypoxic cells lacking HIF-1 function. In a mouse model of astrocytomas, HIF-1 was required for growth in a hypoxic environment, and HIF-1 in endothelial cells also seems necessary for solid tumor growth. Although the complete functional significance of HIF-1 in both normal cells and in cancer remains unclear, most consider HIF-1 activity as important in promoting the survival and adaptation of hypoxic tumors. Thus, the interference of HIF-1 activity is being actively pursued as a therapeutic target in cancer therapy.



Hypoxia. Figure 2 The hypoxia-induced transcription factor, HIF-1, may be highly expressed in both hypoxic as well as normoxic tumors. This over-expression leads to the up-regulation of a variety of genes that allow a tumor to survive and grow.

Because of the important, although unclear, role of HIF-1 in cancer, a major challenge in the field is to determine what genes are regulated by the HIF-1 transcription factor. The full range of HIF-1 targets is not known, but knock-out studies have predicted anywhere from 100 targets to 2.6% of the genome. It is clear that HIF-1α transactivates many genes necessary for hypoxic adaptation, including glucose transporters, glycolytic enzymes, and growth factors important for angiogenesis. It has recently been demonstrated that many HIF-1 targets such as VEGF and erythropoietin are protective against apoptotic cell death. Common HIF-1 targets are vital for tumor invasion, metastasis and angiogenesis, and many of these targets, such as VEGF and LDH, are elevated in many aggressive cancers.

One well-recognized result of hypoxia, and HIF-1 up-regulation, is an increase in anaerobic (glycolytic) metabolism (►glycolytic metabolism). The cancer cells preference to utilize anaerobic metabolism even in the presence of ample oxygen was first noted by Otto ►Warburg. This property of many malignant cells is an inefficient method of energy production, requiring increased utilization of glucose. In fact, the increased utilization of glucose by hypoxic and non-hypoxic tumors forms the basis for ►positron emission tomography (PET) scanning in cancer, where tumor cells may be recognized non-invasively through their high up-take of labeled glucose. Recent studies indicate that this increased metabolism of glucose even in normoxic tumors is due to increased activity of HIF-1, which is known to increase the expression of many of the enzymes involved in glycolysis. HIF-1 also inhibits flux through the Krebs cycle and thus suppresses aerobic metabolism directly.

In addition to the well recognized role hypoxia has on transcription, through HIF-1 and other transcription factors, there are other mechanisms that have been described for altering the expression of proteins important in the neoplastic process in hypoxic cells. The mRNA of an undetermined number of transcripts, including VEGF, are stabilized in hypoxic cells, although the mechanism(s) have not been entirely clarified. More recent studies have documented that hypoxia can suppress protein translation through the ►mTOR pathway and others. Misfolded proteins in the hypoxic cell's endoplasmic reticulum also activate the unfolded protein response (UPR). The UPR is an efficient mechanism to halt protein translation, while paradoxically *increasing* the translation of a select number of mRNAs, including the transcription factor ATF-4. The hypoxic suppression of protein translation is thought to be a protective mechanism by which hypoxic cells conserve energy.

Intriguingly, recent data suggests that some of these regulatory mechanisms may be altered in hypoxic neoplastic cells, potentially providing cancer cells another mechanism to manipulate the hypoxic environment.

Synonyms

HIF-1

Definition

►Hypoxia is widespread within most solid tumors. This stress situation is sufficient to activate the key transcription factor, hypoxia inducible factor (HIF)-1 that mediates the activation of the survival pathways in cancer cells. HIF-1 can also be induced by oxygen-independent genetic deregulations that activate a variety of ►oncogene signaling pathways or inactivate ►tumor suppressors. Increased tumor HIF-1 is often correlated with increased ►angiogenesis, malignant cancer ►progression, poor patient prognosis, and resistance to cancer therapies. HIF-1 is a proangiogenic transcription factor that interacts with a specific promoter sequence, called hypoxia response elements (HREs) in the regulatory region of the target DNA to stimulate transcription of multiple angiogenic factors including ►vascular endothelial growth factor (VEGF). In addition, HIF-1-targeted genes also include genes involved in cell proliferation, survival, ►invasion, and ►drug resistance. Due to its role in several key events of cancer progression, HIF-1 is an important molecular target for cancer therapy.

Characteristics

Mechanisms

Hypoxia, or lack of oxygen, has been recognized as a major driving force of solid tumor progression. Microregions of heterogeneous cell environments are associated with the development of abnormal vasculature formation in malignant tumors, which often consist of distended capillaries with leaky walls and sluggish flow, as compared with the regular, ordered vasculature of normal tissues. Despite the constant effort of tumor cells to recruit new blood vessels, there are significant gradients of critical factors for cell growth such as oxygen, glucose, other nutrients, and growth factors. Hypoxia occurs in tumor cells that are 100–150 μm away from the nearest blood vessel and tend to be widespread in solid tumors. The anaerobic metabolism of glucose provides a major energy source for tumor cells in hypoxic regions. The ability of tumor cells to endure profound hypoxia indicates that their adaptation to hypoxic conditions is a crucial step in tumor progression. HIF-1 is the intrinsic survival factor of tumor cells to overcome O_2 and nutrient deficits during tumor proliferation and progression. Regardless of oxygen tension, cancer cells sustain high aerobic glycolytic rates and produce high levels of lactate and pyruvate. This phenomenon, known as the Warburg effect after its discoverer was first described in cancer more than seven decades ago. Expression of HIF-1 is indirectly upregulated via "gain-of-function" mutations in ►oncogenes and "loss of function" mutations in ►tumor suppressor genes that result in increased HIF-1 transcriptional activity. As a result of genetic alterations together with the intratumoral hypoxia, HIF-1 activation is enhanced in the majority of common human cancers, which is strongly correlated with tumor grade, vascularity, ►metastasis, prognosis, and overall

survival. HIF-1 can induce various gene products that control energy metabolism, neovascularization, survival, and cell ►migration; all of which are promoters of tumor growth. HIF-1 is a heterodimeric transcription factor composed of two subunits, HIF-1α and HIF-1β. The HIF-1α subunit is rapidly degraded under normal O_2 conditions (normoxia) while the β subunit is constitutively expressed. Under low oxygen concentrations, HIF-1α is stabilized and dimerizes with HIF-1β to form an active transcription factor. Both HIF-1 subunits are members of the basic helix–loop–helix (HLH)-containing family of transcription factors. The HLH domain mediates heterodimer formation between the HIF-1 and HIF-1 subunits, which is necessary for DNA binding by the basic domains. HIF-1 is constitutively produced and degraded under normoxia while HIF-1 expression is unaffected by O_2 levels. Oxygen-dependent hydroxylation of three amino acid residues within HIF-1 affects both the stability of HIF-1 and its function as a ►transcription factor. The hydroxylated protein is then recognized by von Hippel Lindau protein (►pVHL), which is a part of an E3 ubiquitin ligase complex, ubiquitinated and targeted for proteasomal degradation. Under hypoxic conditions, HIF-1 remains unhydroxylated and does not interact with pVHL but preferentially binds to p300/CBP transcription coactivators. Following this hypoxic stabilization, HIF-1 translocates to the nucleus where it heterodimerizes with HIF-1 to bind to the DNA sequence 5′-RCGTG-3′ (hypoxia responsive element), located in the promoter of target genes. This subsequently leads to upregulation of factors that promote tumor growth and angiogenesis, including glycolytic enzymes and VEGF. HIF-1 transcriptionally upregulates VEGF production as part of the oxygen-regulation system that stimulates the production of new blood vessels to support tumor growth. Overexpressed VEGF leads to increased capillary leakiness and vascular permeability, which is followed by vascular hyperplasia, leading to increased vessel density. Solid tumors universally develop large areas of hypoxia as tumor growth exceeds the existing vascular supply, which promotes growth of new vasculature through HIF-dependent and -independent mechanisms. These cancers are particularly lethal; hypoxic cells in solid tumors are able to remain viable because they are resistant to both radiation and chemotherapy.

Clinical Aspects

HIF-1 activity is tightly regulated by the stability of HIF-1 in both hypoxic and normoxic conditions in normal tissues. It is deregulated by the activation of oncogenic pathways and the loss of tumor suppressor function (e.g., pVHL, ►PTEN, and ►p53) in many cancers, which causes HIF-1 to accumulate regardless of oxygen tension. The extensive ►immunohistochemical data in multiple human tumors demonstrate unequivocally that the HIF pathway is a major contributor to tumor development and progression in ►prostate cancer, ►breast cancer, ►lung cancer, ►colon cancer, ►bladder cancer, head and neck cancers, ►ovarian cancer, ►renal cell carcinoma, ►hepatocellular carcinoma, ►gastric cancer, ►brain tumors, and ►pancreatic cancer. In some diseases, HIF-1 is an independent prognostic factor and could be used to predict clinical outcome and survival or alternately used to assist in decisions for ►adjuvant therapies. Evidence of the importance of HIF as a key factor in tumorigenesis, ►angiogenesis and tumor progression from the immunohistochemical data of human tumors, and the growing knowledge of the molecular mechanism of its regulation will reveal novel anticancer therapies in the near future. Currently, a number of drug candidates that inhibit HIF-1 accumulation are in clinical trials (http://clinicaltrial.gov) including heat shock protein ►HSP90 inhibitors, ►mTOR inhibitors, and ►2-methoxyestradiol.

IARC *TP53* Database

Magali Olivier, Pierre Hainaut
Group of Molecular Carcinogenesis and Biomarkers, International Agency for Research on Cancer, World Health Organization, Lyon cedex 08, France

Definition

The ►IARC ►TP53 mutation database is a public web-based resource for the analysis and interpretation of the biological and clinical impacts of ►*TP53* gene variations in human cancers (http://www-p53.iarc.fr/). It contains data that are compiled from the scientific literature and includes all *TP53* gene variations that have been reported in human cancers, with related information on tumor pathology, patients demographics, and predicted or experimentally assessed functional impacts of mutations. It can be searched and analyzed online and is useful to draw hypotheses on the nature of the molecular events involved in ►*TP53* mutagenesis and on the natural history of cancer.

With over 25,000 somatic and 400 germline mutations and 2,000 citations in the world literature, this database is recognized as a major source of information on *TP53* mutation patterns in human cancer. The database is meant to be a resource for a broad range of scientists and clinicians who work in different research areas: basic research, to study the structural and functional aspects of the ►p53 protein; ►molecular pathology of cancer, to understand the clinical significance of mutations identified in cancer patients; molecular epidemiology of cancer, to investigate links between specific exposures and ►mutation patterns and to make inferences about possible causes of cancer; molecular genetics, to study genotype/phenotype associations.

Useful Links: TP53 OMIM: 191170; LFS OMIM: 151623; GenBank: X54156; IARC TP53 database: http://www-p53.iarc.fr.

Characteristics

TP53 Gene Mutations in Human Cancers

The tumor suppressor gene *TP53* (OMIM #191170) encodes a transcription factor with multiple, anti-proliferative functions activated in response to several forms of cellular stress. Somatic *TP53* gene alterations are frequent in most human cancers and inherited *TP53* mutations predispose to a wide spectrum of early-onset cancers (►Li-Fraumeni Syndrome, OMIM#151623). More than 72,000 tumor samples have been screened for *TP53* mutations with an overall mutation frequency of 30% (ranging from 5% to 70% depending on the type and stage of cancer), which makes data on *TP53* mutations the largest dataset of mutations in any human gene.

In contrast to other ►tumor suppressor genes that are mainly inactivated by truncating mutations, the most frequent alterations in *TP53* gene are single nucleotide substitutions leading to the production of full-length proteins which differ from the wild-type protein by a single amino-acid substitution (►missense mutation). *TP53* missense mutations cluster within the central

portion of the gene encoding the DNA-binding domain of the protein. Nine missense mutations account for about 30% of all mutations found in human cancers, but more than 1,500 distinct mutant proteins have been found in human cancers. A great amount of data has been generated on the functional impact of p53 missense mutations. In particular, one study has performed a systematic analysis of the trans-activation activity on eight different p53 response-elements (p53-RE) in yeast cells of all possible missense mutations in the entire sequence of *TP53* (2314 mutations). This study showed that a great proportion of missense mutations retain partial trans-activation activity on one or more p53 response-elements and that there is an overall good correlation between complete loss of trans-activation and frequent occurrence in cancer.

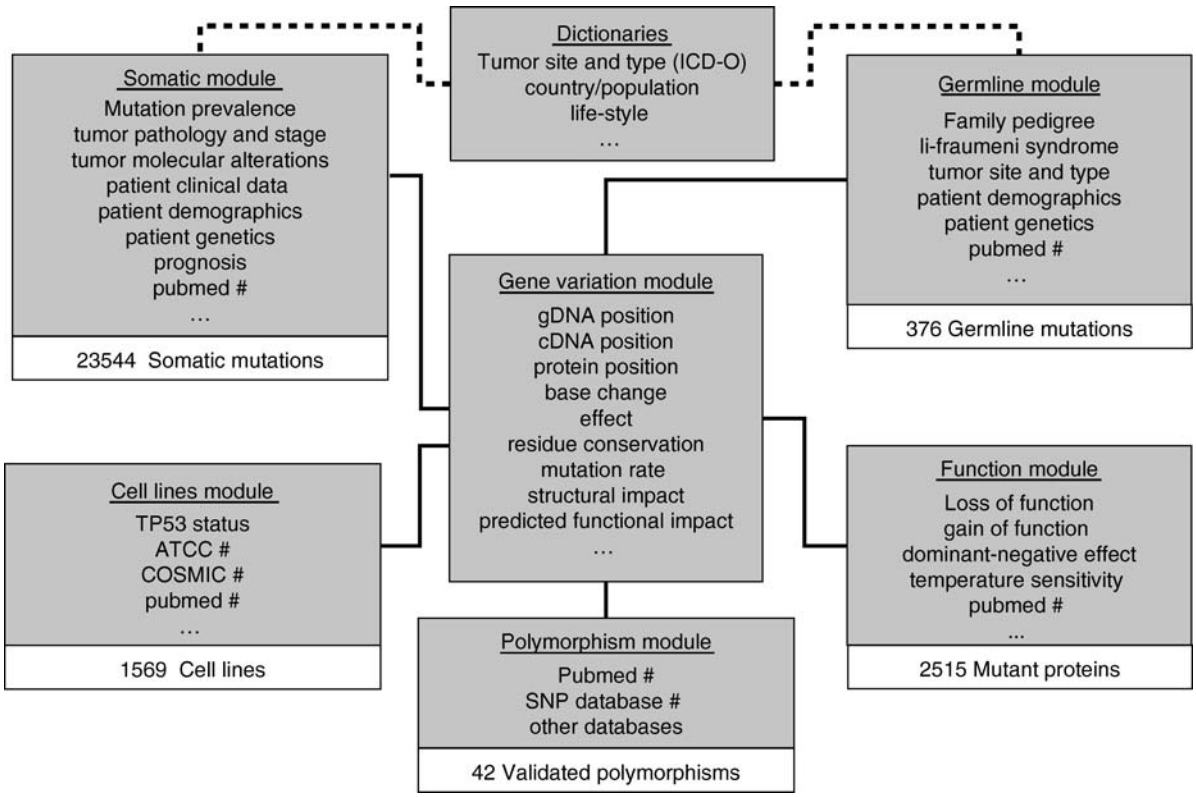
The diversity of mutations observed in cancers is a source of information on the natural history of cancers. The factors that influence the formation of a specific mutation pattern can be seen as a succession of "filters" that select for particular mutations. First, the capacity of exposed cells and tissues to metabolize carcinogens determines the capacity of a given mutagen to induce DNA-damage. Second, the type of damage caused by a mutagen can be specific in its nature and DNA-sequence context. Third, the inherent capacity of cells to repair DNA corrects for most alterations and only those that escape repair will result in fixed mutations. Fourth, biological selective mechanisms favor cells that have acquired a proliferative advantage as a consequence of the mutation. Weighing the contribution of these successive filters in shaping a tumor-specific mutation pattern provides interesting clues on the molecular mechanisms involved in the etiology and pathogenesis of human cancers. The nine frequent mutants are found in all types of cancers and result from transitions at highly mutable ►CpG dinucleotides, at codons encoding residues that play essential structural of chemical roles in specific DNA-binding activities of p53 protein. These mutations result in a complete loss of DNA-binding activity and trans-activation capacity, on which rely the tumor suppressor function of *TP53*. Underlying mutagenicity and loss of function are thus the main driving force for the selection of these mutations during cancer development. In some cancers, characteristic patterns of *TP53* mutations have been observed and linked to exposure to environmental carcinogens, e.g., ►aflatoxin B_1 (AFB_1) exposure and G>T mutations at codon 249 in ►hepatocellular carcinoma of ►HBV chronic carriers; ►ultraviolet radiation and CC to TT tandem mutations in non-melanoma skin cancer; and cigarette smoke and G>T transversions in ►lung cancer of smokers (►tobacco-related lung cancer). Specific mutation patterns in *TP53* may thus help identify environmental exposures that may be involved in ►carcinogenesis.

Database Structure and Content

The IARC TP53 Database contains data that are extracted from peer-reviewed publications or bioinformatics databases and curated manually. The core database is a relational database that integrates data on somatic mutations in sporadic cancers, on germline mutations in familial cancers, on *TP53* gene status of cell-lines, on polymorphisms in human population and on functional assessment of mutations. It is organized around a "gene variation module" to which five modules are connected: a "somatic module," a "germline module," a "function module," a "polymorphism module" and a "cell-line module" (Fig. 1).

The database is a relational database in which different sets of data are integrated in a single scheme. The structure and content presented corresponds to the R11 (October 2006) release of the database that is maintained in SQL sever. This database design and content allow, for every single gene variation, to retrieve data on its functional and structural impact, and data related to its expression in a somatic, cell-line or germline context. Details on database contents and annotations are available at http://www-p53.iarc.fr/Help.html.

The "gene variation module" contains all possible single nucleotide substitutions in the coding sequence and splice sites of *TP53*, plus all other sequence alterations that have been reported in human cancers, each alteration being a unique entry. Gene variation are described at the DNA and protein levels and are annotated with structural and functional information related to the position of the mutation in the protein sequence (functional domain, residue function, structural motif, solvent accessibility of residue). For missense mutations, classifications based on the predicted or experimentally assessed functional impacts are also available. The "►polymorphism" includes common gene variations reported in publications or extracted from ►SNP databases, with links to databases that provide information on population frequency or disease associations. The "somatic and germline modules" contain data related to the somatic or germline expression of mutations respectively, with common set of dictionaries used to annotate pathological, clinical and patient information. The "cell-line module" contains *TP53* gene status of human cell-lines with links to the ATCC catalog (cell-line provider). The "Function module" contains experimental data obtained on the activities and properties of p53 mutant proteins when transfected and over-expressed in human or yeast cells. Each entry in this module corresponds to the results of a set of experiments performed with one mutant in a specific cell-type. Experimental assays that have been included were performed in yeast or human cells and were designed to (i) measure the transactivation activities of mutant proteins on reporter genes placed



IARC *TP53* Database. Figure 1 Structure and contents of the IARC TP53 database (R11, 2006).

under the control of various p53 response-elements, (ii) test the capacity of mutant proteins to induce cell-cycle arrest or apoptosis, (iii) exert dominant-negative effect over the wild-type protein, be temperature sensitive, or display various activities that are independent and unrelated to the wild-type protein (gain of function). A specific vocabulary has been implemented to describe experimental results in a standard format. The detailed annotation system used in all modules is described in the online user guide at http://www-p53.iarc.fr/Help.html.

Web Site and New Search Tools

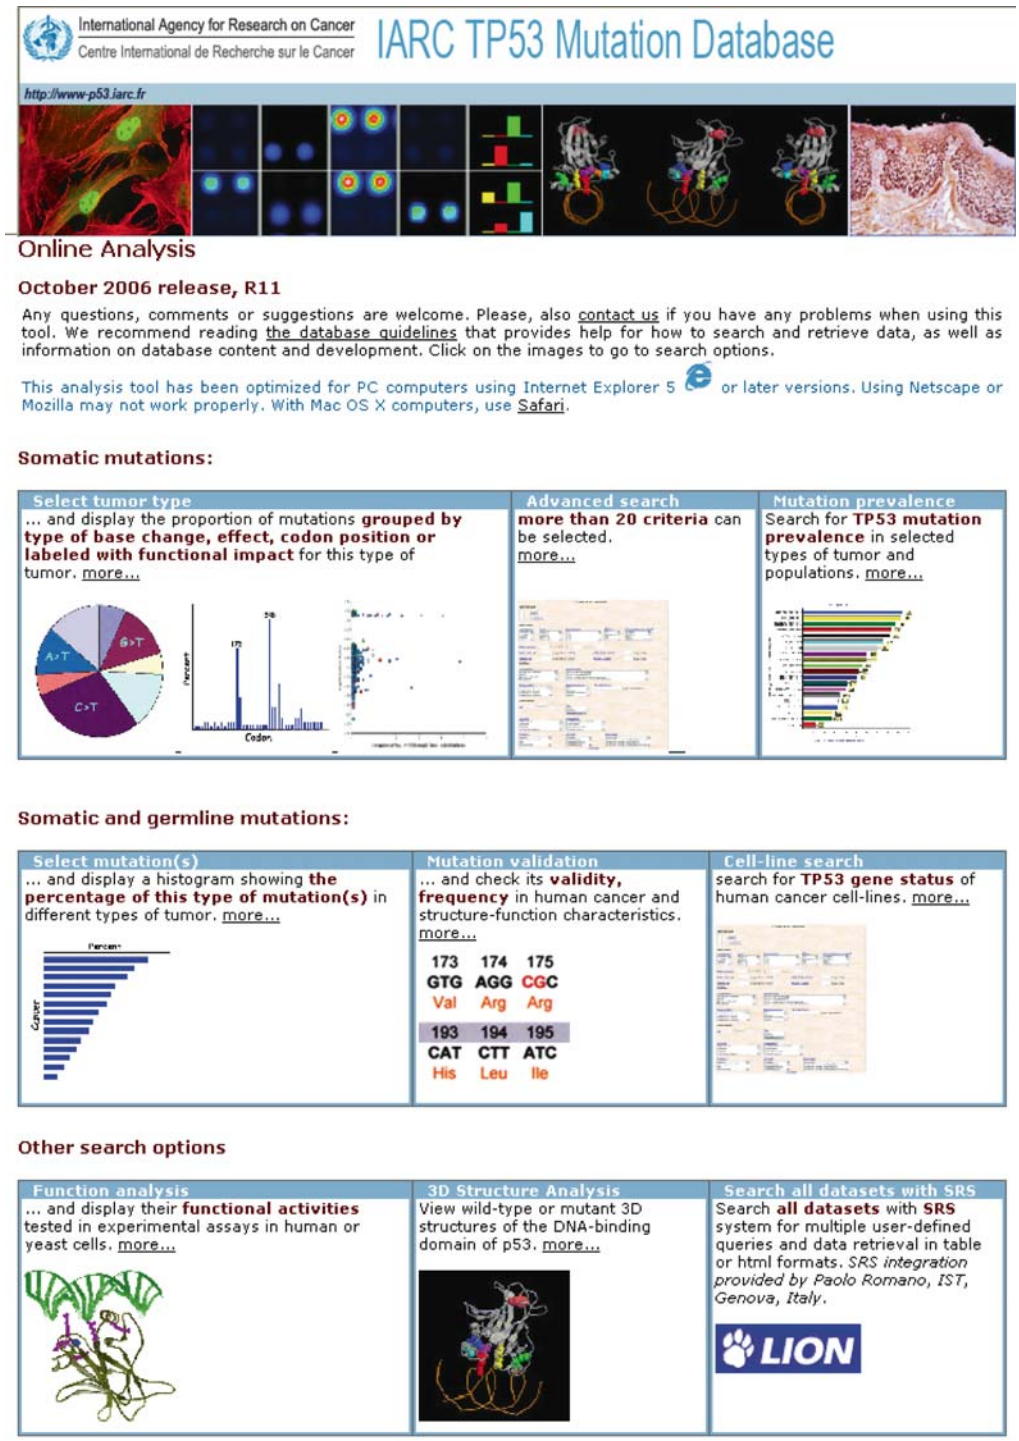
The IARC *TP53* web site (http://www-p53.iarc.fr/) provides a search interface for the core database and includes a comprehensive user guide, a slide-show on *TP53* mutations in human cancer, protocols and references for sequencing *TP53* gene, and links to relevant publications and entries to bioinformatics and cancer databases.

The database interface allows the download of all modules and propose various tools for the selection, analysis and downloads of specific sets of data according to user's query (Fig. 2). Mutations reported in specific types of cancers and/or population groups can be analyzed with graphs that display their type by base substitutions (mutation patterns), codon distribution, position within the 3D structure of p53 DNA-binding domain, and predicted or observed effect on protein (function patterns). Other graphs can be drawn to display the types of tumor associated with specific mutations expressed in a somatic or germline context, and to display the prevalence of mutations found in specific tumor types and/or population groups. Other tools include: a mutation validation tools that allows the retrieval of all data available in the database for a specific DNA variation (frequency as a somatic or germline mutation, predicted and observed functional impact); a search option to retrieve experimental data on functional properties of mutant proteins; a search option to retrieve cell-lines for which *TP53* gene status is known.

Several options and tools are available to retrieve and analyze specific sets of data from the core database according to user defined queries. Different types of graphs are implemented to analyze data and raw data can be downloaded as tables. All datasets can be entirely downloaded as tab-delimited text files. The search page is available at http://www-p53.iarc.fr/P53main.html.

Recommendation to Users

The IARC TP53 database is exclusively based on peer-reviewed publications. Trends in reporting and



IARC *TP53* Database. Figure 2 Search system for the analysis of the IARC TP53 database.

publishing mutations have thus a strong influence on the data included in the database. Studies from which data are extracted have diverse designs and diverse way of reporting mutations and related information. This diversity requires an effort of standardization of annotations and affect database analysis. It thus important that users are aware of the limitations and possible biases that may affect their analysis of the database. These bias are described in details at http://www-p53.iarc.fr/Help.html#Recommendations.

The IARC TP53 database is a free service to the scientific community, and contributions from researchers and journal editors are most welcome to help us develop this important resource for cancer research.

IκB

Definition

Are initially described as proteins that inhibit the function of transcription factor ►NF-κB (inhibitor of κB). Meanwhile, IκBs extended to a protein family of seven members primarily structural related by the presence of several ►ankyrin repeats in their central domain. Through these motifs, they interact with and regulate NF-κB function in various ways.

►BCL3
►Nuclear Factor kappa-B

IκBα

Definition

MAD-3, pp40, RL/IF-1 and ECI6; Is one of a family of proteins that are the natural inhibitors of ►NF-κB. It acts by complexing to NF-κB in the cytoplasm of unstimulated cells. When IκBα is inactivated, NF-κB is allowed to enter the nucleus.

►Hodgkin Disease, Clinical Oncology
►Nuclear Factor kappa-B

IC_{50}

Definition

50% inhibitory concentration; Refers to the concentration of a drug that reduces a biochemical activity (e.g. an enzymatic activity) or cellular parameter (such as cell multiplication) to 50% of its normal value in the absence of the inhibitor.

►Small Molecule Screens

ICAMs

Definition

Intercellular ►adhesion molecules are cell-surface ligands for the ►leukocyte integrins and are crucial in the binding of lymphocytes and other leukocytes to certain cells, including ►antigen-presenting cells and ►endothelial cells. They are members of the immunoglobulin superfamily. ICAM-1 is the most prominent ligand for the integrin CD11a:CD18 or LFA-1. It is rapidly inducible on endothelial cells by infection, and plays a major role in local ►inflammatory response. ICAM-2 is constitutively expressed at relatively low levels by endothelium. ICAM-3 is expressed only on leukocytes and is thought to play an important part in adhesion between T cells and antigen-presenting cells, particularly ►dendritic cells.

►Integrin Signaling

Id1

Definition

Member of the group of ►Id Proteins.

Id Proteins

Definition

Inhibitor of DNA (Id) binding proteins are a family of related nuclear ►helix-loop-helix-proteins implicated

in the control of differentiation and cell cycle progression. Id nuclear proteins interact with ►transcription factors and prevent them from binding to DNA. The primary targets of Id proteins are the basic helix-loop-helix (bHLH) transcription factors, which regulate cell-type-specific gene expression and expression of ►cell cycle regulatory genes. Generally, they act as positive regulators of cell growth and as negative regulators of differentiation. Id proteins lack a basic DNA-binding domain; therefore, heterodimers between Id and bHLH proteins cannot bind to DNA. This mode of regulation is referred to as dominant-negative. Id proteins act as dominant-negative antagonists of other helix-loop-helix transcription factors; Id1, Id2, Id3, Id4, E-box.

- Id1, inhibitor of DNA binding 1, is a protein of 154 amino acids and 16 kD. The gene maps to chromosome 20 band q11.
- Id2, inhibitor of DNA binding 2, is a protein of 134 amino acids and 14 kD. It is expressed in most early fetal tissues but not in the corresponding mature tissues. The gene maps to 2p25.
- Id3, inhibitor of DNA binding 3, also known as Heir-1 is a protein of 119 amino acids and 12 kD. It is expressed abundantly in lung, kidney, and adrenal gland, but lacking in adult brain. The gene maps to 1p36, a region frequently deleted in human cancers including neuroblastoma.
- Id4, inhibitor of DNA binding 4, is a protein of 161 amino acids and 16 kD. The gene maps to 6p22-21.

Idiotype Vaccination

Maurizio Bendandi
University Clinic and Center for Applied Medical Research, University of Navarra, Pamplona, Spain

Synonyms

Anti-idiotype vaccination; Idiotypic vaccination

Definition

►Idiotype vaccination is an ►immunotherapy procedure based on the fact that save for its very early stage of differentiation, each clone of B lymphocytes features a specific antibody on the cell surface. The most variable portion of this antibody is a unique feature of the corresponding clone. Its natural function is that of specifically recognizing an antigen, but it can also be used as an antigen (idiotype) itself, that is as a potential vaccine target and tool. The most relevant context in which this second function is exploited is idiotype vaccination as a treatment for human ►B-cell lymphoma.

Characteristics

Field of Application

The vast majority of B-cell lymphomas consist of the clonal expansion of neoplastic B-cells, all featuring the same surface antibody and consequently the same

idiotype. However, each patient's tumor presents with a different, patient- and tumor-specific idiotype. Therefore, an individualized, custom-made idiotype vaccine must be produced for each patient. Most of what we know about idiotype vaccination in human B-cell lymphoma derives from studies conducted in an indolent subset called ►follicular lymphoma. Far less has been instead concluded so far as to whether or not the same approach could be successful in other B-cell malignancies, such as ►mantle cell lymphoma, ►multiple myeloma, and ►chronic lymphocytic leukemia, or even in certain solid tumors, whenever an anti-idiotype ►monoclonal antibody structurally mimics tumor-associated antigens other than antibodies. Nevertheless, idiotype vaccination stands out as the most successful human cancer vaccine, since over the last 20 years has provided the first formal proofs of principle concerning biological efficacy, clinical efficacy, and clinical benefit of such a procedure.

Formulation

Although idiotypic vaccination has been tested in humans with different formulations, such as soluble protein idiotype associated with an immunogenic carrier and an immunologic adjuvant, ►dendritic cells pulsed with the soluble protein idiotype, or idiotype ►DNA vaccine, most clinical results and all proofs of principle have been obtained using the first of these three options. In particular, the most successful idiotype vaccine formulation consists of soluble protein idiotype, that is the patient- and tumor-specific antigen, which is conjugated with keyhole limpet hemocyanin (KLH), the immunogenic carrier, and administered together with granulocyte-macrophage colony-stimulating factor (GM-CSF), the immunologic adjuvant.

Production

While KLH and GM-CSF are commercially available, soluble protein idiotype needs to be produced one patient at the time through either hybridoma or ►recombinant technology. In the former case, each patient's tumor cells, which are capable of producing the idiotype, but not to release it, are fused with a cell line that vice versa can release an idiotype, but is unable to produce it. The ►hybridoma resulting from the fusion process features both functions, can be cultivated in vitro, and releases therapeutic amounts of the patient- and tumor-specific, soluble protein idiotype. In the latter scenario, the genetic information encoding for the idiotype is introduced by means of a vector inside mammalian, insect, plant, or bacteria cells, which will ultimately replace the hybridoma as a factory for soluble protein idiotype production.

Clinical Aspects

Idiotype vaccination has provided the first formal proof of biological efficacy in 1992, when scientists at Stanford University showed that patients with follicular lymphoma were capable of developing a specific, anti-idiotype immune response after receiving idiotype vaccination. Seven years later, researchers at the National Cancer Institute proved clinical efficacy of idiotype vaccination by showing that in most follicular lymphoma patients who had received it, the immune system had become capable of killing in vivo tumor cells that had survived prevaccine ►chemotherapy. Finally, in 2006 clinical efficacy of idiotype vaccination was proved by showing that all follicular lymphoma patients who respond to the vaccine from an immunologic standpoint experience a significant prolongation of their disease-free survival.

Idiotype vaccination's procedure typically consists of a monthly, subcutaneous injection of 0.5 mg of idiotype conjugated with 0.5 mg of KLH, administered together with 125 mcg of GM-CSF. The same dose of GM-CSF alone is then given daily over the following 3 days at the same site of the complete vaccine formulation delivery. After 5 or 6 monthly doses, further boosts every 2–3 months are becoming increasingly popular and recommended.

Idiotype vaccination's side effects are mild and mostly local, if at all present. Flu-like symptoms are rare and self-limiting.

Open Questions

To date, a number of questions remain open with respect to idiotype vaccination.

For instance, from a clinical standpoint, we do not know whether this form of active ►immunotherapy has the potential to cure or just to control the disease in lymphoma patients who respond to it. Nor do we know whether patients with B-cell malignancies other than follicular lymphoma may benefit from it. The former question implies that it remains currently impossible to determine whether the administration of boosts should or could be stopped in patients who have responded to the vaccine from an immunologic point of view, irrespective of whether that immune response persists detectable, and remain free of disease. The latter question implies instead that only through well-designed ►clinical trials it might be possible to test idiotype vaccination in settings other than follicular lymphoma. In particular, it has to be reminded that typical randomized studies may fail to serve the purpose of proving the clinical benefit of a customized form of immunotherapy. In this respect, surrogate endpoints such as those defining minimal residual disease also need to be used with caution. For instance, in the very case of follicular lymphoma, both ►bcl-2 rearrangement assessed by molecular fingerprinting through qualitative and quantitative polymerase chain reaction and tumor cell phenotype assessed through ►flow cytometry not always correlate with immune responses and clinical outcome. All in all, it is possible that the currently ongoing randomized clinical trials will be at least able to shed some light on whether it may be possible to match the financial concerns of pharmaceutical companies

with the peculiar logistic requirements of a customized treatment like idiotype vaccine.

As for the adequate timing for treating patients with this immunotherapeutic approach, it seems to have become ever clearer that the best clinical setting to use idiotype vaccination is a good quality clinical complete response. This prevaccine result can be achieved nowadays through a variety of old and new therapeutic approaches such as standard or high-dose chemotherapy, cold or passive immunotherapy using ►radioimmunoconjugates. However, it is likely that in lymphoma patients selected to later undergo idiotype vaccination, prevaccine treatment should privilege agents and procedures with the lowest immune suppressive potential. At the opposite side of the widening spectrum of possible applications of idiotype vaccination stand the anecdotal attempts conducted with healthy donors undergoing this totally safe procedure with the myeloma-specific soluble protein idiotype obtained from their sibling recipient before ►hematopoietic stem cell allotransplant. Clinical and biological results remain incompletely understood, though extremely appealing from a purely scientific point of view.

Another crucial context in which idiotype vaccination specialists still struggle is that of defining the relevance of idiotype vaccine-induced humoral and cellular responses. In fact, it is not yet clear whether, though both desirable, just either of them is required for patients to experience clinical benefit. The question is of no little importance, considering that in nearly half of the patients with any vaccine-induced, idiotype-specific immune response, either type of immune response is not detectable. Currently, humoral responses, that is those featuring vaccine-induced anti-idiotype antibodies, are assessed and monitored in the lab by a single, relatively standardized method, whereas at least half a dozen of nonstandardized techniques are used in different labs worldwide to assess and monitor vaccine-induced cellular responses

Imatinib

Brian J. Druker
Oregon Health & Science University Cancer Institute, Portland, OR, USA

Synonyms

Imatinib mesylate; Gleevec; Glivec; STI571; ►STI-571; CGP57148

Definition

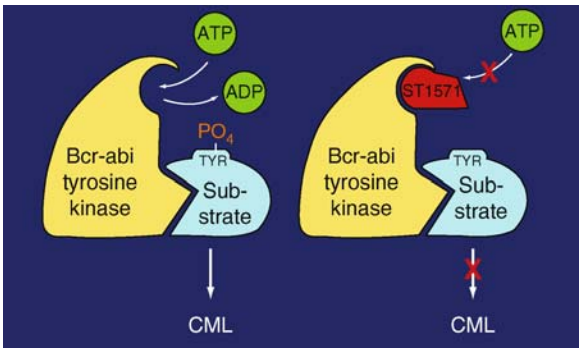
Is a small molecular weight compound that inhibits ►tyrosine kinases including ►ABL, ►KIT (►Kit/stem cell factor receptor in oncogenesis) and PDGFR (►Platelet-derived growth factor receptor). It has significant anti-tumor activity in chronic myeloid leukemia and ►gastrointestinal stromal tumors.

Characteristics

Imatinib (Gleevec, Glivec, formerly STI571 or CGP57148) is a tyrosine kinase inhibitor with activity against all of the ABL tyrosine kinases including ►BCR-ABL, ABL, v-ABL, and ARG (Abelson-related gene). Besides the ABL tyrosine kinase, other kinases inhibited by imatinib are the platelet-derived growth factor receptor alpha (PDGFRA) and beta (PDGFRB) and KIT. Given the critical role of tyrosine kinases in the regulation of cellular growth and known activating mutations that cause several cancers, it was hypothesized that specific inhibitors of these protein kinases might be effective anticancer agents. Beginning in the late 1980s, scientists at Ciba Geigy (now Novartis), under the direction of N. Lydon and A. Matter, performed high throughput screens of chemical libraries searching for compounds with kinase inhibitory activity. From this time-consuming approach, a lead compound was identified. Its inhibitory activity against the PDGFR was optimized by synthesizing a series of chemically related compounds and analyzing their relationship between structure and activity (►Drug design). The most potent molecules in the series were dual inhibitors of the PDGFR and ABL kinases. Of the several compounds generated from this program, imatinib emerged as the lead compound for clinical development based on its superior in vitro selectivity against ►CML cells and its drug-like properties, including pharmacokinetic and formulation properties (►Pharmacokinetics; ►pharmacodynamics).

BCR-ABL and CML as a Target for Imatinib

CML is characterized by the presence of the BCR-ABL ►fusion gene and protein. It arises from a ►reciprocal translocation between the long arms of chromosomes 9 and 22 (►Chromosome translocations) that generates a shortened chromosome 22 termed the ►Philadelphia chromosome. This was the first consistent chromosome abnormality associated with a human cancer. The (9;22) translocation results in fusion of the *ABL* ►oncogene from chromosome 9 with sequences from chromosome 22, the breakpoint cluster region (*BCR*), giving rise to a chimeric *BCR-ABL* gene. This fusion gene is transcribed and translated into a protein that functions as a constitutively activated tyrosine kinase. BCR-ABL induces a CML-like syndrome when introduced into bone marrow cells of mice (►Mouse models), confirming its causative role in the human disease. All of the transforming activities of BCR-ABL are dependent on its tyrosine kinase activity, thus a specific inhibitor of



Imatinib. Figure 1 Schematic representation of the mechanism of action of the BCR-ABL tyrosine kinase and its inhibition by STI571 (imatinib).

this kinase would be predicted to be an effective and selective therapeutic agent for CML (Fig. 1).

In a pivotal set of ►preclinical testing, imatinib was shown to suppress the proliferation of BCR-ABL-expressing cells in vitro and in vivo. In colony-forming assays of peripheral blood or bone marrow from patients with CML, imatinib caused a 92–98% decrease in the number of BCR-ABL colonies formed, with minimal inhibition of normal colony formation.

Activity of Imatinib in CML

Given the central role of the BCR-ABL tyrosine kinase in causing CML and the favorable preclinical profile of imatinib, CML was selected as the initial disease in which to test imatinib. In a standard dose-escalation Phase I study (►Clinical trial) conducted in patients with CML, imatinib was well tolerated. Significant clinical benefits were observed at doses of 300 mg per day and above. In patients with chronic-phase disease who were interferon resistant or intolerant, 53 of 54 (98%) had their previously abnormal blood counts return to normal, typically within 4–6 weeks after beginning imatinib. Ninety percent of these responses lasted beyond 1 year. In patients with myeloid ►blast crisis, the most advanced phase of the disease, 21 of 38 (55%) patients responded, with 18% having responses lasting beyond 1 year. Imatinib rapidly advanced through Phase II and III testing for patients with CML and was FDA-approved in May 2001. It is now the standard initial therapy for patients with CML. A 5-year update of imatinib as initial therapy for patients with CML demonstrates an overall survival of 89%. At 5 years, an estimated 93% of patients remain free from disease ►progression to advanced phases of the disease: accelerated phase or blast crisis. Most of the side effects of imatinib are classified as mild to moderate and include low blood counts, ►Myelosuppression, fluid retention, diarrhea, nausea, muscle and joint aches, and skin rashes.

Mechanisms of Relapse/Resistance to Imatinib

Response rates to imatinib in CML patients with chronic-phase disease are quite high and, thus far, have been durable. Response rates are also quite high in patients with advanced-phase disease, but relapses, despite continued therapy with imatinib, are common. In the largest studies of resistance or relapse, several consistent themes have emerged. In the majority of patients who respond to imatinib but subsequently relapse while remaining on therapy, the BCR-ABL kinase has been reactivated. BCR-ABL kinase activity was analyzed by assessing tyrosine phosphorylation of CRKL, a direct substrate of the BCR-ABL kinase, and the major tyrosine phosphorylated protein in samples from patients with CML. In these studies, between 50 and 90% of relapsed patients have a BCR-ABL point mutation located in one of over 40 different amino acids scattered throughout the ABL kinase domain. Some other patients have amplification of *BCR-ABL* at the genomic or transcript level. In contrast, in patients with primary resistance – that is, patients who do not respond to imatinib therapy – BCR-ABL-independent mechanisms are most common. In patients who relapse as a consequence of reactivation of the BCR-ABL kinase, the BCR-ABL kinase remains a good target. Alternate ABL kinase inhibitors are already in clinical trials (►Nilotinib, ►dasatinib) and dasatinib is FDA-approved for patients with CML with imatinib resistance. There remains at least one imatinib-resistant mutation, T315I, that is not inhibited by either drug.

Activity of Imatinib in Other Diseases

Given the success of imatinib in CML, it was logical to try imatinib in other diseases where activated tyrosine kinases targeted by imatinib have causative roles. Thus, imatinib also has significant activity in patients with ►acute lymphoblastic leukemia who are *BCR-ABL*-positive. Another tumor in which imatinib has shown activity is ►gastrointestinal stromal tumor (GIST). GISTs are mesenchymal neoplasms that can arise in any organ in the gastrointestinal tract or from the mesentery or omentum. The majority of GISTs express KIT, and in 90% of cases, KIT activation is linked to mutations, usually involving exons 9 or 11. Published data suggest that the response rate of GISTs to single- or multi-agent ►chemotherapy is less than 5%. In contrast, the response rate to imatinib as a single agent in patients with advanced GIST was 53–65% with another 19–36% of patients having disease stabilization. Mutational status helps predict response to imatinib in GIST patients. Patients whose tumors contain the most common activating KIT mutation exon 11 have a significantly higher partial response rate (83.5%) to imatinib therapy

than did patients whose tumors had no detectable mutations in *KIT*. Patients whose tumor harbored a *KIT* exon 9 mutation did less well than those with an exon 11 mutation but responded better (response rate of 48.7%) and had a longer time-to-treatment failure than those with no detectable mutation.

Similar to the situation in CML, many imatinib-resistant tumors have acquired kinase mutations in the kinase domain of KIT. However, resistance mechanisms in GISTs are more heterogeneous than those seen in chronic-phase CML as some tumors actually lose KIT expression and other tumors become imatinib-resistant without acquisition of secondary kinase mutations. Again, similar to the situation with CML, novel KIT kinase inhibitors are being tested in patient with imatinib-resistant GIST and one of them, sunitinib, has been FDA-approved for this indication.

Imatinib also has activity in neoplasms that are caused by oncogenic activation of PDGFRs (Platelet-derived growth factor receptor). This includes the subset of patients with chronic myelomonocytic leukemia that results from fusion of the ►*EVT6* (*TEL)* and *PDGFRB* genes. Similarly, dermatofibrosarcoma protuberans, a low-grade sarcoma of the dermis, is characterized by a (17;22) translocation involving the *COL1A1* and *PDGF-B* genes, which results in over-production of fusion COL1A1-PDGF-BB ligand and consequent hyperactivation of PDGFRB. Patients with this tumor also respond to imatinib. Hypereosinophilic syndrome is another example of an imatinib-sensitive disease. In this case a *PDGFRA* fusion gene product (FIP1L1-PDGFRA) is the activated target.

Conclusion

The development of imatinib and its clinical application demonstrate an emerging paradigm in cancer therapy where the tumor is defined by molecular genetic abnormalities instead of the tissue of origin. It further demonstrates that effectiveness of cancer therapy when treatments target events critical to the growth and survival of specific tumors. (►Molecular therapy).

Imatinib Mesylate

►Imatinib

Imiquimod

Definition

A small molecular drug that activates TLR7 and/or TLR8 agonist that is used as a prescription medication to treat ►skin cancer (►basal cell carcinoma, ►Bowen disease, superficial squamous cell carcinoma, some superficial malignant melanomas and actinic keratosis) as well as genital warts.

Immature B Cells

Definition

Are ►B cells that have rearranged a heavy- and a light-chain V-region gene and express surface IgM, but have not yet matured sufficiently to express surface IgD as well.

Immediate Early Genes

Definition

IEGs; A class of approximately 100 structurally and functionally unrelated genes, whose transcription is induced through the phosphorylation and activation of pre-existing transcription factors such as ►ELK-1 by intracellular signaling pathways like ►MAP kinase. A hallmark of immediate early genes (IEGs) is that their transcription is independent from *de novo* protein

synthesis, which distinguishes them from delayed early genes. Examples for IEG products include ►FOS, a component of the ►AP-1 transcription factor complex, and several members of dual specificity phosphatases, which act as negative feedback regulators of MAP kinases.

►B-Raf Signaling

Immediate Early Stress Response

►Stress Response

Immortalization

Definition

Describes the acquisition by a eukaryotic cell line of the ability to grow through an indefinite number of divisions in culture. Cells are capable of indefinite proliferation (or unlimited lifespan) without any other changes in the phenotype necessarily occurring. In long lived multicellular organisms, immortality may be thought of as an abnormal escape from cellular ►senescence.

►Telomerase
►Senescence and Immortalization

Immortalized

Definition

Refers to the status of ►immortalisation of cells.

Immortalized Cells

Definition

Transformed cells that can grow and divide indefinitely in vitro.

►Adult Stem Cells
►Immortalization

Immune Adjuvants

Definition

Substances that are typically added to vaccines to enhance their immunogenicity.

►Peptide Vaccines for Cancer
►Adjuvant

Immune Complex

Definition

The binding of antibody to a soluble antigen forms an immune complex. Large immune complexes form when sufficient antibody is available to cross-link the antigen; these are readily cleared by the reticuloendothelial system of cells bearing Fc and complement receptors. Small, soluble immune complexes that form when antigen is in excess can be deposited in and damage small blood vessels.

Immune Deviation

Definition

Is the deliberate polarization of an immune response from one dominated by T_H1 to one dominated by T_H2, or vice versa.

Immune Escape

Jiahua Qian, Tamara Floyd, Yufei Jiang, Anat Ohali, Raed Samara, Hong Yang, Samir N. Khleif
Cancer Vaccine Section, National Cancer Institute, National Institutes of Health, Bethesda, MD, USA

Definition

Is one of the hallmarks of cancer development and ►metastasis. It is characterized by the lack of ability of

the immune system to eliminate transformed cells prior to and after tumor development.

Characteristics

Several mechanisms have been proposed and tested to explain cancer immune escape. It is now evident that both the host as well as the tumor play important roles in this phenomenon. The host's contribution is manifested by the host's ability to recognize to antigens expressed by tumor cells, a phenomenon known as "Host Ignorance". It happens because of defects in both the innate and adaptive arms of the immune system. The tumor's contribution is manifested by the adaptation of tumor cells to evade the immune systems or developing a ►microenvironment that suppresses the immune system.

Host Ignorance

The innate arm of the immune system forms a first line of defense against cancers. ►Macrophages, ►dendritic cells, and ►monocytes are essential in eliminating cancers. Another type of cell involved in the elimination of cancers is ►NK cells. These cells are capable of recognizing and attacking cells that have down-regulated ►MHC class I expression. This phenomenon is known as "missing self-recognition." NK cells can effectively eliminate cells that have been altered due to cellular transformation, infection, or other carcinogens and cannot present new antigens. If these players involved in the ►innate immune system are defective, cancer cells may escape tumor ►immunosurveillance from not only innate immunity but also ►adaptive immunity as NK cells, macrophages, NKT cells, play a role in the induction and enhancement of ►adaptive immune responses.

The adaptive arm of the immune system has also been shown to play a crucial role in recognizing and eliminating cancer cells. However, several defects have been shown to hamper the ability of this arm to combat tumor cells.

1. Defects in ►antigen-presenting cell (APC). To elicit an effective immune response, antigens must be processed first by the APCs and presented to the immune system. Dendritic cells (DCs) are professional APCs and play an important role in regulation of adaptive immune response. Many tumor patients have shown defects in the DC compartment in terms of cell number and/or altered function. Tumor infiltrating DCs have defective surface expression of HLA and B7 costimulatory molecules, thus are likely to induce anergy rather than to stimulate tumor-specific T cells. Additionally, the immunosuppressive enzyme indoleamine-2,3-dioxygenase (IDO), which has been implicated as one mechanism that helps to maintain maternal ►tolerance toward the fetus during pregnancy, was recently recognized as a potential mechanism of tolerance in malignancies. Expression of ►IDO on APCs was observed in tumor draining lymph nodes, which may be indicative of the creation of a tolerogenic microenvironment. The molecular mechanism by which ►IDO suppresses T cells is still being elucidated. It was suggested to be mediated by depletion of the essential amino acid tryptophan and by the generation of pro-apoptotic metabolites.
2. Negative immune regulation by suppressive cells. There are several types of suppressive cells in the immune system, including ►regulatory T cells, ►myeloid suppressor cells (MSCs) and NKT cells. They exist to keep the immune response under control and prevent autoimmunity. In addition, these cells have been shown to inhibit immune responses against tumor cells. (i) *Regulatory T (Treg) cells* are a subpopulation of $CD4^+$ ►T cells. Tregs are crucial for controlling autoreactive ►T cell responses. At least two distinct subsets of Tregs have been identified: natural and inducible Tregs. Natural Tregs are T cells that arise in the thymus. They require direct cell contact with their target cells in order to exert their regulatory functions. Inducible Tregs arise in the periphery and exert their regulatory functions by the soluble cytokines IL-10 and TGF-β. The exact mechanisms by which Tregs exert their regulatory functions remain largely unknown. However, there is sufficient evidence, both in humans as well as in rodents, demonstrating that Tregs play crucial roles in suppressing anti-tumor responses. (ii) *Myeloid suppressor cells* were first identified by the expression of surface marker CD11b and Gr-1. Their suppressive activity was shown by inhibiting lymphocyte proliferation and inducing apoptosis in CD8 T cells. (iii) *NKT cells* are a unique sub-lineage of T cells. However, in contrast to conventional and regulatory T cells that recognize peptides in the context of MHC class I and II molecules, NKT cells recognize glycolipids presented by CD1d, a non-classical antigen presenting molecule. This difference in recognition means that NKT cells can recognize a class of antigens that conventional T cells cannot recognize. NKT cells have been shown to promote as well suppress immune responses to cancer. Currently, it is still unclear what factors determine their function.
3. Defective anti-tumor T cells. Another factor that leads to a failed immune response to tumor is cells dysfunction in ►tumor-infiltrating lymphocytes (TILs). In a number of studies, TILs have been shown to have defective anti-tumor killing effect. This dysfunction may result from the ineffective granule exocytosis. TILs also have been reported to have defective cytokine production and low expression of B7.1 and B7.2 costimulatory molecules, suggesting anergy could occur.

Tumor Cell Adaptation

To escape immune surveillance, tumor cells deploy several strategies.

1. *Downregulation of MHC class I expression on cell surface.* The presentation of antigen by ►MHC class I is crucial for immune responses. By downregulating MHC class I molecules on the surface, tumor cells may become elusive targets for T cells thereby escape the destruction by ►cytotoxic T lymphocytes (CTLs).
2. *Suppression of the Immune System*. Tumor cells have several "counterattack" methods to fight the immune system. This include: (i) *Secretion of immunosuppressive cytokines such as IL-10, TGF-β, IL-13, etc*. IL-10 interferes with the induction of anti tumor responses. It has been shown to block dendritic cell-mediated priming of T cells into CTL effectors in vitro, and its expression in serum appears to be associated with negative prognosis in certain cancers. ►TGF-β is another cytokine that inhibits activation, proliferation, and activity of T lymphocytes. This ►cytokine is often found at high levels in malignancies and is associated with a poor prognosis as well as lack of response to tumor immunotherapy. Both cytokines can be produced by the tumor cells themselves or by infiltrating stroma cells. Interestingly, TGF-β has also been shown to drive expansion of regulatory T cells, thus bringing together two evasion mechanisms. (ii) *Up-regulation of tumor cells of Fas ligand on the surface to induce apoptosis of tumor killing effector cells.* The death-inducing ►FAS/APO-1/CD95 ligand (FasL/CD95L) has been reported to be expressed on many human tumors of various origins. Expression of FasL in tumors implies that cancer cells are resistant to Fas-induced cell death, which preserves them from extermination by cytotoxic T cells and actively induces death of effector T cells. In addition to local defense, accumulating evidence suggests that the FasL expression may also be relevant for tumor progression and formation of metastasis. It was further described that tumor cells are able to release membrane vesicles (MV) or exosomes containing FasL which induce ►apoptosis of activated T cells. This apoptosis-inducing pathway, via the release of FasL-positive MV, may indeed play a significant role in eliminating the most effective component of the anti tumor T cell response, and provides an explanation for the observed spontaneous T cell apoptosis in the peripheral circulation of cancer patients. (iii) *Inhibition of effector cells by inhibitory ligands including PD-L1, CTLA-4 and LAG-3.* Evidence suggests that tumor cells may evade T and NK cell recognition by receptor ligand interaction. CTLA-4 is a receptor predominantly found on T lymphocytes interacting with CD86 ligand. CTLA-4 is related to CD28 on T lymphocytes, but plays an opposite role. CTLA-4 may act at the level of TCR or CD28 signaling to inhibit T cell activation. Several studies provide evidence that CTLA-4 can up-regulate TGF-β expression and can attenuate CD28 signals on Treg expansion and survival. The precise mechanism of T cell inactivation by CTLA-4/CD86 signaling, however, remains uncertain. The PD-1 – PD-L pathway has been postulated to regulate the immune response in both lymphoid and non-lymphoid organs. PD-Ls are expressed in many tumors such as ►ovarian cancer, ►esophageal cancer, ►kidney cancer and ►brain cancer. It is suggested that tumor associated PD-Ls may promote T cell apoptosis and thus affect immune responses. Another inhibitory ligand associated with ►MHC class II interactions is LAG-3 (lymphocyte activation gene-3). LAG-3-MHC class II could enhance the cross-talk between T cell and DC. In human cells, LAG-3 serves as a negative regulator of activated T cells. A comprehensive understanding of these inhibitory pathways will facilitate the design of effective ►immunotherapy in the future.

Immune Escape of Tumors

Definition

Many tumors grow progressively despite an ongoing tumor-specific immune response. It has been experimentally shown that tumor cells adopt a variety of

strategies to "escape" both ►innate immunity as well as ►adaptive immunity. For example, tumor cells down-regulate or loose tumor antigens or important components of the antigen-processing machinery so that ►T cells are no longer able to recognize peptides bound to major histocompatibility complex molecules on the cell surface. Tumor cells may also express ►cytokines (such as IL-10 or ►TGFβ) or cell surface molecules (such as ►FAS or PD-1) which actively inhibit cellular anti-tumor immunity including the induction of T cell ►apoptosis, T cell anergy and regulatory T cells.

►Melanoma Vaccines
►T-Regulatory Cells

Immune Response

Definition

Is the response made by the host to defend itself against a pathogen.

Immune Responses to Autoantigens

►Autoimmunity and Prognosis

Immune Surveillance of Tumors

Definition

The concept that the immune system is able to recognize and eliminate cancerous or pre-cancerous cells was first postulated in 1909 by Paul Ehrlich and was further propagated by McFarlane Burnet in the 1950s. Studies in genetically modified, immunodeficient mice have led to a refinement of this theory by Robert Schreiber and co-workers and has been called "cancer ►immunoediting." It describes three phases: (i) The elimination phase in which nascent tumor cells are destroyed by elements of the ►innate immunity and ►adaptive immunity; (ii) the equilibrium phase, in which tumor cells persists but are "equilibrated" by the immune system which prevents tumor progression; and (iii) the escape phase, in which tumors actively disable immune recognition by co-opting immune cells for growth, ►angiogenesis and ►invasion.

►Melanoma Vaccines
►Immunoprevention
►Allergy

Immune System

Definition

Refers to the tissues, cells, and molecules involved in ►adaptive immunity, or sometimes the totality of host defense mechanisms.

Immunoassay

Definition

A test using antibodies to identify and quantify substances. Often the ►antibody is linked to a marker such as a fluorescent molecule, a radioactive molecule, or an enzyme.

Immunoblotting

Definition

Is a common technique in which proteins separated by gel electrophoresis are blotted onto a nitrocellulose membrane and revealed by the binding of specific labeled antibodies.

Immunochemical Fecal Occult Blood Test

►Fecal Immunochemical Test

Immunocompetent

Definition
Capable of developing an ►immune response.

Immunocytochemistry

Definition
synonym: ►Immunohistochemistry; Is a method of identifying cell types based on the demonstration of a specific cytoplasmic or nuclear protein or antigen *in situ*. It does this by detecting specific antibody-antigen interactions where the antibody has been tagged with a visible label, most commonly an enzyme. It is very useful for differentiating and subclassifying ►carcinomas, ►sarcomas, ►melanomas and ►lymphomas.

►Fine Needle Aspiration
►Pathology

Immunodeficient Nude Mice

Definition
Are athymic hairless mice without T-cells, that are unable to generate an effective ►immune response. This makes possible the transplantation of human cancer cells without rejection.

►MIC-1
►T cell

Immunodiffusion

Definition
Is the detection of antigen or antibody by the formation of an antigen:antibody precipitate in a clear agar gel.

Immunoediting

Yvonne Paterson
Professor of Microbiology, University of Pennsylvania, Philadelphia, PA, USA

Definition
Changes in the immunogenicity of tumors due to the anti-tumor response of the immune system that result in the emergence of immune-resistant variants.

Characteristics
History
The concept of immunoediting is predicated on the insight that the immune system can recognize tumor cells. The notion that the immune system monitors the host, not only for pathogen invasion but also for neoplastic changes, arose early in the history of Immunology, was first proposed by Paul Ehrlich in 1909 and then resurrected 50 years later by Burnet and Thomas. These early immunologists proposed that the immune system recognizes cells that have undergone neoplastic changes and eliminates them before they can form tumors, a concept known as immune surveillance. However, although this notion has been around for nearly a century it was only quite recently unequivocally demonstrated in murine models when Schreiber and colleagues, in 2001, examined the incidence of adenomas and carcinomas in aging wild type mice compared to mice lacking the ►recombinase activating gene-2 (RAG2). The RAG2 gene controls the ►V(D)J recombination of genes required to generate ►B cell and ►T cell antigen-specific receptors. In its absence, or the absence of its partner in this process, RAG1, the development of lymphocytes that bear these receptors is aborted. Thus in mice that lack RAG1 or RAG2, T cells, B cells and NKT cells fail to develop and the mouse has no adaptive immune response. The Schreiber lab showed that these immunodeficient mice had a higher incidence of spontaneous cancer and were more susceptible to carcinogen induced sarcomas. These tendencies were increased in mice lacking not only the RAG2 gene but in addition the ►*STAT-1* gene, which controls the ►interferon–gamma ►signal transduction pathway. Thus both adaptive immune effector cells and the multifunctional lymphokine IFN-γ were shown to play a clear role in immunosurveillance. However, in the process of studying ►immunosurveillance the Schreiber group made the interesting observation that a high proportion of tumors that emerged in carcinogen treated RAG2 deficient mice failed to grow in wild type mice indicating that within the population of tumor cells that

arose in the immunodeficient mice were cells that could be recognized and eliminated by an intact immune system. In contrast tumors that arose in wild type mice were less immunogenic and would grow when transplanted into either wild type or RAG2 deficient mice. Schreiber termed this process by which the immunological environment alters the immunogenicity of tumors "immunoediting."

The Role of Interferons and Other Immune Components

A large body of work provides evidence that both ►adaptive immunity and ►innate immunity play a role in controlling the immunogenicity of tumors that develop in the mouse. Most of these studies have focused on the formation of carcinogen induced sarcomas in mice genetically manipulated to lack the expression of genes required for the generation of lymphocytes and cytokines. Thus in terms of innate immune cells, ►γδ (gamma delta) T cells, ►Natural Killer cells and NKT cells have been shown to be involved in controlling tumor growth as have conventional αβ (alpha beta) ►T cells, the hallmark of the adaptive cellular immune response. The importance of cytotoxic lymphocytes, such as T cells and ►NK cells, is highlighted by the inability of mice that lack the specific toxic molecules ►perforin and ►Tumor Necrosis Factor-Related Apoptosis-Inducing Ligand (TRAIL), expressed by cytotoxic cells, to control both carcinogen induced and spontaneous tumors. That at least a subset of the lymphocytes that recognize and control tumor growth are ►MHC class I restricted, tumor-specific, ►cytotoxic T cells (CTLs) is evidenced by the fact that mice lacking the ►LMP2 (Low Molecular Mass Protein 2) ►proteasome subunit, involved in processing antigen for recognition by CTL, develop spontaneous ►uterine tumors. The adaptive immune response has evolved to ignore its own tissues, by eliminating self-reactive lymphocytes during their development, in order to avoid ►autoimmunity or "horror autoxicus" as Paul Ehrlich termed it. Thus the participation of CTLs in tumor immunoediting implies that tumors must express ►tumor-associated antigens.

The original observation of immune editing identified a key role for the type II interferon, IFN-γ, in the process. This pleiotropic cytokine is the product of lymphocytes of both the innate (γδ T cells, NK and NKT cells) and adaptive ($CD4^+$, MHC class II restricted ►helper T (Th) cells and $CD8^+$ MHC class I restricted CTLs). It seems likely that both innate and adaptive lymphocytes are the source of the IFN-γ that shapes the immune response to tumors. The effects of IFN-γ on the immunogenicity of tumors could occur though multiple processes since it is known as a key regulator of adaptive and innate immune responses. There is a great deal of evidence that some of its effects are mediated through host cells in addition to tumor cells. However, given that many tumor cells express IFN-γ receptors, it can directly interact with tumor cells and there is evidence that it stimulates tumor cells to increase MHC class I expression, downregulate ►angiogenesis and promote the infiltration of CTLs into the tumor mass. Another cytokine, ►IL-12, has also been shown to promote tumor immunoediting. IL-12 is intimately involved in the regulation of IFN-γ production early in the immune response and probably mediates its effects through its influence on IFN-γ expression.

In addition to IFN-γ, the ►type I interferons have a profound influence on tumor growth. Early studies in mice using type I interferons for tumor ►immunotherapy have been translated into several clinical applications for these cytokines in the therapy of ►melanoma, ►CML, ►follicular lymphoma, ►hair cell leukemia and ►Kaposi sarcoma. There are several important differences in mice and humans between the type I interferon, IFN-γ, which is the sole molecular species, and the type II interferons, IFN-α for which there are at least 12 variants, and IFN-β, which is unique. Unlike IFN-γ, which is the product only of cells of the lymphocytic lineage, type I interferons can be produced by all nucleated cells when stimulated by products of viral infection and also by infection with some bacteria. As such they are a first line of defense against pathogen invasion of the host. In addition, although tumor cells can express receptors for type I interferons, it appears, that unlike IFN-γ, the type I interferons do not act directly on tumor cells and mediate their anti-tumor effects though host cell responses. Exactly which cells are involved requires further study but they appear to be cells of the hematopoietic lineage. Similar to IFN-γ, there are several points at which type I interferons might influence the immune response to tumors since they can activate ►dendritic cells, ►macrophages and ►NK cells and are involved in the priming and survival of T cells. In addition, similarly to IFN-γ they can act on stromal cells within and surrounding tumors to down regulate angiogenic factors. Finally, there is evidence that type I interferons may inhibit the transformation of normal cells by upregulating the expression of the tumor-suppressor molecule, ►p53. The importance of this class of cytokines in shaping the immune response to tumors was confirmed recently by studies in mice lacking the IFN-α receptor. Carcinogen induced sarcomas were found to arise more frequently in these mice and were also shown to be more immunogenic when transplanted into wild type mice.

The Role of Induced Immune Pressure

The editing of tumors in response to immune pressure is exacerbated when the immune system has been specifically primed to a ►tumor-associated antigen.

In a ►mouse model for ►breast cancer in which ►HER-2/neu, a member of the ►epidermal growth factor receptor family, is overexpressed on breast tissue, resulting in the emergence of breast tumors, it was shown that mice immunized with ►cancer vaccines expressing fragments of HER-2/neu could control tumor outgrowth for a significant length of time but eventually succumbed. When HER-2/neu was isolated from the emerging tumors they were found to have accumulated a significant number of mutations in the precise region of the molecule the particular vaccine targeted. In addition, it was verified for one of the fragments that each mutation occurred in a region recognized by CTLs and that this mutation abrogated CTL recognition. This is a clear demonstration of how the host immune system can sculpt a tumor-associated antigen to evade the immune system. Transplanted, syngeneic mouse tumors have also been shown to mutate in a region of an antigen expressed by the tumor and recognized by CTLs after adoptive transfer of T cells that recognize that region.

Evidence of Immunoediting in Human Cancer

Although there is an abundance of evidence for immunoediting in murine models of cancer, the evidence that this occurs in human cancer is largely circumstantial. It has long been known that cancer patients develop immune responses to their own tumors. Indeed, both tumor-specific T cells and antibodies isolated from cancer patients have been harnessed to identify tumor-associated antigens by methods such as ►SEREX. In addition the ability of a patient to mount a response to their tumors, particularly if there is evidence of tumor infiltration of immune effector cells, is a strong predictor of a favorable prognosis. That the immune system sculpts tumor immunogenicity in tumors that arise in cancer patients is supported by the emergence of tumors in patients undergoing antigen-specific immunotherapy that have down regulated the tumor antigen to which the therapy is directed, or components of the cellular machinery that generates the cell surface complex of ►HLA I and antigen recognized by CTLs. These include LMP proteasome subunits and transporter molecules that chaperone antigen peptides from the cytosol to the Golgi apparatus for loading onto HLA class I molecules. Sometimes the HLA I molecule itself is lost, usually by mutation of the beta2 microglobulin subunit, common to all HLA class I molecular complexes. In some cases, however, lack of HLA class I on the surface of a tumor is due not to mutational events in the HLA class I genes themselves but to down regulation of expression of the protein. This can often be reversed by cytokines, such as IFN-γ but it is interesting to note that human tumors have been shown to arise that lack the IFN-γ receptor. The phenomenon of HLA class I loss from the surface of tumor cells has been documented in numerous clinical cancer vaccine trials for ►melanoma, ►prostate carcinoma and for HER-2/neu positive tumors. In addition, even in the absence of immunotherapy, HLA class I expression has been shown to be lost or down regulated in all types of tumors especially in patients with advanced disease. Indeed, the frequency of deletion or down regulation of these cell surface molecules has been found to be as high as 15% in primary melanoma lesions and 50% in primary ►prostate carcinoma lesions. A final piece of evidence for immunoediting in human cancer is that patients that are seriously immunosuppressed, for example post organ transplant, have a higher incidence of cancer than healthy individuals.

Immunogenicity

Definition

The ability of a foreign substance to confer a certain level of immunity to the host.

►T-Cell Response

Immunoglobulin

Definition

Ig; The immunoglobulin molecule, composed of two light and two heavy protein chains, comprising the antibody.

►Immunoglobulin Genes

Immunoglobulin E (IgE)

Definition

An antibody characteristic of the atopic allergic immune response.

►Allergy
►Immunoglobulin Genes

Immunoglobulin Genes

Definition

Cluster in multimember gene families and are located on chromosome 14 (heavy chain gene segments), 2 (κ light chain) and 22 (λ light chain): V genes (variable region genes), D genes (diversity region genes) and J genes (joining region genes) for the heavy Ig heavy chains, V and J region genes for κ and λ light chains. Ig gene rearrangement brings together one representative of these gene families (V, D and J for the heavy chain, V and J for κ and λ light chains). ►V(D)J recombination is a remarkable process since it entails double strand DNA breaks, loss or DNA and re-ligation of DNA strands. Joining of the V-D-J segments is imprecise and involves insertion of non-template nucleotides (N-additions) and trimming back of the beginning/ends of the gene segments. Ultimately, the rearrangement leads to a unique sequence of VH-N-D-N-JH, which generates diversity for antigen recognition, and which acts a marker for each individual B-cell and its progeny.

►B-Cell Tumors

Immunoglobulin Libraries

Definition

Recombinant nucleic acid libraries of natural or synthetic origin that encode antiBody binding sites (Fab or scFv) for which the products (and corresponding genes) can be selected against an antigen of interest and subsequently modified to improve their affinity. Applications: Fast selection of new antiBody binding sites from different species. Modification of pre-existing binding site affinity.

Immunoglobulins

Definition

Immunoglobulins (Ig): All antibody molecules belong to a family of plasma proteins called immunoglobulins (Ig). Membrane-bound immunoglobulin serves as the specific antigen receptor on B lymphocytes. Different immunoglobulin isotypes are called IgM, IgD, IgG, IgA, and IgE.

Immunoglobulin A (IgA): Immunoglobulin A is the class of immunoglobulin characterized by α heavy chains. IgA antibodies are secreted mainly by mucosal lymphoid tissues.

Immunoglobulin D (IgD): Immunoglobulin D is the class of immunoglobulin characterized by δ heavy chains. It appears as surface immunoglobulin on mature naïve B cells but its function is unknown.

Immunoglobulin E (IgE): Immunoglobulin E is the class of immunoglobulin characterized by ε heavy chains. It is involved in allergic reactions.

Immunoglobulin G (IgG): Immunoglobulin G is the class of immunoglobulin characterized by γ heavy chains. It is the most abundant class of immunoglobulin found in the plasma.

Immunoglobulin M (IgM): Immunoglobulin M is the class of immunoglobulin characterized by μ heavy chains. It is the first immunoglobulin to appear on the surface of B cells and the first to be secreted.

Immunohistochemistry

Definition

Immunohistochemistry (IHC) is a technique to detect and localize specific proteins in tissue sections by labeled antibodies that bind specifically to the investigated antigen.

Characteristics

History

Since the introduction of microscopy into the diagnosis of diseases by Bennett in 1842 and Virchow in 1858,

pathologists have searched for better and more specific stains. In 1934, Marrack was the first to employ modified antibodies to visualize cholera and typhoid agents. Nearly a decade later, Coons (1941) used a primary antibody that was labeled with a fluorescent dye, fluorescein isothiocyanate, and utilized it on human tissue. However, as a specialized dark-field microscope and use of frozen sections were needed for the fluorescent dyes, the technique remained mainly a research tool until other labels were developed. In 1974, Taylor and Burns demonstrated that IHC could be performed on routinely processed tissue using immunoperoxidase techniques with chromogenic dyes. This step enabled the use of IHC in routine clinical laboratories.

Techniques

Immunohistochemistry combines the principles of immunology with histochemistry, and involves two basic steps: first, an ►antibody binds to its specific target antigen at the cellular location in the tissue sample. The antigen-antibody binding is then detected by labeling techniques. IHC therefore not only enables pathologists to detect whether or not particular antigens are present within a given tissue, but also allows marking its cellular location.

There are two major types of antibodies in use: polyclonal antibodies or antisera and monoclonal antibodies. Polyclonal antibodies are produced by an injection of an antigen or antigen fragments into a host animal. The most common host animals are rabbit, horse, mouse and goat. If a small antigenic molecule or antigen fragment (hapten) is used as immunogen, immunogenicity is typically enhanced by coupling the hapten with a compound such as keyhole limpet hemocyanin. In the resulting immunologic reaction, host lymphocytes are activated and ultimately plasma cells initiate production of antibodies. As antigens contain various immunogenic determinants, the resulting antiserum will be a heterogeneous mix that recognizes several epitopes. Such potentially cross-reacting specificities are unwanted for use in IHC and must be removed by further purification. Monoclonal antibodies are developed by the hybridoma technique or through molecular engineering using bacteriophages. In the hybridoma technique, activated (antibody-secreting) B-lymphocytes are isolated from the immunized animal (in the past usually mouse, now increasingly common rabbit) and fused with cultured myeloma cells which have limitless proliferative potential. Each of the resulting hybrid cells (hybridoma) produces a single type of antibody, thus being 'monoclonal' in nature.

The detection methods include the 'direct' and the 'indirect' alternatives. In the direct conjugate-labeled-antibody method, the label (such as a fluorescent agent or an enzyme) is chemically attached to the primary antibody. The localization of this fluorescent label is detected by ►immunofluorescence microscopy or if the label is an enzyme (typically, horseradish peroxidase) coupled to antibody, it is detected by its action on a chromogenic substrate. The indirect method uses an unlabeled primary antibody and a labeled secondary antibody (second layer) directed against the primary antibody. Several secondary antibody molecules bind to each primary antibody molecule resulting in signal enhancement, thus in increased sensitivity.

Furthermore, methods involving a third layer for signal amplification can be employed. These include the PAP (peroxidase-antiperoxidase) method, the biotin-avidin mediated procedures (such as those employing the avidin-biotin conjugate or ABC procedure, biotin-streptavidin systems), immunogold or polymer based labels, catalyzed signal amplification and alkaline phosphatase-based methods.

Several efforts have been made to improve the sensitivity, the reliability and the standardization of IHC. A major step was the development of antigen retrieval. The antigen retrieval process breaks protein cross linkages formed during formaldehyde fixation of a tissue and enables these proteins to be accessible for antibodies. Antigen retrieval is performed by exposing tissue to heat for various lengths of time in retrieval buffer solutions with specific pH. Several protocols are available but these often have to be adjusted for optimal results which can be done standardized for various temperatures and durations in a 'test battery' approach.

Several automated immunostaining systems are commercially available. While they significantly increase the reproducibility and standardization, they certainly do not guarantee optimal results. Quality control issues as well as the need for the validation of the results apply for staining carried out with both the automated systems and manual IHC. Interpretation of IHC staining results necessitates a highly trained pathologist and even among experts is subject to inter-observer discrepancies. The development of automated image analysis systems addresses this problem. The currently available systems can both assess the intensity as well as the percentage positivity of antigenic markers. The limitations of the human eye to differentiate colors restrict the use of multiple markers on the same slide. The spectral imaging technology allows to differentiate different chromogens reporting on multiple markers by serially, digitally "erasing" a given chromogen image from the microscope image by a specially designed software.

Uses

IHC plays an essential role in modern pathology. Its most common use is the identification of tumor origin

and tumor type by tissue-specific markers. By IHC a pathologist can specify tumor entities and evaluate tumors of unknown origin as well as stage lymph nodes and bone marrow for the presence of metastatic disease.

More recently, several markers have been identified that can predict disease prognosis, treatment response and serve as therapeutic target.

Use in Research

In a research setting, the expression of relevant markers is investigated. This demands studies on well-defined samples across various tumor stages and clinical outcome. The tissue microarray technique allows an acceleration of such studies in a high-throughput manner. Tissue microarrays (TMA) consist of compendia of 0.6 mm cylindrical biopsy cores from paraffin-embedded tissue that are transferred to defined array coordinates in a recipient block. These multi-tissue-core blocks can then be processed similar to a routine single-tissue block. A difference from the conventional IHC is the high level of standardization since all slides in one TMA experiment are incubated together, ensuring identical reagent concentrations and incubation temperatures.

Clinical Uses

Diagnosis

Intermediate Filaments

The presence of intermediate filaments, which function as cytoskeletal components in both normal and malignant cells, is useful in the initial classification and diagnosis of neoplasms. Five major classes of intermediate filaments exist: ►Cytokeratin (CK), vimentin, desmin, neurofilament and glial fibrillary acidic protein (GFAP). Most neoplasms show a predominant expression of one or more of these intermediate filaments. Based on their molecular weight and isoelectric point, the cytokeratins are subdivided into more than 20 types. Carcinomas are typically CK positive, whereas sarcomas, melanomas, and lymphomas are generally vimentin positive. Tumors of myogenic origin characteristically express desmin and/or muscle actins and vimentin. Glial tumors are predominantly positive for GFAP.

Nuclear Transcription Factors

Transcription factors are proteins involved in the regulation of gene expression. By binding to promoter elements upstream of genes they either facilitate or inhibit transcription. Though not exclusively found in a specific tumor type, transcription factors are highly tissue specific and can be useful in determining the primary site of a tumor.

Carcinoma

Essentially all cells of epithelial origin express cytokeratins, which are therefore highly sensitive markers for carcinomas. However, other tumors such as mesotheliomas and non-seminomateous germ cell tumors also stain positive for CK. More specific markers and sub-typing of keratins have to be applied to further differentiate CK-positive cells and to assess the site of origin of the carcinoma. The profile of cytokeratin sub-types is useful to determine the tumor type. As for example, hepatocellular carcinomas are positive for CK antigens that can be detected by antibodies AE3 and CAM5.2 but are negative for antibody AE1, which is directed against a different set of CK. Recently, the use of CK7 and CK20 profile has proven a useful tool in distinguishing cellular origin. Nuclear transcription factors are useful in the detection of carcinomas. Thyroid transcription factor-1 (TTF-1) is found in the thyroid and lung. CDX-2 is specific for colorectal epithelium. For some tissue types, tissue-specific tumor markers (e.g. prostate specific antigen (PSA) for prostate, or thyroglobulin for thyroid) or tissue-associated markers (e.g. gross cystic disease fluid protein 15 (GCDFP-15) and mammaglobin in breast, uroplakins for transitional urothelial cells, OC 125 for ovarian cells, synaptophysin for neuroendocrine lesions, etc.) are available. It is important to remember that these markers are often not uniquely found in the specific tissue. For instance, the detection of PSA has also been described for samples of salivary glands and breast.

Melanoma

For melanomas, which usually are cytokeratin-negative and vimentin-positive, a sensitive tissue marker, S-100, is available. HMB-45, Melan A and tyrosinase are used to confirm the diagnosis.

Sarcoma

The common IHC pattern for all forms of sarcoma includes vimentin positivity. Generally speaking, sarcomas are CK-negative, but some may yield positive reactions especially for low molecular CKs following antigen retrieval and highly sensitive labelling techniques. Additional stains are then employed to identify the tumor type. Rhabdomyosarcoma and Leiomyosarcoma express markers that are typical for muscular tissue such as desmin and muscle specific actin.

Lymphoma

Lymphomas show a wide variety of morphologic appearances, making IHC especially important in their diagnosis. Membranous staining for ►CD45 can typically be seen in lymphoid tissue. CD3 and ►CD20 are more specific markers and are used to

further confirm lymphomas. ►CD antigens are essential in subclassifying lymphoid tissue.

Infectious Agents

Since the early days of its development, IHC has been used for the detection of infectious agents. Nowadays, microbiologic cultures are the gold standard but for pathogens that are difficult to culture such as cytomegalovirus, mycobacteria, toxoplasmosis, pneumocystis carinii, histoplasma capsulatum, ►Helicobacter pylori and ►human papillomavirus IHC methods are at least as effective.

Tumor Stage and Occult Metastases

The most important factor determining outcome of patients with cancer is the presence of regional and/or systemic dissemination (metastases). While routine pathologic work-up cannot detect small metastatic deposits in many instances, IHC is a highly sensitive way to detect such occult metastases in blood, lymph nodes and bone marrow. This technique is based on the fact that monoclonal antibodies can reveal cells of different histogenesis in the investigated tissue. As normal lymph nodes, bone marrow or blood do not contain cells with epithelial antigens, the finding of CK-positive cells suggests metastases of a carcinoma. The presence of occult metastases has been shown to influence clinical outcome for several cancer types such as breast, lung and prostate cancer. In breast cancer, IHC is able to show the presence of occult metastases in bone marrow in 10–40% of patients with low-stage disease. Lymph node metastases occult to routine pathologic work-up have been described for several tumors including breast cancer in up to 20% of patients and in more than 10% of patients with prostate cancer. The reported sensitivity of this technique ranges from the detection of 1 epithelial cell in 10,000 to 2–5 epithelial cells in a million hematopoietic cells.

Prognosis

Mutations and overexpression of oncogenes and tumor suppressor genes play a vital role in tumorigenesis. The presence or absence of their protein products may predict the biological behavior of tumors more accurately than clinical and pathologic criteria. Since antibodies are available for many of these gene products, tumors with different prognosis can be differentiated by means of IHC.

The best investigated proteins include ►p53, the protein product of the ►Retinoblastoma gene (pRb), p27, ►p21 and ►p16. RB gene alterations resulting in reduced expression are known to characterize tumors with a higher risk for metastatic disease. p21, p16 and p27 are the three major cyclin-dependent kinase inhibitors which negatively regulate pRb activity and are normally required for cell cycle suppression. The loss of *p27* expression is associated with colon, breast, prostate, and gastric cancer progression. Changes in protein expression of p21 have been associated with higher tumor grade and worse prognosis in patients with bladder cancer. p53 plays an important role in cell cycle progression, and apoptosis in response to DNA damage, and is expressed by all human cells. Normal (wild-type) p53 protein has a short half-life of only 6 to 30 minutes because of its ubiquitin action-mediated degredation dictated by its binding with another regulatory protein, ►MDM2. Therefore p53 does not accumulate in normal cells. Overexpression of p53 (by altered p53 gene or because of ineffective MDM2 protein) in the nuclear compartment therefore indicates a dysfunctional p53 pathway, a characteristic of tumors. Alterations in p53, p21 and pRb act in cooperative or synergistic ways to promote cancer progression and simultaneous overexpression has been linked to worse prognosis.

Treatment Response

An increasingly important application of IHC is to identify specific targets for therapy. Consequently, this will allow better selection of patients who will benefit from certain treatment modalities. In several tumor types, treatment decisions already are influenced or determined by molecular findings. An early example is hormonal therapy for breast cancer patients depending on estrogen and progesterone expression of the tumor. Because of its vital role in the apoptotic pathway ►p53 alterations are likely to influence response to chemotherapy. p53 alterations confer increased chemosensitivity on tumors such that combining agents with different actions may have synergistic effects on tumor cell killing.

Targeted Therapy

In breast cancer Her-2/neu overexpression was linked to resistance to tamoxifen therapy and commonly used adjuvant chemotherapy. However, it has been shown that the HER2/neu receptor tyrosine kinase can serve as a therapeutic target. Treatment with the monoclonal antibody ►trastuzumab (brandname: Herceptin) which is directed against this protein is effective only for patients whose tumors show overexpression of Her2/neu. In invasive ►bladder cancer there is evidence to suggest that patients who harbor p53 alterations respond to adjuvant chemotherapy that contains DNA-damaging agents such as cisplatinum.

Immunohistochemistry has allowed for identification of tumor origin, tumor prognosis, and likelihood of response to therapy for an increasing array of tumors. The ability to determine which tumors are most likely

to progress (and thus need further therapy), coupled with the ability to predict specifically the response of individual tumors to chemotherapeutic agents and the ability to identify specific targets of therapy will have a profound effect on the way treatment decisions for patients with cancer are made. It is not difficult to envision the day when drug selection is based on the presence of specific targets and on the resistance patterns of individual tumors to specific agents. Treatment decisions will become less organ based and will reflect the biology of the tumors. This has already helped us to approach patient-specific (as opposed to disease specific) management of care.

Immunoliposomes

Roland E. Kontermann
Institute of Cell Biology and Immunology, University of Stuttgart, Stuttgart, Germany

Definition

Are ►liposomal drug formulations possessing antibody molecules conjugated to the liposomal surface. This allows for a ►targeted drug delivery to tumor cells or other tumor-associated structures (active targeting).

Characteristics

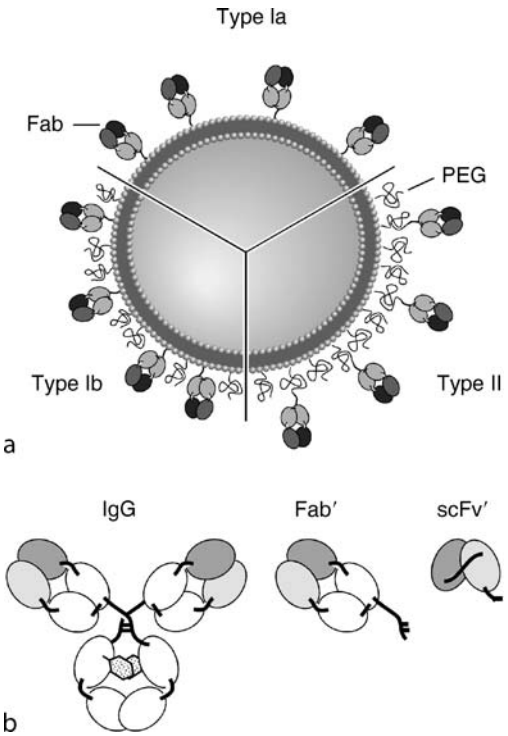
►Liposomes are vesicular particles composed of a lipid bilayer enclosing a hydrophilic inner phase. Liposomes can be used as carrier systems for cancer drugs (►Drug delivery systems) by encapsulating hydrophilic drugs into the interior or by incorporating lipophilic drugs into the lipid bilayer. Liposomes have normally a size (diameter) of 100–200 nm. Several liposomal formulations of therapeutic drugs are approved for cancer therapy, e.g., liposomal doxorubicin (Doxil/Caelyx, Myocet) (►Liposomal chemotherapy). Delivery of these drugs to tumors is a passive process and efficacy depends on long circulation and enhanced permeability and retention in the tumor tissue (EPR effect). New formulations of liposomal drugs (e.g., Doxil/Caelyx) have polyethylene glycol (PEG) chains incorporated into the lipid bilayer to further increase stability and pharmacokinetic properties and to decrease elimination of the liposomes by phagocytic cells. The coupling of antibody molecules to the lipid surface allows for an active targeting by recognition of antigenic structures expressed by the tumor. Thus, immunoliposomes are designed to increase selectivity and efficacy of liposomal drugs.

Immunoliposome Types and Antibody Formats

Immunoliposomes are generated by chemically coupling antibodies or antibody fragments to the liposomal surface. Besides whole ►antibody molecules (e.g., IgG molecules), antibody fragments such as Fab′ fragments or ►single-chain Fv fragments can be utilized for the generation of immunoliposomes. The use of whole antibodies is less favorable since these immunoliposomes are recognized by phagocytic cells via Fc receptors. Consequently, Fab′ or scFv′ fragments are the formats of choice to generate immunoliposomes. Immunoliposomes can be classified depending on the position of coupled antibodies and the liposomal composition. In type I immunoliposomes, the antibodies are coupled directly to the lipid bilayer either in the absence (type Ia) or presence of PEG chains (type Ib). Coupling of the antibodies to the distal end of incorporated PEG chains results in type II immunoliposomes (Fig. 1a).

Coupling of antibodies is facilitated by the use of functionalized lipids, e.g., lipids possessing an amino-reactive succinimidyl moiety or a sulfhydryl-reactive maleimide group. Antibody or antibody fragments can be generated by established ►hybridoma technology and biochemical means or by genetic engineering as recombinant molecules. For example, Fab′ fragments can be produced by enzymatic cleavage of IgG molecules with pepsin resulting in $F(ab')_2$ fragments, which after reduction are separated in Fab' fragments exposing a free sulfhydryl group at the end of the molecule (Fig. 1b). Furthermore, the implementation of antibody engineering allows for the generation of

small antibody molecules with desired properties, e.g., scFv molecules exposing a genetically introduced cysteine residue at the C-terminus used for site-directed coupling (Fig. 1b).



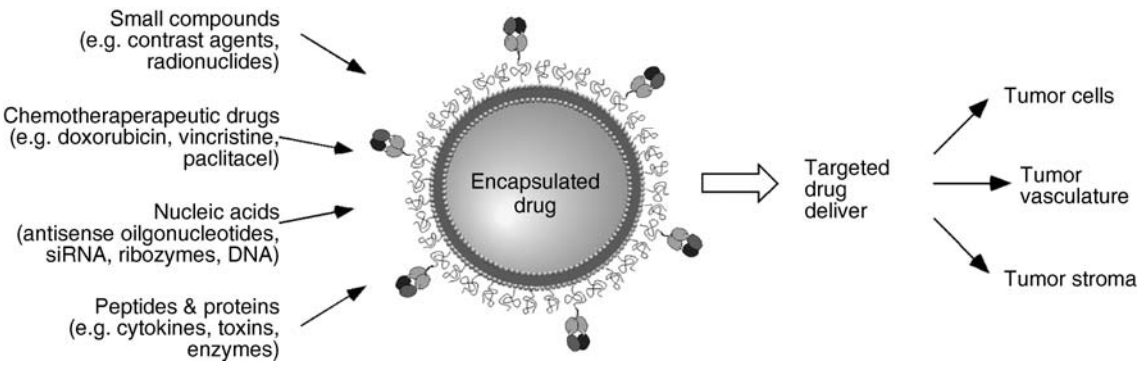
Immunoliposomes. Figure 1 Classification of immunoliposomes and antibody formats. (a) Three types of immunoliposomes can be distinguished. Type I immunoliposomes have the antibody molecules coupled directly to the lipid bilayer, either in the absence (type Ia) or presence (type Ib) of polyethylene glycol (PEG) chains. In type II immunoliposomes, the antibodies are coupled to the distal end of PEG chains. (b) Antibodies formats used for the generation of immunoliposomes. The two variable domains (V_H, V_L) forming the antigen-binding site are shown in dark and light gray.

Drugs and Targets

Immunoliposomes can be combined with a wide variety of different drugs. Besides small compounds and chemotherapeutic drugs, immunoliposomes can also be used for the delivery of nucleic acids (e.g., ►siRNA) or therapeutically useful peptides and proteins (Fig. 2). Encapsulation of drugs into liposomes alters their pharmacokinetic properties, e.g., reduces rapid renal elimination of small molecular weight drugs. In addition, drug encapsulation has been shown to reduce side effects and to increase stability of the drug within the body.

Several modes of action have been described for immunoliposomes. Delivery to extracellular structures may lead to increased accumulation of liposomes in the tumor tissue and slow release of drug, which then can enter the target cell. Alternatively, binding of immunoliposomes to cell surface receptors results in internalization of immunoliposomes (►Endocytosis) and intracellular release of the drug. Several studies have shown that internalization of immunoliposomes leads to increased cytotoxicity and may also bypass drug resistance mechanisms.

Main targets of immunoliposomes are molecules expressed by tumor cells. Thus, various immunoliposomal formulations of chemotherapeutic drugs (e.g., ►doxorubicin, ►vincristine) have been generated using antibodies against tumor-associated antigens including CD19, ►CD20, Her2/neu, ►epidermal growth factor receptor (EGFR), and disialoganglioside GD2 for therapy of lymphoma and solid tumors. In addition, research has been focused on targeting of tumor blood vessels (►vascular-targeting adjents) as well as targeting of extracellular tumor stroma components or tumor stroma fibroblasts, which are more easily accessible for circulating liposomes. Efficacy of immunoliposomes is influenced by several factors. Besides lipid composition, which has an influence on stability and release of drug, and the antibody format used, efficacy depends also on the kind of target molecule as well as its density on the cell surface and sensitivity of target cells for the encapsulated drug.



Immunoliposomes. Figure 2 Active compounds combined with immunoliposomes. Immunoliposomes allow for a targeted delivery of various kinds of active molecules, including small compounds, chemotherapeutic drugs, nucleic acids, and peptides and proteins.

Immunophilins

Definition

Are a group of intracellular proteins that bind to the anti-inflammatory agents ►cyclosporine A and FK506. The complexes interfere with calcineurin-mediated transcriptional activation and inhibit the transcription of genes encoding several proinflammatory molecules. Proteins that bind immunosuppressant drugs.

Immunoprevention

Pier-Luigi Lollini, Patrizia Nanni
Section of Cancer Research, Department of Experimental Pathology, University of Bologna, Bologna, Italy

Synonyms

Immunoprophylaxis of cancer

Definition

Prevention of cancer onset or of early cancer development and ►progression by means of immunological treatments, such as vaccines, antibodies or cytokines.

Characteristics

Immunoprevention of cancer can be applied to tumors caused by viruses (and other infectious agents) or to tumors unrelated to infectious agents. In both cases the aim is the same, however the underlying concepts and the advancement of clinical development are different. Prevention of viral tumors is based on vaccines against viral antigens, whereas immunoprevention of tumors unrelated to infectious agents targets antigens expressed by early neoplastic cells.

Immunoprevention of Viral Tumors

About 18% of all human tumors are directly caused by infectious agents or indirectly by persisting inflammation accompanying chronic infection. In such cases the application of immunological strategies to prevent infection is a type of ►primary cancer prevention because it aims at removing a risk factor that can cause cancer. The first success in this direction was the demonstration that vaccination programs implemented in the 1980s against ►hepatitis B virus (HBV) significantly reduce the incidence of hepatitis virus associated ►hepatocellular carcinoma. Current vaccines are highly effective (90–95%) in preventing chronic HBV infection. Studies in countries where HBV infection is frequent demonstrated that vaccination reduced by half infantile hepatocellular carcinoma incidence and mortality. HBV is responsible for one third (developed countries) to two thirds (less developed countries) of all cases of hepatocellular carcinoma, and ►hepatitis C virus (HCV) causes about one fourth. HCV vaccines under development are expected to contribute a further substantial decrease in the worldwide incidence of hepatocellular carcinoma.

►Human papillomaviruses (HPV) are the most prevalent carcinogenic viruses in humans; various types of HPV cause more than half a million new cases of ►cervical cancer and other tumors worldwide. The first human vaccine against HPV was approved in 2006 in the US, EU, and various other countries. It is a quadrivalent vaccine against HPV types 6, 11, 16 and 18. A divalent vaccine against HPV 6 and 18 is undergoing approval in 2007. Both vaccines are made of ►virus-like particles (VLP). Clinical trials of both vaccines demonstrated 89–100% protection of vaccinated women from persistent HPV infection, 100% protection from histologic evidence of cervical cancer, and no serious adverse events. These vaccines are thus expected to have a major impact on the incidence and mortality of HPV-related cancers. Four critical issues are (i) current vaccines do not include HPV types causing one third of cervical cancers worldwide, hence screening programs should not be abandoned until cross-protection by current vaccines has been demonstrated or novel multivalent vaccines have been developed; (ii) vaccines are currently very expensive, and only a few national or regional health systems are prepared to subsidize the costs; (iii) the matter is further complicated by the need to vaccinate prepuberal (9–12-year-old) girls against a sexually-transmitted virus, an issue that is causing considerable ethical debate in some countries; (iv) the follow-up of vaccinated persons is still too short to estimate the long-term duration of immunity and the need for periodic boosts.

Attempts toward the development of vaccines against ►*Helicobacter pylori*, the third major infectious risk factor of human cancer, until now did not produce a credible candidate for mass vaccination.

On the whole it can be estimated that a full-scale deployment of the approaches described above for HBV, HCV and HPV could lead to the immunoprevention of two thirds of infectious human cancers, or more than 10% of all human cancers. This is a very important result which however leaves open the question of what immunoprevention can do for the majority of human cancer not caused by infectious agents.

Immunoprevention of Tumors Unrelated to Infectious Agents

Immunoprevention of non-infectious tumors is a relatively recent development and is currently at the level of ►preclinical testing. This type of immunoprevention targets early neoplastic cells, hence it can be classified as a kind of ►secondary cancer prevention because it aims at preventing the evolution of incipient tumors into clinically-evident, symptomatic masses.

The ►immune surveillance theory posits prevention of tumor onset as a fundamental function of the immune system, on a par with prevention of infection. In fact cancer incidence in knockout mice lacking ►adaptive immunity and ►non-adaptive immunity is much higher that in immunocompetent mice. However the very existence of progressive, malignant tumors demonstrates that the efficiency of spontaneous immune surveillance is lower than 100%. Thus the aim of cancer immunoprevention is to enhance immune surveillance of tumors by means of treatments that elicit protective antitumor immune responses and/or decrease immunosuppressive components.

Immune targeting of ►preneoplastic lesions or of early neoplastic cells has several advantages with respect to conventional cancer ►immunotherapy, which instead must necessarily target advanced tumors. The efficacy of immune defenses is higher against smaller tumor deposits, a property shared by most antitumor approaches, including chemotherapy. Nascent neoplastic lesions are less protected from immune effectors by ►stromagenesis and ►angiogenesis, tumor progression caused by the accumulation of multiple genetic alterations is still at an early stage, and genomic instability has not yet generated a wide array of heterogeneous tumor variants, eventually leading to the selection of immunoresistant phenotypes.

Demonstrations of cancer immunoprevention were mainly obtained in ►cancer-prone genetically modified mouse models and in some ►chemical carcinogenesis systems. Three different strategies were effective in inhibiting and/or delaying tumor onset in mice: (i) monoclonal antibodies directed against membrane tumor antigens; (ii) immunostimulants, such as recombinant ►cytokines (►interleukin-12), plasmids containing CpG sequences (►CpG islands), or bacterial

derivatives (α-galactosylceramide); (iii) vaccines containing whole cells, recombinant proteins, synthetic peptides or plasmids encoding the target antigen. Using standard categories borrowed from immunotherapeutic jargon, the first approach can be classified as *passive immunoprevention*, because it is based on the administration of a preformed immunological "drug" directly acting on tumor cells, the second as *active, antigen nonspecific immunoprevention* and the third as *active, antigen specific immunoprevention*.

Early attempts provided proof-of-principle demonstrations that stimulation of the immune system in healthy, cancer-prone hosts can effectively delay or reduce tumor incidence later in life. Second generation studies aimed at increasing preventive efficacy through the combination of different strategies, much as it happened in chemotherapy (►Chemotherapy of cancer, progress and perspectives). Various combinations of antigen specific vaccines and powerful immunostimulants completely prevented tumor onset in very aggressive mouse models of cancer development, thus demonstrating that cancer immunoprevention can effectively halt a genetic predisposition to cancer. Microscopic analysis of tumor-free aged mice showed that tumor progression is blocked at the stage reached when vaccination begins. For effective immunoprevention of tumor onset vaccination must start before tumor progression reaches specific critical stages, such as *in situ* carcinoma.

Immune Mechanisms of Cancer Prevention

Highly active vaccines like those used for complete cancer immunoprevention elicit simultaneously many overlapping immune responses in immunocompetent mice, hence vaccination of mice with selective immunodepressions is the only way to dissect protective mechanisms from less important immune components. The most important immune mechanisms at work in cancer immunoprevention comprised both ►T cell responses, including the release of cytokines (interferon-γ, IFN-γ) and, less frequently, ►cytotoxic T lymphocytes (CTL), along with antibodies whenever the target antigen was expressed on the cell surface.

The importance of antibody responses clearly distinguishes cancer immunoprevention from cancer immunotherapy, the latter being mainly based on CTL rather than antibodies. The largely different time scales involved justifies this discrepancy, because cancer immunoprevention requires a long-term protection from tumor onset, ideally extending for the entire life of the host, whereas a rapid destruction of tumors or metastases is the goal of cancer immunotherapy. CTL activity must be of short duration to avoid severe toxicity for the host, whereas protective antibodies persisting for a long time are harmless. The same dualism applies to viral immunity in which acute infection is mostly resolved by CTL, whereas long term immunity from reinfection and protection elicited by vaccination are provided by neutralizing antibodies.

The direct interaction of cytokines like IFN-γ and of antibodies with early neoplastic cells results in multiple molecular blocks of cell growth and tumor progression combining cytostatic and cytotoxic mechanisms. Inhibition of cell proliferation is a logical part of the set of antiviral activities of IFN-γ that can directly block tumor cell growth, moreover it inhibits the release of ►matrix metalloproteinases involved in tumor cell invasiveness (►Invasion) and induces the production of chemokines with antiangiogenic activity. Antibodies binding to surface tumor antigens mediate tumor cell killing via ►complement-mediated cytotoxicity and ►antibody-dependent cell-mediated cytotoxicity (ADCC). Whenever the target antigen is involved in mitogenic signaling, antibodies can directly inhibit tumor cell proliferation without the need of further molecules or cells of the immune system, in practice by acting as "receptor antagonists." In the case of the ►HER-2/neu oncogene, specific antibodies induced by preventive cancer vaccines inhibit dimerization of surface HER-2/neu proteins (a key step required for the initiation of signal transduction) and induce HER-2/neu internalization and recycling, eventually leading to a complete depletion of HER-2/neu surface expression. In HER-2/neu-addicted cells (►Oncogene addiction) a prolonged loss of HER-2/neu expression and signaling blocks cell proliferation and can trigger ►apoptosis.

Target Antigens of Cancer Immunoprevention

The inhibitory mechanisms targeting HER-2/neu can be ineffective against most other tumor antigens, either because the target is not a surface molecule and antibodies cannot bind tumor cells, or because tumor progression leads to a loss of antigen processing machinery (including major histocompatibility complex molecules), required for antigen recognition by T cells. The latter is a very frequent event affecting 80–90% of all human tumors. For cancer immunoprevention it was proposed that the immune recognition of ideal target antigens should persist even if defects in antigen processing impede T cell recognition, hence the antigen should be expressed on the cell surface and recognized by antibodies. A second desirable property is a direct involvement of the target antigen in oncogene addiction or in the maintenance of tumorigenicity, as is the case of HER-2/neu, because this prevents tumor escape from immune defenses through loss of antigen expression, again a frequent phenomenon for most other tumor antigens. Tumor antigens fulfilling both requirements were named ►oncoantigens. Members of this new class of tumor antigens ideally suit the

concepts of cancer immunoprevention, in particular for what concerns the need of persistent, lifelong antitumor responses, however oncoantigens make also attractive new targets for cancer immunotherapy because they are not prone to relevant mechanisms of immunoresistance and therapeutic failure.

Clinical Developments

The mass of preclinical data demonstrating the efficacy of cancer immunoprevention in mouse models warrants the translation of this approach to humans, however this will require a precise definition of the subjects who can benefit from this type of intervention and consequently of the design of clinical trials. The analysis of these issues reveals key scientific issues to be investigated and suggests possible developments. Immunoprevention of hereditary cancer syndromes would be a straightforward translation from preclinical models, however the definition of suitable target antigens in most hereditary tumors is currently lacking and will require adequate immunological studies. Analogous problems face the application of cancer immunoprevention to other human groups at increased risk of cancer due to exposure to carcinogens and/or presence of preneoplastic lesions, moreover the lower level of risk (as compared to hereditary cancer) implies the recruitment of a large number of subjects. Lessons for the clinical deployment of cancer immunoprevention might come from the development of ►tamoxifen, which was first used for therapy of advanced ►breast cancer patients, followed by ►adjuvant therapy *i.e.* for prevention of tumor relapse and ►metastasis; the finding that tamoxifen also prevented the appearance of additional primary tumors eventually led to large prevention trials that demonstrated its efficacy in preventing breast cancer. Early clinical testing of preventive vaccines in advanced cancer patients will also provide much needed data concerning safety and risks of adverse effects.

The Risks of Cancer Immunoprevention

The lack of severe adverse effect registered in the clinical trials leading to the approval of HPV vaccines, along with similar results from worldwide HBV vaccination programs, indicates that the immunoprevention of virus-related cancers will share with other vaccines for infectious diseases an intrinsic high level of biosafety. The main reason is that the target antigens are not expressed by normal tissues of the host, hence the risk of triggering autoimmune reactions is very low.

On the contrary, virtually all tumor antigens unrelated to infectious agents are also expressed by some normal cells during life. In some cases normal cells express a cross-reacting molecule with minor aminoacidic differences from the tumor version, but more frequently the antigens are structurally identical, and the only differences are either quantitative or topographical. The implication is that some autoimmune responses will frequently accompany successful prophylactic or therapeutic vaccination, even though development of autoimmune diseases is not an automatic consequence.

A major difference between cancer therapy and prevention is that both physicians and patients accept inherently high risks of serious adverse effects when dealing with an existing life-threatening disease, whereas preventive treatments to be administered for long periods to healthy individuals need to minimize not only severe, but also mild adverse reactions.

Preclinical studies of cancer immunoprevention did not reveal major risks of ►autoimmunity, however the use of transgenic mouse models implies that in most instances protective immune responses were actually directed against transgenic products rather than against endogenous molecules, thus minimizing "real" autoimmunity. Therefore early clinical trials of cancer immunoprevention in humans will require intensive analyses to discover early signs of autoreactive immune responses and a special attention to the long-term risks of triggering autoimmunity.

Immunoprophylaxis

►Immunoprevention

Immunoreceptor

►Chimeric T Cell Receptors

Immunoreceptor Tyrosine-based Activation Motif

Definition

ITAM; A common cytoplasmic motif, YxxL/I-6-8-YxxL/I, that activates signaling pathways; it is found for example in adapter molecules (DAP12) that associate with NK activation receptors that lack cytoplasmic domains (for example NKp44), which is recognized by downstream signaling molecules of the tyrosine kinase family. This conserved amino acid sequence was originally discovered in receptors found in immune cells, but has also been found in other types of non-hematopoietic, non-receptor proteins. Phosphorylation of two tyrosine amino acids within this motif creates a binding site for other proteins and activates complex signaling pathways.

Immunoscreening cDNA Expression Libraries

Definition

This method utilizes the exquisite specificity of antibodies to recognize a given antigen in the midst of thousands of antigens in a cDNA library. It lends itself to study structure and function of the expressed autoantigen in cDNA expression libraries of the desired cancer, built into a virus such as λgt11, T7, or other virus which are grown in bacteria. The viral coat displays the universe of potential autoantigens selected by autoantibodies in sera which can be arrayed forming a library. The microarray can be probed with multiple sera from patients and controls and finally, associations are sought between positive phages, diagnosis, or other clinical parameters

►Autoantibodies

Immunostimulatory Molecules

Definition

Are molecules that provide signals for antigenic specificity and immune response of T cells. Examples include ►T cell receptor (TCR), CD28, CD40, B7-1 and ►cytokines.

►T-Cell Response

Immunosuppressed

Definition

A state of reduced immune function.

►Immunosuppression
►Allergy

Immunosuppression

Definition

Is a state in which the ability of the body's immune system to fight infections or disease is decreased. A process or act that leads to a reduced activation or efficacy of the immune system.

Immunosuppressive Drugs

Definition

Compounds that inhibit adaptive immune responses are called immunosuppressive drugs. They are used mainly in the treatment of graft rejection and severe autoimmune disease.

Synonyms

Biological therapy

Definition

Immunotherapy is the treatment of cancer or inflammatory/autoimmune disease by inducing, enhancing or suppressing an immune response. Immunotherapy can be nonspecific or (antigen)-specific. Nonspecific immunotherapy aims to enhance the overall host immune response, whereas specific immunotherapy targets the immune system against a particular tumor or increases tolerance towards a specific allergen. There are four main categories of specific immunotherapy: ►adoptive immunotherapy, antibody-based immunotherapy, cancer ►vaccine therapy and ►allergen-specific immunotherapy. From these, adoptive and antibody-based immunotherapies are passive approaches, whereas cancer vaccine therapy and allergen-specific immunotherapy are active approaches.

Characteristics

Despite advances in oncological research, cancer remains a leading cause of death throughout the developed world. Nonspecific approaches to cancer treatment, such as surgery, radiotherapy and generalized chemotherapy, have been successful in the management of a distinct group of leukemias and slow-growing solid cancers. However, many solid tumors show considerable resistance to such approaches, and the prognosis in these cases is correspondingly poor. Immunotherapy is an emerging alternative area of cancer treatment. Cancer immunotherapy includes both passive and active strategies. Passive immunotherapy involves the *ex vivo* creation of established tumor-immune elements (antibodies, immune cells) that are administered to patients to mediate anti-tumor activity directly or indirectly, and which do not stimulate the host immune system. In contrast, active immunotherapy induces a tumor-specific immune response in the patient, leading to the production of specific immune effectors (antibodies and T-cells). Historically, cancer immunotherapy has focused on nonspecific immune stimulants. Pioneer work began more than 140 years ago, when Wilhelm Busch observed that tumors show temporary regression during an infection. Two decades later, Sir William Coley developed and improved this therapeutic concept by vaccinating a large number of sarcoma patients with attenuated mixed bacterial extracts (►Coley toxin).

Nonspecific Immunotherapy

1. ►Bacillus Calmette-Guerin (BCG) is the most effective intravesical nonspecific immunotherapeutic agent, and is used for the prevention and treatment of superficial ►bladder cancer. The proposed anti-tumor mechanism of BCG involves activation of the immune system and the promotion of a local acute nonspecific ►inflammation in the bladder lumen. Immune cell activation in response to BCG is mediated by a family of transmembrane recognition receptors called ►Toll-like receptors (TLRs). Intravesical, BCG-induced inflammation facilitates the infiltration of a broad range of immune cells (►macrophages, ►lymphocytes and ►natural killer cells) and the activation of pro-inflammatory cytokines such as ►interleukin-1 (IL-1), ►interleukin-6 and ►tumor necrosis factor-alpha (TNF-α).
2. ►Cytokines are low-molecular-weight, soluble proteins that regulate the innate and adaptive immune systems. The anti-tumor activity of cytokines is mediated by one of two general mechanisms: first, a direct anti-tumor effect, and second, indirect enhancement of the anti-tumor ►immune response. It has been hypothesized that both the cytokine-activated lymphocytes and their secretory products such as interferon-gamma and tumor necrosis factor-beta (TNF-β) may contribute to the lysis of tumor cells *in vivo*. The exogenous administration of ►interleukin-2 (IL-2) is efficient in a broad spectrum of experimental tumors, including sarcomas, carcinomas, hemoblastoses, melanomas and hepatomas. In humans, IL-2 and interferon-α2b are approved for the treatment of advanced melanoma and for use with ►adjuvant therapy.

Specific Immunotherapy

1. Adoptive Immunotherapy involves the infusion of immunologically-competent, *ex vivo*-expanded, donor-derived lymphocytes (DLI), which specifically destroy tumor cells by ►graft-versus-leukemia (GvL) or ►graft-versus-tumor (GvT) effects. In addition, peripheral blood-derived ►lymphokine-activated killer (LAK) cells and ►tumor-infiltrating lymphocytes (TILs) derived from tumor sections have proven to be effective anti-tumor agents. To address MHC and exogenous cytokine-independent activation of anti-tumor effector functions, T cells can be engineered to express ►chimeric T-cell receptors.

I

Chimeric receptors are composed of a recognition unit (antibody fragment) and an intracytoplasmic signaling molecule. Such receptors can be used to target various types of effector cells including cytotoxic T-cells towards any tumor-associated antigen for which there is a suitable antibody.

2. Antibody-based immunotherapy exploits the highly specific binding between antibodies and their corresponding ►tumor-associated antigens (TAAs), resulting in some significant clinical responses. Tumor-associated antigens are structures presented predominantly by tumor cells, thereby allowing antibodies to distinguish tumors from non-malignant tissue. Therapeutic ►monoclonal antibodies can destroy tumor cells directly by inducing ►apoptosis or indirectly through immunologic mechanisms such as ►antibody-dependent cell-mediated cytotoxicity (ADCC) and/or ►complement-dependent cytotoxicity (CDC). In addition, the natural function of antibodies can be enhanced by conjugating them to toxins (►immunotoxins), radionucleotides (radioimmunoconjugates), liposomes (►immunoliposomes) and cytotoxic drugs. Host immune responses can be enhanced through the induction of ►anti-idiotypic antibodies or through the use of ►bispecific antibodies containing arms with different specificities. Monoclonal antibodies are the largest class of biotechnology-derived proteins, with 19 monoclonal antibodies already approved for human use by the United States Food and Drug Administration (FDA).
3. ►Cancer vaccine therapy represents an active, systemic, tumor-specific immune response of host origin. It is used either to treat existing cancers (►therapeutic vaccines) or to prevent cancer development (►prophylactic vaccines). There are several types of cancer vaccine: isolated whole cell cancer vaccines or tumor cell lysates, protein- or peptide-containing vaccines, viral vector vaccines and anti-idiotype vaccines. Following the administration of a vaccine-antigen that resembles a specific target, the patient's humoral and T-cell-specific immune response induces defense mechanisms to combat the target *in vivo*.

Imprinted Gene

Definition

A gene that is marked in the germline; this denotes its maternal or paternal origin and influences its expression in the developing embryo. Refers to the parent-of-origin-specific monoallelic expression of a gene.

►Imprinting

Imprinting

Christoph Plass
German Cancer Research Center, Toricology and Cancer Risk Factors, Heidelberg, Germany

Definition

►Genomic imprinting; Describes a phenomenon in which a gene is expressed either from the paternal or form the maternal ►allele and thus discriminates these genes from the majority of genes that are expressed from both alleles.

Characteristics

Normally genes are expressed from both the maternal and the paternal allele. Genomic imprinting results in allele specific expression of certain genes from either the paternal or the maternal allele. These genes are marked before fertilization in a way that either the maternal or the paternal allele is transcriptionally silenced in the offspring. One of the first indications that certain autosomal regions are subject to genomic imprinting came from mouse genetic studies using Robertsonian and ►reciprocal translocations. In these studies, uniparental duplications or deficiencies for certain chromosomal regions were analyzed. The failure of a disomy or duplication from one parent to complement a corresponding nullisomy or deficiency from the other parent constituted the genetic evidence for the occurrence of imprinting effects. In addition, embryos that contain either two copies of the maternal or the paternal genomes fail to survive in early development indicating the complementary need for both the maternal and paternal genome. More than 25 imprinted genes have been identified in mice and humans and there are estimates for about 100 imprinted genes in the mammalian genome. Certain characteristic features have been identified for imprinted genes. Most of the imprinted genes have important roles in early development. Interestingly, imprinted genes tend to occur in clusters suggesting a common regulatory mechanism. One of the best studied cluster of imprinted genes is located on mouse distal chromosome 7 (human 11p15.5), encompassing 1.5 Mbp and including the maternally expressed genes p57KIP2, Kvlqt1, Mash2 and H19 as well as the paternally expressed genes Ins2 and Igf2. It is now well accepted that imprinting could be regulated in a tissue specific manner in a way that only some tissues express the gene from one allele while others show biallelic expression. Here, unknown mechanisms exist that allow to by-pass the regulation of imprinting. It is interesting to note that a number of imprinted genes encode for RNAs but do not have an open reading frame and are not translated. It is believed that these RNAs play a role in the regulation of the imprinting process. Interestingly, short GC-rich repeat sequences were identified in the vicinity of many imprinted genes usually located in or near so called differentially methylated sites, ►CpG island-like sequences that are methylated on only one allele.

Cellular and Molecular Aspects

Regulatory mechanisms underlying genomic imprinting are under intense investigations in many laboratories but only incompletely understood. The features of the imprinting signal and the mechanism are unknown, but strong evidence suggests the involvement of DNA ►methylation. Several requirements for the underlying mechanisms can be postulated. First, the imprinting signal, or imprint mark, in the imprinted region must be established before fertilization. Second, the imprint mark must be an ►epigenetic modification and must directly or indirectly affect the transcription of a gene by silencing one allele and leaving the other active. Third, the imprint mark must be stable in ►mitosis and must be transmitted during cell division. Finally, the imprint mark must be reversible in a passage through the opposite germline. At present, DNA methylation is the only mechanism that conforms with the above requirements. Several lines of experimental data support the assumption that DNA methylation plays an important role in imprinted regulation. In mammals, ►DNA methylation occurs only at the cytosine residue of ►CpG dinucleotides. It was shown that DNA methylation in promoter regions can turn off the transcription of a gene. Most genes are subject to a process of demethylation directly after fertilization with most of the CpG sites unmethylated at the 16 cell stage. However imprinted genes are exceptions in this demethylation process by maintaining small regions that show allele specific methylation. DNA methyltransferase generates methylation patterns that are transmitted correctly following DNA replication and cell divisions. Studies of the expression of imprinted genes in DNA methyltransferase-deficient mutant mice indicated that normal level of DNA methylation are required for the control of allele specific expression. Studies with transgenic mice suggested that methylation is the epigenetic modification underlying genomic imprinting. A direct correlation between paternal inheritance, ►transgene, ►hypomethylation and tissue specific expression of the transgene was shown, while the maternally derived copy is methylated and not expressed.

Clinical Relevance

Imprinted genes are involved in critical steps during normal embryonic development. A growing body of

evidence implicates genomic imprinting in the pathogenesis of certain human disorders, inherited tumor syndromes and sporadic tumors. At least ten genetic disorders have been found to be associated with genomic imprinting effects. In some cases, the trait is transmitted exclusively (or mainly) from one parent (either father or mother) or the disease is particularly severe when transmitted from one parent. In other cases the disease is associated with uniparental disomies or parent-of-origin specific aberrations.

The best studied examples of imprinted genetic diseases are the Prader–Willi-Syndrome (PWS) and Angelman syndrome (AS). PWS is characterized by mild to moderate mental retardation, individuals are slow moving and overweight due to severe hyperphangia. Patients with AS show severe mental retardation are thin, hyperactive and show disorders of movement and uncontrolled laughter. Both syndromes are linked to abnormalities on human chromosome 15q11–13. The first hint for a possible imprinting effect in these syndromes came from the finding that the deleted fragments in both syndromes are from opposite parental origins. In PWS the deletion occurred in the paternal copy and in cases of AS the maternal copy was deleted. Additional evidence came from the finding of maternal disomy of chromosome 15 in PWS patients and paternal disomies of chromosome 15 in AS. These data suggest that the PWS gene(s) is transcribed from the paternal allele only and the AS gene(s) is expressed from the maternal allele. Several imprinted genes were identified in the critical region for PWS/AS including paternally expressed SNRPN and maternally expressed UBE3A.

There is also evidence that some of the imprinted genes have oncogenic or tumor suppressor function. Loss of tumor suppressor function of an imprinted gene could be achieved by ►loss of heterozygosity (LOH) involving the usually active copy, as shown for the cyclin dependent kinase inhibitor, p57KIP2, in lung cancers, H19 in ►Wilms tumor and NOEY2, a member of the ►RAS superfamily, in breast and ovarian cancers. Alternatively, uniparental disomy including the normally silent allele could lead to inactivation of an imprinted tumor suppressor gene. Activation of a growth supporting gene such as IGF2 (►Insulin-like Growth Factors) could occur by uniparental disomy involving the normally active copy. In addition, relaxation of imprinting control, also called loss of imprinting (LOI), could lead to biallelic expression and thus overexpression of an imprinted oncogene, as shown for IGF2 in Wilms tumor. The first evidence for the involvement of DNA methylation in LOI came from the finding of complete methylation of the CpG island located immediately upstream of H19 transcription start site. Usually this ►CpG island shows allele specific methylation on the maternal allele. This epigenetic change correlated with LOI in IGF2 and silencing of H19.

Another human disease is the ►Beckwith–Wiedemann Syndrome (BWS) that is characterized by a number of growth abnormalities including gigantism. Between 5% and 10% of BWS patients are prone to Wilms tumor, adrenocortical carcinoma, hepatoblastoma or embryonal rhabdomyosarcoma. Wilms tumors have been shown to exhibit preferential loss of maternal alleles at chromosome 11p. A cluster of at least seven imprinted genes was identified in 11p15.5 including the paternally expressed IGF2 and the maternally expressed H19. The most common abnormality in BWS patients is LOI of IGF2 without any detectable chromosomal abnormalities.

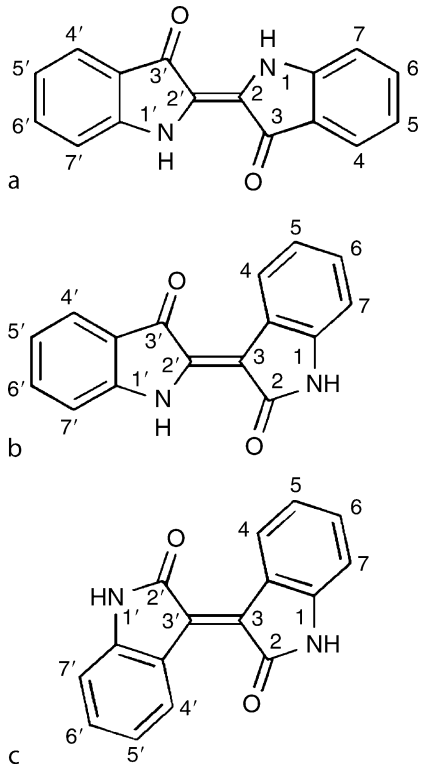
Synonyms

3-(1,3-Dihydro-3-oxo-2H-indol-2-ylidene)-1,3-dihydro-2H-indol-2-one; 2′,3-Biindolinylidene-2,3′-dione: 3-(3-Indolinone-2-ylidene)-indolin-2-one

Definition

Indirubin is the parent compound of a spectrum of 2′,3-bisindoles synthesized to improve the biological activity of this natural 2′,3-bisindole lead structure. Indirubin and its isomers indigo and isoindigo are composed of two indolinone ring systems, linked through a double bond to make up 2,2′-(indigo), 3,2′-(indirubin) and 3,3′-(isoindigo) bisindoles, respectively (Fig. 1).



Indirubin and Indirubin Derivatives. Figure 1
Structures and numeration of indigoid bisindoles. (a) Indigo, (b) Indirubin (E211), (c) Isoindigo.

Characteristics

History

While indigo is one of the oldest dyes known, with a history of use dating back to bronze age, the two other isomers, especially indirubin, have gained reputation as components of traditional medications used against a variety of human diseases.

The discovery of the anticancer activity of indirubin can be traced back to a traditional Chinese medication, consisting of 11 ingredients, mostly of herbal origin, with the name of Danggui Longhui Wan. The preparation is used traditionally for a variety of chronic and acute diseases including chronic myelocytic leukemia (►CML). Chinese scientists achieved the identification of the active ingredient of this medication, Quing Dai, which corresponds to natural indigo, prepared from the leaves of indigo-producing plants. Furthermore, the Chinese scientists discovered that not only the blue dye indigo, but a minor byproduct, the red colored trace constituent indirubin was the active antileukemic principle. In a clinical trial, synthetic indirubin was given orally to CML patients at dosages of 150–450 mg/day. A total of 314 patients participated in the study. Complete remissions were observed in 26%, partial remission in 33%, and some beneficial response in 28% of patients. Treatment was well-tolerated, without major side effects. Studies exploring the mechanism of action reported a spectrum of relatively unspecific biological effects, not really convincing to fully explain the respectable anti-CML activity of the compound.

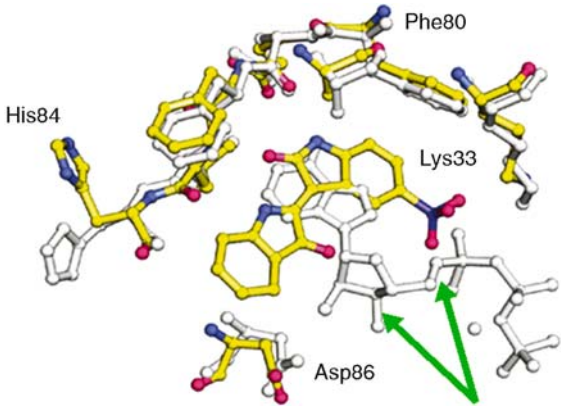
Mechanism

Research on indirubins gained momentum, when in 1999 it was discovered that such 3,2′-bisindoles act as potent inhibitors of serine/threonine kinases, especially of ►cyclin-dependent kinases (CDKs) and of glycogen-synthase kinase 3β (GSK3β). Later it was found that indirubins also inhibit ►receptor tyrosine kinases, such as ►vascular endothelial growth factor receptor (VEGFR) or ►Src kinase and block Stat-3 signaling. Moreover, indirubins have also been discovered to activate the ►aryl hydrocarbon receptor transduction pathway. Thus indirubins exert, in addition to their multimodal kinase inhibitory activity, further bimolecular effects contributing to anticancer activity.

The relative kinase inhibitory profile of individual representatives of these 3,2′-bisindoles, as well as their pharmacokinetic properties is markedly influenced by the type and pattern of substituents attached to the 3,2′-bisindole basic scaffold. Within cancer targets, VEGFR2 and c-Src, as well as specific CDKs are of prime interest, since their respective partner proteins, activators or inhibitors, are aberrantly expressed in many human malignancies.

Structure/Activity

Chemical improvement of the parent molecule initially was driven by the aim to improve solubility and bioavailability without compromising anticancer activity.



Indirubin and Indirubin Derivatives. Figure 2
Superposition of crystal structures of CDK2–E226 (yellow) and CDK2–AMPPNP (white). Green arrows point to 5- and 3′-position of indirubin scaffold. (Reprinted from Davies et al (2001), Structure 9:389; with permission from Elsevier).

Indirubins act as ATP-competitive inhibitors of ATP-dependent kinases. Crystal structures of CDK2–-indirubin complexes have been described in detail. It was shown that the flat disk shape of the 3,2′-bisindole molecule slides easily into the binding pocket and is tightly bound, mainly by virtue of hydrogen bonding and lipophilic interactions with the ATP-binding cleft, situated in the hinge region connecting the amino terminal with the carboxy terminal part of the kinase. The strong binding affinity of indirubin derivatives to the ATP site is practically not affected by additional binding of the activating partner cyclin A to CDK2. A superposition of the structures of the binding complexes of the indirubin derivative, E 226, and of a nonhydrolyzable ATP mimic, AMPPNP, with CDK2, unraveled molecular positions of the indirubin scaffold preferably to be exploited for chemical improvement of the molecule. Thus, positions 5 and 3′ (arrows in Fig. 2) were identified as those of first choice for molecular modifications by attaching appropriate substituents.

The chemistry to achieve the synthesis of such derivatives has been described in detail. A selection of results from comprehensive structure/activity studies is summarized in Tables 1 and 2.

The results show that the inhibitory activity of the parent molecule, indirubin (E211) on isolated

SRB-assay, incubation 3d, IC_{50}-values in μM, Solubility in mg/L.
[a]Structures see Table 1–: not determined.

CDKs could be improved dramatically. While indirubin (E211) itself was somewhat less active than roscovitine, a standard purine-type of CDK inhibitor, several 3′ or 5-substituted derivatives achieved IC_{50} values, especially toward CDK2/cyclin A, CDK2/cyclin E, and CDK6/►cyclin D down to the low nanomolar range (Table 1). At the same time, solubility in water and thus bioavailability could be improved by factors of up to about 400, as compared with the parent compound. In addition, the potency to inhibit human tumor cell proliferation was also strongly improved (Table 2). These novel compounds not only induce arrest in G1/S and G2/M phases of the cell cycle of various human tumor cells but also strongly trigger ►apoptosis and cellular necrosis by several mechanisms, including inhibition of antiapoptotic proteins, such as ►Mcl-1 and ►survivin, and induction of endoreplication.

Thus, within this family of bisindoles, molecular permutations entail major effects on biological activities and allow generation of novel derivatives that lend themselves to clinical application. Since the major cellular targets of these compounds are aberrantly expressed in many human tumors, it is reasonable to expect selective activity toward such human tumors. These encompass amongst others, ►breast cancer, ►renal cancer, ►pancreatic cancer, and ►prostate cancer as well as ►leukemias. However, the state of clinical testing and verification has not been reached at present.

Individual Susceptibility

Definition

Marked variability in the manner in which individuals will respond to a given exposure to a toxic agent. A person’s body size, age, gender, genetics, and health status can affect individual susceptibility.

►Biomonitoring

Individualized Treatment

►Personalized Cancer Medicine

Individually Mutated Tumor Antigens

Definition

Tumor antigens that are only expressed by malignant cells of a particular tumor. These antigens result from

tumor-specific mutations, which creates new peptides that enable antigen-specific T cells to differentiate between normal and malignant cells. Mutations may enhance the binding affinity of peptides to major histocompatibility complex molecules or may engage a different T cell repertoire than the corresponding normal peptide.

►Melanoma Vaccines

Indoleamine

Definition

An aromatic heterocyclic organic compound consisting of a six-membered benzene ring fused to a five-membered nitrogen-containing pyrrole ring and containing an amine group.

►Polycyclic Aromatic Hydrocarbons

Synonyms

IDO

Definition

Indoleamine 2,3-dioxygenase (IDO; EC 1.13.11.42) is an enzyme catalyzing the initial and rate-limiting step in the catabolism of tryptophan. This enzyme induces ►immunosuppression and ►tolerance, and is involved in the ►immune escape of tumor cells, leading to cancer progression.

Characteristics

Enzymatic Properties, Tissue Distribution, and Regulation of Expression

IDO is a heme-containing intracellular enzyme that catalyzes the initial and rate-limiting step of tryptophan catabolism by cleavage of the pyrrole ring of L-tryptophan (Fig. 1). While only a small amount of tryptophan from food is converted to serotonin and further converted into melatonin, most (more than 95%) dietary tryptophan is metabolized by IDO along the kynurenine pathway, leading finally to the biosynthesis of nicotinamide adenine dinucleotide (NAD).

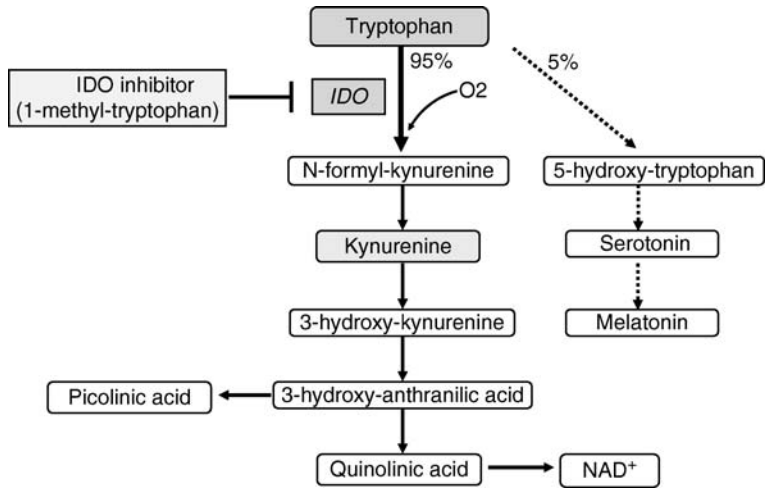
IDO is expressed in a wide range of tissues such as the lung, intestine, brain, and placenta, although within these tissues, expression occurs only in a limited range of cell types. In contrast, in the liver, tryptophan is catabolized by a structurally distinct liver-specific enzyme, tryptophan 2,3-dioxygenase (TDO; EC 1.13.1.12), but not by IDO.

A cDNA encoding human IDO has been cloned and its deduced primary structure is obtained. Human IDO cDNA encodes a protein of 403 amino acids with a molecular weight of approximately 45 kDa. The IDO protein is encoded by a tightly regulated gene that -responds to inflammatory mediators such as interferon-gamma (IFN-γ), tumor necrosis factor-alpha (TNF-α), and lipopolysaccharide (LPS). In humans, IDO is encoded by the *INDO* gene, which is comprised of ten exons spanning approximately 15 kb at chromosome site 8p11-p12. IFN-γ is a major inducer of IDO expression. Transcriptional induction of the *INDO* gene is mediated by the Janus kinase (JAK)/signal transducer and activator of transcription (STAT) pathway, specifically JAK1 and STAT1α. NF-κB also contributes to IDO induction. It has been shown that ►IFN-γ and ►TNF act synergistically through ►NF-κB activation to induce expression of interferon regulatory factor (IRF)-1, which leads to upregulation of IDO expression. In addition, ►prostaglandin E_2 (PGE_2) strongly upregulates IDO.

IDO and Immune Suppression

Accumulating evidence indicates immunosuppressive function of IDO. First, IDO is expressed in placental trophoblasts and macrophages during pregnancy and prevents rejection of the allogeneic fetus, thereby suggesting involvement of IDO in fetal–maternal tolerance. This is based on the findings that a pharmacological inhibition of IDO activity by 1-methyl-tryptophan (1-MT) results in rejection of the fetus in pregnant mice. Subsequent studies clarified the mechanism of IDO ►immunosuppression by locally depleting tryptophan and by producing toxic tryptophan metabolites (e.g., kynurenine, see Fig. 1), which causes arrest of proliferation and the apoptosis of alloreactive T-cells. It has been similarly demonstrated that enzymatic activity of IDO correlates with reduced T-cell-mediated immune responses in several experimental systems, including models of inflammatory diseases, autoimmune diseases, and organ/tissue transplant rejection.

Secondly, IDO is expressed in ►antigen-presenting cells (APCs), especially certain subsets of ►dendritic cells (DCs), and it regulates immune response



Indoleamine 2,3-Dioxygenase. Figure 1 Catabolic pathway of trytophan and kynurenine by IDO.

and induces tolerance. For example, exposure of ►monocyte-derived DCs to a cocktail of cytokines for the purpose of maturation results in strong upregulation of IDO expression. Mature DCs that express functional IDO can be potent suppressors of ►T-cell response and promote tolerance in vivo and in vitro. Expression of functional IDO requires ligation of B7-1/B7-2 (CD80/CD86) molecules on DC cell membranes by cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) expressed by CD4 + CD25- ►regulatory T cells. This binding of CTLA-4 to B7 receptors on DCs activates IFN-α-mediated STAT1-dependent IDO upregulation. Similarly, the synthetic soluble fusion protein CTLA4-immunoglobulin (CTLA-4 Ig) is a potent inducer of IDO expression by DCs. IDO-expressing DCs may also promote the development of regulatory T cells. These findings therefore suggest that IDO-expressing DCs and ►T regulatory cells may cooperate to induce antigen-specific T-cell anergy and create a state of peripheral immune tolerance.

While the mechanisms of IDO-dependent inhibition of T-cell function have been elucidated, less is known about the possible role of IDO in regulating ►natural killer cell activity. NK cell function is also suppressed by IDO, and IDO inhibits the proliferation of NK cells in vitro. Furthermore, L-kynurenine, a tryptophan-derived catabolite produced by IDO activity, inhibits the cytokine-mediated expression of the specific triggering receptors, NKp46 and NKG2D, which are responsible for the induction of NK cell-mediated killing. As a consequence, L-kynurenine-treated NK cells display an impaired ability to kill target cells recognized via NKp46 and NKG2D. These findings suggest that IDO can suppress both T-cell and NK cell responses.

IDO and Cancer

Although many tumor-associated antigens have been identified in various tumor cells, the reason why tumor antigen-specific host T-cells fail to control tumor progression remains obscure. Tumors are known to successfully escape the host immune system by two possible mechanisms; a loss of surface antigens that renders them invisible to immune cells, or an attack on the immune cells that disables their antitumor functions. The accumulated evidence that IDO is physiologically important for establishing peripheral tolerance to alloantigens prompts a hypothetical mechanism that tumors could create a state of tolerance through tryptophan catabolism carried out by IDO. If IDO is actually present in tumor tissues, it could induce local immune suppression, resulting in the protection of tumor cells from host T-cell-mediated rejection and/or attack by NK cells, and subsequently leading to tumor growth and progression.

IDO is expressed in various human cancer tissues, and that it is expressed not only by immune cells, but also by the tumor cells themselves. Tumors expressing IDO can resist immune rejection by tumor-associated antigen-specific host cytotoxic T-cells in mouse models. This effect is accompanied by a lack of accumulation of T-cells at the tumor site, resulting from arrest of T-cell proliferation caused by IDO-mediated local tryptophan depletion. When the IDO inhibitor 1-MT is dissolved in the drinking water given to tumor-bearing mice, the growth of IDO-expressing tumors is significantly reduced.

In contrast, it is shown that IDO is expressed by CD19 + plasmacytoid DCs in tumor-draining lymph nodes in mice, and these specific IDO-expressing DCs potently suppress host antitumor T-cell responses and

induce tolerance to tumor-derived antigens. In humans, IDO + cells of host origin are also present in draining lymph nodes of patients with ►melanoma, ►breast cancer, and other tumors.

Taken together, two possible mechanisms for the immunosuppressive action of IDO in tumor-bearing hosts are proposed. IDO expressed by the tumor cells themselves can create a localized immunosuppressive status within the tumor microenvironment either by suppressing effector T-cell function and proliferation due to tryptophan depletion, or by directly killing tumor-infiltrating T-cells and NK cells using toxic metabolites of tryptophan. Alternatively, host DCs expressing IDO can pick up tumor-derived antigens and migrate into tumor-draining lymph nodes, where these IDO-expressing APCs cannot effectively prime naïve T-cells, resulting in T-cell deletion, failure of clonal expansion, or perhaps induction of regulatory T-cells.

Clinical Relevance

IDO as a Prognostic Indicator for Human Cancer

Historically, it was known that decreased serum tryptophan levels as well as increased serum tryptophan metabolites could be detected in some patients with advanced cancer, suggesting elevated tryptophan catabolism by IDO. Expression of IDO, either by host cells or by tumor cells, is associated with poor outcome in various clinical settings. In patients with malignant melanoma, the presence of IDO-positive cells in sentinel lymph nodes is correlated with a significantly worse clinical outcome. In a gene expression profiling study, IDO is overexpressed in chemotherapy (►paclitaxel)-resistant ►ovarian cancer tissues, and patients with high IDO expression have poor clinical outcomes in serous-type ovarian cancer. Similarly, high IDO expression is also correlated with the advanced disease stage and liver metastasis in ►colon cancer, as well as a reduced number of CD3 + lymphocytes infiltrating into tumor tissues. High IDO expression in tumor cells is found in 46.3% of ►endometrial cancer patients, and is positively correlated with surgical stage, myometrial invasion, lymph-vascular space involvement, and lymph node metastasis. Furthermore, patients with high IDO expression have significantly impaired overall survival and progression-free survival compared to patients with weak or no expression of IDO. Even in early-stage disease (stage I and II), the survival rate of patients with high IDO expression is significantly reduced. On multivariate analysis, IDO expression is an independent prognostic factor for progression-free survival in endometrial cancer. These findings indicate that IDO may be a reliable and promising prognostic indicator for the treatment of human cancers.

Targeting IDO as a Therapeutic Strategy for Cancer Treatment

The idea that IDO has a role in enabling tumors to escape the host immune system could make IDO an attractive new target for cancer ►immunotherapy, and suggests that IDO inhibitors might have utility as anticancer agents.

Small-molecular inhibitors of IDO including 1-MT potentiate the antitumor activity of clinically relevant chemotherapeutic agents in mice. The combination of 1-MT with ►cyclophosphamide, ►cisplatin, ►doxorubicin, or ►paclitaxel regresses tumors synergistically in mouse spontaneous breast cancer models, suggesting that 1-MT could be utilized to block host-mediated immunosuppression and to enhance antitumor activity in the setting of combined chemoimmunotherapy. Furthermore, of the three stereoisomers of 1-MT, 1-methyl-L-tryptophan, 1-methyl-DL-tryptophan, and 1-methyl-D-tryptophan, the D-isomer has been shown to be most effective in reversing the suppression of T-cells generated by IDO-expressing DCs, and is most efficacious as an anticancer agent in chemoimmunotherapy regimens in mouse melanoma and breast cancer models.

In addition to the use of IDO inhibitors, the antitumor efficacy of silencing IDO by siRNA is reported. IDO–siRNA treatment of B16F10 murine melanoma cells prevents catabolism of tryptophan, and inhibits apoptosis of T-cells in vitro. In vivo treatment of B16F10 tumor-bearing mice with IDO–siRNA successfully postpones tumor formation and decreases tumor size, with a concomitant recovery of T-cell responses and enhancement of tumor-specific killing. These findings indicate that IDO–RNA interference has the potential to enhance cancer therapy by reinstalling anticancer immunity.

Implication of IDO for DC-based Cancer Immunotherapy

With respect to peptide-pulsed DC-based immunotherapy protocols, the currently used DC maturation cocktail contains IDO-inducing cytokines such as PGE_2. PGE_2 sensitizes DCs to TNF-α-mediated IDO activation, leading to the development of DC-mediated T-cell tolerance, which is the opposite effect of what is intended. It may be possible to include an IDO inhibitor in the DC maturation cocktail, generating mature DCs with inactivated IDO, and thus increasing the efficacy of DC-based antitumor peptide vaccination. Alternatively, application of ►cyclooxygenase-2 (COX-2) inhibitors such as ►celecoxib, which inhibits the production of PGE_2, in combination with a DC-based ►cancer vaccine significantly augments vaccine efficacy by reducing tumor burden, preventing metastasis, and increasing survival in a mouse breast

cancer model. The improved vaccine potency by COX-2 inhibitors is associated with an increase in the number of tumor-specific cytotoxic T cells, which may be attributed to a significant decrease in levels of tumor-associated IDO activity. These findings suggest a potential clinical relevance of IDO in DC-based therapeutic vaccines, and may be helpful in designing future cancer vaccines.

Indolent Lymphoma

Definition

Lymphoma that tends to progress slowly. Indolent lymphomas include ►chronic lymphocytic leukemia/small lymphocytic lymphoma and follicular small cleaved cell lymphoma.

►Rituximab
►Malignant Lymphoma, Hallmarks and Concepts

Induction

Definition

Happens when levels or activities of enzymes involved in metabolism of parent ►xenobiotic are increased as a response to xenobiotic exposure.

Induction Chemotherapy

Harry H. Yoon[1], Michael K. Gibson[2]
[1]Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins, Baltimore, MD, USA
[2]University of Pittsburgh Cancer Institute, Pittsburgh, PA, USA

Synonyms

Neoadjuvant chemotherapy (►Neoadjuvant Therapy); Preoperative chemotherapy)

Definition

Induction chemotherapy is chemotherapy given before the initiation of another treatment, which can be but is not limited to radiation, surgery or ►chemoradiotherapy. At least in the case of solid tumors, the theoretical benefit is provided by the ability to suppress distant metastases and to shrink the tumor, which in turn facilitates subsequent intensified ►local therapy. Its use is limited to tumors that are loco-regional, often bulky, but where cure remains possible.

Characteristics

The term "induction chemotherapy" differs to some degree when considering solid tumors vs leukemia.

Solid Tumors

When considering overall schemes to cure solid tumors, there are three major types of regimens, which are distinguished by their timing relative to one another and, to some degree, purpose:

1. induction or neoadjuvant therapy – i.e., therapy which precedes ►definitive therapy;
2. ►definitive therapy – i.e., therapy which is potentially curative by itself and forms the backbone of the curative regimen;
3. ►adjuvant therapy – i.e., therapy which follows definitive therapy.

Chemotherapy or radiotherapy may be components of any of these three types of regimens. When chemotherapy comprises an induction regimen, it is called "induction chemotherapy." By contrast, surgery may be a component only of definitive therapy.

The rationale behind most induction chemotherapy rests on the hypothesis that, in delivering ►systemic therapy as early as possible:

1. The tumor may shrink, thereby making subsequent ►local treatment more effective. For example, if the tumor shrinks with induction chemotherapy, the surgeon may have an easier time removing the entire tumor while minimizing the potential for damaging neighboring organs.

2. The development of distant metastases may be suppressed.

A potential advantage of including induction chemotherapy as part of a treatment approach is that the tumor's response to it may predict response to subsequent therapy. This fact is exploited, for example, in patients with bulky ►laryngeal cancer so as to avoid larynx removal. Patients whose tumors shrink substantially with induction chemotherapy (often ►cisplatin and ►5-fluorouracil) receive subsequent chemoradiation and thus avoid laryngectomy. Patients whose tumors do not shrink undergo immediate larynx removal.

Induction regimens are used in many cancer types, such as those in the head, neck, lung, or pancreas. In patients with ►esophageal cancer who have locoregional disease, a common induction regimen in the United States uses chemotherapy (often cisplatin and 5-fluorouracil) concurrent with radiotherapy. This is followed by ►definitive therapy, which in this case is surgical resection of the tumor. In Europe, the more common induction regimen uses chemotherapy alone.

The disadvantages of induction regimens rest on the fact that definitive (i.e., most effective) treatment is delayed. If induction therapy is unsuccessful, the tumor may continue to grow to such an extent that definitive therapy is no longer possible or is compromised. A further concern is that the patient, weakened from the side effects of chemotherapy, becomes a suboptimal candidate for definitive therapy.

Leukemia

In acute leukemia (►Acute Myeloid Leukemia, ►Acute Lymphoblastic Leukemia, and ►Acute Promyelocytic Leukemia), a cancer of white cells in the blood, all adult patients who can tolerate such chemotherapy are given induction chemotherapy. The goal of such therapy is to induce "►remission" – to reduce the number of leukemia cells in the body to undetectable levels and restore normal bone marrow function. It is generally believed that some leukemia cells persist undetected even after successful induction chemotherapy, leaving the possibility of ►relapse if further therapy is not administered.

This further therapy is called "consolidation," and is designed to remove all remaining leukemia cells with a view toward cure. Consolidation therapy usually incorporates further chemotherapy and/or hematopoietic cell transplantation.

Inflammation

Lorne J. Hofseth
Department of Pharmaceutical and Biomedical Sciences, South Carolina College of Pharmacy, University of South Carolina, Columbia, SC, USA

Definition

Is an immune response to infection or irritation. Inflammation is characterized by the following quintet: redness (rubor), heat (calor), swelling (tumor), pain (dolor) and dysfunction of the organs involved (functio laesa). Acute inflammation is short-lasting, lasting only a few days. If it is longer lasting however, then it is referred to as chronic inflammation. Chronic inflammation is a prolonged inflammatory response (weeks,

months, or even indefinitely). It is prolonged by the persistence of the causative stimulus to inflammation in the tissue. The inflammatory process unavoidably causes tissue damage and is accompanied by concurrent healing and repair.

Characteristics

Overall, chronic inflammation is bad for human health. There is a close association between chronic inflammation and prevalent diseases found in the developed world (cardiovascular disease/CVD, cancer, diabetes, and Alzheimer disease/AD to name a few). Evidence for this comes from epidemiological studies; clinical trials, showing decreased risk of disease with the use of anti-inflammatory drugs; and animal studies which show increased disease incidence with genetically (knock-out nice/transgenic animals) or environmentally (chemical/physical/biological) induced chronic inflammation (Table 1).

Extensive laboratory and clinical evidence shows that chronic inflammation drives cancer. At the molecular level, ►reactive oxygen species (RONS) and ►reactive nitrogen species (NOS) and ►aldehydes, produced during chronic inflammation, can induce cancer gene ►mutation and ►posttranslational modifications of key cancer-related proteins. Other products of inflammation, including ►cytokines, growth factors and transcription factors such as nuclear factor-kappa B (►NF-κB), control the expression of cancer genes (e.g. tumor suppressor genes and oncogenes) and key inflammatory enzymes such as ►nitric oxide synthases (NOS) and ►cyclooxygenases (COX). These enzymes in turn directly influence RONS and ►eicosanoid levels. The pro-cancerous outcome of chronic inflammation is increased ►DNA damage, increased DNA synthesis, cellular proliferation, the disruption of ►DNA repair pathways and cellular milieu, the inhibition of ►apoptosis, and the promotion of ►angiogenesis and ►invasion.

Chronic inflammation is also associated with ►immuno-suppression, which is a risk factor for cancer. Alternatively, a careful balance in ►innate immunity and ►adaptive immunity is critical to controlling chronic inflammation. An imbalance in this system (e.g. hyper-active effector T cells or under-active suppressor T cells) can perpetuate inflammation. Because of these and other proposed mechanisms associated with inflammatory-mediated ►carcinogenesis, many potential targets for therapeutic intervention exist.

Current treatment strategies for high cancer risk, ►reactive species overload diseases (Table 2) are frequently aimed at treating or preventing the cause of inflammation.

Although these strategies have led to some progress in combating reactive species overload diseases and associated cancers, exposure often occurs again after eradication, treatment to eradicate the cause fails, or the treatment has long-term side effects. Therefore, the identification of molecules and pathways involved in chronic inflammation and cancer is critical to the design of agents that may help in preventing the progression

Inflammation. Table 1 The evidence linking chronic inflammation to disease

Disease	Evidence
Cardiovascular disease (CVD)	• ►Aspirin reduces ►C-reactive protein levels which is a predictor of cardiovascular disease
	• Anti-inflammatory drugs reduce risk of CVD
	• High inflammatory load is associated with increased CVD risk
	• Induced chronic inflammation in animals increases CVD
	• Genetically knocking out pro-inflammatory molecules (►cytokines) decreases animal CVD
Cancer	• Chronic inflammation in specific human tissues increases risk of cancer in that tissue (Table 2)
	• ►Anti-inflammatory drugs reduce the risk of cancer
	• Inflammatory load in serum is associated with high risk of cancer
	• Low level of antioxidant enzymes in cancer patients
	• Induced chronic inflammation in animals increases cancer in the area where chronic inflammation occurs
Diabetes	• ►Diabetes patients have a high inflammatory load
	• Risk of diabetes increases with a specific serum inflammatory profile
	• Animal models of diabetes have a high inflammatory load
Alzheimer Disease (AD)	• High inflammatory load in AD
	• Anti-inflammatory drugs reduce risk of AD
	• Inducing brain inflammation in animals leads to AD

Inflammation. Table 2 Examples of high cancer risk, reactive species overload diseases

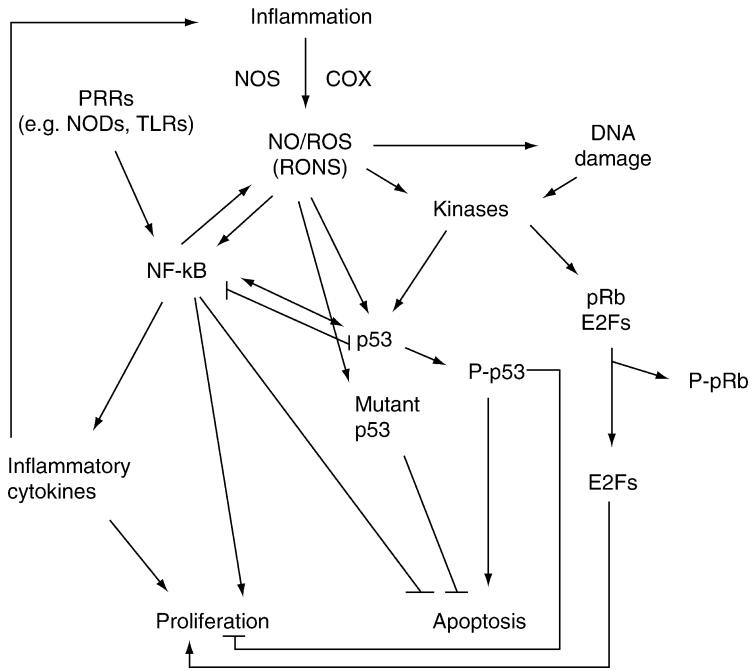
[b]Evidence suggests that obesity is associated with chronic inflammation and an increased risk of colon, breast, endometrium, kidney, esophagus, pancreas, liver, gallbladder, stomach.

of reactive species overload disease and cancer associated with disease progression (Fig. 1).

There are many specific and general mediators of these targets that have strong potential to be used as chemo-preventive agents in inflammation-driven cancer. Successful applications include the use of ►tumor necrosis factor-α (TNF-α) inhibitors (monoclonal antibodies) for inflammatory bowel disease and ►interferon-α (IFN-α) for hepatitis. More general medicines that have consistently been found to inhibit many diseases associated with chronic inflammation (cancer, CVD, diabetes) are non-steroidal anti-inflammatory drugs (NSAIDs), such as ►acetylsalicylic acid (ASA). A derivative, 5-ASA, has been used with remarkable success in ameliorating high colon cancer risk inflammatory bowel disease. The mechanisms of 5-ASA are not fully understood, but it is a weak ►COX inhibitor, it activates apoptosis, inhibits proliferation and ►NF-κB, scavenges ►RONS, and inhibits RON-associated base damage.

To this end, there are many natural food and herbal products that target multiple players in the inflammatory cascade. These include red wine (resveratrol), raw fruits and vegetables, and fiber. Many others, such as ►green tea, ►curcumin, ginkgo biloba (►gingko tree), ►ginseng, ►grape seed extract, and garlic have anti-inflammatory properties.

It is unclear which agents will be better in inhibiting inflammatory-mediated carcinogenesis: those acting ubiquitously against inflammatory pathways (e.g. 5-ASA) or specific inhibitors of key inflammatory molecules and pathways (e.g. NF-κB antisense). Perhaps advances in our knowledge of factors that selectively control RNA expression (e.g. through the use of microRNAs and small modulatory RNAs) and their ability to bind a broad spectrum of distinct mRNAs will advance our therapeutic potential for reactive species overload diseases and associated cancers. Although these would equate to a multi-targeted biological "smart-bomb," a better understanding of the efficacy of these molecules in an inflammatory microenvironment is warranted. Multi-targeting might also be accomplished by combination treatment strategies. Future studies should also be aimed at identifying new key molecular targets, molecular signatures in inflammation and intermediate ►biomarkers of inflammatory-mediated



Inflammation. Figure 1 Some key players involved in the inflammation-to-cancer sequence. PRR, pattern recognition receptors; TLR, toll-like receptors; NOD, nuclear binding oligomerization domain; NF-kB, nuclear factor-kappa B; NO, nitric oxide; ROS, reactive oxygen species; RONS, reactive nitrogen and oxygen species; NOS, nitric oxide synthase; COX, cyclooxygenase; E2F, E2 promoter binding factor.

carcinogenesis. The latter, combined with identifying polymorphisms in key inflammatory genes, will help identify specific populations at risk for free radical-driven cancers and provide insight into individuals sensitive or resistant to anti-inflammatory treatment.

Finally, understanding the mechanisms by which key cancer genes and proteins are altered in reactive species overload diseases will provide important insight into the protection against cancer associated with reactive species overload (Fig. 1). ►p53 is mutated in ►ulcerative colitis and ►hemochromatosis. The p53 pathway is also activated in ulcerative colitis (a type of ►inflammatory bowel disease). Other cancer pathway molecules such as ►hypoxia inducible factor-alpha (HIF-1α), ►signal transducer and activator of transcription (STAT)1, STAT3, ►heme-oxygenase-1, ►poly (ADP-ribose) polymerase (PARP), ►extracellular matrix molecules (►integrins), and ►cyclin D1 and cyclin E are up-regulated during free radical stress. Although the specific consequences of this up-regulation are not fully understood, targeting these molecules holds promise for future research into ►chemoprevention in reactive species overload diseases. Inhibiting PARP has been shown to ameliorate experimental colitis; inhibiting integrins improves ►crohn disease and ►ulcerative colitis; germline p53 disruption inhibits helicobacter-induced pre-malignant lesions and invasive ►gastric carcinoma; and ►myc induces free radical stress, and disables a ►p53-mediated ►DNA damage response, implicating p-53 ►Inflammatory Response and Immunity as a potential target for treatment chronic inflammation and associated cancers. To this end, it is also clear that emphasis should be placed on examining the influence of promising drugs in patients with high cancer risk, reactive species overload diseases in prospective randomized control trials. Only then will we know the true value of targeting inflammation and affected cancer pathways for chemoprevention.

Inflammatory Response and Immunity

Ilan Vaknin, Michal Baniyash
The Lautenberg Center for General and Tumor Immunology, The Hebrew University-Hadassah Medical School, Jerusalem, Israel

Definition

►Inflammation is the first response of the immune system to infection or irritation, and may also be elicited by tissue damage due to an uncontrolled/abnormal growth of self-cells. Various immune system cells and their secreted mediators and products are actively involved in this response. Inflammation is characterized by the following quintet of symptoms: redness, heat, swelling, pain, and dysfunction of the organs involved. The inflammatory response could be acute or chronic.

Characteristics

An Overview of Inflammation

The immune system is composed of a large variety of cells and soluble mediators that interact in a complex and dynamic network to ensure protection against foreign pathogens and elimination of infected tissue or abnormally growing autologous tumor cells. The immune system is divided into two arms, ►innate immunity and ►adaptive immunity, both participating in the generation of acute and chronic inflammation. Acute inflammation is a short-lasting (several days) immunological process that is mediated by activation of innate and adaptive immune cells. In most cases, this response is beneficial to the host as it results in clearance of invading pathogens. Following acute inflammation, the antigenic/pathogenic stimulus is eliminated; immune cells are no longer triggered, and thus, return to their quiescent state. An acute response could be also induced under sterile conditions, in response to tissue damage. Such a response is accompanied by a multifactorial network of chemical signals that initiate and maintain a host response, designed to "heal" the afflicted tissue. This involves activation and directed migration of leukocytes (neutrophils, basophils, monocytes and eosinophils) from the circulation to sites of damage. These cells, while clearing the damaged tissue, secrete ►chemotactic factors that guide various cells such as ►macrophages to the site of tissue injury. There, they engulf the damaged tissue constituents and help activate the adaptive immune system. Mast cells are also important in acute inflammation due to their release of stored and newly synthesized inflammatory mediators, such as histamine, ►cytokines and ►proteases.

In contrast, chronic inflammation is an inflammatory response of prolonged duration (weeks, months, or even indefinite) whose extended time course is provoked by persistence of the initiating stimulus. Chronic inflammation may develop either as the progression of acute inflammation, if the original stimulus persists, or after repeated episodes of acute inflammation. Chronic inflammation may be local or systemic, caused by spreading of inflammatory cells and mediators to the entire body via the blood stream and the lymphatic system. In a variety of pathologies such as autoimmune diseases, chronic infections and cancer that are characterized by the development of chronic inflammation, local and/or systemic ►immunosuppression accompanied by ►opportunistic infections was reported. Immunosuppression observed under chronic inflammatory conditions is evident both in the adaptive and innate immune systems, as T lymphocytes (►T-cell Response) and natural killer (NK) cells (►Activated Natural Killer Cells), respectively, become dysfunctional. This phenomenon is associated with reduced ►ζ chain expression by both cell types, and was shown to be induced by ►myeloid suppressor cells (MSCs). The ζ chain is part of key functional receptors in the immune system; the ►T cell antigen receptor (TCR) and NK killing receptors (NKP30, NKP46 and CD16).

An Overview of Cancer

The multiple factors leading to malignant transformation (oncogenic process) involve mutations in somatic cells and subsequent alterations of morphology and growth characteristics, ultimately resulting in transformation, local invasion, and metastasis. Genes controlling cell growth, DNA repair, and programmed cell death (apoptosis) are prime targets for the oncogenic process. DNA alterations are irreversible and can persist almost indefinitely in otherwise normal tissue until the exposure of cells to chemical irritants such as phorbol esters, factors released at the site of wounding, partial organ resection, hormones or chronic irritation provide the "final hit" leading to abnormal cell growth. A prerequisite for the survival and expansion of cancer cells is the development of strategies for escaping immune system surveillance. The term "cancer immuno-editing" represents a dynamic process comprised of three phases: elimination, equilibrium, and escape. Elimination represents the classical concept of immuno-surveillance against cancer, in which the immune system recognizes and eliminates tumor cells. Equilibrium describes the period of immune-mediated latency after incomplete tumor destruction during the elimination phase, and escape refers to the final outgrowth of tumor cells following their release from the immunological restraints of the equilibrium phase. Tumor growth, characterized by the abnormal expansion of modified self-cells within a normal tissue site, leads to

destruction of surrounding tissue. In addition, the inner part of an overgrowing tumor often becomes necrotic due to inefficient ►angiogenesis, resulting in poor tumor perfusion and cell death. In the course of cell death and tissue necrosis, a sterile inflammatory response ensues, aimed at clearing the dead cells and injured tissue. However, if the tumor persists, with continuing tissue destruction, chronic inflammation develops.

Interrelationship Between Inflammation and Cancer

The link between inflammation and cancer promotion was first observed in the nineteenth century, but only in recent years has it become a generally accepted phenomenon. Epidemiological studies showed that chronic infection and inflammation are two of the most important epigenetic and environmental factors contributing to tumorigenesis and tumor progression. Inflammatory mediators generally contribute significantly to the process of transformation by inducing DNA damage, activating oncogenes, or inducing loss of anti-oncogenic activity. For example, various ►reactive oxygen species (ROS) produced in inflamed tissues (►Oxidative Stress), whose main role is to attack invading infectious agents and foreign elements could cause injury to host cells and induce ►DNA damage and mutations, when produced at excessive levels.

Innate immune cells also contribute to cancer promotion through paracrine regulation of intracellular pathways, in which factors secreted by specific immune cells (cytokines, such as TNFα and IL1β) or released from damaged tissue (necrotic, apoptotic) in the tumor microenvironment, affect other cells in their surroundings via the corresponding ►cytokine receptors and ►Toll-like receptors (TLRs), respectively. Components of invading pathogens, such as gram negative bacterial LPS and double-stranded viral RNA are also involved in the activation of TLR-expressing cells. In the cells affected through paracrine pathways (normal immune cells, pre-cancerous, or cancerous cells), intricate processes are initiated involving changes in intracellular signal transduction pathways that, in turn, modulate expression of transcription factors, such the ►nuclear factor-kappa B (NFκB). This factor is responsible for the transcription of a specific array of genes (pro-inflammatory cytokines, chemokines, growth factors, and anti-apoptotic factors) that are involved in cancer promotion and support of growth. TLRs are among the major activators of NF-κB transcription factor and are the front-line receptors that trigger inflammation in response to microbial infection or tissue damage, aiming at clearing the pathogen or affected tissue. However, the activation of NF-κB through TLR stimulation in local chronic inflammation may also serve as an initiating event, enabling the infected or damaged cells to evolve into cancer cells, with uncontrolled proliferation. Moreover, since NF-κB activity leads to inhibition of programmed cell death (apoptosis), which can eliminate defective cells, NF-κB activation could contribute both to cancer survival/development and resistance of the tumor to drug and radiation therapies that induce cell elimination by apoptosis.

Another mechanism by which chronic inflammation could support transformation is the promotion of angiogenesis by angiogenic factors such as ►vascular endothelial growth factor (VEGF) and ►matrix metalloproteinases (MMPs). These factors are released from the surrounding inflamed tissue or by the transformed cells, thereby contributing to tumor progression. Increased expression of ►cyclooxygenase-2 (COX-2) and subsequent ►prostaglandin production has been shown to promote tumor growth, ►invasion, and ►angiogenesis, and to suppress the anti-tumor ►adaptive immune response. In addition, a variety of secreted inflammatory cytokines and chemokines (e.g ►IL-2, CXCL13) have also been shown to support cell growth and ►migration. Such factors not only confer survival and growth advantages to susceptible tumor cells, but also affect the degree of local cell invasion, thereby enabling metastastatic spread. Inflammatory characteristics are observed in most pre-cancerous and cancerous tissues, as reflected by the migration of innate immune cells into the affected target tissue and the release of specific inflammatory mediators.

Thus, in the course of preexisting chronic inflammatory diseases such as ►autoimmune disease and chronic infections, activated innate and adaptive immune cells could form an optimal environment to induce and support arising tumors by the release of DNA damaging compounds and/or potent pro-survival molecules, both involved in the initiation of neoplastic cell development and enabling uncontrolled cell growth. In addition, in the course of chronic inflammation, immunosuppression of both the innate (NK cells) and the adaptive (T cells and B cells) immune responses is induced, resulting in unresponsiveness of the immune system to abnormal growing tumors. Thus, the initial step of an inflammatory response aimed at destroying pathogens or abnormal self-cells, often leads to a chronic inflammatory response, which in many cases is associated with immunosuppression and cancer. In parallel, activation of innate and adaptive immune cells also elicits anti-tumor responses through T and NK cell-mediated toxicity, antibody-dependent cell-mediated cytotoxicity, and antibody-induced complement-mediated lysis. During the anti-tumor immune response (►Tumor Suppression), an inflammatory tumor microenvironment is generated. When the inflammatory response becomes chronic due to the inefficient clearance of the tumor or due to damage of the surrounding tissue, the proinflammatory factors both support tumor growth and lead to immunosuppression of ►NK cells, ►T cells

and ►B cells, resulting in tumor overgrowth and ►metastasis. Moreover, immunosuppression in tumor-bearing host could also result from the increased frequency of regulatory T cells (Treg) (►T Regulatory Cells) within the peripheral blood of cancer-bearing hosts and/or among tumor-infiltrating lymphocytes and tumor-draining lymph nodes. Tregs are able to inhibit proliferation and cytokine production by effector T cells, as well as NK cell-mediated cytotoxicity. Thus, the delicate balance between anti-tumor immune response, activity of Tregs and developing inflammation, dictates whether a tumor will develop or be rejected (Fig. 1).

Examples of Inflammation-Associated Cancers

Over the past 15 years, numerous cancers have been shown to be associated with local chronic inflammation. Studies on liver cancer suggested that patients with persistent ►hepatitis B virus infections experience inflammation and scarring of liver tissue and thus, are at increased risk of liver cancer (Hepatocellular Carcinoma). Other disease characterized by chronic inflammation including ulcers caused by the bacterium, ►*Helicobacter pylori*, and an immune disorder known as ►ulcerative colitis, predispose patients to ►stomach cancer and ►colon cancer. ►Cervical carcinoma, which is caused by infection with ►human papilloma virus (HPV) has also been suggested to have an inflammatory component. Innate immune cells, most prominently ►mast cells and ►granulocytes, infiltrate the pre-malignant epithelial tissues, followed by the recruitment of macrophages as the cancer develops further. Innate immune cells drive a chronic inflammatory process that promotes overgrowth of epithelial cells, tissue remodeling and angiogenesis, eventually followed by invasive carcinoma. Other examples include the associations between chronic bronchitis and ►lung cancer, schistosomiasis (►schistosomas, gematobition) and ►bladder cancer, chronic pancreatitis and pancreatic cancer, and chronic cholecystitis and gall bladder cancer. In addition, epidemiologic studies showed that regular intake of ►non-steroidal anti-inflammatory drugs (NSAIDs) lowers the risk of developing several types of cancers. However, in the absence of specific risk factors, NSAIDs are not recommended at present, since many of these drugs, such as ►aspirin, can cause severe gastrointestinal complications.

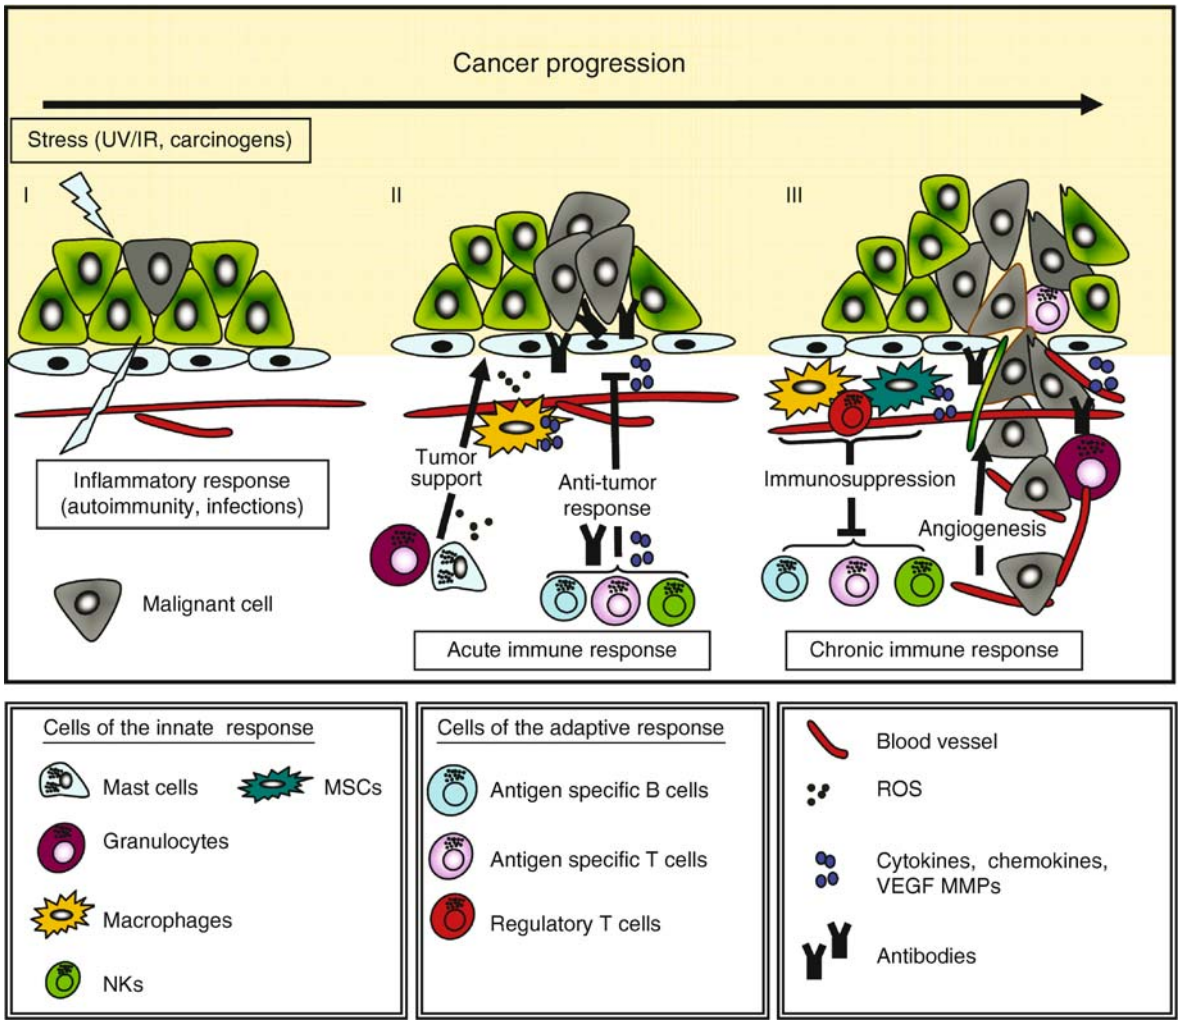
Based on the knowledge accumulated during the last two decade it has been estimated that inflammation contributes to the development of at least 15% of all cancers.

Immunotherapeutic Strategies Against Cancer

One of the major goals in cancer immunotherapy research is to sever the destructive association between chronic inflammation and cancer. Cancer ►immunotherapy is a developing strategy to buttress the immune system, augmenting its ability to destroy tumors. The identification of tumor-associated antigens recognized by the effector arm of the adaptive immune system has opened new approaches towards cancer immunotherapy. However, chronic inflammation predisposes individuals to cancer, and cancer promotes chronic inflammation; under both scenarios, chronic inflammation-dependent immunosuppression is evident in association with tumor overgrowth. Therefore, to attain an effective therapy, anti-inflammatory and immunotherapeutic approaches will have to be combined, as described bellow.

Currently, several forms of immunotherapy are being tested against cancer; these approaches fall into two categories, which are not mutually exclusive: The first category involves a passive attack against the tumor. This could be mediated by administration of ►monoclonal antibodies (Mabs) that are directed against various tumor associated antigens (when the tumor is immunogenic) and are conjugated to anti-cancer drugs, toxins, radioisotopes, or other biologic response modifiers (►Cytokine Receptor as Target for Immunotherapy and Immunotoxin Therapy). When the antibodies bind to the antigen-bearing cells, they deliver their cytotoxic load with the aim of tumor destruction. Mabs could also be directed against specific inflammatory compounds that support tumor growth and suppress the immune system. Thus, by using specific Mabs, inflammatory compounds(s) could be neutralized, leading to inhibition of tumor expansion and recovery of the immune response (►Monoclonal Antibody Therapy). In addition, immune response modifiers such as interferons could potentially stimulate immune system cells to act against the tumor. Other strategies that use anti-angiogenic agents, ►MMP-inhibitors and anti-inflammatory drugs have also met with some success.

The second category is based on inducing an active attack against the tumor. This could be mediated by several approaches: (i) ►Dendritic cell (DCs)-dependent immunotherapy that uses the patient's own DCs, which initiate the adaptive immune response through their role in antigen presentation. DCs isolated from patient blood are loaded with tumor proteins (antigens) and injected back into the patient to initiate a potent specific immune response directed against the cancer cells. This approach is currently being investigated in phase IIb/III clinical trials for ►brain cancer and ►prostate cancer. (ii) T cell immunotherapy that utilizes T cells activated against defined tumor antigens or genetically modified to express ►TCRs that recognize a specific tumor antigen, aiming at efficiently destroying the tumor. In both cases, T cells are taken from the cancer patient, selected or modified, and then injected back to the same patient where they are expected to



Inflammatory Response and Immunity. Figure 1 The interrelationship between cancer and inflammation. (I) Tumors can emerge as a result of stress or excessive inflammatory responses during an infection or autoimmune response. (II) Tumor/pathogen or self antigens presented by DCs in secondary lymphoid organs activate adaptive immune responses, resulting in both tumor-promoting and tumor-inhibitory effects. Activated innate and adaptive immune cells promote tumor development by the release of potent pro-survival molecules and/or DNA damaging ROS, both involved in the initiation of neoplastic cell development. In contrast, activation of cells of the innate and adaptive immune system also elicits anti-tumor responses through T and NK-cell-mediated toxicity, antibody-dependent cell-mediated cytotoxicity, and antibody-induced complement-mediated lysis. The delicate balance between the two types of responses will dictate whether tumor will develop or be rejected. (III) Inflammatory cells induce/support tissue remodeling and angiogenesis. Tissues suffering from chronic inflammation exhibit an increased risk of tumor development due to immunosuppression of NK, T and B cells mediated by MSCs and Treg.

mediate their cytotoxic function. (iii) Vaccine-based immunotherapy that depends upon the administration of a tumor specific component (antigen), or inactivated cancer cells to elicit an immune response (►Cancer Vaccines). For vaccine use, the immunogen is injected into the body in a formulation that targets and activates local dendritic cells, which in turn activate the endogenous immune system.

While each of these active immunotherapeutic approaches have shown some promise, the general success rates are limited due to some critical obstacles. One of the obstacles to effective active tumor immunotherapy is the chronic inflammation and associated immunosuppression that often characterizes developing tumors. Moreover, the increased ►Treg activity in tumor-bearing host may be associated with

poor immune responses to tumor antigens and contribute to immune dysfunction. It is expected that the immunosuppressive environment generated in tumor-bearing hosts due to chronic inflammatory response and the increased Treg activity will limit the response to an active immunotherapy, affecting the endogenous host immune system, as well as suppressing any newly administered immune modulators. Immunotherapy using immune response modifiers such as ►cytokines and ►chemokines also requires a responsive immune system, and therefore these approaches are expected to fail under an immunosuppressive environment. Moreover, it is possible that adjuvants (►Adjuvant Therapy) used to enhance a patient's immune response to weakly immunogenic tumors or pathogenic antigens might even result in activation of chronic inflammation and thus negatively affect the specific anti-tumor response. With this knowledge in mind, the timing of tumor active immuno-therapy must be reassessed to maximize its efficacy. It is therefore critical to develop monitoring strategies that may allow the identification of patients who could benefit from cancer immunotherapies and that would help optimize the timing of these interventions. One such strategy could be based upon measurements of ζ chain expression levels in the host's peripheral T cells. Such measurements could serve as a prognostic marker for the appearance of a chronic inflammation-dependent immunosuppressive environment (associated with ζ chain down-regulation) and for measuring the impact of the disease on the patient's immune system. Accordingly, anti-inflammatory drugs are expected to neutralize the immunosuppressive environment and thus could serve a dual purpose; they could be used in cancer prevention or as a treatment to optimize the patient's response to immunotherapy. In addition, strategies that deplete Tregs, inhibit their function or block their migration, rather than enhance or restore their function, are likely to be advantageous for cancer immunotherapy.

Definition

Inflammatory bowel diseases (IBDs) result from the combined effect, of environmental factors, e.g., endogenous microbial flora, smoking status, and on the other hand of inherited variants of disease susceptibility genes conferring risk of disease and disease phenotype genes influencing response to treatment and location of disease. Their interaction leads to an aberrant, relapsing, and/or sustained intestinal inflammatory and immune response. Two major forms of IBD, ►ulcerative colitis (UC) and ►Crohn disease (CD), have been described. Ulcerative colitis is characterized by a diffuse but usually superficial inflammation of the colonic mucosa, affecting the rectum and extending proximally along a variable length of the colon. Crohn disease is a chronic granulomatous inflammation which may affect the entire gastrointestinal tract with predominant locations at the terminal ileum and/or colon. By contrast to UC, inflammatory lesions in CD patients are often distributed heterogeneously as a patchwork of inflamed and noninflamed fields of intestinal mucosa.

Both UC and CD patients are at higher risk of cancer development, in particular colorectal cancer (CRC) in UC and colonic CD, and less frequently small bowel carcinoma in CD patients. In addition, lymphoma may occur in UC and CD patients as the consequence of the treatment with immunosuppressive agents.

Characteristics

IBD-Associated CRC

The single-layered intestinal epithelium at the interface between the mucosa and the luminal content is an essential actor of the interactions between immunoregulatory factors of the mucosa and environmental factors, mainly enteric bacteria, while being disrupted during ulceration and then repaired at remission. Epithelial repair requires tightly regulated changes in cell functions including increased cell proliferation, apoptosis, and migration. So far, disease susceptibility genes have been described in CD (NOD2/CARD15; IL-23R) and several loci are suspected in CD (OCTN1 and OCTN2 on chromosome 5) and UC (e.g., the IBD2 locus on chromosome 12). NOD2/CARD15 is

expressed both in lymphocytes and in Paneth epithelial cells, and controls the ►NFκB pathway involved in the immune response.

IBDs represent one of the higher risk conditions for CRC (►colon cancer), together with the genetically linked situations of hereditary nonpolyposis CRC (►Lynch syndrome) and ►familial adenomatous polyposis (►APC gene in familial adenomatous polyposis). In contrast to sporadic ►CRC that almost invariably outgrow the mucosa as polyps, morphological changes linked to IBD-associated cancers are highly heterogeneous with flat lesions or elevated lesions generally referred to as dysplasia-associated lesions or masses (DALM). Flat lesions and sometimes raised lesions look like gross abnormalities encountered in IBD, making them difficult to identify during endoscopic examination. Also remarkable is the multicentricity of neoplasms in IBD-associated cancers, reflecting "►field cancerization" unlike sporadic cancers.

Genetic alterations (►chromosome instability and/or ►microsatellite instability) and epigenetic changes (modifications of the ►methylation patterns of DNA) are similar in IBD-associated cancers and in sporadic CRC, suggesting that chronic inflammation plays a causative role for the increased risk of cancer development. However the sequence of the genetic alterations differs. Whereas the loss of function of APC (►APC/β-catenin pathway) and ►p53 are respectively considered as an early event linked to cancer initiation and a late event associated to the adenoma-to-carcinoma transition in sporadic cases, p53 chromosomal loss or mutations are already present in early stages in IBD-associated cancers, while APC alterations occurring later. Moreover, chromosomal rearrangements involving the p53-encoding locus can even be detected at a significant rate (∼20%) in nondysplastic colitis epithelium. The relatively late involvement of APC alterations in IBD-associated cancers may explain the flat morphology of the dysplasia, in contrast to the polyp-like lesions found in sporadic cancers.

Chronic inflammation produces a favorable ►microenvironment for cancer development. It contains elevated amounts of proinflammatory cytokines like ►TNFα and ►interleukins-1β, ►interleukin-4, ►interleukin-6, and ►interleukin-8 secreted by infiltrating mononuclear cells, ►prostaglandins resulting from the induction of ►COX-2 in epithelial cells and in fibroblasts of the lamina propria as well as reactive oxygen and nitrogen species (►RONS). These oxyradicals target a large number of molecules including DNA, RNA, proteins and lipids. In particular, they induce the formation of ►adducts to DNA, generating point mutations in genes like p53 and in ►CpG islands involved in DNA methylation. The mutagenic effect of RONS is thought to participate in the neoplastic transformation of epithelial cells. Moreover, the environment rich in proinflammatory cytokines and prostaglandins prevents apoptosis and sustains cell proliferation, which further facilitates tumor progression. This provides a way to explain how chronic inflammation results in malignant transformation and tumor growth from the resident intestinal epithelium. In addition, recent experimental data obtained in mouse models of gastric cancer linked to ►*Helicobacter pylori*-induced gastritis suggest that chronic inflammation may locally recruit circulating bone marrow stem cells that would further evolve into carcinomas. Although this observation requires confirmation and further studies to investigate if it can be extrapolated to human IBD-associated cancers, it opens new avenues in the field of chronic inflammation-induced cancers.

Compared with the general population, patients with long-standing IBD are at an increased risk for the development of CRC. Early data estimated the risk of CRC at 0.5% per year after 10 years of UC diagnosis, and 1% per year after 20 years. More recently, a meta-analysis reviewing 116 studies representing a total of 54,478 UC patients, determined the cumulative risk of CRC to be 2% at 10 years after diagnosis of UC, 8% at 20 years, and 18% at 30 years. Patients with Crohn's colitis, like UC patients, also are at greater risk (approximately at the same level) for CRC than the general population.

Strategies aimed at preventing IBD-associated CRC need to define the most relevant target population at risk. Several factors have been identified among which duration of colitis (>8 years) and anatomical extent of colitis [standardized incidence ratio (SIR): 1.7, 95% confidence interval (CI): 0.8–8.2 for proctitis; SIR: 2.8, 95% CI: 1.6–4.4 for left-sided colitis; SIR: 14.8, 95% CI: 11.4–19.9 for pancolitis], appear as the most important and reproducible from one study to another. Other factors like family history of sporadic CRC (twofold higher risk), young age of IBD onset, backwash ileitis, and more recently degree of inflammation in the involved colon, are also considered as risk factors. Finally, association to primary sclerosing cholangitis (PSC), although rare (approximately 2–7.5% of IBD patients, more frequently in UC patients), appears as a very important risk factor and has conducted to a specific surveillance strategy in these particular patients since the cumulative incidence of patients presenting both UC and PSC was 33% at 20 years in a population-based Swedish study. By contrast, a few other factors have been suggested to be protective, such as folate, ursodeoxycholic acid, and with the highest degree of evidence, treatment by 5-aminosalicylates (5-ASA).

The goal of surveillance strategies (i.e., surveillance ►colonoscopy) is to detect by using a safe and effective intervention, neoplasia at a curable stage (ideally as ►dysplasia). Dysplasia is defined as an unequivocally

but noninvasive (intraepithelial) neoplasia. Despite the theory proposing that IBD-associated colon carcinogenesis progresses from no dysplasia to indefinite dysplasia, and then to low grade dysplasia (LGD), high grade dysplasia (HGD), and finally invasive cancer, in reality, this conceptually useful model is by no means absolute. This uncertainty thrives on much of the controversy regarding treatment of LGD. Except in the case of dysplasia in DALM which usually is not too difficult to detect for experienced practitioners, macroscopic identification of flat dysplastic lesions (either of low or high grade) appears particularly difficult during conventional colonoscopic surveillance. Nevertheless, this early identification represents a major challenge, as the presence of HGD in the colonic epithelium is associated with concurrent, macroscopically-undetectable CRC in 42–67% of patients (in case of colectomy performed shortly after HGD diagnosis at colonoscopy), and to the finding of a synchronous CRC in up to 19% of patients in case of LGD diagnosis at colonoscopy.

Considering these facts, recommendations for colonoscopic surveillance have been established. Screening ►colonoscopy should be initiated after 8–10 years of disease, including biopsies of each macroscopic lesion (with additional biopsies in the flat mucosa surrounding the DALM) and random biopsies of the macroscopically normal appearing mucosa (four-quadrant biopsies every 10 cm, some authors considering sampling every 5 cm in the rectosigmoid). In patients with PSC, colonoscopic surveillance should begin at the time of diagnosis of PSC and IBD. At each surveillance examination, the whole colon should be examined, and biopsies processed in separate clearly identified specimen containers. Recently, new endoscopic technologies have been suggested to improve the diagnosis yield of early malignancy, especially dysplasia detection in flat mucosa. This is the case for high-resolution and magnifying endoscopy, chromo (or dye) endoscopy based on vital staining with methylene blue or contrast staining with indigo carmine, magnifying chromoendoscopy, narrow-band imaging, and confocal laser endoscopy. These techniques open a new world of endoscopic imaging, but their usefulness for improving dysplasia detection in IBD needs to be carefully assessed before they will be recommended in routine screening. Nevertheless, the most recent data indicate that dye endoscopy with indigo carmine or methylene blue have to be seriously considered in daily practice.

If no dysplasia is identified, surveillance examination is recommended every 1–3 years (some authors proposing a subsequent screening at 3 years between 8 and 20 years of disease, every 2 years between 20 and 30 years, and each year after 30 years of IBD diagnosis), except for IBD patients with concurrent PSC (surveillance colonoscopy recommended each year regardless of IBD duration). In case of LGD detection in flat mucosa, sample analysis by a second pathologist is recommended, and if LGD is confirmed, a surveillance colonoscopy should be performed 6 months later, although some authors propose to perform colectomy. Detection of HGD in flat mucosa indicates colectomy. Decision after LGD or HGD diagnosis in a polypoid lesion should integrate additional information: (i) if the polypoid lesion has been completely removed and no dysplasia has been detected elsewhere in the colon, a control colonoscopy with multiple random biopsies is recommended 6 months later; (ii) if this is not the case (incomplete removal and/or dysplasia detected in other biopsies), colectomy is indicated.

A number of studies have examined the chemopreventive potential of several medications. Until now, 5-ASA have been the most thoroughly studied as potential IBD-associated CRC preventing agents. In fact, at least in vitro but also in some in vivo studies, 5-ASA have been shown to inhibit cell proliferation, to induce apoptosis, to act as potent RONS scavengers, and to enhance DNA repair. Although the optimal dose and duration of 5-ASA treatment to prevent IBD-associated CRC are unclear, data suggest that chronic systemic administration of 5-ASA at a dose of at least 1.2 g/day is the most likely to prevent IBD-associated CRC development.

Small Bowel Adenocarcinoma in Crohn Disease

The incidence of small bowel adenocarcinoma (SBA) is very low. In CD, its relative risk has been reported to be up to 50 times higher than in the general population. In a recent study, its cumulative risk in patients with ileal CD has been estimated to be 0.2% after 10 years of disease, and 2.2% after 20 years, with a median age at diagnosis of 47 years compared with 68 years for patients with SBA de novo. It occurs in a median time of 15 years after CD diagnosis arising from long-standing inflammation. CD-associated SBA is difficult to diagnose and causes premature mortality in early-onset CD patients.

Cancer risk Associated to Immunosuppressive Therapy in IBD

In the recent years, the efficacy of "classical" immunosuppressive drugs [azathioprine, 6-mercaptopurine (6-MP), or methotrexate], as well as that of biological agents (i.e., in current practice, anti-TNFα antibodies such as infliximab) led to their increased use in IBD. This emphasizes the question of their potential carcinogenic effects, in particular considering the risk of lymphoma which has been previously reported in patients treated by azathioprine or 6-MP after renal or hepatic transplantation (although used at doses even higher than in IBD). This question is not definitively resolved, probably due to the heterogeneity

of the different studies, in particular when considering population-based cohorts on one hand and hospital-based cohorts on the other hand. Discrepancies may result from varying factors such as cohort sizes, duration and dosage of treatment, and/or duration of follow-up. Nevertheless, some general statements based on the most relevant studies in the field can be suggested: (i) the absolute risk of ►lymphoma in the general IBD population appears extremely low, (ii) lymphoma risk in IBD patients treated by azathioprine or 6-MP is probably not more than two- to fourfold increased, although the respective responsibility of treatment and underlying disease has to be more accurately investigated, (iii) particular attention needs to be brought to the ►Epstein–Barr virus positive lymphoma risk in azathioprine or 6-MP treated IBD patients, and finally, (iv) the issue of lymphoma risk is likely to become more relevant in the future with the growing number of immunosuppressive and/or biological agents being used (or tested) in IBD, sometimes concurrently. This has been emphasized by the report of hepatosplenic T-cell lymphomas in young petients treated both with purine analogs and infliximab.

Inflammatory Cytokines

Definition

Small proteins that are released primarily by activated immune cells. Inflammatory ►cytokines act by binding to specific cell membrane receptors that are involved in amplification of inflammatory reactions. Cytokines can act in an ►autocrine, ►paracrine, or ►endocrine manner. ►Interleukins, ►lymphokines, and ►interferons are all cytokines.

►Aging and Cancer
►Inflammation

Inflammatory Response

Definition

Refers to the ability of the innate component of the immune system to react to an infection or irritation. An orchestrated cellular and biochemical response of the body to injury or infection. Can be classified into acute and chronic. The response consists of cellular and exudative components. These involve the movement of white cells and fluid containing proteins and antibodies into the tissue to repair damage and inactivate a foreign agent.

Initiation

Definition

In carcinogenesis, the first step in skin carcinogenesis is initiation, which is a reversible process during genetic mutations, gene activation or inactivation occur. Examples of initiation are mutations in the ►RAS oncogene or inactivation of the p53 tumor suppressor gene

►Skin Carcinogenesis

Initiation and Promotion

Definition

In carcinogenesis, the process in which an animal is treated with a low dose of a carcinogen, then this is followed once per week with a tumor promoter, and leads to a synergistic induction of tumors.

►Chemical Carcinogenesis
►Tumor Promotion

Initiation Codon

Definition

The mRNA sequence AUG, which specifies methionine, the first amino acid used in the ►translation process.

Initiation Factors

Definition

Initiation of ►translation involves the small subunit of the ribosome binding to 5′ end of mRNA with the help of initiation factors.

Initiator Caspases

Definition

Are activated independent of cleavage by dimerization of the monomeric zymogen at multiprotein complexes, to which the ►caspase zymogens are recruited by virtue of their N-terminal recruitment domain. In the extrinsinc pathway, ►caspase-8 and -10 are activated at the death-inducing signaling complex (►DISC), whereas in the intrinsinc pathway, the site of activation of caspase-9 is the ►apoptosome.

INK4a

Takehiko Kamijo
Division of Biochemistry, Chiba Cancer Center Research Institute, Chuoh-ku, Chiba, Japan

Definition

Inhibitor of ►cyclin-dependent kinase 4; proteins are cyclin-dependent kinase inhibitors that block the action of cyclin-dependent kinase to induce cell cycle arrest. The four INK4 family proteins (p16INK4a, p15INK4b, p18INK4c, and p19INK4d) contain four tandemly repeated ►ankyrin motifs and have similar biochemical phenotypes. The p16INK4a is an alternative reading frame product (►ARF) of p16INK4a and p15INK4b, which are coded at the human chromosome 9p21 region. The significance of the p16INK4a, ARF, and p15INK4b in tumorigenesis are confirmed by the high frequency of the genetic and epigenetic modifications of these genes in tumor samples.

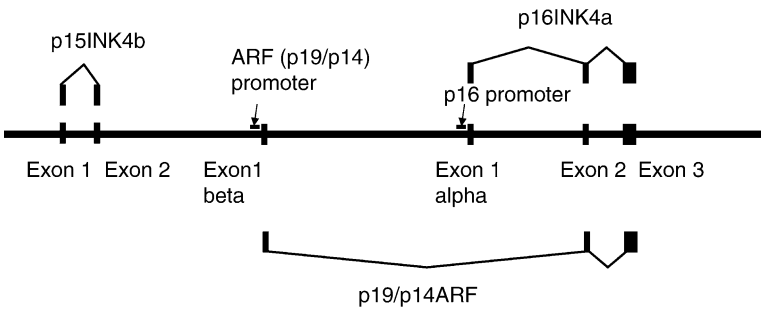
Characteristics

Structure of *INK4b/ARF/INK4a* Locus and Molecular Functions of INK4s/ARF

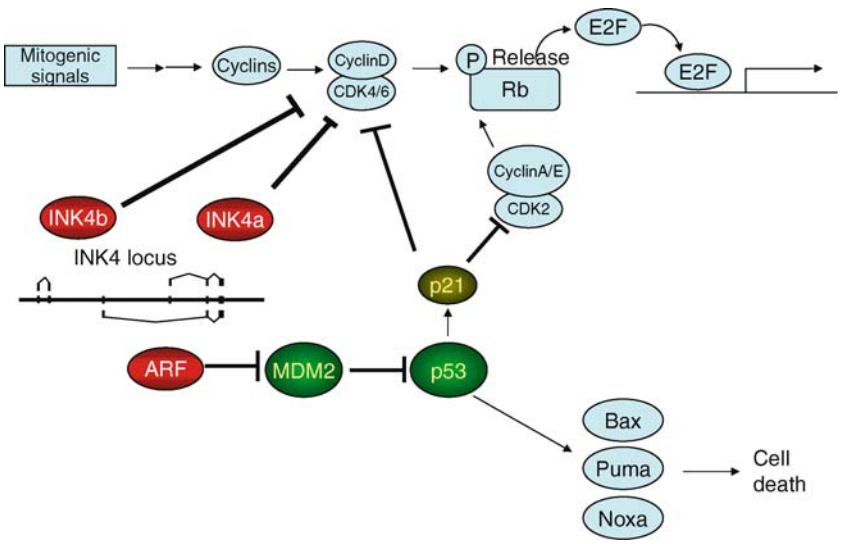
The *INK4b/ARF/INK4a* gene locus is located at the human chromosome 9p21 region. Chromosome region 9p21 is involved in chromosomal ►inversions, ►translocations, and ►deletions in a variety of malignant cell lines and primary tumor samples, including those from ►melanoma, pancreatic adenocarcinoma, ►non-small cell lung cancer, ►leukemia, and ►glioma. These findings indicate that 9p21 contains a tumor suppressor locus that may be involved in the tumorigenesis of several tumor types. In a region of less than 40 kb of the human genome, three related genes, *p15INK4b*, *ARF*, and *p16IN4a* are encoded (Fig. 1).

The INK4 class of ►cell cycle inhibitors, p15INK4b and p16IN4a are homologous inhibitors of the cyclin-dependent kinases, CDK4 and CDK6, which inactivate the tumor suppressor RB1 protein via phosphorylation of its c-terminal region. The association of the INK4 proteins to CDK4/CDK6 induces an allosteric modification that abrogates the binding of these kinases to ►cyclin D, resulting in inhibition of CDK4/6-mediated phosphorylation of retinoblastoma family member proteins. Hence, the existence of p15INK4b and p16INK4a maintains retinoblastoma family member proteins in a hypophosphorylation state, which facilitates binding of ►E2F to induce a cell cycle arrest in the G1 phase (Fig. 2).

ARF and *INK4a* have different first exons, exon 1 beta and exon 1 alpha, respectively. These first exons are spliced to a common second exon and third exon. Although exons 2 and 3 are shared by p16INK4a and ARF, these proteins are encoded in alternative reading frames. The predicted 132-amino acid p14 (ARF) is shorter than the corresponding mouse protein, p19(ARF), and the 2 proteins share only 50% identity. However, both proteins have the ability to elicit a p53 response, manifest in the increased expression of both p21Cip1/Waf1 and several p53-downstream proapoptotic molecules, resulting in a distinctive cell cycle arrest in the G1/G2M phases and apoptotic cell death, respectively. Previous reports showed that ARF binds to ►MDM2 and promotes the segregation of MDM2 in the nucleolus. This interaction is mediated by the exon



INK4a. Figure 1 Genomic stucture of INK4b/ARF/INK4a locus. Residing on chromosome 9p21 in humans and chromosome 4 in mice, the *INK4b/ARF/INK4a* locus includes 2 different genes. *INK4b* and *INK4a/ARF*. *INF4a* and *ARF*, which have the independent exon1 alpha and exon1 beta, respectively, and common exon2/exon3, encode different proteins via an alternative splicing mechanism. In this commentary, p14ARF (murine p19ARF) will be referred to as ARF.



INK4a. Figure 2 Physiological roles of INK4s/ARF. Mitogenic signals activated cyclin D-dependent kinases, which phosphorylate RB and RB family proteins to facilitate entry into S phase. Consititutive oncogenic signals can activate the INK4a/ARF locus. By antagonizing the activity of cyclin D-dependent kinases, p16INK4a and p15INK4b prevent entry into S phase. MDM2 is a p53-inducible gene that normally acts to terminate the p53 response. The ARF protein inhibits MDM2 to induce p53, leading either to p53-dependent apotosis or to induction of the CDK inhibitor p21Cip1, inhibition of cyclinE/Cdk2, and RB-dependent cell cycle arrest.

1-beta-encoded N-terminal domain of ARF and a C-terminal region of MDM2.

Roles in Tumorigenesis

Human cancers frequently harbor ►homozygous deletions of the *INK4b/ARF/INK4a* locus that abrogate expression of all p15INK4b/ARF/p16IN4a. In a large number of human cancers, specific somatic loss of p16INK4a, through ►point mutation or small deletion, has been reported. Furthermore, silencing of p16INK4a through promoter methylation is reported at high frequency in numerous types of human malignancies. Therefore, p16INK4a is an important tumor suppressor in human malignancies.

In the case of p15INK4b, specific ►epigenetic gene silencing by ►hypermethylation of the p15INK4b promoter has been described in ►hematological malignancies including ►leukemia and ►myelodysplastic syndrome and rare cases of glial tumors. In myelodysplastic syndrome, hypermethylation of p15INK4b has been reported in the absence of p16INK4a hypermethylation. p15INK4b seems to be an important tumor suppressor in specific lineages of human malignancies, e.g., hematological malignancies.

Selective inactivation of ARF, in the absence of additive loss of p16INK4a and p15INK4b, has only been reported in a small number of human malignancies, e.g., familial melanoma/astrocytoma patients and somatic ARF-specific mutations and promoter methylations in colon carcinoma patients. Therefore, it seems that ARF cooperates with p16INK4a and p15INK4b in tumorigenesis of human malignancies and their relative and combinational importance in any given tumor types remains to be elucidated.

Roles in Senescence

Cellular ►senescence is a fundamental cellular program that is activated in various situations of stress and acts to prevent further cell proliferation. Senescence induced by extrinsic stress, such as DNA damage or oncogene activation, occurs relatively rapidly, in a matter of days. As a population of cells is propagated in culture, cells are exposed to various extrinsic and intrinsic stresses and the population gradually stops dividing. These findings have led to a distinction between "stress-induced premature senescence," a term referring to rapid senescence triggered by extrinsic stress, and "replicative senescence," a term referring to senescence that occurs following extended proliferation, presumably triggered by various stresses. Cellular senescence is thought to play an important role in tumor suppression and contribute to organismal aging. In fact, the two definitive tumor suppressor pathways, ARF/MDM2/p53 and p16INK4a/Rb, have been shown to play critical roles in the induction of cellular senescence. In tissue culture of primary cells, the accumulation of one or more *INK4b/ARF/INK4a* locus genes can eventually lead to cell cycle arrest through the mechanisms presented in Fig. 2. The cellular senescence is cancelled by downregulation of expression caused by gene deletion or epigenetic regulation, by inactivation of the gene products by mutation, or by cellular resistance to those cell cycle inhibitors. Considering the significance of the *INK4b/ARF/INK4a* locus genes in the cellular life span, p16INK4a plays a central role in senescence in human cells, whereas ARF assumes a prominent role in mouse cells. For mice, p19ARF and p16INK4a both accumulate significantly after passage, but spontaneous escape from senescence occurs through deletion of INK4/ARF or p53 mutation in wild type MEFs. Consistent with this, ARF-null MEFs do not have proliferation failure, but p16INK4a-null and p15INK4b-null MEFs indicate limited proliferation. Whereas senescence generally occurs in the setting of increased expression of p16INK4a, but not ARF, and enforced Ras–Raf pathway activation also appears to induce only p16INK4a, along with senescence in cultured human cells. Furthermore, only p16INK4a induction has been reported with human aging, although ARF expression studies in human aging have not been reported.

Activators of the p15INK4b/ARF/p16INK4a

Ras–Raf–p38MAPK Pathway

Involvement of the Ras signaling pathway into the regulation of the *INK4b/ARF/INK4a* locus-encoded genes has been reported in detail. Expression of oncogenic Ras in primary human or rodent cells results in a permanent G1 arrest of the cell cycle. The arrest induced by ►Ras is accompanied by accumulation of ►p53 and ►p16, and is phenotypically indistinguishable from cellular senescence. Constitutive activation of MAPKK induces both p53 and p16, and is required for Ras-induced senescence of normal human fibroblasts. Ras signaling pathway activation can result in phosphorylation and enhance binding of ►Ets transcription factor to the p16INK4a promoter. These results imply that premature senescence via *INK4b/ARF/INK4a* locus activation acts as a fail-safe mechanism to limit the transforming potential of excessive Ras mitogenic signaling. Whereas oncogenic Ras induces ARF transcription in MEFs, similar effects have not been detected in human cells. One of the key molecules activated by Ras signaling pathway is DMP1, which binds directly to the p19ARF promoter region. Although there are putative binding sites in the human ARF promoter region, the effects of DMP1 have not been demonstrated in human cells.

E2F

The ►E2F transcriptional factors are divided into two groups; (i) transcriptional activating E2F1, E2F2, and E2F3; (ii) transcriptional repressing E2F4, E2F5, and E2F6. Several E2Fs have been detected at the endogeneous ARF promoter by chromatin immunoprecipitation assay and directly activate ARF transcription without association with DP-1. Since ARF transcription is not regulated by a cell cycle-dependent manner, the unphysiological level of E2F seems to be required to induce ARF. Some studies described the inverse correlation between pRb status and p16INK4a expression in tumor cells. However, the physiological relation remains to be elucidated in terms of the relationship between the pRb/E2Fs and INK4 pathway.

Myc Oncogene

►Myc Oncogene has the ability to control p16INK4a transcription in human cells. Myc protein binds to the promoter and first intron of human p16INK4a, which is in line with the reports that Myc upregulates p16INK4a transcription in human cells. However, Myc has little effect on p16INK4a expression in mouse cells.

In mouse cells, establishment of MEFs as continuously growing cell lines is normally accompanied

by loss of the p53 or p19ARF, which act in a common biochemical pathway. Myc rapidly activates ARF and p53 transcription in MEFs and triggers replicative crisis by inducing apoptosis. MEFs that survive Myc overexpression sustain p53 mutation or ARF loss during the process of establishment and become immortal. These observations are consistent with the cooperation of -Myc and Bmi1 in mouse lymphomagenesis, suggesting that the ARF/p53 pathway is a physiological safeguard system against Myc-induced oncogenic stresses.

Suppressors of p15INK4b/ARF/p16INK4a

AML1/ETO

►AML1/ETO chimeric protein results from the t(8;21) translocation in human ►acute myelogenous leukemia. AML1/ETO can bind directly to the ARF promoter regions as well as the POZ/BTB domain protein, ZBT7B. The translocation seems to convert the wild-type AML1 from being an inducer of ARF to a repressor.

p53

One of the most important tumor suppressors, *p53* seems to have a significant role in ARF transcriptional suppression because ARF is generally transcriptionally upregulated in ►p53-inactivated cells. However, the mechanism of the transcriptional repression of ARF by reintroduction of wild-type p53 into p53-null cells remains to be elucidated.

►*Polycomb* Proteins

Traditionally, cancer has been viewed as a genetic disease that is driven by the sequential acquisition of mutations, leading to the constitutive activation of proto-oncogenes and loss of function of tumor suppressor genes. However, it has become increasingly evident that tumor development also involves "►epigenetic changes" patterns of altered gene expression that are mediated by mechanisms that do not affect the primary DNA sequences. The *INK4b/ARF/INK4a* region is known to be regulated by not only the genetic alteration but also by epigenetic modifications.

►Polycomb group (PcG) genes were first identified in Drosophila as a group of genes required for maintenance of stable repression of Hox cluster genes during development. There are increasing lines of evidence that PcG proteins themselves affect cellular proliferation and replicative senescence. Targeted disruption of Bmi1, Mel18, rae28, and M33, which are members of the class II PcG complex, leads to proliferation defects in hematopoietic stem cells and mouse embryo fibroblasts, indicating that inactivation of these PcGs results in cell proliferation failure. Replicative senescence of MEFs derived from Bmi1-, M33-, and Phc2-null mice has been shown to be mediated by derepression of the central mediators of senescence signals, p19ARF and p16INK4a, which are encoded by the *INK4b/ARF/INK4a* region. The molecular mechanism underlying the transcriptional regulation of these genes by mammalian PcG complexes, however, has not yet been appropriately addressed except for physical interactions of Bmi1 and Phc2 gene products to *ARF* and *INK4a* genomic regions.

Future Directions

The significant role of the INK4b/ARF/INK4a region and its products, p15INK4b/p14(p19)ARF/p16INK4a, in suppression of tumor development is well-established. However, regulatory mechanisms controlling these genes remain to be elucidated. The entire genomic region, which covers the genomic region from p15INK4b to p16INK4a (Fig. 1), is frequently deleted in a wide spectrum of tumors as described previously. However, the precise molecular mechanism of the biallelic gene deletion has not been addressed previously. In mouse MEFs, c-Myc induces the accumulation of p19ARF/p53 at the transcriptional level and has a significant proportion of the cells undergo apoptosis, whereas Myc-induced cell cycle accelerators, e.g., cyclin E, cyclin A, and CDC25A, are upregulated. In the face of Myc overexpression, there was a strong selective advantage for cells that sustained p53 mutations or the INK4b/ARF/INK4a deletion, and once such variants emerged, these soon predominated and were able to continuously proliferate. These results suggest that genes encoded by the *INK4b/ARF/INK4a* region are deleted by oncogene-derived stress-induced unknown molecular mechanisms and the safe guard machineries-broken cells continuously proliferate by oncogene-derived stimulations. The precise mechanisms of the locus deletion should be addressed to understand the immortalization and malignant transformation of normal cells.

A particularly important recent finding with regard to the *INK4b/ARF/INK4a* regulation was a coordination of transcription at the locus and DNA replication. The coordination between silencing of the locus and DNA replication was reported. In detail, a DNA replication origin in close proximity to the locus appears to transcriptionally repress p15INK4b/ARF/p16INK4a expression in a CDC6-dependent manner. Obviously, these findings suggest a novel molecular connection between DNA replication and p15INK4b/ARF/p16INK4a transcription. Further analysis of the cooperation between this CDC6-dependent regulation and other known regulatory mechanisms of this locus, both of genetic and epigenetic regulations, seems to be worthwhile.

Innate Immune System

Definition

Comprises the cells and mechanisms that defend the host from infection by other organisms or tumor growth, in an immediate and non-specific manner. The recognition of tumor cells by ►natural killer cells is part of an innate immune response and does not depend upon the adaptive immune system; it does not confer long-lasting or protective immunity to the host.

►Toll-Like Receptors
►Adaptive Immunity

Innate Immunity

Definition

Used together with the term ►adaptive immunity to describe the two functional parts of the immune system. The original strict separation of the two parts of the immune system is currently reconsidered because a deep and intimate interconnection and cross-talk between the humoral and cellular parts of innate and adaptive immunity does exist. Nevertheless, innate immunity describes the immediate (within hours to a few days) reaction of the immune system in response to a given challenge. Typically involves, but is not limited to, (antimicrobial) phagocytes and substances, natural killer cells, certain cytokines and the complement system. Innate immune cells recognize common molecular patterns on infectious agents, cells infected with viruses, and transformed cells. Cells of the innate immune response include ►macrophages, ►dendritic cells, mast cells, neutrophils, eosinophils, natural killer (NK) cells, natural killer T (NKT) cells and γδ cells, and the cytokines they secrete on activation, as well as antimicrobicides that are made by specialized cells and tissues.

Inositol Lipids

Matilda Katan
CRC Centre for Cell and Molecular Biology, Institute of Cancer Research, London, UK

Definition

Are a class of ►phospholipids where inositol is the polar headgroup. The simplest inositol phospholipid is ►phosphatidylinositol (ptdlus). The inositol moiety can be phosphorylated at several different positions giving rise to a number of other molecular species.

Characteristics

Among different inositol lipids, the importance in ►transmembrane signaling and regulation of cell functions are best documented for PtdIns (4,5)P2 and PtdIns (3,4,5)P3. There are several ways in which these low abundance inositol lipids (less that 1% of membrane phospholipids) could provide a signaling link or fulfill other roles in different cellular processes.

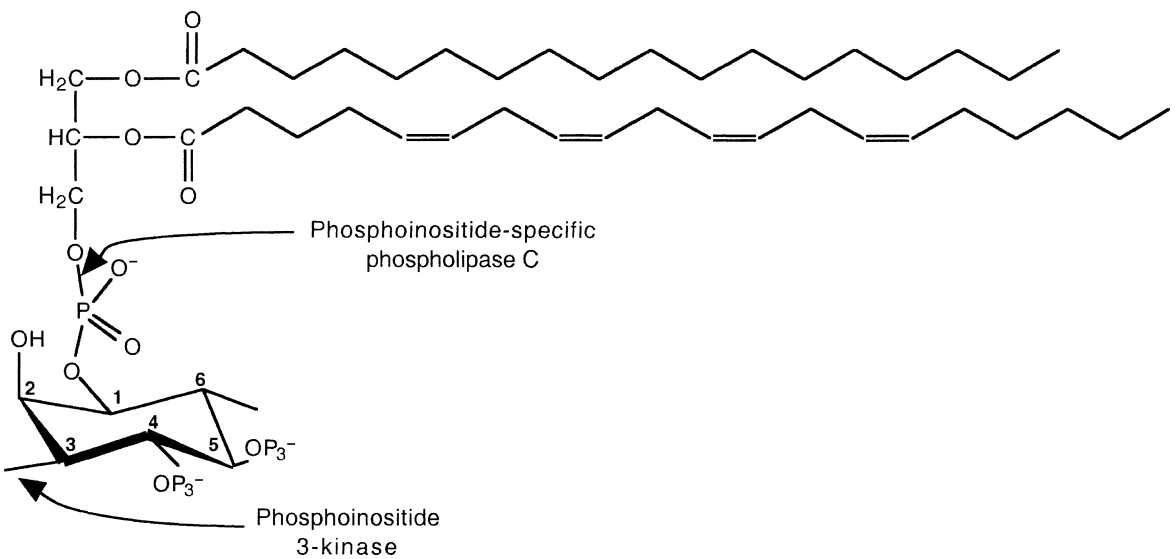
Hydrolysis of PtdIns(4,5)P2 to Generate Second Messenger Molecules

Hydrolysis of PtdIns(4,5)P2 occurs in response to a large number of extracellular signals and generates two ►second messenger molecules, inositol (1,4,5) trisphosphate (Ins(1,4,5)P3) and diacylglycerol (DAG) molecules. The reaction is catalyzed by phosphoinositide-specific ►phospholipase C (PI-PLC) (Fig. 1). There are several ►isoforms of this enzymes (PLCβ, PLCγ, PLCδ, and PLCε) linked to and activated by different cellular receptors. For example, PLCγ is regulated through tyrosine kinase receptors such as receptors for ►epidermal growth factor, ►fibroblast growth factor, and ►platelet-derived growth factor, while PLCε could be a novel target for ►RAS proteins.

The second messengers generated from PtdIns(4,5)P2 interact with specific intracellular targets and, in turn, cause their activation. Ins(1,4,5)P3 binds to specific receptors in the endoplasmic reticulum causing a release of calcium from this intracellular store into the cytoplasm. Membrane resident diacylglycerol (DAG) is required for activation of several isoforms of ►protein kinase C (PKC). These second messengers act as a common component in different signaling pathways, contributing to diverse cellular responses. Specificity of the pathways is provided at the level of a receptor and downstream components (e.g., calcium-regulated proteins and PKC substrates) present in a specific cell type or state.

Binding of PtdIns(4,5)P2 to Specific Proteins

In addition to its role as a precursor of Ins(1,4,5)P3 and DAG, PtdIns(4,5)P2 has emerged as a highly versatile signaling molecule in its own right. These other functions are mediated through direct binding of PtdIns(4,5)P2



Inositol Lipids. Figure 1 Structure of phosphatidylinositol (4,5) bisphosphate (PtdIns (4,5)P2) shows a typical phospholipid containing an inositol ring as a headgroup. The positions on the inositol ring are designated 1–6 and two phosphate groups are present at positions 4 and 5. Phosphatidylinositol (3,4,5) trisphosphate (PtdIns(3,4,5)P3) is generated in a phosphorylation reaction; the third phosphate group is added at position 3 of the inositol ring. Hydrolysis of PtdIns (4,5)P2 at the C-bond separates the hydrophobic part that contains two lipid chains, from water-soluble inositol that contains phosphates at the positions 1, 4, and 5.

to specific protein targets, and include fundamental processes in membrane trafficking and plasma membrane-cytoskeleton linkages. Many proteins that regulate actin cytoskeleton (e.g., gelsolin and profilin) and proteins involved in ►endocytosis (e.g., dynamin and AP-2 adaptor) bind PtdIns(4,5)P2. The binding involves different positively charged protein surfaces that in some proteins are present within the modular ►pleckstrin homology domain (PH-domain). The result of the binding could be a direct change in the protein function or a regulated membrane targeting. For example, the PH domain of phospholipase Cδ1 associates with membranes of many cell types, but after PLC stimulation and the reduction in PtdIns (4,5)P2 concentrations, it translocates to the cytoplasm. Concentration of PtdIns(4,5)P2 is not only regulated at the level of hydrolysis by PLC but also through regulation of several types of inositol lipid kinases and phosphatases.

Generation of PtdIns(3,4,5)P3 and Other 3-Phosphorylated Inositol Lipids and Their Binding to Specific Intracellular Targets

Inositol lipids phosphorylated at the 3-position of the inositol ring (PtdIns(3)P, PtdIns(3,4)P2, PtdIns (3,5)P2, and PtdIns(3,4,5)P3) are generated by ►phosphoinositide 3-kinase (►PI3-K). PI3-Ks are grouped into three classes on the bases of their structure and according to the inositol lipid they preferentially utilize as a substrate. For example, the class I PI3-Ks are receptor-regulated ►signal-transducer proteins that preferentially phosphorylate PtdIns(4,5)P2 in vivo and generate PtdIns(3,4,5)P3 (Fig. 1). Several target proteins for PtdIns(3,4,5)P3 and PtdIns(3,4)P2 have been described and they include protein kinases such as PKB/Akt, PDK1, and Btk. In the case of PKB/Akt, the direct binding to the PH domain (with high affinity and specificity toward 3-phosphorylated inositol lipids compared with more abundant PtdIns(4,5)P2) results in both membrane targeting and conformational changes that lead to phosphorylation and activation of this protein kinase. Activated kinases, in turn, phosphorylate and regulate downstream targets and thus propagate the signal. The 3-phosphorylated inositol lipids also participate in diverse cellular functions including cell survival, proliferation, migration, and vesicle budding. In addition to regulation of PI3-K, the levels of PtdIns (3,4,5)P3 are also controlled by a 3-phosphatase.

Clinical Relevance

There is considerable experimental evidence that the key enzymes involved in the control of inositol lipids, ►PI-PLC and ►PI3-K, play an important role in processes critical for tumor development and spreading, including cell proliferation, survival, and ►migration. However, oncogenic or constitutively active mutants of either PI-PLC or PI3-K have not yet been isolated from human tumors. In the case of PI3-K, an oncogenic form (v-p3k) of the class I PI3-K has been isolated from a chicken ►retrovirus that causes ►hemangiosarcomas. Another oncogenic form of class I PI3-K (mutation in the regulatory subunit) has been isolated from transformed murine lymphoid cells. Nonetheless, the importance of the control of inositol lipid levels in human cancers have been emphasized by the findings that the tumor suppressor protein ►PTEN is a 3-phosphatase that dephosphorylates PtdIns(3,4,5)P3. The *PTEN* gene is deleted or mutated in a wide variety of human cancers. Many human tumors have also been found to express increased levels of PI-PLC or PI3-K.

The role of a signaling protein in generation and spreading of a malignant tumor is not limited to its function as an oncogene or a tumor suppressor gene. For example, it has been documented that the activation of PLCγ is a rate limiting step in breast and prostate tumors that overexpress growth factor receptors. This type of tumor is associated with a poor prognosis. PLCγ seems to be required for cell migration but not for proliferation, and the motility and invasiveness of cancer cells are strongly inhibited either after treatment with a chemical PLC inhibitor (U73 122) or in the presence of molecular inhibitors.

Insertional Mutagenesis

Definition

Is the alteration of a gene by integration of a foreign, often exogenous, DNA sequence. For instance, a virus DNA can integrate into a gene or in the vicinity of a gene.

►Retroviral Insertional Mutagenesis

Insulator

Definition

Is a DNA sequence that acts as a barrier to the influence of neighboring genes.

►CCCTC-Binding Factor

Insulin

Definition

Is a natural hormone produced in the pancreas by the beta cells of the ►islets of Langerhans; controls the level of the sugar glucose in the blood. Insulin permits cells to use glucose for energy. Cells cannot utilize glucose without insulin. People who are Type 1 ►Diabetes mellitus must use manufactured insulin, usually in an injectable form, to replace the natural insulin that is no longer produced by their body (for instance as the result of beta-cell degeneration). People with Type 2 sometimes need to use insulin when their cells become too resistant to the insulin that they produce naturally and when oral medications are no longer working.

Insulin Receptor

Antonio Brunetti
Department of Experimental and Clinical Medicine "G. Salvatore", University of Catanzaro "Magna Græcia", Catanzaro, Italy

Definition

IR; Is a phylogenetically ancient ►receptor tyrosine kinase protein embedded in the ►plasma membrane of virtually all cells. When the peptide hormone ►insulin binds to the IR, the receptor becomes activated and induces a cascade of intracellular events that will lead to several metabolic and growth promoting effects.

Characteristics

The IR belongs to the tyrosine kinase growth factor receptor family and functions as an enzyme that transfers phosphate groups from ►ATP to tyrosine

residues on intracellular target proteins. The IR consists of two identical extracellular alpha subunits (130 kDa) that house insulin binding domains, and two transmembrane beta subunits (95 kDa) that contain ligand-activated tyrosine kinase activity in their intracellular domains (Fig. 1). When insulin binds to the alpha subunits, the receptor is first activated by tyrosine autophosphorylation, and then the IR tyrosine kinase phosphorylates various intracellular effector molecules (e.g. ►IRS proteins and ►Shc) which in turn alters their activity, thereby generating a biological response. The IR exists as two splice variant isoforms: the IR-B isoform that is responsible for signaling metabolic responses involved mainly in the regulation of glucose uptake and metabolism by increasing glucose transporter (►Glut4) molecules on the plasma membrane of the insulin-responsive tissues muscle, liver, and fat, and the IR-A isoform that is capable of binding ►IGF-2 with high affinity and signals predominantly mitogenic responses. As a consequence of these cellular activities, abnormalities of IR expression and/or function can facilitate the development of several metabolic and neoplastic disorders in humans as well as in animal models.

Regulation

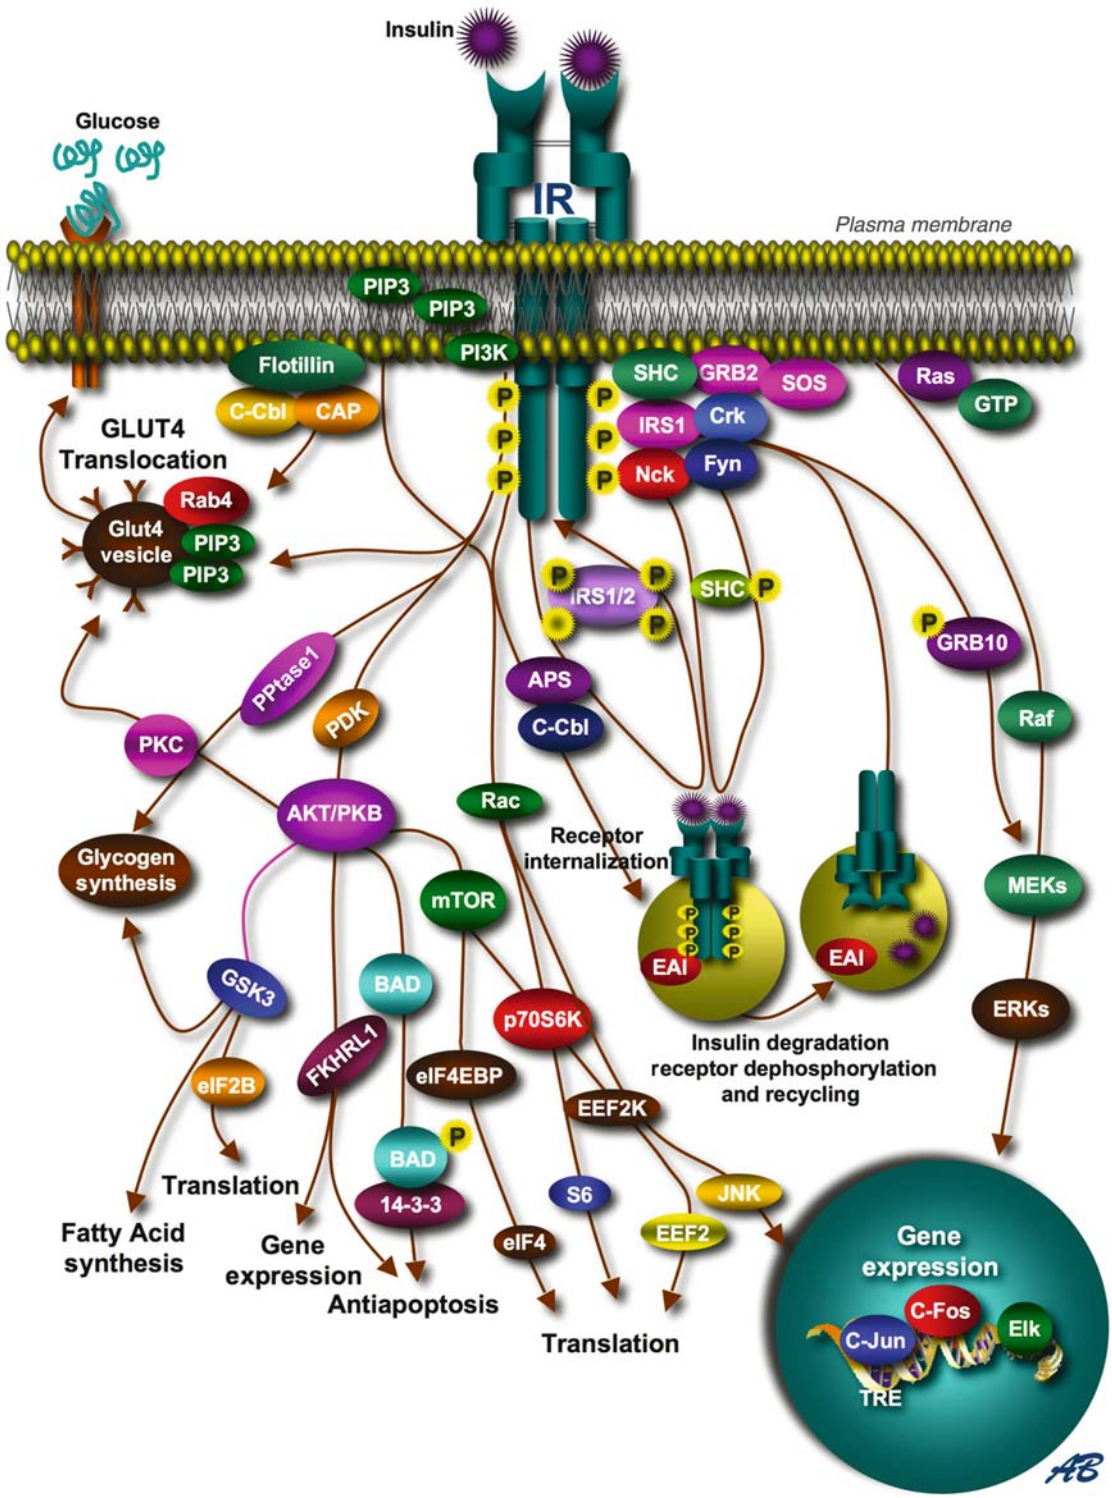
Gene expression in eukaryotic cells is controlled by nuclear regulatory proteins (*trans*-acting factors) that modulate the transcription of genes by binding to specific *cis*-acting transcriptional elements in the promoter of target genes. The IR gene promoter extends over 1,800 bases 5′ upstream from the IR gene ATG codon, contains a series of GGGCGG repeats that are putative binding sites for the mammalian transcription factor Sp1, and has neither a ►TATA box nor a CAAT box, reflecting the common features for the promoters of constitutively expressed genes (so-called housekeeping genes). Like other housekeeping promoters, the IR gene promoter confers a basal level of transcriptional activity common to all cells, whereas significantly higher transcriptional activity is induced in the muscle, liver, and fat, at which levels the IR has been shown to be under the regulation of hormones, metabolites, and differentiation. Promoters of genes that are activated in a tissue specific manner are often regulated by a combination of tissue specific and ubiquitous transcription factors, where the ubiquitous element facilitates or enhances the action of one or more tissue-specific transcription factors. The molecular mechanisms regulating IR gene expression are being elucidated and evidence has been provided showing that the architectural transcription factor ►HMGA1 is required for proper transcription of the IR gene in cells expressing IRs. HMGA1 acts on the IR gene promoter as an element necessary for the formation of a transcriptionally active multiprotein–DNA complex involving, in addition to the HMGA1 protein, the ubiquitously expressed transcription factor Sp1 and the CCAAT-enhancer binding protein beta (C/EBP-beta). By potentiating the recruitment and binding of Sp1 and C/EBP-beta to the IR promoter, HMGA1 greatly enhances the transcriptional activities of these factors in the context of the IR gene. Conversely, repression of HMGA1 function in cells and tissues adversely affects transactivation of the IR gene promoter by Sp1 and C/EBP-beta, and considerably reduces IR protein expression.

Clinical Relevance

The IR is of major importance in certain states of ►insulin resistance in humans, in which abnormalities of the receptor may lead to defective transmembrane signaling. In this respect, dysfunctional IR signaling is implicated in certain common dysmetabolic disorders, including ►obesity, type 1 and type 2 ►diabetes, the dysmetabolic syndrome X, and the polycystic ovary syndrome (PCOS). Also, clinical syndromes due to mutations in the IR gene have been identified in patients with genetic forms of severe insulin resistance (i.e. leprechaunism, type A insulin resistance, and the Rabson–Mendenhall syndrome). Many of these patients have point mutations in the coding sequence of the IR gene, leading to reduced or absent IR expression in target tissues. Recently, defects in IR gene regulation have been reported in individuals with insulin resistance and type 2 diabetes, in which the generation of IR mRNA was considerably impaired, although the IR genes were normal. In these individuals, cell-surface IRs were decreased and the expression of HMGA1 was markedly reduced.

Even though it is an open question whether IR plays a critical role in aging and longevity in mammals, disturbance of the neuronal IR seems to be of pathogenetic relevance in human Alzheimer's disease and depressive disorders, suggesting a neurotrophic role of IR in the brain. According to recent studies, IR in the brain begins to disappear early in Alzheimer's and continue to decline as the disease progresses. It has been shown that stimulation in the brain of a receptor that mediates insulin responses can halt or diminish the neurodegeneration of Alzheimer's disease. Also, a high prevalence of insulin resistance has been reported in patients with depression, and an increased risk of cognitive decline has been found in women with insulin-resistant PCOS.

A relation between IR and cancer has been established following the observation that overexpression of functional IRs can occur in human ►breast cancer and other epithelial tumors including ovarian and colon cancer, in which the IR may exert its oncogenic potential via abnormal stimulation of multiple cellular signaling cascades, enhancing growth factor-dependent proliferation and/or by directly affecting cell metabolism.



Insulin Receptor. Figure 1 In the absence of insulin, most of the IRs in the plasma membrane are in a non-tyrosine phosphorylated inactive state, and only a very small proportion of receptors are lightly phosphorylated and subjected to constitutive ►endocytosis and recycling. Upon binding of insulin, the IR undergoes autophosphorylation which enables the receptor to have a kinase activity and phosphorylates various cytoplasmic substrates, such as IRSs. From this point, signaling proceeds via a variety of signaling pathways (i.e. PI3K signaling pathway, Ras and MAP kinase cascade) that are responsible for the metabolic, growth-promoting and mitogenic effects of insulin.

An explanation for increased IR expression in epithelial tumors has been recently provided for several human breast cancers, in which overexpression of the transcription factor ►AP2-alpha accounts for increased IR expression in neoplastic breast tissue. In these cases, it has been demonstrated that transactivation of the IR gene by AP-2 alpha needs direct physical association of AP-2 with HMGA1 and Sp1, which represents a fundamental prerequisite for AP-2 alpha to activate IR gene transcription in neoplastic breast tissue. Epidemiological and clinical evidence points to a link between insulin resistant syndromes such as obesity and type 2 diabetes and cancer of the colon, liver, pancreas, breast and endometrium. The mechanistic link between insulin resistance and cancer is unknown, but constitutive activation of the tyrosine kinase activity of IR and related downstream signaling pathways by chronic sustained hyperinsulinemia (a hallmark of insulin resistance) in these clinical syndromes appears to have a role in the neoplastic transformation process.

Thus, the IR plays a major role in the pathophysiology of a wide range of metabolic, neurodegenerative and proliferative disorders in humans. Selective modulation of IR expression and/or function may represent a useful therapeutic strategy for these diseases. Also, measures to decrease insulin resistance in insulin resistant patients may offer a general approach to prevention of cancer in these predisposed individuals.

Insulin-like Growth Factors

Ruslan Novosyadlyy, Derek LeRoith
Division of Endocrinology, Diabetes and Bone Diseases, Departmant of Medicine, Mount Sinai School of Medicine, New York, NY, USA

Definition

The insulin-like growth factors (IGF-I and IGF-II) are structurally related molecules that play essential roles in the regulation of cell survival, growth, proliferation,

differentiation and metabolism. The IGF family is comprised of (i) ligands (IGF-I, IGF-II and insulin), (ii) six well characterized high affinity binding proteins (IGFBP-1 through -6), (iii) IGFBP proteases and (iv) cell surface receptors that mediate the biological functions of IGFs. These transmembrane receptors include the IGF-I receptor (IGF-IR), IGF-II/mannose 6-phosphate receptor (IGF-II/M6PR), ►insulin receptor (IR) and insulin receptor-related receptor (IRR). In many tumor cells the IGF-IR is often upregulated and/or hyperactivated. Furthermore, increased circulating IGF-I levels are considered a significant risk factor for the development of various types of cancers. Although the oncogenic role of IGFs (i.e. their ability to initiate ►carcinogenesis) is still under the debate, numerous lines of evidence suggest that these powerful growth factors enhance tumor growth and ►progression.

Characteristics

IGFs

The insulin-like growth factors (IGF-I and IGF-II) are ubiquitously expressed growth factors that are structurally related to insulin. However, in contrast to insulin and other peptide hormones, they are not stored within cells of a specific tissue but are produced by numerous cell types in the body and circulate in approximately 1,000-fold higher concentrations than most other known peptide hormones. These properties suggest more universal functions of the IGFs in the body compared to the more specific metabolic role of insulin. The IGFs are critical in a broad range of functions during pre- and postnatal life. In adult tissues, IGFs are important trophic factors that support normal differentiated functions of various tissues and prevent programmed cell death (►apoptosis). IGF-I is known as a major regulator of postnatal growth. Most of the circulating IGF-I is produced by the liver, although other tissues are capable of synthesizing this peptide locally. Thus, IGF-I has characteristics of both a circulating hormone and a tissue growth factor. In contrast to IGF-I, IGF-II plays a fundamental role in embryonic and fetal growth, whereas due to ►imprinting of the *Igf2* gene, its role in postnatal period of life is less important, especially in rodents.

IGF Receptors

Most of the actions of both IGF-I and IGF-II are mediated *via* the IGF-IR, which is expressed by virtually all cell types except adult hepatocytes. The IGF-IR and IR belong to the large family of ►receptor tyrosine kinases. The two receptors are structurally related and are composed of two α-subunits localized entirely extracellularly and two β-subunits spanning the membrane and localized primarily intracellularly. Both subunits are linked together by disulfide bonds. They assemble a $\alpha_2\beta_2$-configuration with ligand binding primarily mediated by the α-subunits, which form a binding pocket. Binding of the ligand to the α-subunit leads to conformational changes resulting in stimulation of the β-subunit intrinsic tyrosine kinase activity with subsequent multisite phosphorylation of the β-subunit. The current concept is that insulin and the IGFs act as bivalent ligands, both IGF-IR and IR are capable of binding insulin and IGF-I or -II, though each receptor binds its own ligand with a 100–1,000-fold higher affinity than the heterologous peptide. In cells expressing both receptor genes, hybrid insulin/IGF-I receptors can form. The hybrid receptors have ligand specificity profiles more comparable to the IGF-IR than to the IR since they bind IGF-I with an affinity similar to the IGF-IR, but insulin with a much lower affinity. Moreover, the IR is also responsible for some of the mitogenic actions of IGF-II. IGF-II is an agonist of the A isoform of the IR. This splice variant of the IR is expressed at high levels in fetal and neoplastic tissues. IRR and hybrid IR/IRR have not yet been extensively studied, and their ability to bind all the different insulin-like peptides as well as their biological significance remains unclear.

The IGF-II/M6PR is structurally distinct from the IGF-IR and is actually identical to the cation-independent mannose 6-phosphate receptor, which lacks tyrosine kinase activity and is not considered to have any role in IGF ►signal transduction. The IGF-II/M6PR functions as a scavenger receptor and is involved in uptake and degradation of IGF-II. The IGF-II/M6PR is strongly expressed during tissue differentiation and organogenesis, and high levels of the IGF-II/M6PR were found in fetal tissue, which decline in late gestation and in the early postnatal period due to genomic imprinting.

IGFBPs

Unlike insulin, the IGFs are present in the circulation and throughout the extracellular compartments almost entirely bound to a family of multifunctional, structurally related, high affinity IGF-binding proteins (IGFBPs), which can modulate biological effects of the IGFs. To date, six IGFBPs with high affinity have been cloned and sequenced. All share structural homology with each other and specifically bind the IGFs. They differ in molecular mass, binding affinities for the IGFs, posttranslational modifications such as phosphorylation and glycosylation as well as susceptibility to proteolysis. The IGFBPs act as carrier proteins in plasma, control the efflux of the IGFs from the vascular space, and prolong half-lives of the IGFs. They regulate metabolic clearance and tissue- and cell-specific localization of the IGFs thereby modulating

their biological actions in a negative or a positive manner. Finally, some IGFBPs also have intrinsic bioactivities that are independent of the IGFs (Fig. 1).

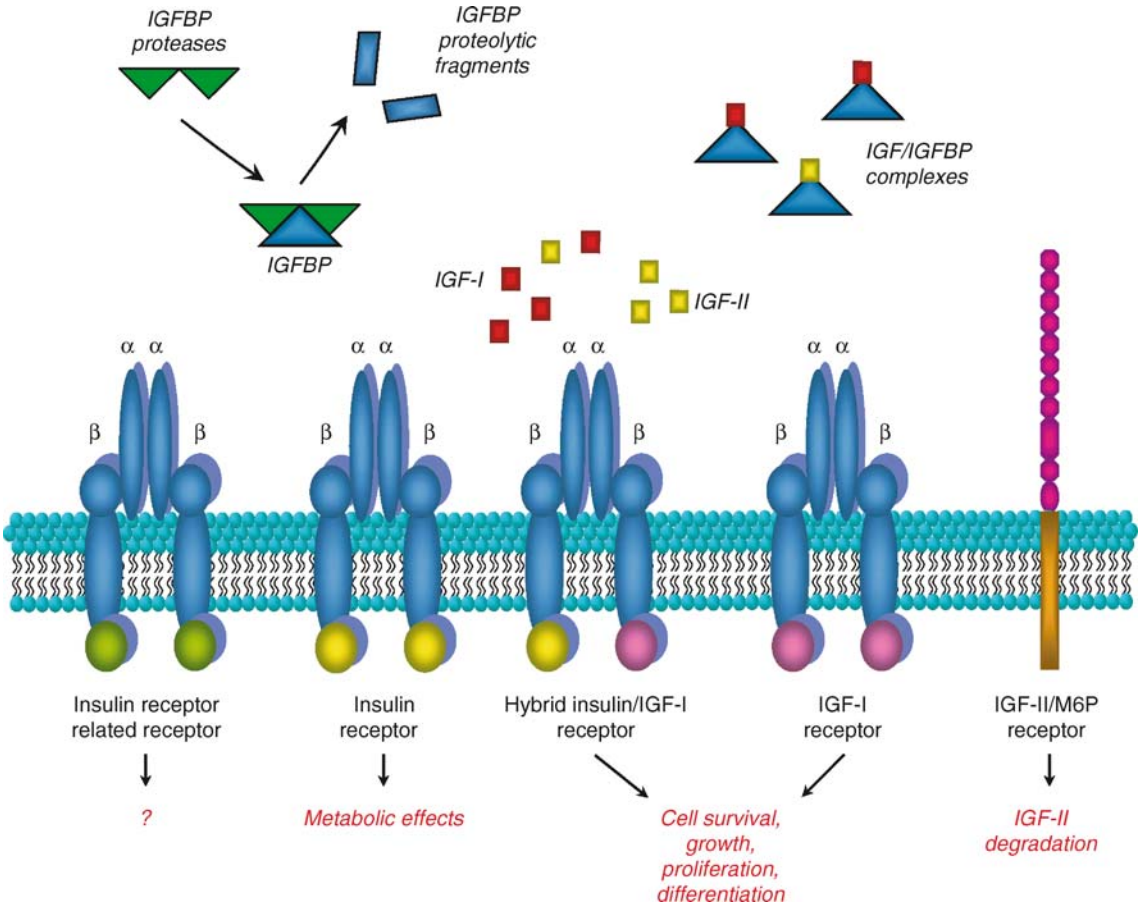
Mechanisms

The biological effects of IGFs are mainly mediated by the IGF-IR and two principal signaling pathways including ►mitogen-activated protein kinase (MAPK) pathway that plays a pivotal role in cell growth and proliferation, and ►phosphatidylinositol-triphosphate kinase (PI3K) pathway, which is mainly involved in mediating the metabolic, antiapoptotic and other more differentiated effects of IGF-I. Upon ligand binding and receptor autophosphorylation, the IGF-IR recruits and phosphorylates several adaptor proteins including ►Shc and members of the insulin receptor substrate (IRS) family of proteins. They bring together and coordinate the activity of other signaling intermediates, finally resulting in activation of the ►MAPK and PI3K pathways. Typically, the MAPK pathway is initiated by the recruitment of growth factor receptor bound 2 protein (Grb2) that *via* the guanine nucleotide exchange factor Son of Sevenless (SOS) stimulate the activity of the GTPases ►Ras and Rac, which, in turn, through the sequential phosphorylation of certain kinases finally lead to activation of terminal MAP kinases ERK1/2, ►JNK and p38 kinase. Although JNK and p38 kinase are primarily activated by environmental stressors, several lines of evidence suggest that they can also be activated in response to IGFs. The activated MAP kinases phosphorylate several important cytoplasmic substrates and also translocate to the nucleus where they phosphorylate transcription factors leading to immediate-early gene induction followed by progression of the cell cycle. Alternatively, signal transduction through the PI3K pathway results in the activation of protein kinase B also known as ►Akt, which is known to block apoptosis by phosphorylating numerous cellular substrates such as Bad, GSK-3, Foxo, Mdm2, CREB, IKK, caspase-9, p21 and p27. The PI3K pathway also activates p70S6 kinase involved in regulation of ribosome biogenesis as well as some isoforms of ►protein kinase C, which are capable of potentiating signal transduction through the MAPK pathway. Thus, IGFs induce cell proliferation both by enhancing cell cycle progression and by inhibiting apoptosis. Furthermore, evidence for both direct and indirect interaction between the IGF-IR and other growth regulatory signals has been demonstrated, thereby expanding the traditional view of highly specific IGF-IR/IGF interactions and rendering the IGF-IR central in cellular response. For instance, in many cell types IGF-IR and ►epidermal growth factor receptor family members physically interact and transphosphorylate each other. ►Estrogen receptor activation augments the IGF-I response in estrogen receptor-positive MCF-7 mammary carcinoma cells at multiple levels. Moreover, estrogens enhance the tyrosine phosphorylation of the IGF-IR and IRS-1 and eventually increase expression of cyclins and reduce the level of cdk inhibitors (Fig. 2).

Altered Expression of the IGF System Components in Tumor Cells

The expression of the components of the IGF system is often altered in malignant cells. In certain tumors, the ►imprinting of the *Igf2* gene is lost, and this results in increased IGF-II gene expression. In general, IGF-II is more commonly expressed by tumors than IGF-I, although increased IGF-I expression has been found in numerous tumors as well.

The IGF-IR is often upregulated or hyperactivated in tumor cells. Expression of the IGF-IR is regulated by tumor suppressors and growth factors in a negative and positive manner, respectively. Tumor suppressors such as ►Wilms Tumor-1 (WT1) and ►p53 bind to the *Igf1r* gene promoter and inhibit receptor gene expression. Mutations of these genes occur in various tumors and paradoxically enhance the activity of the *Igf1r* gene promoter. This explains the upregulation of the IGF-IR gene expression in Wilms tumor (a pediatric kidney tumor) and ►colon cancer, which is often accompanied by p53 mutations. Both WT1 and p53 also inhibit IGF-II gene expression. By analogy with the IGF-I receptor, IGF-II gene expression is increased when *WT1* and *p53* genes are mutated. Thus, the autocrine IGF-IR/IGF-II loop is turned on under these circumstances. Basic ►fibroblast growth factor and ►platelet-derived growth factor are capable of enhancing the IGF-IR gene expression. Since tumors often express these and other growth factors, this could also upregulate the IGF-IR gene expression. Certain ►oncogenes can also regulate the IGF-IR at posttranslational level. For instance, ►Src augments the phosphorylation state of the IGF-IR, thereby increasing its kinase activity. Neoplastic growth can be also enhanced by injections of recombinant human IGF-I into mice. In this case, the latency period is shortened and tumor growth is accelerated. This response is particularly enhanced in tumors with higher levels of IGF-IR expression. In contrast to the IGF-IR, the IGF-II/M6PR expression is often decreased or lost in tumor cells. The IGF-II/M6PR possesses properties of a ►tumor suppressor gene. Tumor cell growth is inhibited when the IGF-II/M6PR expression is restored and is increased when its expression is reduced. In addition to the IGFs and their receptors, the IGFBP expression is also altered in tumor cells. Various IGFBPs are expressed by numerous tumors and often in different combinations. For example, estrogen receptor-positive breast cancer cells release IGFBP-2, whereas estrogen receptor-negative breast tumors

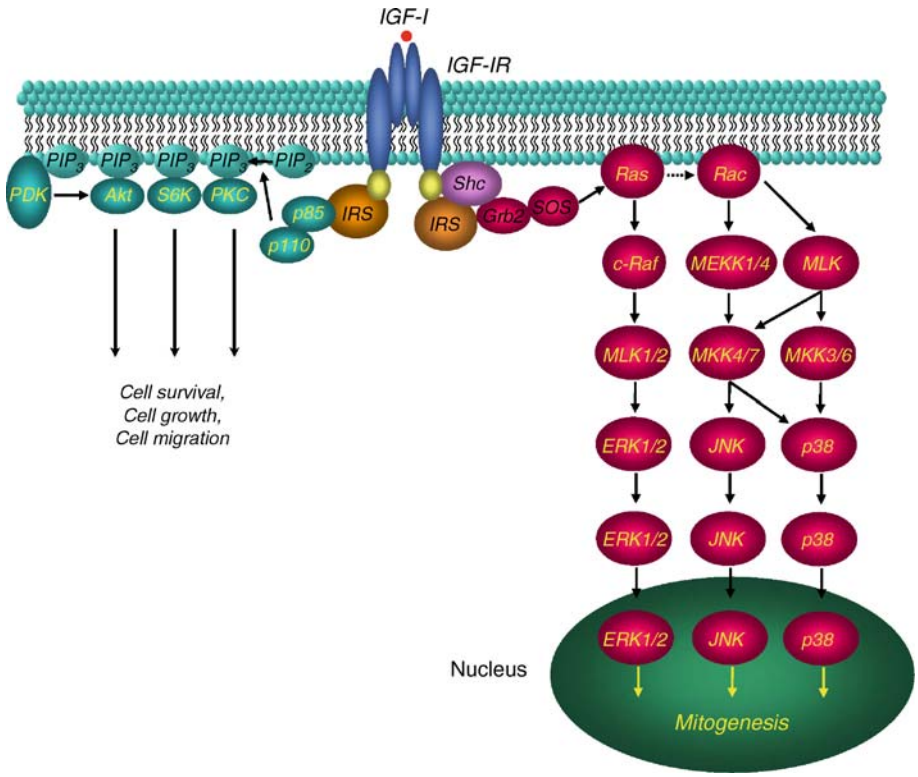


Insulin-like Growth Factors. Figure 1 The IGF family is comprised of (i) ligands (IGF-I, IGF-II and insulin), (ii) IGF-binding proteins (IGFBPs), (iii) IGFBP proteases and (iv) cell surface receptors. IGFBPs act as carrier proteins in plasma, control the efflux of the IGFs from the vascular space, prolong half-lives of the IGFs, regulate their metabolic clearance, provide tissue- and cell-specific localization of the IGFs, modulate biological actions of the IGFs, and some also have intrinsic bioactivities that are IGF-independent. The IGFs can be released from the IGF/IGFBP complexes by the action of IGFBP proteases. The insulin receptor (IR), insulin-like growth factor I receptor (IGF-IR) and insulin receptor-related receptor (IRR) are heterotetrameric complexes composed of extracellular α-subunits that bind the ligands, and β-subunits that anchor the receptor in the membrane and contain tyrosine kinase activity in their cytoplasmic domains. Hybrids consist of a hemireceptor from both IR and IGF-IR. The IGF-II/M6PR is not structurally related to the IGF-IR and IR or the IRR, having a short cytoplasmic tail and no tyrosine kinase activity. IR is responsible for metabolic effects, whereas IGF-IR and hybrid IR/IGF-IR for cell survival, growth, proliferation and differentiation. The insulin-like growth factor II/mannose 6-phosphate receptor (IGF-II/M6PR) functions as scavenger receptor and is responsible for uptake and degradation of the IGFs. This receptor is not considered to have any role in IGF signaling.

release IGFBP-1 and -3. The IGFBP production can be altered by growth factors, steroid hormones, cytokines, and these changes in IGFBP levels may alter biological effects of the IGFs on tumor growth and progression. Interestingly, wild type p53 induces the expression of IGFBP-3 that seems to be critical for the inhibitory function of p53 on cell growth. Furthermore, enhanced IGFBP proteolysis is thought to contribute to carcinogenesis. Numerous IGFBP proteases produced by tumor cells mediate release of the IGFs from the IGFBP/IGF complexes that eventually leads to increased IGF-IR stimulation. For instance, prostate cancer cells secrete ►prostate-specific antigen (PSA), which exerts IGFBP-3 proteolytic activity thereby enhancing the local bioavailability of free IGFs.

Syndrome of Hypoglycemia

An emerging clinical syndrome is tumor-induced hypoglycemia. This phenomenon is often seen in terminally-ill, poorly nourished patients. In addition, it can be also observed in patients with large mesenchymal tumors in the abdomen or thorax that



Insulin-like Growth Factors. Figure 2 Signal transduction cascades initiated by the IGF-IR. Activation of the IGF-IR kinase results in receptor autophosphorylation and tyrosine phosphorylation of several docking proteins such as Shc and insulin receptor substrate (IRS) proteins. Once activated, IRS molecules recruit Src homology 2 (SH2)-domain containing molecules such as Grb2 and the p85 subunit of phosphatidylinositol-3′-kinase (PI3-K). Grb2 *via* SOS stimulates the activity of the GTPases Ras and Rac, which through the phosphorylation of numerous kinases finally lead to activation of terminal MAP kinases ERK, JNK and p38 kinase. Activated MAP kinases are translocated to the nucleus where they activate a variety of transcription factors. Alternatively, the binding of the p85 and p110 subunit of PI3-K to IRS proteins generates phospholipids that participate in the activation of 3-phosphoinositide-dependent kinase (PDK) 1 and 2. In turn, they phosphorylate several targets involved in the regulation of different biological processes including glucose transport, protein synthesis, glycogen synthesis, cell proliferation and cell survival.

secrete large quantities of IGF-II. In these patients, IGF-II is not fully processed, and therefore it is poorly bound to the circulating IGFBPs. This allows IGF-II to interact more readily with insulin receptors thereby causing hypoglycemia. Clinically, tumor-induced hypoglycemia can be diagnosed in cancer patients that have normal or elevated circulating IGF-II levels, whereas their insulin, growth hormone (GH), IGF-I and IGFBP-3 levels are suppressed. These patients usually have a poor prognosis. Surgical excision and ►chemotherapy or ►radiation therapy-induced reduction of tumor size is ►palliative, and GH and corticosteroid therapy provides symptomatic relief.

Clinical Aspects

An increasing body of evidence suggests that the IGF system is a promising target for adjuvant anticancer therapy. If chemotherapy inadequately ablates tumor cells, then blockade of the proliferative and antiapoptotic effects of the IGFs may be helpful. The IGF system could potentially be targeted at various levels. Reduction of circulating IGF-I levels can be achieved by GHRH antagonists or somatostatins as well as GH receptor antagonists. Application of inactive IGF molecules, small-molecule competitive binding antagonists or soluble IGF-I receptors may inhibit binding of endogenous IGFs to the receptor thereby abrogating their tumor-promoting effects. The IGF-IR represents another attractive therapeutic target. Approaches that are currently being tested in preclinical and clinical studies include the use of blocking ►monoclonal antibodies directed against the extracellular portion of the IGF-IR and ►small molecule drugs that inhibit the tyrosine kinase activity of the IGF-IR. Application of ►RNA interference and ►antisense therapy to reduce the IGF-IR expression, as well as overexpression of altered or

truncated IGF-IR that acts in a ►dominant-negative manner, represent additional approaches that have been effective in laboratory studies.

Insulinoma

Boaz Hirshberg
Cardiovascular and Metabolic Diseases, Pfizer Inc, Groton, CT, USA

Synonyms

β-Cell tumor of the islets

Definition

Insulinomas are functioning ►insulin producing tumors of the pancreatic ►islets of Langerhans, resulting in hypoglycemia.

Characteristics

Insulinomas arise from the β-Cell of the pancreatic islets. The nonregulated secretion of insulin from these tumor cells into the blood stream results in fasting hypoglycemia. Insulinomas are relatively rare, with approximately four cases per million person-years. However, they are the most common tumor of the pancreatic islets. Insulinomas may appear at any age, but the majority appears in the fifth decade. Insulinomas are evenly distributed along the pancreas. Insulinomas, associated with ►multiple endocrine neoplasia type 1 (MEN1), tend to appear one decade earlier. Insulinomas are usually solitary and their localization is even along the pancreas, exceptions are those associated with MEN1, where multiple tumors are the rule.

Diagnosis

The presence of ►Whipple Triad (hypoglycemia and neuroglycopenic symptoms that are corrected by the administration of carbohydrate) is the hallmark of the diagnosis of insulinoma. Fasting, therefore, is the major maneuver used in the diagnosis of insulinoma and has two important purposes. The first goal is to document hypoglycemia and its relationship to the patient's symptoms, and the second is to demonstrate inappropriate insulin concentrations in the face of hypoglycemia. The prolonged (48–72 h) fast is the gold standard for the diagnosis of hypoglycemia. This study should be conducted under supervised conditions (i.e., while hospitalized). Diagnosis of insulinoma has been centered on the 72-h fast that was introduced long before to measure insulin or insulin-related components. Now the insulin and proinsulin measurements are widely available, all of the necessary information from a fast can be derived in the first 48 h. Thus, the 48-h fast has become the new standard. The diagnosis is based on detectable insulin levels (≥6 μU/ml), detectable C-peptide, and elevated proinsulin levels, when the patient has symptoms of hypoglycemia and glucose levels <45 mg/dl (2.49 mMol). At the end of the study, a sulfonylurea screen must be obtained to rule out factitious hypoglycemia.

Other diagnostic tests that may be used are the C-peptide suppression test and the ►tolbutamide intravenous test. The C-peptide suppression test is based on the observation that exogenous insulin suppresses C-peptide more in normal islets compared to insulinoma islets. The tolbutamide intravenous test is rarely used today due to the risk of hypoglycemia.

Differential Diagnosis

There are several conditions that may result in hypoglycemia, and thus are part of the differential diagnosis of hypoglycemia.

1. Inadvertent or intentional (factitious) administration of insulin secretagogues or insulin
2. Other medications such as salicylates, haloperidol, beta blockers, pentamidine, trimethoprin – sulfamethoxazole, quinine, acute steroid withdrawal
3. Significant medical conditions such as renal, hepatic and cardiac failure, severe malaria, sepsis and lactic acidosis
4. Neoplastic syndrome associated with large tumors, secondary to secretion of ►insulin like growth factor 2

While the later two conditions are usually clinically obvious, the first is challenging. A properly conducted fasting test will usually be allowed for proper diagnosis.

Treatment

Surgical removal of the tumor is the most effective treatment for insulinoma. Localization of the tumor

prior to surgery may be beneficial. Selective pancreatic angiography with calcium stimulation allows localization of the tumor to the head, body, or tail of the pancreas. The study is based on the ability of calcium, injected into one of the feeding blood vessels of the pancreas, to cause the insulinoma to secrete insulin into the venous drainage of the pancreas. Imaging techniques such as ►magnetic resonance imaging (MRI), ►computed tomography (CT), and ultrasound (US) lack the sensitivity to detect tumors. Finally, the use of intraoperative ultrasonography allows for detection of virtually all tumors. The ability to detect most tumors has made the old practice of blind distal pancreatectomy obsolete.

Medical treatment is limited to diazoxide, calcium channel blockers and ►somatostatin. Medical treatment can be used to control symptoms while the patient is awaiting surgery or when a patient refuses or is not a candidate for surgical intervention.

Based on the experience at the National Institutes of Health, Bethesda MD, the following steps are recommended after the biochemical diagnosis of an insulinoma:

1. Perform an abdominal US and abdominal CT to evaluate the patient's anatomy and to rule out a metastatic disease.
2. Perform a hepatic venous sampling after Ca^{2+} stimulation. While some centers view this step as excessive and costly, because of the nature of the operation, we believe that accurate preoperative localization is valuable.
3. Operation to be performed by a surgeon experienced with the use of intraoperative US or with the assistance of a radiologist.

Insulinoma is a rare tumor, and most internists, endocrinologist, and surgeons will have limited experience with this condition. Thus it is advisable to refer subjects suspected of having this tumor to a center with expertise diagnosing, localizing, and treating pancreatic endocrine tumors.

Malignant Insulinoma

Only 5–12% of the reported cases of insulinoma are malignant. Most patients with malignant insulinoma have lymph node or liver ►metastasis. The prognosis of these patients is relatively poor with a median survival period of ~2 years. Diazoxide therapy for control of hypoglycemia has had the greatest long-term benefit. Some patients have gastrointestinal intolerance to the drug, and in very high doses it may produce ►anorexia. All the other forms of therapy have either had no benefit or relatively short-term benefit and most, such as chemotherapy regimens (such as streptozotocin), are toxic and of little benefit. ►Embolization may have the greatest benefit next to diazoxide.

Integrin

Definition

A family of ►cell adhesion receptors. alphabeta heterodimers of transmembrane proteins that recognize ►extracellular matrix or cell surface ligands. The ►RGD motif is a prototype of the integrin-binding motifs in ligands. Integrins transduce intracellular signals upon ligand binding and are regulated by intracellular signals. Integrins are heterodimeric proteins (alpha and beta subunit) and facilitate cell attachment to the extracellular

matrix. About 18 different alpha and 8 beta subunits of integrins have been characterized. Combinations between these subunits provide a variety of integrins with unique functional properties. Integrin mediated signaling bridges communication between the extracellular matrix and intracellular microfilaments involved cell migration. Integrins bind ►extracellular matrix proteins, including laminins, on their extracellular domain and bind cytoskeletal elements, such as ►actin, on their cytoplasmic domain; integrins then provide a physical link between the extracellular and intracellular skeletons. Integrin signaling affects numerous biological outcomes including cell ►adhesion, ►migration, and ►invasion.

Integrin Signaling

Michael Z. Gilcrease
Department of Pathology, Breast Section, M. D. Anderson Cancer Center, Houston, TX, USA

Definition

Integrins comprise a family of cell surface receptors that bind ►extracellular matrix proteins and cell surface counterreceptors, thereby linking the cell's ►microenvironment to the ►cytoskeleton.

Characteristics

Virtually all cells of multicellular animals express integrins, and most cells of adult mammals constitutively express multiple different integrins. These cell surface receptors play an important role in mediating cell ►adhesion to adjacent connective tissue proteins. Integrins are transmembrane heterodimers that consist of noncovalently bound glycoprotein subunits. Each heterodimer is composed of a single α and a single β subunit, both of which participate in ligand recognition. A total of 18 α and β subunits have been identified, some of which have multiple splice variants, and these combine to form 24 distinct integrin heterodimers. Most integrins (with the notable exception of α6β4) have small cytoplasmic domains that are connected to the cytoskeleton by multiple linkage proteins. They generally lack catalytic activity but participate in ►signal transduction by linking to a variety of cytoplasmic molecules. Cytoskeletal proteins, signaling molecules, and adaptor proteins bind directly to integrin cytoplasmic domains, linking integrins to other proteins and creating elaborate networks underlying the plasma membrane. These protein complexes are capable of undergoing rapid formation and dissolution, allowing rapid changes in the organization of the cytoskeleton and modulation of multiple downstream signaling pathways. In addition to integrin cytoplasmic domains, the transmembrane and extracellular regions of integrins can also interact with a variety of proteins that regulate integrin function.

Expression of particular integrins is cell-type dependent. Epithelial cells, the most common cell type of adult malignancies, generally express several integrins that bind extracellular matrix proteins. These include α6β4 and α3β1 (receptors for laminin isoforms), α2β1 (a collagen receptor), and α5β1 (a receptor for ►fibronectin). In malignant epithelial cells, integrin expression is generally decreased compared to benign cells, although increased integrin expression occurs in some cancer cells. There is also an altered distribution of integrins in malignant cells compared to benign cells. For example, α6β4 is present at the basal surface of benign epithelial cells within hemidesmosomes but is expressed more diffusely in malignant epithelium in vivo and is localized to the leading edge of invading carcinoma cells in vitro. Integrin signaling to a great extent accounts for the anchorage dependence of normal cell proliferation, and the ►anchorage-independent cell growth that characterizes cancer cells is to some extent a reflection of altered integrin signaling in cancer cells.

Signaling

Ligands regulate integrin function by inducing changes in the conformation of the cell surface heterodimers.

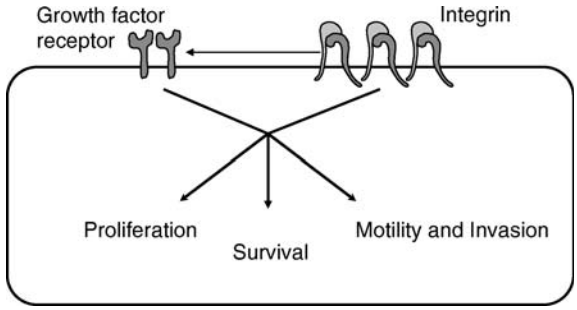
Upon binding to the heterodimer, the ligand opens up a pocket and separates portions of the integrin chains near the amino-terminal ends. This shift in conformation is transmitted along the length of the integrin protein towards the membrane, producing a change in conformation of the intracellular region. Ligands maintain the integrin in an open active configuration in which the integrin cytoplasmic tails are separated and there is high affinity for the ligand. In contrast, the closed inactive form has low ligand-binding affinity. A variety of cytoplasmic regulatory proteins exert their effects in the opposite direction by binding to the cytoplasmic domain, transmitting a conformational change along the integrin towards the amino-terminal ligand binding region, thereby altering ligand recognition. The aggregation or "clustering" of integrins in focal areas on the cell surface is a second important mechanism for regulating integrin function. Lateral migration and clustering of integrins in the plasma membrane enhances integrin-mediated signal transduction.

Integrin signaling regulates a variety of functions in benign and malignant epithelial cells. Epithelial cells are relatively non-motile and quiescent after embryogenesis and development but can be induced to undergo increased ►motility and proliferation under certain conditions, such as wound repair. Malignant epithelial cells usurp some of the integrin-mediated mechanisms underlying normal cell function to facilitate tumor growth and survival and to promote the motility, ►invasion and ►metastasis of cancer cells.

Growth and Differentiation

Full activation of the growth stimulatory pathways in normal epithelial cells requires not only integrin ligation but also cell adhesion to the extracellular matrix. The modulation of growth stimulatory pathways by integrin-mediated matrix adhesion provides a means whereby cell growth can be promoted in favorable environments and inhibited in areas where epithelial cell proliferation would be inappropriate. Cooperative signaling between integrins and growth factor receptors has been demonstrated for a number of growth factor receptors important for epithelial proliferation, including epidermal growth factor receptor (EGFR), ►HER-2/neu, and ►MET (Fig. 1).

Integrin ligation in adherent cells leads to activation of Erk, which translocates to the nucleus and produces increased ►cyclin D1. Integrin signaling through the PI3K-Akt-►mTOR pathway also raises cyclin D1 levels by increasing the translation of cyclin D1 mRNA. On the other hand, integrin signaling leads to degradation of the cyclin-dependent kinase inhibitors p21cip1 and p27kip1. Together, increased cyclin D1 and the degradation of cyclin-dependent kinase inhibitors result in hyperphosphorylation of the retinoblastoma gene product (Rb), leading to release of ►E2F, increased expression of cyclin A, and the formation of cyclin A/cdk2 complexes required for entry into S phase.



Integrin Signaling. Figure 1 Cooperative signaling between integrins and growth factor receptors. Schematic diagram depicting crosstalk between activated integrins and growth factor receptors, leading to integrin-mediated regulation of tumor cell proliferation, survival, and motility and invasion.

Activation of integrin-linked kinase (ILK) through the phosphatidylinositol 3-kinase pathway ►PI3K Signaling can also promote tumor cell proliferation. Activated ILK phosphorylates and inhibits glycogen synthase kinase-3 (GSK3), which relieves the negative regulation of activator protein 1 (►AP-1) and β-catenin/TCF transcription factors. Both of these transcription factors induce expression of cyclin D1, promoting cell cycle progression. Alternatively, integrin signaling through ►focal adhesion kinase (FAK) leads to activation of the small G-protein Rac and Rac-mediated activation and nuclear translocation of NF-κB. The Rac-PAK pathway downstream of FAK also leads to activation of the transcription factor Jun by Jun amino-terminal kinase (►JNK). Both NF-κB and Jun regulate genes involved in cell proliferation.

Integrin signaling not only regulates cell proliferation but also plays an important role in maintaining epithelial polarity and differentiation. Signaling through Rac appears to be critical for establishing epithelial polarity, which is disrupted in cancer cells as a result of altered integrin signaling. Malignant breast epithelial cells with overexpressed β1 integrins grow into non-polarized structures in 3-D culture, and inhibition of β1 signaling in these malignant cells results in reversion to a normal polarized phenotype.

Motility and Invasion

Migratory stimuli induce a relocalization of integrins to facilitate cell motility. Integrin signaling at the leading edge of migrating epithelial cells leads to

phosphorylation and activation of Rac through both ILK- and FAK-mediated pathways. Rac signaling through PAK downstream of ILK stimulates phosphorylation of ►Raf kinase, leading to activation of Erk. Activation of Erk leads to phosphorylation and activation of myosin light chain kinase (MLCK), which phosphorylates and activates myosin II, the main motor protein in eukaryotic non-muscle cells. Erk activation at the leading edge of motile cells, therefore, leads to actin-myosin contraction within sheet-like projections, or lamellipodia, and the generation of traction forces.

The α6β4 integrin plays a role in cell motility distinct from that of other integrins. In cells with hemidesmosomes, stimuli that induce migration, such as EGF, induce a relocalization of α6β4 from hemidesmosomes to the leading edge of migrating cells. α6β4 localizes initially within finger-like projections, or filopodia, anchoring them to laminin matrices. The stabilized filopodia then act as tracks to guide the subsequent spreading of lamellipodia. Signaling by α6β4 activates phosphodiesterases, which degrade cAMP, releasing the inhibitory effect of cAMP on ►Rho family proteins activity. α6β4-mediated Rho activation appears to stimulate the actin-myosin contraction necessary for the generation of traction forces at the leading edge of the cell. Rho downstream of α6β4, therefore, appears to play a role similar to that of Rac downstream of other integrins.

Integrin signaling through ILK in some types of epithelium induces downregulation of ►E-cadherin and loss of β-catenin from cell–cell ►adherens junctions. β-Catenin undergoes nuclear accumulation and activation, where it activates members of the T cell factor (TCF) family of transcription factors that regulate a variety of genes required for ►epithelial-mesenchymal transition (EMT), a process in which malignant epithelial cells undergo dedifferentiation and acquire mesenchymal-like properties, including the ability to undergo single cell invasion. Although ILK can be regulated downstream of other pathways such as the ►WNT signaling pathway, its direct linkage to β1 integrins implicates these integrins as important regulators of EMT. Signaling through ILK also promotes ►matrix metalloproteinase expression and secretion, facilitating cancer cell invasion of the surrounding connective tissues.

Survival

In stable adherent epithelial cells, integrins are clustered in focal adhesions. Focal adhesion kinase (FAK) binds to the β subunit of most integrin heterodimers in focal adhesions. FAK serves as a multifunctional adaptor linking integrins to multiple downstream signaling pathways, including the PI3K-Akt pathway. Signaling through Akt mediates cell survival in adherent epithelial cells by phosphorylating and preventing the pro-apoptotic activities of ►Bcl-2 family proteins BAD and Bax. Integrin signaling through the Erk pathway also promotes cell survival in adherent epithelial cells by downregulating the pro-apoptotic protein Bim. Although signaling through unligated β1 integrins can induce ►apoptosis by recruiting ►caspase-8 to the cell membrane, apoptosis generally results from loss of integrin-mediated survival signals, such as occurs in detached epithelium. In contrast to normal cells, cancer cells develop mechanisms for preventing apoptosis under anchorage-independent conditions.

The α6β4 integrin does not bind FAK but activates Akt-mediated survival pathways through an alternate mechanism, possibly through phosphorylation of the adaptor proteins IRS-1 and IRS-2. In addition, α6β4 has also been shown to activate the mammalian target of rapamycin (mTOR) downstream of Akt. Signaling through the mTOR pathway induces phosphorylation of 4E-binding protein (4E-BP1), a translational repressor that binds to and inhibits eukaryotic translation initiation factor 4E (eIF-4E). Phosphorylation of 4E-BP1 induces its dissociation from eIF-4E, and unbound eIF-4E promotes cap-dependent mRNA translation. Proteins induced through this pathway include ►vascular endothelial growth factor (VEGF), which also appears to promote PI3K-Akt signaling through an autocrine loop mechanism.

Integrin-mediated signal transduction regulates many cellular functions in addition to cell adhesion, including cell survival, proliferation, morphogenesis, differentiation, motility, invasion and metastasis. Although there remain significant gaps in our knowledge about the mechanisms underlying these various functions of integrins, abundant information is becoming available about specific pathways and mediators of integrin signaling in cancer cells. Detailed information about integrin signaling in cancer has important practical implications, not the least of which is the potential therapeutic targeting of integrin signaling pathways or growth factor receptor pathways modulated by integrin signaling.

Intensity-modulated Radiation Therapy

Definition

IMRT; is a form of advanced ►radiation therapy. In IMRT, the beam intensity varies across the treatment field, and numerous small beams with modulated intensities are irradiated through multiple ports to the target to ensure that a prescribed dose is homogeneously delivered to the target while a reduced dose is given to adjacent critical organs.

►Proton Beam Therapy

Intercellular Junctions

Definition

Synonym cell-cell junctions, ►gap junctions, ►adherens junctions. Refers to protein structures that connect the ►plasma membrane of adjacent cells. There are several types of intercellular junctions. These include ►cadherins, ►connexins, ►mucins, ►selectins, and some ►integrins. These junctions mediate numerous processes including ►adhesion, signaling, metabolic coupling, homeostasis, and maintenance of cell morphology. Intercellular junctions are often disrupted in tumor cells, thereby disturbing functions related to these processes. Some intercellular junction proteins, such as connexins and cadherins, can act as ►tumor suppressors. In addition, intercellular junctions between transformed and nontransformed cells can help control tumor cell growth by ►contact normalization.

►Gap Junctions
►Adherens Junctions

Interferon

Definition

A protein substance produced by white blood cells and other types of cells. These substances have anti-viral properties, and have been used successfully in combating hepatitis and liver cancer associated with hepatitis.

►Inflammation

Interferon-α

Angela Märten
National Centre for Tumour Diseases, Heidelberg, Germany; Department of Surgery, University Hospital Heidelberg, Heidelberg, Germany

Synonyms

B-cell interferon; Leukocyte interferon; Type I interferon

Definition

Interferons (IFNs) belong to the group of cytokines and are produced by various cells as part of an immune response to a viral infection or other immune trigger. IFNs are a family of molecules that include more than 15 expressed genes and a number of pseudogenes coded on chromosome 9. IFN-α belongs to the type I IFNs.

Characteristics

IFN-α is produced by monocytes/macrophages, lymphoblastoid cells, fibroblasts, and plasmacytoid ►dendritic cells (DC). It is detectable under physiological conditions but markedly enhanced during infections, especially viral infections. IFN-α binds to the IFN-α/β receptor CD118; binding to the Epstein–Barr virus receptor CD21 is also described. Binding to the IFN receptor activates the transcription of several different genes inducing the synthesis of host cell proteins that contribute to the inhibition of viral replication. In addition to its antiviral properties, IFN-α exhibits several other features that are of interest especially for the use in combination treatments of cancer, as there are: (i) direct inhibitory effects on tumor cell growth; (ii) ►radiosensitization and ►chemosensitization effects; (iii) ►antiangiogenic properties; (iv) enhancement of immunogenicity of tumors, and (v) modulation of the immune system.

IFN-α has a nearly 50-year long tradition in oncology. It has never fulfilled the overdrawn promises of the beginning but it has its niches; some has been lost during the last years but new entities like ►pancreas carcinoma show promising results as targets of IFN-based regimens.

Malignant Melanoma

High-dose IFN α-2b (HDI) is the only effective ►adjuvant therapy for ►melanoma patients at high risk for recurrence and death. Adjuvant therapy with HDI has been shown to increase significantly disease-free survival and overall survival in large, randomized, cooperative group trials compared with observation in patients with resected stage IIB and III melanoma.

These data are mature regarding the disease-free survival but less convincing regarding the overall survival as the large Intergroup trial E1690 failed to show an overall survival benefit. However, two large studies, the E1684 and the E1694 trial, were positive regarding the overall survival in the HDI arm. The approved regimen consists of intravenous induction therapy with 20 million international units/m^2/d, five times per week for 4 weeks, followed by 10 million international units/m^2 subcutaneously, three times per week for 48 weeks as maintenance. The toxicity associated with this regimen is substantial and can adversely affect acceptance of this regimen. With appropriate monitoring, dose modifications, and aggressive supportive care, HDI can be administered safely and is tolerable for the majority of patients. There have been no toxic deaths in the cooperative group trials of HDI over the past decade since the adoption of formal dose modification guidelines during the early phases of the first trials.

Pancreas Carcinoma

There are data showing that combined ►chemoradiotherapy plus Low-dose IFN-α (LDI) after curative resection of ►pancreatic ductal adenocarcinoma result in a 5-year survival of 50%, while chemoradiotherapy alone is described with a 5-year survival lower than 25%. However, a randomized controlled trial clearly proofing that IFN-α is responsible for this enormous difference is still outstanding. Recent data from translational research show strong immune responses in LDI-treated patients who develop first an unspecific immune response which later on result in a pancreas carcinoma-specific immune response.

Renal Cell Carcinoma/Leukemia/Multiple Myeloma

There is no evidence to support a benefit for ►adjuvant, ►Immunotherapy in high-risk patients who have undergone potentially curative surgery of ►renal cell carcinoma (RCC). At least five randomized trials failed to demonstrate a survival benefit from this approach. In the metastatic situation the role of IFN-α is unclear. The activity of monotherapy with IFN-α in metastatic RCC has been extensively evaluated, including several large, well-designed trials. Using a variety of preparations, doses, and schedules, the overall response rate may be as high as 15%; the median time to response is about 4 months, and most responses are partial and rarely persist beyond 1 year. Although no clear dose-response relationship has been shown, daily doses ranging from 5 to 10 million units appear to have the most favorable therapeutic index. Combinations with ►IL-2 and chemotherapy has been tested, the best results were obtained together with ►5-FU. Nearly one third of the patients responded. Nowadays, the tyrosine kinase inhibitors ►Sorafenib and ►Sunitinib seem to be better candidates for therapy of metastatic RCC.

IFN-α, initially partially purified IFN-α followed by recombinant IFN-α-2a, has been nontransplant standard therapy for chronic myeloid leukemia for several decades until the tyrosine kinase inhibitor Imatinib had its triumphal procession.

IFN-α has been used in ►multiple myeloma, however clinical activity is limited. In randomized studies no benefit of IFN-α maintenance therapy has been proven.

Hairy Cell Leukemia

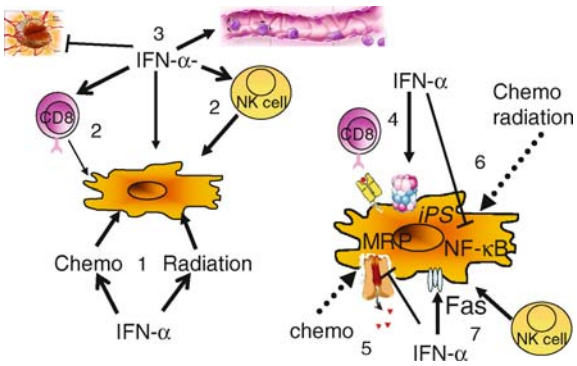
Since 1984, IFN-α is known to be an effective therapy for ►hairy cell leukemia, numerous large studies have confirmed this. The precise mode of action is not known but it might be mainly an immunomodulatory one, especially dealing with interleukin-6 production. IFN-α is administered with 2 million units/m² three times a week.

Direct Effects of IFN-α

IFN-α directly inhibits proliferation of tumor cells, prolongates the ►cell cycle, i.e., has a cytostatic mechanism. This is thought to be achieved by modulation of 2′,5′-oligoadenylate synthetase activity or modulation of cellular ►oncogenes. It has proapoptotic effects, downregulates oncogene expression, inhibits ►ornithine decarboxylase, an important biosynthetic enzyme, thus may resulting in depletion of metabolites required for tumor growth and induces tumor suppressor genes. However, at clinical achievable dosage concentrations these effects are not striking so other mechanism should contribute Fig. 1.

Radio- and chemosensitizing Effects

IFN-α acts synergistically with chemo- and radiotherapy. Treatment with IFN-α upregulates, for example, thymidine phosphorylase (TP) mRNA in tumor tissue.



Interferon-α. Figure 1 Pleiotropic mode of action of IFN-α.

TP is an enzyme which catalyzes the conversion of the pyrimidine antimetabolite ►5-fluorouracil (5-FU) into the active form. Furthermore, IFN-α prevents resistance mechanisms like ►NF-κB upregulation due to chemo- and radiotherapy. The transcription factor NF-κB is of great importance for cellular survival. By inducing certain antiapoptotic target genes, NF-κB is capable of conferring cellular resistance against various apoptotic triggers, including death receptor activation and DNA-damaging insults.

Antiangiogenic Effects

IFN-α, especially at low dosages, has antiangiogenic properties as most obviously in ►Kaposi sarcoma. ►Angiogenesis is a fundamental process that ensures adequate metabolic supply to tissues even in tumors. Angiogenesis starts with vasodilation and an increase in vascular permeability as a response to proangiogenic factors such as ►vascular endothelial growth factor (VEGF). This is accompanied by detachment of ►pericytes from the vessel wall and ►basement membrane and ►extracellular matrix degradation. In the next step, the underlying endothelial cells migrate into the perivascular space, multiply, and form new vascular sprouts. This ►neovascularization results in a hierarchical vascular network. Tumors lose the ability to form stable, hierarchically organized vessels. IFN-α has been shown to downregulate the expression of the proangiogenic molecules basic fibroblast growth factor (bFGF) and the matrix metalloproteinases, MMP-2 and MMP-9. Downregulation of angiogenesis-related genes and therapy of solid tumors is dependent on optimization of biological dose and schedule of IFN-α. In an animal model it was clearly shown that addition of IFN-α to 5-FU leads to tumor regression of pancreatic carcinoma. The animals had lower ►VEGF serum level and thus less VEGF receptor expression. Furthermore, vessel density was reduced and vessel structure and hierarchy normalized and pericyte marker decreased. Furthermore, after IFN-α therapy more leukocytes attached to the endothelium of the tumor vessels were able to migrate into the tumor.

Immunogenic Effects

IFN-α is described to enhance the immunogenicity of tumors. This phenomenon is provoked by an increase of ►MHC class I expression which enhance immune recognition. Both the increase in ►MHC molecules as well as a stabilization of MHC molecules formed has been described. Furthermore, IFN-α is described to induce the immunoproteasome. Intracellular proteins are degraded to peptides by the proteasome; a large proteolytic complex whose primary function is the controlled elimination of proteins marked for degradation by ubiquitin, and then presented to ►cytotoxic T lymphocytes (CTLs) by MHC class I molecules. It is well known that stimulation with IFN-γ induces the replacement of the three catalytic subunits of the proteasome by their homologous subunits LMP-2, MECL-1, and LMP-7, to form so-called "immunoproteasomes" (iPS). The efficiency of the modified proteasome to eliminate proteins remains unchanged, but its preferences for cleavage are modified. Several antigenic peptides, including tumor epitopes, were found to be processed differentially by the two proteasome types, thus implying a different ability to be recognized by ►CTLs. Treatment of carcinoma cells with IFN-α also resulted in a switch to the immunoproteasome thus determining the immunodominance hierarchy so that it has direct impact on ►CD8 ►T cell responses by modifying the repertoire of responding $CD8^+$ T cells. Presently it is discussed that the immunoproteasome is more competent at producing class I binding peptides. There are also several reports from tumor epitopes which are better processed by cells carrying immunoproteasomes. IFN-α pretreated tumor cells are getting more vulnerable to T cells.

Furthermore, IFN-α enhances production of antibodies to tumor cells thus resulting in an increased ►antibody-dependent cellular cytotoxicity (ADCC), linking ►natural killer cells (NK cells) to tumor cells and increasing ►complement-dependent cytotoxicity (CDC).

Immunomodulation

IFN-α acts on T, NK, and DC and monocytes thus releasing cytokines. IFN-α enhances the survival of T cells by expression of antiapoptotic genes, induces the generation of $CD8^+$ memory cells and it promotes differentiation of naïve T helper cells to T helper 1 cells ►T_H1 cells. IFN-α is also important for the proliferation and long-term survival of antigen-specific T cells. In clinical studies classical secretion of Th1 cytokines as interleukin-2 (IL-2), IFN-γ (IFN-γ), tumor necrosis factor-α (TNF-α) and ►interleukin-12 (IL-12) in response to IFN-α administration were observed. Th1 cytokines are thought to confer protective immunity to tumors. IFN-α makes T cells more responsive to IL-12 thus promoting a Th1 immune response.

►NK cells which kill tumor cells by ►Fas-induced ►apoptosis as well as by ►perforin release are activated by IFN-α. ►FasL is upregulated on ►T cells and ►NK cells in response to IFN-α stimulation and therefore an enhanced ability of immune cells to kill via the Fas pathway is given.

Furthermore, IFN-α plays an essential role in the differentiation, maturation and functions of ►dendritic cells, and enhances ►macrophage activities. These

►antigen-presenting cells stand in the beginning of the immune cascade and enables that a switch from the unspecific immune system to the specific immune system occurs. Antigen-specific cells could uptake tumor material and prime naïve IFN-α stimulated T cells in an antigen-specific way.

IFN-α functions are as follows: (i) IFN-α acts as radio-and chemosensitizer. (ii) IFN-α enhances NK cell mediated cytotoxicity and to a lesser extent CD8 cells. (iii) IFN-α acts antiangiogenic and enhances leucocyte–endothelium interactions. (iv) Treatment with IFN-α induces the switch to the immunoproteasome resulting in an increased immunogenicity. (v) IFN-α prevents the induction of multidrug-resistance proteins. (vi) Chemo- as well as radiotherapy induces NF-κB, known to promote growth of carcinoma cells. IFN-α inhibits NF-κB upregulation or even downregulates NF-κB. (vii) IFN-α induces upregulation of Fas thus resulting in an increase in NK cell cytotoxicity.

Interferon Gamma

Definition

IFN-Gamma, Type II IFN; A natural protein involved in the regulation of immune and inflammatory responses. IFN-gamma is produced in activated T-cells and ►natural killer cells, and has direct anti-viral and anti-tumor effects (generally weak), however it also potentiates the effects of the type I IFNs. IFN-γ released by Th1 cells recruit leukocytes to an infection site, resulting in increased ►inflammation. It also stimulates ►macrophages to kill bacteria that have been engulfed. IFN-γ released by Th1 cells is also important in regulating the Th2 response.

►GAGE Proteins
►Immunoediting

Interferons Type I

Definition

The type I interferons are a multi-member ►cytokine family that bear structural resemblance to other cytokines, including IFN-γ. Although there are a total of seven type I interferons in mice and five in humans from an immunological perspective IFN-α and IFN-β are the most important. There are 12 known varieties of IFN-α in mice and 13 in humans, whereas only one species of IFN-β exists for both species. Both IFN-α and -β bind to the same receptor, which consists of IFNAR1 and IFNAR2 subunits. Signaling occurs through the JAK/STAT pathway. Although all cells can produce type I interferons in response to pathogens, a specialized ►dendritic cell produces up to 1,000 times more IFN-α and -β than other cell types.

Interleukin

Definition

IL; Is a generic term for ►cytokines produced by ►leukocytes. In use is the more general term cytokine, but the term interleukin is used in the naming of specific cytokines such as ►IL-2.

►Interleukin-4
►Interleukin-6

Interleukin-1

Definition

IL-1; A cytokine, endogenous messenger of cells of the immune system, which promotes ►inflammation and destruction of chondral tissue.

►Interleukin

Interleukin-1 beta

Definition

IL-1β; is a potent immuno-modulator that mediates a wide range of immune and inflammatory responses including the activation of B- and T-cells.

►Interleukin

Interleukin-2

Definition

IL-2; Is the cytokine that is most central to the development of an ►adaptive immune response.

Interleukin-4

William L. Farrar
National Cancer Institute – Frederick, Frederick, MD, USA

Definition

IL-4; Is a prototypic immunoregulatory cytokine secreted by activated ►CD4 T cells of the ►T helper (Th) 2 subset and by ►basophils and ►mast cells. IL-4 has an important role in regulating antibody production, hematopoiesis, ►inflammation and the development of effector ►T-cell responses.

Characteristics

IL-4 is a 15–20 kD ►glycoprotein composed of 129 amino acids. IL-4 contains six cysteine residues that are all involved in intramolecular disulfide bridges. The secondary structure of IL-4 was shown to consist of a four-helix bundle with a unique up-up-down-down helix topology. The X-ray structure reveals that IL-4 is a highly compact and globular protein with a predominantly hydrophobic core.

Human IL-4 receptor (IL-4R) is found on ►T cells, ►B cells, ►mast cells, ►basophils, ►macrophages, ►fibroblasts, ►endothelial cells, hepatocytes, keratinocytes, stromal cells and neuroblasts. IL-4 receptor is a heterodimer composed of an α subunit, with IL-4 binding affinity, and the common γ subunit that is also part of other cytokine receptors. It functions to enhance the binding of IL-4 to its receptor, presumably by direct interaction with the ligand, and to induce intracellular signals transduction events such as ►JAK/STAT signal pathway. Janus kinases JAK1 and JAK3 and ►signal transducers and activators of transcription 6 (STAT6) have been found to play a unique role in IL-4 receptor-mediated intracellular signaling and hematopoietic cell development.

IL-4 is a highly tissue-specific gene that is expressed in the Th2 cell subset and not in the Th1 cell subset. The human IL-4 gene is a single copy gene in the haploid genome. It spans about 10 kb and is located on chromosome 5q23–31 along with the IL-3, IL-5, and GM-CSF genes. Several transcriptional factors such as STAT6, NFAT (nuclear factor of activated T cells), c-Maf and GATA3 also influence gene expression and production of IL-4. For example, STAT6-►knock-out mice are unable to produce Th2 cytokines. The Th2-specific transcription factor c-Maf promotes IL-4 promoter activity. NFAT1 is involved in termination of the late phase of IL-4 gene transcription, thereby inhibiting Th2 responses.

Generally, antigens and antibodies that cross-link the T-cell receptor induce IL-4 production. The initiation of IL-4 production, a key event in the control of IL-4 production may, in naïve T cells, require limited T-cell receptor (TCR) signaling in co-stimulation with surface CD28 and CD40 ligand. Once IL-4 production is initiated, IL-4 feeds back on the differentiating cells and accelerates Th2 commitment in an autocrine fashion.

Effects of IL-4 depend upon binding to and signaling through IL-4 receptor complex. The IL-4R, which lack intrinsic tyrosine kinase activity, uses multiple intracellular domains to induce proliferative and gene expression responses. The membrane proximal region of IL-4R contains sequences known as Box 1 and Box 2 for binding of Janus family kinases JAK1 (bound to IL-4Rα) and JAK3 (bound to γc). Distal to this region is the I4R motif for binding of insulin receptor substrate (IRS)-1 and IRS-2. IRS-1 and IRS-2 links the IL-4R to downstream signaling cascades including phosphoinositol 3′ kinase (PI-3-K) and mitogen-activated kinase to induce cell growth. A more distal region of the IL-4R, termed the gene expression domain, contains three tyrosine residues, which mediate activation of STAT6 through tyrosine phosphorylation. STAT6 phosphorylation is believed to induce transcriptional activation after the STAT dimers translocate from the receptor to the nucleus, where they bind to specific targeting sequences and influence gene transcription. In short, the JAK/STAT signal pathway connects activation of the receptor complexes directly to transcription of genes. Upon IL-4 receptor oligomerization induced by a polypeptide ligand, JAKs are activated,

presumably by trans-auto phosphorylation on tyrosines. Subsequently, JAKs phosphorylate STAT proteins, which form homodimeric or heteromeric complexes via their Src-homology 2 (SH2) domains. These complexes translocate to the nucleus and bind directly to response elements present in the promoters of target genes, thus triggering induction of transcription.

Bioactivity

IL-4 was initially called B cell growth factor-1 because of its role in the early steps of B cell activation. IL-4 has now been shown to regulate a wide spectrum of cellular functions in B cells, T cells, monocytes/macrophages and other hematopoietic and non-hematopoietic cells. IL-4 plays a central role in regulating the differentiation of antigen-stimulated naïve T cells. IL-4 causes such cells to develop into cells capable of producing IL-4 and a series of other cytokines including IL-5, IL-10 and IL-13. IL-4 controls the specificity of immunoglobulin class switching. IL-4 also has an important role in tissue adhesion and inflammation.

IL-4 has been shown to have antitumor and immunomodulatory activity against many human hematopoietic and solid tumor cells in vitro. In isolated cases, however, IL-4 was found to have mitogenic activity toward human T-cell leukemia cells. IL-4 receptors are expressed on solid human tumor malignancies. IL-4 inhibits the growth of many solid tumor cell types including malignant ►melanoma, ►breast carcinoma, ►ovarian carcinoma, ►mesothelioma, neurofibrosarcoma and ►renal cell carcinoma, ►non-small cell lung carcinoma and ►colon carcinoma. Antitumor activity of IL-4 has been explored in various animal models. For example, when injected around tumor draining lymph nodes directly into a solitary tumor nodule or intraperitoneally for systemic metastasis, IL-4 has been shown to have significant antitumor activity. Also, transfection of the IL-4 gene induces killing of many tumor types in vivo. In addition, IL-4 potentiates the antitumor effects of TNF or IFN-γ on a variety of tumor cell lines.

Clinical Relevance

IL-4 has diverse effects on health and many pathological states. IL-4-mediated Th2 cell response may avoid the extensive inflammatory tissue injury and prevent autoimmunity by downregulating Th1 cell response. IL-4 has also been shown to have potent antitumor activity in vitro. On the other hand, IL-4 and its receptor are the essential mediators in the development of allergic and inflammatory diseases. Inappropriately high IL-4 production has also harmful effects in infectious diseases. In addition, abnormality in IL-4 receptor/JAK/STAT signaling contributes to hematopoietic disorders and tumorigenesis.

IL-4 and Allergic and Inflammatory Diseases

IL-4 is mainly responsible for Th2-driven tissue ►inflammation. IL-4 has been implicated in allergic and inflammatory diseases including allergic rhinitis, urticaria, conjunctivitis, food allergies, asthma and systemic anaphylaxis. A dysregulation of IL-4 production or a change in IL-4 responsiveness may be the underlying abnormality in atopy, the tendency to produce excessive IgE in response to allergens. Allergen-specific T cells from atopic subjects preferentially develop into IL-4-producing Th2 cells and their CD4+ cells exhibit high IL-4 production when stimulated by antigens other than allergens. Moreover, IL-4-deficient mice develop attenuated airway inflammation compared with wild type mice. IL-4 plays a significant role in viral, bacterial and parasitic infections. IL-4 may be involved in the progression of acquired immune deficiency syndrome (AIDS) caused by ►human immunodeficiency virus (HIV-1).

Human Severe Combined Immunodeficiency (SCID)

Human ►severe combined immunodeficiency (SCID) is a set of primary immunodeficiency diseases characterized by profoundly impaired cell-mediated and humoral immunity. More than 50% of SCID cases are X-linked SCID, which manifests complete or profound defects of T cells and NK cells, but carry normal or slightly increased numbers of B cells, leading to death mostly within a year after birth if not treated with bone marrow transplantation. XSCID is commonly associated with mutations that chromosomally map to Xq13 in the γc receptor gene. Mutations occur throughout the entire γc gene, including the extracellular and cytoplasmic domains, which impair cytokine ligand binding as well as signal transduction. These mutations are manifested as deletions, insertions, splice junction defects, point mutations and premature stop codons in the γc gene. The complete dysfunction of the γc subunit in ligand binding and signal transduction results in the typical phenotype associated with XSCID. A form of autosomal SCID exists with clinical symptoms identical to XSCID in which the gene encoding JAK3 is affected.

Definition

IL-6; Is a member of a family of cytokines that includes ►leukemia inhibitory factor (LIF), ciliary neurotrophic factor (CNTF), ►oncostatin M (OSM), IL-11 and cardiotrophin-1 (CT-1). These cytokines are functionally redundant and structurally similar. They also share receptor subunit for signal transduction, and thus elicit similar and overlapping physiological responses. IL-6 is a multifunctional cytokine. In addition to its important roles in the immune response, inflammation and hematopoiesis, IL-6 is also involved in other important physiological processes such as promotion of osteoclast resorption of bone and regulation of the growth of many tumor cells.

Characteristics

The human IL-6 gene was cloned in 1986. It contains five exons in its 5 kb genomic DNA, which is mapped to human chromosome 7p21–p14. IL-6 is first synthesized as a precursor protein of 212 amino acids and the mature IL-6 is a glycoprotein composed of 185 amino acids. Different ►post-translational modifications (e.g., glycosylation and phosphorylation) of the protein results in various molecular masses of 22–28 kDa. The promoter of the IL-6 gene contains binding sites for various transcription factors, including binding sites for ►NFκB and C/EBPβ (CAATT-enhancer-binding protein β), allowing the transcriptional regulation (induction or repression) of the IL-6 gene in response to various stimuli such as ►estrogen, ►interleukin-1 (IL-1) or ►tumor necrosis factor (TNF). IL-6 is produced in various cell types. Major sources of IL-6 production include stimulated ►monocytes, ►fibroblasts and ►endothelial cells.

Genes

The receptor for IL-6 (IL-6R) is composed of IL-6Rα, an 80 kDa IL-6 binding protein and a signal transducer termed gp130. IL-6Rα is similar to other cytokine receptors in the type I cytokine receptor superfamily. Gp130 is a membrane-associated 130 kDa glycoprotein, which is shared among the receptors for CNTF, LIF, OSM, IL-11 and CT-1. The sharing of gp130 provides an explanation for the functional redundancy among the IL-6-related family of cytokines. Binding of IL-6 to IL-6Rα triggers the association of IL-6Rα with gp130. The signal is then transduced through activation of tyrosine kinases, Janus kinase (►JAK), and subsequent activation of downstream transcription factors ►STATs (►signal transducer and activator of transcription), resulting in activation of gene expression. There are a few members within the JAK family tyrosine kinases. Among them, JAK1, JAK2 and Tyk2 have been shown to associate with gp130 and to be activated by IL-6. STATs are tyrosine phosphorylated transcription factors that are activated by JAK tyrosine kinases. There are also a few members in the STATs family. Of these STATs, STAT1, STAT3 and STAT5 are activated in response to IL-6. Numerous studies indicate that STAT3 is essential in IL-6-induced, gp130-mediated signal transduction, regulating various important physiological processes including cell growth, survival and differentiation. Another pathway activated by IL-6 is the ►MAP kinase pathway, which is an important pathway involved in regulating cell differentiation, cell growth and death in response to IL-6 and other growth factors. IL-6 receptor is expressed in both immune- and non-immune tissues, such as prostate tissue and neuronal tissue. As a multifunctional cytokine, IL-6 is able to induce differentiation of B cells, T cells, myeloid leukemic cells and even neuronal cells. IL-6 is also able to induce cellular growth of myelomas, keratinocytes, mesangial cells, ►renal-cell carcinoma, ►Kaposi sarcoma and tumor cells such as ►prostate cancer cells. IL-6 is able to inhibit growth of myeloid leukemic cells and some other tumor cells, such as ►breast cancer, ►cervical cancer, human ►lung cancer cell lines and ►melanoma. The biological activity of IL-6 can be enhanced by other factors such as ►glucocorticoid, which has been recognized to be able to synergize the IL-6 response. In many cases, STAT3 plays essential roles in the synergy between IL-6 and other factors. Soluble form of IL-6Rα can also interact with gp130. Thus, cells lacking IL-6Rα are not responsive to treatment with IL-6 alone but are responsive to co-treatment with IL-6 and soluble IL-6Rα.

Clinical Relevance

IL-6 is related to various diseases. It has been found that abnormal IL-6 production and abnormal expression of IL-6 receptor are related to ►autoimmune disease. Serum IL-6 level may be related to various diseases. Low serum IL-6 levels are observed in some diseases (e.g., ►monoclonal gammopathy), while elevated serum IL-6 levels are associated with other diseases such as human ►prostate cancer. A growing number of clinical observations have revealed the frequent association of

high serum IL-6 levels with ►androgen-independent prostate cancers, suggesting the involvement of IL-6 in prostate cancer androgen-independent progression. IL-6 receptor is expressed in both prostate cancer tissues and prostate carcinomas cell lines. In the absence of androgen, IL-6 is able to activate the androgen receptor, which is involved in prostate cancer androgen-independent progression. STAT3 has been shown to be required for IL-6 to activate androgen receptor in prostate cancer cells. In addition to its role in prostate cancer progression, studies also indicate that IL-6 could function as a growth factor and could be involved in the oncogenic process of other human tumors such as ►renal-cell carcinoma, ►Kaposi sarcoma, ►lymphoma and ►breast cancer. IL-6 is also essential for the osteoporosis (accelerated bone loss) caused by estrogen deficiency. Estrogen has been shown to be able to inhibit IL-6 production. Thus, one of the most common forms of ►osteoporosis is postmenopausal osteoporosis found in women after menopause or ovariectomy, due to overproduction of IL-6 caused by loss of estrogen production. ►Estrogen replacement therapy has thus been used to prevent postmenopausal osteoporosis.

International Agency for Research on Cancer

Definition

IARC; Is an organization under the World Health Organization. IARC evaluates the carcinogenic risks of chemicals, exposures to complex mixtures and other agents to humans. The evaluations are published in monographs in which data on carcinogenicity are critically reviewed. The evaluations result in a classification according to the evidence for carcinogenicity.

Interphase Cytogenetics

Thomas Ried
Genetics Branch, Center for Cancer Research, National Cancer Institute, NIH, Bethesda, MD, USA

Definition

Refers to the analysis of genes and chromosomes in non-dividing nuclei. The method does not require the preparation of metaphase chromosomes, which is necessary for chromosome banding analysis or spectral karyotyping. Interphase cytogenetics is particularly useful for the visualization of ►chromosomal translocations, ►aneuploidy, gene deletions or ►amplifications and structural and numerical chromosomal aberrations in tissue sections, cytological preparations, and other fixed specimen. The technique involves the hybridization of nucleic acid probes labeled with either fluorescent or chromogenic dyes, followed by microscopy and signal assessment.

Characteristics

Interphase cytogenetics employs fluorescence in situ hybridization (►FISH), in which nuclei acid probes tagged to fluorescent molecules are hybridized to cytological preparations from non-dividing cells or tissue sections (chromogenic dyes are used less commonly). The analysis requires a microscope equipped for epifluoresence, and, preferably, a digital imaging system, which can now be complemented with software for image acquisition and signal enumeration. For instance, a trisomy for chromosome 21 could be visualized with DNA probes that specifically recognize this chromosome. All cells that would carry this particular chromosomal aberration would reveal three fluorescent signals, as opposed to two that all normal cells have. And this pattern is independent from the cell cycle, because metaphase chromosomes maintain their structural integrity at all stages, and three signals in interphase cells indicate unambiguously the presence of an extra copy of this chromosome.

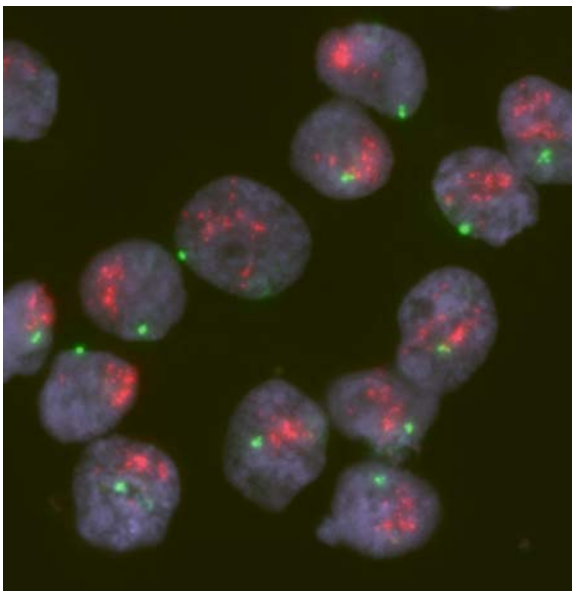
The application of chromosome banding techniques, and molecular cytogenetic analyses, including fluorescence in situ hybridization (FISH), ►comparative genomic hybridization (CGH), and ►spectral karyotyping (SKY) to the analysis of cancer genomes has firmly established that ►chromosomal aberrations are a defining feature of this disease. Chromosomal aberrations in cancer cells occur in different facets. Most of the ►hematological malignancies are characterized by ►chromosomal translocations, which generate an oncogenic fusion protein or cause deregulation of oncogenes. The cells of most solid tumors of epithelial origin (carcinomas), however, contain chromosomal ►aneuploidy that result in tumor type and tumor stage specific ►genomic imbalances. Chromosomal translocations in hematological malignancies comprise, e.g., the ►Philadelphia chromosome, which is a reciprocal, balanced translocation between chromosomes 9 and 22. The detection of this reciprocal translocation in interphase cells can be achieved using either whole chromosome painting probes, or, better, with locus specific probes that hybridize adjacent to the breakpoint. Fluorescence in situ hybridization techniques allow labeling of such probes with different colors, and hence the design of probe cocktails that specifically pinpoint the genetic aberration. For instance, the colocalization of red and green labeled probes in interphase cells would result in a merged yellow color that denotes the juxtaposition of two probes that are separated in normal cells. Similarly, the deletion of tumor suppressor genes can be assessed. Such deletions appear as a lack of hybridization signals. Another class of relevant chromosomal aberrations in cancer cells are chromosomal trisomies. Chromosomal ►trisomy are among the earliest genetic insults in the genesis of solid tumors. For instance, the progression risk of early dysplastic lesion in the uterine cervix can be predicted by the emergence of copy number increases

of the long arm of chromosome 3, which results in the genomic ►amplification of human ►telomerase gene. At advanced stages of carcinogenesis tumors can acquire multiple copies of oncogenes. These ►amplification events correlate in general with poor prognosis, however, can in some instances also stratify patients for specific therapeutic regimens, such as in the case of the ►*HER*-2/neu oncogene amplification in ►breast cancer. Gene amplifications can be very elegantly visualized and quantified by interphase cytogenetics (Fig. 1). A DNA probe that targets the particular oncogene will display multiple copies in interphase cells, and the copy numbers can be correlated to non-involved chromosomes detected with a second fluorochrome.

The application of interphase cytogenetics with sophisticated probe sets has become mainstream for routine diagnostic procedures in hematological malignancies. With the emergence of strictly conserved patterns of genomic imbalances in solid tumors it is conceivable that the visualization of such abnormalities in routine diagnostic samples, for instance in Pap smears or in fine needle aspirations of the breast, will become standard practice as well. One particular advantage of interphase cytogenetics is that the genetic information can be evaluated on individual cells together with such relevant parameters as histo- or cytomorphology. Interphase cytogenetics therefore serves as a tool that allows one to combine pertinent genetic information directly with morphological changes in the progression of solid tumors. This combination of genetics and morphology will improve diagnosis, prognosis and therapy planning, because more predictive information can be obtained. Interphase cytogenetics has the potential to not only systematically integrate tumor phenotype with genotype in hematological malignancies but also in solid tumors.

Future developments of interphase cytogenetics can be envisioned in several areas: (i) it would arguably be useful to increase the numbers of chromosomal targets that can be visualized simultaneously. This can be achieved by combining multiple probes each tagged with a different fluorochrome. Recent developments in fluorescent dye chemistry and in microscope hardware and software along with novel imaging tools, such as spectral imaging, are likely to increase the multiplicity of interphase cytogenetics; (ii) a combination of genetic and chromosomal markers for specific cancers and cancer stages with morphological markers, for instance markers for cell lineage in hematological malignancies, would increase the value of the respective approaches for cancer diagnostics; (iii) finally, automated digital imaging systems and image analysis algorithms for fully automated signal enumeration would facilitate the conversion of interphase cytogenetics towards a high-throughput genetic analysis.

In summary, interphase cytogenetics offers a unique approach for the visualization of genetic and chromosomal aberrations in cancer tissues and cytological preparations on a single cell level. The maintenance of the cellular morphology offers great promise that interphase cytogenetics could contribute significantly to the diagnostic enhancement of the mainly morphologically based evaluation of cancer and its precursor lesions.



Interphase Cytogenetics. Figure 1 The image shows cells from an invasive breast carcinoma after hybridization with a probe cocktail that contains the *HER* 2 oncogene (red). Interphase cytogenetics allows precise enumeration of copy numbers of this growth factor receptor. Only one signal is present for the probe specific for the tumor suppressor gene ►*TP* 53 (green). Such deletions are common in breast cancer.

Interstitial Cells of Cajal

Definition

ICC; Is a type of cell found in the ►gastrointestinal tract. It serves as a pacemaker that triggers gut contraction. ICC serve as electrical pacemakers and generate spontaneous electrical slow waves in the gastrointestinal (GI) tract. Interstitial cells of Cajal embedded in the musculature of the gastrointestinal tract are involved in the generation of electrical pacemaker activity for gastrointestinal motility. This pacemaker activity manifests itself as rhythmic slow waves in membrane potential, and controls the frequency and propagation characteristics of gut contractile activity.

Synonyms

Intrinsically disordered proteins; Intrinsically unstructured proteins; Intrinsically unfolded proteins; Naturally disordered proteins; Naturally unstructured proteins; Naturally unfolded proteins; Disordered domain; Unstructured domain; Unfolded domain

Definition

Intrinsically unstructured proteins are entire proteins or proteins with large segments that lack a rigid three-dimensional structure under physiological conditions.

Characteristics

Proteins fall into a continuum of different structure types that include tightly folded single domains, multidomains interconnected with flexible disordered regions, compact but disordered molten globules, and highly extended unstructured domains. Entire proteins or large segments of proteins (often over 50 residues) may have backbone bonds and angles that vary significantly, and thus, lack a rigid three-dimensional structure.

Bioinformatics studies predict that a significant fraction of many species' genomes codes for intrinsically unstructured domains. These regions are highly conserved between species and the percentage of intrinsically unstructured regions increases with species complexity. Experimentally, over 100 proteins have been shown to be at least partially disordered. It was previously thought that unlike small unstructured proteins and unstructured polypeptide hormones, larger proteins had to be structured to be functional. However, recent work has shown that unstructured domains are more than just flexible linkers, having roles in the assembly of macromolecular arrays, transcriptional regulation, translation, and signal transduction. In fact, the increased intrinsic disorder in more complex organisms may be related to the corresponding increase in complexity in cell signaling and regulation.

In typical cell-signaling networks, most proteins have only one or two binding partners while a few "hub" or "signaling node" proteins have tens, hundreds, or even more partners. Unstructured domains are likely the key to hub promiscuity; hubs may possess unstructured domains that bind multiple proteins or structured hubs may bind unstructured domains in many different proteins. These unstructured domains typically undergo coupled folding and binding, adopting a more rigid three-dimensional fold as they bind their partners.

Many ►tumor suppressor genes and ►Oncogenes are signaling nodes, affecting a wide range of cellular processes. The identification and study of unstructured domains in cancer-related proteins (►Cancer) has revealed multiple roles for these domains in cancer pathophysiology.

Identification of Unstructured Proteins

Classical biochemical methods for identifying protein activities typically select against unstructured proteins; unfolded proteins are more sensitive to degradation by proteases in homogenates, and the low copies of regulatory proteins may provide for low assay activity. However, with the increasing availability of large-scale genome sequencing data and records of already-known unstructured proteins, the prediction of unstructured regions is becoming more efficient. Although one cannot predict the tertiary structure of globular proteins from sequence data (unless there is high sequence homology to a known protein/domain structure), the prediction of unstructured domains is much simpler. Disordered domains are typically composed of polar and charged amino acids (commonly glutamine, glutamic

acid, lysine, serine, and proline; less commonly alanine and glycine), possess a low proportion of bulky hydrophobic amino acids (isoleucine, leucine, methionine, phenylalanine, tryptophan, tyrosine, and valine), and often contain repetitive sequences. Computer programs available for the prediction of unstructured domains include DisEMBL, DISOPRED2, FoldIndex, GLOBPROT 2, and PONDR. DISPROT is a recently established database of protein disorder.

Experimentally, crystal-structure analysis can be used to identify the presence of unstructured states (through the absence of electron density), but long regions of disorder will not crystallize. NMR spectroscopy is the primary method currently used to study disordered proteins, although other methods may include circular dichroism, infrared spectroscopy, vibrational circular dichroism spectroscopy, Raman spectroscopy, fluorescence spectroscopy, size exclusion chromatography, or analytical ultracentrifugation.

Unstructured Proteins and Cancer

In a computational analysis of four protein datasets, ~79% of human cancer associated proteins are predicted to contain ≥30 consecutive disordered residues, compared to 66% for signaling proteins, 47% for eukaryotic proteins from ►SWISS-PROT, and 13% for nonhomologous protein segments with ordered three-dimensional structure. Furthermore, among the human proteins in SWISS-PROT, human cancer associated proteins are predicted to have approximately twofold greater extent of disorder than biosynthesis, degradation, G-protein-coupled receptor (►G-proteins), inhibitors, membrane, metabolism, kinase, or transport proteins. The role of many human cancer associated proteins as signaling hubs, which require selective binding of multiple different targets, points to the importance of disordered domains in cancer biology. Several examples that illustrate the diverse role of unstructured domains in cancer include:

- p53: (►*p53* gene family, ►p53 protein, biological and clinical aspects, ►TP53) The tumor suppressor p53 contains an N-terminal transcriptional-activation domain and a C-terminal regulatory domain. Both are intrinsically disordered (~70% of p53 is unstructured), and the structural flexibility is likely essential for allowing the wide variety of posttranslational modifications known to occur at these sites. Side chains are consequently exposed and regions can reconform to an acceptable structure for different modifying enzymes' active sites. Furthermore, coupled folding and binding likely allows p53 to interact with a variety of proteins, including CBP (cAMP-response element-binding protein) and p300 (►CBP/p300 coactivators). A study of ►*MDM2* –p53 N-terminal transactivation domain binding suggests that this unstructured p53 domain functions as a "fishing line" with a loosely folded "hook." The "hook" adopts a more folded structure after initial ►MDM2 binding; this Mdm2–p53 interaction can hence be regulated by posttranslational modifications.
- p21: (►p21 (WAF1/CIP1/SDI1)) The N-terminal portion of p21 lacks a stable secondary or tertiary structure in free solution. However, this fragment adopts an ordered, stable conformation when bound to cyclin-dependent kinase 2 (Cdk2) (►Cyclin-dependent kinases). The unstructured domain may therefore be responsible for p21 promiscuity, as p21 inhibits a diverse number of cyclin–Cdk complexes (including cyclin A–Cdk2, cyclin E–Cdk2, and cyclin D–cdk4 (►Cyclin D)).
- Cdk2: Cdk2 is almost completely ordered, with only two small regions of disorder. These two regions, however, overlap with the regions that interact with cyclin-dependent kinase inhibitor protein p27/1B ($p27^{Kip1}$).
- ►Bcl-2: This antiapoptotic protein contains a large unstructured loop. Loop phosphorylation can either enhance or inhibit Bcl-2. Upon stimuli such as DNA damage (►DNA damage-induced apoptosis), p53 can inhibit Bcl-2 by binding to its loop domain, and loop phosphorylation prevents this interaction. Taxol (►Paclitaxel, ►Taxol) induces unstructured loop phosphorylation and consequent inhibition of Bcl-2, and may also inhibit Bcl-2 via direct binding. Bcl-x_L, a member of the antiapoptotic Bcl-2 family, can be deamidated (and as a result inactivated) at two asparagines in its unstructured loop.
- WT1: In ►Wilms tumor suppressor protein, alternative splicing can lengthen an unstructured linker, which increases its flexibility and inhibits DNA binding. Both the function and subcellular localization of this protein is altered.
- ►SRC: In Hck and Src, C-terminal tyrosine phosphorylation induces the unstructured linker between the SH2 and SH3 domains (►SH2/SH3 domains) to clamp both domains. This inducible "snap lock" results in protein inactivation. Unstructured domain "snap locking" may also be the mechanism by which ►Cis_2His_2 zinc fingers have their helices stabilized, thereby allowing for the correct orientation to bind to DNA major grooves.
- ►E-cadherin: The cytoplasmic domain of E-cadherin is intrinsically disordered and contains motifs that function as signals for ubiquitin-proteasome-mediated degradation. β-catenin (►APC-β-catenin pathway) binding, however, renders these sequences inaccessible.

Other Roles in Cancer Biology

Disordered domains are involved in many other aspects of cancer pathophysiology, particularly in ►hypoxia-related proteins, histone function, and in other

cell-signaling proteins. Another layer of complexity is added by the fact that intrinsically disordered regions are often located at the sites of ►chromosomal translocations. It is likely that translocations in structured domains lead to the production of nonfunctional and rapidly degraded misfolded proteins, whereas translocations in unstructured domains may lead to a fusion protein with aberrant functions (e.g., joining two structured domains from different proteins). The multiple roles of unstructured proteins in cancer are only beginning to emerge, and further analyses both on a global-scale and on an individual protein basis will advance our understanding of these domains in cancer and disease.

Invasion

Michael Gilcrease
Department of Pathology, Breast Section,
M. D. Anderson Cancer Center, Houston, TX, USA

Synonyms

Tumor cell invasion; Infiltration

Definition

Is a process in malignant cells consisting of penetration of and movement through surrounding tissues.

Characteristics

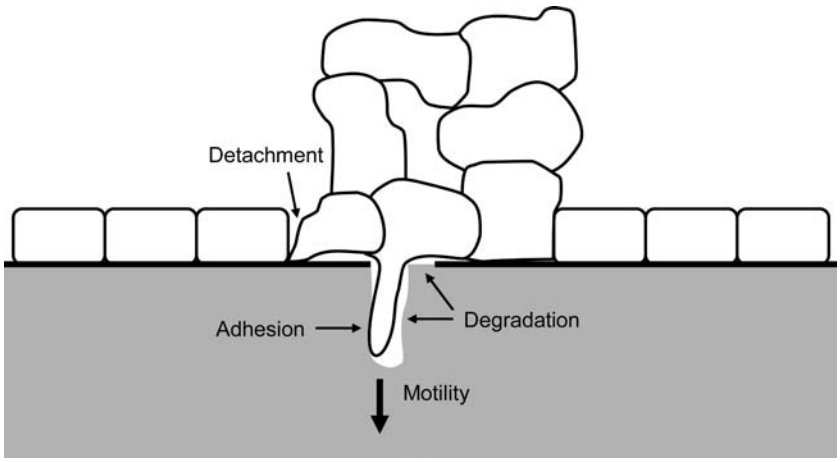
Following an initial period of cell proliferation at the tissue site of origin, malignant cells acquire the capacity to undergo invasion of the surrounding tissues. Some malignant neoplasms undergo extensive local invasion without metastasizing, but invasion is a prerequisite for the development of ►metastasis.

Although the process is not the same for all types of malignancies, the invasion of epithelial-derived malignant cells (the most common type) involves the following steps (Fig. 1):

- Detachment from adjacent cells and underlying ►basement membrane
- Disruption and degradation of surrounding matrix
- ►Adhesion to surrounding matrix components
- ►Migration through the adjacent tissue

Epithelial cells are normally connected to each other by means of ►tight junctions, ►adherens junctions, and ►desmosomes. Transmembrane ►adhesion proteins, particularly the ►cadherin family of membrane glycoproteins, are important components of these cell junctions. Epithelial cells are also adherent to an underlying basement membrane by means of focal adhesions and hemidesmosomes, and integrins are important components of these cell-matrix adhesion complexes. The detachment of tumor cells from adjacent cells and the underlying basement membrane involves disruption of such cell-cell and cell-matrix adhesion structures.

In order to invade the surrounding connective tissue, tumor cells must penetrate the underlying basement membrane. Tumor cells induce secretion of a variety of proteases that become activated and cleave basement membrane proteins, such as collagen IV and laminin. Disruption of the basement membrane provides the malignant cells access to the surrounding connective tissue. Further degradation of connective tissue components by proteases and other enzymes provides a



Invasion. Figure 1 Schematic representation of the steps involved in tumor cell invasion.

pathway that allows the tumor cells to traverse the connective tissue matrix.

Upon dissociating from adjacent cells and detaching from the basement membrane, malignant cells extend filopodia and ►lamellipodia, plasma membrane-covered protrusions of actin-rich cytoplasm, into regions of degraded connective tissue matrix. These protrusions adhere to the surrounding matrix components to initiate tumor cell motility. ►Migration through the connective tissues occurs through a repeating cycle of tumor cell extension at the front of the cell, adhesion to matrix, contraction of actin-myosin filaments, and release of cell attachments at the rear.

In addition to invading connective tissue stroma, malignant tumor cells can invade the perineurium. Particular types of malignant cells are more prone to do this than others. Invasion of the perineurium allows unimpeded tumor extension along the nerves. Invasion of ►lymphatic vessels and blood vessels results in lymphatic and hematogenous dissemination, respectively, with the production of distant metastases.

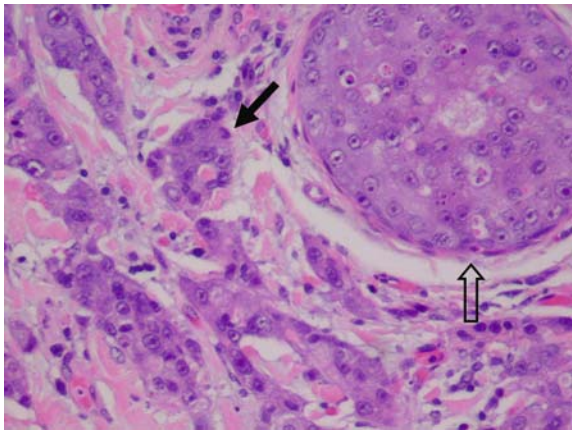
Mechanisms

Detachment of malignant cells from each other and from the underlying basement membrane, the first step in tumor cell invasion, is a consequence of altered cell-cell and cell-matrix adhesion. ►E-cadherin, a principal component of ►adherens junctions in epithelial cells, forms complexes with various members of the catenin family to promote cell-cell adhesion in normal cells. The catenins link E-cadherin to the actin filament network. Downregulation of cell-cell junctions occurs either through decreased E-cadherin expression or increased ►Wnt signaling, which depletes beta-catenin from junctional complexes.

Integrins within hemidesmosomes promote anchorage-dependent growth and survival of normal cells by signaling cooperatively with growth factor receptors to activate cell proliferation and survival pathways. Tumor cell detachment from the basement membrane results from downregulation of cell-surface integrins or dissociation of adhesion complexes.

To disrupt the underlying basement membrane and degrade surrounding matrix, tumor cells upregulate expression of a number of proteases, including serine-, cysteine-, aspartyl- and ►matrix metalloproteinases (MMPs). Plasminogen activators (►plasminogen-activating system) are among the group of serine proteases. Both MMPs and plasminogen activators have specific inhibitors involved in their regulation. Both are known to bind tumor cell surface receptors, thereby localizing matrix degradation to the invading front of the tumor, and protease-mediated cleavage of some cell surface receptors also contributes to tumor cell invasion. In addition to protease secretion by the tumor cells themselves, tumor-stromal interactions induce production of MMPs by surrounding fibroblasts and macrophages.

The migration of tumor cells is stimulated by secreted cytokines and growth factors. The cleavage products of some matrix components are also likely to promote tumor cell migration, as some are known to have chemotactic activity. In addition, alterations in Wnt and integrin signaling associated with cell-cell and cell-matrix detachment, respectively, also promote tumor cell migration. Growth factors can induce not only dissociation of adhesion complexes but also a relocalization of specific integrins to the leading edge of tumor cells. Integrins at the leading edge signal through ►RAS motility pathways to promote tumor cell migration. Wnt signaling not only leads to cell-cell detachment but also promotes tumor cell migration by inducing nuclear localization of beta-catenin with subsequent activation of genes involved in cell motility.



Invasion. Figure 2 Photomicrograph of an invasive ductal carcinoma of breast, the most common form of invasive breast cancer. The portion of the tumor undergoing invasion of the connective tissue stroma (closed arrow) is shown adjacent to a residual component of noninvasive ductal carcinoma in situ (open arrow).

Clinical Aspects

The size of the invasive tumor is used in ►tumor staging to predict the likelihood of tumor recurrence after treatment. The size of the invasive tumor is essentially a quantitative measure of invasion, and tumor size is one of the main determinants of the type and extent of therapy. Microinvasion (less than 1 mm of invasion) has minimal risk of tumor progression after treatment. Greater amounts of invasion increase the likelihood of both local and systemic recurrence (Fig. 2). Tumor invasion can extend beyond the area of involvement identified clinically, resulting in local recurrence following surgical excision. Invasion of lymphatic and blood vascular channels can lead to distant metastasis with widespread dissemination of tumor cells. Although distant metastasis is the cause of death for most cancer patients, extensive local invasion of a malignant neoplasm can compress adjacent vital structures and cause death in the absence of distant metastasis.

Invasive Ductal Carcinoma

Definition

IDC; Ductal carcinoma refers to the development of cancer cells within the milk ducts of the breast. Invasive DC have the capability to invade into the surrounding tissue.

►Endothelins
►Ductal Carcinoma In situ

Inverse PCR

Definition

Has been used for the amplification of unknown DNA segments that lie outside the boundaries of the known sequence. Genomic DNA is digested with appropriate restriction enzymes and self-ligated at low DNA concentration. The circular DNA is used as a template for polymerase chain reaction (►PCR), using primers designed against known sequences. The resulting PCR product contains an unknown segment that is flanked by known sequences.

Inversion

Is a ►chromosomal rearrangement that occurs when a chromosome segment is clipped out, turned upside down and reinserted within the same chromosome.

Ion Channels

Definition

Are transmembrane proteins allowing the passage of ions. Most of ion channels require specific signals to switch from a closed to an open state. Activating signals include membrane potential, temperature, vibrations and a variety of ligands like neurotransmitters, hormones and ATP.

►Ether à-go-go Potassium Channels

Ionization

Definition

Is the departure of an electron from an atom.

►Proton Beam Therapy

Ionizing Radiation

Definition

Is any type of radiation with energy sufficient to eject one or more from outmost orbital electrons from the atom or molecule; this process is called ionization. Examples of ionizing radiation used in radiation therapy are protons, electrons, X- and γ-rays. The proton is the nucleus of the hydrogen atom. The hydrogen atom consists of one positively charged proton and one negatively charged external electron. The proton is about 1,800 times heavier than electron. Protons can be accelerated to high energy in a cyclotron. Hospital-based cyclotrons are being used to treat a broad spectrum of cancer patients. Electrons can be accelerated to high energy by such devices as linear accelerator. Linear accelerators are widely used in cancer therapy. A positively charged electron is called positron. ►Isotopes that emit positrons are used in a nuclear medicine imaging procedure called ►positron emission tomography (PET scan). X- and γ-rays rays are bundles of electromagnetic energy that travel with the speed of light. In many interactions X- and γ-rays act as particles without mass or charge (photons). X-rays are used in the imaging procedure called CT (►computed tomography) or CAT scan. γ-rays are used in specialized procedure called Gamma Knife stereotactic radiosurgery, an alternative to open brain surgery. The Gamma Knife consists of 201 beams of γ-radiation emitted by radioactive cobalt, focusing on one area of the brain. This new technique is very useful at treating certain malignant and benign tumors that could be inaccessible or inadequate for open surgery.

Definition

Ionizing radiation therapy, or radiotherapy, is the clinical use of ionizing radiations for the treatment of ►cancer.

Characteristics

►Ionizing radiation consist of photons or charged particles which interact with molecules to break covalent bonds. The aim of their use in radiotherapy is to cure cancers by killing tumor cells. This is done by the production of reactive free radicals that damage DNA, the genetic material within a cell, which is the main target. Multiple types of ►DNA damage are produced including ►DNA double-strand breaks where both strands of the helix are broken. Cells have mechanisms for ►repair of DNA double-strand breaks, but some will be repaired incorrectly or left unrepaired. Incorrectly repaired DNA damage may lead to mutations. Unrepaired double strand breaks lead to cell death from the formation of damaged chromosomes. In some situations irradiated cells can commit suicide via the process of ►apoptosis, or programmed cell death. Many things modify the effectiveness of ionizing radiations to kill cells. One important modifier is oxygen, which normally sensitizes cells to radiation. In the most solid tumors, due to poor blood supply, which is highly disrupted within a tumor, ►hypoxic regions lacking oxygen can occur which are more resistant to radiation treatment.

Radiation can be used as either a ►palliative or ►curative treatment. For palliative use, the requirement is not to cure the tumor but to reduce pain and swelling, prevent bleeding or prevent tissue damage and ulceration with a view to improving quality of life under conditions where the tumor is incurable.

For curative use the aim is to optimize the delivery of dose to the tumor whilst minimizing the dose delivered to surrounding normal tissues. Damage to surrounding normal tissues can lead to a risk of complications including loss of function and increased secondary cancer risk. In many cases radiation therapy is combined with other treatments including chemotherapy

and surgery as either an ►adjuvant, ►concomitant or ►neoadjuvant treatment.

Whole body or total body irradiation (►TBI) can also be used when bone marrow cells from another donor are to be transplanted, especially in cases of ►leukemia.

Radiation can be delivered from external beams which nowadays are electron linear accelerators (Linacs) of 6 or 18 MV. These use microwave technology to accelerate electrons onto a solid target to produce X-rays. The radiation exits the accelerator via a gantry which can move around the patient who is on a moveable treatment couch. The beams from these linacs can be directed to irradiate the tumor using either conformal or stereotactic approaches.

►Intensity modulated radiation therapy (IMRT) is becoming common where both the profile and intensity of the beam is modulated using sophisticated multileaf collimators. The aim is to shape the beam to deliver maximal dose to the tumor whilst avoiding or minimizing dose to critical tissues, such as the spinal cord.

Treatment planning is used to determine the site of the tumor and delivery regime for irradiations. The tumor size is defined by the gross tumor volume (GTV). Due to uncertainties on the extent of the tumor interaction with normal tissues at is edges, movement of the patient and organs during irradiation, a larger volume, termed the treatment planning volume (PTV) is used. Combinations of conventional diagnostic X-ray images, computed tomography (CT), magnetic resonance imaging (MRI) or more recently ►positron emission tomography (PET), which uses tracer radionuclides such as 18-Fluorodeoxy-glucose, are used to image the tumor volume to allow the PTV to be prescribed. A new approach is to use real-time imaging coupled with real-time adjustment of the beams to improve uncertainties via image guided radiation therapy (IGRT).

The dose to be delivered is dependent on the volume of the tumor, the ►radiosensitivity of the tumor cells and the surrounding normal tissue. Most radiotherapy schedules are given as fractionated doses typically varying from 1.8 to 3 Gy per day delivered over a 6–8 week period delivering total dose of up to 75–80 Gy. The aim is to maximize the effect in tumors whilst protecting normal tissues. For palliative treatments reduced numbers of fractions are typically given with higher dose per fraction.

►Brachytherapy involves the delivery of high dose within a tissue or organ using implanted seeds or wires containing radioisotopes. It is commonly used for accessible tumors such as cervix, head and neck and prostate. For example Iodine-125 seeds can be permanently placed into prostate tissue (interstitial brachytherapy) to treat prostate tumors. Radioactive wires, commonly Iridium-192 can also be placed in tissues using automatic (after-loading machines) procedures to minimize radiation exposure of personnel. The procedures aim to deliver localized high doses to tumors, minimizing dose to other critical organs and reducing side-effects.

Radioisotopes can also be infused into tumors via the blood supply to be selectively taken up at particular sites. These include using Strontium-89 to treat bone ►metastasis, Iodine-131 to treat ►thyroid cancer and radiolabeled ►somatostatin analogues or Meta-iodobenzylguanidine (MIBG) to treat ►neuroendocrine tumors. Radioisotopes can also be tagged to specific antibodies designed to recognize antigens or receptors expressed by tumors. This is called ►radioimmunotherapy. For example Iodine-131 and Ytrium-90 have been tagged to anti-►CD20 antibodies for the treatment of ►non-Hodgkin lymphoma. These have the advantage that they can be used for small tumors and disseminated diseases including metastasis but disadvantages in that uptake into tumors can be limited. The radioisotopes of choice are those which emit short-range electrons or alpha-particles to minimize killing of cells to localized regions. In the future it may be possible to combine PET imaging of specific targeted isotopes with therapy to get good estimates of dose-delivery.

Charged particles such as protons and carbon ions are used as alternative to electrons or gamma rays. Charged particles deposit their energy in a characteristic way leading to the production of a Bragg peak. This allows these radiation to produced defined dose delivery to depths within the body. This advantageous when tumors are very close to critical structures and in the use of radiotherapy in children. Protons have a similar biological effectiveness to electrons and X-rays, but carbon ions are more effective or damaging per unit dose. Carbon ions can also overcome the limitations of low oxygen concentration in tumors as they are equally effective in the presence or absence of oxygen.

Tissues respond in different ways to radiation exposure. Some react quickly, via what are termed “early effects” These can occur in weeks to a few months after exposure and mainly involve parenchymal cells. Others respond at much later times, months to years after radiation exposure, mainly involving connective tissue and are called “late effects.”

Examples of early effects include mucositis, dermatitis and depletion of the cellular compartments of the bone marrow. Many of these response can be transient in nature and dependent on the rate of turnover of epithelial cells.

Examples of late effects include radiation nephropathy, telangiectasia, lung or subcutaneous fibrosis, chronic myelopathy and bone necrosis. They tend to be restricted to slowly turning over tissues such as CNS, lung, liver, heart and kidney. Some tissues can show both early and late effects. For example, the skin can show early epidermal reactions followed by later fibrosis.

IQGAP1 Protein

Laurent Balenci, Jacques Baudier
INSERM Unité Mixte 873,
Grenoble Cedex 09, France

Synonyms

IQ motif-containing GTPase activating protein

Definition

IQGAP1 is the best-characterized member of the IQGAP family of eukaryotic proteins that were first identified in 1994 in metastatic human osteosarcoma cells. This family of proteins is found in a wide spectrum of species and is highly conserved throughout the evolution from yeast to human. The name refers to the presence of "IQ" motifs and a domain similar to Ras ►GTPase-activating proteins (GAP).

Characteristics

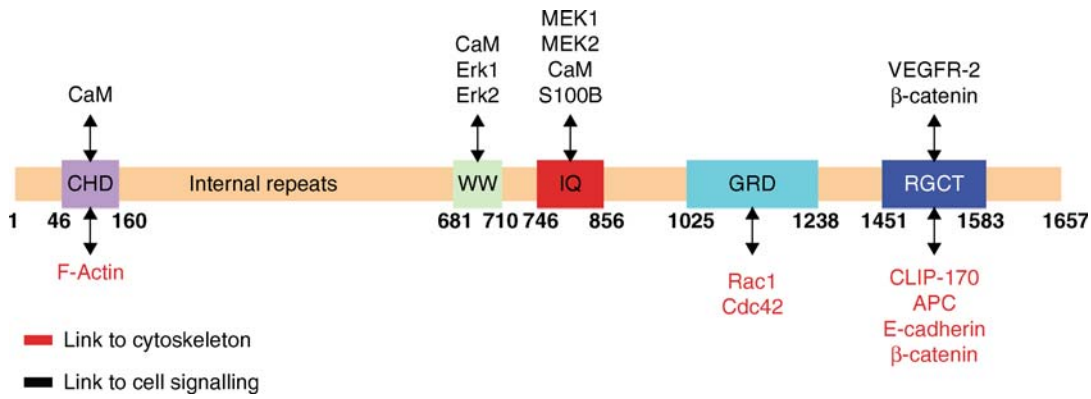
IQGAP1 is a member of IQGAP family that has been characterized in yeast, Hydra, worms, and mammals. The human IQGAP1 isoform is most similar to mouse IQGAP1 (94% identity) and has 62% identity to human IQGAP2. IQGAP1 is the prototype of this family and the most extensively studied member. IQGAP1 is a multi-modular scaffolding protein that binds to a diverse array of signaling and structural molecules which confers it many different roles in cell physiology. IQGAP1 domains and target proteins are presented in Fig. 1. IQGAP1 contains a calponin homology domain (CHD), four IQ motifs (IQ), a GAP-related domain (GRD) homologous to the GTPase-activating domains of Ras family GTPases, and a RasGAP C terminal (RGCT) domain. Moreover, if IQGAP1 presents a domain that has RasGAP homology (GRD), the catalytic activity is missing. Instead, IQGAP1 inhibits the intrinsic GTPase activity of Rac1 and Cdc42 Rho-family GTPases by stabilizing them in their active GTP-bound form.

The primary sequence of IQGAP1 contains numerous binding domains able to link many proteins involved in different biological responses. These domains are CHD, poly proline protein–protein domain (WW), IQ motif (IQ), Ras GTPase-activating protein related domain (GRD), and RGCT. Numbers represent amino acid residues. Different target proteins in red represent a link with cell cytoskeleton and, in black, a relationship to cell signaling.

Functions

For several years IQGAP1 has been demonstrated as one of the principal regulator of ►cytoskeleton architecture. More recently, IQGAP1 has been considered as a signaling crossroads by linking components of signaling cascades or membrane receptors which initiate them. Firstly, through its CHD domain or its partners as Rac1/Cdc42 Rho GTPases, IQGAP1 is able to act directly or indirectly on actin network to regulate cell ►migration and neurite outgrowth. Moreover, IQGAP1 is present at cell–cell contacts where it interacts with ►E-cadherin and β-catenin to modulate cell–cell ►adhesion. In epithelial cells, IQGAP1 captures and stabilizes ►microtubules through the microtubule-plus-end binding proteins CLIP-170 and APC near the cell cortex, leading to establishment of cell polarity and to a directional cell migration. Through its global impact on cell cytoskeleton IQGAP1 appears as a major coordinator of actin and microtubule networks which is primordial for a tuneful cell migration.

Secondly, IQGAP1 can influence a large range of cellular functions by participating in several signaling pathways and by interacting with a heterogeneous group of receptors. For example, in endothelial cells, the interaction between IQGAP1 and the cytoplasmic domain of ►VEGFR-2 (Flk-1) controls endothelial cell ►migration and proliferation. In other respects, IQGAP1 can interact with calmodulin and S100B both



IQGAP1 Protein. Figure 1 Structural binding domains and partners of IQGAP1 protein.

proteins susceptible to Ca^{2+} and with components of ►Mitogen Activated Protein Kinase (MAPK) signaling which impacts on underlying biological responses from ►migration to proliferation/differentiation processes. Surprisingly in light of the multiple functions that have been attributed to IQGAP1, *Iqgap1*-►knock-out-mice do not show any drastic defects during development or for most of their adult life. Their only obvious phenotype is a late onset gastric hyperplasia, suggesting that the protein may carry out a nonredundant function to maintain the integrity of the gastric mucosa in older animals.

IQGAP1 and Cancer

Convergent evidence hypothesize a putative role of IQGAP1 in ►carcinogenesis. IQGAP1 is overexpressed in numerous neoplasms, including ►gastric cancer, ►colorectal cancer, and ►ovarian cancer particularly at the ►invasion front. In advanced gastric carcinomas, IQGAP1 is located at cell–cell junctions where it inhibits ►E-cadherin-mediated cell–cell adhesion. These cell–cell contacts are important for self-renewal, differentiation, and regulation of cell homeostasis. Other interacting partners of IQGAP1 such as ►Rho, ►GTPases, ►calmodulin, and ►β-catenin are also known to be present and upregulated in several malignant and metastatic cancers to stimulate cell proliferation and/or to enhance cell ►migration. In human glioma cell lines IQGAP1 was overexpressed and concentrated at the leading edges of migrating cells. Recent studies provided evidence of the existence of a specific tumor subpopulation within a variety of tumor types with a tumorigenic potential that have a lot of common features with ►stem cells. The thorough characterization of these tumorigenic cells in a rat model of N-ethyl-nitrosourea (ENU, an ►alkylating agent) induced glioma and in human glioma gave rise to the identification of IQGAP1 protein as a reliable marker and allowed to discriminate ►glioblastoma (GBM) from ►oligodendroglioma. Glioma are the most common primary ►brain tumors which are subdivided into two major groups: oligodendroglioma and ►astrocytoma including the most malignant form, the GBM. In ►GBM, the expression of IQGAP1 characterizes a high mitotic cell population which forms perivascular niches. Moreover, this IQGAP1-positive cell subpopulation isolated from human GBM have numerous features of "►cancer stem-like cells" by growing in clonal tumor spheres in suspension culture and by expressing ►stem cell markers. The GBM "cancer stem-like cells" which have the exclusive ability to drive tumor formation, represent a minor population within the tumor bulk and could provide an effective target for therapies. Taking into consideration the well-known function of IQGAP1 in the regulation of cell migration, IQGAP1 might also play an essential role in the invasive character of malignant tumors by promoting the dissemination of these amplifying cancer stem-like cells.

Irinotecan

Floris Aart de Jong
Amgen BV, Breda, The Netherlands

Synonyms

CPT-11; Campto®; Camptosar®

Definition

An intravenously administered classical anticancer drug, registered for the first- and second-line treatment of ►colorectal cancer. Other administration routes, e.g., oral formulations, have been studied as well.

Characteristics

Colorectal cancer (►Colon cancer) includes cancer of the colon and the rectum. To give an impression of its burden of disease, in Europe about 375,000 new cases of colorectal cancer are diagnosed yearly, whereas its incidence in the US is estimated to be about 150,000 new cases per year, with a small overrepresentation of males (odds ratio, 1.1). Yearly, in Europe about 200,000 people die from colorectal cancer, making it the second most common cause of cancer death (►Aging). Over the last years, the death rate from colorectal cancer has gone down somewhat, which is in part attributed to a declining incidence. In addition, as a result of the emerging (systematic) use of screening tests in combination with higher symptom awareness, colorectal cancer is more often detected in an earlier stage (►Colorectal premalignant lesions), improving the chances of cure. Unfortunately, still more than 60% of cases are detected when the cancer is advanced, that is irresectable and/or metastasized to other parts of the body. As a result of the blood flow from the digestive system through the portal venous system directly to the liver, not infrequently metastases of colorectal cancer are confined to the liver. For most cancers, metastasized disease means a poor prognosis, and primary purpose of treatment is palliation (►Palliative therapy). However, there is increasing evidence that this picture is quite different for colorectal cancer when metastases are found solely in the liver. At present, for patients with metastases confined to the liver, resection is considered the standard of treatment. If surgery is possible, the 5-year survival rate is over 40%, otherwise median survival is about 6–9 months. Preferably, patients with irresectable and/or metastasized (not confined to the liver) colorectal cancer should be treated with anticancer drugs that have been found to be effective in the treatment of colorectal cancer, such as irinotecan.

Mechanism of Action

In the early sixties of last century, the cytotoxic potential of ►camptothecin, a plant alkaloid isolated from *Camptotheca acuminata* (family Nyssaceae), was discovered. Unfortunately, in the early development, severe and unpredictable adverse effects, in particular ►myelosuppression, diarrhea, and hemorrhagic cystitis, were seen in clinical studies, limiting its further clinical development.

Later on, these adverse effects were attributed to the rapid and full conversion of the pharmacologically active lactone form of camptothecin to its toxic and inactive carboxylate form in plasma. This finding resulted in a renewed interest in this drug and the development of various (semi-)synthetic and water-soluble derivatives, including 9-aminocamptothecin and 9-nitrocamptothecin, diflomotecan, topotecan, lurtotecan, and the ►prodrug irinotecan. Like other analogues of camptothecin, irinotecan and in particular its active metabolite ►SN-38 reversibly stabilize the "►cleavable complex," that is the covalent interaction between DNA and the nuclear enzyme ►topoisomerase I, by binding to it, thus preventing the resealing of single strand breaks. In this way, irinotecan prevents the replication fork to proceed, which ultimately results in its antitumor effect and its characteristic adverse effects on rapidly dividing tissues, such as bone marrow and intestinal mucosa.

Position of Irinotecan

After its introduction into clinical practice in the late fifties, ►5-fluorouracil has become the mainstay of chemotherapeutic treatment for advanced colorectal cancer. The introduction of irinotecan and oxaliplatin to the drug market in the nineties has resulted in significant steps forward. Indeed, in large prospective randomized trials (►Clinical trial), the addition of irinotecan or oxaliplatin to 5-fluorouracil and leucovorin has been shown to result in a significant clinical benefit in terms of response rate, progression-free survival, overall survival, and quality of life, irrespective of regimen. Both in the US and Europe, irinotecan has been approved for the first- and second-line treatment of irresectable and/or metastatic colorectal cancer in 2000. In trials investigating the benefits of the addition of irinotecan or oxaliplatin to 5-fluorouracil and leucovorin, it has been shown that overall survival increases with the number of patients who are able to receive second-line therapy. However, since only half of patients may actually be well enough to receive a second-line therapy, the choice of a most advantageous first-line regimen is critical. For the moment, taking into account all the published data regarding antitumor effects and adverse effects of irinotecan and oxaliplatin, a clear choice cannot be made for the preferential use of one of both drugs. Apart from colorectal cancer, responses to irinotecan therapy are also seen in various other types of cancer, including lung (►Non-small cell lung carcinoma), ►esophageal cancer, ►pancreatic cancer, and ►gastric cancer) malignancies. In Europe, irinotecan monotherapy is given at a dose of 350 mg/m^2 every 3 weeks, whereas in the US, irinotecan is administered on a weekly basis (125 mg/m^2). Irinotecan is also combined with both 'classical' and targeted anti-cancer agents.

Adverse Effects

Regardless of its schedule of administration, ►myelosuppression and delayed-type diarrhea are the most common severe adverse effects of irinotecan therapy (grade 3 or 4, according to the Common Terminology Criteria for Adverse Events (►CTCAE) Version 3.0). Myelosuppression is seen in about 15–20% of patients, whereas severe delayed-type diarrhea is characteristically seen in 20–25% of patients about 5 days after start of therapy. In particular the occurrence of diarrhea can be debilitating and potentially life-threatening and may have significant clinical implications, as it affects the dose that can be safely administered. The interindividual variability in both systemic and intestinal exposure to SN-38 has been associated with its occurrence. There is fairly strong evidence that patients with low capacity to detoxify SN-38, such as patients with ►Gilbert syndrome, have a higher risk of irinotecan-induced ►neutropenia as well as diarrhea. Given this association as well as the lack of sufficient information to recommend a relatively safe dose for patients with hepatic dysfunction, irinotecan should not be given to patients with Gilbert's syndrome, or serum bilirubin levels over 2.0 mg/dl and/or transaminase levels over three times the institutional upper limit of normal (in case of liver metastasis, over five times).

Other relatively frequently reported adverse effects of irinotecan include nausea, vomiting (►Emesis), anorexia, constipation, anemia, asthenia, abdominal pain/cramping, pain, and ►alopecia. If cholinergic symptoms of rhinitis, increased salivation, miosis, lacrimation, diaphoresis, flushing, and intestinal hyperperistalsis that can cause abdominal cramping and early diarrhea occur, they are usually seen during, or shortly, after infusion. Since cholinergic symptoms are thought to be related to the anticholinesterase activity of irinotecan, they can be (prophylactically) dealt with intravenously or subcutaneously administered atropine.

Metabolism and Excretion

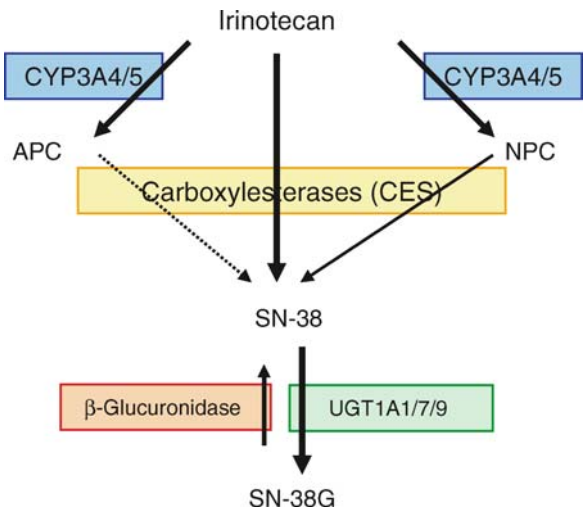
In humans, irinotecan (7-ethyl-10-[4-(1-piperidino)-1-piperidino]carbonyloxycamptothecin) is hydrolyzed into its active metabolite SN-38 (7-ethyl-10-hydroxy-camptothecin) by ►carboxylesterases, present in serum, in the epithelial lining of the intestines, in tumor tissue, and in high content in the liver. It has been suggested that activation of irinotecan into SN-38 in the tumor itself might be even more important than systemic circulating SN-38 levels formed by hepatic carboxylesterases. Besides being hydrolyzed into SN-38, irinotecan is also sensitive to a Phase I oxidative reaction, mediated by ►cytochrome P450 3A (CYP3A) isoforms and resulting in the formation of inactive metabolites, including APC (7-ethyl-10-[4-N-(5-aminopentanoic

acid)-1-piperidino]carbonyloxycamptothecin) and NPC (7-ethyl-10-(4-amino-1-piperidino)carbonyloxycamptothecin). Although in different extents, these substances are supposed to be further metabolized into SN-38 by carboxylesterases. The primary pathway of ►detoxification of SN-38 is a Phase II glucuronic acid conjugation reaction that results in the formation of a β-glucuronic acid conjugate (SN-38G; 10-*O*-glucuronyl-SN-38). This ►glucuronidation is mediated by uridine diphosphate-glucuronosyltransferase (UGT) isoforms, especially 1A1, in decreasing order of importance (Figs. 1 and 2).

Exposure to irinotecan and its active metabolite SN-38 is substantially reduced in patients concomitantly receiving CYP3A enzyme-inducing drugs, such as phenytoin, phenobarbital, carbamazepine, rifampin, and rifabutin. Indirectly lowering the exposure to SN-38 and thus reducing the potential antitumor effects of irinotecan, such pharmacokinetic (►Pharmacokinetics/►pharmacodynamics)-based drug–drug interactions may have major clinical ramifications. Since activity and expression of CYP3A are easily influenced, also complementary alternative medicines (►CAM), such as ►St. John's wort and garlic, may affect the pharmacokinetic and clinical profile of irinotecan. Conversely, inhibition of CYP3A by ketoconazole, for example, may result in lower formation of APC and NPC, leaving more irinotecan available for conversion into SN-38. Likewise, modulation of ►UGT1A1 by concomitantly taken inhibitors (such as atazanavir sulfate, indinavir, and ►genistein) or inducers (such as rifampicin and cigarette smoking) may influence systemic SN-38 levels. Although systemic circulating levels of SN-38 are relatively low, distinct relations between systemic exposure to SN-38 (defined as the area under the plasma-concentration vs. time curve; (►AUC) and risk and severity of toxicity have been demonstrated. Therefore, irinotecan should not be prescribed without taking into account the interacting potential of concomitantly used (prescribed) comedication, over-the-counter medication, and CAM-products which are often not mentioned by patients without being asked actively by their physician.

Both the parent compound irinotecan and its metabolites, including SN-38, are excreted by drug-transporting proteins from the adenosine-triphosphate (ATP) binding cassette (ABC) transporter superfamily (►ABC drug-transporters), including ABCC2 (cMOAT; MRP2), and to a lesser extent, ABCC1 (MRP1), ABCC4 (MRP4), ABCB1 (►P-glycoprotein), and ABCG2 (ABCP; MXR; BCRP), via a hepatobiliary pathway into the feces, and to a lesser extent into urine. Besides influencing the renal and hepatobiliary secretion, can play a role in acquired (multi) drug resistance, and can also affect intestinal reabsorption, since both SN-38 and irinotecan are thought to undergo reuptake from the intestines with resulting reentrance of the systemic circulation (►Enterohepatic recirculation).

In the intestines, hepatobiliary excreted irinotecan and NPC may be converted into SN-38 by local carboxylesterases, whereas SN-38G is subjected to endogenous bacterial ►β-glucuronidase-mediated deglucuronidation. In addition to a higher hepatobiliary excretion of SN-38 and a less effective detoxification of SN-38 into SN-38G in the intestinal mucosa itself, both processes are supposed to play a role in the occurrence of local toxic effects of SN-38 on the intestinal mucosa resulting in delayed-type diarrhea.

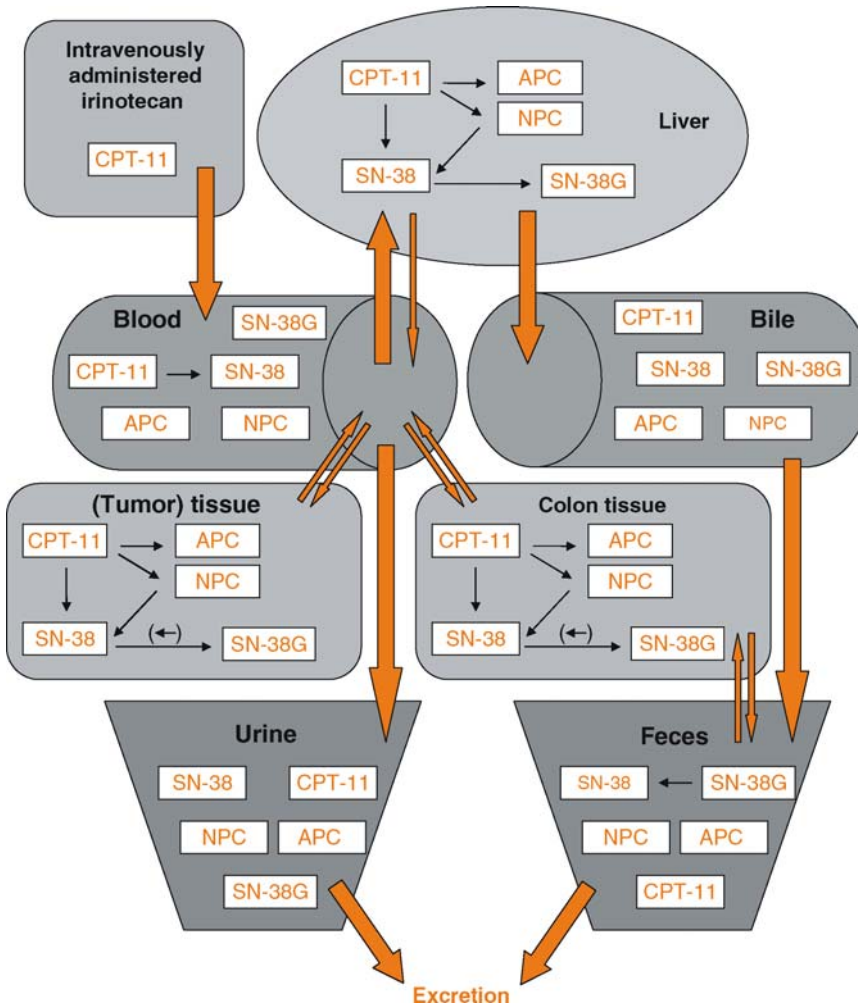


Irinotecan. Figure 1 Schematic representation of irinotecan metabolism.

Dosage Individualization

As is the case for most intravenously administered anticancer drugs, the traditional method of individualizing irinotecan dosage is by using a formula derived from weight and height (that is body-surface area; ►BSA) alone. In the US, single agent irinotecan is generally administered on a weekly basis (125 mg/m^2), whereas in Europe, irinotecan is normally administered once every 3 weeks (350 mg/m^2). However, since irinotecan pharmacokinetic parameters appear to be insufficiently related to BSA, the usefulness of normalizing irinotecan doses to BSA in adults has been questioned. The implementation of a flat-fixed dosing strategy, thus independent of BSA, has been suggested until better dosing methods become available, which might, for example, be based on factors known to impact on irinotecan ►elimination. Many attempts have been made to understand the complex pharmacokinetic profile of irinotecan. As mentioned before, the metabolic pathway of irinotecan involves various

I



Irinotecan. Figure 2 Schematic representation of the ►disposition of intravenously administered irinotecan.

metabolizing enzymes and drug transporters. Since variations in their encoding genes may lead to a significantly altered expression and/or function, such variations may contribute to the variability in pharmacologic profiles between patients. Besides other factors, genetic variations in these genes may therefore be valuable to truly individualize and optimize irinotecan treatment.

Role of Genetic Screening

In particular, the ►*UGT1A1* gene contains many genetic variants influencing the expression and functional properties of its encoded protein (UGT1A1). Polymorphisms resulting in absent or low UGT1A1 activity, have been associated with three heritable unconjugated hyperbilirubinemia syndromes: ►Crigler-Najjar syndrome type 1 and 2, and Gilbert syndrome. Gilbert syndrome has normally no serious consequences. It is frequently seen in Caucasians and has been associated with the presence of an additional, seventh, dinucleotide (TA) insertion (*UGT1A1*28*) in the TATA-box of the *UGT1A1* promoter region, leading to a considerable reduced enzyme expression of about 30–50%. Besides being associated with decreased activity and SN-38 glucuronidation in humans, in particular the homozygous presence of *UGT1A1*28* is a well-known risk factor for the occurrence of severe toxicity. In 2005, the US Food and Drug Administration approved a molecular assay for use in identifying such patients. Following this, the package label of irinotecan was changed, now stating that "Individuals who are homozygous for the *UGT1A1*28* allele are at increased risk for neutropenia following initiation of irinotecan treatment. A reduced initial dose should be considered for patients known to be homozygous for the *UGT1A1*28* allele. Heterozygous patients (carriers of

one variant allele and one wild-type allele which results in intermediate UGT1A1 activity) may be at increased risk for neutropenia; however, clinical results have been variable and such patients have been shown to tolerate normal starting doses." Unfortunately, a precise dose reduction is not yet established, and subsequent dose modifications should be considered based on individual patient tolerance. In addition, showing the limitations and the clinical complexity of the use of ►pharmacogenetics (that is, dichotomous distributions) as basis for dosing strategies, the association between *UGT1A1*28* genotype and diarrhea is far less clear compared to neutropenia. For example, the presence of one or two *UGT1A1*28* alleles explains only about half of all cases of severe diarrhea following treatment with irinotecan, indicating its multifactorial origin. Furthermore, evidence is beginning to emerge that polymorphisms in other *UGT1A* genes may influence irinotecan-related toxicity. For example, variations in the gene encoding extrahepatically expressed UGT1A7 resulting in less transcriptional activity and lower enzyme activity have recently been associated with lower gastrointestinal irinotecan-induced toxicity and higher antitumor response.

Isoflavones

Wim Vanden Berghe, Nathalie Dijsselbloem, Guy Haegeman
Lab of Eukaryotic Gene Expression, LEGEST-University Gent, Gent, Belgium

Definition

Are nonsteroidal phenolic compounds, originally derived from plants, which mainly belong to the family of Leguminosae (soy bean, red clover, various beans, and sprouts). There, they play a role in plant–microorganism interactions, as part of the host's defense mechanisms. However, these molecules constitute a range of other activities as well, by which they may exert health-beneficial effects in humans.

Characteristics

History

Initial interest in isoflavones is based on the history of their discovery in the 1940s. Animals grazing on clover-rich pastures became infertile. Research revealed that isoflavones harbor estrogen-like activities, which lead to their classification into the group of phytoestrogens or plant-derived estrogens. This revelation attracted much interest of the scientific world, as conventional or classical ►hormone replacement therapy (HRTs) for women in the menopausal state were contra-indicated due to negative outcomes of long-term clinical trials.

Examples

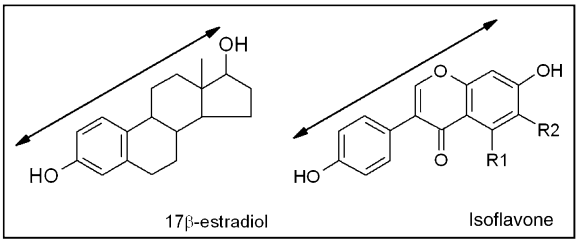
The most abundant isoflavones of soy bean include ►genistein (4′,5,7-trihydroxyisoflavone), daidzein (4′,7-dihydroxyisoflavone), and to a lesser extent, glycitein (4′,7-dihydroxy-6-methoxyisoflavone). Red clover, in contrast, contains mainly the 4′-methyl esters of genistein and daidzein, biochanin A and formononetin, respectively. As soy bean-derived products are widespread, humans are exposed to isoflavones via their diet. In addition, food supplements containing isoflavones exist, mainly manufactured to attenuate menopausal symptoms.

Metabolism

In plants, isoflavones predominantly exist in soluble, inactive sugar-conjugated forms (malonyl glucosides). After ingestion, bacterial and intestinal enzymes hydrolyze and metabolize them on their passage through the gastrointestinal tract. This allows absorption of aglycones into the blood stream and subsequent extensive biotransformations by tissue cells, possibly followed by enterohepatic circulation in case of excretion by bile. Unfortunately, knowledge of the metabolites and their potencies is scarce, as well as the active concentration to which the organs and tissues are exposed.

Mechanisms

Their potential to exert estrogen-like actions lies in their chemical structure, which resembles the planar shape of endogenous estrogen 17β-estradiol (see Fig. 1). Most importantly, the distance of 11–12 Å between the hydroxyl groups at the endings of both skeletons is virtually identical. These characteristics account for their potential to bind to the ligand binding pocket of ►estrogen receptors (ER), and subsequently induce conformation changes that translate in selective gene expression. A mechanistic model of estrogen actions



Isoflavones. Figure 1 Chemical structures of estrogen molecules 17β-estradiol and the isoflavone skeleton.

has emerged, based on the ligand-dependent conformation changes of the complex, which is dynamically modulated by recruitment of ►cofactors and ►post-translational modifications of ER and/or cofactors. The differential structure of the binding platform for cofactors between estrogens and isoflavones determines the specificity in ER-dependent gene transcription, which is furthermore context-dependent as a cell- or tissue-specific balance in coactivators or corepressors for ER exists. Due to their tissue-specific effects, isoflavones are categorized as ►selective estrogen receptor modulators (SERMs) and may be favorable as alternatives in HRT to combat ►osteoporosis and other menopause-associated complaints such as climacteric changes (night sweats, hot flushes), mood fluctuations, vaginal atrophy, etc.

Besides this hormonal function, most studies support their role in cancer prevention and treatment. Many different mechanisms have been reported, including induction of tissue differentiation, inhibition of tissue growth by induction of ►apoptosis, or inhibition of progression through the cell cycle. Isoflavones also diminish the risk on cancer as ►antioxidants, by scavenging radicals and as such, counteracting oxidative stress that intracellularly affects the integrity of DNA and proteins. By inhibiting enzymes in the hormone metabolism (aromatase), isoflavones lower the endogenous estrogen production, which is an essential growth factor for ER-dependent cancer cells. Another essential activity of isoflavones is their capacity to inhibit ►tyrosine kinases, which plays an important role in transmitting growth signals from the environment via growth factor receptors (such as ►EGFR, ►HER-2/neu, ►VEGFR, ►IGFR), to elicit intracellular responses. Also, cross-talk between these signaling pathways and ER in cancer cells leads to estrogen-independent activation of ER proteins, tumor growth, and antiestrogen therapy resistance. As such, interference of isoflavones on the level of tyrosine kinases may affect many growth processes.

At the molecular level, many studies revealed that isoflavones interfere with Rel-dependent transcription. These ►NFκB proteins (of the Rel family) control gene expression involved in apoptosis and ►inflammation. Most breast cancer cells amplify Rel genes or express constitutively active Rel transcription factors to elevate their survival capacity and metastatic potential. Rel inhibition by isoflavones may be multifaceted and acts at multiple levels on the signaling pathways towards activation of NFκB as well as ER.

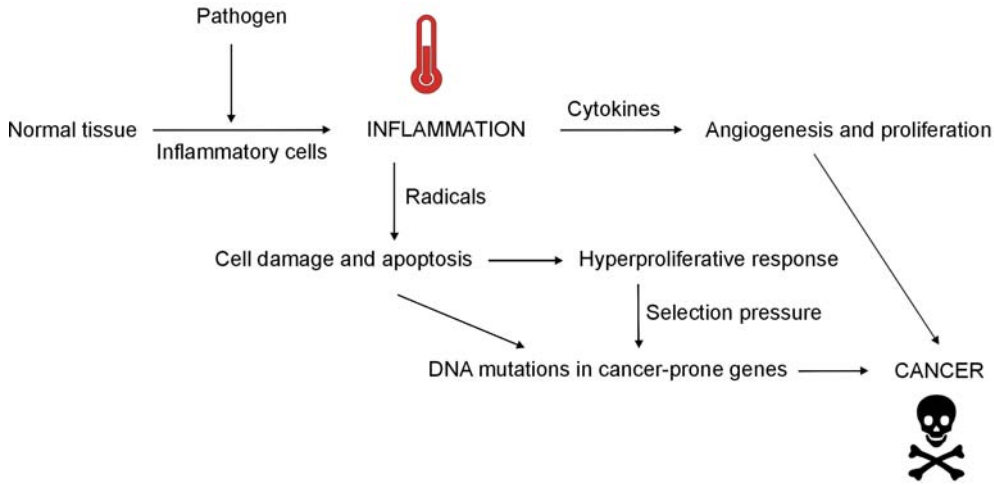
Finally, mice fed with a soy isoflavone diet reveal changes in ►DNA methylation patterns in their offspring. As such, prevention or reversal of hypermethylation-induced inactivation of key tumor suppression genes by isoflavones may be an effective approach to protect against cancer.

Diseases

Besides their possible favorable effect on physiological systems that depend on a good endocrine balance, isoflavones may influence disease onset or pathology too. Epidemiological studies on the relation between isoflavone intake and cancer underscore the potentially protective function of isoflavones. These studies have observed large ethnic differences in breast and prostate cancer rates, among other cancer types. Relatively to US people, a significantly lower incidence and mortality of these hormone-dependent cancers exists in Asian populations, who consume higher amounts of soy bean-based foods. To determine the extent of genetic versus environmental factors, migrant studies have been performed. Emigration towards the West substantially significantly increases the risk on breast cancer and leads to cancer risks tending towards the levels of the native people in the destination country. These findings suggest that rather environmental, behavioral and lifestyle factors influence the cancer frequency between populations. Among these factors, isoflavones play a substantial role as molecular investigation has shown their anticarcinogenic and carcinoprotective feature (see mechanisms). However, controlled clinical trials with isoflavone food supplements are absolutely required to definitely rely cancer protection on isoflavones in man.

In 1863, Rudolf Virchow noted ►leukocytes in neoplastic tissues, and speculated that the chronic inflammatory infiltrate, observed in tumors, reflects the origins of cancer. It has been estimated that more than 15% of all cancers are initiated by chronic inflammatory diseases. This is exemplified by hepatitis or inflammatory bowel disease that predispose to liver cancer or colon cancer, respectively. However, for many inflammation-associated cancers, the initiating influence remains obscure. The finding that long-term use of ►nonsteroidal anti-inflammatory drugs (NSAIDs), such as ►aspirin, markedly decreases ►colorectal cancer risk and strengthens the proposed link between inflammation and cancer (Fig. 2). The proposed mechanism leading to neoplasia includes the ►respiratory burst from inflammatory cells that launches superoxide free radicals, which contribute to malignant transformation by peroxidating lipids in cellular and organellar membranes. Other reactions by free radicals with amino acids or DNA result in protein

I



Isoflavones. Figure 2 Overview of the mechanisms and processes that provide the link between inflammation and cancer.

fragmentation or single-stranded breaks and genetic mutations, respectively. Such cellular damage stimulates apoptotic cell death which elicits a hyperproliferative response in the surrounding tissue and selects for outgrowth of cancer cells. Ultimately, populations of cells bearing survival advantages constitute the phase of malignant transformation and cancer progression, which is further enhanced by ►cytokine-mediated ►angiogenesis and growth. In turn, cancer cells avoid immunosurveillance through outgrowth of poorly immunogenic tumor cell variants (immunoselection) and through subversion of the immune system, by actively suppressing the immune response. Since isoflavones act as antioxidant and interfere with inflammatory cytokine expression, they may attenuate neoplastic transformation by interrupting the intimate connection between (chronic) inflammation and cancer initiation.

Jasmonates in Cancer Therapy

Eliezer Flescher
Department of Human Microbiology, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel

Definition

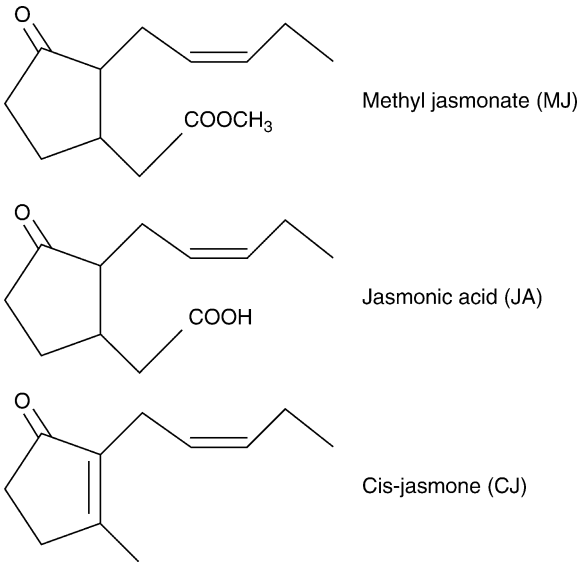
Jasmonates are plant stress hormones that exhibit anticancer activities.

Characteristics

Jasmonates are a family of plant stress hormones. They are lipid regulators that mediate responses to mechanical and infectious stresses in plants. These compounds are derived principally from linolenic acid, and are structurally similar to certain ►prostaglandins (Fig. 1). Programmed cell death often accompanies the antimicrobial response of plants, resulting in the formation of a zone of dead cells around the infection site. Thus, cellular suicide is a characteristic of the ►stress response in both plants as well as animals.

Anticancer Activities of Jasmonates In Vitro and In Vivo

Jasmonates including jasmonic acid and methyl jasmonate (►MJ) can suppress proliferation, induce necrosis and ►apoptosis in various types of ►hematological malignancies, ►leukemia, and ►lymphomas and solid cancers (►colon cancer, ►breast cancer, ►prostate cancer, ►lung cancer, hepatoma, ►melanoma). These compounds are effective against ►drug resistant cancer cells expressing mutant ►p53 or overexpressing ►P-glycoprotein. Interestingly, jasmonates bypass the mutant p53-induced apoptotic block by inducing necrosis. In addition, jasmonates were found to kill preferentially transformed cells, even when these are part of a mixture containing normal and leukemic cells in blood drawn from ►chronic lymphocytic leukemia (CLL) patients. Jasmonates synergize with various chemotherapeutic drugs in their cytotoxic activity. Furthermore, they are capable of suppressing cell motility (an ability essential for ►metastasis) at subtoxic concentrations. MJ prolonged significantly the survival of lymphoma-bearing mice (when



Jasmonates in Cancer Therapy. Figure 1 Members of the jasmonate hormones family occurring in plants.

administered orally as a monotherapy) and leukemia-bearing mice (when administered i.v. together with ►adriamycin). Furthermore, MJ suppressed the colonization of mouse lungs in an experimental metastasis melanoma model. Several studies compared various synthetic derivative of MJ and discovered some that exhibit superior activity in vitro, e.g., methyl 4,5-didehydrojasmonate, and even in vivo, i.e., 5,7,9,10-tetrabromo derivative of MJ.

The Mechanisms of Action of Jasmonates in Cancer Cells

Two major sources of cellular ATP, ►oxidative phosphorylation and ►glycolysis, as well as various mechanisms of ATP consumption, determine the steady state levels of ATP. ATP depletion can result in different settings in either necrosis or apoptosis. MJ induced a decrease in ATP cellular levels hours before signs of cytotoxic effect could be recorded, in a variety of cancer cell types. A positive correlation has been established between the susceptibility of a given cell type to the cytotoxic effect of MJ and the degree of ATP depletion induced in that cell. It was hypothesized that jasmonates induce cancer cell death via a pathway involving ATP depletion. MJ-treated B lymphoma cells exhibited a rapid time- and dose-dependent decrease in cellular ATP levels. When these cells were pretreated with oligomycin (►OM; an inhibitor of oxidative phosphorylation) before treatment with MJ, it did not increase ATP depletion induced by MJ. It thus appears that MJ and OM act on the same ATP biosynthetic source, namely, the ►mitochondria; and that MJ perturbs these organelles to an extent that renders the OM effect irrelevant. Inhibition of glycolysis (by ►2-deoxy-D-glucose) enhanced significantly the effect of MJ on ATP levels, yielding a drastic depletion in cellular ATP levels. Accordingly, high glucose levels protected the B lymphoma cells from MJ-induced ATP depletion, while high levels of pyruvate did not. These results suggest again that in the presence of MJ, mitochondria are unable to utilize pyruvate in order to generate ATP via oxidative phosphorylation. Thus, these findings support the hypothesis that ATP depletion is a major mechanism of MJ-induced cytotoxicity. Furthermore, oxidative phosphorylation in the mitochondria appears to be the target of MJ-induced bioenergetic perturbation. Consequently, the direct effects of jasmonates on mitochondria isolated from cancer cells were studied. Jasmonates induced mitochondrial membrane depolarization in leukemic cells. Further analysis focused on the potent jasmonate derivative MJ. Mitochondria were isolated from human leukemia and hepatoma cells, and their fate in the presence of MJ was determined. The permeability transition pore complex (►PTPC) regulates movement of compounds across the mitochondrial membrane. Abnormally long opening of this pore can be associated with cytochrome c escape into the cytosol, initiating a cascade of molecular events, which culminates in cell death. MJ induced the release of cytochrome c from mitochondria isolated from leukemia and hepatoma cells. However, MJ did not induce release of cytochrome c from mitochondria isolated from normal lymphocytes, suggesting that the preferential effects of jasmonates on cancer cells stem from differences at the mitochondrial level. Inhibitors of the PTPC opening that act via interaction with proteins in the mitochondrial inner membrane: cyclosporin A and bongkrekic acid inhibited the MJ-induced release of cytochrome c from mitochondria isolated from cancer cells. To summarize the bioenergetic mechanism, jasmonates are capable of perturbing directly and selectively mitochondria from cancer cells, thereby depleting their ATP generation capacity, resulting in cell death. This proposed mechanism of action fits the findings that MJ-induced cytotoxicity is transcription- and translation-independent. An essential issue that needs to be addressed is the basis for the selective effect on mitochondria from transformed cells. Several findings suggest that the composition and function of mitochondria in cancer cells and normal cells differ. These include a higher mitochondrial membrane potential, possible modulation of the expression of PTPC components, and enhanced rates of ATP generation through glycolysis rather than through oxidative phosphorylation (a phenomenon known as the ►Warburg effect) in cancer cells.

Two additional mechanisms of action were reported as instrumental in the anticancer activities of jasmonates. One such mechanism is based on the concept of

►redifferentiation, according to which an anticancer agent may suppress neoplastic growth by inducing a reprogramming of the cellular phenotype, resulting in a state closer to its normal tissue of origin. Several markers of differentiation were induced by MJ in HL-60 cells. These include nitroblue tetrazolium (►NBT) reduction, a typical marker of myelomonocytic differentiation (which was also induced by MJ in other myelomonocytic leukemia cells, e.g., U937 and THP-1); Morphologic differentiation into ►granulocytes with some properties of monocytes such as monocytic granules; Expression of both monocyte-specific surface antigen ►CD14 and granulocyte-specific antigen ►CD15; Finally, MJ induced α-naphthyl acetate esterase activity, a marker of monocytic differentiation. Known inducers of granulocytic and monocytic differentiation, all-*trans* retinoic acid and 1α,25-dihydroxyvitamin D_3, respectively, synergized with MJ in the induction of HL-60 differentiation. MJ induced mitogen-activated protein (MAP) kinase activity in HL-60 cells, and PD98059 (a ►MAP kinase inhibitor) suppressed differentiation (NBT reduction) induced by MJ. Thus, MAPK signaling is probably functional in the redifferentiation induced by MJ. MJ was reported to induce the expression of the transcription factor CCAAT/enhancer-binding protein (C/EBP) δ in HL-60 cells, which might contribute to MJ's ability to induce granulocytic differentiation in human myeloid leukemia cells.

A third mechanism of action is focused on ►reactive oxygen species (ROS). MJ-induced ►apoptosis in A549 human lung adenocarcinoma cells can be suppressed by certain antioxidants, including N-acetyl cysteine and catalase (specific for hydrogen peroxide), but not by inhibitors of hydroxyl radicals and superoxide ions. MJ induced an increase in the proapoptotic members of the ►BCL-2 family, Bax and Bcl-X_s, but not in the levels of antiapoptotic proteins, BCL-2 and Bcl-X_L. Catalase prevented the MJ-induced modification in the levels of BCL-2 family members. Thus, induction of apoptosis in A549 cells by MJ appears to be mediated by a cascade involving hydrogen peroxide generation, and an increase in the expression of proapoptotic members of the BCL-2 family of proteins. Since BCL-2 proteins affect mitochondria, and MJ treatment enhanced the levels of mitochondrial ROS in A549 cells, ROS may be involved in MJ-induced mitochondrial perturbation in these cells. This would further support the findings positioning mitochondria at the heart of the jasmonate anticancer mechanism of action.

Biochemical Outcomes Shared by Jasmonate-Treated Plant and Animal Cells

The basis for the study of jasmonates as anticancer agents is in fact part of a much larger scientific endeavor to identify plant-derived molecules as novel potential bio/chemotherapeutic drugs. It is therefore of great significance to identify biochemical outcomes shared by jasmonate-treated plant and animal cells, since such molecular events may further direct the search for new and promising drug candidates. Studies suggest that jasmonates can induce similar metabolic, i.e., ROS generation, signaling, i.e., MAP kinase induction, and stress-associated, i.e., heat shock proteins (HSP) expression, modifications in plant cells as well as in cancerous animal cells. Such alterations are known to mediate cell death and suppression of cellular proliferation.

Conclusions

Since 2002, several research groups in different countries have described the anticancer effects of the plant family of stress hormones called jasmonates. The search for new anticancer agents is mostly driven by the excessive toxicity of currently available chemotherapeutic drugs, as well as the resistance emerging sooner or later toward those drugs. Thus, jasmonates with their high level of selectivity toward neoplastic cells and their efficacy against drug resistant cancer cells, present a unique opportunity to become a novel class of anticancer drugs consisting of a structure dissimilar to any known family of cancer drugs. Furthermore, the most well studied mechanism of action of jasmonates, that of bioenergetic depletion, positions these compounds in the forefront of a very timely approach to cancer therapy based on manipulations of the energy metabolism peculiar to cancer cells. This approach has recently been the focus of leading research groups aiming at decreasing the ATP levels in cancer cells via modifications of its biosynthesis and/or catabolism. Detailed analysis of the effects of jasmonates on cancer cell energy metabolism will undoubtedly embolden our understanding of their mechanism of action, and should eventually lead to the application of jasmonates in clinical oncology.

Synonyms

JNK1; SAPKγ; MAPK8; JNK2; SAPKα; MAPK9; JNK3; SAPKβ; MAPK10; c-Jun N-terminal kinase; Stress-activated protein kinase

Definition

JNK is an intracellular protein kinase that transmits rapidly and efficiently various different types of signals originating from outside of a cell in the process called ►signal transduction. Like other protein kinases, JNK is an enzyme that transmits its signals via phosphorylating its specific substrate proteins. The most studied JNK substrate is c-Jun, a component of the dimeric transcription factor ►AP-1, which gives rise to its name: c-Jun N-terminal kinase. Another name for JNK is a stress-activated protein kinase (SAPK). The p38 MAPKs are also called SAPKs and thus the term SAPK actually refers to both JNK and p38 subfamilies.

Characteristics

JNK subfamily consists of three ►isoforms: JNK1, JNK2, and JNK3. They are encoded by three separate genes: *MAPK8, MAPK9* and *MAPK10*. Alternative ►splicing of these genes can produce at least ten different JNK mRNAs (four JNK1, four JNK2, and two JNK3 splice variants). The JNK protein products that result from these mRNAs are ~46 and 55 kDa in size and differ from each other in their ability to bind to and phosphorylate their substrates like c-Jun (AP-1) and ►ATF2 (AP-1) and in the length of their carboxyl terminus. The JNK1 and JNK2 are ubiquitously expressed and the expression of JNK3 is almost exclusively restricted to heart, brain, and testis.

JNK is constitutively present in cells and its function is regulated by activation. JNK is activated via specific upstream kinase cascade known as ►JNK cascade or ►MAP kinase cascade and phosphorylation events resulting in the phosphorylation of the specific threonine and tyrosine motifs (Threonine–Proline–Tyrosine; TPY) close to the amino terminus of JNK. These motifs are identical in all the different JNK isoforms and splice variants. The specificity of the JNK signaling is believed to be achieved by spatiotemporal regulation of the association of JNK and its upstream kinases with the specific JNK ►scaffold proteins leading to controlled JNK activation. Additional level of specificity can be achieved by the existing isoforms, splice variants and substrates of JNK within the cell, the specific JNK upstream kinases and regulators involved, as well as by cross talk between JNK and other signaling pathways activated by the given stimulus.

JNK can transmit various different types of signals within the cell including inflammatory, developmental, growth-supporting, cancer-promoting, ►apoptosis-inducing, and other stress-related signals. The most studied JNK activators involve ►UV radiation and ►TPA as well as various growth factors and cytokines. JNK can also be activated by ►reactive oxygen species. One important evidence supporting for the role of JNK subfamily in cancer is the fact that JNK resides on the same signaling pathway or is known to signal via many known cancer-promoting ►oncogenes, ►tumor suppressors, and cellular survival proteins that protect cells from apoptosis or ►programmed cell death, including proteins such as ►RAS, ►Myc, ►Her2/neu, ►SRC, ABL (►BCR–ABL), c-Jun (AP-1), ►p53 protein, ►BCL-2, and ►AKT among others.

JNK transmits signals via phosphorylating its specific substrate proteins. The phosphorylation of substrate will change its function or availability by, for example, changing its conformation, activity or stability, and thereby leading to cellular response. JNK is a Serine/Threonine kinase and the consensus JNK phosphorylation site is Serine or Threonine followed by Proline (SP or TP). This sequence is, however, quite common in proteins and can not be used by itself to predict a JNK substrate. The first found and most studied JNK substrate is the protooncogene c-Jun, a part of the dimeric transcription factor ►AP-1. JNK can also phosphorylate other transcription factors, as well as proteins involved in signal transduction, protein degradation, ►migration and programmed cell death, cellular processes whose regulation is altered in cancer.

Experimental evidence suggests both ►tumor suppressor and tumor initiator role for JNK. Probably one of the strongest evidence for the tumor initiator role of JNK comes from the findings that the oncogenic ►RAS augments the activity of JNK and that JNK augments the oncogenic activity of AP-1. Supporting its tumor suppressor role, mutations in JNK3 that inactivate it have been found in human brain tumors. Furthermore, inactivating mutations of ►MKK4, a JNK upstream kinase, associated with reduced JNK activity have been found in human colon cancer, pancreas cancer, breast cancer, and prostate cancer.

Studies of JNK ►isoform-specific knockout mice (►Knockout mouse) and cells derived from them point for divergent biological functions for different JNK isoforms in respect to cancer as well as in respect to other diseases and cellular processes. For example, JNK2 knockout mice are more resistant to

►TPA-induced experimental skin cancer (►Skin carcinogenesis) and mice lacking JNK1 are less susceptible to diethylnitrosamine-induced hepatocarcinogenesis (►Hepatocelxlular carcinoma) than corresponding wild-type mice. Isoform-specific differences can also be observed in RAS transformation of immortalized (►Senescence and immortalization) murine fibroblasts. Experiments involving down regulation of isoform-specific messenger RNAs and subsequent protein levels by expression of antisense oligos or overexpression of ►dominant negative JNK isoforms for the competition of JNK substrates in cells demonstrate different roles for JNK1 and JNK2 in the proliferation of some human cancer cell lines. These studies strongly support for the development of JNK isoform-specific inhibitors. The data of the differences of the various JNK isoforms in cancer have just begun to emerge. The role of different JNK splice variants in cancer development and progression as well as their usability for the development of cancer therapeutics is a subject that will most likely be explored in the near future.

Synonyms

Tissue kallikreins; Kallikrein-related peptidases

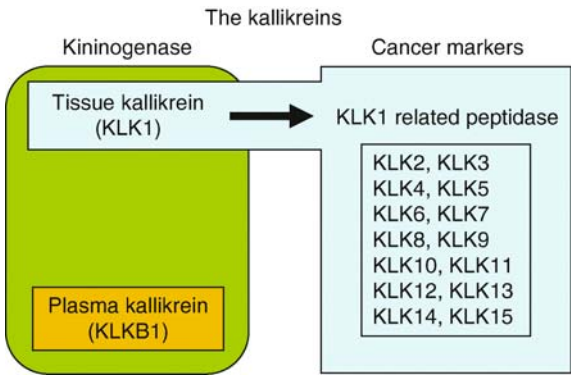
Definition

Kallikreins are a family of ►serine proteases encoded by genes clustered on chromosome 19q13.4. Their expression is associated with progression of several cancers, and they serve as ►biomarkers. Among the kallikreins, ►prostate specific antigen (PSA; kallikrein 3, KLK3) is the most well-known kallikrein.

Characteristics

Kallikreins play important roles in cancer development. For several decades, kallikreins have been known as enzymes that generate bioactive peptides, called kinins, involved in blood-pressure regulation. When the first kallikrein (kallikrein 1) was discovered in 1930, the enzyme was reported to have a hypotensive effect and be present at high concentrations in the pancreas, the organ known as *kallikreas* in Greek. It is now known that kallikrein 1 produces ►bradykinin from ►kininogen. In addition to kallikrein 1, another enzyme found in the blood plasma and encoded by the *KLKB1* gene in chromosome 4q35 also produces bradykinin. To distinguish these two different enzymes, kallikrein 1 is also known as tissue kallikrein and the second enzyme is known as plasma kallikrein. Of all the kallikreins, only kallikrein 1 (tissue kallikrein) and plasma kallikrein have significant kininogenase activity. Discoveries of kallikrein 1 related peptidases and their association with cancers have given new meaning to the term kallikrein (Fig. 1).

More than 20 kallikreins with high sequence similarity to kallikrein 1 were discovered in rat and mouse salivary glands in the 1980s and were assigned to a serine protease family known as the glandular kallikrein family. However, only two kallikreins with homology to kallikrein 1 have been identified in humans. For about two decades, the human kallikrein



Kallikreins. Figure 1 The kallikrein proteases. Kallikreins can be categorized based on their function or structural homology. The conventional kallikreins include tissue and plasma kallikreins, which are kininogenases. The tissue kallikrein-related peptidases are increasingly recognized as cancer markers.

gene family consisted of only three members: *KLK1* (tissue kallikrein, pancreatic/renal kallikrein), *KLK2* (glandular kallikrein), and *KLK3* (prostate specific antigen). Owing to the Human Genome Project and the increased numbers of available genome sequences, a cluster of serine protease genes adjacent to kallikrein 1 have been identified on chromosome 19q13.4. The chromosome location, sequence similarity, and similar expression patterns of these genes in many tissues indicate an extended kallikrein gene family. At present, the human kallikrein family consists of 15 structurally homologous genes.

The Kallikrein Genes

The kallikrein gene family members cluster consecutively on chromosome 19q13.4 and all have several common features in their gene structure. For example, all 15 kallikreins have five coding exons, the first of which contains the 5′-untranslated region. Kallikreins are serine proteases and contain the catalytic triad characteristic of serine proteases. The three amino acid residues – histidine, aspartate, and serine – that constitute the catalytic triad are conserved in the kallikreins. The catalytic triad residues are located on the same exons in all kallikreins: histidine near the end of the second exon, aspartate in the middle of the third exon, and serine at the start of the fifth exon.

Kallikreins are expressed in various tissues at different levels. The most ubiquitous kallikreins, *KLK10* and *KLK11,* are expressed in more than 30 organs. Most kallikreins are expressed in the salivary gland as well as endocrine-related tissues, and the mRNAs of all 15 kallikreins are detectable in the prostate, testis, thymus, and thyroid. All 15 kallikrein genes have more than one transcriptional variant. There are more than 50 splice variants of the 15 kallikrein genes. Some gene transcripts of kallikreins are tissue-specific. Kallikrein expression is regulated by many stimulators and inhibitors. The expression patterns of many kallikrein gene transcripts reflect the different degrees of malignancy and may have clinical diagnostic and prognostic values. The strong expression pattern of kallikreins in endocrine-related tissues prompted several investigators to conduct experiments on the effects of sex steroid hormones on kallikrein expression regulation. The investigations found that most kallikreins are regulated by steroid hormones such as androgens, estrogens, progestins, glucocorticoids, either individually or in different combinations. The results also showed that, in different tissues, different kallikreins are regulated by different steroid hormones. For example, the expression of *KLK4* is upregulated by androgen in prostate and breast cancer cells but by estrogen in ►endometrial cancer cell lines.

The Role of Kallikreins in Tumor Progression

Over the past several years, intensive research on the expression of kallikreins in several ►hormone-related cancers has shown that kallikrein expression levels are associated with cancer. Studies on hormonal cancers have shown that kallikreins may be downstream targets of signaling pathways activated by ►hormones. The study of kallikreins and their molecular mechanisms in tumor formation and progression is an emerging field. The roles of kallikreins in tumorigenesis have not been well characterized; however, it has been suggested that genetic aberrations in the *KLK* locus may account for altered expression of kallikreins during tumorigenesis. Several kallikreins have been found to have dual and disparate roles in tumor growth and invasion.

KLK1, KLK2, and KLK3 may promote tumor growth and survival by degrading ►insulin-like growth factor binding proteins (IGFBPs) to release the mitogenic growth factor ►insulin-like growth factor 1 (IGF1). Kallikreins could also stimulate tumor growth through the ►protease-activated receptors (PAR). Conversely, KLK3 is known to release ►transforming growth factor-β (TGFβ) from its latent form to suppress tumor growth.

Kallikreins have been found to activate tumor growth factor and promote ►angiogenesis via a proteolytic cascade that activates the ►urokinase plasminogen activator (uPA)–urokinase plasminogen activator receptor (uPAR) system. KLK1 stimulates the angiogenic response by releasing bradykinin from kininogen. Bradykinin promotes angiogenesis by upregulating the basic ►fibroblast growth factor (bFGF) or by stimulating the formation of ►vascular endothelial growth factor (VEGF). However, KLK3, KLK6, and

KLK13 are capable of generating an angiostatin-like fragment from plasminogen to inhibit angiogenesis.

Many kallikreins are known to degrade ►extracellular matrix (ECM) proteins either directly or indirectly through proteolytic cascades. Cancer ►metastasis consists of a series of linked, sequential steps, such as attachment of cells to the ECM, production of ECM-degrading enzymes, and increased cell motility; therefore, it is not surprising that proteases such as the kallikreins are reported to promote tumor ►invasion. The molecular mechanisms of kallikreins in tumor-cell invasion and metastasis have not yet been well characterized. Different kallikreins play different roles in tumor invasion and may act differently in different cancers. Although tumor-cell invasion may be due to the proteolytic activity of kallikreins, overexpression of some kallikreins results in suppression of invasion and a favorable prognosis. For example, KLK8 degrades ►fibronectin to disrupt the fibronectin-associated ►integrin signaling pathway. The altered integrin signaling retards tumor cell ►motility to confer a favorable prognosis. All kallikreins share common sequence and function features with proteases. The different roles of kallikreins in tumor growth and invasion may be due to the tumor type and its ►microenvironment.

Kallikreins are secreted proteases and can be found in body fluids or tissues, which allow them to be used as diagnostic and prognostic markers for cancers and for therapy efficacy assessments. Most of the research on kallikreins as markers for diagnosis and prognosis has involved hormonal cancers such as breast, ovarian, testicular, and prostate cancers. Over the past several years, investigators have extended the study of kallikreins to cancers other than hormone-dependent malignancies, including ►leukemia, ►lung cancer, and other cancers. Compared with hormone-dependent cancers such as ►breast cancer, ►ovarian cancer, and ►prostate cancers, much more work is needed to fully investigate the role of individual kallikreins in non-hormonal cancers and their clinical use as diagnostic and/or prognostic markers.

Kallikreins as Diagnostic and Prognostic Markers

Aberrant amounts of kallikrein gene transcripts and/or proteins are found in malignancies such as breast, prostate, testicular, and ovarian cancers. Of the 15 kallikreins, KLK1 and KLK12 have not been established as diagnostic or prognostic markers for many of the cancers investigated so far. KLK3, or prostate specific antigen (PSA), is the most well-characterized kallikrein for prostate cancer diagnosis. KLK2 and KLK11 complement KLK3 to give more accurate diagnosis of prostate cancer. The gene transcripts of many kallikreins are overexpressed in cancer tissues. Antibodies against several kallikreins have been developed for immunoassays. The kallikreins that have been clinically validated as diagnostic markers are listed in Table 1. Given the ubiquitous gene expression of kallikreins in many cancer tissues, kallikreins have great potential as diagnostic markers and further

Kallikreins. Table 1 Kallikreins as serological diagnostic and prognostic markers

Markers	Serological diagnosis	Favorable prognosis	Unfavorable prognosis
KLK1	–	–	–
KLK2	Prostate	–	–

KLK12	–	–	–
KLK13	–	Breast, ovary, testicular	–
KLK14	Breast, ovary	Ovary, testicular	Breast, prostate
KLK15	–	Breast	Ovary, prostate

Abbreviations: ALL, acute lymphoblastic leukemia; RCC, renal cell carcinoma; SCC, squamous cell carcinoma (head and neck); –, not established or not applicable.

investigation in more cancer types than those listed in Table 1 is warranted.

Different kallikreins either promote or inhibit tumor ►invasion and ►metastasis and can be markers of favorable or unfavorable ►prognosis. Different kallikreins have different roles in tumor progression and may act differently in different cancers. Although proteases are known to degrade ECM components to facilitate tumor-cell invasion, Several kallikreins are associated with a favorable prognosis in patients with the cancers listed in Table 1. Of the kallikreins, *KLK5*, *KLK10*, *KLK11*, *KLK14*, and *KLK15* are markers of favorable prognosis for some cancers but of unfavorable prognosis for other cancers. This shows that whether kallikreins promote or inhibit tumor progression depends on the tissue type and the tumor microenvironment. However, further investigation is needed to determine the roles of kallikreins in cancer biology.

Kallikreins are emerging ►biomarkers for cancers. As yet, use of kallikreins as diagnostic markers has been established for only a limited number of cancers. Further investigations are needed to characterize the roles of individual kallikreins in tumor growth, angiogenesis, ►extracellular matrix remodeling, invasion, and metastasis. The use of kallikreins as diagnostic and prognostic markers for more hormonal and non-hormonal cancers, and as therapeutic targets and predictive markers for therapy responses warrants further investigation.

Kaplan–Meier Product Limit Estimator

►Kaplan-Meier Survival Analysis

Kaplan-Meier Survival Analysis

Warren L. May
Department of Preventive Medicine, University of Mississippi Medical Center, Jackson, MS, USA

Synonyms

Kaplan–Meier product limit estimator; Life table estimates; Time-to-event analysis

Definition

Kaplan–Meier survival analysis is a nonparametric method of summarizing survival event probabilities in tabular and graphical form.

Characteristics

Often, the focus of ►cancer epidemiology studies is on measurement of disease-free ►survival time (see also, ►epidemiology of cancer). For example, the success of a breast cancer treatment might be discussed in terms of time-until-relapse or cancer-free survival time. To measure time effectively, a meaningful origin is chosen such as birth, first diagnosis of cancer, beginning of treatment or last known occurrence of the disease. In a randomized study or ►clinical trial, we might begin measuring time at the point of ►randomization to treatment. Typically, time is measured prospectively in a survival study in contrast to the retrospective measurement of exposure in the ►case control association study.

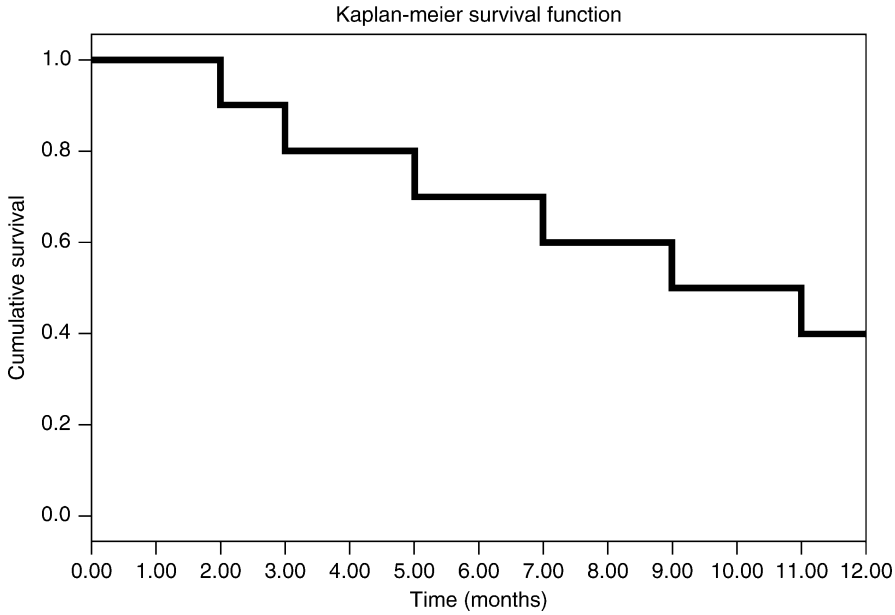
The outcome of interest is often measured as time-until-failure or some other well-defined event. In a cancer study, we might consider death, treatment intolerance or tumor recurrence as failure. Survival analysis methods allow us to discuss the event times in positive terms of survival rather than in negative terms of failure. If t represents the time to a failure or event, then

$$F(t) = P(T \leq t) = P\,(\text{failure occurs at or prior to time } t)$$

is called the cumulative distribution function of the failure times. The complement of the cumulative failure distribution is

$$S(t) = 1 - F(t) = P(T > t) = P(\text{surviving past time } t)$$

and is called the survival function. Note that although t measures the time-until-failure, it also represents the disease-free survival time. Fig. 1 illustrates a typical Kaplan–Meier survival function estimate.



Kaplan-Meier Survival Analysis. Figure 1 Kaplan–Meier survival curve.

K

Censoring

If all individuals in the study fail, we can precisely describe the survival distribution, $S(t) = 1 - F(t)$ Suppose we have decided to follow patients in a clinical trial for 5 years and that our outcome is recurrence at a specific tumor site. For those who are diagnosed with recurring tumor during the study period, exact failure times are recorded. Those who complete the 5-year follow-up but do not have a recurrence are said to be right censored. By focusing on survival instead of failure, we are able to conclude that the survival time was at least 5 years for the censored individuals without knowing the exact time of failure beyond that 5-year study period. In other words, we may not know the exact time of failure for individuals that survived longer than 5 years, but we do know they lived without recurrence for at least 5 years.

In addition to ►censoring by the limits of the study design, individuals may also be censored due to factors beyond the investigators control, such as death from other causes. Although the analysis itself does not distinguish between these types of censoring, one caveat in generalizing results is that intermittent censoring must be non-informative so that the reason for censoring should not be related to the either the time of failure or the treatment choice. In other words, this type of censoring should be random.

Parametric, Semi-Parametric and Nonparametric Survival

Three major divisions are made in the types of survival analyses; ►parametric, semi-parametric and ►nonparametric. If survival times are assumed to follow a specific mathematical distribution, the parameters of that distribution can be estimated from the sample. Perhaps the simplest parametric assumption in survival analysis is one of a constant hazard rate, λ, leading to the failure distribution, $F(t) = 1 - e^{-\lambda t}$, and the complementary survival distribution, $S(t) = e^{-\lambda t}$ that we recognize as exponential decay. Metabolism studies, for example, may exhibit exponential decay. The parameter, λ, is estimated from the data as $\hat{\lambda} = r/T$ where r is the total number of events and $T = \sum t$ is the total of all survival times. Other useful parametric survival distributions are the Weibull, lognormal and gamma distributions.

Another common approach introduced; by D. R. Cox in 1972 and called ►Cox proportional hazards modeling has become one of the most common methods of survival analysis and is based on semi-parametric estimation where the background hazard rate is not estimated. Cox assumed the survival distribution, $S(t) = [S_0(t)]^{\exp(\sum \beta x)}$ where $S_0(t)$ is a baseline hazard rate that is typically treated as a nuisance, x is some covariate of interest and β is the slope parameter associated with that covariate. In this type of analysis, we are usually interested in comparing covariate parameters so that S(t) itself is not estimated fully.

Finally, nonparametric methods including actuarial and life table methods are useful for summarizing survival distributions. Perhaps one of the nonparametric approaches to survival analysis that is most often used in the medical literature is that introduced by E. L Kaplan and P. Meier in 1958. Useful in visualizing

survival data, the Kaplan–Meier curve is plotted as a starting point in most survival analyses. Unlike the parametric and semi-parametric approaches to quantifying a survival distribution, the nonparametric Kaplan–Meier method requires few assumptions other than independence of failure time observations.

Kaplan–Meier Product Limit Estimator

Many of the survival analysis methods, such as Cox proportional hazards models and parametric models, require iterative solutions and specialized software. The Kaplan–Meier Product Limit Estimator, on the other hand, is easily calculated. The r event times are ordered from smallest to largest so that $t_1 < t_2 < t_3 < \cdots < t_r$. For example, assume the relapse times (in months) for ten cancer patients are recorded as (2, 3, 5, 7, 9, 11, 12, 12, 12, 12). If there is no censoring, the Kaplan–Meier estimator at any event time, j, is simply the proportion with event times greater than t_j. For example, at $t = 7$ months four have relapsed and six have not so that the probability of surviving more than seven months is $\hat{S}(7) = 6/10$. In the case of single right censoring at the end of the study, the calculations are similar. If the relapse times are (2, 3, 5, 7, 9, 11, 12+, 12+, 12+, 12+) where "+" indicates censoring, $\hat{S}(7) = 6/10$ is the proportion surviving longer than 7 months as before. In addition to the plot of these data in Fig. 1, we might choose to report summary statistics in the form of quantiles, medians or means. For these data, the median is 9 months since $\hat{S}(9) = 0.5$. The mean is related to the area under the survival curve and, for data sets in which the largest observation is censored, the mean is based on the truncated failure times so that the estimate of the mean is too low. In this case, the mean is 8.5 months.

The probability of surviving can be found using simple counting rules and the multiplication rule for joint conditional probabilities. At each distinct event time, there are n_j individuals at risk of whom d_j relapse and $n_j - d_j$ do not relapse. Assume the event times are recorded as follows: (2, 3, 5, 7, 9, 11, 12+, 12+, 12+, 12+). At 7 months, we find $n_j = 7$ individuals still at risk of relapse of whom $d_j = 1$ relapses and $n_j - d_j = 6$ do not. Applying the multiplication rule to the conditional probabilities for each distinct event time, the probability of surviving past 7 months is

$$\hat{S}(7) = \left(\frac{9}{10}\right)\left(\frac{8}{9}\right)\left(\frac{7}{8}\right)\left(\frac{6}{7}\right) = \frac{6}{10}$$

as we found previously.

If any censored times are less than any event times, we must alter the formula slightly. In essence, the Kaplan–Meier product limit estimator is still an application of counting rules and conditional probabilities but the numbers at risk at some event times are altered due to censoring. Suppose we find that one observation is censored prior to seven months and the event times are recorded as (2, 3, 5+, 7, 9, 11, 12+, 12+, 12+, 12+). In terms of an event, all we know of the individual who was censored at five months is that they at least survived longer than the previous event time of 3 months. The product of the conditional probabilities using only event times is

$$\hat{S}(7) = \left(\frac{9}{10}\right)\left(\frac{8}{9}\right)\left(\frac{6}{7}\right) = 0.6857$$

and is slightly different from the estimate when no censoring prior to seven months was observed. The censored observation provides additional information for the first two periods by increasing the overall sample size. The median survival time for these data is 11 months, illustrating the effect of censoring on the estimates. The mean is 9.1 months but, again, may be too low due to the censoring of all observations at 12 months. In general, the Kaplan–Meier estimator is defined as

$$\hat{S}(t) = \prod_{t_j < t} \left(\frac{n_j - d_j}{n_j}\right)$$

where the product is over the conditional probabilities of all event times prior to time t. The quantity in brackets is the estimated conditional probability of surviving to time $t_j{+}_1$ given the individual has survived to time t_j. The graph is a step function as illustrated in Fig. 1.

Comparing Survival Functions

In many survival studies, a major interest is in comparing survival experiences of two or more groups. For example, if $n_1 = 100$ women given hormone replacement and $n_2 = 100$ women given a placebo are followed for 10 years with age at first diagnosis of breast cancer is recorded, cancer-free survival time between the groups is an important outcome for study. The null hypothesis of interest is $H_0 : S_{\text{HRT}}(t) = S_{\text{Placebo}}(t)$ against the alternative $H_1 : S_{\text{HRT}}(t) S_{\text{Placebo}}(t)$, say. If no observations are censored, a nonparametric ▶Mann–Whitney U-test can be used to compare the distributions. For more than two distributions, the Wilcoxon generalization of the Mann–Whitney test is appropriate.

With censoring, however, several variations for comparing two or more groups have been proposed. Two of the most common tests for comparing two groups are the generalized Wilcoxon test and the log-rank test. The log-rank test, for example, is based on a chi-square statistic using the Observed and Expected number of failures

$$X^2 = \frac{(O_1 - E_1)^2}{E_1} + \frac{(O_2 - E_2)^2}{E_2}$$

where $E_1 = \sum_{j=1}^{r_1} e_{1j}$ and $E_2 = \sum_{j=1}^{r_2} e_{2j}$ are summed over the ordered failure times for groups one and two,

respectively. At each failure time, the expected number of deaths for each group is calculated similar to the usual chi-square test of independence as $e_{ij} = n_{ij} d_j/n_j$ where n_{ij} is the number of deaths in group i at time j, d_j is the total number of deaths in both groups at time j, and n_j is the total number at risk in both groups at time j. The log-rank test is more sensitive to differences that occur later in time than the Wilcoxon test that gives more weight to the earlier failures.

Kaposi Sarcoma

Chris Boshoff
Cancer Research Campaign Viral Oncology Group, Wolfson Institute for Biomedical Research, University College London, London, UK

Definition

KS; Is a vascular tumor, often affecting the skin. Discovered by Moritz Kaposi in 1872, Four epidemiological forms exist:

- Classic KS occurs mainly in elderly HIV negative male patients of Southern European and Middle Eastern origin.
- Endemic KS: In some African countries, KS has existed for many decades, long preceding HIV. Unlike classic KS, endemic KS also occurs in children, where they often present with lymphadenopathy, rather than skin lesions. Endemic KS is generally a more aggressive disease than classic KS, though less so than African AIDS-associated KS.
- Post-transplant or iatrogenic KS is also known to develop after an organ transplant. Patients of Mediterranean, Jewish or Arabian ancestry are over-represented among immunosuppressed patients who develop KS after a transplant, indicating that those born in countries where classic KS occurs continue to be at risk of developing KS even if they migrate to "low-risk" countries.
- AIDS-KS: In 1981 the occurrence of two rare diseases in young gay men from New York City (NY, USA) and California were reported: Kaposi sarcoma and Pneumocystis carinii pneumonia. This was the beginning of the AIDS epidemic and AIDS-KS is today the most common form of KS. In HIV-infected individuals the underlying immunosuppression can lead to an aggressive disease that starts with skin or mucosal lesions, but without treatment, often develops into disseminated disease affecting various organs including lung, liver, gut and spleen.

Characteristics

Histology

Histologically, KS is a complex lesion: in early KS lesions there are a collection of irregular endothelial lined spaces that surround normal dermal blood vessels and these are accompanied by a variable inflammatory infiltrate (patch-stage). This stage is followed by the expansion of a spindle-celled vascular process throughout the dermis. These spindle cells form slit-like, vascular channels containing erythrocytes (plaque-stage). The later nodular-stage KS lesions are composed of sheets of spindle cells. The spindle cells form the bulk of established KS lesions and are therefore thought to be the neoplastic component. Most of the spindle cells in KS lesions express endothelial markers, including CD31 and CD34. Recently, it was also shown that these spindle cells express markers associated with lymphatic, rather than vascular endothelial cells including vascular endothelial growth factor receptor (VEGFR)-3 and podoplanin. This suggests that these spindle cells might belong to the lymphatic lineage of endothelial cells. Early KS ("patch stage") is probably a non-clonal proliferation of lymphatic endothelial cells or endothelial precursors, with a prominent inflammatory and angiogenic response, whereas advanced disease can develop into a true clonal malignancy with metastases of clonally derived spindle cells to different sites.

Studies of AIDS case surveillance support the pre-AIDS data on the existence of a sexually transmissible KS cofactor: KS occurs predominantly in gay and bisexual men with AIDS, less commonly in those acquiring HIV through heterosexual contact and rarely in AIDS patients with hemophilia or in intravenous drug user.

Virus Involvement

Sequences of Kaposi sarcoma-associated herpesvirus (KSHV or human herpesvirus-8) were first identified in Kaposi sarcoma biopsies. KSHV is a gammaherpesvirus and related viruses are found in non-human

primates. The KSHV genome consists of an ~140 kb long unique coding region (LUR) flanked by ~800 bp noncoding tandemly repeated units. Over eighty five open reading frames (ORFs) have thus far been identified, including nearly seventy with sequence similarity to related gammaherpesviruses. Novel ORFs not present in other herpesviruses were designated K1–K15, although many of these now appear to be present in related viruses. KSHV encodes for a number of cellular homologs and these include a viral cyclin, bcl-2, IL-6, interferon regulatory factor (IRFs), FLICE inhibitory protein (FLIP) and chemokine homologs (vMIP I, II and III).

Viral Strains

ORF-K1 is use to subtype KSHV:subtypes A, B, C and D have been identified which display between 15 and 30% amino acid differences between their ORF-K1 coding regions. These subtypes have close associations with the geographic and ethnic background of individuals. Within these four subtypes, over 13 clades have now been described. Subtype B is found almost exclusively in patients from Africa, subtype C in individuals from the Middle East and Mediterranean Europe, subtype A in Western Europe and North America and subtype D has only so far been described in individuals from the Pacific Islands.

KSHV Latent Proteins

A number of KSHV ORFs are transcribed during latency and these proteins could be involved in oncogenesis:

- Latent nuclear protein (ORF 73/LNA) of KSHV encodes a latent immunogenic nuclear protein (LNA) detected as nuclear speckling by immunofluorescence using KSHV positive sera on ►PEL cells. LNA is expressed in all KS spindle cells latently infected with KSHV, in all the immunoblasts in KSHV associated Castleman disease and in all cells of (►primary effusion lymphoma (PEL)). Like EBNA-1, LNA is essential to maintain the KSHV episome (extrachromosomal persistence). Furthermore, LNA tethers KSHV DNA to chromosomes during mitosis to allow the segregation of viral episomes to all progeny cells. LNA therefore maintains a stable episome during mitosis. LNA also interferes with p53 andpRb pathways to deregulate the cell cycle. Strategies including the development of small molecules that interfere with the functions of LNA could be useful to abort latent KSHV infection and therefore prevent KSHV associated diseases.
- V-cyclin; cellular cyclins [►cyclin D] are critical components of the cell cycle: cyclins are regulatory subunits of a specific class of cellular kinases. By physically associating with an inactive cyclin-dependent kinase core (cdk), cyclins lead to the formation of active kinase holoenzymes which recognize and phosphorylate an array of cellular substrate molecules. The phosphorylating activity of these holoenzymes is responsible for regulating the passage of cells through the replication cycle. Cyclins associate with their partners (the cyclin dependent kinases, CDKs) to be fully active. The KSHV cyclin has highest sequence similarity to the cellular D-type cyclins. The KSHV cyclin is expressed during latency inferring a possible role in tumorigenesis. The KSHV-cyclin form active kinase complexes with CDK6 to phosphorylate the retinoblastoma protein (pRb). Furthermore, unlike cellular D cyclin/CDK6 complexes, KSHV-cyclin/CDK6 activity is resistant to inhibition by CDK inhibitors (CKI) p16, p21 and p27. Ectopic expression of v-cyclin prevents G1 arrest imposed by each inhibitor and stimulates cell-cycle progression in quiescent fibroblasts. KSHV cyclin/CDK6 also phosphorylates (inactivates) p27, the CKI known to be an effective inhibitor of cyclin E/CDK2 activity. This suggests that this viral cyclin can activate both pathways necessary for G1/S-phase progression (i.e. cyclin D/CDK6 and cyclin E/CDK2). The expression of the KSHV-cyclin in latently infected spindle and ►PEL cells, indicate a possible role in either the proliferation or the arrest of differentiation of these cells.
- ORF-K15 latent membrane protein. At the far right-hand end of the KSHV genome, the ORF K15 encodes a putative latent transmembrane protein. Two highly divergent forms of K15 have been identified; the predominant (P) and minor (M) forms. These two alleles have only 33% amino acid homology to each other, yet retain the 12 transmembrane spanning domains and a cytoplasmic signal-transducing carboxyl-terminus. K15 induces NFκB activation and this activity localises within the last 18 amino acids of K15, which contains the putative TRAF-binding motif. K15 is also able to activate JNK. This ability to activate JNK, like that of NFκB activation, is located within the last 18 aa of the K15 extreme C-terminus. The JNK signaling pathway is known to lead to the activation of ►AP-1, a pleotropic transcription factor implicated in cellular transformation and phenotypic changes.

Neoplasms Associated with KSHV

Three neoplasias are consistently linked with KSHV infection: Kaposi sarcoma, a subtype of ►Castleman disease and PEL. KSHV sequences have also been described in squamous carcinoma, multiple myeloma and other vascular tumors, however, most studies could not confirm any association between KSHV and these tumors. The detection of KSHV in some of these reports might be due to PCR contamination.

- Kaposi sarcoma. Four observations link KSHV to Kaposi sarcoma (although none of these findings on their own are sufficient to support a causative role):
  - KSHV DNA is present, by the polymerase chain reaction (PCR), in all four epidemiological forms of KS and in nearly all KS biopsies tested. However, KSHV DNA is rarely, if at all, detectable in other vascular tumors.
  - The detection of KSHV DNA by PCR in the peripheral blood of HIV infected individuals predicts who might subsequently develop KS, indicating that those at risk of KS have a higher viral load than those not at risk.
  - Seroepidemiological surveys show that general populations at risk of developing Kaposi sarcoma have a higher prevalence of KSHV infection. The incidence of classic KS and AIDS-KS in different populations correlates broadly with the prevalence of the virus in these populations.
  - In nodular KS lesions, KSHV is latently expressed in nearly all the tumor (spindle) cells. This is reminiscent of other viral driven cancers e.g. ►Epstein-Barr virus (EBV) latent infection in post-transplant lymphoproliferation or human papillomavirus infection in cervical cancer.
- Plasmablastic variant Multicentric Castleman's Disease; Castleman's disease (CD) is a lymphoproliferative disorder. Recently CD is more often diagnosed in HIV infected patients. A systemic variant of CD is associated with multiple organ involvement, especially spleen and lymph nodes with systemic symptoms such as weight loss and fever. This is called multicentric ►Castleman's disease (MCD). MCD has been associated with increased circulating IL-6 levels. KSHV DNA is found in some cases of MCD. KSHV is present in plasmablasts in MCD and these plasmablasts are not present in KSHV negative MCD. These KSHV positive plasmablasts belong to the B cell lineage. KSHV appears also to be present in all tumor cells of plasmablastic lymphoma that develops in patients with the KSHV positive plasmablastic variant of MCD. The development of plasmablastic lymphoma therefore appears to represent a further evolution of this disorder. Unlike KSHV positive primary effusion lymphoma cells, the plasmablasts in MCD are only positive for KSHV, and not for EBV.

Current studies suggest that KSHV positive MCD has a poorer prognosis that the KSHV negative cases. In contrast to KS lesions that can resolve by partly restoring the immune system (e.g. by HAART for HIV positive patients), KSHV positive MCD often continues to progress.

- ►Primary Effusion Lymphoma (PEL); PEL is a body cavity-based lymphoma that usually presents and persists as an effusion: pleural, pericardial or ascitic. The lymphoma cells in these cases are negative for most lineage-associated antigens, although immunoglobulin (Ig) gene rearrangement studies indicated a B-cell origin. These lymphomas occur predominantly in HIV+ individuals with advanced stages of immunosuppression, but are occasionally seen in HIV negative patients. Like KS which can occur in the same patient, PEL occurs primarily in gay men and not in other HIV-positive risk groups. PEL cells contain between 50 and 150 copies each of the KSHV genome. The majority, but not all, PELs are co-infected with EBV, suggesting that the two viruses may cooperate in neoplastic transformation. Terminal repeat analysis indicates that EBV is monoclonal in most cases, implying that EBV was present in the tumor cells prior to clonal expansion. PEL cells consistently lack molecular defects commonly associated with neoplasia of mature B cells including activation of the proto-oncogenes bcl-2, bcl-6, n-ras, and k-ras, as well as mutations of p53. KS, MCD and PEL have all been described in one patient and up to 30% of HIV infected patients with KSHV positive MCD, will also have or develop KS.

KSVH and Immunity

The introduction of aggressive anti-HIV therapies lead to a decline in the incidence of KS in AIDS patients and also in the resolution of KS in those already affected. This suggests that cellular immune responses, compromised in AIDS, but recovering after highly active antiretroviral therapy (HAART), could be important in the control of KSHV infection and in the development of KS. This is further supported by the observation that post-transplant KS lesions can regress when immunosuppressive treatment is stopped.

KSHV, like other herpesviruses, is able to elicit HLA class I restricted ►cytotoxic T cell (CTL) responses. In one pilot study, KSHV specific CTL responses were not present in most patients with KS, indicating that a decline in cellular immune responses against KSHV may be present in HIV+ patients with KS and could contribute to KS pathogenesis. This would be reminiscent of the lack of EBV specific CTLs seen in immunosuppressed patients which correlates with the onset of EBV driven lymphoproliferation.

Anti-Herpesviral Drugs

In vitro, KSHV replication is insensitive to ganciclovir and acyclovir, but is moderately sensitive to foscarnet (phosphonoacetic acid) and sensitive to cidofovir. These agents target lytic herpesviral infection and if lytic infection is necessary to drive tumor formation

or to recruit inflammatory cells to form KS lesions, these drugs might prove useful in the management of some patients. Foscarnet has been shown to induce KS lesion regression in one small study and to reduce the onset of KS in other studies. Foscarnet and cidofovir are however associated with significant toxicity and would seem to be inappropriate therapy for most KS patients.

Treatment for KS

In ►immunocompetent patients with single lesions, excisional biopsy is often all that is required. Patients with a few lesions, especially if these are confined to a limited region, is best treated with local radiotherapy. Total-skin electron beam therapy has also been used to treat more disseminated skin lesions. Patients with disseminated disease can be treated with systemic chemotherapy. Single agents that often lead to responses include ►bleomycin, ►vinblastine/vincristine, oral ►etoposide and ►doxorubicin. In HIV infected patients, these agents seldom lead to long-term control of the disease. A major disadvantage of doxorubicin and oral etoposide is ►alopecia. Taxol has also been used, but this agent is associated with significant toxicity. Liposomal doxorubicin is better tolerated and is associated with high response rates. Systemic interferon has also been used and responses have been seen for many months (even years). If tolerated, subcutaneous interferon injections remain a therapeutic option to treat KS. More experimental therapies include thalidomide, retinoic acid and human chorionic gonadotropin. However, these agents only produce transient responses in some patients.

KS often regress with the cessation or modification of immunosuppressive therapy in organ transplant recipients. Effective treatment of HIV infection should prevent KS and has already lead to remission of KS in some patients.

Karnofsky Performance Score

Definition

A medically derived metric from 0 to 100 that reflects a person's ability to perform certain ordinary tasks in order to determine a patient's suitability for therapy or to evaluate a patient's progress after a therapeutic procedure with 100 being completely intact, 70 being unable to carry on these normal activities, 50 indicating a need for considerable assistance, 40 being totally disabled, and hospitalization recommended for scores of 30 or less.

Karyoplast

Definition

Cell nucleus surrounded by thin band of cytoplasm and enveloped by plasma membrane.

►Microcell-Mediated Chromosome Transfer

Karyotype

Definition

The complete set of chromosomes of one cell. Usually represented as a map with photographs of mitotic chromosomes arranged in homologues pairs. Chromosome complement of cells. In a karyotype, the total number of chromosomes is given first, followed by sex chromosome constitution and a description of numerical and structural aberrations. A normal male karyotype is thus written 46,XY; the normal female complement is 46,XX.

KCNH1

►Ether à-go-go Potassium Channels

KCS

►Sjögren Syndrome

Keap1

Definition
Kelch-like ECH-associated protein 1, is the principal repressor of ►Nrf2. Keap1 binds to Nrf2 and targets it for ►ubiquitin-mediated proteasomal degradation.

►Phase 2 Enzymes

Kennedy Disease

►Androgen Receptor

Keratinocyte

Definition
A major cell type of the epidermis that synthesizes keratin. It originates from the division of keratinocyte stem cells in the basal layer and undergoes gradual differentiation through different layers until reaching the stratum corneum and forming an effective barrier of dead cells against foreign material and infectious agents.

►Stefins

Keratoconjunctivitis Sicca

Kin-Cohort Study

Definition

A study design used to estimate ►penetrance. The sample of individuals is unselected for family history. Genetic testing is performed on the subjects, and the family histories of the mutation carriers are compared with the family histories of the non-carriers.

►Epidemiology of Cancer
►Cancer Epidemiology

Kinase

Definition

An enzyme that transfers a phosphate group from a donor, usually ATP or ADP, to a serine, threonine or tyrosine residue on an acceptor protein.

►Molecular Chaperones
►Signal Transduction
►Receptor Tyrosine Kinases
►Cyclin Dependent Kinases

In vitro Kinase Assay

Definition

Analytical method to measure the activity of protein or lipid kinases *in vitro*. Kinases are usually purified from cell extracts by immunoprecipitation and then mixed with ATP and an appropriate substrate. ►Kinase activity is then analyzed by measuring the phosphorylation status of the substrate, either by immunochemical methods (►ELISA or Western Blotting) using phospho-specific antibodies or by its labeling with radioactive phosphorus.

Kinesin

Definition

A large family of microtubule-dependent motor proteins with different functions. While some kinesins are responsible for transporting organelles, proteins, and mRNAs to specific destinations along ►microtubules by hydrolyzing ATP, others are required for mitotic spindle assembly and chromosome separation during mitosis and cytokinesis.

►KSP Mitotic Spindle Motor Protein
►Doublecortin

Kinesin-5

►KSP Mitotic Spindle Motor Protein

Kinesin Spindle Protein

Kinetic Parameters

Definition

The properties of chemical agents or enzymes in the efficiency and speed of their action upon a chemical reaction.

►Biomonitoring

Kinetochore

Definition

Is the protein structure in eukaryotes that localizes on the ►centromere and connects the chromosome to microtubule polymers from the mitotic spindle during ►mitosis and meiosis. A region of the chromosome centromere to which microtubular spindle fibers attach. Each ►centromere contains two kinetochores, each receiving spindle fibers from one of the opposite poles.

►Micronucleus Assay
►Genomic Imbalance

Kinetochore Outer Plate

Definition

Disk-shaped proteinaceous structure forming on the outside of chromosomal centromeres during ►mitosis; involved in chromosome segregation.

Kininogen

Definition

There exist high and low molecular weight kininogen (HMWK and LMWK). Both are inhibitors of thiol proteinases. HMWK plays an important role in blood coagulation since it brings together prekallikrein, factor XI and factor XII. A physiologically active peptide, bradykinin, is released from HMWK by plasma kallikrein. ►Bradykinin is a potent vasodilator. In contrast, LMWK is not involved in coagulation and inhibits platelet aggregation.

►Proteinase-Activated Receptors

KiSS1

Danny R. Welch, Kevin T. Nash, L. Joe Stafford
Department of Pathology and Comprehensive Cancer Center, University of Alabama-Birmingham, Birmingham, AL, USA

Definition

KiSS1 (GenBank Accession No. U43527) is a human ►metastasis-suppressor gene that was discovered in human ►melanoma cells. The name is derived from SS for putative Suppressor Sequence, the Ki was added to remind people of its discovery in Hershey, Pennsylvania. Upon introduction into metastatic cells, which normally do not express the gene, the cells retain the ability to form tumors while losing their ability to metastasize.

Characteristics

As melanomas progress toward increasing malignancy, numerous nonrandom chromosomal changes occur. One particular change involving deletions involving the long arm of chromosome 6, tends to occur at a time coincident with acquisition of metastatic potential. This suggested that a metastasis suppressor gene was encoded at that site. This hypothesis was validated upon introduction of chromosome 6 into metastatic human melanoma cells using the technique of ►microcell-mediated chromosome transfer. Metastatic potential was lost but tumorigenicity was retained in the chromosome 6-melanoma hybrids. By comparing mRNA expression between parental (metastatic) cells and chromosome 6 hybrids (nonmetastatic) using subtractive hybridization, KiSS1 was identified as being expressed exclusively in the nonmetastatic cells. Transfection of KiSS1 into the metastatic melanoma cells also suppressed metastasis without affecting tumorigenicity.

The KiSS1 gene maps to chromosome 1q32, suggesting that a gene(s) on chromosome 6 regulates its expression. The regulatory gene CRSP3, encoded

on chromosome 6q, was deleted in the advanced, metastatic melanoma cells. Re-expression of CRSP3 restores KISS1 expression.

Does KiSS1 Suppress Metastasis of Other Human Cancers?

Transfection of KiSS1 into at least two human melanoma cell lines, a human breast carcinoma cell line and a human ovarian carcinoma cell line results in significant suppression of metastasis. Tumorigenicity (growth of injected cells at orthotopic sites) is not suppressed by KiSS1 expression.

How Does KiSS1 Suppress Metastasis?

The KiSS1 gene encodes a predominantly hydrophilic protein of 145 amino acids (approximately 15.4 kDa). A signal peptide regulates Golgi localization and processing before secretion. Nascent KiSS1 is proteolytically processed into a number of peptides, termed kisspeptins. A 54-amino acid polypeptide, termed metastin or kisspeptin-54, was found to bind to a G-protein coupled receptor (alternatively named GPR54, AXOR12 or hOT7T175). KiSS1 binding to GPR54 in the hypothalamic-pituitary axis to induce GnRH secretion which, in turn, induces puberty. KiSS1 (kisspeptin)–GPR54 interactions have recently been discovered not to be involved in metastasis suppression. Therefore, the molecular mechanism of action of KiSS1 remains unknown.

The cellular mechanism of action appears to be prevention of tumor cell growth at ectopic sites. KiSS1-expressing melanoma cells can complete every step of the metastatic cascade antecedent to colonization of lungs.

Is KiSS1 a Marker of Metastasis?

Using a series of cell lines representing the progression of normal melanocytes to metastatic melanomas, KiSS1 expression is lost as the cells convert from radial to vertical growth phase (benign to malignant transformation). Several additional studies show that high KiSS1 expression is generally correlated with good prognosis and reduced recurrence for multiple cancer types.

Clinical Relevance

►Metastasis is the most life-threatening attribute of cancer cells. Any gene/protein that could block or slow metastasis would benefit long-term survival rates among cancer patients. Likewise, any marker that could allow physicians to more accurately stage the disease would aid in treatment planning and monitoring. KiSS1 offers potential in both arenas.

To the extent that KiSS1 plays a role in the suppression of metastasis at late stages and blocks metastasis to multiple organs, it may provide or lead to therapeutic targets designed to inhibit the ability of the cells to form tumors at secondary sites.

KIT

Definition

Activating mutations in the KIT receptor tyrosine kinase cause ligand-independent activation of its tyrosine kinase function which initiates a cascade of intracellular signaling involved in tumorigenesis. Exon 9 KIT defines a distinct subset of gastrointestinal tumours that are often located in the small bowel and have an aggressive clinical behavior. Kit is an example of a cancer target that has been successfully blocked with a new small molecule inhibitor, ►Gleevec (or ►imatinib). This drug blocks the receptor's tyrosine kinase activity in stromal tumors of the gastrointestinal tract. In these tumors, a mutation in *c-kit* constitutively activates the receptor tyrosine kinase independently of ligand binding.

Definition

Kit/SCF-R is a receptor protein ►tyrosine kinase (RPTK) encoded by the ►proto-oncogene c-kit, which is allelic with the murine dominant white-spotting (W) locus on chromosome 5, and whose human homolog is located on human chromosome 4 (4 q11–12).

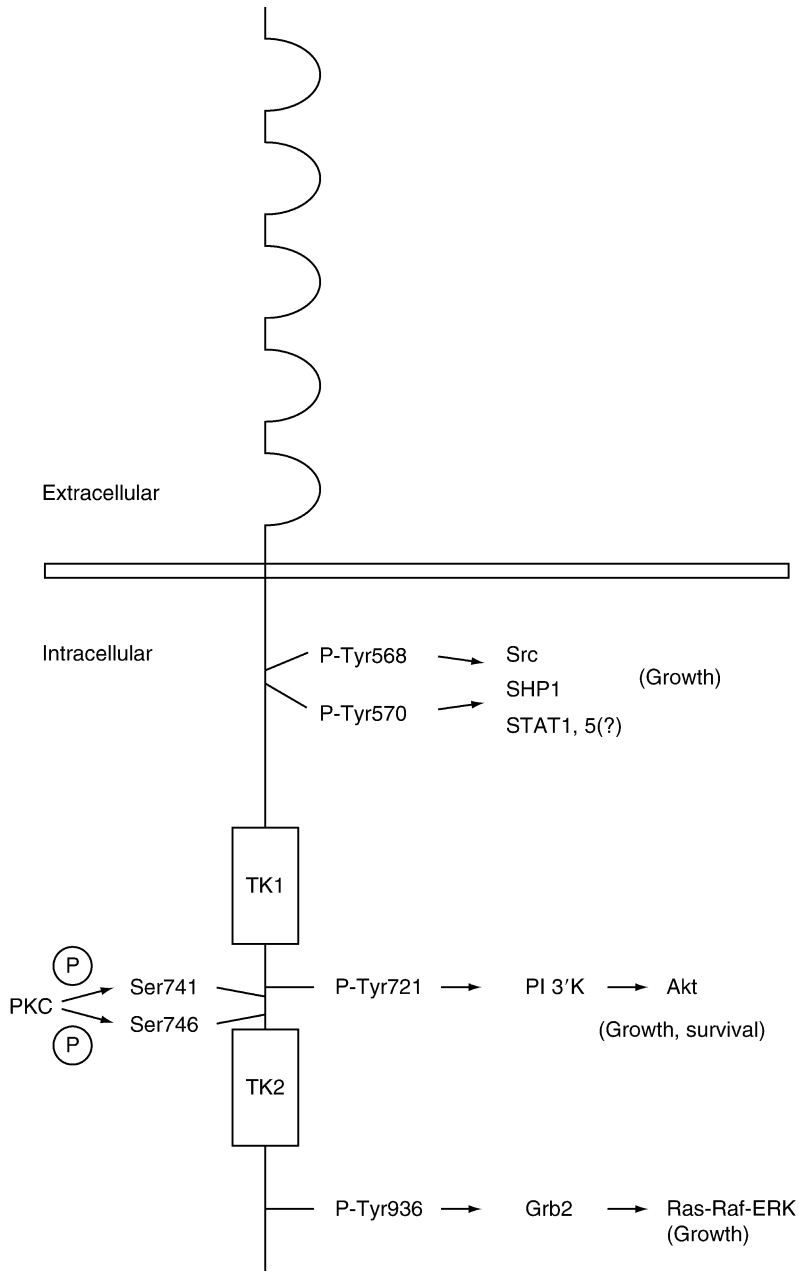
Characteristics

Going from the N-terminus towards the C-terminus, all RPTKs contain an extracellular ligand-binding domain, a single transmembrane-spanning domain and an intracellular domain composed of a hydrophilic juxtamembrane (JM) region, followed by the highly conserved tyrosine kinase domain and a hydrophilic C-terminus. Based on structural similarities, Kit/SCF-R belongs to the subclass III of RPTKs that includes the receptors for platelet-derived growth factor (►PDGF) α and β, colony-stimulating factor-1 (CSF-1) and the Flt-3/Flk-2 RPTK. These proteins are ∼950 to ∼1100 amino acids in length, with ∼550 extracellular amino acids and 400–550 intracellular amino acids. Their overall identity is 25–40%, but the identity in their intracellular domains is between 45 and 55%, and in the kinase domains proper between 63 and 85%. They are characterized by five immunoglobulin-like repeats in the extracellular ligand-binding domain and a long (75–100 amino acids) hydrophilic kinase insert region, which interrupts the tyrosine kinase domain between the ATP-binding region and the conserved catalytic base. The Kit/SCF-R is expressed in hematopoietic, melanogenic and gametogenic precursors and derivatives, and in interstitial cells of Cajal. The development of these cells depends on Kit/SCF-R and its ligand. However, Kit is expressed in numerous other tissues/cell types including mammary duct epithelial cells, thyrocytes and cerebellar basket cells. Two alternative RNA transcripts, resulting from alternate usage of 5′ splice donor sites, generate two forms of Kit/SCF-R in all tissues examined. The only difference is the presence or absence of four additional amino acids, GNNK, in the extracellular domain close to the membrane. When overexpressed, the shorter isoform of Kit/SCF-R (ΔGNNK-Kit/SCF-R), which is the most prevalent in most tissues examined, is constitutively tyrosine phosphorylated, causes tumorigenesis in nude mice and greater activation of ERK/MAPK. However, ΔGNNK-Kit/SCK-R has not been directly associated with any tumors in man or mouse.

Molecular and Cellular Regulation

The general mechanisms of ligand-induced activation of Kit/SCF-R and its downstream signaling have been fairly well characterized, and very similar principles seem to govern ligand-induced signaling by all subclass III RPTKs. In outline, binding of the bivalent ligand, SCF, induces dimerization of Kit/SCF-R leading to activation of its tyrosine kinase domain and subsequent autophosphorylation on specific tyrosine residues. The phosphorylated tyrosine residues and 3–5 amino acid residues immediately N- or C-terminal to each of these, in turn, create specific binding sites for intracellular signaling molecules leading to their recruitment from cytosolic compartments to the membrane, where the activated RPTK is located. The binding of signaling molecules to the phosphorylated tyrosine residues occur through conserved protein-protein interaction domains, such as Src homology 2 (SH2) and protein tyrosine binding (PTB) domains. The SH2 and PTB domains have a defined, conserved primary sequence of ∼100 and ∼110 amino acids, respectively, and they exist as independently folded domains in a variety of intracellular proteins including proteins possessing a catalytic domain, pure adaptor molecules, structural proteins and translocated transcription factors. The conformational changes induced in the signaling molecules upon binding to an RPTK can unmask other protein-protein interaction domains allowing for interaction, recruitment and activation of yet other intracellular signaling molecules. Several other protein-protein interaction domains that have been identified include proline-rich-binding SH3 and WW domains, phospholipid-binding PH (pleckstrin homology) domains, phosphoserine/phosphothreonine-binding 14-3-3 (►14-3-3 proteins)] and FHA (Forkhead-associated) domains. The specificity of signaling from different RPTKs is to a large extent determined by the primary sequence surrounding the autophosphorylated tyrosine residues in the receptors. This enables the activated RPTK to “select” a specific subset of signaling molecules within the cell, which, in turn specifically interact with, and/or activate, other signaling molecules, and a network of activated catalytic proteins and of multiprotein signaling complexes result. Examples of Kit/SCF-R-induced signaling molecules and pathways of importance for cell

growth control include the Ras-Raf-ERK and Src-activated pathways, which are mainly involved in cell proliferation and the phosphatidylinositol 3′-kinase (►PI3-Kinase) and JAK/STAT (►Signal transducers and activators of transcription in oncogenesis) signaling pathways involved in cell proliferation and cell survival (Fig. 1). Several signaling components within each of these pathways are able to interact with and/or



Kit/Stem Cell Factor Receptor in Oncogenesis. Figure 1 Schematic representation of known tyrosine autophosphorylation sites in human Kit/SCF-R together with the signaling molecules they recruit and activate. Several signaling molecules have been shown to bind to the juxtamembrane tyrosine autophosphorylation sites Y568 and Y570. Concentration differences of these molecules in different cell types, as well as differences in their subcellular distribution, may determine their recruitment to the autophosphorylation sites in vivo. Note that Grb2 has been shown to bind to the activated Kit/SCF-R in vivo, but that its binding to phosphorylated tyrosine 936 has only been mapped in vitro. Grb2 is an upstream activator of the Ras-Raf-ERK cascade. SHP1 is a protein tyrosine phosphatase, expressed in hematopoietic cells.

modify the activity of each other, allowing for so-called ►signal transduction cross-talk. This is important for fine tuning and modulation of signaling. It is becoming increasingly clear that such Kit/SCF-R-initiated signaling pathways eventually impinge on and regulate the cell cycle machinery including the ►p16-cyclin D-►Rb pathway, as well as the DNA damage response pathways including p19ARFand p53. It is perhaps exclusively through these latter effects that the signaling pathways ultimately regulate proliferation and/or anti-apoptosis, respectively. For some recent reviews on RPTK-initiated signal transduction and mitogenic/survival signaling pathways [2, 3].

Once the appropriate Kit/SCF-R-induced signaling pathways have been activated, it is crucial that further Kit/SCF-R signaling is down-regulated and inactivated to achieve a proper cell biological response. Several mechanisms prevail to achieve this, including negative feedback mechanisms, ligand-induced receptor internalization and degradation, and coordinated activation or organization of negative intracellular regulators including phosphatases and scaffolding proteins. In the case of Kit/SCF-R, SCF stimulation causes activation of ►PKC, which acts in a negative feedback loop to inhibit further Kit/SCF-R tyrosine kinase activity by directly phosphorylating two serine residues in the receptor (Fig. 1). SCF stimulation also induces Kit/SCF-R internalization with a $T½ < 0.5$ h, and it has been shown that the internalized receptors undergo regulated degradation, in part through ►ubiquitin-mediated proteolysis. The ligand-induced Kit/SCF-R down-regulation is likely to play an important regulatory physiological role in development, since SCF-expressing stromal cells interact with Kit/SCF-R-expressing parenchymal cells in gonads, bone marrow and cerebellum during development. In these tissues SCF exists in a mainly transmembrane form, which does not induce Kit down-regulation to the same extent as the soluble form of SCF, thus allowing for more sustained Kit signaling. There is some evidence that there are quantitative and qualitative differences in the activated signaling molucules induced by the two forms of SCF. The transmembrane form of SCF is important for stem cell self renewal and survival, while the soluble form is important for chemotaxis and cell proliferation. As part of a long-term mechanism to ensure proper Kit/SCF-R signaling, the Kit expression level is regulated in a cell- and tissue-specific manner at the transcriptional level as well. The c-kit promoter contains Sp1, SCL/Tal1 and AP-2-binding sites and its expression is tightly and positively regulated by each of these transcription factors.

Perturbation of the normal regulatory mechanisms governing Kit/SCF-R-induced signal transduction has serious clinical consequences. Accordingly, both in humans and mice, naturally occurring ►loss-of-function mutations and ►gain-of-function mutations in Kit/SCF-R have been reported that result in developmental defects or malignancies.

Clinical Relevance

W-mutant and Steel mutant mice have naturally occurring loss-of-function (LOF) mutations in Kit/SCF-R or in SCF, respectively, resulting in varying degrees of anemia, mast cell depletion, white-spotted depigmentation, decreased fertility and constipation. A similar phenotype is found in humans suffering from piebaldism, a syndrome caused by LOF mutations in Kit/SCF-R homologous to several of those found in W mutant mice. The W mutations provided the first reported examples of germ-line mutations in a mammalian proto-oncogene and the first in vivo evidence of the importance of RPTKs for not only cellular proliferation but also normal development and differentiation in mammals. Many of the W mutations are single base c-kit substitutions causing in-frame point mutations of highly conserved residues in the kinase domain of Kit/SCF-R, resulting in decreased or abolished kinase activity. Such mutations are dominant negative, which means that the phenotype in afflicted heterozygous individuals is more severe than would be expected from only one allele being mutated. A likely explanation for this is that SCF induces the formation of homo- and heterodimers of wild type (wt) and mutant (mut) Kit/SCF-R, and that only the wt/wt homodimers are fully signaling active, while the mutant receptor suppresses signaling from heterodimers. Since the ratio of wt/wt:wt/mut:mut/mut Kit/SCF-R dimers in a cell heterozygous for mutation in Kit/SCF-R is expected to be 1:2:1, only ~1/4 of all the Kit/SCF-R molecules are engaged in active signaling complexes, which is probably sub-threshold levels for most signaling pathways. An increased frequency of germ cell tumors and myeloid leukemias has been reported in some of the W mutant mice. This might indicate a possible role for Kit/SCF-R as an anti-oncogene, and again points to the importance of proper regulation of RPTK-induced signaling to ensure normal differentiation and development. For reviews on the physiological roles of Kit [4, 5].

The proto-oncogene c-kit was originally identified as the cellular counterpart of the ►oncogene v-kit, which encodes the transforming protein of the HZ4-feline sarcoma virus (FeSV) derived from a feline fibrosarcoma. HZ4-FeSV originated through transduction of feline c-kit sequence by feline leukemia virus. The protein encoded by the v-kit oncogene is essentially a doubly truncated version of Kit/SCF-R, where the extracellular, transmembrane and ~50 most C-terminal amino acids have been deleted. Its identification from a feline tumor immediately implicated v-kit as a tumorigenic oncogene. More recently numerous

gain-of-function (GOF) mutations have been identified in Kit/SCF-R that are strongly implicated in several kinds of human malignancies, including mast cell leukemia/mastocytosis, acute and chronic myeloid leukemias, gastrointestinal stromal tumors, germ cell tumors and possibly thyroid carcinomas. The mutations identified thus far are mainly located in exon 11, which encodes part of the juxtamembrane region, and in exon 17, which encodes part of the C-terminal half of the kinase domain. However, mutations have also been identified in other regions of Kit/SCF-R including the extracellular domain. All the GOF mutations in exons 11 and 17 cause ligand-independent dimerization of Kit/SCF-R resulting in its constitutive kinase activation. Future research into signal transduction by such mutated receptors should reveal more about the mechanisms responsible for transformation. For an overview of all Kit/SCF-R mutations associated with human malignancies identified to date, see Fig. 2.

Mastocytosis/Mast Cell Leukemia

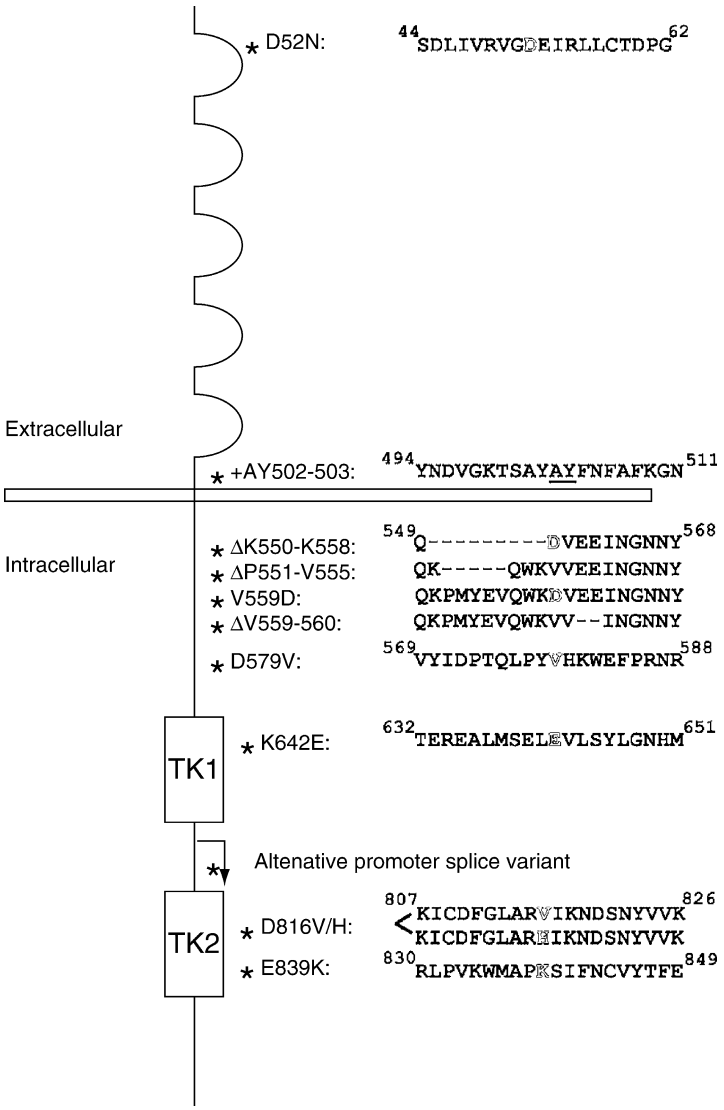
These are relatively rare conditions, characterized by mast cell hyperplasia in bone marrow, liver, spleen, lymph nodes, gastrointestinal tract and skin. There is often clinical evidence of mast cell activation, including urtication, pruritus, abdominal pain, nausea, vomiting, diarrhea, bone pain, flushing, vascular instability and headache. Mastocytosis is classified into four groups:

- Indolent forms
- ►Mastocytosis with associated hematological disorders, including myeloproliferative/myelodysplastic disorders
- Aggressive mastocytosis
- Mast cell leukemia

The prognosis is good for patients with indolent mastocytosis but generally poor for the other three groups, with mast cell leukemia having the most fulminant behavior. In 1993, two activating mutations in Kit/SCF-R, D816V in exon 17 and V560G in exon 11 were reported in the human mast cell line HMC 1, which was established from a patient with mast cell leukemia. Subsequent studies confirmed the presence of these mutations, in particular D816V, in Kit/SCF-R in mast cells from patients with mastocytosis. The D816V mutation has been associated with mainly sporadic, systemic mastocytosis in adults, while the G839K mutation was reported to be typically associated with cutaneous, mainly pediatric cases. Mutations at analogous sites have been identified in mast cells and mast cell lines from other species, including mouse, rat and dog. Mastocytosis is one of the most common tumors in dogs, is usually malignant and as a general rule associated with Kit/SCF-R mutations. The above mutations have been identified in such cases, but the most common mutations involve exon 11 and 12, including tandem duplications and other intragenic rearrangements. The mechanisms for transformation are unknown, but it is possible that a general increase in signaling caused by the Kit/SCF-R mutations is enough to cause mast cell transformation. Accordingly, mice reconstituted with bone marrow cells expressing another constitutively active RPTK v-ErbB, develop malignant mastocytosis with associated acute myeloid leukemia (AML) that can be transplanted to secondary recipients. The V559G and the D814V mutations in murine Kit/SCF-R cause constitutive tyrosine autophosphorylation in retrovirally transduced Ba/F3 and myeloid FDC-P1 cells, and leukemia in nude mice upon injection of the transduced cells. One study showed that in murine mast cells transfected with D816V-Kit/SCF-R there was an enhanced tyrosine phosphorylation of a 130 kDa protein and enhanced ubiquitin-mediated degradation of SHP-1, a cytoplasmic protein tyrosine phosphatase that negatively regulates Kit/SCF-R signaling. In conclusion, the D816V-Kit/SCF-R and to some extent exon 11 mutations, are recurrent mutations associated with, and supposedly causally involved in, aggressive forms of mastocytosis and mast cell leukemia.

Gastro-Intestinal Tumors

A strong association between Kit/SCF-R GOF mutations and ►gastrointestinal stromal tumors (GISTs) has been established. GISTs are the most common mesenchymal tumors of which ~1 out of ten cases is malignant. The primary tumors are located mainly in the ventricle and small intestine, and the highest incidence of new cases is in persons >40 years of age with an even sex distribution. Interestingly, >60% of GISTs are associated with exon 11 mutations in Kit/SCF-R, but none with mutations in exon 17, including of D816. Kit exon 11 GOF mutations occur mainly in malignant GISTs, which tend to be larger, with necrosis, hemorrhage, intra-abdominal spread and liver metastases and frequent recurrences. Hence, the exon 11 mutations portend poor prognosis with a 3 year survival <30% versus >65% for exon 11 mutation negative tumors, and it has been reported that Kit exon 11 mutations are an independent prognostic factor for GIST survival. The Kit/SCF-R (CD117) expression is diagnostic for GI stromal tumors versus ►leiomyomasa and gastric Schwannomas. Most cases examined are also CD34-positive, and ultrastructurally cells look like ►interstitial cells of Cajal (ICC), which is why it has been proposed that the ICC is the cell of origin for most GISTs. However, tumors phenotypically identical to GISTs (CD117+, most CD34+) occur as primary tumors in the omentum and mesentery as well, which indicates that GISTs might not all originate



Kit/Stem Cell Factor Receptor in Oncogenesis. Figure 2 Schematic representation of mutations in Kit/SCF-R, associated with human malignancies and dysplasias. Amino acid residues are denoted with single letters, numbers indicate the residue number in the human Kit protein sequence. Point-mutated amino acid residues are shown in outline, amino acid deletions with a dash and amino acid additions are underlined. The D52N mutation has been associated with myelodysplastic syndromes that include myelofibrosis and chronic myeloid leukemia. The AY duplication, the juxtamembrane mutations and the K642E mutations have mainly been associated with gastro-intestinal stromal tumors, but also with mast cell leukemias. The D816V and E839K mutations have been connected with mast cell leukemias. The D816H mutation has been connected with seminomas and dysgerminomas. Mutations, found in the hydrophilic region between the N- and C-terminal region of the kinase domain result -due to alternative promoter usage- in truncated versions of Kit. These isoforms have been identified in various cell lines which derived from colon carcinomas and hematopoietic malignancies.

from ICCs, but rather from a multi-potential precursor cell. A characteristic of GISTs is mitochondrion-rich ICCs, and some GISTs are gastro-intestinal autonomic nerve tumor (GANT)-like stromal tumors. An immunohistochemical and histological re-evaluation of archived paraffin-embedded esophageal tumor samples disclosed that ~25% of these were indeed Kit-positive GISTs with exon 11 mutations rather than leiomyomas or leiomyosarcomas, which was the original classification. This is important, since

esophageal GISTs are malignant, while leiomyomas, which are Kit-negative, are benign. Analysis of eight GISTs devoid of exon 11 mutations in Kit/SCF-R revealed exon 9 mutations in 6 and an exon 13 mutation (K642E) in 2, the latter causing constitutive tyrosine autophosphorylation of Kit/SCF-R. Finally, in colon carcinoma cell lines certain intron 15 alternative promoter splice variants, causing either a 78 bp deletion or a truncated Kit/SCFR with 25 unique amino acids fused to the C-terminal 257 amino acids, have been reported sporadically. The functional consequences are unknown. However, a potential autocrine loop of Kit/SCF-R and SCF might exist in colon cancer, since colonic mucosal cells usually express SCF, but areKit/SCF-R-negative. In conclusion, a majority of GISTs harbor GOF mutations in exon 11 of Kit/SCFR and there is overwhelming evidence that these are involved in the oncogenesis. Kit expression and exon 11 mutations are both of significant diagnostic and prognostic value for GISTs, the prognosis being significantly more severe if both are present.

Acute and Chronic Myeloid Leukemias

A vast number of publications have attempted to address the putative role of Kit/SCF-R in myeloid leukemias. While it is still unclear whether Kit/SCF-R is causally involved in these diseases, it does have an important diagnostic and prognostic value. While only 1–3% of normal mononuclear marrow blasts express Kit/SCF-R, a big European multi-center study concluded that 67% of all ►acute myeloid leukemia (AML) cases, ~30% of all biphenotypic acute leukemias and all undifferentiated acute leukemias express Kit/SCF-R. Kit/SCF-R is expressed mainly in M4 and M5 AML subclasses, but the highest expression levels are found on blasts in M1 and M2 subclass AML cases. A high proportion of megakaryocytic and erythroid leukemic cells are also positive for Kit expression, as is most blasts in chronic myeloid leukemia (CML). In general, Kit/SCF-R expression is useful in the differential diagnosis between AML (mostly positive) and acute lymphocytic leukemia (ALL; all negative). Negative expression for Kit/SCF-R in AML also identifies with some certainty two M5b subgroups. AML blasts express between 600 and 29,000 Kit molecules/cell, but there is no correlation between expression level and prognosis. Despite conflicting reports, it seems to be the consensus from the literature that there is no correlation between Kit expression and prognosis for AML in general, but that expression of Kit/SCF-R in the M1 subclass indicates a worse prognosis. This might be due to a strong correlation between expression of a non-P-glycoprotein multidrug resistance protein and Kit/SCF-R. Mutations in exon 8 of c-kit have been identified in a high proportion of AML cases, and all had the inv. 16 re-arrangement. Conversely, ~20% of inv. 16 AMLs had c-kit exon 8 mutations. All exon 8 mutations involved either deletion or replacement of the codon for D419. The functional consequences of these mutations for the kinase activity of Kit/SCF-R are unknown at present. However, retroviral transduction of murine hematopoietic precursors with D816V-Kit and transplantation of these cells into syngeneic hosts resulted in myeloid leukemias in a significant proportion of cases, showing that GOF mutations in Kit is sufficient for leukemic progression in mice. It has been suggested that constitutive association of ►BCR-ABL1 with activated Kit/SCF-R is responsible for the basophilia and myeloid growth in the chronic phase of ►CML. However, the ability of SCF to stimulate blast growth has also been utilized to mobilize peripheral CD34+/CD38– and other committed progenitors in patients about to undergo bone marrow transplantation for subsequent autologous transplantation. Addition of SCF together with G-CSF and with standard chemotherapy is superior to G-CSF and chemotherapy for this purpose.

Germ Cell Tumors

All carcinoma-in-situ (►CIS) testis, ~90% of seminomas and dysgerminomas, but only ~5% of non-seminomas express Kit/SCF-R. Isochrome 12p is a marker of ►germ cell tumors, and ►loss of heterozygosity on the long arm of chromosome 12 implicates SCF as a tumor suppressor. Furthermore, intersex gonads (45X/46XY and other cases with additional Y chromosome material) have delayed Kit expression and increased testicular cancer risk. This could indicate an anti-oncogenic role of Kit/SCF-R and its ligand for germ cell tumor development under some circumstances. However, other results might indicate that SCF and Kit/SCF-R can drive tumor progression. Hence, ectopic expression of Kit and SCF has been found in cervical and ovarian carcinomas and ovarian teratomas. Furthermore, there is an association between mediastinal germ cell tumors (MGCT) and hematological malignancies (e.g. acute leukemia and malignant histiocytosis), and often Kit-positive areas are found in these mediastinal tumors. This and other results have made it clear that Kit/SCF-R expression is a diagnostic aid for extragonadal seminomas. All classical seminomas are Kit-positive, aneuploid and positive for placental alkaline phosphatase, while 40% of spermatocytic seminomas are Kit-positive, and all are diploid or polyploid and negative for placental alkaline phosphatase. This indicates that some spermatocytic seminomas might originate from primordial germ cells. In line with this, experimental testicular teratomas can be generated by transplanting E12 male genital ridges to

testes of adult mice. Importantly, it was recently found that tumors of seminoma/dysgerminoma type had a D816H mutation in Kit/SCF-R causing its constitutive activation. In conclusion, Kit/SCF-R expression is of diagnostic help for seminomas/dysgerminomas, and GOF mutations in Kit/SCF-R might be oncogenic and involved in the generation of such tumors.

Malignant Melanoma

Normal melanocytes depend on ►bFGF, ►HGF and SCF in vitro. ►Melanoma cells become independent of these growth factors, in part through autocrine bFGF stimulation. Interestingly, Kit mRNA and protein are down-regulated in human and murine ►melanoma cell lines. This correlates with in vivo findings: While Kit/SCF-R is expressed in normal melanocytes, benign and dysplastic naevi and nontumorigenic melanomas, expression is lost in dysplastic naevi, tumorigenic primary melanomas and metastases. In addition, transfection of Kit/SCF-R into highly metastatic melanoma cell lines, induced slowed growth rate and fewer lung metastases in nude mice. The transcription factor AP-2 controls expression of c-kit and the gene for MCAM/MUC18 positively and negatively, respectively. AP-2 is down-regulated in melanomas and this is thought to be the reason for loss of Kit expression, allowing the malignant cells to escape SCF-induced apoptosis. Conversely, enforced AP-2 expression suppresses tumorigenicity and metastatic potential, possibly through c-kit transactivation and subsequent SCF-induced apoptosis. It has been proposed that AP-2 loss is a crucial event in malignant melanoma development.

Other Neoplastic/Malignant Lesions

Kit/SCF-R and its ligand have been found co-expressed in cells from ►small cell lung cancer and ►neuroblastoma, and it was reported that it might be involved in malignant progression in these cases. In ►neurofibromatosis 1 (NF-1) there is infiltration with Kit-positive mast cells in the neurofibroma tissue, which is composed mainly of Schwann cells with an increased SCF mRNA expression compared to normal skin. The mast cells produce collagen VIII, which might contribute to the fibrosis in this disease. There is an abnormally high expression level of Kit in NF-1-derived Schwann cell lines and decreased neurofibromin expression (Ras-GTPase). The proliferation is Kit-dependent. In myelodysplastic lesions, Kit mutations might be involved in the pathogenesis. A recurrent D52N-Kit/SCFR mutation has been reported in these cases. Finally, down-regulation of Kit/SCF-R has been reported in breast cancer and in ►thyroid carcinoma, despite expression by normal mammary duct epithelial cells and thyroid cells. It has been proposed that the Kit/SCF-R downregulation enables de-differentiation of the cells in these tumor types.

Gene Transfer, Immunotherapy, Vaccination

SCF might be useful in expansion of peripheral blood leukocytes and of hematopoietic progenitors in culture before retroviral transduction or re-introduction in conjuction with autologous bone marrow transplantation. Phase II and III trials are currently being conducted on advanced stages of breast cancer and certain leukemias for this purpose. SCF might also be useful in conjuction with immuno-therapy. For instance, following high-dose ►cyclophosphamide and IL-3, ►dendritic cells can be mobilized and expanded ex vivo from CD34+ cells in the presence of GM-CSF, TNFα, Flt3 ligand and SCF. Dendritic cells are competent antigen-presenting cells for CD8+ cytotoxic T cells, so they can be used to stimulate the host immune defense against undesirable antigens, including tumor antigens. Ongoing phase II trials are examining the use of such expanded dendritic cells for immunotherapy or vaccination. Finally, in the past five years several small molecule protein kinase inhibitors have been approved as drugs for the treatment of specific types of cancer. Among these are two that act as inhibitors of Kit tyrosine kinase activity. ►Imatinib (STI571/GleevecTM), an Abl, PDGFR and Kit inhibitor, was originally approved by the FDA for the treatment of chronic myelogenous leukemia (►CML) in 2001. Shortly thereafter, imatinib was shown to be efficacious for treatment of gastrointestinal sarcomas (GIST), which are caused by mutant forms of Kit and PDGFRalpha, and was approved by the FDA for treatment of GIST in 2002. In 2006, a second tyrosine kinase inhibitor (TKI), ►sunitinib (SU11248/SutentTM), was approved for the treatment of imatinib-resistant GIST. Several additional TKIs have either approved or are in clinical trials for the treatment of cancer and other diseases caused by mutant Kit and other activated tyrosine kinases, and the number of approved TKI drugs is likely to grow significantly in the next ten years.

Klatskin Tumors

Tania M. Welzel, Katherine A. McGlynn
Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Bethesda, MD, USA

Synonyms

(Peri-) Hilar Cholangiocarcinoma; Extrahepatic; cholangiocarcinoma; Cholangiocellular carcinoma; Bile duct carcinoma

Definition

Klatskin tumors are anatomically defined as extrahepatic ►cholangiocarcinomas that occur at the confluence of the left and right hepatic duct (Fig. 1a). Morphologically, most Klatskin tumors (hilar cholangiocarcinomas) exhibit a nodular-sclerosing growth pattern. Few are papillary tumors and mass-forming hilar lesions are rare. Histologically, the vast majority of these tumors are adenocarcinomas.

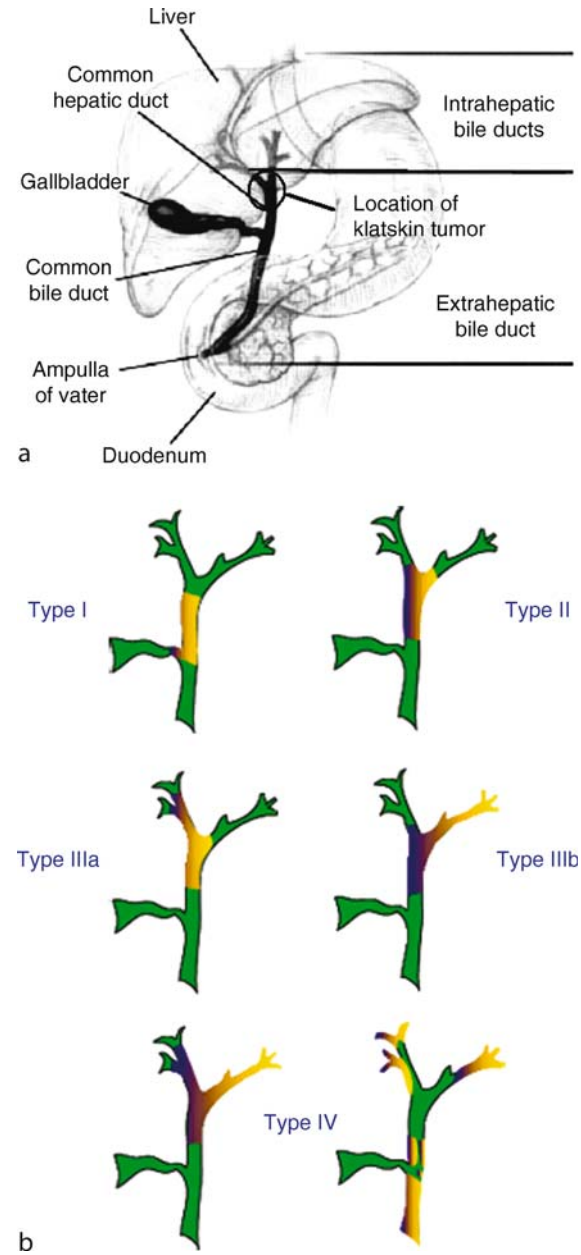
Characteristics

History and Classification

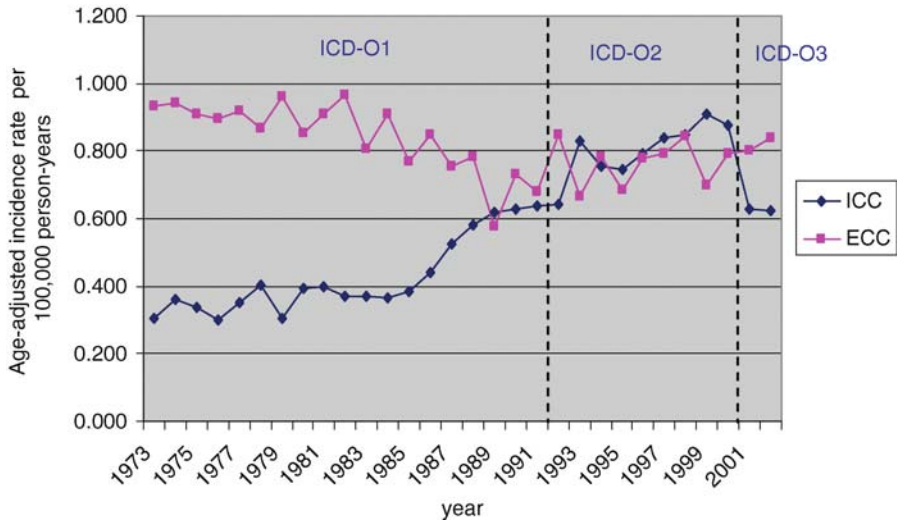
Hilar cholangiocarcinomas were first described by Klatskin and were further classified by Bismuth and Corlette (Fig. 1b): Bismuth type I tumors involve the common hepatic duct below the confluence of the right and left hepatic ducts; Bismuth type II tumors involve the confluence of the left and right hepatic duct; Bismuth type III tumors involve the common hepatic duct and the right (type IIIa) or left hepatic duct (type IIIb). Bismuth type IV tumors involve either the confluence of the hepatic ducts and the right and left hepatic duct, or are multicentric.

Epidemiology

Over the last decades, the incidence of intrahepatic cholangiocarcinoma increased in the United States, as it did worldwide. In contrast, the incidence of extrahepatic cholangiocarcinoma remained constant (Fig. 2). A recent study showed, that extrahepatic cholangiocarcinomas (including Klatskin tumors and distal extrahepatic lesions) represent ~50% of all cholangiocarcinomas in the Surveillance Epidemiology and End Results (SEER) cancer registries of the United States. A frequently cited study reported that 67% of cholangiocarcinomas were hilar tumors. However, the study was a retrospective examination of cholangiocarcinoma patients who underwent surgical exploration at a tertiary medical center. Due to the study design, the patients were unlikely to be representative of all cholangiocarcinoma patients in the United States. In addition, the International Classification of Diseases for Oncology (ICD-O) assigned Klatskin tumors a histology code rather than a topography code, and the histology code was cross-referenced to the topography code for intrahepatic rather than extrahepatic tumors. This misclassification has introduced error into the reporting of cholangiocarcinoma rates in the U.S. SEER cancer registries, making it impossible to define Klatskin tumor incidence on a population-based level.



Klatskin Tumors. Figure 1 (a) Anatomical location of Klatskin tumors. (b) Bismuth Corlette classification of Klatskin tumors (hilar cholangiocarcinoma).



Klatskin Tumors. Figure 2 Age-adjusted incidence rates for intrahepatic CC (ICC), extrahepatic CC (including Klatskin's tumors under 8162/3; ECC) diagnosed in SEER9 registries, 1973–2002. The dashed line represents the incidence of tumors reported in SEER to histology code 8162 (Klatskin). It must be noted that these tumors are unlikely to comprise all Klatskin tumors, since according to the ICD-O coding (1992–to date) could also be coded as ECC using other histology codes.

Etiology and Risk Factors

There is recent evidence that the molecular pathogenesis of Klatskin tumors/extrahepatic cholangiocarcinoma and intrahepatic cholangiocarcinoma may differ. Conditions that are associated with biliary inflammation increase the risk for cholangiocarcinogenesis. Well defined risk factors for Klatskin tumors and other extrahepatic cholangiocarcinomas include primary sclerosing cholangitis, infection with liver flukes (*Opisthorchis viverrini, Clonorchis sinensis*), choledochal cysts, ►Caroli Syndrome, biliary stones, smoking and ►Thorotrast exposure. Hepatitis C virus has been reported to be associated with intrahepatic cholangiocarcinoma and, in some reports, with hilar cholangiocarcinoma. Many patients do not exhibit any of the known risk factors, highlighting the need for further studies on etiopathogenesis of these tumors.

Biology

Diagnosis

Clinical Symptoms. Patients present with obstructive jaundice (icterus, dark urine, pale stools, pruritus) and weight loss, and frequently signs of bacterial cholangitis. Abdominal pain and ascites may be present in patients with advanced disease.

Biochemical Investigations. Parameters indicating *obstructive* cholestasis such as increased alkaline phosphatase, gamma glutamyltranspeptidase, serum bilirubin, and sometimes transaminase concentrations, may be found in patients with Klatskin tumors. ►Tumor markers such as ►CA 19-9 and ►CEA, may be elevated. These tumor markers, however, are not specific for Klatskin tumors/cholangiocarcinoma and CA19-9 may also be elevated in conditions with benign cholestatic disease.

Imaging Methods. Accurate diagnosis is key to delineate benign from malignant biliary strictures and to determine the resectability of Klatskin tumors. Ultrasound is the initial diagnostic test to evaluate hilar cholangiocarcinoma and may show intrahepatic duct dilatation and caliber changes of bile ducts, but may fail to show liver infiltration of smaller tumors. On ►computed tomography (CT), the primary obstructing hilar lesion may be invisible. On contrast enhanced CT, (infiltrative) lesions may show as thickening of the duct. Further signs include dilatation of the intrahepatic bile ducts or the atrophy-hypertrophy complex. Used to assess resectability, the accuracy of CT ranges from 60 to 75%. On ►magnetic resonance imaging, Klatskin tumors appear hypointense on T1- and hyperintense on T2-weighted images. Compared to the liver parenchyma, most Klatskin tumors are hypovascular. Gadolinium chelates and ferumoxide contrast agents can be used to assess liver invasion because of a good liver-tumor contrast. Magnetic resonance cholangiopancreatography (MRCP) can be used to visualize the obstructing lesion and intrahepatic bile duct dilatation and, in a small study, was shown to have an accuracy of 84% to assess the level of bile duct involvement.

Endoscopic retrograde cholangiopancreatography (ERCP) can be used to endoscopically determine the

location and extent of biliary tract obstruction. ERCP also allows palliative stent implantation for biliary drainage, and to obtain tumor cytology or biopsy. However, according to the specific growth pattern of Klatskin tumors, the sensitivity of brush cytology is 30%, and the combination of brush cytology/biopsy only ranges up to 70%.

Treatment

To date, the only curative approach to hilar cholangiocarcinomas is surgery with resection of the bile ducts and hepatojejunostomy, and/or partial hepatectomy to achieve tumor free margins. However, at the time of diagnosis, only few/a small proportion of patients have resectable disease. Resection is contraindicated for Bismuth Type IV tumors or in the presence of any of the following: vascular encasement, occlusion or invasion of the main portal vein or hepatic artery, distant or lymph node metastases, liver invasion, or invasion of extrahepatic organs. Surgery for hilar cholangiocarcinoma with curative intent is associated with 5-year survival rates of 40%. Recently, there has been some evidence that liver transplantation, together with neoadjuvant chemoradiation may improve survival in selected patients with unresectable hilar cholangiocarcinoma.

►Palliative approaches include the endoscopic placement of biliary stents or percutaneous biliary drainage to improve the symptoms of cholestasis. ►Photodynamic therapy with hematoprophyrin based photosensitizers, in addition to bilateral endoprosthesis insertion, has been shown to prolong survival by several months and improve quality of life in several randomized controlled trials. So far, ►radiation, as well as systemic ►chemotherapy has not led to a significant improvement of survival rates, however, several new protocols are currently under investigation.

Survival

The prognosis of hilar cholangiocarcinoma is poor, with 5 year survival rates ranging between 5 and 10%.

Knock-out Mice

►Knock-out Mouse

Knock-Out Mouse

Definition

Knock-out mouse is a genetically engineered mouse carrying one or more of its genes made inoperable through a ►gene knockout (usually an inactivating mutation). Knockout is a technical approach to functionally characterize a gene that has been sequenced but has an unknown or incompletely known function. Because genes between mouse and humans are evolutionary conserved and, a priori, are assumed to have similar functions, the phenotype that a knock-out gene has in the mouse may be used to extrapolate its function in humans. For many genes, however, disease-associations in humans did not identify a similar phenotype in a knock-out mouse. Different strains of the mouse also may develop different phenotypes upon knock-out of a particular gene.

Knockdown

Definition

Gene knockdown refers to the experimental reduction of expression of a gene. This is commonly achieved by introducing small interfering RNAs (►SiRNAs) or other anti-sense oligonucleotides into cells.

►Antisense Nucleic Acid

Knudson Hypothesis

Definition

Originally described as a model where in retinoblastoma two genetic "hits" result in cancer; subsequently, the two "hits" were identified as occurring as inactivating mutations in the two alleles of a gene today known as the ►retinoblastoma gene (*RB1*). The two mutations can occur somatically in an individual. More often, one mutation inactivates one allele in a germ cell, the developing embryo then has one inactivated and one normal allele. Because of the ►recessive nature of the *RB1* gene, there will be no phenotype in the child, it does have however an increased risk. In most cases, the remaining normal allele will mutate in the retina during early childhood resulting in cells with both *RB1* alleles inactivated. As the consequence, the child will develop retinoblastoma.

This two-hit hypothesis has been generalized to entertain the idea that most cancers develop following this model. Accordingly, numerous ►loss-of-heterozygosity studies have been done on virtually every tumor entity to identify genomic regions deleted on one tumor cell chromosome with co-existing gene mutation on the other chromosome. Only in few models the two-hit model could be convincingly verified, and today the Knudson hypothesis more or less appears to be restricted to few cancer types. Instead, there are convincing data now to support the idea that cellular effects supporting the process of malignant cellular conversion can result from the inactivation of one of the alleles. The basic concept here is ►haploinsufficiency.

Koch's Postulates

Roy J. Duhé
Department of Pharmacology and Toxicology, University of Mississippi Medical Center, Jackson, MS, USA

Synonyms

Henle–Koch postulates

Definition

A set of criteria used to identify the specific pathogen that causes an infectious disease.

Characteristics

Koch's postulates are attributed to Robert Koch, who received the 1905 Nobel Prize in Medicine or

Physiology "for his investigations and discoveries in relation to tuberculosis." Jakob Henle was a professor at the University of Göttingen when Koch enrolled as a student there in 1862, and Henle was one of the early proponents of the idea that contagious diseases were caused by microorganisms. In the early days of bacteriology there were numerous heated arguments over the identity of pathogenic agents. The presence of commensal microorganisms alongside pathogenic microorganisms often resulted in the misidentification of the real disease-causing organism. At that time there was also a school of thought which held that there were no true bacterial species, but rather that a bacterium could adopt nearly limitless morphologies and physiologies, which would allow it to cause tuberculosis, anthrax, food spoilage, or other problems depending on the particular form adopted by the bacterium. It was against this backdrop that Koch proposed the following three criteria (as translated by Thomas M. Rivers) for identifying a microbiological cause of disease.

1. "The parasite occurs in every case of the disease in question, and under circumstances which can account for the pathological changes and clinical course of the disease."
2. "It occurs in no other disease as a fortuitous and non-pathogenic parasite."
3. "It, after being fully isolated from the body and repeatedly grown in pure culture, can induce the disease anew."

Koch famously applied these principles as he isolated *Bacillus anthracis* and *Mycobacterium tuberculosis* and identified them as the causes of anthrax and tuberculosis, respectively. By establishing a theoretical framework for determining cause and effect, Koch's postulates had a profound effect on infectious disease research. Within a few decades, the identities of dozens of new pathogens were revealed. Yet these precepts had obvious limitations arising from the simple fact that not all pathogens can be propagated in pure form as autonomous living organisms. Viruses were the first such examples to be considered by the scientific community, and it was soon apparent that Koch's postulates had to be revised to accommodate the scientific discoveries of the twentieth century. Over the years since Koch's postulates were first postulated, many investigators have articulated a revised set of criteria to permit the systematic evaluation of viruses, prions, serum cholesterol, tobacco smoke, chromosomal translocations (►chromosomal translocation) and other factors as the underlying cause of a disease, contagious or otherwise.

In 1976, Alfred S. Evans proposed the following ten criteria as a "unified concept" for disease causality, which could be applied to either chronic or acute diseases.

1. *Prevalence* of the disease should be significantly higher in those exposed to the putative cause than in case controls not so exposed.
2. *Exposure* to the putative cause should be present more commonly in those with the disease than in controls without the disease when all risk factors are held constant.
3. *Incidence* of the disease should be significantly higher in those exposed to the putative cause than in those not so exposed as shown in prospective studies.
4. *Temporally*, the disease should *follow* exposure to the putative agent with a distribution of incubation periods on a bell shaped curve.
5. *A spectrum* of host responses should follow exposure to the putative agent along a logical biologic spectrum from mild to severe.
6. *A measurable host response* following exposure to the putative cause should *regularly appear* in those lacking this before exposure (i.e. antibody, cancer cells) or should *increase* in magnitude if present before exposure; this pattern should not occur in persons so exposed.
7. *Experimental reproduction* of the disease should occur in higher incidence in animals or man appropriately exposed to the putative cause than in those not so exposed; this exposure may be deliberate in volunteers, experimentally induced in the laboratory, or demonstrated in a controlled regulation of natural exposure.
8. *Elimination or modification* of the putative cause or of the vector carrying it should decrease the incidence of the disease (control of polluted water or smoke or removal of the specific agent).
9. *Prevention or modification* of the host's response on exposure to the putative cause should decrease or eliminate the disease (immunization, drug to lower cholesterol, specific lymphocyte transfer factor in cancer).
10. The whole thing should make biologic and epidemiologic sense.

The correct identification of the cause of a cancer is essential, because the cause can either be avoided, thereby preventing cancer, or the cause can be targeted through drug design, thereby curing the cancer. It is also clear that if one invests preventive or drug design efforts into the wrong cause, then one will have accomplished naught. Obvious limitations of Koch's postulates arise when one attempts to apply them to non-contagious diseases, when suitable animal models for reproducing the disease do not exist, or when there is an inordinately long latent period between initial exposure to the causal agent and the disease's manifestation. These circumstances often apply to the development of cancer. The ability of a pathogenic agent to cause cancer is also dependent upon the presence or absence of various tumor

suppressors, which causes some individuals to be more susceptible to developing cancer than others. For these and other technical reasons, it is often unwise to dogmatically invoke Koch's postulates in an effort to disprove a particular agent as a cause of disease. An infamous controversy arose in the late 1980s and early 1990s when Koch's postulates were invoked in an attempt to disprove that HIV-1 caused AIDS, although that pathogenic link is now universally accepted. Koch's postulates are of great historical significance because they marked the application of logic and reason to the field of pathology. As many scholars have noted, it is unwise to insist upon the application of the original postulates when we now know that there are pathogenic mechanisms that do not conform to the lifestyles of protozoa, fungi, or bacteria. It is the rigorous application of logic and reason to the elucidation of the cause of disease which remains as the lasting legacy of Koch's postulates.

KSP Mitotic Spindle Motor Protein

Weikang Tao
Department of Cancer Research, Merck Research Laboratories, West Point, PA, USA

Synonyms

Eg5; Kinesin spindle protein; KSP; Kinesin-5; Kinesin-like protein KIF11

Definition

KSP mitotic spindle motor protein is a microtubule-associated molecular motor belonging to the ►kinesin superfamily, which plays an essential role in the separation of centrosomes, the assembly of bipolar spindles, and the faithful segregation of chromosomes into daughter cells during ►mitosis.

Characteristics

KSP is a plus-end-directed ►microtubule motor protein, well conserved from yeast to mammals. It can generate directed mechanical force by hydrolyzing ATP and move along microtubule filaments from the minus end (oriented towards the nucleus) to the

plus end (oriented towards the cell periphery). The KSP protein contains a highly conserved N-terminal motor domain encompassing the head and neck motifs, a coiled-coil stalk domain, and a tail region containing a characteristic BimC box close to the C-terminus. Based on the N-terminal motor domain sequence, the vertebrate KSP belongs to the BimC subfamily of ►kinesins, a large family of ►microtubule-based motor proteins. More recently, KSP was classified to the kinesin-5 subgroup according to a new nomenclature system. The globular motor domain of KSP is responsible for catalyzing hydrolysis of ATP, interacting with microtubules and nucleotides, and driving the movement along microtubules empowered by ATP hydrolysis, whereas the stalk domain mediates protein–protein interactions to form homotetramers. Active KSP is a homotetramer in which two polypeptides first dimerize to form a parallel coiled-coil and then two dimers form an antiparallel tetramer containing four motor domains with a dimeric motor unit at each end (Fig. 1). As a tetramer, KSP is able to crosslink and translocate along two adjacent microtubules with each dimeric motor unit interacting with a single microtubule fiber. Fluorescence studies suggest that when binding to two antiparallel microtubules, KSP can slide them apart, thereby pushing spindle poles apart. If binding to two parallel microtubules, KSP can mediate bundling of parallel microtubules, contributing to the assembly and integrity of mitotic spindles (Fig. 2).

Like other ►kinesins of the BimC subfamily, human KSP is required early in prometaphase for the separation of duplicated centrosomes and the formation of bipolar mitotic spindles. Inhibition of KSP with neutralizing antibodies, small molecule inhibitors, or small interfering RNAs (siRNAs) causes formation of the characteristic monopolar mitotic spindle (also termed monoaster), a radial array of microtubules surrounded by a ring of chromosomes, and cell cycle arrest at prometaphase. Further studies indicate that suppression of KSP activates the ►spindle assembly checkpoint, thereby preventing the onset of anaphase and causing mitotic arrest. Prolonged mitotic arrest induces apoptosis.

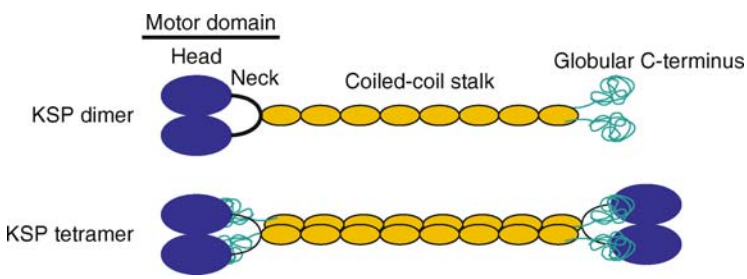
Inhibition of KSP does not affect postmitotic cells, indicating that KSP is only required for cell proliferation and that it functions exclusively in mitosis. Consistent with its exclusive role in cell division, KSP is preferentially expressed in proliferating tissues, such as thymus, bone marrow ,and intestine epithelium, with minimal or no expression in nonproliferating tissues such as the central nervous system. In addition, it displays much more abundant expression in actively proliferating tumor tissues than in normal adjacent tissues.

Regulation

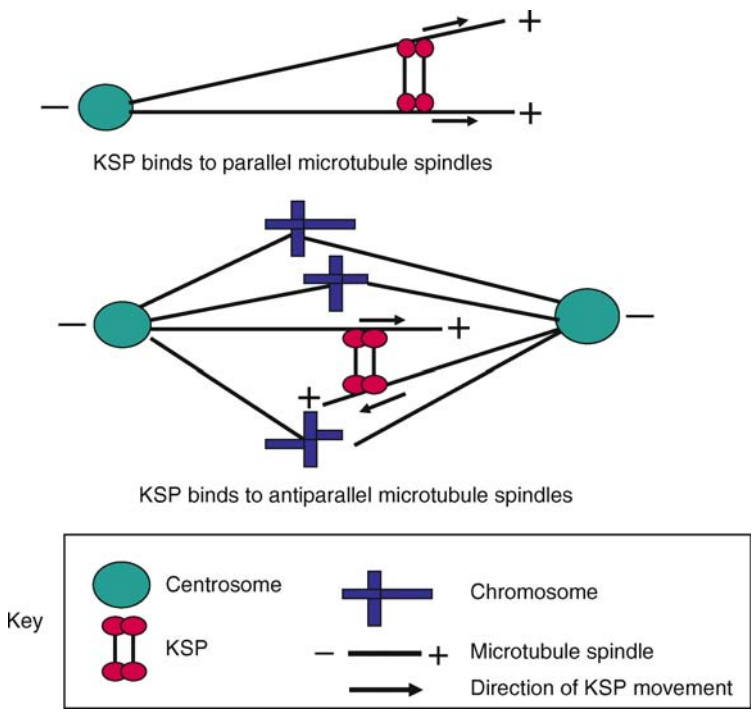
The ATPase activity of KSP is essential for its function and it is stimulated by the interaction with microtubules. The control of ATPase activity by interactions with microtubules is thought to prevent futile hydrolysis of ATP. It has been shown that there is an evolutionarily conserved $p34^{cdc2}$ phosphorylation site (Thr-927 in human KSP) located in the BimC box of KSP, and that $p34^{cdc2}$-mediated phosphorylation of this site controls the association of KSP with the microtubule spindles. Moreover, KSP can be phosphorylated by ►Aurora kinase, a mitotic kinase, but the functional importance of this phosphorylation remains to be determined.

Relevance to Cancer

The mitotic spindle is a protein complex consisting of multiple components including microtubules and motor proteins and it is a pharmaceutically validated target for cancer therapeutics. ►Vinca alkaloids and ►taxanes that interfere with the dynamics of microtubules by binding to β-tubulin perturb mitosis and have been used in the clinic for decades for the treatment of many human malignancies. However, since microtubules have essential functions beyond mitosis in nonproliferating cells, including intracellular transport



KSP Mitotic Spindle Motor Protein. Figure 1 Schematic representation of the structures of KSP dimmer and tetramer.



KSP Mitotic Spindle Motor Protein. Figure 2 Schematic illustration of KSP functions.

and organelle positioning, drugs that target microtubules cause microtubule-dependent side effects, such as peripheral neuropathy. In addition, an increasing number of tumors have acquired resistance to these antimicrotubule drugs via various mechanisms including acquired mutations on β-tubulin, altered expression of tubulin isoforms, changed microtubule dynamics as well as elevated expression of membrane drug efflux pumps like ►P-glycoproteins (P-gp). Thus, agents that are able to selectively disrupt the mitotic spindle via a novel mechanism of action and without P-gp liability are greatly desired for cancer therapy.

There are several important traits that make KSP an attractive target for cancer treatment: (i) KSP is a crucial component of the mitotic spindle and is essential for spindle bipolarity and proper segregation of chromosomes during mitosis. (ii) KSP functions exclusively in dividing cells and there is no evidence that inhibition of KSP affects nonproliferating cells. (iii) KSP is overexpressed in tumor tissues relative to adjacent normal tissues. (iv) Since KSP is an ATPase and the ATPase activity is required for its function, KSP is a druggable target. Indeed, a number of small molecule inhibitors of KSP ATPase with distinct chemical structures have been generated and currently at different stages of development. Some specific inhibitors of KSP have exhibited broad antiproliferative activity in tumor cell lines and significant antitumor efficacy in various murine tumor models. A few KSP inhibitors have entered clinical trials. Among them ispinesib demonstrated some activity in taxane-treated patients with metastatic breast cancer in a phase II study. As expected, the clinical trial data indicate that KSP inhibitors could not exhibit neurotoxicity because of their lack of effect on microtubule dynamics.

Although KSP inhibitors hold great promise for cancer treatment, their clinical antitumor activity remains to be determined. The clinical development of these novel antimitotic agents holds many challenges. A critical issue is how to identify the responders in the clinic, or what ►biomarkers could predict clinical response of tumors to KSP inhibitors. Preclinical studies suggest that tumor cells with a competent spindle assembly checkpoint are more sensitive to KSP inhibitor-mediated cell death than those with a deficient spindle checkpoint. This awaits confirmation in the clinic. Additionally, a better understanding of the mechanism that mediates the lethality of these agents or the link between KSP inhibition and induction of cell death is required to guide the selection of dosing schedules and the identification of determinants of drug sensitivity. Finally, since antimicrotubule drugs and KSP inhibitors may kill cancer cells through a partially overlapping pathway, elucidation of the mechanisms that cause resistance to microtubule inhibitors in the clinical setting would tell whether KSP inhibitors should be used for the treatment of antimicrotubule agent-resistant tumors.

Kupffer Cells

Peter Thomas
Departments of Surgery and Biomedical Sciences, Creighton University, Omaha, NE, USA

Synonyms

Hepatic (Liver) fixed macrophages

Definition

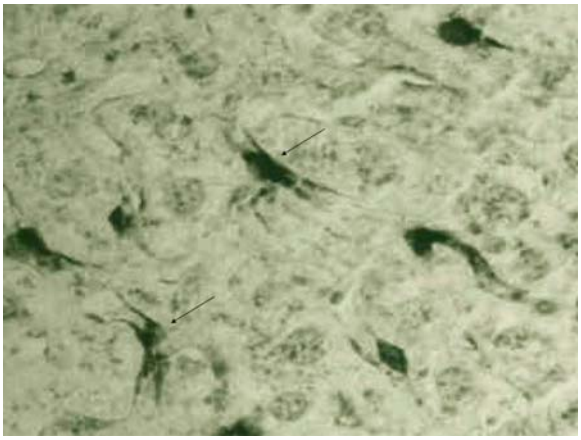
Kupffer cells are ►macrophages that are fixed within the sinusoids of the liver. They are the body's most abundant source of fixed macrophages.

Characteristics

Kupffer cells were first described in 1876 and are named for, the German pathologist Karl Wilhelm von Kupffer who called them the star cells (sternzellen) of the liver. Kupffer cells are tissue macrophages that are located in the hepatic sinusoidal blood flow attached to the endothelial cell lining. They represent 10% of all liver cells and are the body's largest population (approximately 80%) of fixed macrophages. They are the first macrophage population to contact bacteria, bacterial debris and ►endotoxins arising in the gastrointestinal tract. Kupffer cells are both highly endocytic and phagocytic and a major function is to remove particulate matter from the circulation. They are also an important component of innate immunity which is the most rapid response to dangerous stimuli and can modulate immune responses by antigen presentation and suppression of T-cell activation. Thus, the main role of Kupffer cells is to protect the body by removing potentially harmful substances from the blood. In addition Kupffer cells function to remove and destroy old red blood cells. Kupffer cells have also been implicated in cancer cell surveillance (see below). Kuppfer cells originate in the bone marrow. These bone marrow monocytes enter the circulation and become implanted in the liver where they differentiate into fixed tissue macrophages. Kupffer cells are considered terminally differentiated and the cells no longer divide (Fig. 1).

Kupffer Cells and Liver Disease

Kupffer cells are involved in the development of alcoholic liver disease. Kupffer cells become activated when they are exposed to the bacterial cell wall component endotoxin (Lipopolysaccharide, LPS). This results in the secretion of signaling molecules including ►cytokines and ►reactive oxygen species (ROS), which can be damaging to liver cells especially those that have been affected by alcohol ingestion and contain a large amount



Kupffer Cells. Figure 1 Section of mouse liver showing stellate shaped Kupffer cells (arrows). The cells are stained by the immunoperoxidase method for the presence of a breast cancer associated antigen, the gross cystic disease fluid protein (GCDFP-15), 15 min after intravenous injection of the purified protein.

of fat (alcoholic steatosis). Endotoxin is produced by gram negative bacteria in the large intestine and ingestion of alcohol alters the permeability of the intestine (leaky gut) to endotoxin causing an increased level in the portal blood entering the liver. To activate Kupffer cells and other macrophages endotoxins combine with a serum protein, lipopolysaccharide binding protein (LBP). This complex reacts with a cell surface receptor, ►CD14 which in turn interacts with the Toll like receptor ►TLR4 and the intracellular signaling protein ►MyD88. This causes a cascade of intra-cellular signals that activate transcription factors such as ►NFκB and result in the synthesis and secretion of cytokines and ROS.

Relationship of Kupffer Cells to Primary and Secondary Liver Cancers

The liver is a favored site for the secondary spread of many cancers including those of the large intestine and breast. The role of Kupffer cells in the development of cancers in the liver is controversial. There is no doubt that they play an important part in both the development of primary liver cancer (►hepatocellular carcinoma or hepatoma) and in the formation of ►metastasis from a distant site including cancers of the lungs, breast, colon and other gastrointestinal cancers. Some experimental studies have shown that elimination of Kupffer cells from the liver results in enhanced metastatic disease. Other studies have implicated Kupffer cells as agents that interact with the tumor cells entering the liver and their pro-inflammatory responses can induce tumor cell implantation and growth allowing increased metastatic disease. In primary liver cancer recent evidence has shown a role for Kupffer cell activation in carcinogenesis and progression of the cancer. Some liver carcinogens are able to activate Kupffer cells and induce cytokines and other factors that promote hepatocyte growth. These factors can also effect growth of pre-neoplastic cells and lead to the development of hepatoma. Evidence has accumulated that the pro-inflammatory cytokine IL-6 plays an important role in promoting hepatoma cell survival and proliferation. This tumor cell related increase in IL-6 is mediated through the MyD88/NFκB signaling cascade in Kupffer cells. In the case of colorectal cancer metastasis to the liver cytokines produced by Kupffer cells play a part in both tumor cell implantation and their subsequent survival and growth. During the development of colorectal cancer metastasis to the liver, Kupffer cells respond to the glycoprotein carcinoembryonic antigen (►CEA). The cells bind CEA via a pentapeptide that reacts with a surface protein that is identical to the RNA binding protein hnRNP M4. This results in Kupffer cell activation and a cytokine cascade that includes IL-1, IL-6, IL-10 and TNF-α. The high local concentration of cytokines produced within the hepatic sinusoids has multiple effects that influence cancer cell implantation, survival and proliferation. The initial effect of the Kupffer cell produced cytokines seems to be on the sinusoidal endothelial cells. They become activated and produce adhesion molecules such as ►E-selectin and ►ICAM-1 on their cell surfaces. This allows the cancer cells to attach to the endothelial cell layer and arrest in the liver sinusoids. When this happens the tumor cells can break through the endothelial cell layer and invade the parenchyma Cytokines, in particular IL-10 are also protective against the effects of ischemia/reperfusion (IR) injury caused by blockage of the blood supply by tumor cell infiltrates into the small sinusoids. IR causes oxidative stress and cell death. Secretion of anti-inflammatory cytokines such as IL-10 counteracts these effects and aids the initial survival of the cancer cells following implantation in the sinusoids. These studies were largely carried out using human colorectal cancer cells in culture or in metastasis models in immuno-suppressed mice and imply that Kupffer cells are important participants in metastasis development. However, other experiments using syngeneic animal tumors have shown a role for Kupffer cells in preventing liver metastasis. Experiments where Kupffer cells have been depleted prior to injection of tumor cells have often resulted in extensive tumor growth in the liver. Similarly when Kupffer cells have been activated prior to tumor cell injection reduced tumor growth in the liver is seen.

Kupffer Cell Cancers

Cancer originating in Kupffer cells is very rare and few cases have been reported in the literature. They are described as Kupffer cell ►sarcomas or hemangioendotheliosarcomas of the liver. The tumors contain

phagocytic giant cells and numerous other cells with morphology similar to Kupffer cells. These hemorrhagic tumors tend to be quickly fatal with abdominal discomfort, ascites and jaundice as symptoms. Kupffer cell cancers will metastasize to distant sites including the pancreas and lung. Similar tumors to those found in humans can be induced in rats by exposure to low doses of carcinogens during liver regeneration.

Lactoferricin Antiangiogenesis Inhibitor

David W. Hoskin
Departments of Pathology, and Microbiology and Immunology, Dalhousie University, Halifax, NS, Canada

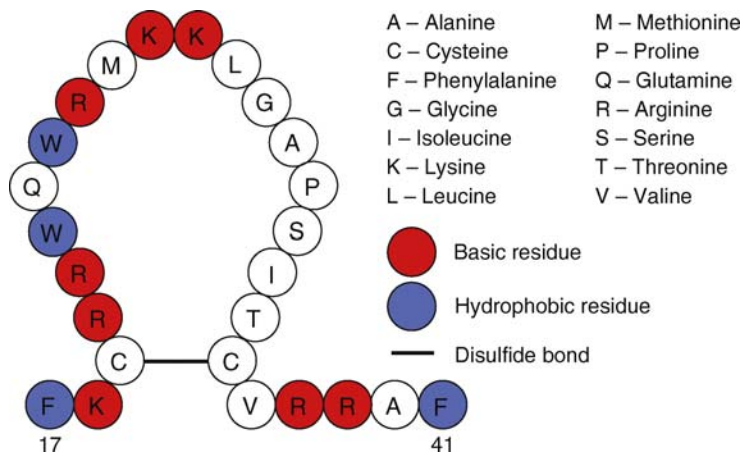
Definition
Lactoferricin is a cationic peptide that is generated by the acid-pepsin hydrolysis of mammalian ►lactoferrin present in the secretory granules of neutrophils (polymorphonuclear leukocytes), as well as in exocrine

secretions, including milk, tears, and saliva. Interestingly, substantial quantities of lactoferricin are generated in the stomach following the ingestion of lactoferrin-containing milk. Lactoferricin possesses potent antimicrobial, antiviral, immunomodulatory, and antitumor activities. In terms of anticancer activity, the best studied of the lactoferricins is bovine lactoferricin, which consists of amino acid residues 17–41 from the NH_2-terminal region of bovine lactoferrin (Fig. 1). A disulfide bond that forms between cysteine residues located at each end of the peptide creates a looped or hairpin structure. In an aqueous environment, bovine lactoferricin assumes an ►amphipathic, twisted β-sheet configuration with clear positively charged and hydrophobic faces. The relatively high proportion of asymmetrically clustered basic amino acid residues (arginine and lysine) and the hydrophobic tryptophan residues that in part comprise bovine lactoferricin are believed to be important for the peptide's biological activity.

Characteristics

The *in vitro* and *in vivo* anticancer activity of bovine lactoferricin has been attributed to the selective cytotoxic effect (either by membrane lysis or ►apoptosis induction) exerted by this cationic peptide on a broad range of cancer cell types, including leukemias, lymphomas, fibrosarcomas, and various carcinomas. However, recent studies indicate that bovine lactoferricin is also able to inhibit ►angiogenesis. A similar, but less potent, antiangiogenic activity has also been reported for bovine lactoferrin. Although ►neovascularization is normally tightly regulated by the opposing effects of proangiogenic and antiangiogenic factors, this process becomes dysregulated during tumor growth. The action of proangiogenic factors, in combination with basement membrane degradation by proteolytic enzymes, results in the proliferation, migration, and differentiation of tumor-associated endothelial cells. Neovascularization is an essential step in ►tumorigenesis since the new blood vessels provide oxygen and nutrients to rapidly dividing cancer cells and remove metabolic wastes from the tumor ►microenvironment. This allows solid tumors to grow in size, as well as promoting the development of metastatic disease. Diffusible, tumor-associated growth factors that stimulate angiogenesis include ►vascular endothelial growth factor$_{165}$, ►platelet-derived growth factor, ►heparin-binding epidermal growth factor-like growth factor, and basic ►fibroblast growth factor (also known as fibroblast growth factor 2).

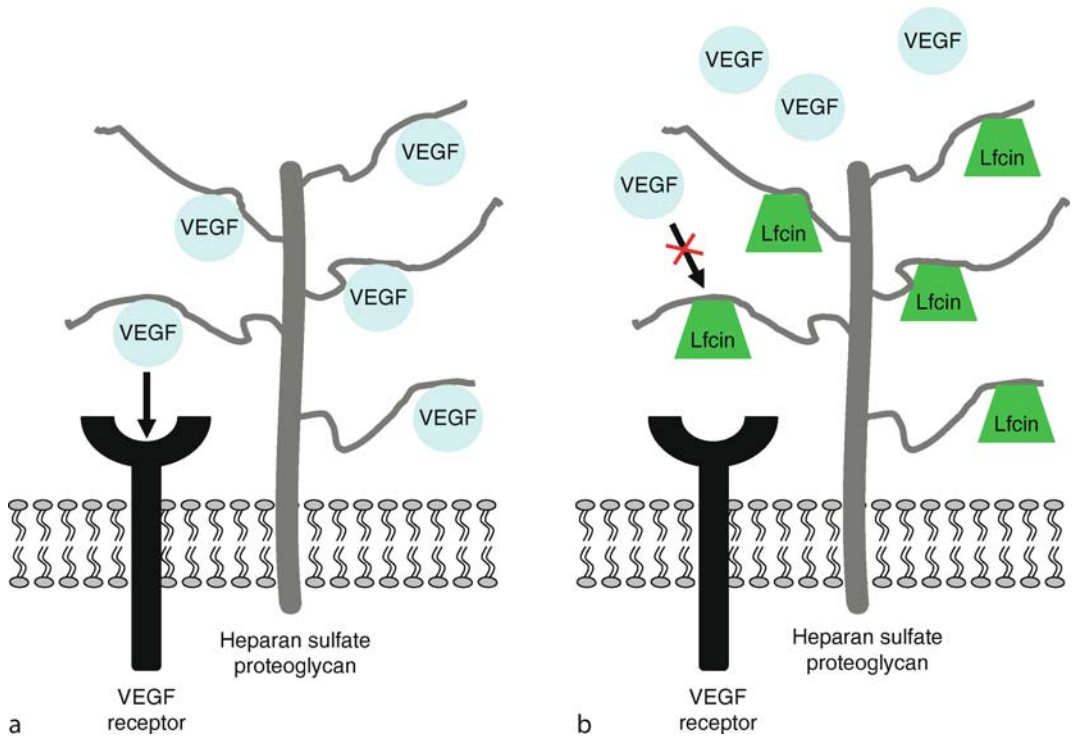
Bovine lactoferricin is a potent *in vivo* inhibitor of vascular endothelial growth factor$_{165}$- and basic fibroblast growth factor-induced angiogenesis in the mouse ►Matrigel-plug assay. This finding is consistent with the observation that administration of bovine lactoferricin by subcutaneous injection reduces the number of tumor-associated blood vessels in B16-BL6 melanoma-bearing mice. In addition, bovine lactoferricin exhibits a dose-dependent inhibitory effect on the *in vitro* proliferation of human umbilical vein endothelial cells in response to vascular endothelial growth factor$_{165}$ or basic fibroblast growth factor, as well as inhibiting the *in vitro* migration of human umbilical vein endothelial cells across transwell membranes in response to vascular endothelial growth factor$_{165}$ or basic fibroblast growth factor. Bovine lactoferricin therefore inhibits endothelial cell proliferation and



Lactoferricin Antiangiogenesis Inhibitor. Figure 1 Primary structure of bovine lactoferricin. The amino acid sequence of bovine lactoferricin is indicated by single-letter code (see the accompanying key). Basic and hydrophobic amino acid residues are important for peptide function and are colored red and blue, respectively. The disulfide bond, indicated by the solid bar between cysteine residues at opposite ends of the peptide, forms a loop consisting of 18 amino acids. Numbers indicate the sequence position in bovine lactoferrin.

migration, which are essential steps in neovascularization. Importantly, bovine lactoferricin does not affect the viability of human umbilical vein endothelial cells, suggesting that the antiangiogenic activity of bovine lactoferricin is independent of its membranelytic and apoptosis-inducing activity.

Vascular endothelial growth factor$_{165}$ and basic fibroblast growth factor must first interact with ►heparan sulfate proteoglycans on the surface of endothelial cells in order for these proangiogenic factors to bind to and trigger signal transduction through their respective cell-surface receptors. Other heparan sulfate proteoglycan-dependent proangiogenic factors that have been linked to tumor progression include platelet-derived growth factor and ►heparin-binding epidermal growth factor-like growth factor. Positively charged bovine lactoferricin mediates its inhibitory effect on basic fibroblast growth factor- and vascular endothelial growth factor$_{165}$-induced angiogenesis by interacting with negatively-charged heparin-like structures on the surface of human umbilical vein endothelial cells, thereby competing with basic fibroblast growth factor and vascular endothelial growth factor$_{165}$ for the heparan sulfate proteoglycans that are required for these proangiogenic factors to bind to and signal through their specific cell-surface receptors (Fig. 2). Although not yet formally proven, it is likely that bovine lactoferricin will have a similar inhibitory effect on angiogenesis induced by other heparin-binding tumor-associated proangiogenic factors. However, ►electrostatic interactions alone do not govern the binding of bovine lactoferricin to the heparan sulfate proteoglycans that are involved in cell-surface receptor signaling caused by heparin-binding proangiogenic factors. Thus, a scrambled form of bovine lactoferricin that retains the net positive charge of the native peptide is unable to inhibit the binding of vascular endothelial growth factor$_{165}$ or basic fibroblast growth factor to human umbilical vein endothelial cells. The primary and secondary structure that is conferred on bovine lactoferricin by its amino acid sequence is therefore an important factor in the selectivity of bovine lactoferricin for heparin-like structures that are involved in basic fibroblast growth factor and vascular endothelial growth factor$_{165}$ interactions with their respective receptors on human endothelial cells.



Lactoferricin Antiangiogenesis Inhibitor. Figure 2 Model of bovine lactoferricin-mediated blockade of heparin-binding growth factor-induced angiogenesis. (a) Heparin-binding proangiogenic growth factors such as vascular endothelial growth factor$_{165}$ (VEGF) must interact with heparin-like binding sites on heparan sulfate proteoglycans in order to bind to and signal through receptors on the surface of endothelial cells. (b) Bovine lactoferricin (Lfcin) complexes with heparin-like binding sites on cell-surface heparan sulfate proteoglycans, thereby competing with heparan sulfate proteoglycan-dependent proangiogenic growth factors for heparin-like binding sites and preventing proangiogenic growth factor receptor signaling from taking place.

Clinical Perspectives

Starving a solid tumor of its blood supply by preventing or interfering with tumor-induced neovascularization has generated considerable interest as an alternative to conventional chemotherapy for the prevention of tumor growth and metastasis. Indeed, several different inhibitors of angiogenesis are currently being used in the treatment of human cancers. However, the results obtained to date in clinical practice have been less than was hoped for on the basis of preclinical studies, most likely because the current generation of anti-angiogenic agents only target a single proangiogenic growth factor receptor, whereas multiple proangiogenic factors are typically associated with tumor-induced angiogenesis. In this regard, the ability of bovine lactoferricin to inhibit neovascularization in response to multiple heparin-binding growth factors may allow bovine lactoferricin to be more effective than current antibody-based antiangiogenic agents for the blockade of tumor-induced angiogenesis. However, the susceptibility of bovine lactoferricin to enzymatic degradation and inactivation through interactions with anionic serum components remains a major obstacle to any future use of this host defense peptide as an antiangiogenic agent. One possible solution is to synthesize an all-►D amino acid analogue of bovine lactoferricin since cationic peptides that consist of all-D amino acids exhibit dramatically increased stability in serum. Alternatively, tumor-targeted ►liposomes might be used to encapsulate and deliver bovine lactoferricin directly to tumor sites while retaining the peptide's ability to mediate antiangiogenic activity. Although preclinical studies have revealed that bovine lactoferricin is a potent inhibitor of angiogenesis, additional research will be needed in order to realize the potential of bovine lactoferricin as a novel antiangiogenic agent for the treatment of human cancers.

Laminin

Definition

LM are large, heterotrimeric, cruciform matrix glycoproteins composed of highly homologous α, β, and γ subunits. Five α (α1–5), four β (β1–4), and three γ (γ1–3) chains variably assemble to create 14 known isoforms that convey a variety of important biological functions. Specific LM isoform expression and post-translational processing can directly influence cellular response to growth factors, intracellular signaling, cell proliferation, susceptibility to apoptosis and migratory capacity. Changes in LM isoform expression in vessel walls have been shown to foster angiogenesis as well as leakage in vessels, rendering them attractive to tumor cells and susceptible to metastatic invasion. Laminins are expressed in both normal and malignant tissue, but different specific isoforms predominate in each case.

[2]Reuven Reich is affiliated with the David R. Bloom Center of Pharmacy at the Hebrew University

Definition

►Lamininś are a family of glycoproteins with an apparent molecular weight between 400 and 900 kDa. They are heterotrimers of three subunits, α, β, and γ held together by disulphide bonds to form triple helical coiled coil in a shape of a cross. Five α chains, three β chains, and three γ chains have been identified and by combination they assemble to form over 14 laminin isoforms that have different tissue distributions and functions. Laminins are essential for basement membrane assembly, promote cell attachment and ►angiogenesis, induce neurite outgrowth, affect gene expression and are involved in cell proliferation, migration, and differentiation. Biochemical dissection related some of the laminin functions to specific parts of the glycoproteins. It appears that different parts in the molecules have different effects on cells. Some of these parts are cryptic and interact with cells only after proteolytic cleavage of the laminin molecules. In vitro, most structural and functional studies have been performed on laminin-1 (α1β1γ1).

Characteristics

Laminin Signaling

Laminins activate various ►signal transduction pathways. It was shown that ►chemotaxis induced by laminin-1 is pertussis toxin sensitive, indicating on the involvement of a pertussis toxin-sensitive G protein in the process, while ►haptotaxis seems to involve a different mechanism. It was shown that human osteoclast-like cells selectively recognize laminin isoforms. The cells adhered to laminin-2 but not to laminin-1, and a sharp increase in intracellular Ca^{2+} was detected upon addition of soluble laminin-2 to the cells. Another study showed that laminin-1 induced a rapid and transient mRNA expression of c-fos and c-Jun in PC12 cells, and stimulated the DNA binding activity of the complex of these proteins to the ►AP-1 site. In tumor cells, addition of laminin-1 resulted in a time- and dose-dependent activation of phospholipase D (PLD) followed by generation of ►phosphatidic acid that is involved in signal transduction events leading to the induction of ►MMP-2 and enhanced invasiveness of metastatic tumor cells. This effect of laminin-1 was not seen in normal cells in vitro. Laminins' signaling has

been shown to involve kinase/phosphatase cascades since bound laminin-1 and laminin-5 induce protein ►dephosphorylation in neural cells during process formation. A recent study performed in our laboratory showed that mitogen activated protein kinases (►MAPK) are involved in laminin signaling. Addition of exogenous soluble laminin-1 resulted in a significant decrease in the ►phosphorylation (activation) of ERK, JNK, and p38 after 30 min of incubation. This laminin-induced dephosphorylation of all MAPK was dose-dependent and transient. Another study demonstrated that incubation of macrophages with a peptide from the laminin-α1 chain, but not intact laminin-1, triggered protein kinase C-dependent activation of ERK1/2, leading to upregulation of proteinase expression. Several recent studies using laminin-5 have shown activation of ERK1/2 via focal ►adhesion kinase (FAK), while other studies have shown activation of Rac1 via phosphoinositide 3 kinase (PI3K). Although some functions may be common to all laminin variants, other may be unique and isoform-specific, depending on the tissue or organ in which they are expressed. In addition, various signal transduction pathways may be activated by different ►laminin receptors.

Laminin Receptors

The biological effects of laminins are mediated by numerous laminin receptors that are divided into two major groups: ►integrin and nonintegrin receptors (Table 1).

Integrins

Integrins are a large family of cell-membrane receptors for extracellular matrix proteins (Table 1). Integrins are heterodimeric combination of various α-subunits with various β-subunits. The ligand specificity for different integrins can be altered depending on the type of divalent cation present, the surrounding lipid environment, and various cell-specific factors. Inside the cell, the short cytoplasmic domains of integrins associate with various cytoskeletal proteins that mediate integrin signal transduction. At least eight integrins bind laminin; some of them bind additional extracellular matrix components as well. Integrins recognize mainly laminin-α chains and hence determine cell adhesion and response to laminin isoforms.

Two possible integrin-related signal transduction pathways have been identified. First is direct signaling, where binding to integrins by extracellular proteins triggers intracellular signaling events. The second is integrin modulation of mitogen-initiated signaling; in this case, integrin-mediated cell anchorage influences signaling pathways activated by growth factors. In general, integrin direct signaling activates FAK, small GTPases of the ►Rho family, and MAPK, resulting in accumulation of highly ►phosphorylated proteins and cytoskeletal molecules at the adhesion sites. Binding to integrins is followed by receptor clustering that initiates activation and autophosphorylation of FAK. Tyrosine-phosphorylated FAK can recruit Src family kinases to focal contact sites. This sets up additional tyrosine phosphorylation of proteins such as cytoskeletal proteins and adaptor proteins such as Grb2. Small GTPases of the Rho family (Rho, Rac, and Cdc42) are involved in ►integrin signal transduction and affect cytoskeleton arrangement. Rho contributes to cell adhesion to extracellular matrix. Rac and Cdc42, via PI3K, mediate the increase in cell motility and invasiveness induced by the integrin. Some integrins activate MAPK cascades. For example, laminin binding to the integrin α6β4 results in activation of an associated kinase and consequently tyrosine phosphorylation of the β4-subunit cytoplasmic domain, followed by association of the adaptor protein Shc with tyrosine-phosphorylated β4 integrin subunit. Shc is then phosphorylated on tyrosine residues, presumably by an integrin-associated kinase, and combines with the adaptor protein Grb2 which exists in a complex with the ras GTP exchange factor

Laminin Signaling. Table 1 Laminin receptors and their additional ligands

Receptor	Ligands
Integrins α1β1	Collagen (I,II,IV), laminin (1, 2)
Integrins α2β1	Collagen (I,II,IV), laminin (1, 2), chondroadherin
Integrins α3β1	►Fibronectin, collagen (I), laminin (2, 5, 8, 10, 11), nidogen, epiligrin, perlecan
Integrins α6β1	Laminin (1, 2, 5, 8, 10, 11)
Integrins α6β4	Laminin (1, 2, 5, 10)
Integrins α7β1	Laminin (1, 2, 8, 10)
67 kDa laminin receptor	Laminin[a]
Dystroglycan	Laminin (1, 2), agrin, perlecan
Heparan sulfate	Laminin (1, 2), collagen XVIII

Laminin-4 receptor interactions presumed to be similar to those of laminin-2.
[a]Most studies on laminin-1.

SOS. This leads to Ras activation followed by activation of a kinase cascade consisting of Raf, MEK (MAPK/ERK kinase), and ERK, resulting in increased cell motility and proliferation. In addition, integrin α6β4 activates the JNK cascade, via Rac1, resulting in jun protein expression. Jun associates with fos, whose expression is induced by ERK cascade, to form the AP-1 transcription factor. In human hepatocellular carcinoma cells, laminin-binding integrin α6β1 stimulation resulted in FAK tyrosine phosphorylation, leading to FAK–GRB2 association and ERK cascade activation, which promotes tumor cell migration. Interestingly, aggregation of integrin receptors, even in the absence of ligand occupancy, is sufficient to induce a prompt transmembrane accumulation of at least 20 signal transduction molecules, including Src, Rho, Rac1, Ras, ERK1/2, and JNK.

Nonintegrin Receptors

The 67kDa laminin receptor is a nonintegrin receptor. A highly conserved 37 kDa protein is the precursor of the receptor, but the exact manner by which it configures its mature form is not clear. The amino acid sequence of the 37 kDa precursor is extremely well conserved through evolution, however, it corresponds to that of additional proteins, suggesting a multifunctional protein. The cDNA of the 37 kDa precursor is virtually identical to a cDNA encoding the ribosomal protein p40. In addition, the 37 kDa precursor acts as a receptor for cellular prion protein and is involved in the life cycle of prions. It has also been found that the 37 kDa precursor is identical to the oncofetal antigen protein that is expressed by tumors.

The 67 kDa laminin receptor mediates cell attachment to laminin. Colocalization of the 67 kDa laminin receptor with the cytoskeleton constituents α-actinin and vinculin, and the focal adhesion plaque was found. The receptor is involved in several physiological processes such as implantation [56], invasive phenotype of trophoblastic tissue, angiogenesis, T-cell biology, and shear stress-dependent endothelial nitric oxide synthase expression. Increased expression of the 67 kDa laminin receptor correlates with cell proliferation, migration, and ►invasion capacity. Clinical data suggest a correlation between 67 kDa laminin receptor expression in tumor cells and tumor progression. Expression of the receptor has been shown to be upregulated in neoplastic cells compared to their normal counterparts and directly correlates with an enhanced invasive and metastatic potential in numerous malignancies. Malignant ►mesothelioma is one of the most aggressive human cancers, however, no tumor is less susceptible to distant ►metastasis and still associated with such high mortality rates. In a recent study, we wound frequent expression of 67 kDa mRNA but very rare expression of the protein in clinical malignant mesothelioma samples in contrast to metastatic breast or lung carcinomas. These findings suggest that the differences between malignant mesothelioma and carcinomas regarding expression of the 67 kDa laminin receptor may account at least in part for the reduced ability of MM to metastasize to distant organs, due to lack of the signaling mediated by the receptor.

By stable transfection of A375SM melanoma cells, we established lines expressing reduced or elevated 67 kDa laminin receptor. We found that stable antisense-transfected cells that expressed reduced 67 kDa laminin receptor demonstrated significantly less aggressive tumor phenotype, as reflected by their reduced invasiveness through Matrigel, diminished attachment to laminin, and decreased MMP-2 expression and activity. Further, the basal phosphorylation extent (activity) of ERK, JNK, and p38 was significantly higher in cell lines expressing reduced 67 kDa laminin receptor, compared to parental cells. The increase in MAPK phosphorylation in cells expressing reduced 67 kDa laminin receptor was accompanied by a significant reduction in MKP-1 mRNA level and a significant increase in PAC-1 mRNA level. It seems that the 67 kDa laminin receptor induces downregulation of MKP-1 expression that may contribute to the reduced activity (dephosphorylation) of MAPK induced by the receptor, which is followed by an upregulation of PAC-1 expression, possibly as a negative feedback.

67 kDa Laminin Receptor and Integrins

There are studies that indicate an association between the 67 kDa laminin receptor and the α6 integrin subunit that is a part of the laminin-binding integrins α6β4 and α6β1. Biochemical analyses indicate on coimmunoprecipitation of the 67 kDa laminin receptor with the α6 integrin subunit. Specific reduction of the α6 integrin subunit by an antisense was accompanied by a proportional decrease in the cell surface expression of the 67 kDa laminin receptor. Other studies targeting the 67 kDa laminin receptor, showed a significant reduction in one of the α6 integrin subunit isoforms. Analysis of α6 integrin subunit and of the 67 kDa laminin receptor in ►ovarian carcinoma samples showed no statistical correlation between the two.

►Dystroglycan

Dystroglycan consists of two subunits, which are translated from a single mRNA as a propeptide that is proteolytically cleaved into two noncovalently associated proteins. Dystroglycan was originally isolated from skeletal muscle as an integral membrane component of the dystrophin–glycoprotein complex (DGC). The exact function of the entire DGC is not completely determined but evidence indicates that it confers structural stability to the sarcolemma during contraction. In fact, mutations in components of this complex

lead to various types of muscle disorder such as Duchenne muscular dystrophy and limb-girdle muscular dystrophies.

Dystroglycan is also expressed in many other cell types and it plays important roles outside skeletal muscle. It has been implicated in early mouse development, structure and function of the central nervous system, myelination and nodal architecture of peripheral nerves, epithelial morphogenesis, cell adhesion, synaptogenesis, and signaling. In addition, several extra- and intracellular proteins are less tightly associated with the DGC, such as nitric oxide synthase [nNOS], dystrobrevin, and laminin-2. Molecules that bind to the cytoplasmic tail of β-dystroglycan include the signaling molecule Grb2, components of the ERK–MAP kinase cascade including MEK and ERK, and rapsyn. Binding of laminin-2 to dystroglycan induces phosphorylation of Grb2 followed by Sos binding. This phosphorylation initiates activation of Rac1 pathway that is further followed by MAPK activation.

Langerhans, Islets of

Definition

Are groups of specialized cells in the pancreas that produce and secrete hormones. Named after the German pathologist Paul Langerhans (1847–1888), who discovered them in 1869, these cells are arranged in groups that Langerhans likened to little islands in the pancreas. There are five types of cells in an islet: alpha cells that produce ►glucagon, which raises the level of glucose (sugar) in the blood; beta cells that produce ►insulin; delta cells that produce ►somatostatin which inhibits the release of numerous other hormones in the body; and PP cells and D1 cells, about which little is known. Degeneration of the insulin-producing beta cells is the main cause of type I (insulin-dependent) diabetes mellitus.

Langerhans Cell

Definition

Langerhans' cells are immature ►dendritic cells found in skin containing Birbeck granules and expressing CD1a. They are the most efficient antigen processing and presenting cells of dendritic cell family.

Histiocytosis X

Definition

►Langerhans Cell Histiocytosis (LCH), previously referred to as Histiocytosis X, is a rare clonal disorder of Langerhans cell proliferation, involving the skin, bone and other organs. The disease family consists of the syndromes originally described as ►eosinophilic granuloma, ►Hand–Schüller–Christian disease, and ►Letterer–Siwe disease. Modern classification of LCH consists of single-system versus multisystem and unifocal versus multifocal.

Characteristics

Epidemiology

Most patients diagnosed with LCH are children with a peak percentage of diagnoses occurring between 1 and 3 years of age. The incidence of LCH has been estimated to be five cases per million per year in children. It appears to be more common in boys than in girls (1.2–2:1). The incidence of LCH in adults is thought to be one-half of that in children. Development of the disease is usually sporadic; however, the fact that about 1% of patients have relatives with LCH and monozygotic twin pairs are concordant for LCH suggests a genetic predisposition. A higher frequency of malignant disorders has been reported in patients with LCH than in the normal population. Acute lymphoblastic leukemia is the most common malignancy preceding or co-occurring with LCH.

Etiology

Whether LCH is a neoplasm or is reactive in nature has been a controversial issue. Pathological Langerhans cells (LCH cells) are monoclonal, and sometimes show chromosomal deletion or gain, suggesting a neoplastic etiology. While LCH lesions often regress spontaneously, there is no evidence that LCH cells are immortalized, supporting the possibility of a reactive nature. Although infection may play a role in the development or reactivation of LCH, no well-accepted environmental risk factors are associated with the disease, except for cigarette smoking in adult pulmonary LCH. It has been demonstrated that 77% of adult patients with LCH pulmonary lesions are smokers.

Pathophysiology

LCH lesions not only contain LCH cells but also various inflammatory participants, including T lymphocytes, macrophages, plasma cells, eosinophils, osteoclast-like multinucleated giant cells and neutrophils. These cells stimulate each other to produce abundant cytokines, such as granulocyte-macrophage colony-stimulating factor (GM-CSF), interferon (IFN)-γ, tumor necrosis factor (TNF)-α, interleukin (IL)-1, IL-2, IL-4, IL-5, IL-7, IL-10, transforming growth factor (TGF)-ß, ►RANKL and ►osteoprotegerin. This cytokine storm plays a role in the proliferation of LCH cells and of other infiltrating cells, and is responsible for the various clinical features of LCH. LCH cells in the bone, lymph node and some skin lesions contain immature ►dendritic cells. These cells do not express CD83 or CD86, but do express intracellular the major histocompatibility complex (MHC) class II antigen. They also express the immature dendritic cell marker ►CCR6 and produce the ligand for CCR6 (►CCL20/MIP-3α) as well as ►CCL5/RANTES and ►CXCL11/I-TAC. These ligands may play a role in recruiting eosinophils and CD4 positive T cells into the lesions, respectively. LCH cells show a greater proliferative capacity and a lower antigen presenting capability, suggesting maturation is arrested at an activated state. It is hypothesized that IL-10 as well as TGF-ß could be key factors in the inhibition of maturation of these cells.

Clinical Manifestations

LCH affects a number of different organs, so clinical signs and symptoms may be extremely variable. Patients can present with either single-system or multisystem involvement. Single-system presentations most often occur in the bone with single-site or multifocal involvement, but can also occur in the skin. Most commonly, the initial manifestations include the occurrence of soft tissue mass, bone pain, skin rash and fever. Laboratory findings include normochromic and normocytic anemia and an elevated erythrocyte sedimentation rate. Elevations in IgM are also common.

The bone is involved in about 80% of patients with LCH. The skull is most often affected followed by the extremities, ribs, spine, and mandible and maxilla. Osteolytic "punched out" lesions with sharp margins are typically seen on X-ray. Bone lesions may be asymptomatic or accompanied with pain and soft tissue swelling, which may cause compression of adjacent structures such as the optic nerve or the spinal cord. The clinical course of LCH when localized solely to the bone is generally benign and it sometimes resolves spontaneously over a period of months to years. However, it may result in permanent sequelae including the collapse of vertebral bodies, orthopedic deformities and growth impairment.

Skin involvement is seen in approximately half of patients. Patients present with lesions that are seborrhea-like eruptions on the scalp or an erytematous rash on the trunk, abdomen and inguinal areas. Ulcerative lesions in the genital or inguinal region may also be present. There may be bleeding into the lesions, even in the absence of thrombocytopenia.

Lymph nodes in the cervical, axillary and inguinal areas are most commonly affected. Rarely, the nodes can become massive and cause upper airway obstruction.

Earinvolvement usually appears as an aural discharge caused by external otitis, which is often associated with the destruction of mastoid. Ossicle or vestibular damage of the middle ear may cause a loss of hearing.

Hepatosplenomegaly occurs in 20% of patients with the infiltration of histiocytes into hepatic sinuses. Various degrees of liver dysfunction may appear, including hyperbilirubinemia, hypoproteinemia, hypoalbuminemia, elevation of γ-GTP, alkaline phosphatase and/or transaminases, ascites and edema. Histological examination of the liver shows portal infiltrates which can cause bile duct destruction and periportal fibrosis (sclerosing cholangitis) leading to biliary cirrhosis with portal hypertension and ultimately secondary hypersplenism.

Pulmonary involvement in children is usually part of multisystem disease, but in adults the lung involvement may be solitary and frequently regresses after the cessation of smoking. The lung pathology is associated with tachypnea, dyspnea, cyanosis, cough, pleural effusion and recurring pneumothorax. High resolution computed tomography may reveal reticular or micronodular opacities as well as large nodules and honeycombing. Typical histological findings are alveolar destruction and diffuse interstitial infiltration of histiocytes. Pulmonary fibrosis develops in 10% of patients and can lead to respiratory failure.

Hematopoietic involvement is seen in disseminated LCH and defined by anemia (hemoglobin < 10 g/dl in the absence of iron deficiency), leukopenia (leukocytes $< 4.0 \times 10^9$/l) or thrombocytopenia (platelets $< 100 \times 10^9$/l)

with or without bone marrow involvement. In severe cases, serious anemia and thrombocytopenia may develop, often associated with a secondary hemophagocytic syndrome.

Oral mucosa infiltration may appear as ulcerations or swelling of gingiva resulting in the loss of teeth. Infiltration of the small bowel may occur and cause malabsorption of nutrients. Diarrhea with blood and/or mucus suggests involvement of the colon. Occasionally the pancreas is also involved.

In the central nervous system (CNS), infiltration and dysfunction of the pituitary gland and/or adjacent hypothalamus occurs in about 20% of cases in those with multisystem involvement. The most frequent manifestation is diabetes insipidus (DI), which may precede, co-occur, or follow other symptoms and signs of the disease. DI occurs more often among patients with skull involvement (known as "CNS risk lesions"). Infiltration of the anterior pituitary is less common and may cause growth retardation and panhypopituitarism. These pathologies usually develop in those with DI after a disease course of 10 years. Magnetic resonance imaging (MRI) findings of LCH involvement of the pituitary gland and the hypothalamus are demonstrated by the loss of the physiologic high intensity signal of the posterior pituitary lobe on T1-weighted images. There can also be thickening of the pituitary stalk or a hypothalamic mass.

Progressive, degenerative CNS disease may develop over the years after onset of disease, often when the disease is considered quiescent. CNS involvement causes ataxia, tremor, dysarthria, dysphagia and hyperreflexia. Changes in personal behavior, judgment and cognitive function may also develop. In this case, MRI studies using T2-weighted or FLAIR images may reveal bilateral symmetric lesions in the cerebellar white matter and basal ganglia. Histologically, the neurodegenerative LCH is characterized by the presence of CD8 positive T lymphocyte infiltration, microglia activation, gliosis, neuronal and axonal destruction with secondary demyelination. There may be a lack of ►CD1a positive LCH cells, as is seen in autoimmune encephalitis. Currently there is no established therapy for LCH-CNS disease.

Pathology and Diagnosis

A pathological examination is indispensable in the diagnosis of LCH. With hematoxylin-eosin staining, LCH cells have a distinctive homogeneously stained pink cytoplasm. The nuclei appear twisted with a longitudinal groove and a small nucleolus, often with a "coffee bean" appearance. Immuno-histochemical staining of ►S-100 protein and ►langerin (CD207) is helpful for detection of LCH cells. In active lesions of the disease, LCH lesions show granulomas caused by the aggregation of LCH cells as well as a number of various inflammatory cells. A definitive diagnosis can be made by either positive staining for CD1a or electron microscopic demonstration of ►Birbeck granules in the granulomatous lesional cells. In the later stages of LCH, macrophages are more predominant than LCH cells in the lesions, and xanthomatous and fibrotic changes are characteristic. It is not uncommon that lesions at different stages of disease may be mixed in the same organ simultaneously.

Prognosis

The clinical course of LCH varies quite widely depending on the extent of organ involvement. Multisystem disease can be separated into two categories based on whether or not "risk organs" are involved. Risk organs are defined as the liver/spleen, lung or the hematopoietic system. LCH may resolve spontaneously in patients with localized, unifocal disease. Patients with single-system disease or without risk of organ involvement have a mortality of less than 5%. Prognosis is worse in children with multisystem and risk organ involvement who often have fatal outcomes despite intensive treatment Mortality rates of 10–50% have been reported. Infants younger than 2 years at diagnosis tend to have risk organ involvement, more often than older children; however, a recent study revealed onset age itself is not a prognostic factor. A major, positive prognostic factor appears to be a favorable response to the first 6 weeks of systemic multi-agent chemotherapy. Patients without an initial response tend to have an extremely high mortality rate with reports of 15–70%. This is in contrast to that of less than 5% in patients with a good initial response. In adults, lung disease may be a life threatening complication; it has been reported to contribute to a mortality rate of approximately 25%. Reactivation can occur unpredictably in more than half of patients, even those treated with multi-agent chemotherapy. Reactivated lesions may sometimes resolve spontaneously but there is an increased risk of permanent sequelae.

Treatment

Treatment of LCH should be planned according to the clinical presentation and the extent of organ involvement.

In single-system LCH, the major aims of treatment are to lessen symptoms and to reduce the chance of permanent sequelae. In the case of a single bone lesion without symptoms, a wait-and-see approach or diagnostic curettage is the standard method of care. Steroids may be used for symptomatic bone lesions. Systemic chemotherapy with vinca alkaloids and corticosteroids for 6 or 12 months could be applied for patients with CNS-risk lesions or multifocal symptomatic bone disease. Radical operation of jaw lesions is discouraged as this often results in disfigurement and loss of

teeth. Radiation is rarely used because of the reported increased risk of secondary tumors. When there is skin involvement only a wait-and-see approach is considered optimal. Alternatively, patients can be provided therapies such as topical corticosteroids or thalidomide. In patients with isolated pulmonary LCH with functional impairment, systemic chemotherapy is indicated to reduce further parenchymal destruction.

In multisystem LCH, the major aims of treatment are to increase survival and to reduce the incidence of late sequelae. Systemic chemotherapy with vinca alkaloids and corticosteroids for 12 months is the most commonly used regimen. In cases with risk-organ disease, more aggressive chemotherapy combined with agents such as cytarabine (Ara-C), 6-mercaptopurine and methotrexate may be considered. Etoposide (VP-16) is no longer considered a reasonable therapeutic agent because there is no reported significant efficacy and it has been shown to cause therapy-related acute myeloid leukemia (t-AML).

In patients with refractory progressive disease, myeloablative therapy with a combination of high dose Ara-C and cladribine (2-CdA) is currently being tested. Immuno-suppressive therapy with cyclosporin A, anti-thymocyte globulin or anti-TNF agent, and immuno-modulation agents like thalidomide, IFN-α or bisphosphonate are also used on an investigational basis. Allogeneic hematopoietic stem cell transplantation has proved to be efficacious in some cases. Additionally, liver or heart and lung transplants have been performed successfully in patients with end-stage organ involvement.

Late Sequelae

Permanent sequelae are common events in many LCH patients. They are most often the result of the infiltrative nature of the disease itself which causes tissue destruction and granulomatous fibrosis or gliosis of various tissues. Seventy percent of patients with multisystem disease and 25% of single-system disease patients suffer one or more life-long sequelae, including DI (24%), orthopedic problems (20%), hearing loss (13%), neurologic problems (11%), growth hormone deficiency, loss of teeth, pulmonary fibrosis and biliary cirrhosis with portal hypertension.

t-AML may develop as a consequence of LCH treatment with chemotherapy, especially following the use of topoisomerase II inhibitors, such as VP-16. The cumulative incidence of t-AML in patients treated with VP-16 for LCH has been estimated to be around 1%. In addition, secondary solid tumors, particularly sarcomas and brain tumors may develop in irradiated areas.

Large-Cell Undifferentiated Carcinoma

Definition

About 10–15% of ►lung cancer are this type. It can start in any part of the lung. It tends to grow and spread quickly.

Non-small cell lung cancer is a common disease. It is usually treated by surgery (taking out the cancer in an operation) or radiation therapy (using high-dose x-rays to kill cancer cells). However, chemotherapy may be used in some patients.

The prognosis (chance of recovery) and choice of treatment depend on the stage of the cancer (whether it is just in the lung or has spread to other places), tumor size, the type of lung cancer, whether there are symptoms, and the patient's general health. Patients unsuitable for surgery may be offered curative intent radiotherapy. ►Adjuvant therapy may be given to more advanced resected cases. For late stage cases, chemotherapy with or without palliative radiotherapy are the conventional options, although the long term survival rates are very low.

Laryngeal Carcinoma

Charlotte Jin
Departments of Clinical Genetics, University Hospital, Lund, Sweden

Definition

The vast majority of malignant neoplasms of the larynx arises from the surface epithelium and therefore classified as keratinizing or nonkeratinizing ►squamous cell carcinomas (SCC). The other rare malignant forms include verrucous carcinoma, adenocarcinoma, fibrosarcoma, and chondrosarcoma. Histopathologically, laryngeal SCC can further be classified into: well differentiated (more than 75% keratinization), moderately differentiated (25–75% keratinization), poorly differentiated (<25% keratinization).

Characteristics

Laryngeal carcinoma accounts for a small fraction (less than 2%) of all human malignancies, but the incidence varies among different countries. It is most common between the ages of 45 and 75 years. Men are four or

five times more frequently affected than women. The etiology is unknown, but exposure of the mucosa to a wide variety of ingested and inhaled exogenous carcinogenic agents, such as tobacco smoke (►Tobacco Carcinogenesis) and alcohol, greatly increases the risk of developing these tumors.

Laryngeal carcinoma infiltrates locally in the mucosa and beneath the mucosa and could metastasize via the lymphatic system and the bloodstream. According to their anatomical localization, laryngeal carcinomas could be subdivided into ►supraglottic carcinomas, confined to the supraglottic space and spreading interiorly into the preepiglottic space, ►glottic carcinomas, rarely spreading into the supraglottic area but rather into the subglottic space, and ►subglottic carcinomas, often showing an infiltrative growth pattern unrestricted by tissue barriers.

Carcinomas of the supra- and subglottic larynx are more likely to be non-keratinizing and poorly differentiated, and, in general, they have a more aggressive behavior and tend to ►metastasize (Metastasis) early (20–40% of the cases). In contrast, lesions of the true vocal cords are more often moderately to well differentiated, rarely metastasize, and tend to be associated with a better prognosis.

Genetic Changes in Laryngeal Carcinomas

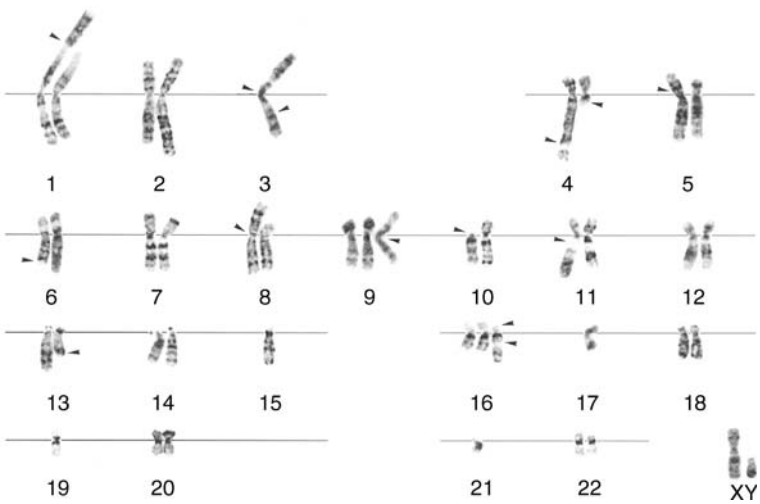
Chromosome Abnormalities in Laryngeal Carcinomas

One hundred fifteen laryngeal carcinomas with clonal ►chromosome abnormalities have been reported. In general, the ►karyotypes are relatively complex with a nonrandom pattern of deleted and amplified ►chromosome segments. This is in line with the notion that laryngeal carcinoma, like most other malignancies, develops through the accumulation of multiple genetic changes. The chromosomes most frequently involved in structural rearrangements are chromosomes 1, 2, 3, 4, 5, 7, 8, 11, 12, and 15, with breakpoints clustering to the pericentromeric regions, i.e., the ►centromeric bands p10 and q10 and the juxtacentromeric ►bands p11 and q11, accounting for 43% of the total breakpoints. The most common imbalances brought about by numerical and unbalanced structural rearrangements are loss of chromosomal region 3p21-pter, part of or the entire chromosome arms 4p, 6q, 8p, 10p, 13p, 14p, 15p, and 17p, and gain of chromosomal regions 3q21-ter, 7q31-pter, and 8q. A total of 17 recurrent structural aberrations, mostly in the form of whole-arm translocations (►Chromosome translocations), ►isochromosomes (i), and ►deletions (del), have been identified. The most common among them were i(8q), i(3q), i(5p), del(3)(p11), and ►homogeneously staining regions (hsr), a cytogenetically detectable sign of gene ►amplification, in band 11q13 (Fig. 1).

A subgroup of laryngeal SCC have had multiple, unrelated abnormal ►clones, with simple, often balanced structural rearrangements or numerical changes. These clones have always had near-diploid chromosome numbers. The finding of such ►cytogenetic polyclonality could be interpreted as evidence of "►field cancerization" but it can not be ruled out that the ►cytogenetically unrelated clones are united by a submicroscopic, pathogenetic mutation; the cytogenetic differences would then only reflect differences in clonal evolution. The third alternative is that some of the near-diploid clones actually represent preneoplastic lesions or genetically damaged, nonneoplastic epithelial or stromal cells in the tumor surrounding.

Fluorescence in Situ Hybridization (FISH)

FISH analysis has recently been undertaken to verify and in detail characterize the most common recurrent

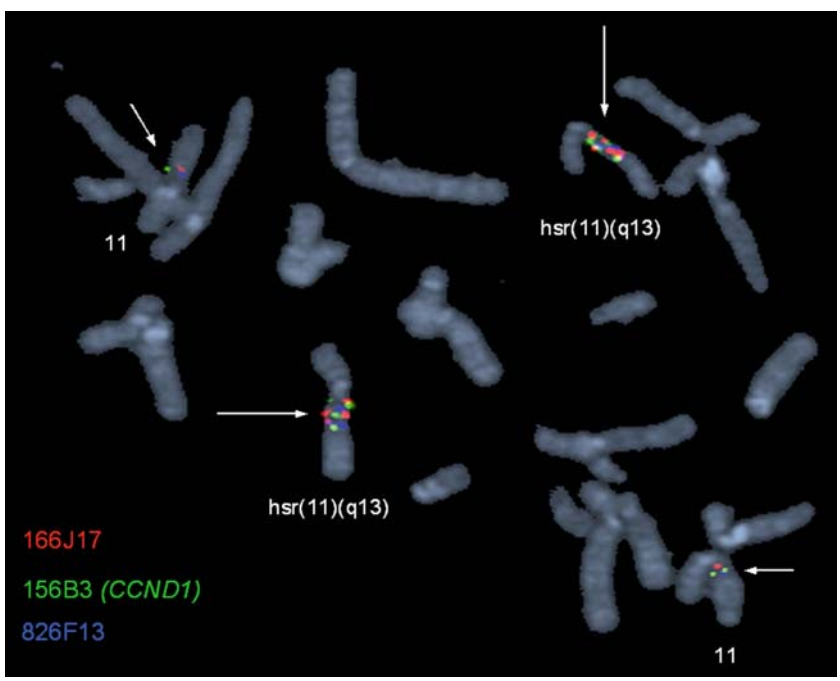


Laryngeal Carcinoma. Figure 1 Representative karyogram from a laryngeal SCC showing complex karyotypes with multiple numerical and structural rearrangements. Arrowheads indicate breakpoints in clonal aberrations.

chromosomal changes in head and neck SCC, including laryngeal SCC. FISH has demonstrated that cytogenetically detectable hsr in these tumors almost always corresponds to amplification of DNA sequences originating from 11q13, and that CCND1 (Cyclin D) is always included in the amplicon (Fig. 2). The amplicons mapped vary in size from 3.5 to 4.5 Mb with a core of 1.5–1.7 Mb and often many oncogenes in this region are coamplified, including CCND1, FGF3, FGF4, EMS1, and SHANK2. Another finding is that the amplification of 11q13 is often concomitant with deletion of distal 11q, indicating that not only the amplification of one or more dominantly acting oncogenes in 11q13, but also loss of a tumor suppressor gene in the distal part of 11q is critical for the development of laryngeal SCC. Detailed FISH characterization of pericentromeric rearrangements, in particular for chromosomes 1 and 8, with the use of YAC clones spanning the pericentromeric region of chromosomes, suggests that the essential outcome of these rearrangements at the DNA level is the resulting genomic imbalances, i.e., loss or gain of neoplasia-associated genes, and not rearrangement of genes in the euchromatin near the centromere. Furthermore, more precise mapping of breakpoints on chromosomal arms 1p and 8p has delineated critical regions for deletions within 1p11–p13 and the subtelomeric region of 8p.

Molecular Genetic Findings

A large scale effort has been devoted to the identification of tumor suppressor gene loci and amplified oncogenes in laryngeal carcinomas. Loss of heterozygosity (LOH) studies have pointed out the frequent loss of alleles from 3p, 8p, 9p, 13q and 17p in laryngeal SCC. A number of recent studies based on allelotyping or comparative genomic hybridization (CGH) indicate that head and neck SCC, including laryngeal SCC, display massive and widespread genomic imbalances and certain chromosome segments are lost more often than others. Apart from LOH from 3p, 9p, 13q, and 17p in more than 50% of the cases, deletions in 3q, 4p, 4q, 6p, 6q, 8p, 8q, 11q, 14q, 17q, 19q, and 20p have been found in 30–50% of the cases. Some candidate tumor suppressor genes in frequently deleted regions, e.g., FHIT in 3p, CDKN2A in 9p, RB1 in 13q, and TP53 in 17p, have been investigated with regard to homozygous deletions or inactivating mutations. Extensive analysis of TP53 (p53 gene family) mutation and the alteration of its protein in laryngeal SCC and its precursor lesions have shown that TP53 mutation occurs at an early stage of these neoplasms. Furthermore, correlation studies have shown that overexpression of mutated TP53 predicts poor disease-free and poor overall survival rates in patients with laryngeal SCC. Using various detection techniques such as immunohistochemistry and RT-PCR, it was shown that loss of CDKN24



Laryngeal Carcinoma. Figure 2 Metaphase plate from a laryngeal SCC hybridized with three bacterial artificial chromosome clones: 166J17 (red), 156B3 (*CCND1*, green), and 826F13 (blue), showing the amplicon of 11q13, including CCND1 locus. Short arrows indicate signals in normal chromosome 11, and long arrows indicate amplified signals in derivative chromosome 11 harboring hsr.

expression, through either homozygous deletion or promoter hypermethylation, was present in 52–82% of HNSCC including laryngeal SCC. A number of studies have further disclosed that the decreased expression of this gene was associated with poor survival in laryngeal SCC. FHIT was investigated in laryngeal SCC and its precursor lesions. In a recent study, decreased expression of this gene, through deletion or promoter methylation was detected in about 42% of SCC and 23% of dysplasia lesions. Although allelic loss of RB1 was shown in high frequency in laryngeal SCC in a few studies, expression analysis of RB1 revealed inconsistent results in different research groups. Thus, the role of this gene in laryngeal SCC has not been clearly established. Several candidate oncogenes in frequently gained regions, i.e., CCND1 in 11q13, EGFR in 7p, and MYC and PTK2 in 8q have been investigated. The most frequently amplified DNA sequences are located in chromosomal band 11q13; reported frequencies vary between 15 and 60%, with an average of 30% in primary head and neck SCC, including laryngeal SCC. FISH and molecular studies have implicated CCND1 as the prime target in this amplification process. Several attempts have been made to correlate cytogenetic or molecular genetic data with clinical outcome in patients with laryngeal carcinoma, and it has been shown that 11q13 rearrangements and amplification/overexpression of CCND1 seem to be associated with a poor prognosis.

L

Definition

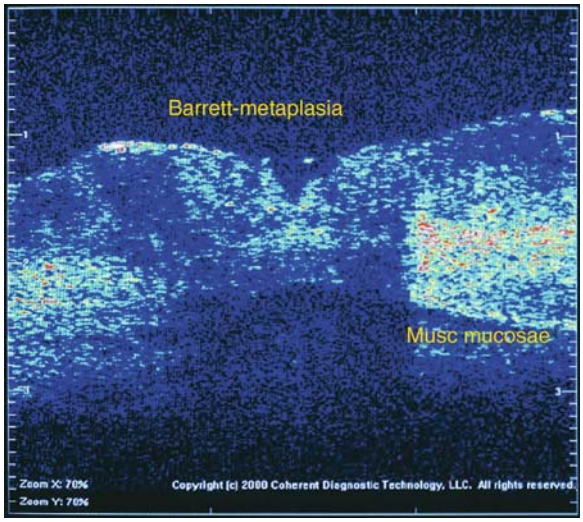
Laser diagnostics are procedures designed to detect or to differentiate neoplastic tissues based upon various forms of interaction of laser-emitted photons with tissues (Fig. 1).

Characteristics

The interaction of light with tissue may result in absorption or scattering of the photons. These phenomena may be directly observed for diagnostic purpose in a transillumination approach. Actual research in ►optical mammography focuses on time-resolved systems able to separate scattering from absorption. The thermal expansion of a tissue area absorbing more light that the surrounding tissue may be used for an acoustic recognition in so-called photoacoustic diagnostic systems (still at an early experimental phase).

Furthermore, fluorescence may result from absorption. Natural fluorophores are rare, thus, fluorescence spectroscopy may sensitively detect the presence of an exogenous or a specific endogenous fluorophore accumulating in malignant or premalignant lesions (►fluorescence diagnostics).

The phenomenon of backward scattering of incident photons is exploited for imaging of superficial tissues by optical coherence tomography (OCT). The backscatter intensity of any point in the tissue is determined



Laser Diagnostics. Figure 1 Optical coherence tomography of esophageal mucosa registered ex vivo with a clinical OCT-prototype (Coherence Diagnostic Technologies/Carl Zeiss). An island of Barrett esophagus epithelium is surrounded by normal squamous cell epithelium. The actual depth limitation enables imaging of the mucosal layer only (dimensions are not calibrated; the vertical scale represents about 3–4 mm, the lateral scale 12 mm).

by interferometry using very short coherence light sources, one of which are short pulsed lasers. Scanning vertical and lateral dimensions, tissue may be imaged at almost microscopic resolution. The vertical resolution of OCT-systems depends on the medium coherence length of the light source and is actually limited at 4–10 μm, which is at least 10-fold better than the limits of high-frequency ultrasonography. However, the strong absorption and random scattering of tissues limits OCT to superficial tissue layers with a maximum depth of about 2 mm. In oncology, OCT may thus be suitable for the recognition of early neoplastic lesions of the aerodigestive tract, the urinary tract and eventually of the skin.

Definition

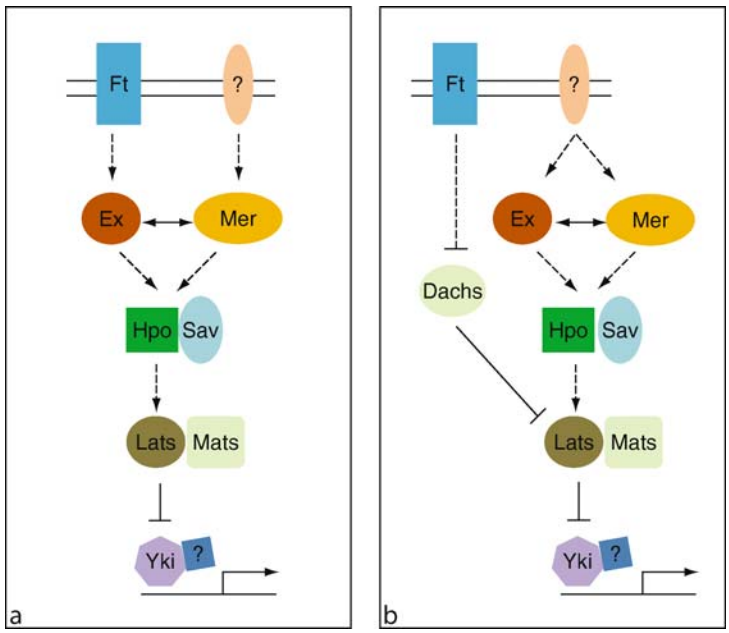
The *lats* (*la*rge *t*umor *s*uppressor) gene, also known as *warts* (*wts*), is a ►tumor suppressor gene originally discovered in the fruit fly *Drosophila melanogaster*. Loss-of-function mutations in the gene cause dramatic overproliferation including developmental defects in ►mosaic tissues within the larval ►imaginal discs (Fig. 1). The *lats* gene encodes a Serine/Threonine protein kinase with a catalytic domain that is highly similar to the human myotonic dystrophy protein kinase. Together with other related members, which include the *Saccharomyces cerevisiae* Dbf2, Dbf20 and Cbk1, *Schizosaccharomyces pombe* Sid2 and Orb6, *Neurospora crassa* Cot1, *Ustilago maydis* UKC1, *Caenorhabditis elegans* Sax-1, *Drosophila* Trc, and mammalian NDR1 and NDR2, they comprise the NDR kinase family, a subclass of the AGC protein kinases.

The *Drosophila* genome contains a single gene for *lats*, whereas there are two homologs, LATS1 and LATS2, in mammals and humans. The genes are functionally conserved since the expression of the human cDNA for either *LATS1* or *LATS2* in the fly rescues the *lats* mutant phenotypes. The overgrowth phenotype of *lats* mutant has been attributed to the coordinated deregulation of both cell cycle progression and ►apoptosis. Recent genetic analyses in *Drosophila* reveal Lats as a key component of the Hippo (Hpo) ►signal transduction pathway (Fig. 2). Mammalian orthologs exist for each component of the pathway and are likely to function in a similar manner. Studies so far indicate that this pathway plays a major role in the developmental regulation of cell proliferation, cell survival, as well as tissue growth and organ size, all of which are key aspects that are also important in tumorigenesis. Whereas knockout mice deficient for *LATS2* are lethal, mice deficient for *LATS1* develop soft-tissue sarcoma, ovarian stromal cell tumors, and pituitary dysfunction (Fig. 1b). In various human cancers, the *LATS1* and *LATS2* genes are found to be mutated or down-regulated. In addition, they are able to suppress tumor growth when overexpressed in human cancer cells. Furthermore, cells lacking LATS function display characteristic ►cancer hallmarks such as being multinucleated and having defects in cytokinesis, ►centrosome amplification, and genomic instability. Thus, like their fly counterpart, the *LATS* genes also function as tumor suppressors in mammals.

Characteristics

The *Drosophila* imaginal disc tissues afford an excellent *in vivo* context for studying growth, cell proliferation and survival. The ability to efficiently

Lats in Growth Regulation and Tumorigenesis. Figure 1 Lats in growth regulation and tumorigenesis. Lats has a tumor suppressor function in flies and mice. (a) Adult fly showing a clone of *lats* mutant cells which have overproliferated to form a large tumor outgrowth. (b) The homozygous LATS1 knockout mouse also develops tumors in the form of a soft tissue sarcoma.



Lats in Growth Regulation and Tumorigenesis. Figure 2 Alternative models of the Hpo-Lats tumor suppressor pathway. (a) Components function in a linear fashion. (b) Lats plays a central element for alternative inputs from upstream signaling events. On the one hand, Lats stability is regulated by Ft mediated by Dachs by-passing the requirement for Ex function. Alternatively, Lats activity is regulated by Hpo signaling. Solid lines indicate observed direct interactions (adapted from Pan 2007).

generate mosaic animals carrying clones of homozygous mutant cells in the developing imaginal discs and to follow their growth over time allow a powerful means to study the effects of mutations in essential genes. Such genetic mosaic approach has been used effectively in genetic screens to look for tumor suppressors or negative regulators of growth, which cause overgrowth when both copies of a gene are inactivated. This inactivation closely recapitulates the *in vivo* condition in human cancer patients carrying somatic mutant cells.

Using this approach, mutations in the *lats* gene were identified on the basis of the ►hyperplastic growth phenotype in mosaic flies. Somatic cells mutant for *lats* overproliferate cell autonomously to form large tumorous overgrowths in a wide variety of adult integumentary tissues (Fig. 1A). The tumors can be as large as 1/5 of the body size. Histological examination of the *lats* tumors reveals that they form lobes and folds in the epithelial structures, yet their tissue organization is still characteristically maintained as a monolayer and cell polarity is not affected. Although the mutant tissue is still capable of differentiation, defects are evident in the deposition of extra cuticle and malformed bristles and hairs. On the cellular level, mutant cells appear morphologically irregular such that the apical surface of the cells bulges away from cell body in what is known as "apical hypertrophy". In addition, mutant clones induced in the imaginal discs also appear starkly different from wild type clones in being rounded and having smooth edges rather than jagged and geometric. Such observation suggests a lack of directional cell division or a modification of cell ►adhesion properties. Since apical-lateral junctions are still present in the mutant, *lats* may potentially regulate some functional aspects of the ►adherens junctions.

When comparing the growth of clones that are mutant for other *Drosophila* tumor suppressors, such as *lethal(2) giant larvae*, *discs large* or *hyperplastic discs*, *lats* mutant clones exhibit several distinctive behaviors. When clones for other tumor suppressors are induced, the mutant cells appear to be unresponsive to stimulating growth signals. They grow much slower than wild-type cells and are unable to differentiate. As a result, these cells have a growth disadvantage and are competed away such that very small or no mutant tissues are eventually detected in the adult. Analysis of clone areas and cell numbers in *lats* mosaics, on the other hand, reveals that the mutant cells grow astonishingly faster than wild-type cells in sibling clones. Interestingly, there is no apparent change in the size of *lats* mutant cells, which means there must be a concomitant increase in cellular growth in order to support the faster pace of the cell cycle. Thus, the

dramatic expansion of the *lats* mutant clones is not only attributable to an increase in cell number, but also to an increase in tissue mass. This suggests that the deregulation of growth, as well as the inappropriate engagement of the cell cycle, represent key steps where many tumor suppressors may act in tumorigenesis.

The increased rate of proliferation of *lats* mutant cells is due to the shortened phases of the cell cycle which are equally affected. In contrast to proliferative defects seen with other tumor suppressors, *lats* mutant cells do not cycle indefinitely but exhibit a much delayed exit as compared to wild-type cells in the same developmental context. For example, in the developing eye disc, wild-type cells undergo two rounds of cell division and exit the cell cycle after the so-called second mitotic wave (SMW). However, in *lats* mutant clones, cells continue to divide and undergo mitoses at a much later time as indicated by BrdU incorporation and anti-phosphorylated H3 staining of cells posterior to the SMW. Another key finding is that cells within *lats* mutant clones are highly resistant to apoptosis. This is particularly evident during pupal eye development where normally there is a major wave of cell death to remove excess cells that have not been recruited for differentiation. In *lats* mutants, this scheduled cell death is absent leading to the appearance of extra interommatidial cells in the pupal retina. Thus, the effects of increased rate of cell proliferation together with growth and the inhibition of apoptosis contribute to the *lats* dramatic overgrowth phenotype.

Insights into the function of *lats* initially came from the identification of the LATS1 and LATS2 homologs in human and mouse where biochemical studies highlight their roles in the regulation of mitosis and apoptosis. The activity and phosphorylation status of the LATS proteins oscillate in a cell cycle-dependent manner. Both have been shown to interact with the cyclin-dependent kinase CDC2 and inhibit its kinase activity when they are overexpressed, resulting in cell cycle arrest in ►G2/M by LATS1 and in G1/S by LATS2 through the displacement of CDC2. LATS2 has also been shown capable of arresting cells at G1/S by downregulating Cyclin E/CDK2 kinase activity. The localization of the LATS proteins to the mitotic apparatus further points to its role in regulating mitotic events. For example, an interaction with the actin filament assembly factor Zyxin has been detected for LATS1. Recently, LATS1 has been shown to colocalize with and bind to the cytoskeletal protein kinase LIMK1 at the contractile ring during ►cytokinesis, the consequence of which is the inhibition of LIMK1-induced cytokinesis defects and phosphorylation of Cofilin. Interestingly, the mechanism of inhibition of both LIMK1 and CDC2 doesn't appear to involve LATS kinase activity. Nevertheless, consistent with these observations, the removal of LATS1 function leads to defects in mitotic exit and aberrant cytokinesis where the mutant cells are multinucleated, display centrosome amplification, and exhibit ►genomic instability. Similar defects are also observed with the expression of a kinase-dead LATS1, which delays mitotic progression through the activation of a spindle assembly check point. These mitotic defects are hallmarks of cancer cells and clearly support the function of the LATS proteins as tumor suppressors.

A role for LATS2 in the regulation of mitosis has also been documented. Its localization to the ►centrosome requires phosphorylation by the centrosomal ►kinase Aurora-A. LATS2 also functions in a checkpoint pathway to prevent ►tetraploidization via p53, which is activated upon binding of LATS2 to MDM2 and feeds back to upregulate *LATS2* expression in G2/M cells. Finally, a recent genetic screen has identified two miRNAs, *miR-372* and *miR-373*, which function as novel ►oncogenes in testicular germ cell tumors by downregulating *LATS2* through direct biding to sites in its 3′UTR, the effect of which is to relieve the CDK inhibition by p53.

Although no mitotic defects have been observed in *Drosophila* for *lats* mutants, its role in controlling mitotic events and progression is corroborated by the finding of genetic interactions between *lats*, *cdc2* and *cyclin A*. Mutations in either *cdc2* or *cyclin A* can suppress both the lethality and cell proliferation defects of *lats* mutants. Furthermore, the loss of *lats* function leads to the accumulation of Cyclin A, supporting the idea that Lats limits cell proliferation by negatively regulating Cdc2/Cyclin A activity. The studies above present evidence that may explain in part how mammalian LATS can contribute to tumorigenicity through the regulation of the cell cycle and mitotic events, but they cannot fully account for the effect in *Drosophila* of *lats* mutations on the expansive growth and cell survival. However, further clues do point to an additional role for LATS in regulating apoptosis to suppress growth. For example, the pro-apoptotic proteins Bax and Caspase-3 both have been shown to be upregulated in response to LATS1 overexpression. LATS1 has also been shown to be not only a substrate for the serine protease Omi/HtrA2, but whose activity is also dependent on LATS1 binding. The overexpression of LATS2, on the other hand, can induce cell death through the downregulation of the apoptosis inhibitors ►Bcl2 and Bcl-xL.

Thus far, although the kinase activities of LATS1 and LATS2 are clearly required for cell cycle regulation and play a role in tumorigenesis, we know relatively little of the mechanisms by which they act on cell cycle progression, cell growth and survival. This is hampered by the fact that substrates and effectors of LATS have not been identified, nor do we know what the nature of the upstream regulators is. In recent years, however, work in *Drosophila* has discovered several new tumor

suppressor genes that share similar overgrowth phenotypes as *lats*. The first breakthrough was the identification of the *salvador* (*sav*) gene in a genetic mosaic screen for mutations affecting tissue growth. The *sav* gene encodes a WW domain-containing protein and lacks any other enzymatic domains making it likely to serve as a scaffolding protein. Indeed, biochemical assays reveal that Sav protein interacts directly with Lats through the WW region. Mutant clones of *sav* display the same cell autonomous overgrowth phenotype as for *lats* clones. Like *lats*, this is attributed to an increase in cell number and suppression of cell death. These two aspects have been linked to elevated levels of Cyclin E and the inhibitor of apoptosis, Diap1, respectively, in mutant clones for either *lats* or *sav*. The mechanism by which *lats* and *sav* regulate these downstream targets at this point has not been elucidated, but they have been used as key signatures in examining other tumor suppressors and genes that might function similarly to *lats*. Of course, as discuss below, these are not the only targets since the overexpression of *cyclin E* alone does not impart any growth effects, and neither does its co-expression with *Diap1*. Of significance is the ability to coordinate both cell proliferation and cell death that represents a key common feature of the tumor suppressor function of genes such as *lats* and *sav*.

With the discovery of mutations in *hippo* (*hpo*), which also share similar loss-of-function overgrowth phenotypes as *lats* and *sav*, a signal transduction pathway begins to take shape since *hpo* also encodes a Ser/Thr kinase belonging to the Sterile-20/Mst kinase family (Fig. 2). In the budding yeast, the Cdc15 kinase is the closest homolog to Hpo and functions to phosphorylate Dbf2, a *lats*-related kinase. These kinases comprise a signal transduction pathway that regulates mitotic events and cell morphogenesis in the yeast. The conservation of these modular functions suggests that Hpo may also act upstream of Lats. Indeed, Hpo has been shown to phosphorylate and activate Lats in biochemical assays and in tissue culture. This activity requires Sav where it has been suggested to function as a scaffolding protein to bring Lats and Hpo together into an activation complex. The parallel to the yeast modular pathway also makes another prediction where the Dbf2 kinase requires a binding partner, namely Mob1, which has no obvious domains and has been postulated to function analogously to the cyclins for modulating CDK activities. The identification of *Mats* (*Mob as tumor suppressor*) confirms this notion. Mutations in *mats* behave identically to *lats*, *hpo*, and *sav*. Mats has been shown to bind to and modulate Lats intrinsic kinase activity. These four genes, thus, comprise the core components of the Hpo signaling pathway and function to negatively regulate the gene expression of *cyclin E* and *Diap1* (Fig. 2).

Through a yeast two-hybrid screen, Yorkie (Yki) was identified as an interacting protein with Lats, and encodes the *Drosophila* ortholog of the mammalian transcriptional coactivator yes-associated protein (YAP). The overexpression of Yki in clones completely reproduces all aspects of the overgrowth phenotypes of loss-of-function mutations in the Hpo core components, including the upregulation of target genes, which makes Yki a *bona fide* link in the pathway and, significantly, represents a critical transcriptional effector of the Hpo/Lats kinase cascade. Lats has been shown to directly bind and phosphorylate Yki, leading to its inactivation. Yki is capable of activating transcription; however, it lacks a DNA-binding domain, which suggests that it may require a transcription partner or complex to regulate gene expression. As mentioned before, *cyclin E* and *Diap1* are not the only target genes of Hpo signaling since both cannot confer the growth aspect of the pathway. In an overexpression screen, a ►microRNA has been found to stimulate imaginal disc growth, as well as to affect both cell proliferation and apoptosis. The microRNA is encoded by the *bantam* gene and has been shown to be a transcriptional target for Yki. However, the growth defect associated with *yki* loss-of-function can only be partially rescued by *bantam* overexpression and, likewise, the overgrowth phenotype of *yki* overexpression can only be partially suppressed by the loss of *bantam* function. The combined effect of *bantam*, *cyclin E*, and *Diap1*, however, still cannot fulfill all of the signaling output of the Hpo pathway as defects in differentiation and cell adhesion, for example, are not accounted for.

How the Hpo pathway is regulated has been an outstanding question until a candidate approach reveals ►Merlin (Mer) and Ex (Expanded), which encode related members of the FERM domain-containing protein family, as possible upstream components (Fig. 2). This is suggested by their function as adaptor proteins associated with plasma membrane proteins and the cytoskeleton. Mutations in either gene alone have been shown to have relatively weak effects on growth of imaginal discs. However, since Mer and Ex can heterodimerize and function redundantly, double mutants have characteristic phenotypes of Hpo pathway mutants.Genetic epistasis experiments have placed both genes upstream of *hpo* where their overexpression can influence the phosphorylation of Lats. The mechanism is unknown and additional intervening components remain to be identified since neither Mer nor Ex binds to Hpo. Interestingly, Ex expression is also regulated by Yki, thus, forming a regulatory feedback loop. Despite their membrane localization, Mer and Ex are still intracellular proteins and, therefore, the existence of a receptor for mediating physiological responses to effect Hpo signaling still remains to be seen.

The protocadherin Fat (Ft) recently has been identified as one candidate receptor since loss of its function causes phenotypes similar to *hpo* and *lats* mutants and they all share each other target gene expression. Ft has been known to function as a tumor suppressor, but exactly how it influences growth is not understood. Several studies have placed *ft* genetically upstream of *ex* and *hpo* in a linear pathway since the overexpression of either can bypass the requirement for *ft* (Fig. 2). Furthermore, Hpo and Lats are phosphorylated and activated in response to the overexpression of Ft in cell transfection, which also lead to the repression of Yki-dependent target gene expression. Interestingly, Ft is required for the localization and stability of Ex but not Mer, suggesting that the latter might function in parallel, consistent with the similar phenotypes displayed by *ft mer* and *ex mer* double mutants. Thus, there may be yet another receptor that can regulate Hpo activity through Mer. Although *ft* functions upstream of *hpo* and *lats*, there is an alternative line of evidence to suggest that the pathway may not be linear after all, since Ft can affect the stability of Lats protein specifically and not other downstream components (Fig. 2B). This function is mediated through Dachs, an unconventional myosin downstream of and acts antagonistically to Ft. *dachs* acts genetically upstream of *lats,* and their proteins coprecipitate in biochemical assays. In light of these observations, Lats remains the central element of the pathway but its activity and abundance may be affected differently by various upstream inputs. Nevertheless, further studies are required to resolve the biochemical relationships among the components of the Hpo pathway.

Clinical Relevance

The kinase cascade comprising Hpo and Lats is conserved from yeast to mammals. Many components of this pathway also have orthologs across species and may function in a physiological relevant manner as demonstrated by the ability of some human gene counterparts to rescue the corresponding *Drosophila* mutants. In *Drosophila*, loss-of-function mutations in many components of the Hpo pathway result in overgrowth of ►epithelial tissues, which in many ways resemble tumor formation in humans and mammals. Indeed, cells of these imaginal discs possess cellular behavior and properties that reflect closely those of cycling mammalian cells, an especially important consideration when extrapolating mechanistic insights to mammalian models of cancer. Importantly, in most cases cell cycle progression and kinetics in *Drosophila* are punctuated by growth phases characterized by similar G1-S and ►G2-M transitions as in mammals. In addition, developing disc tissue structures exhibit a polarized epithelium mirroring mammalian tissues that are highly prone to cancer.

These studies have revealed an emerging tumor suppressor pathway that has profound effects on growth with consequences on body, organ, and cell size as well as on cell number. The phenotypic consequences on cell growth coupled to the coordinated deregulation of both cell proliferation and survival provide a growth advantage to mutant cells in mosaics clones, but also very likely confer such traits to tumor cells. Thus, there is a strong link between these developmental processes and tumorigenesis. Consistent with the overgrowth phenotype in *Drosophila*, knockout mice for LATS1 develop soft-tissue carcinoma, ovarian stromal cell tumors, and pituitary dysfunction (Fig. 1B). Although mutations in either LATS1 or LATS2 have rarely been detected, epigenetic modifications of these genes, for example, downregulation by methylation, have been associated with human breast cancers. Many cancer cell lines derived from human melanoma or mouse mammary gland carcinoma have been shown to carry mutations in genes for *SAV1 (WW45)* and *MATS1 (MOBK1)*. The human ortholog of Mer, ►NF2 (►Neurofibromatosis 2), gene is notable in the Hpo pathway in being the only one so far that has been discovered as a *bona fide* tumor suppressor. Patients carrying mutations in the NF2 gene develop tumors mainly affecting the central nervous system as found in sporadic tumors as well as in the familial cancer syndrome neurofibromatosis type 2. The loss of NF2 also leads to other tumors such as malignant mesothelioma. From the *yki* overexpression phenotype in *Drosophila*, the mammalian YAP is predicted likely to function as an oncogene. Indeed, the mouse locus at 9qA1, which contains the YAP gene, has been found to be highly amplified in a mouse model of a liver carcinoma as well as mammary cancer. Similar finding has also been found for the human locus at 11q22 where amplification occurs in cancers of the liver, lung, ovary, pancreas, and esophagus.

Lead Chromate

Definition

($PbCrO_4$); A water-insoluble chromium-containing compound consisting of lead, and hexavalent chromium in the chromate anion, that is only very sparingly soluble in water. This compound used to be used to manufacture paint used on aircraft and the yellow line in the middle of streets to demarcate traffic lanes. It gives the yellow and yellowish orange color to paints and pigments. When prepared in small particle sizes (<10 μm), this chromium compound is phagocytosed by mammalian cells and can cause cytotoxicity, chromosomal aberrations, and morphological transformation of mammalian cells, and lung tumors when lower animals inhale it.

►Chromium Carcinogenesis

Lead Exposure

Edwin van Wijngaarden
Department of Community and Preventive Medicine, University of Rochester School of Medicine and Dentistry, Rochester, NY, USA

Definition

Lead (Pb) is a heavy, low melting, bluish-gray metal that occurs naturally in various mineral forms in the earth's crust. Lead compounds are substances in which lead is combined with two or more other elements. Organic lead refers to lead compounds which contain carbon, whereas inorganic lead refers to those substances that do not contain carbon and includes metallic lead.

Characteristics

Sources of Lead Exposure

Exposure to lead is predominantly due to ►anthropogenic activity, which has occurred since industrial lead production started millennia ago. The greatest potential for exposure has been experienced by industrial workers, and lead exposure is currently generally well controlled in major lead-using industries such as ►smelting and battery manufacture (Table 1). However, cases of clinical lead poisoning in certain industries still occur and workers using end-products containing lead, such as lead-based paints, continue to be exposed and little to no decreases in lead exposure levels have been observed in certain work environments such as the construction industry. It has been estimated that about one-fifth of the United States general population has a history of exposure on the job.

Historically, the largest source of environmental lead exposure in the United States has been through inhalation and ingestion of air, dust, soil, water and food contaminated from the use of lead in pipes, paints, food and drink cans, and gasoline. These uses have been phased out in many developed countries, including the United States, resulting in a decline in blood lead levels by more than five-fold. Nevertheless, segments of the general population continue to be exposed to excessive amounts of lead, especially from lead-based paints and

Lead Exposure. Table 1 Industrial processes and activities with risk of lead exposure

Industrial processes	Activities
Abrasive blasting	Ceramics making
Battery manufacturing	Drinking from a private well
Gas welding and cutting	Enameling
Metal preparation and pouring	Glassblowing
Metal thermal spraying	Home remodeling
Painting (pigments, binders, and biocides)	Ingesting an herbal remedy
Semiconductor manufacturing	Jewelry making
Silk-screen printing	Living in a house with old plumbing or old paint (pre-1979)
Smelting copper or lead	Living near a smelter
Soldering	Lost wax casting
Steel producing	Painting
Welding	Smoking cigarettes
Welding over coatings	Stained glass making

From HazMap: Occupational Exposure to Hazardous Agents (http://hazmap.nlm.nih.gov/).

contaminated soil in urban settings with an older housing stock. Additionally, drinking water continues to be an important source of lead exposure.

Lead accumulates in the body and may become biologically available long after the occupational or environmental exposure has ceased. Therefore, lead exposure remains a public health concern worldwide.

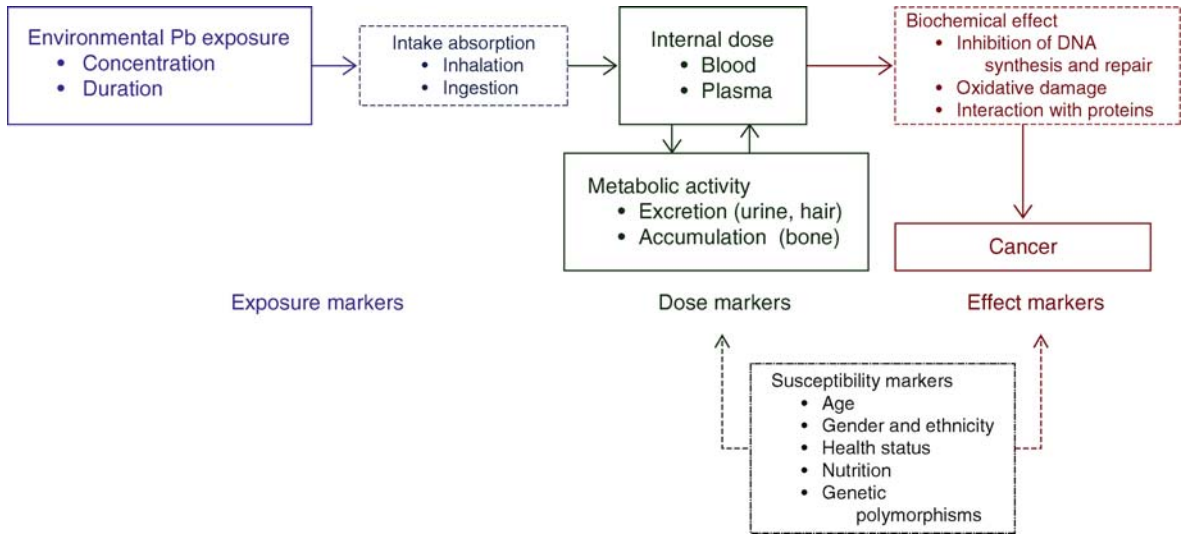
Biological Markers of Lead Exposure

A variety of ►biomarkers exists to measure exposure to lead, including lead in urine, blood, hair, nails, teeth and bone. Blood lead levels are the most common indicator of internal lead exposure in epidemiological studies. However, these levels tend to decline rapidly over time because of a half-life of about one month and therefore represent only recent exposures. For children aged <6 years, the U.S. Centers for Disease Control and Prevention (►CDC) has defined an elevated ►BLL as ≥10 μg/dl. For adults, the highest BLL acceptable by standards of the U.S. Occupational Safety and Health Administration (OSHA) is 40 μg/dl. In the United States, the state-based Adult Blood Lead Epidemiology and Surveillance (►ABLES) program tracks laboratory-reported adult BLLs in an effort to reduce the proportion of adults (age 16 or older) who have BLLs of 25 μg/dl or greater, whereas the CDC tracks children's BLLs by using both National Health and Nutrition Examination Surveys (►NHANES) and state and local surveillance data.

Lead accumulates in the skeleton and remains there for many years. In children, up to 80% of absorbed inorganic lead is stored in the bone, whereas in adults this figure rises to more than 90%. Organic lead compounds are oxidatively dealkylated in the body, and any inorganic lead produced in this way will be distributed like exogenous inorganic lead. The turnover rate of skeletal lead varies by compartments in bone. The half-life of lead in ►cortical bone (e.g. tibia), which constitutes about 80% of skeleton, can be several decades whereas a considerably shorter half-life of only several years has been reported for ►trabecular bone (e.g. patella, calcaneus) which constitutes about 20% of the skeleton. While blood lead levels reflect primarily recent exposures (ongoing steady-state or recently elevated exposures) and the mobilization of lead from the skeleton back into the circulation, bone lead levels have been shown to accurately reflect accumulated exposure. By providing a biological marker of cumulative dose, bone lead may be used in epidemiological studies of lead carcinogenicity to more accurately evaluate dose–response associations in studies of populations in which lead exposure is occurring through multiple possible pathways. Bone lead levels can be determined with a direct, non-invasive measurement using X-ray fluorescence (►XRF) spectroscopy.

Lead Carcinogenesis: Possible Etiologic Mechanisms

Experimental evidence demonstrates that various water-soluble and -insoluble lead compounds can induce ►renal carcinoma and ►brain tumors (gliomas) in rodents. Lead is known to be toxic to the peripheral and central nervous system as well as the kidney. However, there does not seem to be a direct carcinogenic effect of lead since it does not seem to directly result in ►DNA damage. Rather, current mechanistic evidence for a role of lead in ►carcinogenesis suggests a facilitative role involving inhibition of DNA synthesis and repair, ►oxidative stress, and interaction with DNA-binding proteins and ►tumor suppressor genes. This facilitative role suggests that lead exposure may interact with other possible risk factors in the etiology of cancer.



Lead Exposure. Figure 1 Conceptual framework for the association between environmental lead exposure and cancer of the brain and central nervous system.

A general conceptual framework for the carcinogenic effects of lead exposure is presented in the figure. Individual indicators of susceptibility may influence the nature of this relationship, such as age, gender, and genetic polymorphisms. For example, anemia due to glucose-6-phosphate dehydrogenase (►G6PD) deficiency and polymorphisms in the enzyme delta-aminolevulinic acid dehydratase (►ALAD) may affect the susceptibility to lead toxicity, including cancer, by affecting the toxicokinetics of lead in the body (Fig. 1).

Lead Exposure and ►Cancer Epidemiology

The relationship between cancer in human populations and exposure to lead from environmental or occupational sources has been considered in several epidemiological studies. These studies primarily consist of case–control and cohort studies. In ►case–control association studies, cases diagnosed with a disease of interest and controls without that disease are asked about lead exposure (on the job, from hobbies, or from living in older homes) at any point in their life. In cohort studies, cancer mortality or incidence rates are compared between groups of people with and without elevated lead exposure (based on high-lead jobs compared to the general population, or blood lead levels). This literature has been reviewed on several occasions. Most epidemiological studies evaluating the carcinogenic effects of lead exposure have generally suffered from limited statistical power due to a small number of cancer deaths or diagnoses, and the lack of biological measures of exposure. Most studies lack quantitative data on dose–response – one of the key parameters in determining causality – and only few studies divided individuals in high and low exposure groups. Nevertheless, occupational cohort studies have been considered particularly informative with respect to cancer risk because of high documented exposures. These studies were predominantly based on highly exposed battery or smelter workers who were exposed several decades ago (1940s–1970s). These studies have reported on a variety of cancer types, including those of the lung, stomach, kidney and brain. Most studies show a weak to moderate positive association between lead exposure and cancer, in particular for cancers of the stomach and brain, and to a lesser extent for lung and kidney cancer. Follow-up studies of general population samples in the United States and case-control studies shed little further light on these associations.

The International Agency for Research on Cancer (IARC) recently concluded that there is limited evidence in humans for the carcinogenicity of inorganic lead compounds, and inadequate evidence for an effect of organic lead compounds on human cancer.

Lead Generation

Definition

Chemical modification of a structure to increase desired but non-optimized biological activities.

►Lead Optimization

Lead Optimization

Mark R. Player
Johnson & Johnson Pharmaceutical Research & Development, Exton, PA, USA

Definition

The synthetic chemical modification of a biologically active molecule to address pharmacokinetic, pharmacodynamic and toxicologic issues in order to enable its clinical utility.

Characteristics

Drug discovery activities that occur prior to lead optimization such as the choice of target, assay development, ►high throughput screening and early molecular optimization and testing, are typically referred to as ►lead generation. Leads typically have been somewhat optimized for their molecular properties (solubility, removal of covalent modifiers, chemical stability), have been subjected to *in vitro* assays to predict their (►Pharmacokinetic) properties (Caco-2 flux, liver microsomal stability, protein binding, inhibitory activity toward (►Cytochrome P450 isoenzymes) (CYP450s), possess reasonable *in vitro* and cellular potencies toward the molecular target, and have been subjected to some selectivity measurements (kinase selectivity screen and a broad receptor/transporter selectivity screen).

Lead Optimization, the subject of this entry, encompasses chemical modifications of the molecular structure that improve its druglikeness, particularly with respect to issues of potency, selectivity, safety/toxicity and pharmacokinetic (absorption, distribution, metabolism, excretion) parameters. Efficacy in an animal model of disease also is first evaluated during this phase. This essay focuses on optimization of (►Small molecule drug) candidates, though biologics leads are optimized as well.

During (►Preclinical testing), the candidate drug is further examined to assess its suitability for first-in-human safety trials (Phase 1 clinical trials). Development of medium-scale chemical synthesis, in order to produce (►Good manufacturing practices) (GMP) drug substance, is explored. Further assessment of the compounds pharmaceutical properties and formulation work is also undertaken. The initial pharmacokinetic studies are usually repeated in multiple species. This phase also further examines the safety of the candidate drug in non-human species. Target candidate drug exposure is then compared to the dose causing overt toxicity in a rodent, dog or monkey species to evaluate the safety window of the candidate in first-in-human trials. The typical procedure to assess toxicologic risk is based on the compound safety margin which is the ratio of the no adverse event level (NOAEL) in the most sensitive species to the expected therapeutic dose in man.

Chemotherapeutic agents constitute a significant subset of cancer drugs (as well as antibiotics) but are much less used for treatment of other diseases. Chemotherapeutic drugs rely on selective toxicity for cancer cells, either as a result of favorable differences in distribution or favorable differences in biochemistry.

Physicochemical Optimization

Intravenously administered drugs must have high solubility. Drugs administered *via* a peroral route should have adequate solubility in order to be able to reach the site of action within the organism. During *in vitro* testing solubility of a potent compound is usually not an issue, but when animals must be dosed with larger quantities of drug substance in order to measure efficacy or tolerability, absorption may be limited by the failure of the compound to dissolve in the gastrointestinal tract. Thus solubility, permeability and potency are in dynamic tension during optimization. For instance, high solubility can sometimes overcome low permeability with a drug of moderate to high potency.

Solubility can be measured in a number of ways. One way is to initially dissolve the compound in dimethylsulfoxide, a polar aprotic solvent, which overcomes crystal lattice energy. This is the characteristic of a kinetic solubility method. Some compounds soluble at aqueous 0.5–5% DMSO that would not easily or at all attain dissolution if tested with a thermodynamic method, which entails dissolution initially in a buffered aqueous medium. A thermodynamic method however, is perceived to be more relevant to the *in vivo* situation

and should be evaluated at a range of biologically relevant pHs. There are a number of strategies used to optimize the solubility of sparingly soluble drug candidates. The most important is to introduce solubility directly into the molecule during optimization, through introduction of water solublizing moieties at a permissible part of the structure. Another common approach is the formation of a suitable salt. Almost half of present day drugs are salts, and this strategy may be undertaken very early in the lead optimization process. Also, formulation with appropriate organic solvents, surfactants and lipids can be explored during lead optimization and during preclinical development.

Besides solubility, there are a number of other physiochemical parameters that begin to be evaluated during the lead optimization phase, namely chemical stability, morphic states (monomorphic vs. polymorphic), crystallinity and hygroscopicity.

It is also important during the lead optimization phase to bridge the chasm between the discovery chemistry (large number of compounds synthesized in milligram amounts) and the chemical development (few compounds in kilogram amounts) departments. This can occur *via* the formation of specialized teams that bridge that scalability gap, or by the presence of chemists in the discovery chemistry departments that work on process improvements, or both.

Pharmacokinetic Optimization

In years past, a substantial percentage of drugs failed in the clinic secondary to poor pharmacokinetic properties. Today, that number is greatly reduced, chiefly as a result of the focus on ADME (Absorption, Distribution, Metabolism, Excretion) properties during lead optimization. Ideal ADME properties for a drug candidate depends on the clinical target, but typically encompass good ►bioavailability, ►systemic clearance, and ►volume of distribution that may be expected to yield the desired dosing regimen. A low probability for drug-drug interactions and metabolism-based toxicity is also highly desirable.

Analysis of current orally administered drugs and drug candidates has been a primary guide to correlating physical properties with successful clinical developability. It would be useful to develop models that quantify to some extent known effects of easily calculated molecular properties on absorption. The Lipinski "Rule of Five" states that poor absorption frequently occurs with a molecular weight over 500, a logP over 5, and the number of hydrogen bond donors and acceptors each greater than 5. In addition to Lipinski's original rules concerning molecular weight, lipophilicity and the number of H-bond donors or acceptors; a number of studies have also discussed the negative absorption impact of water complexation by amide bonds, high molecular flexibility and high polar surface area.

Bioavailability is a term used to describe the rate and extent of absorption of an orally administered drug in comparison to intravenous administration. High oral bioavailability is almost always an important consideration for the development of good drugs. Oral bioavailability is affected by both the extent of absorption into the intestinal cells in the gut lumen as well as the compounds presystemic elimination by both the intestine and the liver. So structure-specific recognition factors do limit oral bioavailability, such as (►P-glycoprotein) (PGP) transport in the gut, CYP450 metabolism or other enzymatic clearance mechanisms in the gut or liver.

If absolute oral bioavailability is >20% in dogs and rodents then frequently oral bioavailability in humans is >20% as well. However, since there is reasonable correlation between clearance, volume of distribution and half-life data between rat and human as well, this may be tracked during Lead Optimization. It is widely assumed that monkeys are good predictors of human oral bioavailability but this is frequently not the case. They are a good predictor of the fraction absorbed (Fa) but as they have elevated metabolic clearances and hepatic enzyme activities, the oral bioavailability in monkeys is typically lower.

Consideration must be given to the ability of a compound to undergo *in vivo* biotransformation as this is an important component of systemic bioavailability and systemic clearance. It is frequently necessary to decrease the rate of hepatic oxidative metabolism and first-pass elimination in a chemical series during optimization. A number of *in vitro* methods are available to monitor progress. One of the most common and high throughput entail the use of liver microsomal preparations. These retain activity of key components of enzymes involved in drug metabolism such as cytochrome P450s and ►flavin monooxygenases. The drug candidate is incubated in the presence of such preparations, a half-life estimation is made and this can be compared to standards with known first-pass eliminations. The compound's metabolites should be identified in human, efficacy and tolerability species. This can frequently give ideas for means by which the structure can be modified to decrease oxidative metabolism and reduce clearance.

Metabolism of a lead compound may also be evaluated in liver slices or hepatocytes. When a compound induces an enzyme involved in its own metabolism, evidence for which is usually found during multiple-dose pharmacokinetic or efficacy studies, the use of the latter are quite useful. When ►Phase II metabolism is important, again the use of liver slices may be more appropriate as well as *in vitro* glucuronidation assays in microsomal preparations in the absence of NADPH.

Metabolism-based drug interactions comprise one of the major concerns during drug development. If two or more drugs are competing with each other for the same metabolic enzyme, the circulating therapeutic drug concentrations can become elevated and may cause undesirable toxic effects. These are even more clinically important when a drug has a narrow therapeutic index or when the pharmacokinetics are markedly changed. Cytochrome P450 proteins are a critical family of enzymes involved in the metabolism of drugs. Of these the most important are CYP1A2, 2C9, 2C19, 2D6 and 3A4.

CYP3A4 has primarily been associated with *in vivo* drug-drug interactions leading to the withdrawal of marketed drugs. CYP3A4 is responsible for 25% of total CYP content and has broad substrate specificity. CYP2D6 is responsible for basic amine functionality metabolism, and this is important because of the prevalence of these in marketed drugs. Strong inhibitors <1 μM for 3A4 and 2D6 (cDNA expressed CYPs) are certainly major concerns.

Mechanism-based inhibition of 3A4 (irreversible binding or covalent modification) is also a major concern. Furans, some amines and unsaturated distal groups (double and triple bonds) are common culprits. For instance, the triple bond on ethinylestradiol modifys the heme group, though the CYP protein may be modified as well. Care is required when evaluating compounds, as they may initially appear to be only weak inhibitors of CYP3A4 because the inhibition is time-dependent. High liver distribution can exacerbate this issue, as many drug candidates are highly distributed to liver, where CYP3A4 is found in high concentration.

Clearance is a measurement of the ability of the body to eliminate a drug from the body and is made up of hepatic (metabolic and biliary) and renal clearance. For the majority of compounds hepatic metabolism is a major clearance mechanism, so clearance may be expressed relative to hepatic blood flow in the species in which the pharmacokinetic measurement was obtained. The drug concentration seen in the plasma depends on the amount of drug present in the whole body as well as how extensively it is distributed to various compartments. The volume of distribution is a measure of this. High steady state volumes of distribution are associated with more binding in tissue than in plasma and are found frequently in basic drug candidates, while the reverse is true of a low volume of distribution which is frequently found in association with acidic drugs. Since the half-life of a drug is inversely proportional to the clearance, and directly proportional to the volume of distribution, optimization of these parameters is frequently necessary.

Plasma protein binding can be important when activity is driven by the free fraction of drug in plasma. This may be a significant issue when there is a target within the vasculature and a lead with a small volume of distribution, but may be less of an issue with an extravascular target with a high volume of distribution. In the blood, acid glycoprotein binds weakly basic drugs while albumin, which constitutes 50–60% of total serum protein, binds neutral drugs and weak acids.

Toxicological Optimization

Just as the number of compounds in development that fail for pharmacokinetic issues have decreased, the number of compounds that fail during development for toxicity issues have increased. Even so, Adverse Drug Reactions (ADRs) may account for up to 5% of all hospital admissions and 10–20% of hospital inpatients for marketed drugs.

Toxicity issues are frequently observed during lead optimization either when tolerability is being examined specifically, or when dosing pharmacokinetic or efficacy studies. Toxicity is typically first identified in rats or dogs. Toxicologic effects of a compound frequently do require optimization, especially in backup programs where such issues may be better understood as a result of the identification of toxicology in previously identified drug candidates. ADRs may generally be grouped into two classes. Predictable adverse drug reactions can be predicted based on the pharmacology of the drug and are dose-dependent, idiosyncratic drug reactions are unpredictable, cannot be correlated to the pharmacology of the drug and are typically non dose-dependent. Optimization for predictable toxicity normally occurs *via* the identification of a (►Biomarker) or *in vitro* readout for the toxicity followed by the development of a structure-activity relationship around the toxicity in order to remove it during optimization.

Idiosyncratic toxicity is more difficult to approach. Hepatotoxicity is the most common idiosyncratic reaction. These effects can be serious (hepatic necrosis) and skin dyscrasias can be as serious as Stevens-Johnson syndrome (toxic epidermal necrolysis). Mechanistically, the hapten hypothesis is that modification of an endogenous protein by a reactive metabolite or directly by a reactive parent drug generates a foreign protein that may lead to an immune-mediated adverse reaction. The alternative danger hypothesis stipulates that rather than the hapten formation triggering the immune system, cellular damage produced by the reactive metabolite generates a danger signal. If cells are resistant to the stress or the toxic metabolites cannot cause cell injury at all times, no idiosyncratic toxicity occurs. This accounts for the interindividual variations in idiosyncratic drug reactions and the nature of differential responses to various reactive metabolites.

The human liver and blood systems are the most active at forming reactive metabolites.

Several enzymes from ►Phase I metabolism are recognized as important in generating reactive intermediates such as CYP450s, ►myeloperoxidases, ►cyclooxygenases and flavin monooxygenases. CYPs are the most important because electrons are transferred. Phase II metabolism is potentially less of an issue although there are some reports on acyl glucuronide toxicity (these may bind to proteins with or without cleavage of the glucuronide). A large number of electrophiles (generated from *in vitro* experiments such as with HLMs) can be trapped as glutathione adducts or N-acetyl cysteine/N-acetyl lysine adduct mixtures. This method is unlikely to produce false negatives, since safe compounds normally do not generate glutathione conjugates.

Cardiovascular safety is another important consideration during lead optimization. Frequently ►HERG activity needs to be removed from a compounds list of off-target effects.

This channel is the target of a wide range of agents which increase the risk for ►Torsade de Pointes (TdP), as well as many which do not. The growing list of non-antiarrythmic drugs that cause this increased QT interval, and the increasing number of drugs that have been withdrawn from the market because of their ability to trigger TdP, has resulted in increased regulatory scrutiny for this particular safety issue. Unfortunately there is no single cell based assay, or *in vitro* heart preparation or animal model that is very strongly predictive for TdP in humans. Not all drugs which prolong the electrocardiographic QT interval cause TdP, nor is there a quantitative correlation between the magnitude of QT interval increases and the arrythmia. Because there is no gold standard test of the torsadogenic potential of a lead, the use of multiple *in vitro*, *ex vivo* and *in vivo* assays is currently recommended by most experts during the lead optimization phase.

Leiomyosarcoma

Definition

Belongs to a group of cancers called soft tissue sarcomas. Sarcomas are cancers that develop in the supporting or connective tissues of the body (such as muscle, fat, nerves, blood vessels, bone, and cartilage). They are rare. Leiomyosarcomas are one of the commoner types of sarcoma to occur in adults over the age of 50.

►Non-Rhabdomyosarcoma Soft Tissue Sarcomas

Lentigines

Definition

Are benign lesions that occur on the sun-exposed areas of the body. The backs of hands and face are common areas. The lesions tend to increase in number with age, making them common among the middle age and older population. They can vary in size from 0.2 to 2 cm. These flat lesions usually have discrete borders, are dark in color, and have an irregular shape.

►Liver Spots

Lentiginosis

Definition

Presence of ►lentigenes in very large numbers or in a distinctive configuration. Centrofacial lentiginosis, uncommon autosomal dominant syndrome of small hyperpigmented macules in a horizontal band across the centre of the face at one year, increasing in number up to ten years, and associated with skeletal and neural defects.

Synonyms

Leptomeningeal disease; Leptomeningeal seeding; Leptomeningeal metastasis; Neoplastic meningitis; Subarachnoidal spread

Definition

Tumor cell spread into leptomeningeal structures of the brain and/or spine.

Characteristics

Leptomeningeal spreading is a major disease complication in primary central nervous system (CNS) tumors, in solid tumors outside the CNS such as breast, lung, gastrointestinal cancer, melanoma, and as well in hematological malignancies. Leptomeningeal dissemination can occur at initial diagnosis (►primary dissemination) or during the course of the disease following initial therapy (►secondary dissemination), but it is usually a late manifestation of malignant diseases and almost always associated with active tumor disease. Primary leptomeningeal disease is found mostly in primary brain tumors, sarcomas, neuroblastomas, lymphomas and leukemia. Secondary dissemination occurs mostly in lung and breast carcinomas, but also in leukemia and lymphomas and primary CNS malignancies. The way of neuroaxis dissemination for primary CNS tumors and tumors outside the CNS is thought to be hematogenous via arachnoid vessels. Primary brain tumors may also disseminate throughout the neuroaxis by direct extension, by spreading along the nerves or by release of tumor cells into the ►cerebrospinal fluid (CSF). Due to the physiology of the CSF-flow leptomeningeal metastases can involve all structures of the neuroaxis.

In brain tumors, leptomeningeal dissemination is well known in primary CNS lymphomas and medulloblastomas, occurring in up to 33% of all patients at the time of initial diagnosis, in germ cell tumors and also glioblastomas. Patients with evidence of CSF spread are considered to have a poorer prognosis compared with CNS negative patients. In children with high-grade gliomas, the rate of leptomeningeal dissemination is reported to range between 7% and 28% and as with other tumors leptomeningeal spread is a sign of frank tumor dissemination and carries a worse prognosis. In patients with acute lymphoblastic leukemia initial CNS involvement is found in up to 7.4% of patients depending on the individual risk profile of the patient. Although CNS involvement was reported to be negatively correlated with event-free survival (EFS) in one study, this observation could not be confirmed by others. The percentage of initial CNS involvement in patients with acute myeloblastic leukemia (AML) ranges between 5.9% and 12.2%, patients with CNS-negative AML do better than those with initial CNS involvement.

Classification of cerebral leptomeningeal metastasis according to Chang's guideline for cerebellar medulloblastoma (Chang 1969):

Metastasis stage	
M0	No evidence for metastasis
M1	Tumor cells in CSF
M2	Gross nodular seeding of brain CSF spaces
M3	Gross nodular seeding of spinal CSF spaces

Symptoms

The most common symptoms in patients with proven or suspected leptomeningeal dissemination are headache, nausea, vomiting, fluctuating consciousness, cranial or spinal nerve palsy (palsies), and spinal radicular symptoms. Clinical presentation may fluctuate, because several levels of the neuroaxis are affected simultaneously. Duration of symptoms may vary from several days to weeks or even months. In patients with medulloblastoma, secondary diffuse CSF seeding can lead to sudden neurological deterioration and spinal

cord compression. Intracranial hypotension syndrome was described in diffuse meningeal melanomatosis. The symptoms could also mimic cerebral vasculitis, meningitis or viral encephalitis.

Diagnosis

If leptomeningeal dissemination in a patient with an underlying malignant disease is suspected meningitis and viral encephalitis have to be excluded. Other rare diseases should also be considered such as granulomatous angiitis, histiocytosis, Lyme disease, multiple sclerosis, vasculitis, Wegner's granulomatosis, sarcoidosis, post-liquorpuncture changes, and opportunistic infections.

Neuroimaging

In former days conventional myelography and CT myelography improved detection of metastatic disease and can still be used today in cases in which MR imaging is not feasible; it could show nerve root thickening, nodularity, thecal sac irregularity and spinal cord enlargement. Nowadays magnetic resonance imaging (MRI) is the diagnostic tool of choice in patients with suspected leptomeningeal dissemination of a malignant disease and may show hydrocephalus, pial linear or nodular enhancement, subependymal and/or neural deposits, or dural enhancement; however MRI has low specificity (i.e. meningeal enhancement on MRI does not always indicate metastases). Strong methionin uptake on positron emission tomography (PET) may help to confirm diagnosis even before CSF became positive. The time-point of neuroradiographic evaluations should also be considered: False positive spinal MRI findings of subarachnoidal spread of primary CNS tumors have been described, when MRI studies were performed within two weeks after surgery. In medulloblastoma, metastases are generally located along the posterior margin of the spinal cord. More sophisticated MRI techniques such as FLAIR sequences were discussed to be the clue to detect leptomeningeal abnormalities. Contrast enhanced FLAIR imaging sequences seem to improve the detection rate of leptomeningeal disease compared to routine contrast-enhanced T1–weighted imaging by suppression of signal intensity of normal vascular structures on the surface of the brain and spine. Importantly, in patients with primary brain tumors, MRI imaging of the whole spinal axis should be done as a staging procedure before starting treatment and during follow-up (Fig. 1).

Laboratory Findings

Lumbal puncture for cytologic detection of malignant cells is an important diagnostic feature. In at least 50% an elevated opening pressure can be seen. An elevated protein in CSF is found in 80% of patients, whereas about one third of the patients have low CSF glucose levels.

Leptomeningeal Dissemination. Figure 1 Sagittal T1-weighted postgadolinium magnetic resonance imaging (MRI) in a 12-year old girl with glioblastoma multiform showing multiple nodular enhancing lesions of the entire spinal cord.

Detection of CSF seeding by means of cytopathological analysis of CSF specimens has low sensitivity, since only 15–60% of patients with leptomeningeal metastases have positive results. This could be explained by the paucity of viable tumor cells released in the CSF of patients with minimal disease and the presence of confounding reactive lymphocytes in more than one half of patients with leptomeningeal metastases, especially in patients with lymphoma and leukemia. Patients with low tumor burden who would probably most benefit from treatment are, therefore, more likely to be falsely negative. Several consecutive CSF samples and punctures may be required to identify malignant cells. Since positive CSF cytology correlates with a poor outcome regardless of the time of assessment, CSF cytology was found to be highly predictive for overall survival. In addition cytologic examination of lumbar CSF was shown to be superior to cytologic examination of ventriculoperitoneal shunt CSF for the detection of leptomeningeal spread in children with primary brain tumors. Of note MRI imaging and cytologic analysis CSF performed simultaneously might increase the detection rate of CSF dissemination.

Another diagnostic tool is the analysis of specific markers for leptomeningeal dissemination such as PSA for prostate cancer CA-125 for ovarian cancer and CA153-3 for breast cancer, and of non-specific markers such as beta-glucuronidase, lactate dehydrogenease (LDH), and carcinoembryonic antigen (CEA). These markers are helpful, when clinical symptoms strongly suggest dissemination in patients with negative neuroimaging and negative CSF cytological examination. These markers should be detected in serum and CSF levels and might be used for monitoring (in case of leptomeningeal dissemination: ratio <60:1).

Flow cytometric techniques of CSF in patients with lymphoma or leukemia allow the detection of meningeal dissemination with high sensitivity and PCR analysis of clonal immunoglobulin heavy chain (IgH) seems to have both high specificity and sensitivity.

Treatment

Management of leptomeningeal dissemination has to focus on both, treatment of symptoms and treatment of the malignant disease. ►Symptom management includes anticonvulsant treatment in case of seizures and pain medications in case of painful radiculopathy. Corticoids are not very helpful because edema in leptomeningeal metastases is not common.

Because leptomeningeal dissemination is often diagnosed in advanced disease stage, therapy is mainly palliative (except in leukemia and lymphoma, and germ cell tumors), aiming at preserving neurological function and potentially improving quality of life. As to whether the treatment of LM is ►palliative or ►curative depends on various clinical parameters, particularly on the underlying disease. Treatment of leptomeningeal metastases must be directed to the entire CNS, because leptomeningeal metastasis spreads throughout the neuroaxis by way of CSF flow. Treatment consists mainly of involved field irradiation, systemic and intrathecal chemotherapy.

►Intrathecal chemotherapy could be administered via lumbal puncture or Ommaya reservoir, which is the preferred route of administration due to a better distribution of the drug in the CSF and subarachnoid space. Only few chemotherapeutics are available for intra-CSF drug therapy (methotrexate, cytarabine, etoposide, mafosfamide and thiotepa). These agents were primarily tested in patients with primary brain tumors, leukemia and lymphoma. Liposomal formulation such as liposomal cytarabine may increase the therapeutic drug level over extended periods of time and are new approaches to enhance efficacy of drugs administered into the CSF. Other drugs are under investigation: i.e. darcarbazin, melphalan and topotecan. Except for hematopoetic neoplasms and, to even lesser extent, for breast cancer, intrathecal chemotherapy might be efficacious only in cases, where free tumor cells float within the CSF. It is, however, insufficient to treat solid tumor desposits or even bulky disease. Experimental intrathecal treatment includes immunotherapy (intrathecal administration of monoclonal antibodies, cytokines or lymphokine activated killer cells) or the use of targeted toxins.

The use of ►systemic chemotherapy is being re-evaluated for the treatment of leptomeningeal disease. It seems to be more effective when it is given as part of the initial treatment. In highly malignant medulloblastoma (and germ cell tumors) CNS-directed therapy is mainly based on craniospinal irradiation, whereas intrathecal chemotherapy with MTX via ventricular access devices is given to young children not amenable to CSI or to patients with leptomeningeal dissemination. In primary CNS lymphomas in which leptomeningeal involvement is common, intrathecal MTX is frequently used in combination with HD MTX. Nevertheless, patients with an initial diagnosis of meningeal leukemia are treated more intensively than CNS-negative patients, i.e. they will receive additionally intrathecal chemotherapy. In addition, intensive systemic chemotherapy may substitute for radiotherapy.

Even today with new ►radiation techniques radiation is almost strictly avoided in children younger 18 months. Overall in children, the attempt is to minimize radiation and its long-term sequelae by using more intensive chemotherapy. The total dose and fractions depend on tumor entity and age of patients, and could vary between 12–30 Gy. In children with ALL prophylactic cranial irradiation is administered to high risk patients to reduce the risk of leptomeningeal disease: Due to improved systemic and intrathecal chemotherapy, doses of radiotherapy could be lowered to 12 Gy and craniospinal irradiation is no longer necessary; whether patients with AML require prophylactic cranial irradiation is a matter of debate. Furthermore radiation is used to stabilize or improve neurologic function, pain and CSF flow. Additionally, chemotherapy was described to be more effective after radiation. In summary, radiotherapy in leptomeningeal metastases is almost only be used to treat symptomatic areas.

Summarizing the treatment of leptomeningeal dissemination, there is an urgent need to develop new drug-based or radiation-based treatment. For this purpose new and better surrogate markers for response must be developed to identify clearly the effectiveness of a therapeutic regimen.

Leukemia

Definition

Leukemia is a group of cancers originated from blood cells. It can be divided into different types based on the

type of blood cells involved, the stage of differentiation when normal cells become leukemic cells and the speed of disease development. When leukemia arises from the lymphocyte precursors it is called lymphoblastic leukemia and when it arises from the myeloid precursors it is known as myeloblastic leukemia.

Leukemia Diagnostics

Wolfgang Kern, Susanne Schnittger, Claudia Haferlach, Torsten Haferlach
MLL Munich Leukemia Laboratory, Munich, Germany

Definition

Leukemia diagnostics comprises the combined application of different methodologies in a standardized fashion, allowing the precise diagnosis, subclassification, and determination of prognostic parameters.

Characteristics

Introduction

The diagnosis of leukemias today is based on a comprehensive approach applying a variety of different methods in combination. While ►cytomorphology and cytochemistry have been the mainstay of diagnostics for decades and have been used to differentiate between acute myeloid leukemia (AML), acute lymphoblastic leukemia (ALL), chronic myeloid leukemia (CML), chronic lymphatic leukemia (CLL), and myelodysplastic syndromes (MDS) the current up-to-date approach includes ►immunophenotyping/Multiparameter flow cytometry (MFC) as well as ►cytogenetics and ►molecular genetics to correctly diagnose and subclassify leukemias.

►Multiparameter flow cytometry (MFC) is used for immunophenotyping of the leukemic cells which is essential particularly to diagnose and classify lymphatic leukemias. Karyotyping and ►fluorescence in situ hybridization (FISH) are applied to detect chromosomal alterations which are considered disease-defining lesions in an increasing number of entities. Different molecular genetic techniques (►PCR, ►fragment analysis (Genescan), ►heteroduplex analysis, ►melting point analysis, ►nested PCR, ►real time PCR, ►sequence analysis, ►Single stranded conformation polymorphism analysis (SSCP)) allow the identification of leukemia-specific fusion genes and gene mutations and are also an integral part of the diagnostic work-up of leukemias.

The basis for establishing this diversified diagnostic approach has been the growing body of insight into the genetics of leukemias, which not only allowed the definition of recurring genetic aberrations but also their strong correlation to distinct disease subtypes with specific clinical characteristics, including prognostic impact. As a consequence, today the decision to treat a patient suffering from a particular leukemia and the specific therapeutic option to select for him or her largely depends on the presence or absence of these genetic alterations.

The monitoring of minimal residual disease (MRD) increasingly gains clinical relevance in patients with leukemias. While conventional methods like cytomorphology can be used to assess the prognostically highly relevant achievement of complete remission, newly developed methods like multiparameter flow cytometry and quantitative real time PCR allow the exact quantification of the amount of residual malignant cells in patients with complete remission. The level of this MRD in many cases significantly correlates with the further course of the disease and is incorporated into the guidance of a risk-adapted therapy.

The present essay provides, in the first step, an overview of the methods applied in leukemia diagnostics and then focuses on the respective leukemia subentities and their specific diagnostic findings. The content is then summarized by comprehensive algorithms detailing the modern diagnostic work-up for the different leukemias.

Methods Applied in Leukemia Diagnostics

Cytomorphology and Cytochemistry

Cytomorphologic analysis and cytochemistry are performed on peripheral blood and bone marrow smears which are air-dried without fixation before staining. A panoptic staining (Pappenheim or May Gruenwald Giemsa) is used for the general assessment of cell characteristics. Cytochemistry applies myeloperoxidase staining and non-specific esterase staining for the identification of myeloid and monocytic cells, respectively, while the use of Schiff's reaction, acid phosphatase, and chloroacetate esterase (CE) have been substituted by immunophenotyping. Iron staining is applied in the diagnostic setting of MDS.

Immunophenotyping

Immunophenotyping by multiparameter flow cytometry allows the identification, quantification, and characterization of cell populations in peripheral blood or bone marrow samples. Cells are differentiated from each other, based on their light scatter features during their pass across a laser beam (higher cell sizes result in higher forward scatter signal [FSC]; higher heterogeneity of cell content results in higher side scatter signal [SSC]) as well as on their antigen expression patterns.

As 1,000–2,000 cells are analyzed per second, the simultaneous analysis of the expression of five antigens in 10,000 cells within seconds is current standard. Populations can be characterized even if their concentration is only around 1%. During the monitoring of minimal residual disease (MRD), 250,000 cells are analyzed.

While the detection of FSC and SSC signals is possible in unmanipulated cells, the detection of antigens requires the use of monoclonal antibodies against the respective antigens, which are coupled to a fluorescent dye. Five or even more different fluorescent dyes can be routinely used as the light emitted differs in wave length and is specifically recognized by different detectors. Sophisticated compensation programs, however, are necessary to account for overlaps in the spectrum of the emitted light.

Due to its expression on all peripheral blood and bone marrow at different levels, CD45 represents an ideal antigen for performing a differential count. Thus, monocytes feature the strongest expression of CD45 and may be separated from lymphocytes, which also express CD45 quite strongly, based on differences in the SSC signal. Granulocytes express CD45 at a lower level and feature the strongest SSC signal. Importantly, erythrocytes hardly express CD45 and blasts show a CD45 expression level similar to granulocytes; however, both the latter populations are easily separated from each other, based on their SSC signal (low SSC signal in blasts). Therefore, CD45 gating is useful for the analysis of different cell populations, particularly for the analysis of blasts.

The simultaneous detection of the expression of multiple antigens within one tube allows the comprehensive assessment of antigen expression patterns in different cell populations, which, in comparison to single and dual color approaches, leads to quick and valid results in diagnostics, particularly in the quantification of MRD. The panel of antibody combinations is selected, respectively, in consideration of the suspected diagnosis and may be supplemented based on primary results.

Cytogenetics

Importance of Chromosome Analysis, Indication

Chromosome analysis today is an essential part of the diagnosis in hematologic neoplasias. The results help in establishing the diagnosis. Most importantly, however, chromosome analysis provides prognostic information which is derived from the karyotype of the malignant cells. The neoplasia-associated chromosome aberrations are acquired genetic alterations and are limited to the malignant cells. Thus, the non-malignant cells in patients with hematologic neoplasias are cytogenetically normal.

Material

For chromosome analysis, bone marrow is preferred to peripheral blood because malignant cells are present at higher percentages and have a higher proliferative activity. If bone marrow cannot be obtained, the cytogenetic analysis may be done on peripheral blood cells. Since viable cells are needed for metaphase cytogenetics, the bone marrow should be shipped into the cytogenetic laboratory within 24 h. The cells must not be frozen.

Conventional Chromosome Analysis Using Banding Techniques

A sufficient number of good quality metaphases is needed for chromosome analysis. Bone marrow cells are arrested in the metaphase by the addition of colchicine either directly after drawing the sample or after short-term cultivation (24–72 h). To maximize the gain of metaphases the leukemic cells can be stimulated by cytokines during cultivation. The addition of hypotonic potassium chloride solution swells the cells and they are fixed in multiple steps by the use of a methanol acetic acid solution. Then the cells are dropped on to glass slides. To allow the unequivocal identification of each chromosome, a banding technique must be applied. The most frequently applied banding techniques are G- (Giemsa-), Q- (Quinacrin-), and R- (reverse) banding. These techniques lead to the appearance of light and dark bands on the chromosomes which are specific for each chromosome and allow an unequivocal identification of each chromosome. To allow a valid report a complete analysis of 20–25 metaphases is required according to the respective international consensus.

Nomenclature – ISCN Cytogenetics

Chromosomes are classified according to their size, the position of the centromere (which divides both arms of the chromosomes), and the characteristic banding patterns. Each chromosome has a short arm (p) and a long arm (q). Based on the banding pattern, each chromosome is divided into regions and bands, which are numbered from the centromere to the telomere. The internationally accepted cytogenetic system of nomenclature (ISCN: International System of Cytogenetic Nomenclature) allows the exact description of all numeric and structural aberrations in a karyotype formula. The karyotype formula in the first place gives the number of chromosomes followed by the sex chromosomes. Thus, the normal female karyotype is 46,XX and the normal male karyotype is 46,XY.

The numeric chromosome aberrations include monosomies (loss of a chromosome) and trisomies (gain of a chromosome). Furthermore, the complete set of chromosomes may be multiplied. In normal cells a double set of chromosomes (diploid chromosome set) is

present. Three- and fourfold sets of chromosomes are designated as triploid and tetraploid.

The most frequently occurring structural chromosome aberrations are deletions (losses of parts of chromosomes), translocations (exchange of parts of chromosomes between different chromosomes), inversions (twisting of a part of a chromosome by 180°), and isochromosomes (a chromosome consisting of either two short arms or two long arms while the respective other arms are lost).

In the karyotype formula a gain of a chromosome is indicated by a "+" and a loss of a chromosome is indicated by a "–"; e.g. 47,XX,+8 is a trisomy of chromosome 8 and 45,XY,−7 is a monosomy of chromosome 7. There are abbreviations for structural chromosome aberrationens which are internationally agreed on, e.g. "t" for translocation and "inv" for inversion: t(8;21)(q22;q22) indicates a break in chromosome 8 at band q22 and a break in chromosome 21 at band q22 as well as an exchange of the fragments between both chromosomes. Different chromosomes and breakpoints in different chromosomes are divided by in the karyotype formula, while breaks within a chromosome are listed without a separator, e.g. inv(16)(p13q22): breaks occurred in chromosome bands p13 and q22 of a single chromosome 16 with a fragment being twisted by 180°. Another example is del(5)(q13q31): breaks occured in the bands q13 and q31 of a single chromosome 5 with a loss of the area between q13 and q31.

Chromosome aberrations are designated clonal if an identical structural aberration or a gain of a chromosome is observed in at least two metaphases or if a loss of the same chromosome is observed in at least three metaphases.

Comparative Genomic Hybridization (CGH)

Comparative genomic hybridization allows a comprehensive analysis of the tumor genome with regard to over- and underrepresented DNA sequences (losses and gains of chromosomes, deletions, amplifications). The technique is based on the simultaneous staining of both test DNA of a healthy volunteer and tumor DNA using two different fluorescent dyes. Identical aliquots of both DNA samples are then mixed and hybridized on normal metaphases. Differences in the numbers of copies in different sequences between normal and tumor DNA are detected by the quantification of the ratio of fluorescence intensity (tumor DNA to normal DNA) in each region of the normal metaphase chromosomes. Balanced translocations, inversions, or other aberrations which are not accompanied by a change in the number of copies are thus not detectable by CGH. CGH may play an important role particularly if a chromosome analysis is not possible, e.g. if living tumor cells are not available or if tumor cells do not proliferate in vitro.

Fluorescence In Situ Hybridization (FISH)

The FISH technique relies on the hybridization of DNA probes which identify specific chromosomal structures. Probes can be used which are specific for the centromeric region of particular chromosomes, for genes, or for complete chromosomes. The DNA of both the applied probe and of the patient sample are denaturated, i.e. both DNA strands of the double helix are separated. During the following renaturation, the DNA probes attach to the complementary section of the patient DNA (hybridization). The DNA probes are either directly conjugated to a fluorescent dye or are analyzed using fluorescence conjugated antibodies. The respective chromosome structures therefore are assessable as fluorescence signals.

A significant advantage of the method lies in its applicability not only to metaphases but also to interphase nuclei. A disadvantage is that information is obtained only on chromosomes and genes for which probes are used.

The role of the FISH technique differs between the different leukemia subgroups (see respective chapters).

Interphase FISH

Due to the multitude of different chromosome aberrations, which are observed particularly in acute leukemias, a screening based on FISH on interphase nuclei covers only a fraction of potentially present aberrations and therefore cannot substitute the classic chromosome analysis. However, if a specific question should be answered, e.g. the detection of the translocation t(15;17)(q22;q12) when acute promyelocytic leukemia is suspected, the FISH technique represents a fast and reliable method, providing a result within 4 h.

In follow-up assessments during therapy the FISH technique can be used for the detection of residual disease if at diagnosis aberrations have been found by chromosome analysis for which FISH probes are available. The sensitivity for this method is higher than for the chromosome analysis; however, it is lower than for PCR.

Metaphase FISH

In addition to the probes applicable to interphase nuclei, so-called chromosome painting probes can be applied to metaphases which specifically bind to the complete DNA of a chromosome. This technique is used mainly for the confirmation of the conventional chromosome analysis in difficult cases.

The 24-color-FISH method allows the display of all 22 different pairs of chromosomes as well as of the sex chromosomes in one single hybridization. It is applicable to metaphase chromosomes only and helps in identifying complex structural aberrations.

Molecular Genetics

PCR

PCR is the most frequently applied method to detect molecular genetic changes in leukemia. By using oligonucleotides specific for certain sequences, regions of interest can be amplified and further analyzed. All the following methods are based on this standard method.

RT-PCR

In specific cases, especially when fusion genes are analyzed in which breakpoints are distributed over a wide genomic range, it is advantageous to use cDNA as the template for PCR.

Nested PCR

Using this method, both the sensitivity and specificity of a PCR can be increased. In hematology, it is frequently applied to detect small amounts of molecules, i.e. mainly for the detection of minimal residual disease. For a nested PCR a fraction of a finished PCR is used for a new PCR. Oligonucleotides that hybridize within the first amplificate are used as primers. This additional amplification increases the sensitivity significantly. Depending on the type of mutation and the initial material, one malignant cell in 10^4 to 10^8 normal cells can be detected. Thus, this is the most sensitive method currently available for most sequences targeted for the detection of minimal residual disease (MRD). However, due to the high sensitivity, this method also carries the highest risk of contamination. In order to minimize this risk, different precautions must be applied and control reactions must be performed in parallel.

Real Time PCR

Another method for the amplification and detection of PCR products is the real time PCR. Different from other methods of detection, this is not an end-point analysis, but the measurement is performed during the phase of PCR when a logarithmic amplification of PCR products occurs. This allows an exact quantification of the target sequences in the material which is assessed. The method is based on the addition of fluorescence-conjugated probes to the specific primers required for the PCR. These probes hybridize during the running PCR with the continuously increasing amplification products and release fluorescence signals, which are detected in an optical device specifically constructed for this approach. Thus, an increase of fluorescence intensity occurs during PCR. The time point (PCR cycle) at which a fluorescence higher than baseline is detected for the first time in a sample correlates with the number of targeted molecules in the sample. The fluorescence intensity of the targeted gene is normalized to a constantly present gene or transcript, based on which the number of malignant cells present in the sample can be calculated. Also, for this method of detection, the application of specific PCR machines equipped with optical devices is needed. Using these machines it is also possible to conventionally detect PCR products; however, the strength of real time PCR is its capacity for an exact quantification for follow-up analyses.

Mutation Screening

Different methods are available, which allow the screening of defined gene regions for mutations without the necessity of sequencing. Some examples are listed below:

Heteroduplex Analysis

As the first step in this analysis, a region with a suspected mutation is amplified by PCR. Since in man two alleles of each locus are normally present, two different PCR products occur. After completion of the PCR, these are denaturated (conversion to single-strand state) and then renaturated. Consequently, four renaturated products are possible: a normal double strand, a mutated double strand, and two heteroduplices, in which one base, respectively, is not paired to the other strand, i.e. a mismatch is present. These heteroduplices are detectable on specific gels or by a dHPLC device (►WAVE).

SSCP Analysis (Single Stranded Conformation polymorphism Analysis)

In this analysis denaturated single strands are separated using a non-denaturating surrounding by gel or capillary electrophoresis. It takes advantage of the fact that mutated single strands lead to other secondary structures as compared to unmutated ones and thereby have different features within the electric field.

Melting Point Analysis

In addition to the classic real time PCR, a further step is applied. Fluorescence-marked probes, which lie on a potentially mutated area, are slowly melted off the PCR products. In case of a mutation under the probes, a so-called mismatch occurs. Thus, the probes fit less well in the wildtype and faster melt off the PCR product.

Fragment Analysis (Genescan)

As an alternative to the gel analysis, PCR fragments can be detected by a fragment analysis which is also called Genescan-analysis. This method is performed using sequencing machines equipped with special software. To allow the detection, one of the two PCR primers is conjugated to a fluorescent dye. The advantage of this method is its capacity to determine the length of the amplificates exactly. In addition, with some limitations, it is possible to quantify the amplificates in comparison with another gene, which is generally the unmutated wild type. The method needs more extensive equipment

and resources, due to the use of primers conjugated to fluorescent dyes, as compared to the standard gel analysis. It is frequently used in the context of multiplex PCR reactions, i.e. reactions employing multiple primers with the parallel amplification of up to four different loci. An example of this application is the chimerism analysis after allogeneic stem cell transplantation with microsatellite markers.

Sequence Analysis

The exact delineation of the base sequence of a region of a gene is frequently needed. To allow this, sequencing reactions are performed with nucleotides being integrated during PCR based reactions. Each of the four different nucleotides is labeled to a fluorescent dye and a dideoxy group, respectively, and leads to a chain stop in the PCR reaction. Subsequently, the products are separated according to their length on a matrix (e.g. a gel or a polymer) and are detected by an optical device allowing the exact determination of the base sequence.

For some gene regions the sequence analysis is feasible as a primary approach in a limited number of patients. In case of a screening of multiple gene regions in one patient or of one gene in many patients, the direct sequencing requires large resources. In this instance, different screening approaches are available for the assessment of mutations in particular gene regions without the need for a full sequence analysis.

Diagnostic Procedures in Leukemia

Diagnostic Workup of AML

Cytomorphology

The examination of both bone marrow and peripheral blood smears by cytomorphology and cytochemistry is necessary to diagnose AML according to FAB criteria (Table 1). Based on the FAB (French-American-British) classification, which was established in 1976 and revised in 1985, AML is subdivided into 11 morphologically different groups. Some of these groups correlate with distinct genetically defined forms of AML;

Leukemia Diagnostics. Table 1 Definition of subgroups of AML according to FAB, association with genetic aberrations

FAB-Subtype	FAB-criteria				Association with		
	Granulopoiesis	Monopoiesis	Erythropoiesis	Immunologic marker	Cytogenetics	Molecular genetics	Frequency
M0	<10% POX <3%	<20%	<50%	Myeloid positive Lymphoid negative			
M1	<10% POX >3%	<20%	<50%		t(8;21)	AML1-ETO	1.7%
M2	>10% maturation	<20%	<50%		t(8;21)	AML1-ETO	12.5%
M3	Hypergranular Auer-rods	<20%	<50%	HLA-DR negative	t(15;17)	PML-RARA	98%
M3v	Microgranular Monocytoid nuclei	<20%	<50%	HLA-DR negative	t(15;17)	PML-RARA	
M4	>20%	>20%	<50%				
M4Eo	>20% Abnormal eosinophils	>20%	<50%		inv(16)/t(16;16)	CBFB-MYH11	100%
M5a	<20%	>80% Immature	<50%		11q23 Aberr.	MLL-Fusion	31%
M5b	<20%	>80% Mature	<50%		11q23 Aberr.	MLL-Fusion	17%
M6	>30% of NEC are blasts	variable	>50%				
M7	>30% megakaryoblasts	variable	<50%	CD41/CD61 positive			

Bold = typical finding; NEC = non-erythroid cells.

however, most of them do not. Increasing insights into the biology of AML as well as the identification of specific chromosome aberrations prompted the WHO to suggest a new classification in 2001, based on biology and cytogenetics.

The FAB classification subdivides AML based on cytomorphology and cytochemistry into different subgroups. With only a few exceptions, the diagnosis of AML requires bone marrow blasts of at least 30% of all nucleated cells; at least 3% of the blasts must react positive for myeloperoxidase. The threshold for blasts is 20% in the WHO classification.

The AML classification suggested by the WHO combines the methods previously used for the FAB classification, i.e. cytomorphology, cytochemistry, and immunophenotyping, with cytogenetics and molecular genetics as well as with clinical parameters (Table 2). The genetic characterization of AML, in particular, not only allows a classification according to the prognosis, but provides the basis for the definition of distinct subgroups with recurrent balanced translocations. Thus, the WHO classification divides AML into four groups:

1. AML with recurrent cytogenetic aberrations
2. AML with myelodysplasia-associated features
3. Therapy-related AML and MDS
4. AML not otherwise categorized

Leukemia Diagnostics. Table 2 WHO classification of AML

AML with recurrent cytogenetic aberrations
AML with t(8;21)(q22;q22), AML1(CBF-alpha)-ETO
Acute promyelocytic leukemia (AML with t(15;17)(q22;q11-12) and variants, PML-RARA)
AML with abnormal bone marrow eosinophils (inv(16)(p13q22) or t(16;16)(p13;q22), CBFB-MYH11)
AML with 11q23(MLL)-fusions
AML with multilineage dysplasia
AML following a myelodysplastic syndrome
AML without antecedent myelodysplastic syndrome
AML and myelodysplastic syndrome, therapy-related
Alkylating agent-related
Topoisomerase type II inhibitor-related (some may be lymphoid)
Other types
AML not otherwise categorized
Minimally differentiated AML
AML without maturation
AML with maturation
Acute myelomonocytic leukemia
Acute monoblastic or monocytic leukemia
Acute erythroid leukemia
Acute megakaryoblastic leukemia
Acute basophilic leukemia
Acute panmyelosis with myelofibrosis

The first group comprises biologically and clinically largely consistent subgroups of AML. The WHO classification thus represents a significant development of the FAB classification. The independent biologic and prognostic impact of groups 2 to 4, however, has not been demonstrated yet. Importantly, the subdivision of group 4 essentially reflects the FAB classification. A further new definition in the WHO classification is the deletion of MDS-RAEB-t and the reduction of the limit between MDS and AML from 30 to 20% bone marrow blasts.

Immunophenotyping

AML is diagnosed on the basis of cytomorphology and cytochemistry. The only exceptions are AML M0 and AML M7 in which immunophenotyping is also necessary. Furthermore, some genetically defined subgroups feature typical although not fully specific immunophenotypes which are therefore used to guide further diagnostics only.

According to the abundance of promyelocytes, the AML M3 shows characteristic findings in the scatter plot and in addition is negative for HLA-DR and has a strong unspecific fluorescence signal. However, some of these findings can be present also in AML M2.

Typically, in AML M2 with t(8;21) there is an aberrant coexpression of CD19 and CD56; this can also be found in some AML without t(8;21).

The same is true for the immunophenotype of AML M4Eo with positivity for CD2 and an asynchronous coexpression of CD15 and CD34 which, however, may be present in other AML subtypes as well.

AML M0 is undifferentiated and lacks myeloperoxidase positivity in cytochemistry. Thus, the diagnosis cannot be made based on morphology alone. Immunophenotyping allows the distinction from ALL based on the expression of CD13, CD33, and CD117 and other myeloid antigens and at the same time a lack of lymphatic antigens or, respectively, a low lymphatic score not sufficient to diagnose a biphenotypic acute leukemia. In half of the cases an expression of MPO can be detected although cytochemistry shows negativity for myeloperoxidase.

AML M7 is negative for myeloperoxidase in cytochemistry. The expression of CD41 or CD61 is detected flow cytometrically. Due to the frequently occurring myelofibrosis a cytologic examination may not be possible in some cases.

Monitoring of Minimal Residual Disease (MRD)

In patients with AML a significant prognostic impact of immunologically determined levels of MRD has been demonstrated. Due to the similarity of immunophenotypes between AML and normal bone marrow

in some cases early work focused on highly aberrant leukemia-associated aberrant immunophenotypes (LAIPs) including mainly the aberrant expression of lymphoid markers (CD19, CD7, CD56) and the asynchronous expression of progenitor cell and differentiation markers (e.g. CD34+CD117-CD15+).

For MRD levels determined after the achievement of complete remission and completion of consolidation therapy, a significant impact on both relapse-free and overall survival has been demonstrated, which has been largely independent of other prognostic parameters.

Newer studies have aimed at extending the immunologic MRD analysis to patients with less aberrant LAIPs and thus at the applicability of the method to each patient with AML. By the use of a comprehensive panel of monoclonal antibodies this task has been accomplished with a median sensitivity of 0.05%. Further analyses using this approach have confirmed the prognostic impact of MRD levels. Thus, as early as on day 16 of the induction therapy, patients can be divided into two prognostically differing groups based on the MRD level (2-year event-free survival: 53% vs. 19%, $p < 0.0001$; 2-year overall survival: 58% vs. 43%, $p = 0.0133$). Furthermore, the MRD levels determined after both achievement of complete remission and completion of consolidation therapy, demonstrate a similar prognostic impact, which is independent of other parameters.

In patients with AML, thus, multiparametric flow cytometry allows the quantification of MRD in virtually all cases, while molecular techniques allow this in half of the cases. Current studies will determine the role and place of both methods in AML. Table 3 shows a comprehensive panel of antibodies, which can be used to define a LAIP in AML.

Cytogenetics

More than 50 recurrent structural chromosome aberrations have been described in AML. The karyotype of the leukemic blasts is the most important independent prognostic parameter in AML.

50 to 75% in adult AML and 75 to 85% in childhood AML carry clonal chromosome aberrations. The incidences of the respective chromosome aberrations are age-dependent. However, the prognostic relevance of the karyotype is largely independent of age.

A variety of characteristic chromosome aberrations are known in AML, which define distinct entities with typical morphology and clinical course. The newly defined WHO classification of AML includes cytogenetic aberrations as central classification criteria. Thus, the classification is primarily based on specific cytogenetic rearrangements:

- AML with t(8;21)(q22;q22), AML1/ETO
- acute promyelocytic leukemia/AML M3/M3v with t(15;17)(q22;q11–12) and variants, PML/RARA
- AML with abnormal bone marrow eosinophils and inv (16)(p13q22) or t(16;16)(p13;q22); CBFB/MYH11
- AML with 11q23(MLL)-anomalies

Based on cytogenetics and pathogenesis AML can be separated into three groups according to the karyotype:

1. AML with normal karyotype (40 to 45%).
2. AML with balanced chromosome aberrations (20 to 25%), the most frequent ones being t(8;21)(q22;

q22), inv(16)(p13q22)/t(16;16)(p13;q22), t(15;17)(q22;q12), and 11q23-rearrangements involving the MLL gene. Less frequent ones include inv(3)(q21q26), t(6;9)(p23;q34), and t(3;21)(q26;q22).
3. AML with unbalanced karyotype abnormalities (30 to 40%) including trisomies (e.g. +8, +11, +13, +21), monosomies (e.g. −7), and deletions (e.g. 5q-, 9q-) as well as the large group of complex aberrant karyotypes (3 and more chromosome aberrations, but none of the recurrent balanced aberrations).

With regard to prognosis AML are divided into three groups based on the karyotype:

1. Favorable karyotype: t(15;17)(q22;q12), inv(16)(p13q22)/t(16;16)(p13;q22), t(8;21)(q22;q22)
2. Intermediate karyotype: normal karyotype, all aberrations not grouped into 1 or 3
3. Unfavorable karyotype: complex aberrant karyotype, -5/5q-, -7/7q-, 17p aberrations, 11q23/MLL-rearrangements, inv(3)(q21q26), t(6;9)(p23;q34)

For a variety of infrequent karyotype aberrations the prognostic impact has not been clearly defined yet. Significant insights into correlations between genetic alterations and response to therapy led to the approach of increasingly selecting therapy according to the karyotype.

The prognostic relevance of the karyotype is valid within all age groups as well as in both de novo and therapy-associated AML.

Fluorescence In Situ Hybridization

In the diagnostic setting of AML, the FISH analysis is used mainly in addition to the classical chromosome banding analysis. Since the karyotype aberrations occurring in AML are highly heterogeneous, even a large-scale FISH screening on interphase nuclei would cover only a small part of these aberrations. Thus, FISH cannot replace the classic chromosome banding analysis.

However, in targeting a specific alteration, e.g. the translocation t(15;17)(q22;q12) (on the molecular level the rearrangement of the PML and RARA genes) when an acute promyelocytic leukemia is suspected, the FISH technology on interphase nuclei provides a fast and valid result within 4 h. Furthermore, the frequently occurring genetic aberrations, t(8;21)(q22;q22), inv(16)(p13q22) and rearrangements of the MLL gene are used for stratification in the newly defined WHO classification of AML. These alterations are detectable by FISH as are the frequently occurring deletions, e.g. deletions on the long arm of chromosomes 5 or 7, and monosomies (−7) and trisomies (+8, +11, +13, +21). A large portion of AML with complex aberrant karyotype is detectable by FISH with the help of a medium-scale set of probes.

The so-called chromosome painting using 1 to 3 or even 24 colors (24-color-FISH) on metaphase chromosomes is applied in addition to the classic chromosome analysis, if the karyotype cannot be fully resolved on the basis of the chromosome analysis after classic banding, which is not uncommon in complex aberrant karyotypes.

FISH can further be used during the course of therapy for the detection of residual disease. It is more sensitive and specific compared to cytomorphology or chromosome banding analysis; however, it is less sensitive compared to real time PCR and immunophenotyping. FISH has its role in the detection of residual disease, mainly in AML with complex aberrant karyotype, since this subgroup in general lacks genetic alterations detectable by PCR.

Molecular Genetics

Detection of Fusion Genes

The detection of fusion genes using RT-PCR plays an important role in the molecular diagnosis of AML. Reciprocal chromosome rearrangements are found in about 25% of all AML. The molecular correlates and fusion genes, respectively, of most reciprocal cytogenetically detectable rearrangements, are known. The most frequently occurring reciprocal translocations t(15;17), t(8;21), and inv(16)/t(16;16) are represented by the fusion genes PML-RARA, AML1-ETO, and CBFB-MYH11, respectively, on the molecular level. Rearrangements of the MLL gene are present in 5% of all AML with more than 50 different translocation partner genes. Furthermore, some reciprocal rearrangements occur infrequently and are present in less than 1% of AML; however, they may be useful for diagnostic purposes and defining prognosis. The most frequent fusion genes in AML are listed here.

The following fusion genes are detectable by RT-PCR (Table 4):

AML1-ETO, AML1-EVI1, BCR-ABL, ETV6-MDS/EVI1, CBFB-MYH11, PML-RARA, RARA-PML, MLL-ENL, MLL-ELL, MLL-AF6, MLL-AF9, MLL-AF10, MLL-AF1q21, MLL-AF17, MLL-MSF, MLL-p300, CALM-AF10, MLL-PTD, FUS-ERG, EFG-FUS, CHIC2-ETV6, NUP98-HOX9, DEK-CAN, MOZ-CBP.

For the fusion genes PML-RARA, AML1-ETO, and CBFB-MYH11 it has been demonstrated that the quantification of their expression at diagnosis is prognostically relevant. For all other fusion genes, the quantification at diagnosis is also useful since this evaluation may be used as the starting point for assessment during follow-up.

Detection of Molecular Mutations

In recent years a variety of mutations and small gene rearrangements, which are not detectable cytogenetically, have been described. Nonetheless, they play an important role in molecular diagnosis and estimation of prognosis in AML.

Leukemia Diagnostics. Table 4 Translocations and respective fusion genes in AML

			Frequency	
Cytogenetics	Fusion gene	Subtype	Children	Adults
t(8;21)(q22; q22)	*AML1-ETO*	M2/(M1)	10–15%	8–12%
inv(16) (p13q22)	*CBFβ-MYH11*	M4eo	6–12%	8–12%
t(15;17)(q22; q12)	*PML-RARA*	M3/M3v	8–15%	8–10%
t(6;11)(q27; q23)	*MLL-AF6*	M4/M5a	2–5%	<1%
t(9;11)(p22; q23)	*MLL-AF9*	M5a	8–10%	1–2%
t(10;11)(p13; q23)	*MLL-F10*	M5a	<1%	1–2%
t(11;19)(q23; p13)	*MLL-ENL*	M5a	<1%	<1%
t(11;19)(q23; p13)	*MLL-ELL*	M5a	<1%	<1%
t(3;21)(q26; q22)	*AML1-EVI1*	–	1%	<1%
t(6;9)(p23; q34)	*DEK-CAN*	M1/M2/M4	1–2%	<1%
t(8;16)(p11; p13)	*MOZ-CBP*	M4/M5	<1%	<1%
t(1;22)(p13; q13)	*OTT-MAL*	M7	2%	–
t(7;11)(p15; p15)	*HOXA9-NUP98*	M2	–	<1%
t(10;11)(p13; q14)	*CALM-AF10*	M0/M1/M5	–	<1%
t(16;21)(p11; q22)	*FUS-ERG*		–	<1%

Mutation	Most frequent subtypes	Frequency (total)	Prognosis
MLL-PTD	Normal karyotype (11%)	6.5%	Unfavorable
	trisomy 11 (20 to 50%)		
FLT3-LM	Normal karyotype (40%)	23%	Unfavorable
	t(15;17) (35%)		
FLT3-TKD	All AML	6.5–7%	Dependent on additional defects
KITD816	t(8;21) (12%)	1.5%	Unfavorable
KITexon8	inv(16) (10%)	<1%	Unfavorable
NRAS	inv(16) (45%)	10%	Intermediate
	inv(3)/t(3;3)		
KRAS	inv(16); t(8;21) (5–20%)	<1%	
	(in childhood AML)		
AML1	M0 (22%), trisomy 21 (30%), trisomy 13 (80%)	5%	Unfavorable
CEBPA	Normal karyotype (18%)	10%	Favorable

Among these molecular mutations are the partial tandem duplications of the MLL gene (MLL-PTD) and the length mutation of the FLT3 gene. These mutations are found mainly in AML with a cytogenetically normal karyotype and are associated with an unfavorable prognosis. The FLT3-LM is found in 10 to 15% of all childhood AML and in 20 to 25% of all adult AML. Furthermore, in another 6 to 7% point mutations are found within the tyrosine kinase domain of the FLT3 gene (TKD mutations). Thus, with a total of about 30% FLT3 is one of the most frequently mutated genes known so far in AML.

In an additional 10% of all AML, mutations are found in the transcription factors CEBPA and AML1, which play an important role in hematopoiesis. Furthermore, 30% of all AML and 55% of AML with normal karyotype, carry NPM1 mutations. Mutations of both CEBPA and NPM1 are considered prognostically favorable.

Some point mutations like those of KIT and RAS are not specific for AML; however, they contribute significantly to leukemogenesis, in particular in cooperation with AML1-ETO and CBFB-MYH11. Accordingly, a two-hit-hypothesis has been suggested for leukemogenesis. Mutations of tyrosine kinase genes like ABL, FLT3, and KIT as well as RAS mutations are designated type I mutations, which lead to an increased proliferation of hematopoietic cells. Fusion genes and mutations of transcription factors are designated type II mutations, which lead to a stop in differentiation. Only the cooperation of both types of mutations results in the clinically evident acute leukemia.

A variety of methods are available for the detection of these molecular mutations. Among others these comprise conventional RT-PCR (FLT3-LM, MLL-PTD), ►GeneScan analysis (FLT3-LM, NPM1), ►melting curve analysis (FLT3-TKD, NPM1, NRAS, KITD816), dHPLC/WAVE (FLT3, AML1, CEBPA, NPM1, KIT), and consequently sequence analysis (for all mutations).

In addition to the prognostic relevance in AML, these molecular markers may be used as targets for the PCR-based detection of minimal residual disease.

Monitoring of Minimal Residual Disease (MRD)

The detection of minimal residual disease using PCR-based methods is feasible for all markers with a sensitivity between 1:100 and 1:1,000. The methods mainly applied are conventional and nested RT-PCR, fragment analysis, and WAVE analysis.

An even higher sensitivity (1:10,000 to 1:1,000,000) is achieved by "real time PCR." This method is established for the fusion transcripts: AML1-ETO (applicable in 7–10% of all AML cases), CBFB-MYH11 (7–10%), PML-RARA (7–10%), DEK-CAN (1%), different MLL translocations (5%), MLL-PTD (6%), and NPM1 mutations Typ A, B, and D (25%). Furthermore, it is possible to build patient-specific real-time PCR assays for the FLT3-LM (23%) and rare NPM1 mutation types (5%).

Diagnostic Workup of ALL

Cytomorphology

Cytomorphology and cytochemistry are used to diagnose bone marrow blasts negative for myeloperoxidase and non-specific esterase in ALL; however, the exact diagnosis and further subclassification rely on immunophenotyping. The exception is the typical L3-morphology of blast cells in Burkitt's lymphoma and mature B-ALL.

Immunophenotyping

Acute lymphoblastic leukemias (ALL) are grouped into B-precursor- and T-precursor-leukemias, based on the immunophenotype. They are further subdivided according to the degree of maturation of the leukemic blasts into Pro-B-ALL, common-ALL, Pre-B-ALL, and mature B-ALL, and into Pro-T-ALL, Pre-T-ALL, cortical T-ALL, and mature T-ALL, respectively. In general, in case of the respective morphologic findings (negativity for MPO) a B-precursor-ALL is diagnosed if both cCD22 and CD19 are expressed. A T-precursor-ALL is present if c/sCD3 and CD7 are expressed. The definition of ALL with aberrant expression of myeloid antigens as a separate entity is not preferred since these findings in most cases are associated with genetically defined and clinically relevant aberrations. Table 5 provides the antigen expression patterns of the respective entities.

Monitoring of Minimal Residual Disease (MRD)

In T-precursor-ALL the coexpression of cCD3 and TdT is mainly useful as LAIP. In B-precursor-ALL it is the coexpression of CD19 and CD10. Furthermore, in many cases the aberrant coexpression of myeloid antigens as well as the expression of CD34 can be used.

The first area in which the significant prognostic impact of immunologically determined MRD levels has been demonstrated has been after the achievement

c=cytoplasmic; s=membrane.

of complete remission in childhood ALL: the detection of residual leukemic cells was associated with a significantly increased risk of relapse. This association was independent of other prognostic parameters. Further analyses have demonstrated that as early as on day 19 of the induction therapy MRD levels are equally significant with regard to prognosis.

These results have been reproduced in adult ALL. Thus, patients with low-level MRD after completion of induction therapy have a longer relapse-free survival. Also in this context, the impact of MRD was independent of other prognostic parameters.

Multiparameter flow cytometry is, compared to molecular techniques, feasible for the quantification of MRD in virtually all patients with ALL. Current trials will define the respective roles of both methods, based on direct comparisons.

Cytogenetics

A large number of chromosomal aberrations with prognostic and therapeutic relevance have been described. On the one hand, ALL are subdivided into ploidy groups based on the karyotype, i.e. according to the number of chromosomes (Table 6). On the other hand, they are grouped according to structural aberrations (Table 7). The most frequent aberration in adult ALL is the t(9;22)(q34;q11) which is associated with a very unfavorable prognosis. With the availability of the tyrosine kinase inhibitor, imatinib, the detection of this Philadelphia-translocation and of its molecular genetic correlate, the BCR-ABL rearrangement, is even more important as treatment with this specific drug improves outcome. In addition, the detection of translocations involving the MLL-gene, which is located on the long arm of chromosome 11, is prognostically important and requires specific therapeutic approaches.

Cases with a t(8;14)(q24;q32), a t(2;8)(p12;q24), or a t(8;22)(q24;q11) – all of which come along with rearrangements of the CMYC gene – have a high chance of cure in case of the application of a specific therapeutic protocol which significantly differs from protocols applied in cases with other ALL subtypes.

Leukemia Diagnostics. Table 6 Frequencies of groups according to ploidy in adult ALL

Group	Frequency (%)
Normal karyotype	26–34
Hypodiploidy <46	2–8
Pseudodiploidy	7–59
Hyperdiploidy 47–50	7–17
Hyperdiploidy > 50	4–9
nearly triploid	3
nearly tetraploid	2

Fluorescent In Situ Hybridization

In the diagnostic setting of ALL FISH analysis is used mainly in addition to the classic chromosome analysis. Since multiple karyotype abnormalities occur in ALL, even an extensive FISH "screening" using interphase nuclei would detect only a part of these abnormalities. Therefore, the chromosome analysis cannot be replaced by FISH.

However, in case of focusing on a specific aberration, the FISH technique on interphase nuclei represents a fast and reliable method, giving the result within 24 h. The genetic aberrations occurring frequently in ALL, i.e. the Philadelphia-translocation t(9;22)(q34;q11) (rearrangement of BCR and ABL on the molecular level), an MLL-rearrangement, or a CMYC-rearrangement, all of which have therapeutic implications, can be identified using FISH on interphase nuclei.

A FISH-screening targeting the most frequent aberrations is useful in particular in cases with no valid result of the chromosome analysis. This should be considered also in cases with a normal karyotype with the selection of probes according to the immunophenotype.

The so-called "chromosome painting" with 1 to 3 or 24 colors (24-color-FISH) on metaphase-chromosomes is applied in addition to the classic chromosome analysis if the karyotype cannot be fully described after the classic banding approach, e.g. in complex aberrant karyotypes.

Furthermore, the FISH method can be used for the detection of residual disease during the course of therapy. It is more sensitive and more specific than cytomorphology; however, it is less sensitive than real time PCR and immunophenotyping. The FISH method

Leukemia Diagnostics. Table 7 Frequent chromosomal aberrations in adult ALL

Aberration		Gene	Frequency
t(1;19)(q23;p13)	Pre-B-ALL	E2A-PBX1	3%
t(4;11)(q21;q23)	Pro-B-ALL	MLL-AF4	6%
t(9;22)(q34;q11)	c-ALL	BCR-ABL	25–30%
t(8;14)(q24;q32)	Mature B-ALL	IGH-MYC	5%
t(10;14)(q24;q11)	T-ALL	HOX11-TCR	3%
t(12;21)(p13;q22)	Pre-B-ALL	ETV6-ALL1	<1%
9p	T, Pre-B	$p16^{INK4A}$	15%
6q	c, Pre-B,T		6%
14q11	T-ALL	TCR	6%

is used for the detection of residual disease mainly in ALL with unbalanced karyotypes as these cases lack genetic alteration detectable by PCR.

Molecular Genetics

Two types of genetic alterations are present in lymphatic leukemias and lymphomas: Somatic mutations which are involved in the pathogenesis and rearrangements of immunoglobulin genes and T-cell receptor genes as markers of clonality.

The molecular diagnostic approach in ALL primarily focuses on the detection of high-risk cases with t(9;22) and t(4;11) in which an RT-PCR for BCR-ABL and MLL-AF4 is performed as a substitute or supplement to cytogenetics and FISH.

In contrast, the ETV6-AML1-rearrangement, which occurs frequently in childhood ALL, and is associated with a favorable prognosis, can be identified exclusively on the molecular level and/or using FISH.

Activation of the MYC gene due to various Ig rearrangements (Tables 8 and 9) is found in 4% of adult ALL representing the leukemic form of Burkitt's lymphoma. The molecular detection is accomplished by Southern blot. The use of FISH makes this diagnostic step simpler and faster; however, it requires the smear of intact cells.

Between 4 and 7% of all T-ALL cases feature rearrangements of the HOX11-gene (Tables 10 and 11). HOX11 codes for a transcription factor. The transforming action of overexpressed HOX11 leads to an immortalization of T-cells.

In cases without fusion genes a characterization of clonal Ig- and TCR-gene-rearrangements should be performed. These can be used as markers for residual disease during the course of therapy. Since the latter alterations are identified in DNA while fusion genes are analyzed in RNA it is important to asservate both DNA and RNA at the time of diagnosis.

Leukemia Diagnostics. Table 8 Fusion genes in ALL

			Frequency	
Cytogenetics	Fusion gene	Subtype	Childhood	Adult
t(1;19)(q23;p13)	*E2A-PBX1*	Pre-B-ALL	5–6%	3%

Diagnostic Workup of CML

Cytomorphology

Cytomorphology typically reveals hypercellularity in both peripheral blood and bone marrow with an increase of immature myeloid cells as well as of eosinophils and basophils.

Immunophenotyping

MFC is applied in CML only in case of blast crisis in order to delineate the cell lineage, i.e. lymphatic or myeloid.

Cytogenetics

In 90 to 95% of all patients, a Philadelphia translocation is present on the cytogenetic level: t(9;22)(q34;q11). This is a translocation between the long arm of a chromosome 9 and a long arm of a chromosome 22. The remaining patients carry so-called variant Philadelphia translocations or a normal chromosome set. The variant Philadelphia translocations are divided into simple ones, in which the long arm of chromosome 22 is translocated to another chromosome (and not to chromosome 9), and complex ones, in which further chromosome are involved besides chromosoms 9 and 22. Patients with CML and a normal karyotype carry a BCR-ABL-rearrangement detectable by both FISH and RT-PCR. By applying FISH and using metaphases the BCR-ABL-fusion gene is detected either on chromosome 22 or, less frequently, on chromosome 9. Submicroscopic insertions are discussed as underlying mechanisms which are not detectable by classic cytogenetics. This group of CML is designated Philadelphia-negative BCR-ABL-positive CML. The clinical and hematologic course of patients with classic and variant Philadelphia-translocation does not differ from the

course in patients with Philadelphia-negative BCR-ABL-positive CML.

During the progression into the accelerated phase or into blast crisis in 75 to 85% of the patients, additional karyotype aberrations occur. The most frequently occurring aberrations (so-called clonal evolution) are trisomy 8 (+8), isochromosome of the long arm of chromosome 17 (i(17)(q10)), an additional Philadelphia-chromosome (+der(22)t(9;22)), as well as trisomy 19 (+19). The occurrence of additional karyotype aberrations is a prognostically unfavorable parameter and precedes the clinical manifestation of a blast crisis by 2–6 months in most cases.

In CML follow-up, assessments during therapy are prognostically most important with consequences for the further management of the disease. The classic chromosome analysis represents the gold standard for the assessment of a cytogenetic remission. At least 20 metaphases should be analyzed to obtain a valid result. A complete cytogenetic remission (no Ph+ metaphases) is differentiated from a "partial" remission (1 to 32% Ph+ metaphases), a "minor" remission (33 to 66% Ph+ metaphases), a "minimal" remission (67–95% Ph+ metaphases), and no remission (≥95% Ph+ metaphases). The complete and the partial remission are grouped together as "major" remission.

During therapy with imatinib, the occurrence of karyotype aberrations has been observed in some patients in clones lacking a Philadelphia translocation. Most frequently this aberration is the trisomy 8. Further aberrations are monosomy 7 as well as different translocations. The clinical impact of this phenomenon is yet unclear and is being evaluated in clinical trials.

Fluorescence In Situ Hybridization

Using FISH on interphase nuclei, the presence of a BCR-ABL rearrangement can be detected or ruled out within 24 h. The FISH analysis has some advantages as compared to the classic chromosome analysis: Using this method a CML can be diagnosed and monitored even in patients with Philadelphia-negative BCR-ABL-positive CML. Furthermore, it is more sensitive compared to the classic chromosome analysis in detecting residual disease. FISH may be applied on interphase nuclei but also on metaphases. Using the so-called "Hypermetaphase-FISH"-technique, up to 500 metaphases may be assessed for the presence of a BCR-ABL rearrangement, while only 20 to 25 metaphases are analyzed by the classic chromosome analysis. However, additional cytogenetic aberrations and Ph-negative clones cannot be detected using FISH alone and require conventional chromosome banding analysis.

Molecular Genetics

The molecular correlate of the Philadelphia translocation is the BCR-ABL fusion gene. The diagnosis of a CML

can be made only if the Philadelphia translocation is detected by cytogenetics or by FISH or if the BCR-ABL rearrangement is detected by RT-PCR. Since 5% of all CML cases carry a cryptic BCR-ABL rearrangement that is not detectable cytogenetically, a FISH and/or PCR assessment should be done in parallel to cytogenetics at diagnosis. Furthermore, a PCR-based quantification of the BCR-ABL expression provides a starting value for follow-up assessments.

The PCR-based monitoring of BCR-ABL during therapy is a standard procedure in CML. Independent of the therapy applied, a response to therapy is most effectively assessed by real time PCR with regard to both quantity of response and sensitivity. In contrast to most other leukemias, follow-up assessment in CML is possible using peripheral blood. It is recommended to do a peripheral blood evaluation every 3 months.

In patients under imatinib therapy, an association between an increase of the BCR-ABL expression and the occurrence of a resistance against imatinib has been described. In 2 to 5% of all CML cases, a primary resistance against imatinib is present. Many of these resistances are due to point mutations of the ABL gene within the BCR-ABL fusion gene. Other patients acquire secondary mutations in the tyrosine kinase loop of the BCR-ABL fusion protein during therapy with imatinib, which lead to a resistance against the drug. In some cases this resistance can be superseded by an increase of the dose of imatinib or by the combination with IFN-α. Therefore, the early detection of these resistances increasingly carries clinical importance. Mutations have been described in 23 different codons so far. Some of these lead to changes in conformation while others directly inhibit the binding of imatinib to the activating domain of the tyrosine kinase ABL. The type of mutation therefore provides information on the usefulness of an increase of the imatinib dose. The point mutations can be detected by sequencing the ABL part of the fusion gene.

Diagnostic Workup of CLL

Cytomorphology

The diagnosis of CLL per definition requires a lymphocytosis >5,000/µl, although a chronic elevation of the absolute lymphocyte count in the peripheral blood and the presence of both the typical morphologic findings and the typical immunophenotype are increasingly considered diagnostic. Cytomorphologically, CLL cells are small lymphocytes with a narrow cytoplasm and a dense nucleus without nucleoli. Furthermore, shadow cells of Gumprecht are present.

Immunophenotyping

CLL features a typical immunophenotype with a coexpression of CD5 and the B-cell-associated antigens CD19, CD20, and cCD79a. A weak surface expression of CD22 and Ig is present, with a clonal light chain restriction. The positivity of CD23 which is commonly present in CLL allows the distinction from mantle cell lymphoma. The latter is further characterized by a strong surface expression of Ig as well as by an expression of CD22 and FMC7. Overall, no single marker allows the diagnosis of CLL. Rather, the comprehensive evaluation of all the antigens assessed and the application of the Matutes-score have been proved useful (Table 12).

The presence of four or five of the findings characteristic for B-CLL was found in a large series in 87% of all B-CLL and in only 0.3% of other B-cell lymphomas. Conversely, only 0.4% of B-CLL and 72% of other B-cell lymphomas had none or only one of these criteria.

The expression of CD38, as well as the cytoplasmic expression of ZAP70, is prognostically important. Both findings are associated with an inferior prognosis.

If CLL/PL is diagnosed by cytomorphology (10 to 55% prolymphocytes in peripheral blood) often accompanied by a trisomy 12, which occurs more frequently in these cases, the immunophenotype may show a stronger expression of CD20 and of sIg as compared to CLL. Furthermore, there is a weaker expression of CD23 as well as a positivity for CD22 and CD79b.

In contrast to B-CLL, the co-expression of CD5 is not, or only weakly, present in B-PLL (>55% prolymphocytes in peripheral blood), the surface expression of Ig and of CD20 is stronger and CD22 and FMC7 are expressed.

Besides diagnosis, immunophenotyping allows the quantification of minimal residual disease (MRD). The CLL cells typically carry the phenotype CD19+ CD20+CD79-CD5+ and thereby differ from normal B-lymphocytes. The prognostic relevance of the MRD-level, which can be assessed with high sensitivity, has been demonstrated in multiple studies.

Cytogenetics

The classic chromosome analysis has played only a minor role in the past due to the difficulties in cultivating the cells in vitro. By using FISH analysis, the strong prognostic impact of chromosome aberrations could be demonstrated. Recently, a reliable cultivation of CLL cells has been shown to be feasible and chromosome aberrations have been detected by chromosome analysis at higher frequencies compared to FISH analysis.

Leukemia Diagnostics. Table 12 Matutes-score of B-CLL

Characteristics of B-CLL
CD5+
CD23+
FMC7−
sIgM(+)
sCD22(+) or CD79b(+)

Fluorescence in Situ Hybridization

FISH analysis detects the most frequent chromosomal aberrations in CLL in a targeted way. These comprise 13q deletions, trisomy 12, 11q deletion, and 17p deletion. The presence of a 17p deletion or of a 11q deletion indicates a more aggressive course of disease compared to a normal karyotype, while the sole presence of a 13q deletion confers a favorable prognosis. Furthermore, the assessment of t(11;14) is useful for the distinction between CLL and mantle cell lymphoma.

Molecular Genetics

Half of the patients with CLL carry so-called somatic mutations in the variable region of immunoglobulins. The presence of 2% or less mutations in this area of the immunoglobulins as compared to the original DNA sequence is designated "unmutated" while the presence of more than 2% mutations is designated "mutated." The unmutated status is associated with an unfavorable prognosis even in early stages of the disease.

Diagnostic Workup of MDS

Cytomorphology

During the cytomorphologic examination at least 200 bone marrow cells and 20 megakaryocytes should be evaluated. Dysplastic findings should be present in at least 10% of the cells. A particular diagnostic role is played by the so-called pseudo-Pelger neutrophils, ringed sideroblasts, mikromegakaryocytes, and augmented blasts. These morphologic aberrations correlate in part with clonal markers and show a low inter-observer variability. This is true particularly for the prognostically favorable and therefore clinically relevant 5q-syndrome. The assessment of hypogranulation in neutrophils should not be the only diagnostic criterion for dysplasia. Accordingly, an early stage of refractory anemia (RA) with cytopenia in only one lineage is often difficult to diagnose and requires the assessment of follow-up samples. With regard to the differentiation between hypoplastic MDS and aplastic anemia, it is important to notice that dysplastic findings in erythropoiesis may be present also in the latter. They therefore play no diagnostic role in this instance, unlike dysplastic findings in the other lineages and augmented bone marrow blasts. PNH should be considered as differential diagnosis. With regard to the separation of MDS and AML a cut-off of 20% bone marrow blasts has to be used according to the presently applied WHO classification.

Immunophenotyping

Multiparameter flow cytometry allows the qualitative assessment of dysplasia in the different cell lineages, granulopoiesis, monopoiesis, and erythropoiesis through the detection of aberrant antigen expression patterns. Furthermore, the quantification of blasts can be done with a high correlation to cytomorphologic findings. The flow cytometric findings are of particular diagnostic value in cases difficult to judge by cytomorphology. Further studies will define the role of multiparameter flow cytometry in comparison to cytomorphology and cytogenetics with regard to both diagnostics and prognostication.

Cytogenetics

In the context of diagnostic assessment of MDS the chromosome analysis plays a significant role by detecting karyotype aberrations typical for MDS and particularly so in cases difficult to judge by cytomorphology.

The typical aberrations, which are also considered for the prognostically highly relevant IPSS (Tables 13 and 14), include loss of Y chromosome, del(5q), del (20q), as well as complex aberrations and aberrations of chromosome 7. In cytomorphologically defined borderline cases a distinction between AML and MDS can be accomplished by the detection of t(8;21)(q22;q22), t(15;17)(q22;q11-12), or inv(16)(p13q22)/t(16;16)(p13;q22) which define an AML, respectively.

Fluorescence In Situ Hybridization

FISH analysis may be used in case of lack of adequate material for cytogenetics, e.g. in case of a dry tap, smears may be obtained from a bone marrow biopsy and analyzed by FISH. The analysis includes probes targeting the aberrations most relevant for determining the prognosis: -Y, del(5q), del(20q), aberrations of chromosome 7, del(17p).

Molecular Genetics

In contrast to AML there are no specific molecular markers for MDS. In case of rare reciprocal translocations

Leukemia Diagnostics. Table 13 IPSS, basis

			Points		
	0	0.5	1	1.5	2
% bone marrow blasts	5	5–10		11–20	21–30
Karyotype	Favorable	Intermediate	Unfavorable		
Cytopenias	0/1	2/3			

Karyotype favorable: normal, -Y sole, del(5q) sole, del(20q).
Karyotype unfavorable: complex aberrant (≥3 aberrations), aberrations of chromosome 7.

Leukemia Diagnostics. Table 14 IPSS, prognostic grouping

Points	0	0.5–1.0	1.5–2.0	≥2.5
Risk group	Low	Int-1	Int-2	High

fusion gene-specific PCRs can be applied which, however, do not play a major role in routine diagnosis. Some of the AML-specific mutations like the partial tandem duplication of MLL (MLL-PTD), FLT3 length mutations (FLT3-LM), RAS mutations, as well as mutations of AML1 and CEBPA may be present in MDS with high blast counts. They are indicative of a progress of MDS to AML. Similarly, an increasing expression of WT1 represents a marker for the progress of MDS.

Diagnostic Algorithms in Leukemia Diagnostics

Based on the data provided above, algorithms for the diagnostic work-up of leukemias have been proposed. These are outlined below and should be applied and evaluated in the context of large clinical trials. Leukemia diagnosis has undergone steady development and is expected to become even more refined within the next few years, particularly taking into consideration gene expression profiling with microarrays, which may be incorporated.

Diagnostic Algorithm in AML

In AML (Fig. 1) a combination of cytomorphology, cytochemistry, immunophenotyping, and cytogenetics should be applied in the first step. Results of cytomorphology and cytochemistry guide the selection of antibody panels to be used for immunophenotyping. Results of these three methods guide the selection of culture conditions for cytogenetics.

In case of specific cytomorphologic findings, the respective genetic alterations should be analyzed by FISH and PCR (AML M3/M3v: t(15;17)/*PML-RARA*; AML M4eo: inv(16)/*CBFB-MYH11*; AML M1/2 with characteristic long Auer rods: t(8;21)/*AML1-ETO*; AML M5a: 11q23/*MLL* rearrangements). The combined analysis of genetic alterations by both FISH and PCR provides a maximized diagnostic security as well as information on variant translocations or submicroscopic deletions, which are only detectable by interphase FISH.

Based on cytogenetic results, FISH analysis using specific probes is applied for numerical (e.g. +8, −7) and structural aberrations (e.g. 5q-, 7q-). Cases with complex aberrant karyotype can further be investigated by 24-color FISH. FISH may be used in infrequent cases without cytogenetic result to identify the most frequent and prognostically relevant aberrations.

RT-PCR is used, according to cytogenetic results, for the detection of fusion genes as well as for the analysis of *FLT*3-LM, *MLL*-PTD, or *NPM*1.

Follow-up assessment during complete remission should be performed by cytomorphology, FISH, PCR, and MFC, whenever a specific marker has been identified at diagnosis. The latter two highly sensitive methods are particularly useful for the quantification of the prognostically important MRD levels.

Diagnostic Algorithm in ALL

Cytomorphology and immunophenotyping should be applied in the first step in ALL (Fig. 2). Cytomorphology identifies acute leukemia negative for peroxidase and reveals cases suspicious for Burkitt's lymphoma/mature B-ALL. MFC allows the diagnosis of ALL as well as the subclassification into different B-precursor ALL and T-precursor ALL classes.

Cytogenetics follows the results of MFC with specific culture conditions for B- and T-precursor ALL.

FISH analysis for BCR-ABL and MLL rearrangements follows MFC in case of B-precursor ALL.

FISH analysis for CMYC rearrangements follows cytomorphology in case of findings typical for Burkitt's lymphoma as well as MFC in case of mature B-ALL.

In childhood B-precursor ALL, FISH analysis for ETV6-AML1 is applied.

In case of cytogenetics not yielding a result, FISH and PCR are applied for the detection of BCR-ABL and MLL rearrangements.

Real time PCR is applied for MRD monitoring, targeting either fusion transcripts or IgH receptor-/T-cell receptor rearrangements. MFC is also used for MRD monitoring.

A complete reevaluation should be performed at relapse.

Diagnostic Algorithm in CML

The diagnosis of CML is made by a combined approach of cytomorpholgy, cytogenetics, FISH, and PCR, identifying characteristic peripheral blood and bone marrow features as well as the t(9;22) and the BCR-ABL fusion gene (Fig. 3).

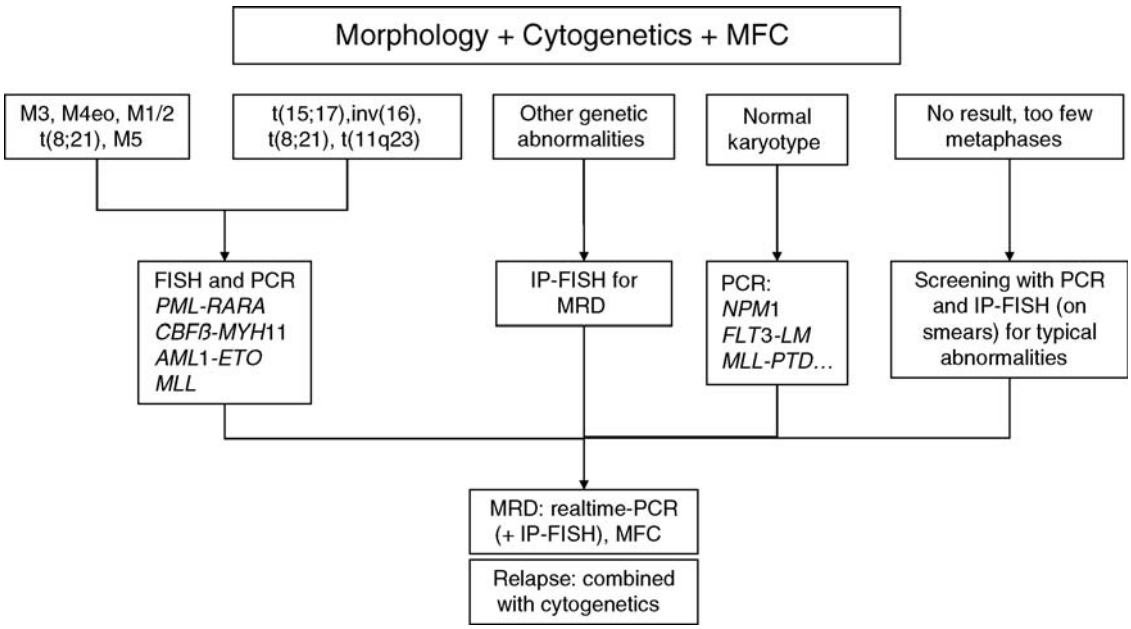
During therapy all methods are applied in combination to quantify the amount of residual disease as well as additional chromosomal abnormalities.

In case of failure or suboptimal response an analysis for BCR-ABL mutations conferring resistance to imatinib should be performed.

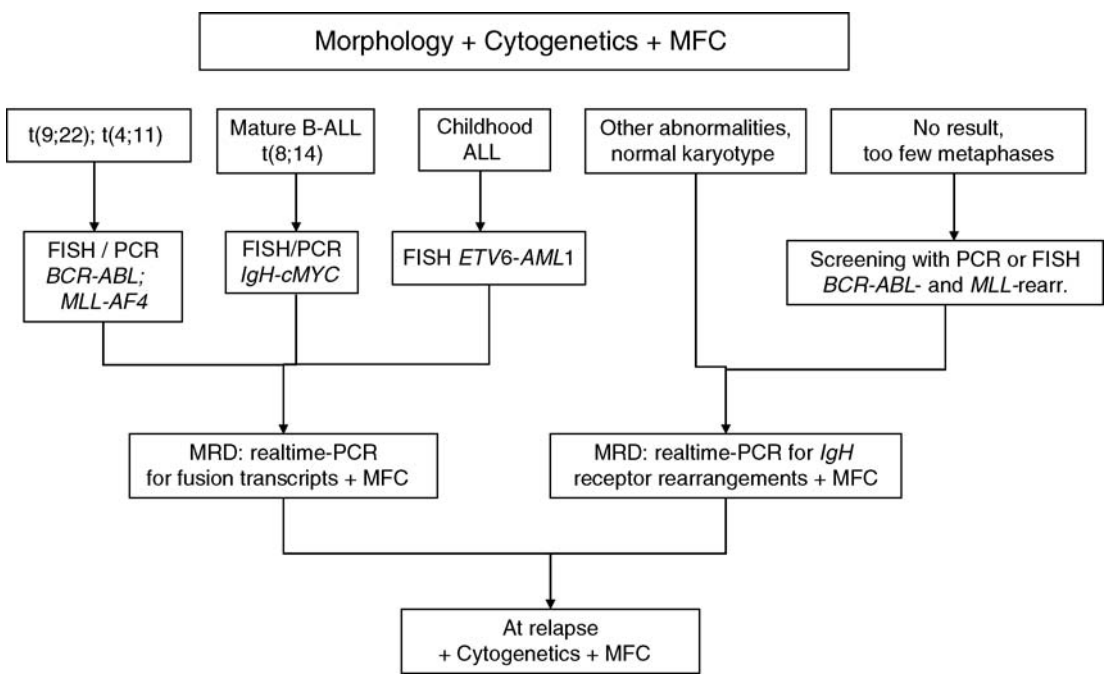
Immunophenotyping should be performed in blast crisis to delineate the lineage (lymphatic or myeloid).

Diagnostic Algorithm in CLL

Cytomorphology and immunophenotyping should be applied in the first step in CLL (Fig. 4). Cytomorphology identifies mature lymphocytosis. MFC allows the



Leukemia Diagnostics. Figure 1 Algorithm for diagnosis and follow-up in AML.



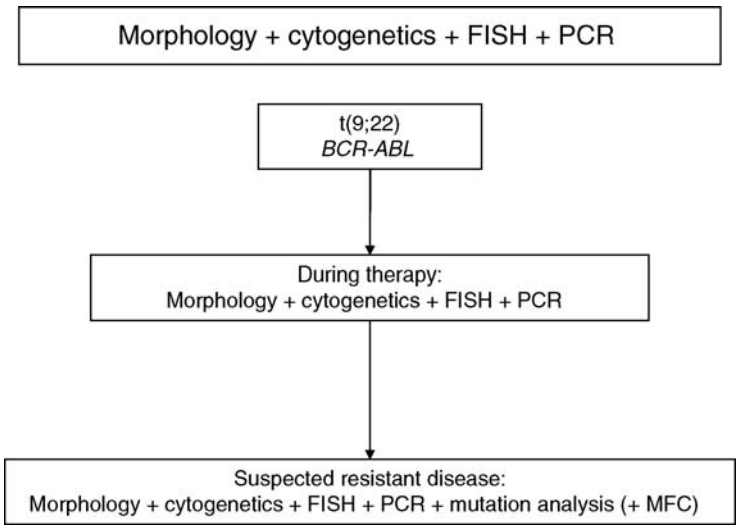
Leukemia Diagnostics. Figure 2 Algorithm for diagnosis and follow-up in ALL.

diagnosis of CLL and its discrimination from other indolent lymphomas according to the Matutes score.

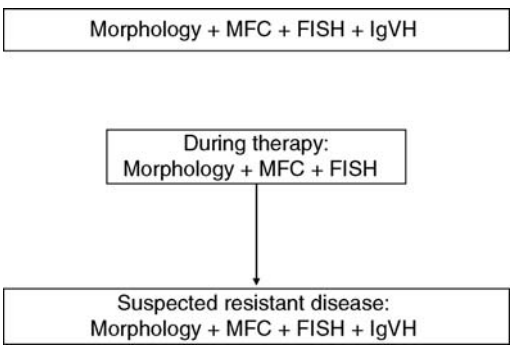
In addition, MFC is used for the determination of the expression of both CD38 and ZAP-70.

FISH analysis is performed to identify the most common and prognostically important chromosomal abnormalities, i.e. 6q-, 11q-, trisomy 12, 13q-, and 17p- as well as t(11;14). A cytogenetic analysis is capable of identifying additional chromosomal abnormalities which may yield further prognostic information.

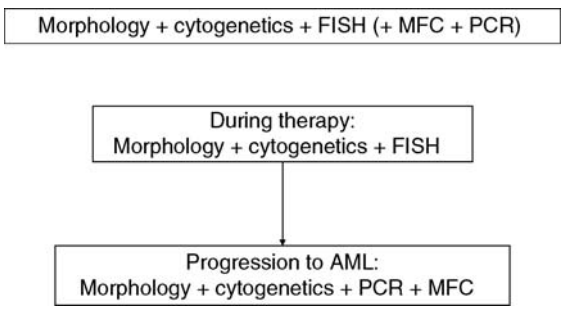
Molecular genetics is applied to determine the IgVH mutational status.



Leukemia Diagnostics. Figure 3 Algorithm for diagnosis and follow-up in CML.



Leukemia Diagnostics. Figure 4 Algorithm for diagnosis and follow-up in CLL.



Leukemia Diagnostics. Figure 5 Algorithm for diagnosis and follow-up in MDS.

Monitoring during therapy is performed by a combination of cytomorpholgy, MFC, and FISH.

Diagnostic Algorithm in MDS

The diagnosis of an MDS is based, besides the presence of cytopenias, on cytomorphology (Fig. 5). Cytogenetics is used to identify chromosomal abnormalities which subclassify MDS and yield prognostic information. In cases of equivocal findings in cytomorphology cytogenetics can assure the diagnosis. Immunophenotyping may be used to identify aberrant antigen expression patterns typical for MDS. PCR may be performed in MDS.

During the course of therapy, which may be limited to supportive measures, cytomorphology in combination with cytogenetics and FISH should be applied.

In case of progression to AML, cytomorpholgy, cytogenetics, PCR, and MFC should be applied.

Leukemia Inhibitory Factor

Mariusz Z. Ratajczak
Stem Cell Institute at James Graham Brown Cancer Center, University of Louisville, Louisville, KY, USA

Synonyms

D-factor; Hepatocyte stimulating factor-III; HSF-III; Cachexia-inducing agent; DIA; DRF; CNDF; HILDA; MLPLI; LIF

Definition

►Leukemia Inhibitory Factor (LIF) is a cytokine belonging to a family of ►interleukin-6 related cytokines that signal through gp130 protein coupled receptors and whose inducible production (e.g. due to hypoxia) can occur in ►hypoxia-inducible factor-1 manner in multiple tissues. LIF is a pleiotropic cytokine that affects several biological processes, and its current name implicating "a leukemia inhibitory factor" has merely historical meaning.

Characteristics

LIF

LIF was purified from Krebs-II ascites tumor cell line and then cloned from a murine T-lymphocyte cDNA library and originally identified as a factor that inhibits the proliferation of undifferentiated and highly clonogeneic murine myeloid leukemic cell line M1 and induces its differentiation into macrophages. At the molecular level human and murine LIF is a glycoprotein with a 180-amino-acid single 4-α-helix polypeptide chain with a conserved disulfide bond. Natural occurring LIF is heavily glycosylated, showing an apparent molecular weight of 32–62 kDa, depending on the source. It is accepted that the absence of glycosylation appears not to affect its biological activity. Human and mouse LIF share 78% sequence homology. Human LIF can activate mouse cells, but vice versa mouse LIF cannot activate human cells.

LIF Receptor

LIF interacts with the heterodimeric human LIF-receptor (LIF-R) comprising a 190 kDa LIF-binding α-chain (130 kDa mouse) and a 130 kDa signal-transducing β-chain (gp130). LIF receptors have been identified on several cells, including monocytes, liver, neural cells, muscle cells, primordial germ cells, placenta and embryonic stem cells. Therefore LIF-R is a member of the gp130 superfamily of receptors. Accumulated data that the LIF-binding α-chain shows some level of "molecular promiscuity" and can be also part of the type II receptor for ►oncostatin M (OSM), and part of the receptors for ciliary neurotropic factor (CNTF) and carditrophin-1 (CT). Thus LIF in addition to LIF-R can also signal for example through the OSM receptor.

LIF Over Expression and LIF Knockouts

Prolonged over expression of mice to LIF leads to ►cachexia coupled with a hypermotile state, overgrowth of bone tissue and osteoblasts in the bone marrow cavities, loss of spermatocytes from the seminiferous tubules of the testis, absence of corpora lutea in the ovaries, a reduced number of Purkinje cells in cerebellum, thymus atrophy and an involution of the pancreas. Mice with LIF knocked-out ($LIF^{-/-}$) are viable, however they show abnormalities of the hippocampus and an accumulation of olfactory receptor neurons. Interestingly $LIF^{-/-}$ mice are unable to get pregnant, which is explained by a crucial role of secreted LIF in the uterus during the process of blastocyst implantation.

Pleiotropic Effects of LIF

LIF plays an important role in several biological processes in embryogenesis, tissue regeneration, metabolism and cancer ►metastasis. It activates in normal cells Jak-STAT-3, MAPKp42/44and PI-3K-AKT signaling pathways and in murine embryonic stem cells (ES) LIF also regulates expression of Oct3/4. Biological effects of LIF are controlled by circulating soluble LIF-R that blocks the action of any LIF in circulation. At the cellular level LIF signaling is negatively controlled by ►suppressors of cytokine signaling (SOCS).

LIF was identified as a factor that maintains totipotency of murine ES and is crucial for blastocyst implantation in mice. LIF is also one of the factors that promotes dedifferentiation of murine primordial germ cells into embryonic germ cells. In humans LIF has no effect on totipotency of human ES cells. However, LIF was recently demonstrated to reduce the vertical transmission of HIV-1 virus though the placenta. Finally, LIF enhances the proliferation of normal primordial germ cells and spermatocyte differentiation.

LIF is playing an important role in the development of hippocampal and olfactory receptor neurons. It stimulates the proliferation of skeletal muscle satellite cells and is a hyper trophic factor for myocardium. Therefore, LIF may play a role in regeneration of neural tissue, myocardium and skeletal muscle. In support of this LIF is up regulated in damaged brain, heart and skeletal muscle. It is possible that LIF in cooperation with other factors such as stromal derived factor-1 (SDF-1) and hepatocyte growth factor (HGF)/►scatter factor recruits circulating stem cells and macrophages to damaged organs.

In the hematopoietic system, LIF shows positive co-stimulatory effects on megakaryocyte maturation and platelet formation. LIF also stimulates proliferation of the human factor-dependent hematopoietic cell lines TF-1

and DA as well as proliferation of the murine factor dependent GB2 cell line. LIF together with Flk ligand has been shown to enhance blast colony formation by murine bone marrow cells. These blast colonies are enriched in macrophages and ►dendritic cells. LIF receptors on murine hematopoietic populations are mainly restricted to cells of the monocyte lineage. Thus, the potential influence of LIF on the compartment of hematopoietic stem cells requires further study.

LIF also exerts several metabolical effects such as inhibits lipid transport to adipocytes, enhances production of acute-phase proteins by the liver and was also identified as a factor capable of switching autonomic nerve signaling from an adrenergic to a cholinergic mode. LIF also has several endocrine effects being a major regulator of ACTH production in the pituitary and inhibits production of prolactin and growth hormone.

LIF and Oncogenesis

LIF appears to be an important developmental motto-morphogene that displays several pleiotropic biological effects in vitro and in vivo. Recent evidence has accumulated that this interesting cytokine affects survival, proliferation and differentiation of many cell types not only normal but malignant cells as well. For example while LIF stimulates proliferation or differentiation of several established malignant hematopoietic stem cell lines (TF-1, DA, GB2, or M1), it inhibits in vitro proliferation of ►breast cancer cells. LIF also may play some role in tumor vascularization and ►angiogenesis.

Recently, based on the observation that LIF stimulates proliferation of skeletal muscle satellite cells and myocytes, as well as cardiomyocytes we hypothesized that the LIF–LIF-R axis could be involved in progression of human ►rhabdomyosarcomas (RMS). We found that in RMS cells LIF stimulates (i) phosphorylation of MAPKp42/44, AKT and STAT3, (ii) ►adhesion and chemotaxis and (iii) increased resistance to cytostatics. Thus, we presented evidence for the first time that the LIF–LIF-R axis exerts chemotactic activity and may direct RMS metastasis. The role of this axis in progression of other non-hematopoietic malignancies requires further study.

Clinical Aspects

The LIF–LIF-R axis has emerged as an important axis regulating both the development and homeostasis of an adult organism. The novel recognized role of LIF in trafficking of normal and ►cancer stem cells may lead to the development of better therapeutic strategies aimed at directing ►migration of normal stem cells to regenerate damaged organs (e.g. heart or brain) but on the other hand inhibiting metastasis of LIF-responsive cancer stem cells. Thus, a new area of investigation on the role of gp130 signaling molecules in cancer metastasis has been established.

White blood cells found in peripheral blood and tissues, in particular the bone marrow and spleen.

►CD Antigens

Leukopenia

►Neutropenia

Leukoplakia

Definition

A white patch on the mucosa that does not rub off and is not attributable to any obvious cause. It is a diagnosis of exclusion and is not a disease entity in itself. It has a relatively low frequency for malignant transformation into squamous cell carcinoma.

►Squamous Cell Carcinoma

Leukotriene Receptors

Definition

Are seven transmembrane G-protein coupled receptors (GPCR). Two receptors for LTB_4, the high affinity receptor BLT_1 and the low affinity receptor BLT_2 are known. Two distinct receptors for the cysteinyl leukotrienes (CysLTs), the high affinity receptor $CysLT_1$ and the low affinity receptor $CysLT_2$ have been isolated and characterized. There are several antagonists for the $CysLT_1$ receptor, which are used in clinical treatment of asthma including Singulair™ (Monteluskast) and Accolate™ (Zafirlukast), but only one known antagonist for $CysLT_2$ receptor, Bay-U9773. Several antagonists are also known for the BLT_1 and BLT_2, such as U-75302, LY293111, and CP-105696, which block the BLT_1 receptor at low concentration and BLT_2 at higher concentrations.

►Leukotriene

Leukotrienes

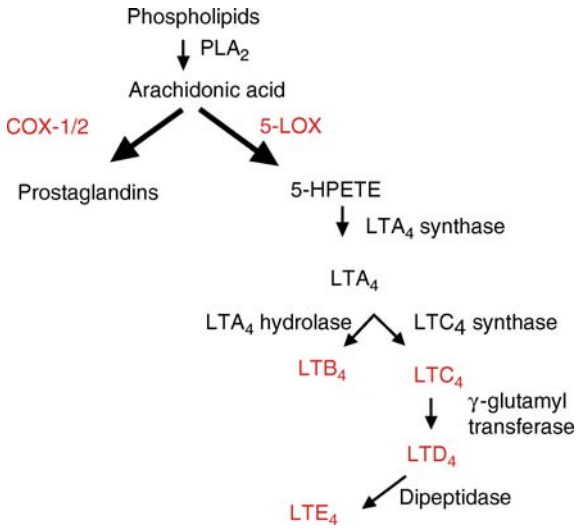
Anita Sjölander
Cell and Experimental Pathology, Department of Laboratory Medicine, Lund University, Malmö University Hospital, Malmö, Sweden

Definition

►Leukotriene, the dihydroxy leukotriene, ►LTB_4, is formed via the ►5-LO pathway through the enzyme leukotriene A_4 hydrolase. LTB_4 is one of the most chemotactic molecules known. It has a preferential action on leukocytes, producing chemotaxis and chemokinesis of neutrophils and mononuclear cells, as well as aggregation, degranulation and adherence of leukocytes to endothelial cells. The cysteinyl ►leukotrienes, including ►LTC_4, ►LTD_4, and ►LTE_4, are also known as the slow-reacting substance of anaphylaxis. ►CysLTs enhance contraction of smooth muscle, increase vascular permeability as well as migration and chemokine production in monocytic cells. CysLTs are produced in high amounts in activated eosinophils, basophils, macrophages, and mast cells. ►5-Lipoxygenase (5-LO) catalyzes the biosynthesis of proinflammatory leukotrienes that have both autocrine and paracrine mechanisms and may play an important role in ►inflammation-induced carcinogenesis. Inflammation is an important component of tumor progression. Many tumors start from the sites of infection and inflammation.

Characteristics

Leukotrienes and ►prostaglandins are metabolites of ►arachidonic acid that play major roles in various inflammatory conditions (Fig. 1). The release of these mediators, by cells recruited to or present at the site of



Leukotrienes. Figure 1 Biosynthetic pathway of prostaglandins and leukotrienes.

inflammation, modulates or influences the magnitude of the inflammatory response. An increased understanding of eicosanoids and how their receptors trigger intracellular signaling during inflammatory conditions is helping to elucidate the well-known connection between chronic inflammatory disease and neoplastic transformation. Here, we summarize the role of leukotrienes in cancer. In addition, we delineate how continuous ►leukotriene receptor activation and signaling can increase cell survival and proliferation as important early steps toward oncogenicity.

Today, it is clear that the tumor microenvironment, including inflammatory cells, is an important participant in the neoplastic process, proliferation, survival, and migration. A microenvironment rich in inflammatory cells, generating growth factors, and DNA-damage agents, potentiates the risk of neoplastic formation. Several mutations of key genes also seem to be important for the transformation of the ►inflammation–dysplasia–carcinoma sequence.

The leukotrienes potentiate biological activities in the pathogenesis of many diseases. In most chronic inflammatory conditions, such as inflammatory bowel disease, the levels of leukotrienes are increased. The strongest association of chronic inflammation with malignant disease is seen in colon carcinogenesis arising in individuals with inflammatory bowel disease. Indeed, patients suffering from inflammatory bowel disease have a 30–50% increased risk of developing colon cancer. In chronic inflammatory bowel diseases, elevated levels of leukotrienes are found, which increases the risk for development of cancer and thereby a reduced survival of these patients. As expected, it has been established that a cause-and-effect link between chronic inflammation and colon cancer, occurs via activation and overexpression of the two enzymes, 5-LO and COX (►Cyclooxygenase, COX-1 and -2), responsible for regulating the production of leukotrienes and prostaglandins, respectively (Fig. 1).

The expression of ►COX-2, is highly upregulated both during inflammatory conditions and cancer. Elevated prostaglandin production at the site of the tumor is a good indicator of increased COX-2 activity in colon cancer tissue. There are vast amounts of data suggesting that ►nonsteroidal antiinflammatory drugs (NSAIDs), ►COX inhibitors, reduce the risk of colon cancer. These inhibitors were shown to suppress the proliferation of intestinal cancer cell lines that express high levels of COX-2.

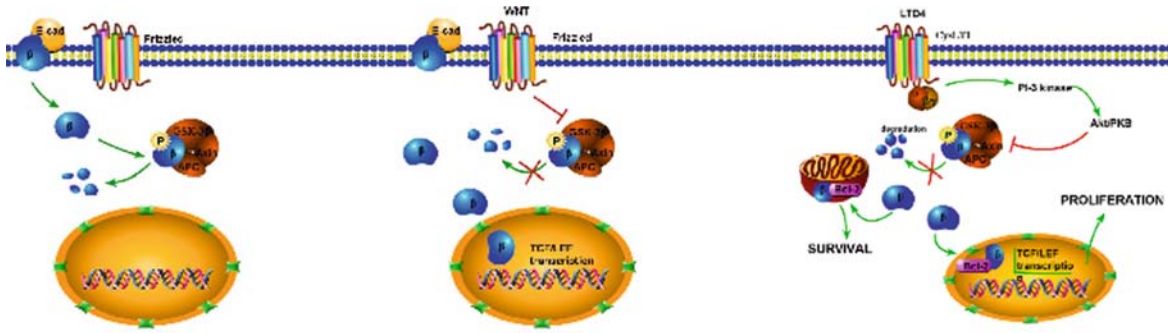
The production of different leukotrienes from arachidonic acid is dependent on the expression of 5-LO, an enzyme that regulates the first step in the synthesis of leukotrienes. Induction of experimental colitis in mice lacking the 5-LO protein significantly reduced the degree of infiltration of inflammatory cells and colonic injury. A number of other studies have shown that inhibition of 5-LO decreases growth and promotes cell death in several transformed cell lines.

In a recent tissue array study using colorectal cancer and control specimens, elevated levels of 5-LO and COX-2 were found in colorectal carcinomas. In accordance, similar observations were made in different colon carcinoma cell lines when these were compared with nontransformed intestinal epithelial cell lines. Interestingly, activation of ►$CysLT_1$ receptor signaling led to an increased COX-2-mediated production of prostaglandin E_2, PGE_2. Mediating COX-2 activation and PGE_2 production, has a major impact on intestinal epithelial cell survival.

5-LO metabolites may contribute to the development of several human tumors, including pancreatic, esophageal, prostate, breast, and colon cancer. COX-2 and 5-LO have been reported to be simultaneously upregulated in colorectal cancer. It is possible that blocking one of these enzymatic pathways may activate the other. Therefore combined treatment of these pathways could be a better treatment option. There is an additive effect of inhibiting proliferation, inducing apoptosis, decreasing Bcl-2 levels, and increasing Bax levels in cancer cells, after combined treatment with inhibitors of COX-2 and 5-LO.

►Leukotriene receptors are upregulated in colon cancer, and their signaling facilitates the survival and proliferation of cancer cells and reduces apoptosis. In agreement with this, an increased expression level of leukotriene receptors in different colon cancer cell lines correlates well with the ability of leukotrienes to increase the survival of these cells.

Apart from Bcl-2, there are a number of other cellular proteins that are closely connected to the regulation of cell proliferation, survival, and apoptosis. One of these is ►β-catenin. This protein became of interest in



Leukotrienes. Figure 2 A simplified signaling cascade leading to accumulation of free β-catenin and increased cell proliferation.

relation to LTD_4-induced survival signaling when a novel LTD_4-triggered association between Bcl-2 and β-catenin in the mitochondria from intestinal epithelial cell lines was identified. It could be hypothesized that LTD_4 may enhance cell survival via activation and association of β-catenin with Bcl-2 in the mitochondria. β-catenin activation and signaling execute an anti-apoptotic effect through protection of cytochrome c leakage from the mitochondria.

β-catenin is a protein with many roles, one well established as an effector molecule of the ►Wnt signaling pathway. The Wnt receptors, Frizzleds, belong to the same GPCR family of receptors as the leukotrienes. The presence of a Wnt signal allows β-catenin to translocate to the nucleus where it activates the transcription factors TCF/LEF. Normally, β-catenin is regulated by the adenomatous polyposis coli (►APC) complex to control the intracellular levels of β-catenin. LTD_4 can inactivate GSK-3β, known to phosphorylate β-catenin and induce its ubiquitination and degradation, and thus has the potential to increase the amount of free β-catenin if inactivated. LTD_4 induces inactivation of GSK-3β via PI3-kinase/Akt pathway allowing free β-catenin to be able to enter the nucleus and activate the transcription factor TCF/LEF, which activates potentially oncogenic genes, such as cyclin D1, c-myc, and COX-2 (see Fig. 2).

The infection–inflammation–dysplasia–carcinoma sequence is exemplified by *Helicobacter pylori* (HP) infection, a well-known risk factor for gastric adenocarcinoma. HP infection may also be a possible risk factor for respiratory system disease, which triggers a marked local inflammatory response and a chronic system immune response. Some of the possibly mediators involved in the pathogenesis of these infections include leukotrienes that may have a role in the development of lung cancer in association with HP infection. The risk of lung cancer in patients with gastric ulcers is around three times higher than in individuals without ulcers.

Activation of leukotriene receptor signaling pathways and subsequent effects on proliferation and survival of epithelial cells indicate that the inflammatory mediator, leukotrienes, can contribute to growth of cells during pathological inflammatory conditions. This, in turn, indicates that these receptors have an important role in neoplastic transformation and development of cancer.

Histo-blood group Lewis antigens

Definition

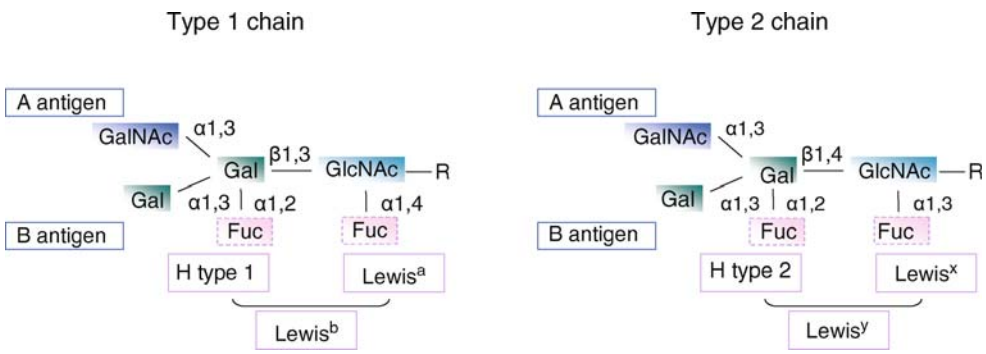
►Lewis antigens are fucosylated carbohydrates linked to lipids or to proteins and thus present as glycolipids or glycoproteins.

Characteristics

►Fucosylated ►Lewis antigens are expressed in normal tissues on two major carbohydrate type chains, type 1 and type 2, according to the linkage type between the galactose (Gal) residue and the N-acetyl-glucosamine residue (GlcNAc), β1,3 and β1,4, respectively (Fig. 1). Type 1 Lewis structures are widely expressed in endodermally derived tissues, such as glandular epithelia, in body fluids and saliva, and are adsorbed from plasma circulating glycolipids onto the surface of erythrocytes and lymphocytes. The presence or absence of type 1 antigens in a particular individual depends upon the presence of active enzymes responsible for the addition of the fucose monosaccharide. The α1,2 fucosyltransferase, the product of the secretor gene (*Se*) (►Secretor (Se) enzyme), acts on the terminal galactose and produces the H type 1 structure that forms the substrate for the α1,4 fucosyltransferase, the product of the Lewis gene (*Le*) (►Lewis (Le) enzyme), that synthesizes the difucosylated Le^b antigen. Individuals that have inactivating mutations of the *Se* gene are unable to synthesize the H type 1 structure and the Le^b antigen, are called nonsecretors and constitute 20% of human populations. Type 2 Lewis antigens are expressed in ecto- and mesodermally derived tissues, including skin and erythrocytes, and in a more restricted manner in endodermally derived epithelia like stomach glands. The α1,2 fucosyltransferase that acts on the terminal galactose and produces the H type 2 structure, is the product of the *H* gene, the ►H enzyme, that forms the substrate for the α1,3 fucosyltransferase, the product of the Lewis gene (*Le*), that synthesizes the difucosylated Le^y antigen. Other ►fucosyltransferases may be involved, in a tissue-specific manner, in the synthesis of Lewis antigens: an α1,3 fucosyltransferase activity has been described for FUT3, FUT4, FUT5, FUT6, FUT7, and FUT9, and an α1,4 activity was described for FUT3 and FUT5. The secretor and Lewis status of individuals are implicated in susceptibility to several diseases, mostly human infections, with the most dramatic example being the virtual absence of gastrointestinal infections by Calicivirus in nonsecretors.

Lewis Antigens in Cancer

Malignant cells frequently have abnormal ►glycosylation with expression of modified carbohydrate antigens, among which stand sialylated forms of the Lewis antigens – sialyl-Le^a and sialyl-Le^x (Fig. 2). Sialyl-$Le^{a/x}$ cell-surface molecules, linked to lipids and proteins, when tumor cells become invasive and depolarized gain access to circulation, either linked to the cell-surface or shed into the serum. The relevance of these sialylated structures in cancer was first revealed, in the 1980s, when monoclonal antibodies raised against cancer cells were shown to recognize sialyl-$Le^{a/x}$. They are widely used as tumor markers (CA19-9 for sialyl-Le^a and SLX for sialyl-Le^x) for initial serum diagnosis of cancer and for detection of cancer recurrence after surgery or treatment with radio- and chemotherapy. Later, in the 1990s, sialyl-$Le^{a/x}$ were identified as cancer cell-surface molecules involved in ►adhesion to endothelial cells, through ►E-selectin-mediated adhesion (and P-►selectin). Binding of tumor cells to endothelial cells, in a model that mimics leukocyte extravasation, contributes to the establishment of tumor growth at distant sites by hematogenous metastization. Several studies, analyzing cancers from different organ origins,



Lewis Antigens. Figure 1 Schematic representation of type 1 and type 2 ABH and Lewis antigens. Histo-blood group A is defined by the α1,3 terminal GalNAc, histo-blood group B is defined by the α1,3 terminal Gal, and the absence of further elongation of the H structure is characteristic of histo-blood group O individuals. Synthesis of type 1 Lewis antigens (Le^a and Le^b) and type 2 Lewis antigens (Le^x and Le^y) depends upon activity of fucosyltransferases (see text for details). showed that expression of these sialylated Lewis antigens correlated to the prognosis of the patients, reinforcing their role on metastatic behavior. They are more frequently overexpressed in carcinomas, mainly adenocarcinomas, but also in leukemia. Mechanisms underlying overexpression of sialyl-Le$^{a/x}$ in cancer cells have been recently clarified in some cancer models and essentially result from altered expression of α2,3 ►sialyltransferases and/or of α 1,3/4 fucosyltransferases, responsible for their synthesis (Fig. 2). A viral gene product that induces HTLV-1 viral-associated leukemias, was shown to transactivate fucosyltransferase VII, an α1,3 fucosyltransferase with rate-limiting activity for the synthesis of sialyl-Le^x in leukocytes, and therefore induces a strong constitutive expression of sialyl-Le^x in leukemic cells. Other mechanisms controlling gene expression, including methylation and identification of transcription factors, are under investigation.

The role of sialylated Lewis antigens in the metastatic process led to the development of several new candidate therapeutic approaches. Therapeutic strategies have been attempted to reduce the biosynthesis of sialylated Lewis antigens. Specifically, the synthesis of sialyl-Le^x was successfully inhibited in colon carcinoma cell lines by using a disaccharide competitive substrate as a decoy. An alternative approach is to use monoclonal antibodies directed to sialyl-Le$^{a/x}$ or analogs of the sialyl-Le$^{a/x}$ to block adhesion of tumor cells to endothelial cells and prevent metastization.

Li-Fraumeni Syndrome

Magali Olivier, Pierre Hainaut
International Agency for Research on Cancer (IARC), Lyon, France

Definition
Li-Fraumeni syndrome (LFS) is a rare autosomal disorder characterized by a familial clustering of tumors, with a predominance of sarcomas, breast cancers, brain tumors and adrenocortical carcinomas, diagnosed before the age of 45 years. Other cancers, such as leukemia, lung cancer, gastric cancer, skin melanoma, pancreatic cancer, and ovarian cancer are also present in excess in some families and, in some cases, germ cell tumors, choroid plexus papilloma and Wilms' tumor have been reported as part of the spectrum.

Characteristics
Diagnostic Criteria
The clinical criteria used to identify a classic LFS family are:

- Proband with sarcoma before the age of 45.
- A first degree relative with any tumor before age 45.
- Another close relative (second or first degree) with cancer before age 45 or a sarcoma at any age.

Several clinical criteria for the diagnosis of LFS-like (LFL) families have also been proposed:

- *LFL-E1* (Eeles definition 1): two different tumors which are part of extended LFS in first or second degree relatives at any age (sarcoma, breast cancer, brain tumor, leukemia, adrenocortical tumor, melanoma, prostate cancer, pancreatic cancer).
- *LFL-E2* (Eeles definition 2): sarcoma at any age in the proband with two of the following (two of the tumors may be in the same individual): breast cancer at <50 years and/or brain tumor, leukemia, adrenocortical tumor, melanoma, prostate cancer, pancreatic cancer at <60 years or sarcoma at any age.
- *LFL-B* (Birch definition): proband with any childhood cancer or sarcoma, brain tumor or adrenocortical

carcinoma at <45 years, with one first or second degree relative with typical LFS cancer (sarcoma, breast cancer, brain tumor, leukemia, or adrenocortical carcinoma) at any age, plus one first or second degree relative in the same lineage with any cancer diagnosed under age 60.

- *Chompret*: (i) proband affected by a narrow spectrum cancer (sarcoma, brain tumor, breast cancer or adrenocortical carcinoma) before 36 years and at least one first or second degree relative affected by a narrow spectrum tumor (other than breast cancer if the proband is affected by breast cancer) before 46 years or multiple primary tumors; or (ii) a proband with multiple primary tumors two of which belong to the narrow spectrum and the first of which occurred before 46 years, whatever the family history; or (iii) a proband with ADC whatever the age at onset and the family history.

Genetics

The genetic origin of LFS was discovered in 1990 when four LFS families had been found to carry a germline mutation in the tumor suppressor gene ►TP53 (OMIM#191170). Since then, more than 400 families or individuals who are carriers of a TP53 mutation have been reported in the scientific literature. A database that compiles data from the literature and serves as a repository for data on patients and families with a TP53 germ-line mutation, or with LFS/LFL syndromes is maintained at IARC (http://www-p53.iarc.fr/Germline.html). Data from the IARC TP53 database show that in approximately 81% (116/143) of LFS cases, and 67% (97/145) of LFL cases, affected family members carry a germline mutation of one allele of the TP53 tumor suppressor gene. In some families, mutations in other genes have been reported. Two LFS and 3 LFL families had a heterozygous CHEK2 germline mutation, while one LFL family had a ►CDKN2A mutation and one LFS family a ►PTEN mutation. These genes are all connected to the p53 pathway. CHEK2 (OMIM#604373) (►Checkpoint Kinases) encodes a protein kinase that is involved in checkpoint control in response to DNA damage and acts upstream of p53 in the G1 checkpoint. CDKN2A (OMIM#600160) encodes two proteins, the cyclin-dependent kinase inhibitor p16(INK4) and the tumor suppressor p14(ARF). P14(ARF) is activated by oncogenic stress and promotes cell-cycle arrest via the inhibition of the neutralization of p53 by MDM2. PTEN (OMIM#601728) is a tumor suppressor gene encoding a protein phosphatase that negatively regulates the PI3-kinase/Akt (OMIM#164730) signaling pathway. PTEN is also a transcriptional target of p53 that acts downstream of p53. Alteration of the p53 pathway is thus the main cause of LFS/LFL syndromes, mutation of the TP53 gene being the most prevalent alteration. In fact, it is now recognized that CHEK2 does not predispose to LFS/LFL, but only to the breast cancers that have occurred in the context of these families. A study on 16 LFS families with wild-type TP53 has excluded PTEN, CHEK2 and CDKN2A as candidate genes in LFS.

The clinical criteria proposed by Chompret are currently recognized as the best criteria for predicting the presence of a TP53 germline mutation.

TP53 Germline Mutations

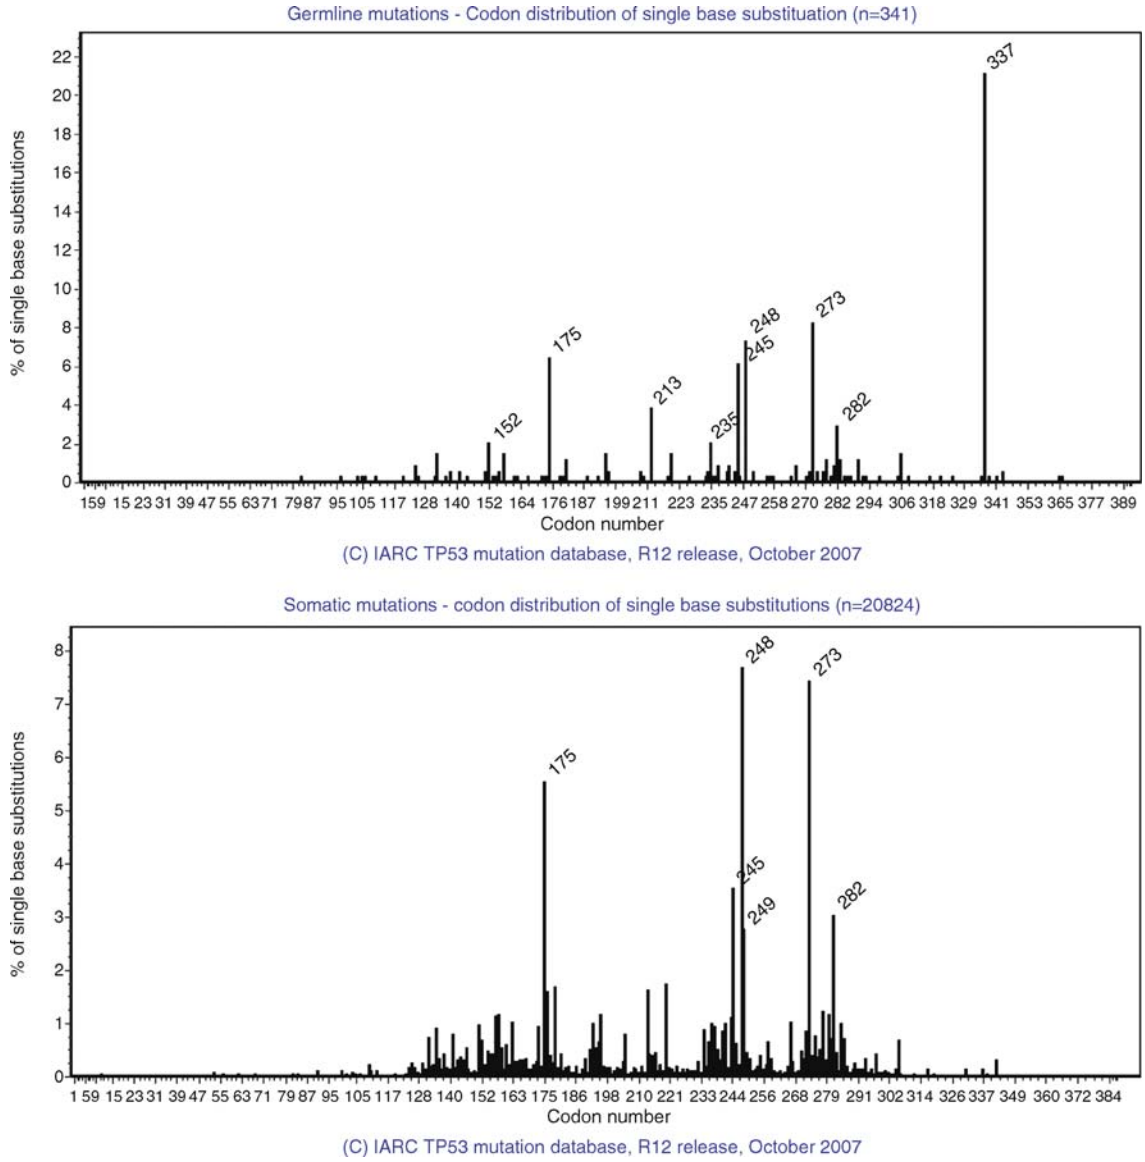
The tumor suppressor gene TP53 (OMIM:191170, synonym: P53), located on chromosome 17p13.1, has 11 exons that span 20 kb. Exon 1 is non-coding and exons 5–8 are remarkably conserved among vertebrates. The TP53 gene encodes an ubiquitous phosphoprotein involved in many overlapping cellular pathways that control cell proliferation and homeostasis, such as cell-cycle, apoptosis and DNA repair. The p53 protein is a transcription factor constitutively expressed in most cell types and is activated in response to various genotoxic and non-genotoxic stress signals. Loss of p53 function is thought to suppress a mechanism of protection against accumulation of genetic alterations.

Type and Origin of TP53 Mutations

Among TP53 germline mutations, point mutations are the most frequent (90%), followed by deletions (7%), insertions (2%) and other complex mutations.

As with somatic TP53 mutations, TP53 germline mutations are located in highly conserved regions of the DNA-binding domain (exons 5–8), with major hotspots at codons 175, 245, 248, and 273 (Fig. 1). These mutations correspond to G:C > A:T transitions at CpG sites that are considered to be of endogenous origin, i.e. formed as a result of deamination of 5-methylcytosine, a reaction that occurs spontaneously but which is usually corrected by DNA repair mechanisms. The occurrence of such mutations may be increased by factors that enhance the rate of methylation or the rate of deamination of 5-methylcytosine, as well as by defects in mismatch repair. Compared to somatic mutations, TP53 transitions at CpG sites are more frequent, representing 55% of all germline mutations compared to 25% in sporadic cancers. Overall, the spectrum of TP53 germline mutations is consistent with a formation through endogenous mutagenesis, rather than with causation by exposure to exogenous mutagenic carcinogens.

A germline-specific mutation hotspot has recently been described, R337H. It also results from a G:C > A:T transition at a CpG site but is located outside the DNA-binding domain, in the oligomerisation domain. This mutant has been found in Brazilian children affected by adrenocortical carcinomas and in Brazilian LFL families. It is considered of low penetrance and its prevalence in Brazil has been shown to be due to a founder effect.



Li-Fraumeni Syndrome. Figure 1 Similar to sporadic cancers, TP53 germline mutations preferentially occur in hotspot regions at codons 175, 245, 248 and 273. Specific to the germline, a mutation at codon 337 (R337H, in the conserved oligomerisation domain) is frequently found in the Brazilian population. (IARC TP53 database, R12, October 2007).

Tumor Spectrum in TP53 Mutation Carriers

Breast cancers, sarcomas (soft tissue sarcomas and osteosarcomas), brain tumors and adrenocortical carcinomas account for about 80% of all tumors arising in TP53 germline mutation carriers (Table 1). Childhood adrenocortical carcinomas (ADR, 14% of tumors) have been shown to be a hallmark for the presence of a TP53 germline mutation. Brain tumors (12% of all tumors) are mostly of astrocytic origin (65%). Pediatric brain tumors, including medulloblastomas and related primitive neuroectodermal tumors, and choroid plexus tumors are less frequent. This correlates with the occurrence of TP53 mutations in sporadic brain tumors, which prevail in astrocytomas and are considerably less frequent in medulloblastomas. In addition to the four main types of cancers strongly associated with TP53 mutation, seven types of cancers account for 14% of all cancers. They include leukemia/lymphomas, Wilms' tumor, malignant phyllodes tumor, carcinoma of the pancreas, stomach and colorectal cancers, that were found to be weakly to moderately associated with TP53 germline mutation, and lung and ovarian cancers. Although the frequent occurrence of lung and ovarian cancer might be due to the fact that they are frequent in

Li-Fraumeni Syndrome. Table 1 Tumor type, age at onset, and gender distribution in TP53 germ-line mutation carriers (IARC TP53 database, R12, October 2007)

[a]Data based on cancer registries from United States, France, and United Kingdom compiled in Cancer Incidence in Five Continents v. 7, 1997.

the general population, they occur significantly earlier in TP53 germline carriers compared to sporadic cases (Table 1).

Age Distribution in Relation to Tumor Type

While the histopathologic characteristics of tumors associated with TP53 germline mutations are very similar to their sporadic counterparts, their age at onset show marked organ-specific differences (Fig. 2). Adrenocortical carcinomas associated with a TP53 germline mutation develop almost exclusively in children, while sporadic adrenocortical carcinomas have a broad age distribution with a peak beyond age 40 (Table 1). Bone sarcomas occur mainly in adolescents while soft-tissue sarcomas are more frequent in childhood. Brain tumors have a biphasic age distribution, with a first pick in childhood and a second pick between 20–40 years. Breast carcinomas are more prevalent in the 20–40 age range.

Gender Distribution of Patients with TP53 Germline Mutations

The gender distribution for these tumors (Table 1) shows an excess of males for brain tumor, hematopoetic cancers, and stomach cancer, whereas an excess of females was observed for adrenocortical carcinoma and skin cancer. All of the breast cancers were in females. This gender distribution is similar to the one of sporadic cancers observed in the general population with the exception of adrenocortical carcinoma, which occur significantly more frequently in females than in males in TP53 mutation carriers compared with sporadic cases in the general population.

Functional Consequences and Phenotype of Germline Mutations

The majority of TP53 germline mutations are missense mutations (80%), followed by nonsense, frameshift deletions and insertions, mutations in splice sites and other intronic or complex mutations. p53 mutant proteins resulting from missense mutations differ from each other in the extent to which they have lost transactivation activities, and in their capacity to inhibit wild type p53 in a dominant-negative manner. In addition, some p53 mutants appear to exert an oncogenic activity of their own, but the molecular basis of this gain-of-function phenotype is still unclear. It is thus expected that p53 germline mutants exert distinct biological activities that could influence tumor penetrance in term of organ sites or age at onset. Genotype/phenotype correlations have been reported in recent studies:

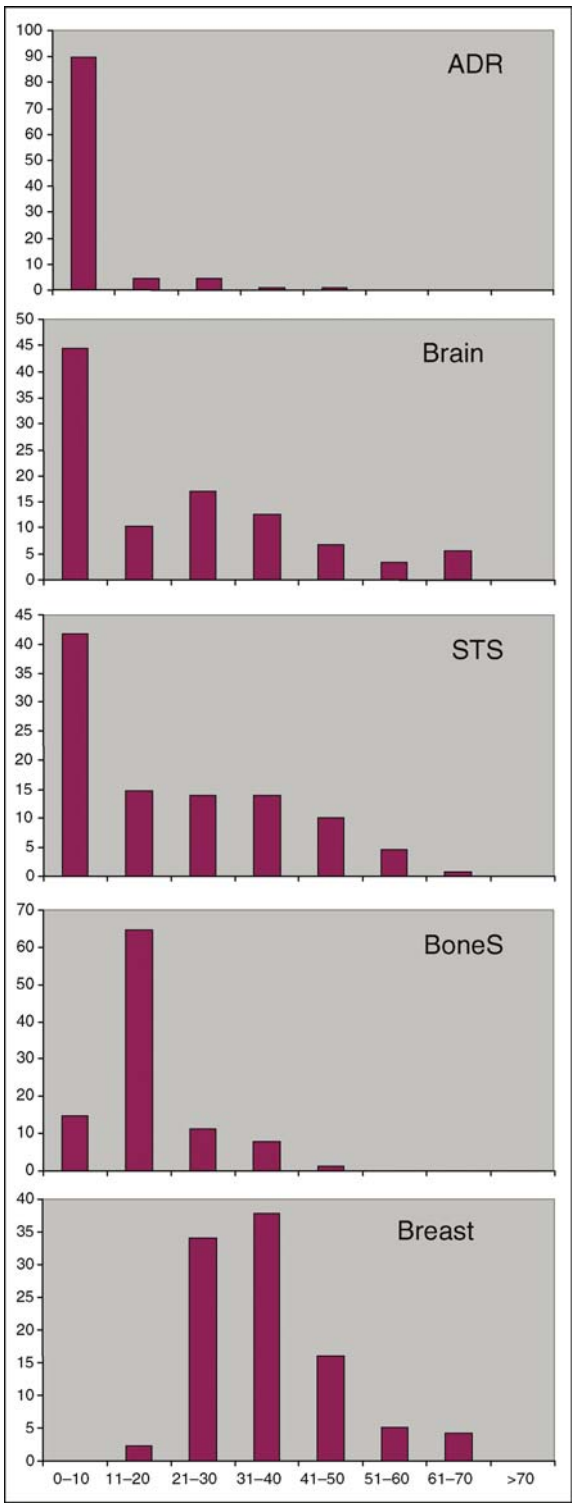
Brain tumors were more likely to be associated with missense mutations located within the DNA-binding surface of p53 protein that makes contacts with the minor groove of DNA.

Adrenocortical carnimoas were more likely to be associated with missense mutations located outside the DNA-binding surface.

Mutations with complete loss of transactivation activities were associated with earlier onset breast and colorectal cancers compared to mutations that retain some trans-activation capacities.

Truncating mutations were associated with earlier onset brain tumors compared to all other mutations.

Thus, the penetrance of a mutation may be related to its degree of loss of trans-activation capacities,



Li-Fraumeni Syndrome. Figure 2 Distribution of the age at onset of the five main types of tumors associated with TP53 germline mutations (IARC TP53 database, R12, October 2007). ADR, adrenocortical carcinoma; STS, soft tissue sarcoma; BoneS, bone sarcoma.

at least in some tissues. The notion that loss of function is in itself sufficient for causing LFS is substantiated by the fact that a large deletion encompassing the whole TP53 gene has been reported in an LFS family.

These observations show that the degree of loss of trans-activation capacities may affect the type and age at onset of tumors in LFS patients. It is not yet known how other functional properties contribute to mutation phenotypes.

Mutation Detection Methods and Results Interpretation

TP53 germline mutations are very diverse and scattered along the entire gene coding sequence, including splice sites in introns. These mutations have different biological effects that may affect their phenotype. Large deletions of the gene have also been reported in some LFS families. To fully assess TP53 status in an individual, it is thus recommended to (i) use sequencing techniques to precisely identify the mutation, (ii) screen all exons and splice junctions of the gene, and if no mutation is found, (iii) search for large gene deletions. A protocol for direct sequencing of TP53 is available in the IARC TP53 database (http://www-p53.iarc.fr/Download/TP53_DirectSequencing_IARC.pdf). A kit for detecting large deletions is available commercially (MLPA, http://www.mlpa.com/pages/p056pag.html).

For interpreting sequence analysis results, it is recommended to follow guidelines proposed by the ACMG (http://www.acmg.net/resources/policies/pol-027.pdf) working group and to consult the IARC TP53 Database to retrieve information on mutation prevalence and phenotype. If the mutation has already been reported as a germline mutation, the associated tumor spectrum can be retrieved (http://www-p53.iarc.fr/TumourCriteria.ASP). If the mutation has never been described in cancer families, data on its frequency in sporadic cancers and biological impacts (assessed in functional assays or predicted by sequence conservation models) can be retrieved (http://www-p53.iarc.fr/MutationValidationCriteria.asp) to estimate its functional severity.

If no alteration is found in TP53 gene, the family history may be carefully checked since certain families with LFS/LFL resemble families with hereditary breast cancer, who are candidates for BRCA1 or BRCA2 testing (see BRCA1/BRCA2 Hereditary Breast Cancer), while other families may resemble kindreds with familial brain tumors.

LIM Domain

Definition
Is a cysteine-rich domain composed of two tandem zinc fingers that are joined by a two-amino acid spacer. It functions as a modular protein-binding interface. The acronym "LIM" is derived from the first three proteins shown to harbor LIM domains: *C. elegans* LIN-11, rat Isl1, and ►C. elegans MEC-3. A single LIM domain consists of about 55 amino acids of which eight, mostly cysteines and histidine, are highly conserved. The latter bind two zinc ions, one for each zinc finger. The LIM consensus sequence has been defined as $CX_2CX_{16-23}HX_2CX_2CX_{16-21}CX_2$(C/H/D) (X represents any amino acid). LIM domains occur in a wide variety of eukaryotic organisms but are absent from prokaryotes. LIM proteins have a function in a wide variety of biological processes, such as cytoskeletal functions and control of gene expression.

LINE

Definition
Synonym LI element; Long interspersed nuclear element; typically 6–8 kb pair long and frequent DNA sequences randomly distributed throughout the genome. In humans, LINE sequences make up approximately 20% of the genome, frequent are LINE-1, LINE-2, and LINE-3 elements. They mostly localize to AT-rich regions in the euchromatin. Because LINES move by copying themselves (instead of moving, like transposons do), they enlarge the genome. The human genome, for example, contains about 900,000 LINE sequences.

LINE sequences are transposable elements, which use RNA as an intermediary step. They encompass genes encoding two proteins: one RNA-binding, the other having activities of reverse transcriptase and endonuclease, which enable them to copy themselves. Their distribution pattern is unique for each individual genome, and their position therefore is diagnostic for the identity of individuals; ►Sticker sarcoma.

LINE-1 Elements

Suzanne M. Benjes, Christine M. Morris
Cancer Genetics Research Group, University of Otago at Christchurch, Christ Church, New Zealand

Definition
Long interspersed nuclear elements (LINE-1 or L1) are a family of DNA repeat sequences with ~500,000 copies comprising ~17% of the human genome.

Characteristics
Structure
Full-length elements are ~6 kb, include a 910 bp 5′ untranslated region (UTR), two open reading frames

(ORF-1 and ORF-2) that are separated by a 63 bp inter-ORF region, a 205 bp 3′UTR, a variable length poly-A tail and are typically flanked by short direct target site duplications of 2–20 bp. The 5′UTR contains an internal promoter which drives L1 expression and also has an antisense promoter permitting transcription of the 5′UTR and its upstream genomic region. ORF-1 encodes a ~40 kDa protein (p40 or ORF1p) with RNA-binding affinity and nucleic acid chaperone activity. ORF-2 encodes a ~150 kDa protein (ORF2p) with endonuclease, reverse transcriptase and cysteine-rich domains (Fig. 1). The majority of L1 copies are either 5′ truncated, inverted or contain point mutations. An estimated 3,000–10,000 copies are full-length with only ~1% of these elements able to encode the factors needed for autonomous movement (►retrotransposition) enabling copying of L1 sequence and insertion into a new genomic location.

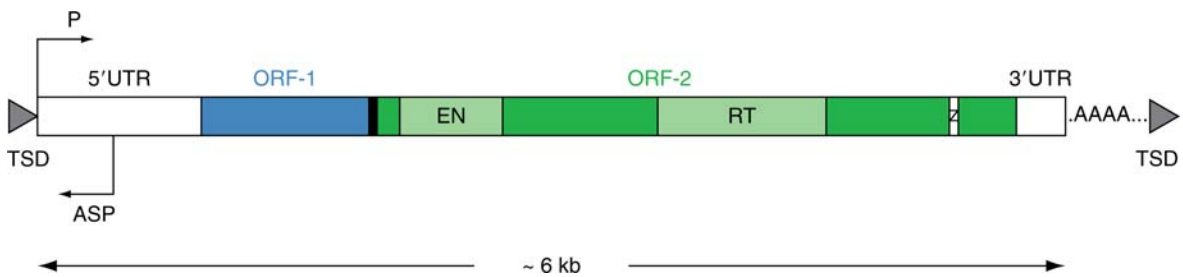
Genomic Impact

Although once considered "junk DNA" it is now realized that repetitive DNA families have influenced and shaped the human genome in both detrimental and beneficial ways. L1 elements can cause constitutional and somatic cell disease through not only retrotransposal insertion, but also as facilitators of recombination giving rise to genomic deletions, translocations and other chromosomal rearrangements. L1 elements have contributed substantially to the increase in DNA mass of human cells over evolutionary time. Over one-third of the human genome can be attributed to the activities of these elements either directly through self replication and insertion or indirectly by providing retrotransposal proteins enabling expansion of the nonautonomous ►Alu element, ►processed pseudogene and ►SVA repeat families. L1 elements contribute to reshuffling and relocation of DNA sequence through transduction of genomic sequence either 3′ or 5′ of the parent L1 during the retrotransposition process. Further proposed roles of L1 elements include involvement in ►X chromosome inactivation, downregulating or altering mRNA expression of the host gene in some cases of intronic insertion and repair of double strand DNA breaks by L1 insertion.

Role in Human Cancer

L1 element expression is normally restricted to developing germ cells. In somatic cells their activity is believed to be suppressed by a number of mechanisms including DNA ►methylation, TP53 activity, effects leading to L1 RNA instability and packaging into inactive chromatin. However, in some cancer cells L1 sequences become reactivated, largely through widespread ►hypomethylation of repetitive sequence. Cancer subtypes showing hypomethylation of L1 sequences identified so far include ►testicular, colon, liver, ovarian, bladder, prostate, breast and the hematological malignancies ►chronic lymphocytic leukemia (CLL) and chronic myeloid leukemia (CML, ►BCR-ABL1). In some instances hypomethylation is found early in the disease, for example in colon and bladder cancers. In other cases, including CML, CLL, prostate, ovarian and breast cancer, L1 hypomethylation is reported to occur as the disease progresses. Limited studies also suggest that L1 hypomethylation may be associated with clinical outcome.

It would be expected that with reactivation of L1 elements, assaults to the genome associated with retrotransposition i.e. mutagenesis, illegitimate recombination, altered transcriptional activity and gene regulation would occur. However, whereas there is considerable evidence pointing to L1 transcriptional reactivation through hypomethylation, there are limited documented examples of L1 elements associated with cancer. Rare cases have been reported and include L1 insertions into the ►*APC* and upstream of the ►*MYC* genes resulting in deregulation of these genes causing colon and breast cancer, respectively. L1 elements are found at breakpoint sites, for example inserted into the junction of a t(11;22) in a ►desmoplastic small round



LINE-1 Elements. Figure 1 Structure of a full-length human L1 element. The ~6 kb retrotransposon is flanked by target site duplications (TSD) and consists of (i) a 5′UTR with internal sense (P) and antisense (ASP) promoters; (ii) two open reading frames, ORF-1 encodes a 40 kDa RNA-binding protein, ORF-2 encodes a 150 kDa protein with endonuclease (EN) and reverse transcriptase (RT) activity, and contains a conserved zinc knuckle-like domain (Z) residing within a cysteine-rich region; (iii) a 3′UTR terminating in a poly-A tail.

cell tumor or are enriched at carcinoma genomic breakpoints e.g. 3p14.1 and 9p21 deletions.

Reasons for the small number of reports in this field of interogation could be due to either technical or biological factors. Current laboratory techniques used to investigate genetic alterations may have difficulty detecting subtle changes in L1 activity and limited numbers of cases are examined at the detailed level required to identify L1 insertions or other L1 mediated genomic rearrangements. There also may be additional safeguards within cells that provide protection against the activities of L1 elements. Therefore, it remains to be clarified the actual extent that reactivation of L1 elements in cancer cells plays in the initiation and progression of cancer.

Lineage

Definition

The natural progression from an immature cell type to one or more differentiated cell types.

Lineage Differentiation Tumor Antigens

Definition

Tumor antigens that are expressed in a cell type-restricted manner by malignant cells and their normal counterpart. For example, proteins of the tyrosinase family of enzymes, which are responsible for the synthesis of melanin pigment in melanocytes, are frequently recognized by the cellular as well as the humoral immune system in melanoma patients.

►Melanoma Vaccines

Lineage Restriction

Definition

The inability of one lineage to give cell types of another, that is, to cross lineage boundaries.

Linear Accelerator

Definition

LINAC; is a device that accelerates electrons and other charged particles using electromagnetic waves. For radiotherapy applications, a high-energy electron beam is guided through a vacuum conduit to hit the metal foil in the path of the electron beam and to generate high energy X-rays.

►Radiation Oncology

Linearly Patterned Programmed Cell Necrosis

Definition

Is a kind of cell death. It shares morphological characteristics of traditional ►necrosis, but it is regulated by the ►apoptosis-related gene programme. Under the stimuli of ►hypoxia, a cluster of tumor cells exert this death and connect with each other by lines and networks, providing the space basement for vasculogenic Mimicry.

►Vasculogenic Mimicry

Lingual Cancer

►AAV

Linkage

Definition

Tendency for ►alleles at two genetic locations to be transmitted from parent to child in combination

►Linkage Disequilibrium

Linkage Disequilibrium

Ellen L. Goode
College of Medicine, Mayo Clinic, Rochester, MN, USA

Synonyms

Allelic association; LD

Definition

Linkage disequilibrium refers to the non-random association of ►alleles at two or more ►loci in a general population. When alleles are in linkage disequilibrium, ►haplotypes do not occur at the expected frequencies. Linkage disequilibrium between two alleles is related to the time of the mutation events, genetic distance, and population history. It can be used to improve the power of cancer ►genetic association studies.

Characteristics

Introduction to Linkage Disequilibrium

Two or more alleles are said to be in linkage equilibrium when they occur randomly in a population. Conversely, alleles are in linkage disequilibrium when they do not occur randomly with respect to each other.

Consider two neighboring polymorphic loci A and B with two alleles each (A_1 and A_2, and B_1 and B_2, respectively) having the allele frequencies shown in Table 1.

Under linkage equilibrium, the four haplotypes formed by these loci have the frequencies shown in Table 2. These are equal to the product of the component allele frequencies. The alleles are independent; for example, whether an individual carries allele A_2 at locus A is not dependent on whether this individual carries allele B_2 at locus B on this chromosome.

Under linkage disequilibrium, haplotypes do not occur at the frequencies expected when the alleles were independent. Positive linkage disequilibrium exists when two alleles occur together on the same haplotype *more* often than expected, and negative LD exists when alleles occur together on the same haplotype *less* often than expected (Table 3). For example, suppose linkage disequilibrium existed such that the alleles A_2 and B_2 tended to occur together, i.e., alleles A_2 and B_2 were in positive linkage disequilibrium. The probability that an individual carries allele A_2 at locus A is, to some extent, predictable based on whether this individual carries allele B_2 at locus B on this chromosome. The observed haplotype frequencies will differ from that expected as shown in Table 3.

Linkage Disequilibrium. Table 1 Allele frequencies

Locus	Allele	Observed frequency
A	A_1	p_1
A	A_2	p_2
B	B_1	q_1
B	B_2	q_2

Linkage Disequilibrium. Table 2 Haplotype frequencies under linkage equilibrium

Haplotype	Expected frequency
A_1B_1	$p_1 \times q_1$
A_1B_2	$p_1 \times q_2$
A_2B_1	$p_2 \times q_1$
A_2B_2	$p_2 \times q_2$

Measures of Linkage Disequilibrium

Deviation of the observed from expected haplotype frequencies can be quantified by several linkage disequilibrium measures. The basic linkage disequilibrium parameter, D, was introduced in 1918 and is defined as $D = x_{11} - p_1 \times q_1$. This difference between observed and expected haplotype frequencies is presented in Table 4. Although D is simple to calculate, its disadvantage is that it is sensitive to allele frequencies at the extreme values of 0 to 1. D maximizes when allele frequencies are both 0.5 and is not calculated if an allele frequency equals 0 or 1.

In 1964, Lewontin suggested D', a normalized D calculated by dividing D by its theoretical maximum for the observed allele frequencies ($D' = D/D_{max}$; Table 5). D' thus ranges from −1 to 1 and reflects both positive and negative linkage disequilibrium. D' is commonly used to characterize linkage disequilibrium, particularly, in the definition of haplotype blocks (see below).

A particularly useful metric of linkage disequilibrium is r^2 which is equivalent to the Pearson correlation coefficient. r^2 is calculated as $D^2/(p_1 \times p_2 \times q_1 \times q_2)$ and ranges from 0 to 1. Because it is less sensitive to extreme allele frequencies than D or D', r^2 is commonly

Linkage Disequilibrium. Table 3 Haplotype frequencies under linkage disequilibrium

Haplotype	Observed frequency	A_2 and B_2 in positive LD	A_2 and B_2 in negative LD
A_1B_1	x_{11}	$x_{11} > p_1 \times q_1$	$x_{11} < p_1 \times q_1$
A_1B_2	x_{12}	$x_{12} < p_1 \times q_2$	$x_{12} > p_1 \times q_2$
A_2B_1	x_{21}	$x_{21} < p_2 \times q_1$	$x_{21} > p_2 \times q_1$
A_2B_2	x_{22}	$x_{22} > p_2 \times q_2$	$x_{22} < p_2 \times q_2$

used to describe linkage disequilibrium in genetic epidemiologic studies of cancer. In addition, r^2 has utility in adjustment of estimates of statistical power in genetic association studies (see below) in which an assayed ►polymorphism may be in linkage disequilibrium with the truly causal polymorphism. Sample size must be increased by a factor of $1/r^2$. For example, if a sample size of 2,000 were required to detect a particular association between phenotype and a causal polymorphism ($r^2 = 1.0$), a sample size of 2,500 (= 2,000 × 1.25) would be required to detect the association if the causal polymorphism was in linkage disequilibrium with an assayed polymorphism at $r^2 = 0.8$ but was itself not assayed.

Estimation of Linkage Disequilibrium

Estimation of linkage disequilibrium between alleles at two loci requires observations of haplotype frequencies which is not currently technologically feasible in diploid organisms. Haplotype frequencies are, therefore, often estimated using statistical tools such as the expectation maximization (EM) algorithm. These methods take as input the observed combined ►genotype frequencies at the two loci (for example, the distribution of the nine possible combinations of A_1A_1, A_1A_2, and A_2A_2, with B_1B_1, B_1B_2, and B_2B_2).

Estimates of the observed haplotype frequencies are used for calculation of linkage disequilibrium measures. Numerous software packages facilitate these calculations ranging from EH (which provides estimates of observed haplotype frequencies) to Haploview (which calculates and graphically displays multiple linkage disequilibrium measures, Fig. 1).

Haplotype Blocks

Because of linkage disequilibrium in the human genome, there are regions in which only a reduced set of haplotypes occur relative to all possible haplotypes. These are referred to as haplotype blocks, and they can be defined in a variety of ways. A common definition for haplotype blocks is a region without "substantial" ancestral recombination; pairs of polymorphisms are considered to be in "strong LD" if the one-sided upper 95% confidence bound on D' is ≥0.98 and the lower bound is ≥0.70. Pairs are deemed to have "strong evidence of historical recombination" if the upper confidence bound on D' is ≤0.90. Based on this, haplotype blocks can be defined as regions over which ≤5% of comparisons among informative polymorphism pairs show strong evidence of historical recombination (Fig. 2).

Linkage Disequilibrium. Table 4 The linkage disequilibrium parameter D

Haplotype	Observed frequency
A_1B_1	$x_{11} = p_1 \times q_1 + D$
A_1B_2	$x_{12} = p_1 \times q_2 - D$
A_2B_1	$x_{21} = p_2 \times q_1 - D$
A_2B_2	$x_{22} = p_2 \times q_2 + D$

Linkage Disequilibrium. Table 5 The linkage disequilibrium parameter D'

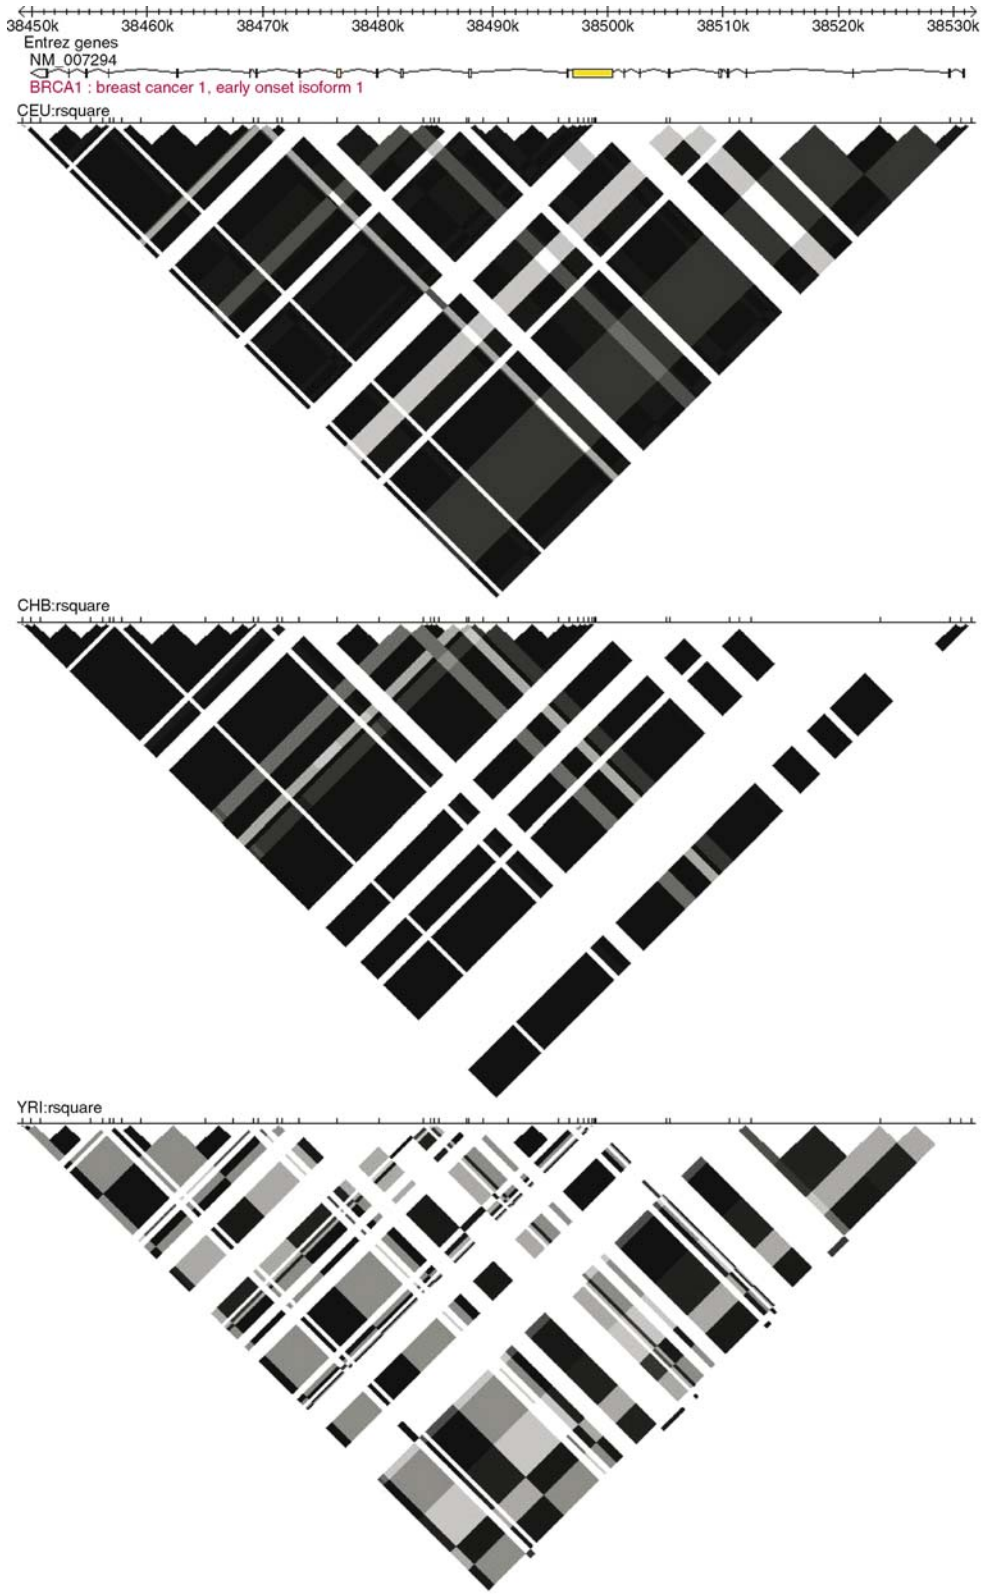
D	D′
$D > 0$	$D' = (x_{11} - p_1 \times q_1)/\min(x_{12}, x_{21})$
$D < 0$	$D' = (x_{11} - p_1 \times q_1)/\min(x_{11}, x_{22})$
$D = 0$	$D' = 0$

Linkage Disequilibrium *versus* Linkage

Genetic ►linkage exists when two alleles are co-inherited within a pedigree and this phenomenon is observed across multiple pedigrees. These loci are in linkage because they occur near enough to each other on the same chromosome such that the frequency of recombination (measured as θ) is relatively low. Linkage disequilibrium differs from linkage, in that the former describes alleles while the latter describes loci.

Origins of Linkage Disequilibrium

Linkage disequilibrium arises when a mutation event gives rise to a new allele on a particular chromosome in an individual. The new allele will be associated with the alleles already present on that individual's chromosome for all other loci. In time, as this person reproduces and the population grows, recombination between the new mutation and surrounding loci will return alleles in this



Linkage Disequilibrium. Figure 1 Plots of pairwise linkage disequilibrium (r^2) for polymorphisms in the ►*BRCA1* region genotyped in three populations by the International HapMap Project. Linkage Disequilibrium. Figure 2 Plot of haplotype blocks among polymorphisms in the *MLH1* region (▶colon cancer) genotyped in Utah residents with ancestry from northern and western Europe by the International HapMap Project.Black, strong linkage disequilibrium; grey, uninformative; white, recombination; HapMap Release 22; chromosome 3 NCBI Build 35.

region to equilibrium, and the new mutation will occur on chromosomes regardless of the background of surrounding loci.

In stable populations, two factors inhibit this return to linkage equilibrium: time and genetic distance. The closer two loci are, the more time (number of recombination events) is required for linkage disequilibrium to break down, and the more recent the mutational event occurred, the larger the region of linkage disequilibrium.

Linkage Disequilibrium in Human Populations

Linkage disequilibrium can also reflect instability or changes in populations. Because modern human chromosomes represents the bottom generation of a very large *Homo sapiens* pedigree, patterns of linkage disequilibrium track with human migration patterns. The migration out of Africa into Europe and Asia is seen, for example, in the observation that modern-day Africans tend to have less linkage disequilibrium, generally, than Europeans or Asians. The relatively small number of "founding" chromosomes which migrated to new continents limited the variation induced by recombination. Therefore, more linkage disequilibrium is generally observed in populations which arose relatively recently.

The International HapMap Project is a large consortium formed in 2002 which seeks to characterize haplotypes and linkage disequilibrium in a variety of human populations. Researchers have performed genotyping on millions of genetic markers in individuals from four populations including Yoruba in Ibadan, Nigeria; Japanese in Tokyo, Japan; Han Chinese in Beijing, China; and Utah residents with ancestry from northern and western Europe. These data are publicly available to researchers who aim to analyze these genetic markers in relation to health conditions, including cancer.

An alternative way to characterize linkage disequilibrium in human populations involves resequencing genes of interest in a variety of DNA samples. Resequencing data has the advantage that a variety of polymorphism types may be detected (including insertions and deletions) and that rare alleles may be characterized. In 1998, the U.S. National Institute of Environmental Health Sciences embarked on the Environmental Genome Project including resequencing of key environmentally-responsive cancer candidate

genes in the populations also assessed by the International HapMap Project. These dense polymorphism data complement the genome-wide HapMap approach and allow researchers access to finer-scale linkage disequilibrium information in key genes involved in ►DNA repair, ►inflammation, ►apoptosis, ►cell cycle, and other pathways.

Using Linkage Disequilibrium to Select Informative Markers

Genetic association studies in ►cancer epidemiology aim to identify common inherited variants which are related to risk of cancer (►case–control studies), treatment response, survival, and other endpoints. These studies often focus on particular candidate genes (suspected because of known biological function related to cancer). Candidate gene studies may utilize linkage disequilibrium in that, rather than genotyping every genetic marker in a suspected gene or genomic region, only those markers thought to be independent are assessed. This "tagging SNP" approach can allow for greater gene coverage and cost efficiency. For example, in a study of 260 candidate genes related to the ►NF-κB pathway, 17,360 common polymorphisms were estimated to be captured by 2,181 tagging polymorphisms.

Numerous methods have been developed to identify subsets of tagging polymorphisms based on analysis of multiple polymorphisms in a genomic region. For example, pairwise-binning methods aim to identify the subset of polymorphisms which are linkage disequilibrium at a specific r^2 threshold with all available polymorphisms, and haplotype-tagging methods aim to aim to identify the subset of polymorphisms which tag all estimated haplotypes over a certain haplotype frequency threshold. ldSelect and Tagger are two commonly-used software tools for identifying tagging polymorphisms.

Data from the HapMap Project, the Environmental Genome Project, other public sources, as well as study participant data, can be used for selection of the optimal set of tagging polymorphisms. It is important to note that population differences in linkage disequilibrium (for example, due to ethnicity or sampling variation) between the more densely genotyped samples (for example, HapMap populations) and the target population (for example, a cancer genetic association study population) must be accounted for when using tagging polymorphisms.

Utility of Linkage Disequilibrium to Genome-wide Association Studies

Genetic association studies can also search the entire genome allowing for identification of cancer-related loci in unpredicted regions. Genome-wide association studies would not be feasible without capitalizing on linkage disequilibrium. This allelic association allows for a reduced set of markers to represent the over 12 million common polymorphisms thought to exist. Numerous commercial panels are available for high-throughput assessment of genome-wide polymorphisms, including from 300,000 polymorphisms to 1,000,000 polymorphisms. For example, a panel available in 2007 from Illumina Corporation (San Diego, CA) assessed approximately 550,000 polymorphisms but was estimated to offer as much genetic information (at $r^2 = 0.85$) as assaying 57%, 89%, 90% of the 3.7 million HapMap polymorphisms among the Yoruban, Asian, and Utah populations described above.

Other Uses of Linkage Disequilibrium in Cancer Research

Linkage disequilibrium also informs hypothesis testing in genetic association studies. The causal allele, if it exists, may be included in the set of assayed markers or it may lie on a haplotype defined by the set of assayed markers. Analysis of haplotypes may, therefore, provide additional information on association. Numerous methods exist for testing haplotype associations with disease (including score tests, logistic regression, and Bayesian methods). All methods first estimate haplotype frequencies (or probabilities) because haplotypes are usually not directly observed.

If an association signal is detected, linkage disequilibrium can be used in refinement of the signal where an association is detected (fine-mapping). A particular polymorphism found to be associated with disease may be in linkage disequilibrium with the truly causal allele. Thus, additional analysis of nearby polymorphisms may increase the association signal and provide a targeted region for functional genomics analysis. In summary, incorporation of linkage disequilibrium has the potential to improve the power and efficiency of genetic association studies leading to increased understanding of the genetic causes of cancer.

N-Linked Glycan

Definition

Asparagine (Asn/N)-linked glycan is a major structural type of sugar chain in glycoproteins. Oligosaccharides with Glc3Man9GlcNAc2 are initially transferred to Asn residues in the consensus Asn-X-Ser/Thr sequence in the newly synthesized glycoproteins in the endoplasmic reticulum (ER). The glycans are processed and modified in the secretory pathway in the ER and Golgi apparatus.

►Calreticulin

O-Linked Oligosaccharide

Definition

A glycan glycosidically linked to the hydroxyl group of the amino acids serine, threonine, tyrosine, or hydroxylysine. Regarding mucin glycosylation, the term **O**-glycan is used to denote the common linkage GalNAcα1-O-Ser/Thr.

►Mucins

Linoleic Acid

Hiroki Kuniyasu
Department of Molecular Pathology, Nara Medical University School of Medicine, Kashihara, Nara, Japan

Definition

Linoleic acid (LA) is an 18-carbon, polyunsaturated fatty acid (PUFA), which contains two *cis* double bonds. Because mammals cannot introduce a double bond at carbon atoms beyond *C-9* in the fatty acid chain, linoleic acid (18:2 *cis*-Δ^9,Δ^{12}) and linolenic acid (18:3 *cis*-Δ^9, Δ^{12},Δ^{15}) are two essential fatty acids. LA possesses low melting temperature and provides fluidity to cell membranes. LA is mainly contained in plant oils, such as safflower oil and corn oil.

Characteristics

The effect of linoleic acid (LA) on health is still controversial. LA is one of the two essential fatty acids, which means dietary supplementation of LA is necessary for maintaining cell activity. Saturated fatty acids have been implicated in obesity, heart disease, diabetes, and cancer while PUFAs generally have a positive effect on health; however, a high ω-6/ω-3 ratio, which is associated with today's Western diets, promotes the pathogenesis of many diseases, including cardiovascular disease, inflammatory diseases, and cancer. Several in vivo studies suggest that a high amount of ω-6 PUFA such as LA might enhance the incidence of some types of cancers via stimulation of epithelial cell proliferation. Experiments in animal models of mammary and colorectal carcinogenesis suggest that fatty acids promote tumor development; ω-6 PUFA generally stimulate tumor growth, while ω-3 fatty acids oppose this effect.

Other studies lead to opposite conclusions. The associations between monounsaturated fatty acids, trans fatty acids, PUFAs such as LA, alpha-linolenic acid (ALA), docosahexaenoic acid (DHA), or ω-3/ω-6 ratio, and colorectal cancer are not convincing. Contrary to data from animal experiments, human studies do not show an association of breast cancer risk with ω-6 PUFA intake. High LA and arachidonic acid (AA) concentrations have been observed in insulin resistance-associated diabetic complications and in some tumors, but these are multifactorial processes that include many lifestyle determinants. It is therefore questionable to involve only ω-6 fatty acids in their etiology.

The controversial roles of LA might be due to the possibility that different metabolic pathways result in opposite effects. ω-6 PUFAs play a significant role in inflammatory and/or immune responses by bioactive molecules including PGE2.

LA is integrated into cytoplasmic membrane and is metabolized to AA through γ-linolenic acid, and dihomo-γ-linolenic acid (►Arachidonic acid-pathway and cancer). AA is stored as phospholipids in cytoplasmic membrane and serum, and is released by cleavage with phospholipase A2. AA is metabolized by cyclooxygenase-1 and cyclooxygenase-2 (COX-2) (►Cyclooxygenase-2 in colorectal cancer) to ►prostaglandins (PGs), thromboxanes (TXs), and ►leukotrienes (LTs). COX-2 is an inducible enzyme of COXs, which is absent in normal cells. In contrast, COX-1 is a constitutive enzyme expressed ubiquitously. COX-2 expression is induced in carcinogenic processes in many malignancies, involving colorectal, esophageal, breast, lung, pancreatic, and bladder cancers. Induced COX-2 expression in epithelial cells and also in stromal cells provides PGE2 in the local tissues. PGE2 possesses immunosuppressive and proinflammatory effects. COX-2-dependent overproduction of PGE2 is hypothesized to be an important part of sustained proliferative and chronic inflammatory conditions in colorectal epithelium, which are closely associated with

carcinogenesis (►Inflammation in cancer). PGE2 also has a strong association with colorectal cancer progression by promoting cell survival, cell growth, migration, invasion, and angiogenesis (►Colon cancer). The various biological effects exerted by PGE2 are through the G-protein coupled cytoplasmic membrane E-prostanoid receptors termed EP1 to EP4.

15-Lipoxygenase-1 (15-LOX-1) is known for its antiinflammatory properties and has a profound influence on the development and progression of cancers. 15-LOXs belong to the structurally and functionally related nonheme iron dioxygenases family. 15-LOXs are responsible for oxidative metabolism of ω-6 PUFAs, such as LA and AA to eicosanoids. Two isoforms are known in 15-LOXs; 15-LOX-1 (leukocyte type) and 15-LOX-2 (epidermis type). Both isoforms are expressed in normal and tumor tissues in various combinations. Different from other LOXs, such as 5-LOX and 12-LOX, 15-LOXs, 15-LOX-1 is revealed also as an ►apoptosis inducer in human cancers and inhibits cancer progression in several types of cancers, including colorectal, and breast cancers. By the contrary, reduction of 15-LOX-1 is correlated with the disease progression of breast and colon cancers.

For antitumor effects, 15-LOX-1 is closely associated with peroxisome proliferator-activated receptor γ (PPARγ) (►Peroxisome proliferator-activated receptor and cancer) activation. The oxidative metabolites of LA by 15-LOX-1 can function as endogenous activators and ligands of PPARγ. In particular, 9-hydroxyoctadecadienoic acid (9-HODE), 13-hydroxyoctadecadienoic acid (13-HODE), and 13-oxooctadecadienoic acid (13-OXO) have biological effects as a PPARγ ligand. PPARγ is originally identified to induce adipocyte differentiation. PPARγ is a nuclear hormone receptor superfamily of ligand-activated transcription factors. PPARγ is dimerized with retinoic X receptor (►Retinoid receptor crosstalk in cancer), and binds specific responsive element within promoter DNA sequence to regulate gene expression. PPARγ initiates transcription of genes associated with energy homeostasis, cell growth, and anti-/proinflammatory effect. PPARγ is activated by endogenous secreted prostaglandins and fatty acids. 15-Deoxy-δ(12,14)-prostaglandin J2 is a strong endogenous ligand of PPARγ. Decrease in PPARγ expression is associated with cancer metastasis. PPARγ play a role in transcriptional regulation of cancer-related genes. Ligand activation of PPARγ in colorectal cancer cells attenuates colonic inflammation and causes a reduction growth via the induction of apoptosis. Conjugated LA (CLA), a strong ligand for PPARγ, has a substantial anticarcinogenic effect. Synthesized PPARγ ligands including troglitazone have been shown to be effective chemopreventive agents in a rat model of carcinogenesis and in AOM-induced colon cancer in mice. In in vitro transformation model, LA inhibits intestinal cell transformation. Inhibitory effect of PPARγ to cancer metastasis is also reported in several cancers, such as nonsmall cell lung cancer, colon cancer, thyroid cancer, and breast cancer. Downregulation of EGFR, TGF-α (►Epidermal growth factor receptor ligands), and upregulation of Bax, p21Waf-1 (►p21(WAF1/CIP1/SDI1)), ►E-cadherin by PPARγ activation induce antiproliferative, proapoptotic, and prodifferentiation effects. These alterations of gene expressions provide LA-induced anticarcinogenic, antitumor, and antimetastatic effects on cancer cells.

The sequential alteration of concurrence of COX-2 upregulation and 15-LOX-1 downregulation is found in the adenoma-carcinoma transition in colorectal neoplasia (►Colorectal premalignant lesions). Low grade adenomas express 15-LOX-1 but not COX-2; high grade adenomas and early carcinomas show decreased 15-LOX-1 expression and induction of COX-2 expression; and advanced carcinomas express COX-2 but not 15-LOX-1. It possibly shows close association of the switching of LA-metabolizing pathways with colon cancer development and progression. In expression of 15-LOX-1, several conditions play an important role. Cytokines, such as IL-4 (►Interleukin-4) and IL-13, high ratio of ω-3/ω-6 fatty acids, and ►nonsteroidal antiinflammatory drugs (NSAID), such as sulindac sulfone induce 15-LOX-1 expression and activation of PPARγ. Reciprocally, activated PPARγ represses COX-2 by inhibition of NFκB (►Nuclear factor κB) and ►AP-1. This negative regulation of COX-2 expression by PPARγ activation might be one of mechanisms of reverse expression between 15-LOX-1 and COX-2. Furthermore, promoter DNA methylation is responsible for silencing of 15-LOX-1 expression (►Epigenetic gene silencing). The epigenetic alteration might be a trigger to switch 15-LOX-1 repression and COX-2 upregulation along with malignant transformation and cancer progression in colon cancer.

Excess uptake of LA increases cancer metastasis by enhancing cell embedding into the target organs. LA-derived TXA2 accelerates platelets aggregation involving cancer cells. LA also affects cancer cell activity. Short-term treatment with LA induces apoptosis in cancer cells. In the nude mice peritoneal dissemination model, LA treatment inhibits formation of peritoneal metastasis. In contrast, cancer cells exposed to LA for long-term show quiescent condition in vitro and dormancy in transplanted animals. In these cells, decrease of EGFR, VEGF (►Vascular endothelial growth factor), and increase of ►BCL-2 are observed. Thus, LA might play a role in formation of cancer cell dormancy and delayed metastasis.

In summary, the effects of LA on human health are still not clearly figured out. As LA is an essential fatty acid, we cannot cease LA uptake. In further studies, it is

important to make use of the beneficial side of the double-edged sword of LA for prevention and treatment of cancer.

Lipid Mediators

Ewa Ninio
INSERM UMRS, Université Pierre et Marie Curie-Paris, Paris, France

Synonyms

Lipid second messengers; Bioactive lipids

Definition

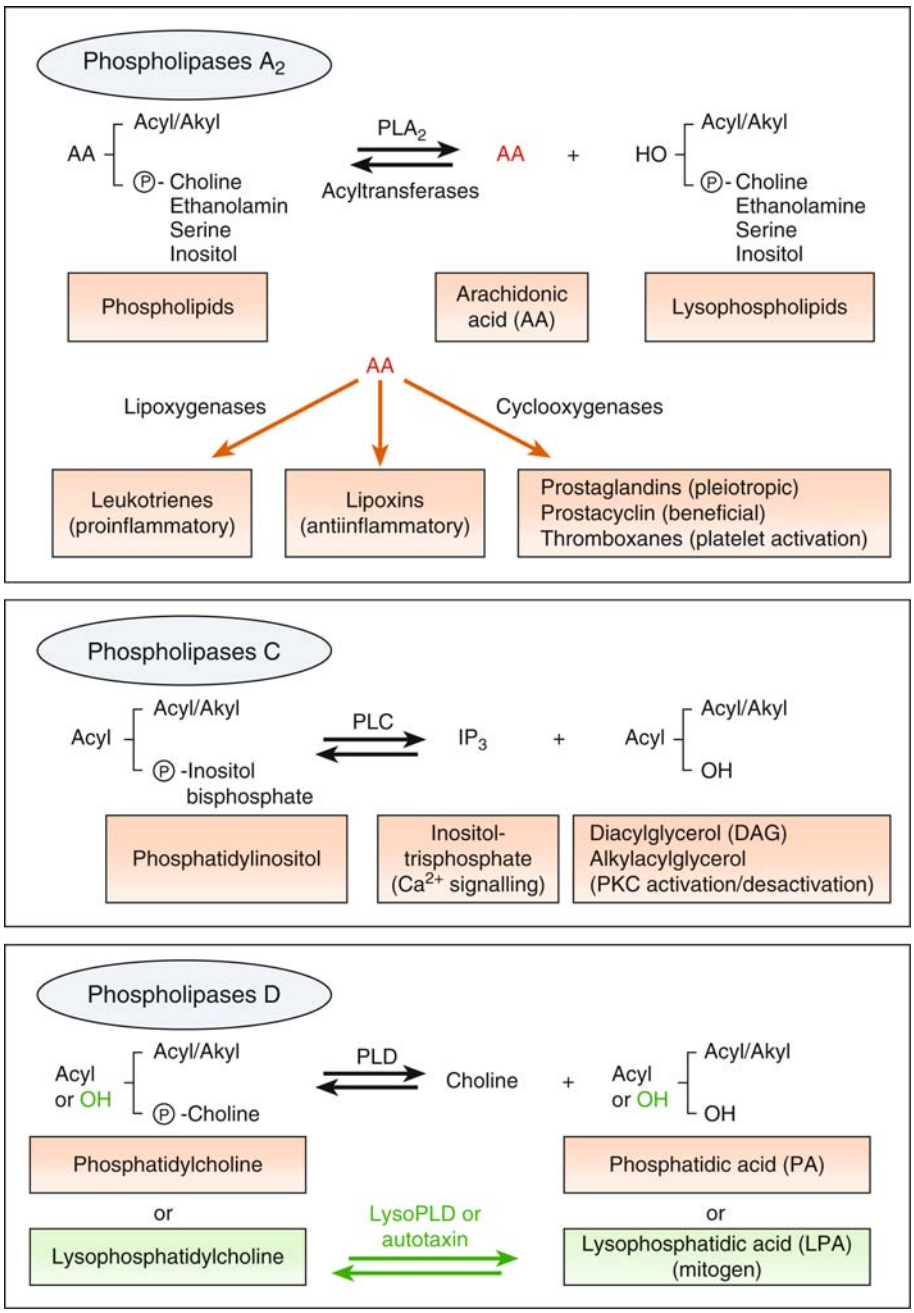
Lipid mediators are bioactive molecules rapidly produced upon cell activation either by enzymatic process or by oxidative fragmentation of polyunsaturated fatty acids attached to their glycerol backbone. The majority of lipid mediators are products of degradation and/or phosphorylation/dephosphorylation of glycerophospholipids by defined enzymes acting in concert and commonly designated as ►phospholipases (PLs), phosphokinases and phosphatases. Hydrolysis of ►phospholipids also generates free fatty acids, including arachidonate, a direct precursor of ►eicosanoids.

Characteristics

Within seconds after cell activation, certain phospholipids are either selectively hydrolyzed by defined phospholipases leading to highly bioactive molecules (lipids and/or fatty acids) or phosphorylated by specific kinases to bioactive ►phosphoinositides Inositol lipids. Essentially three phospholipase (PL) families, namely ►Phospholipase A2 (PLA2), ►Phospholipase C (PLC) and ►Phospholipase D (PLD) (Fig. 1) are involved in the degradation of structural phospholipids, leading either to direct formation of lipid mediators (►lysophosphatidylcholine in Cancer, ►inositoltrisphosphate (IP3) and ►diacylglycerol (DAG)) or to freeing of their immediate precursors (polyunsaturated fatty acids, including arachidonic (►Arachidonic acid-pathway and cancer) and ►Linoleic acid). Among PLA2s, the secretory group II PLA2 can produce (►Lysophospatidic acid (LPA) directly from phosphatidic acid. Recently described ►autotaxin, which is widely implicated in tumor progression, possesses lysoPLD activity and generates LPA from lysophosphatidylcholine (Fig. 1).

Free arachidonate, produced by degradation of phospholipids by PLA2, is a substrate for three major classes of lipid mediators (Fig. 1) (►Arachidonic acid-pathway and cancer): prostanoids/thromboxanes (►Prostaglandins), (►Leukotriene) and lipoxins, the latter being beneficial as they induce the resolution of the inflammatory response (►Inflammation). Upon (►Oxidative stress) arachidonate esterified to phospholipids at the sn-2 position of glycerol is oxidized either to ►isoprostanes, very potent proinflammatory mediators (►Bioactive lipid signaling) or to several ►oxidized phospholipids with xshort carbon chains resembling ►Platelet-activating-Factor (PAF) and endowed with potent capacity to modulate the immune response and (►Angiogenesis). Interestingly, an analogue of PAF containing a non-hydrolysable methyl group at the sn-2 position of glycerol, ►ET-18-OCH3 or edelfosine, is a selective antitumor phospholipid targeting (►Apoptosis) via endogenous activation of Fas/CD95 death receptor.

►Sphingolipids are a subclass of phosholipids which enter many metabolic pathways and constitute an interconnected network of signaling molecules with crucial roles in both cancer development and progression (►Cancer). ►Sphingomyelin, a structural phospholipid, is hydrolyzed by sphingomyelinases to a tumor suppressor lipid, ►ceramide, with proapoptotic and antiproliferative properties (Fig. 2) (►Ceramide). Ceramide may be either phosphorylated to ►ceramide-1-phosphate (C1P) with proinflammatory and antiapoptotic properties or may be degraded to ►sphingosine, a substrate for phosphorylation leading to S1P, a potent tumor-promoting lipid endowed with angiogenic and immunosuppressive properties. Additionally ceramide is glycosylated into ►gangliosides, bearing various sugars and endowed with highly tumorogenic properties (Fig. 2) (►Ganglioside). It is admitted today that the balance between the tumor suppressor molecule – ►ceramide – and its tumor-promoting metabolites is of prime importance in (►Carcinogenesis) and anticancer therapy.

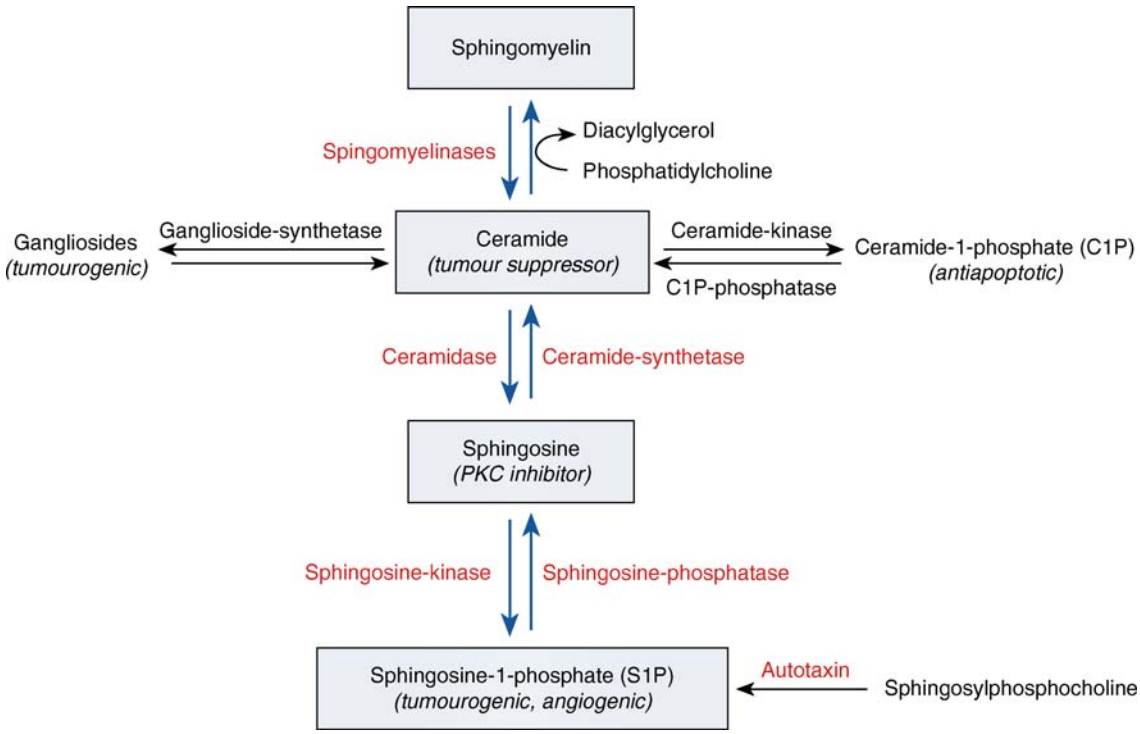


Lipid Mediators. Figure 1 Schematic representation of production of various lipid mediators by phospholipases.

►Conjugated linoleic acid (CLA), which is a mixture of positional and stereoisomers of octadecadienoate (18:2) found in foods derived from ruminants, may reduce carcinogenesis; however the data are still controversial. Equally, prostaglandin J2, which derives from oxidation of arachidonate by cyclooxygenases (COXs) is an emerging antineoplastic agent as it induces death receptor 5 (DR5), a specific ►receptor for TNF-related apoptosis-inducing ligand (TRAIL).

The majority of lipid mediators target distinct families of G-protein coupled receptors and activate vital cellular defenses usually defined as inflammatory reactions; however, some of these mediators, including LPA, modulate cell proliferation, growth, survival and (►Migration) enabling the expansion of defined cell subsets. LPA levels are elevated *in situ* and in circulation in ovarian tumors and in multiple myeloma, supporting its causal effect in proliferation and thus eventual use as a target and/or a diagnostic marker.

►Protein kinase C (PKC) isoformes are a family of serine/threonine protein kinases commonly divided into three subfamilies: classical, novel, and atypical. PKC



Lipid Mediators. Figure 2 Schematic representation of bioactive sphingolipid formation from sphingomyelin.

L

isoformes, whose expression is cell type-specific and developmentally regulated, are key transducers in many agonist-induced signaling pathways (►Protein kinase C family). At least ten different PKC isoforms have been identified and are believed to play distinct regulatory roles. PKC isoforms are catalytically activated by several lipid cofactors, including DAG generated by receptor-mediated hydrolysis of membrane phospholipids. IP3 triggers Ca^{2+} release from internal stores, and the elevation of cytosolic Ca^{2+} acts synergistically with DAG to activate the relevant forms of PKC. PKC isoforms reside in the cytoplasm in an inactive conformation and undergo translocation to the plasma membrane or cytoplasmic organelles upon cell activation; however, PKC isoenzymes are also capable of translocating to the nucleus and certain isoforms can even reside within the nucleus. Certain PKC isoforms are often overexpressed in cancer. Tumor promoting phorbol esters and DAG activate classical and novel PKC isoforms. Naturally occurring retinoids (►Retinoic Acid), antisense oligonucleotides against specific PKC isoforms and specific PKC inhibitors can block this activation. Beta carotene and retinoid derivatives act as anticarcinogenic agents and can antagonize some of the biological actions of phorbol esters and oxidants.

One of the major inositol-containing lipid second messengers, the ►phosphoinositide-3,4,5-trisphosphate (PIP3) (►Phosphoinositide-3,4,5-trisphosphate-kinases (PI3-kinases)) is generated by the action of PI3-kinases activated in response to a variety of extracellular signals (►PI3K Signaling). Phosphatase ►PTEN, one of the most frequently mutated genes in human cancer, acts as a tumor suppressor by dephosphorylating PIP3, thus preventing both elevated levels of PIP3 and tumorogenesis (►PTEN). Loss or inactivation of PTEN leads to the formation of a variety of tumors, probably by deregulating ►the mammalian target of rapamycin (mTOR) signaling pathway. As mTOR activity can be suppressed by various compounds, including (►Rapamycin), it may be useful to treat tumors carrying inactivated PTEN with such drugs.

Inflammation has been associated with cancer recently. Beside cytokines and chemiokines incriminated already, lipid mediators are also implicated since the discovery that cyclooxygenase-2 (COX-2) inhibitors (►coxibs) (►Celecoxib) slow the progression of colorectal cancer (►Cyclooxygenase-2 in colorectal cancer) and that the COX-2 levels are increased in several tumors (colon, breast, ovarian and melanomas); for this reason the gene encoding for COX-2 is now considered an (►Oncogene). Equally, the products of 5-lipoxygenase may play a role in human tumors (brain, skin). Finally, the relatively recently discovered ►oxidized phospholipids, the analogues of the mediator PAF, are involved in the induction of immune suppression and might be instrumental in inducing cancer.

Lipid Peroxidation

Aikaterini T. Vasilaki, Donald C. McMillan
University Department of Surgery, Royal Infirmary, Glasgow, UK

Definition

►Lipid peroxidation is the metabolic process in which ►reactive oxygen species (ROS) result in the oxidative deterioration of lipids. This may significantly affect cell membrane structure and function.

Characteristics

Lipid peroxidation most often affects ►polyunsaturated fatty acids, because they contain ►methylene -CH2- groups which contain hydrogen that is especially reactive with ROS. Increased ROS production occurs in inflammation, during radiation, or during metabolism of hormones, drugs and environmental toxins. This can overwhelm endogenous protective ►antioxidant mechanisms and increase ROS-mediated damage to membrane structure and function. Such ROS reactions can also lead to protein damage, including DNA repair enzymes and polymerases, impairment, and production of aldehyde by-products such as malondialdehyde (MDA; β-hydroxy-acrolein) and 4-hydroxy-2-nonenal (HNE). MDA is formed during homolytic decomposition of lipid hydroperoxides that contain more than two double bonds. MDA reacts with DNA to form primarily a propane adduct with 2′-deoxyguanosine (M1G-dR). Although they have important physiological roles in cell proliferation, transformation, differentiation and ►apoptosis these aldehydes are also strongly carcinogenic. Mutagenicity of MDA and HNE, the major aldehyde products has been clearly demonstrated. These can promote the formation of DNA-adducts which are required to be repaired in order to maintain the fidelity of the DNA. If not, DNA ►mutations can occur. For example, the reaction between the epoxide of HNE with DNA leads to the formation of unsubstituted ethenodAdo adducts. Etheno adducts are mutagenic and have been detected in human tissue samples providing an important link between lipid peroxidation and in-vivo DNA-adduct formation. Alternatively, lipid peroxidation and ROS are triggers and essential mediators of apoptosis, which eliminates precancerous and cancerous, virus-infected and otherwise damaged cells. This suppression of cell cancer growth is enhanced by prooxidants and eliminated by antioxidants, and this elimination is proportional to the inhibition of lipid peroxidation products by antioxidants. Lipid peroxidation may also play an important role in the potential anticarcinogenic effects of other dietary factors including soy, marine n-3 fatty acids, isothiocyanates, green tea and vitamin D and calcium.

Mechanisms

As with any radical reaction the reaction consists of three major steps: initiation, propagation and termination. Initiation is the step whereby a fatty acid radical is produced. The initiators in living cells are most notably ROS such as hydroxyl radical, which combines with a hydrogen atom to make water and a fatty acid radical. The fatty acid radical is not a stable ►molecule, so it reacts readily with molecular oxygen, thereby creating a peroxyl-fatty acid radical. This too is an unstable species that reacts with another free fatty acid producing a different fatty acid radical and a ►hydrogen peroxide molecule or a cyclic peroxide molecule if it had reacted with itself. This cycle propagates itself as the new fatty acid radical reacts in the same way. This results in a chain reaction and the only way to stop a radical reaction is for two radicals to react and produce a non-radical species. This occurs when the concentration of radical species is high enough for there to be a high probability of two radicals actually colliding. However, in organisms there are a number of different molecules which bind and quench free radicals and so protect lipids from oxidation. These are usually lipid soluble vitamins such as alpha-tocopherol or vitamin E.

ROS-mediated formation of lipid hydroperoxides involves the initial abstraction of a bis-allylic methylene hydrogen atom. Lipid hydroperoxides can also be formed by the action of cyclooxygenases and lipoxygenases on polyunsaturated fatty acids (PUFAs). LOX and COX-mediated pathways of PUFA metabolism can potentially provide a rich source of lipid hydroperoxides.

Clinical Aspects

Chronic inflammation, part of the host immune response, has long been recognised to be associated with the development and progression of cancer. The combination of excess oxidant production and antioxidant depletion, and therefore, oxidative stress, may play a role in the development and progression of cancers. High ROS generation and persistent oxidative stress have been recognised as characteristics features of carcinoma cells both in vivo and in vitro. Also, it is widely accepted that patients with advanced cancer have reduced circulating antioxidant concentrations.

Therefore, in the cancer patient the risk for structural and functional damage of cell membranes is likely to be increased. Higher levels of circulating plasma MDA have been observed in different malignancies, including lung, gastrointestinal and hormone dependent cancers. However, whether such increased MDA concentrations are primarily due to the tumour, the ►inflammatory response or some other factors remain to be determined.

Lipoma

Definition

Is a benign neoplasm of adipose tissue. One of the most common soft tissue tumors in men and form part of the daily practice of every surgical pathologist. Like fat, lipomas are mainly composed of mature fat cells, but the cells vary slightly in size and shape and are somewhat larger. The tumors are usually thinly encapsulated and have a distinct lobular pattern. A minority of all lipoma patients has multiple lesions, but most patients only have one tumor. Most of these solitary lipomas cause few problems other than those of a localized mass.

►Cowden Syndrome

Lipoma Preferred Partner

Marleen M. R. Petit
Department of Human Genetics, University of Leuven, Leuven, Belgium

Synonyms

LIM domain containing preferred translocation partner in lipoma; LPP

Definition

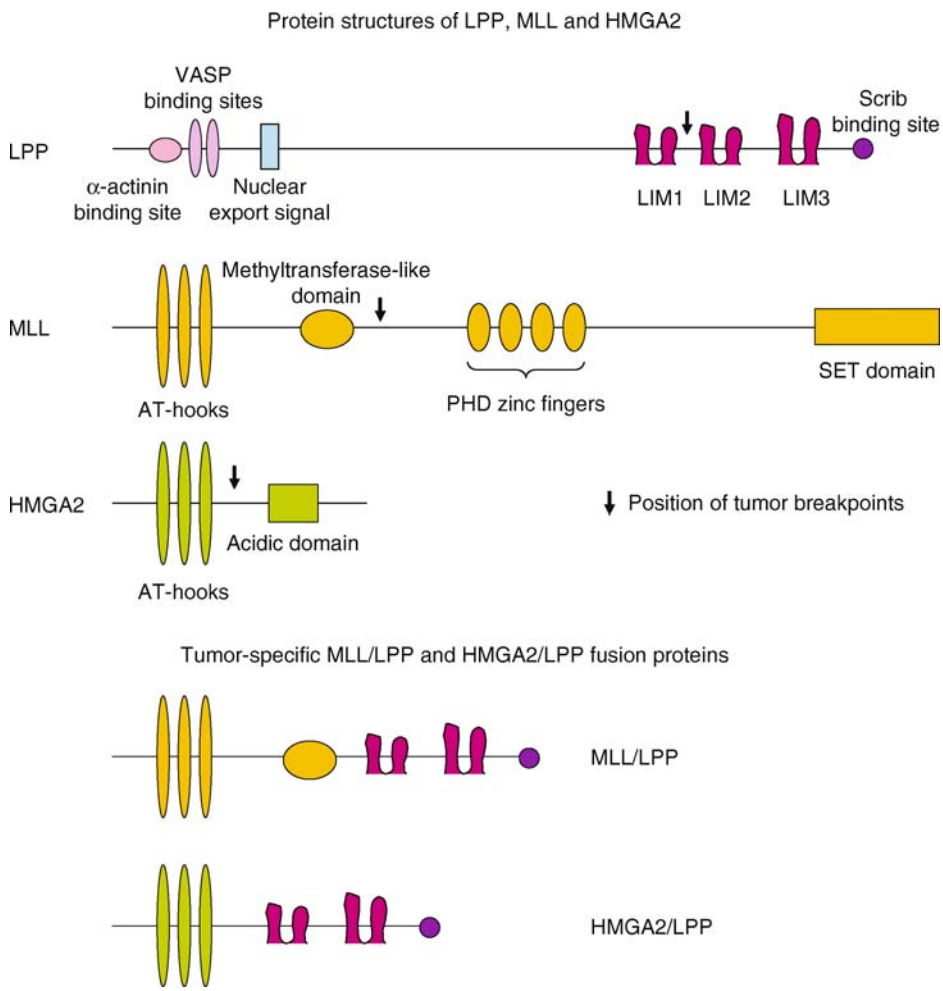
Lipoma preferred partner (LPP) is a ►LIM domain protein that belongs to the ►zyxin family of cytoskeletal

adaptor proteins. LPP is localized in cellular adhesion sites and is in certain conditions also detected in the nucleus where it acts as a transcriptional co-activator. It is highly expressed in smooth muscle cells and plays a role in cell migration. In particular tumors, aberrant LPP proteins are expressed in which the LIM domains are fused to DNA-binding domains. These tumor-specific LPP fusion proteins function as transcription factors.

Characteristics

LPP and Tumors

►Lipomas are benign tumors of adipose tissue and one of the most commonly occurring soft tissue tumors in humans. A minority of patients has multiple tumors, however most patients have only one tumor. More than 60% of human solitary lipomas have an abnormal ►karyotype. Two thirds of the latter carry chromosomal aberrations, mostly translocations, involving chromosomal region 12q15. The gene on 12q15 that is affected by these translocations is ►HMGA2. The HMGA2 protein consists of three AT-hooks (DNA binding domains) followed by an acidic carboxyterminal tail (see Fig. 1). By means of the translocation, the DNA binding domains are separated from the acidic tail. Multiple chromosomes have been identified as translocation partner of 12q15 in lipomas by cytogenetic analysis, indicating that many different genes are able to act as translocation partner of HMGA2 in these tumors. However, in a quarter of the cases, chromosome 3 at bands q27-q28 is found as the translocation partner of chromosome region 12q15. This means that the most consistent chromosomal aberration in lipomas is represented by t(3;12)(q27-q28;q15), being present in about 10% of all solitary lipomas. In 1996, the gene on 3q27-28 that is affected by the t(3;12) was discovered in the lab of Wim Van de Ven from the University of



Lipoma Preferred Partner. Figure 1 Upper part: Schematic representation of the LPP, MLL and HMGA2 proteins. Lower part: Schematic representation of the tumor-specific MLL/LPP and HMGA2/LPP fusion proteins.

Leuven, Belgium and named "*LPP*" for "lipoma preferred partner." After publication, the HUGO gene nomenclature commission advised to change the name of LPP in "LIM domain containing preferred translocation partner in lipoma." Indeed, the LPP protein contains three LIM domains in its carboxyterminus that are preceded by a proline-rich pre-LIM region (Fig. 1). Through the t(3;12), an *HMGA2/LPP* fusion gene is created encoding an HMGA2/LPP fusion protein consisting of the three DNA-binding domains of HMGA2 followed by the two most carboxyterminal LIM-domains of LPP (see Fig. 1). Fusion transcripts encoding identical HMGA2/LPP fusion proteins have also been detected in others tumors including pulmonary chondroid hamartomas, a ►parosteal lipoma, and a soft tissue chondroma. The HMGA2/LPP fusion protein localizes in the nucleus of cells and is a tumor-specific transcription factor: it binds DNA in the promoter of its target genes with the DNA-binding domains of HMGA2 and activates transcription through the LIM domains of LPP. In addition to benign tumors, rearrangements of the *LPP* gene have also been found in a case of malignant secondary acute monoblastic leukemia with a t(3;11)(q28;q23). In the latter, the two most carboxyterminal LIM domains of LPP are fused to the AT-hooks (DNA binding domains) of the mixed lineage leukemia (►MLL) protein (see Fig. 1). As such, as well in benign as in malignant tumors, tumor-specific fusions proteins are composed of AT-hooks, either from HMGA2 or from MLL, and LIM domains from LPP.

Cell Biological Characteristics of the LPP Protein

LPP is a member of the zyxin family of LIM domain proteins, which consists of seven members: zyxin, TRIP6/►ZRP1, LPP, ►ajuba, ►LIMD1, ►WTIP, and ►migfilin/Cal. LPP is most closely related to zyxin and ►thyroid receptor interacting protein 6 (TRIP6). All members of the zyxin family contain a proline-rich region (in LPP this region covers the amino-terminal 2/3 of the protein), which is followed by three LIM domains. LPP contains multiple protein-protein interaction domains. Known binding partners include the cytoskeletal proteins α-actinin, VASP (vasodilator-stimulated phosphoprotein) and palladin, the ETS domain transcription factor PEA3, and the tumor suppressor Scrib. In addition, LPP probably also interacts with a number of yet unidentified proteins that bind its three carboxyterminal LIM domains, which are modular protein binding interfaces.

In cultured fibroblasts and aortic SMCs, LPP colocalizes with vinculin at focal adhesions, which are attachment sites to the extracellular matrix. The three LIM domains of LPP cooperate to target the protein to these adhesion sites. LPP is also found in cell-cell contacts, and in transverse sections of bladder smooth muscle, an association of LPP with peripheral dense bodies is suggested. In addition to these cytoskeletal localizations, LPP also shuttles to the nucleus. Its nuclear-cytoplasmic localization is regulated in part by a nuclear export signal (NES) which is sensitive to the drug leptomycin B.

LPP as a Transcriptional Coactivator

In 2006, the lab of Andy Sharrocks from the University of Manchester, U.K., discovered a nuclear function for LPP as a coactivator for ►PEA3. PEA3 is an ETS domain transcription factor whose expression is regulated by a number of signaling cascades, including the mitogen-activated protein (MAP) kinase pathways. PEA3 is a transcriptional activator and regulates transcription of multiple genes, including the matrix metalloproteases (MMPs) MMP-1 and MMP-9. MMP's are enzymes that degrade the extracellular matrix during normal remodeling events and cancer metastasis. PEA3 is expressed during normal mammary gland development and is an important player in breast tumor metastasis. Also LPP is expressed in normal and cancerous breast tissue, and is recruited to the MMP-1 promoter in a PEA3-dependent manner.

LPP as a Smooth Muscle Marker

In 2003, two independent laboratories (the Somlyo lab from the University of Virginia, USA and the Lindahl lab from the University of Göteborg, Sweden) identified LPP as a novel smooth muscle cell marker. Although, in adults, LPP is ubiquitously expressed, it is highly expressed in vascular as well as visceral smooth muscle-containing tissues such as uterus, stomach, bladder, aorta and portal vein. Concerning the function of the LPP protein in smooth muscle cells, LPP is involved in the regulation of their migration, as shown in in vitro experiments.

Liposomal Chemotherapy

Mirco Ponzoni
Differentiation Therapy Unit, Laboratory of Oncology, G. Gaslini Children's Hospital, Genoa, Italy

Synonyms

Drug delivery vehicles; Drug carriers

Definition

The central problem in cancer chemotherapy (►Chemotherapy of cancer, progress and perspectives) is the severe toxic side effects of anticancer drugs on healthy tissues. The use of ►liposomes as drug delivery vehicles (►Drug delivery systems in cancer) for antitumor therapeutics has great potential to revolutionize the future of cancer therapy. As tumor architecture causes liposomes to preferentially accumulate at the tumor site, their use as drug carrier result in the localization of a greater amount of the drug load at the tumor site, thus improving cancer therapy and reducing the harmful nonspecific side effects of chemotherapeutics. In addition, targeting of liposomal anticancer drugs to antigens expressed or overexpressed on tumor cells provides a very efficient system for increasing the therapeutic indices of the drugs.

Characteristics

The Magic Bullet Concept

Within medical practice, there has long been the desire to achieve selective delivery of drugs to specific areas in the body in order to maximize drug action and minimize side effects. It is well-known that many drugs, while having a beneficial action, can also exhibit deleterious effects that may limit their clinical utility. Drugs used in cancer chemotherapy represent a clear example of this problem. Cytotoxic compounds can kill target cells, but also normal cells in the body.

The ►magic bullet concept, first expounded by the German physician Paul Ehrlich, represents an early description of the drug-targeting paradigm. Indeed, about one century ago Ehrlich coined the word "chemotherapy" to indicate the possibility to design and produce, by chemical synthesis, drugs, the so-called "magic bullets" as they were able to kill infectious agents

without affecting the human body. However, at that time, the recipe for the synthesis was based on four "G": Geld (money), Geduld (patience), Geschick (skill), and Glùck (luck). Indeed, until the last decade of the twentieth century, the most impressive progression in discovery of new chemotherapeutics has been due to "serendipity."

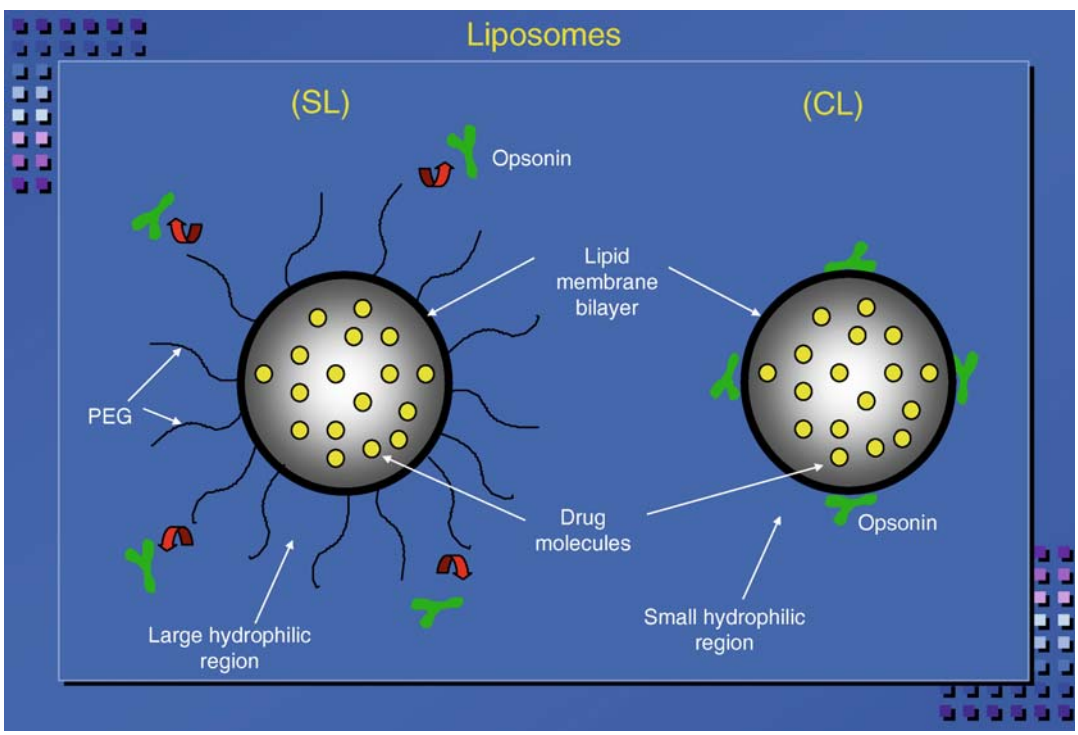
Drug Delivery Technology

The medical community has recently sought alternative therapies that improve selective toxicities against cancer cells. Nanobiotechnology, defined as biomedical applications of nano-sized systems, is a rapidly developing area within ►nanotechnology. ►Nanoparticles, such as liposomes, allow unique interaction with biological systems at the molecular level. They can also facilitate important advances in detection, diagnosis, and treatment of human cancers and have led to a new discipline of nano-oncology. Nanoparticles are being actively developed for tumor imaging in vivo, biomolecular profiling of cancer biomarkers, and targeted drug delivery.

Sterically Stabilized (Stealth) Liposomes

Several nanotechnological approaches have been used to improve delivery of chemotherapeutic agents to cancer cells with the goal of minimizing toxic effects on healthy tissues while maintaining antitumor efficacy. Among the most popular and well-investigated drug carriers are liposomes. Conventional liposomes (CL), first described by professor Alec D. Bangham in 1965, are made up of amphiphilic phospholipids and cholesterol, which, upon hydration, self-associate to form bilayers surrounding an aqueous interior (Fig. 1). Liposomes are artificial phospholipid vesicles with sizes varying from 50 to 1,000 nm, which can be loaded with a variety of water-soluble drugs (into their inner aqueous compartment) and sometimes even with water-insoluble drugs (into the hydrophobic compartment of the phospholipid bilayer).

One of the major drawbacks of conventional liposomes has been their rapid clearance from blood, due to adsorption of plasma proteins (opsonins) to the "naked" phospholipid membrane, triggering recognition and uptake of the liposomes by the mononuclear phagocytic system (MPS), also referred to as the reticuloendothelial system (RES). A major advance in the field of liposomes came with the development of sterically stabilized (Stealth®) liposomes (SL), which utilize a surface coating of a hydrophilic carbohydrate or polymer, usually a lipid derivative of polyethyleneglycol (PEG), to help evade MPS recognition (Fig. 1). The inclusion of PEG or other hydrophilic polymers extends the half-life of liposomes from less than a few minutes (classical liposomes) to several hours (Stealth liposomes).



Liposomal Chemotherapy. Figure 1 Comparison of the chemical structure of second generation liposomes (sterically stabilized, SL) liposomes.

Both conventional and Stealth liposomes rely on "passive" targeting to increase the localization of anticancer drugs to solid tumors. Growing solid tumors, as well as areas of infection and inflammation, have capillaries with increased permeability as a result of the disease process (e.g., tumor ►angiogenesis). Pore diameters in these capillaries can range from 100 to 800 nm. Drug-containing liposomes that have diameters in the range of approximately 50–200 nm are small enough to extravasate from the blood into the tumor interstitial space through these pores (►extravasation). Normal tissues contain capillaries with tight junctions that are impermeable to liposomes and other particles of this diameter. This differential accumulation of liposomal drugs in tumor tissues relative to normal cells is the basis for the increased tumor specificity of liposomal drugs relative to free drugs. In addition, tumors lack lymphatic drainage and therefore there is low clearance of the extravasated liposomes from tumors.

Passive targeting can result in increases in drug concentrations in solid tumors of several-fold relative to those obtained with free drugs. The mechanism of action of the liposomal drugs is thought to be due to sustained release of drug from the liposomes and diffusion of the released drug throughout the tumor interstitial fluid, with subsequent uptake of the released drug by tumor cells. This phenomenon has been termed the enhanced permeability and retention effect (►EPR).

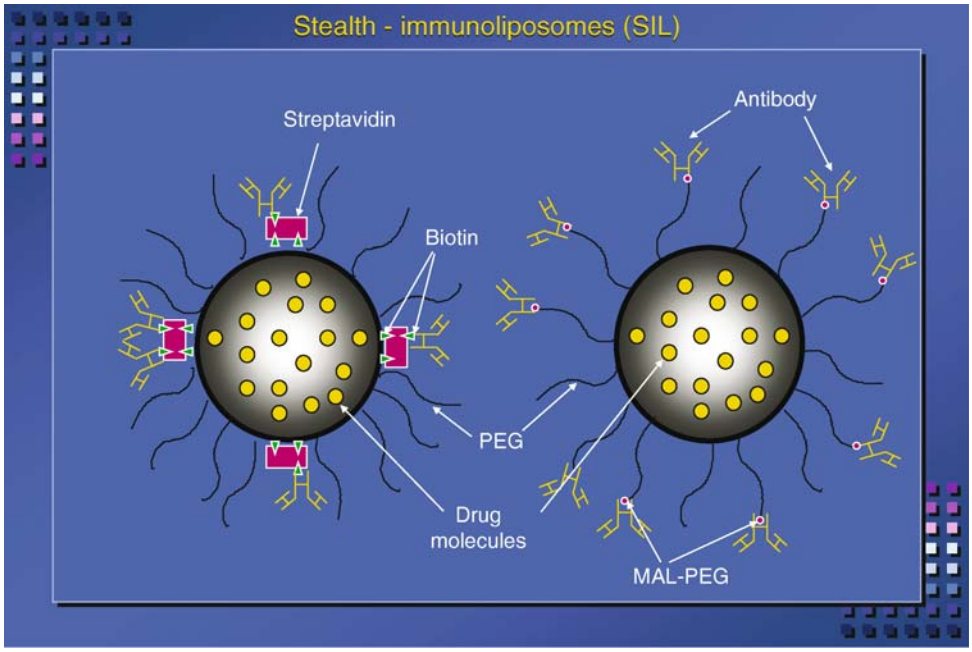
Liposomal formulations of few ►anthracycline anticancer drugs have received clinical approval. Three liposomal chemotherapeutic agents, all of which are nanoparticles measuring about 100 nm, are indeed being assessed in human cancer: liposomal daunorubicin, (Daunosome®), approved in the USA and Europe to treat AIDS-related Kaposi's sarcoma; liposomal doxorubicin, Myocet®, which, in combination with cyclophosphamide, is approved for the treatment of metastatic breast cancer in Europe; and pegylated liposomal doxorubicin, Doxil®/Caelyx®, approved for both Kaposi's sarcoma, refractory ovarian cancer, and metastatic breast cancer in Europe and USA. In addition, many other liposomal anticancer drugs are in clinical trials (i.e., liposomal cytosine arabinoside, Depocyt®, for the treatment of lymphomatous and neoplastic meningitis, liposomal cisplatin for patients with malignant pleural mesothelioma, sphingosomal vincristine for treatment of recurrent or refractory adult acute lymphocytic leukemia, liposomal muramyltripeptide phosphatidylethanolamine for patients with osteosarcoma).

Ligand-Targeted Stealth Liposomes

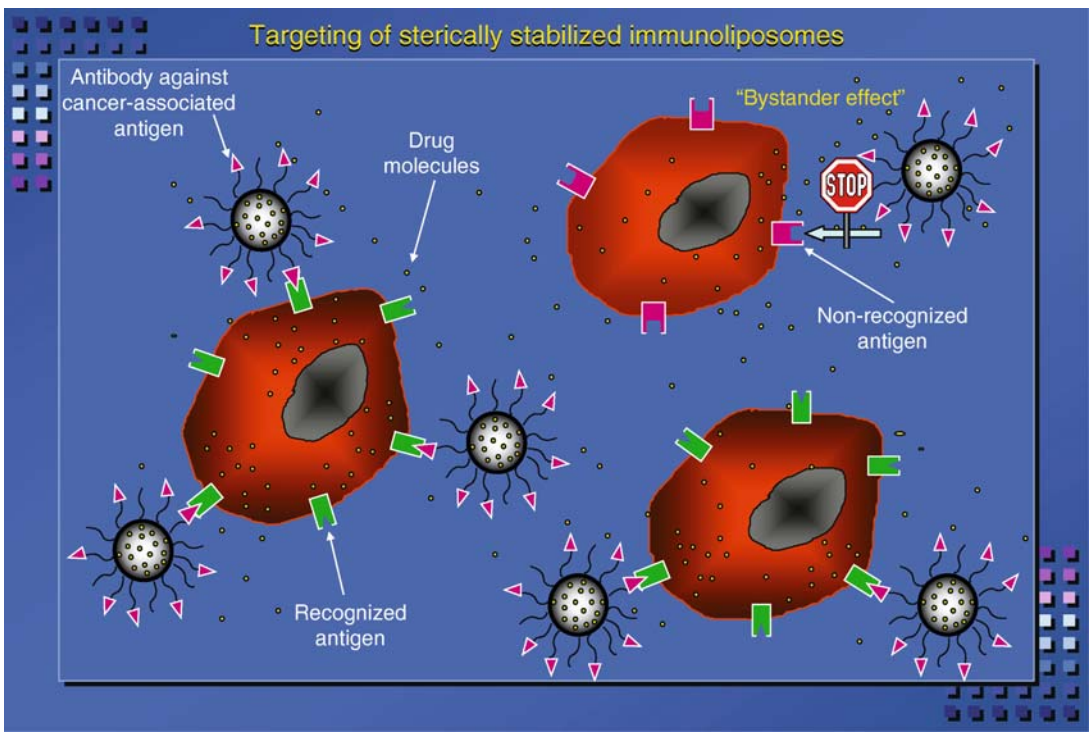
In the attempt of increasing the specificity of interaction of liposomal drugs with target cells and the amount of drug delivered to latter, recent efforts in the liposome field have been addressed to the development of ligand-targeted liposomes. These liposomes utilize targeting moieties coupled to the liposome surface to selectively deliver the drug–liposome package to the desired site of action (active targeting). Targeting moieties may include antibody molecules, or fragments thereof, small molecular weight, naturally occurring or synthetic ligands like peptides, carbohydrates, glycoproteins, or receptor ligands, i.e., essentially any molecule that selectively recognizes and binds to target antigens or receptors overexpressed or selectively expressed on cancer cells.

To date, liposomes chemically coupled to antibodies or antibody fragments have been the most extensively used ligand-targeted Stealth liposomes (stabilized ►immunoliposomes or SIL) (Fig. 2). This chemical complexation can be either noncovalent or covalent in nature. In the former case a biotin–streptavidin–biotin bridge between the liposome and the antibody is involved, while covalent binding can be achieved through the use of heterobifunctional cross-linkers or maleimide-derivatized PEG–lipid complexes (PEG–MAL). The great advantages of SIL encapsulating cytotoxic drugs over free drugs have been unquestionably demonstrated in a number of experimental models of cancer. The mechanism whereby SIL appears to act is related to localized release of the encapsulated drug at the targeted cell surface following binding of the drug carrying liposomes to the cell. With some particular antibodies, moreover, internalization of the liposomal drug package may occur and also contribute to the mechanism of cytotoxicity. Interestingly, it has been shown that approximately 400-fold more monoclonal antibody was required to achieve similar results with antibody–drug conjugates. Hence, high drug:antibody ratios can be achieved with SIL, thus decreasing the need for expensive and potentially immunogenic antibodies. Since most tumors are heterogeneous with regard to tumor-associated antigen expression, another advantage may be the "►bystander effect": specific binding of a SIL to a tumor cell, with release and diffusion of the drug and uptake by surrounding tumor cells may result in cytotoxicity of bystander cells lacking the specific epitope (Fig. 3).

In conclusion, liposomal formulation of chemotherapeutic drugs is considered a very promising modality of drug delivery because liposomes are biologically inert and completely biocompatible, they do not cause toxic or antigenic reactions, and the drugs included into liposomes are protected from the destructive action of the external environment. Association of drugs with carriers, such as liposomes has pronounced effects on the ►pharmacokinetic profile of the drug resulting in delayed ►drug absorption, restricted drug biodistribution, decreased volume of drug biodistribution, delayed drug clearance, and slower drug metabolism.



Liposomal Chemotherapy. Figure 2 Immunoliposomes: Liposomes chemically.



Liposomal Chemotherapy. Figure 3 Mechanisms of drug delivery of immunoliposomes: specific targeting to tumor cells.

Future Perspectives for Liposomal Chemotherapy

Monotherapy is not common in chemotherapy. A combination of drugs generally produces better therapeutic results. The rationale for use of multiple agents takes into consideration the heterogeneity of the tumor cells and differences in tumor cell sensitivity to individual drug classes. Treatment strategies generally include drugs with different mechanisms of action and

nonoverlapping side effects in order to attain maximum therapeutic benefit. The evaluation of targeted liposomes using drug or ligand combinations is only beginning to be explored, e.g., targeting either the same liposomal drug against different epitopes, targeting different drugs against the same epitope, or targeting different drugs against different epitopes. Combinations of liposomal drugs might also help to lower drug dosages and increase responses, which could help reduce drug toxicities. Given the exhaustive possibilities available to liposome chemistry, research will be quickly directed at multi-functional liposomes, combining tumor-targeting and tumor therapy in an all-in-one system, providing a useful multi-modal approach in the battle against cancer.

Liposomes

Definition

Are artificial lipid bilayer vesicles formed from an aqueous suspension of phospholipids and cholesterol. These vesicles can be used to incorporate water-soluble materials, including drugs, proteins, and nucleic acids, enabling the delivery of such molecules to various cells. Synthetic cationic lipids can be used to form electrically charged (cationic) liposomes, which show robust association with DNA and enhance the efficiency of its delivery to target cells.

Liver Cancer – Molecular Biology

Marie Annick Buendia
Oncogenesis and Molecular Virology Unit, Inserm U579, Institut Pasteur, Paris, France

Definition

Primary liver cancer includes four major histological tumor types. The most frequent form is hepatocellular carcinoma (HCC), a malignant epithelial neoplasm that develops from hepatocytes, the basal liver parenchymal cells. Hepatoblastoma is a rare embryonic liver tumor arising from immature hepatocytes, mainly in children under 2 years of age. Cholangiocarcinoma (CC) develops from the epithelium of intrahepatic biliary ducts, and angiosarcoma is a rare malignant mesenchymal (vascular) tumor. This chapter presents only the molecular biology of HCC.

Characteristics

Epidemiology

Liver cancer is one of the most common human cancers worldwide, with an estimate of 626,000 new cases diagnosed each year, and incidence is continuously rising in America and Europe. It ranks fifth in frequency in the world in terms of relative cancer incidence rates, but it shows heterogeneous geographical distribution, with the highest rates in Asia and Africa. HCC develops more frequently in males than in females, sex ratios ranging between 1.5 and 3 in most countries. It occurs predominantly in the second half of life, with increasing incidence between the ages of 40 and 80. Generally, HCC arises in the context of extensive liver lesions, including liver cirrhosis in 80% of cases, or chronic hepatitis.

Etiology

HCC is one of the few human neoplasms seroepidemiologically related to viral infections. More than 80% of HCC cases worldwide are associated with chronic infection with hepatitis B virus (HBV) (►hepatitis viruses) or ►hepatitis C virus (HCV). Other major risk factors include alcoholic cirrhosis, dietary intake of aflatoxin B1, a fungal metabolite which contaminates crops in some tropical areas, and inherited metabolic disorders such as tyrosinemia, hemochromatosis, and α1-antitrypsin deficiency. Recently, diabetes and obesity have also been recognized as significant etiological factors of HCC. The risk of developing HCC is greatly increased in chronic viral carriers exposed to other recognized risk factors, including aflatoxin B1, alcoholic cirrhosis, and diabetes.

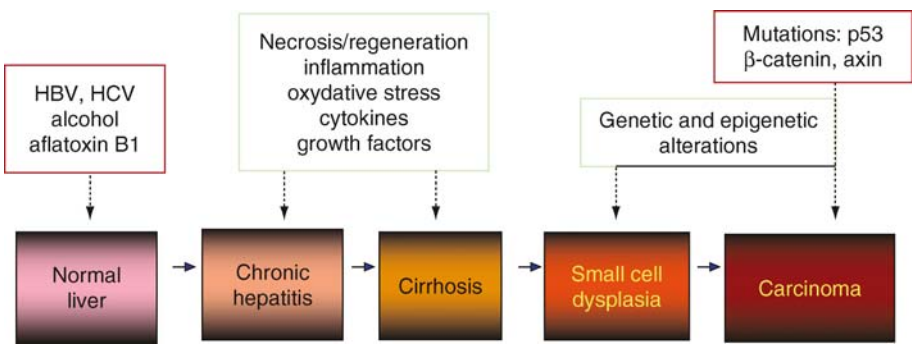
Role of Viral Factors

In HCC as in other human tumors, multiple steps involving independent lesions are required to reach the fully malignant phenotype. Chronic HBV infection plays a complex role in liver carcinogenesis, involving various cooperative mechanisms (Fig. 1).

Following liver injury by viral infections (HBV or HCV) or by excessive intake of alcohol or aflatoxin B1, a long period of necroinflammatory liver disease is generally followed by liver cirrhosis. Small cell dysplastic nodules are considered as direct precursor lesions of HCC. Accumulation of genetic and epigenetic changes, including mutations of the p53 and ►axin 1 tumor suppressors or the β-catenin oncogene lead to the fully malignant phenotype.

Direct Mutagenic Role

HBV DNA frequently integrates into host cell chromosomes. HBV integrations seem to occur randomly over the entire human genome, with no preferential site. Viral DNA integration is frequently associated with gross genetic alterations such as chromosomal translocations, deletions, or amplifications of large chromosomal regions. Therefore, it may promote genomic destabilization, in turn favoring the accumulation of genetic mutations at early steps of HCC development. Insertion of HBV DNA into cellular genes and



Liver Cancer – Molecular Biology. Figure 1 The multistep process of liver carcinogenesis.

subsequent modification of target gene expression or function (a process called ►insertional mutagenesis) is another potential oncogenic mechanism. Initial studies of four independent HCC cases identified viral DNA integration sites within cellular genes that play important roles in the control of cell growth, differentiation, or viability: retinoic receptor-beta, cyclin A2, mevalonate kinase, and SercA1 genes. These tumors produce viro-cellular chimeric proteins endowed with transforming capacities. The recent development of PCR-based technologies for rapid isolation of viral integration sites has allowed to better evaluating the prevalence of such oncogenic insertional events. Large scale analysis of HBV integration sites provided evidence for viral integration into transcribed regions in 62% of cases and for recurrent insertion sites in the human telomerase (hTERT) and mixed lineage leukemia (MLL) genes.

Another argument favoring a direct tumorigenic role of HBV comes from studies of animal models for virally induced liver cancer. Woodchucks chronically infected with the woodchuck hepatitis virus (WHV), a hepadnavirus closely related to HBV, develop frequent and early onset HCC. WHV DNA is found integrated in the vicinity of an oncogene of the ►*MYC* family (either *MYC* or ►*MYCN*) in more than 80% of woodchuck liver tumors. *MYC* genes act as important regulators of cell growth, death, and differentiation, and their abnormal expression has been implicated in the genesis of multiple human neoplasms. The critical role of WHV DNA integration in *MYC* oncogenes has been demonstrated in transgenic mice recapitulating the multistep process of liver carcinogenesis.

Oncogenic Potential of the HBx Transactivator

The HBV regulatory protein X (HBx) has pleiotropic functions and it can interfere with multiple cellular pathways controlling cell cycle, proliferation, DNA repair, and apoptosis. In particular, HBx has been reported to modulate calcium homeostasis, mitochondrial functions, proteasome activity, and signal transduction pathways. Described as a weak transcriptional activator, HBx exerts its functions by interacting with a variety of cellular partners such as DDB1 (a subunit of the Cul4A ubiquitin ligase complex), the histone acetyltransferases CBP/p300, and p53. In transgenic mouse strains, liver expression of HBx can either induce liver cancer or act as a cofactor and a tumor promoter in liver carcinogenesis.

Immunopathogenesis

There is a general consensus that hepatocellular damage in human hepatitis B is caused by the host immune response and not by the viral replication itself. Transgenic mouse models have provided evidence for an indirect role of HBV in cancer formation. Sustained viral replication and expression of most viral genes in the liver can be achieved in HBV transgenic mice with no pathological consequence. However, sustained expression of the large envelope protein of HBV in the mouse liver induces a process of necrosis and regeneration which ultimately leads to malignant transformation. Moreover, stimulation of cellular immune responses in mice transgenic for the HBV surface antigen (HBsAg) leads to frequent emergence of liver tumors. Thus, an important factor in tumorigenesis is the accelerated turnover of infected hepatocytes resulting from continuous cell death triggered by the host immune response and subsequent cell proliferation. Hepatocyte DNA lesions during persistent HBV infection may be induced by exposure to mutagenic products secreted by inflammatory cells, endogenous production of mutagens such as oxygen free radicals and nitrosamines, and impaired detoxification pathways or DNA repair mechanisms.

Chromosomal Aberrations

In the recent years, global insights into chromosomal alterations profiles have been provided by genetic studies of large sets of tumors. These studies have shown that a large variety of genetic and epigenetic alterations are present in different combinations among individual HCC cases. Therefore, HCC might rank among the most complex and heterogeneous types of human solid tumors, which is consistent with the multiple etiologies of HCC and the long period of chronic inflammatory disease that fosters accumulation of genetic and epigenetic defects.

Studies using PCR-based microsatellite marker analysis (MSA) and Comparative Genomic Hybridization (CGH) have identified the major genetic changes in HCC of various geographical and etiological origins. In MSA studies, the highest percentages of allelic deletions (LOH: ►loss of heterozygosity) were found at chromosomes 8p23, 4q22–24, 4q35, 17p13, 16p13–15, 16q23–24, 6q27, 1p36, and 9p12–14. The relative frequency of allelic losses may vary with the associated risk factors, implying that viral and chemical agents implicated in liver cancer may preferentially select some pathways rather than others. Importantly, genomic instability has been found at higher rates in HBV-related tumors than in tumors associated with HCV or other risk factors. CGH studies have confirmed prevalent chromosomal losses and demonstrated frequent DNA copy gains at 8q, 1q, 6p, and 17q.

Moreover, specific chromosomal gains and losses were found to occur at different stages of tumor progression, suggesting nonrandom chromosomal gains and losses occuring in an orderly fashion in liver cancer. The recent development of array-based CGH might allow more accurate evaluation of chromosomal changes and identification of cancer-related genes located on affected chromosomal arms.

In addition to genetic mutations, epigenetic mechanisms such as hypermethylation of promoters containing CpG island have been shown to modify gene expression patterns in HCC. A number of tumor suppressor genes including $p16^{INK4A}$, SOCS-1, APC, RASSF1A, GSTP1, and E-cadherin, are silenced by DNA methylation in a large proportion of liver tumors, and this process often starts at preneoplastic (cirrhotic) stages.

Tumor Suppressor Genes and Oncogenes

►*P53 is probably the most common molecular target involved in human carcinogenesis*. The p53 tumor suppressor protein is activated in response to DNA damage, inducing either cell cycle arrest to permit DNA repair, or apoptosis. Loss of p53 function occurs mainly through allelic deletions at chromosome 17p13, where the gene is located, and missense mutations within the DNA-binding domain. In HCC, LOH at chromosome 17p13 has been observed in 25–60% of tumors in different studies, and the worldwide prevalence of p53 mutations can be estimated to around 28%, with however important geographical variations. It is now well established that a mutation at codon 249 of the p53 gene is frequent in some regions of Africa (Mozambique, Senegal) and the southeast coast of Asia (Qidong, Vietnam) where chronic HBV infection is highly endemic and the aflatoxin B1 content of the diet is high. Thus, the specific "hot spot" 249 mutation appears to be a hallmark of dietary exposure to aflatoxin B1. In other countries, p53 mutations are seen at lower rate, and they are distributed over the coding exons.

The Retinoblastoma Gene. Allelic deletions at chromosome 13q14 have been associated with the inactivation of the RB tumor suppressor gene (►RB1). RB has been implicated in cell cycle control, and disruption of the RB pathway renders cells insensitive to antiproliferative signals. In liver cancer, LOH at the RB locus has been found in 25–48% of cases, and RB expression is strongly downregulated in 30–50% of tumors. While no mutation of the RB gene itself has been documented, inactivation of the RB pathway is achieved mainly by methylation-dependent silencing of $p16^{INK4}$, an inhibitor of cyclin-dependent kinases which blocks the cell cycle. In addition, overexpression of gankyrin, a new oncogene homologous to a subunit of the 26S proteasome, promotes RB degradation by the ubiquitin–proteasome pathway.

β-Catenin. Activation of the Wnt pathway has been implicated in liver oncogenesis by the finding of frequent mutations in the β-catenin gene. β-catenin is an important multifunctional protein involved in cell–cell adhesion and in transduction of differentiation signals during embryogenesis. Mutations in the β-catenin gene have been detected in about 22% of liver tumors. All mutant forms of β-catenin harbor missense mutations or short deletions in the amino-terminal domain (so-called "destruction box") and they are resistant to degradation. Thus, wild type β-catenin is expressed at the cell membrane in normal epithelial cells, whereas the mutants accumulate in the cytoplasm and nucleus of tumor cells. In about 7% of HCC cases, activation of β-catenin is also achieved in HCC by loss-of-function mutations of axin 1, a tumor suppressor protein known to bind β-catenin and promote its degradation. In contrast with colorectal cancer, another β-catenin partner, the adenomatous polyposis coli (►APC) tumor suppressor gene, is not mutated in HCC. Interestingly, β-catenin mutations are less frequent in HBV-related HCCs than in HCV-related or nonviral HCCs. No mutation of β-catenin could be evidenced in intrahepatic cholangiocarcinoma.

TCF1. The finding of frequent LOH at chromosome 12q24.2 in hepatocellular adenomas has led to identify mutations and bi-allelic inactivation of the TCF1 gene encoding the liver-enriched HNF1-α transcription factor. This finding links MODY 3 diabetes to benign liver tumors, and also occasionally to HCC.

►*Ras Family Oncogenes*. None of the genes of the ras family has been found to be mutated at significant rate in HCC, whereas K-ras mutations are frequent in intrahepatic cholangiocarcinoma.

Oncogenic Pathways

Deregulation of various signaling pathways has been reported in different HCC subtypes, comprising Wnt/β-catenin signaling and the $p14^{ARF}$/p53, $p16^{INK4A}$/RB, TGF-β, and PTEN/Akt pathways [3]. Evidence for activation of the Ras and Jak/Stat pathways in HCC by epigenetic silencing mechanisms has also been reported. Additionally, altered expression of growth factors such as HGF, IGFs, amphyregulin, and their receptors, as well as genes involved in angiogenesis have been involved in the development and progression of HCC.

Molecular characterization of HCC by gene expression profiling using DNA microarray technology has allowed to distinguish several tumor subtypes harboring significant biological differences. Importantly, these newly discovered subtypes may differ also by a number of clinicopathological features, such as tumor stage, etiological factor, association with recurrence or metastasis, and survival of the patients. New progress will come from integrating gene expression profiles and comprehensive genetic surveys of HCC.

Conclusions

Our understanding of the molecular pathogenesis of HCC has been obscured by the striking clinical and biological heterogeneity of this tumor. It is surmised that new tools provided by sequencing of the human genome and high-throughput screening of DNA, RNA, and protein alterations in HCC would permit a comprehensive view of the signaling networks

operating in liver cell transformation. Great insights will come from integrating the signals from different pathways at pretumoral and tumoral stages. Because HCCs carry a severe prognosis and remain refractory to current chemotherapy regimens, it is urgent to accurately evaluate new molecular targets for therapeutic treatments.

Liver Cell Carcinoma

►Hepatocellular Carcinoma

Liver Cirrhosis

Definition

Cirrhosis is a chronic disease of the liver caused by damage from alcohol, chronic viral hepatitis, biliary disease, iron accumulation, etc. Normal parenchyma is replaced by delicate bands or broad scars of fibrous tissue, active parenchymal nodules created by hepatocyte regeneration, and passive nodules created by constrictive scarring, with disruption of liver architecture. These changes are irreversible and vascular intrahepatic system is reorganized with the creation of interconnections between vascular inflow and hepatic vein outflow channels. The end stage of cirrhosis is the complete loss of liver function. In some instances, cirrhosis predisposes to liver cancer.

Synonyms

Senile involution

Definition

A descriptive term, involution refers to a progressive decrease in the size of an organ that is usually associated with a decline in its function. Organs that undergo involution include the post-partum uterus, the ovaries after menopause, the thymus gland, and breast. Except for the post-partum uterus, involutional changes are regarded as a manifestation of aging and are often irreversible.

Characteristics

Anatomy of the Human Breast

The adult human female breast consists of 15–20 irregular lobes that are separated by layers of connective tissue as they fan out from the nipple into the mammary gland proper. These lobes empty independently into the nipple through the lactiferous ducts, which conduct milk to the nipple. The ducts subdivide and terminate in multiple small lobules, which subdivide into multiple glandular acini or alveoli that produce milk during lactation. These lobules are the functional units of the mammary gland. If the terminal duct is also included, they are often referred to as terminal ductal lobular units. A system of branching intralobular ducts, which eventually converge with the larger lactiferous ducts, connects the individual lobules within each lobe. The highest concentration of lobules is usually found in the upper outer quadrant of the breast. The development of the breast begins at puberty. Its maximum development is reached sometime after the twentieth year with atrophic changes setting in by the age of 35. Lobules are not present in the male breast.

Involution

The breast continually undergoes structural changes depending on the menstrual cycle, pregnancy, and age. Thus, for normal development and function, a balance must exist between cell proliferation, differentiation, and death. A major change entails involution, which refers to two markedly different physiological processes that affect the lobules. The first relates to pregnancy and the production of milk. During pregnancy, in preparation for lactation, these lobules increase in size as a result of cellular proliferation. There is rapid epithelial proliferation with additional branching of the ducts and lobulo-alveoli growth. Following the cessation of lactation, the lobules shrink and return to their pre-pregnancy size, a process described as post-lactational involution. In animals, this process is very rapid occurring in a matter of days through a process of ►apoptosis. In humans, the time in which this occurs is somewhat uncertain because of the limitations on the opportunity for tissue sampling. This process repeats after each pregnancy. The second process, which greatly differs from the first, is not associated with pregnancy. It is referred to as age-related lobular involution and usually begins near the end of child bearing.

Age-Related Lobular Involution

In humans, information on age-related lobular involution is limited primarily to morphological descriptions. Involution is characterized by a gradual reduction in the number of the terminal lobular structures of the breast. The lobules progressively regress in size, that is atrophy, until they disappear ultimately being replaced

by fat and fibrous tissue. Nearly all of the lobular structures are eventually lost in the process of age-related involution. A few partially involuted lobules or glands persist in the breast years after menopause, usually surrounded by a dense fibrous tissue stroma.

Although it is a normal physiological process, the age of onset, rate, and extent of age-related lobular involution varies greatly among women. In most women, involution begins around age 35, at least 10–15 years before the time of menopause. In some women, however, it may start in the early 30s or even later. It is a relatively slow process often continuing for many years, even into menopause. By age 55, involution is practically complete and the breast has in a general way returned to its prepubertal condition. Involution is not uniform in the breast, but occurs in a patchy or focal distribution. Some areas of the breast may show nearly complete involution while others show only minimal change. Age 35 years appears to be a crucial year. A full term pregnancy before age 35 confers some degree of protection against future ►breast cancer. Pregnancy after age 35 has been associated with an increased risk of subsequent breast cancer.

The mechanism of lobular involution has not been extensively studied. Post-lactational involution involves apoptosis. Therefore, it can be presumed that age-related lobular involution also involves apoptosis, which in contrast occurs at a much slower rate than post-lactational involution.

Factors Affecting Involution

Very little is known about the factors that govern involution. The process does not follow the regular pattern of aging seen in other organs or tissues. Most likely, the physiological aging process in the breast is under the influence of various hormones. Although it is unknown what factors control the onset and rate of involution, the following associations exist. Oopherectomy at a young age leads to atrophy of the lobules and involution of the lobular epithelium, which resembles the atrophy normally seen in older women. This is of some interest, because oopherectomy also reduces the risk of breast cancer. Since involution predates menopause by many years, it is possible that early changes in ovarian function that precede menopause trigger the onset of involution.

There have been no international comparisons on the extent of physiologic involution in different populations. Surveys of the incidence of different histological tumor types of breast cancer in different geographic areas have suggested international variations exist. This possibility depends on the assumption that the incidence of different tumor types reflects lobular involution. Variation in lobular involution would offer one explanation for the substantial variability of breast cancer observed between populations.

More than 55 years ago, Clemensen showed that the age specific incident rate of breast cancer increased until age 50, then decreased for a few years, then increased again, but at a much slower rate than previously. Although many reasons were advanced for the decrease, it has been proposed that Clememsen's hook reflects involution with its loss of glandular epithelium. The second increase has been attributed to persisting ductal-lobular structures that are susceptible to malignant transformation.

Measurement of Involution

Currently, there is no way to assess quantitatively the extent of involution. Radiologically, dense ►mammographic parenchymal patterns have been associated with mammary gland mass, which apparently reflects the amount of epithelial tissue present. In general, there is an inverse association between the prevalence of dense parenchyamal patterns and age. However, parenchymal patterns are variable; they often vary in women who are the same age. There is no explanation as to why some women have dense breasts and others do not even at the same age. A decrease in the prevalence of dense parenchymal patterns with age most likely reflects the loss of epithelial lobular structures as a result of involution. Dense parenchymal patterns are also a predictor of breast cancer risk, the greater the density the greater the risk for breast cancer, which suggests a relationship between the amount of epithelial tissue and cancer.

Failure to Involute

It is tempting to speculate on the consequences of a delay or failure of involution to occur at the appropriate time. It is known that lobular epithelium can persist beyond the time of normal involution, which has lead to speculation about the association between abnormal lobular involution and the increased risk of breast cancer. Abnormal involution could involve incomplete involution, genetically abnormal involution, or normal but delayed involution.

In the only systematic examination of age-related lobular involution in the context of breast cancer, a strong inverse relationship was shown between the extent of lobular involution and breast cancer risk, independent of all known breast cancer risk factors investigated. Among women with benign breast disease, lobular involution was significantly associated with reduced breast cancer risk.

There are several possible biologic mechanisms by which aberrant involution could modify a woman's breast cancer risk. It has been suggested that the progressively smaller number of epithelial cells present

upon gradual lobular involution could lead to a reduction in breast cancer simply because a lesser amount of tissue is available for malignant transformation. It has also been suggested that abnormal involution may merely be a surrogate for an underlying susceptibility to breast cancer. Failure of timely involution allows for prolonged exposure of epithelial cells to mutagenic stresses thereby increasing breast cancer risk.

Certain known breast cancer risk factors may interfere with the process of involution. Women whose first full term pregnancy occurs after 35 years of age are at increased risk of breast cancer compared to both nulliparous women and women with earlier first full term pregnancies. It is likely that the ductal-alveolar epithelium proliferation that accompanies the late pregnancy may interrupt the process of involution. The persistent estrogen activity that results from a late age at menopause possibly explains the increased risk of breast cancer.

Synonyms

Local ablation therapy

Definition

There has been no clear definition for locoregional therapy. Most often, locoregional therapy refers to various minimally invasive therapeutic procedures. With the aid of ultrasound guidance, an antitumoral device, drug or chemical is introduced directly into the tumor and causes tumor death.

Characteristics

For most human cancers, surgical resection remains the standard treatment modality. However, resection is sometimes possible in only a minority of patients. When surgical treatment is less likely to perform, physicians may choose other therapeutic procedures. Among the available methods, locoregional therapy has been frequently used to treat cancer. It is so named because the tumors can often be treated locally. The best example to demonstrate the role and usefulness of locoregional therapy is applying this kind of therapy in patients with ►hepatocellular carcinoma, or ►HCC, which is primary liver cancer originated from transformed liver cells. HCC is one of the common malignant tumors in the world, and most cases are found in Asia and Africa. Among the various locoregional interventions, ►transarterial chemoembolization, ►percutaneous ultrasound-guided therapy including injection of

►ethanol or ►acetic acid, and thermal ablation using ►radiofrequency and ►microwave energy, are the most commonly used methods (Table 1). These locoregional therapies possess the advantages of preserving the uninvolved liver parenchyma and avoiding potential morbidity and mortality of major hepatic surgery.

Transarterial Chemoembolization (TACE)

Most liver cancers, when formed, have a feeding artery that delivers nutrition and oxygen to tumor cells to enable their growth. TACE, using iodized oil and chemotherapeutic agents, combines the effect of targeted chemotherapy with that of ischemic necrosis induced by arterial embolization. Although TACE was originally used for ►metastatic liver tumors from colorectal cancers or other malignancies, it was later used to treat primary HCC because HCC nodule frequently has a high arterial blood supply (hypervascular lesion). In addition, TACE can target single- or multi-nodular HCCs in one treatment session and could be repeatedly administered. TACE is generally a palliative treatment for unresectable HCC, and a better outcome can only be expected in properly selected patients.

Percutaneous Ethanol Injection (PEI)

PEI was originally developed in the 1980s when the real time ultrasound-guided aiming became possible. The injected chemical, pure ethanol, induces local tumor necrosis as a result of direct protein denature, cellular dehydration and thrombosis of blood vessels. HCC usually is hypervascular and well-encapsulated by a tumor capsule that can limit the spread of ethanol. These characteristics have made PEI one of the most commonly used methods of local ablation therapy. Usually PEI is limited to patients with small-sized tumor nodules. Compared with the transarterial approach, PEI has the advantages of being safer, less expensive, and easy to perform. In addition, PEI allows selective treatment of HCC without significant damage to the adjacent liver parenchyma, and can be used for patients with moderately advanced cirrhosis. Side effects are mostly minimal.

Percutaneous Acetic Acid Injection (PAI)

Acetic acid induces profound tumor necrosis at a concentration of 15–50% through a similar mechanism as ethanol. It has a strong ability to penetrate cancer cells, and can dissolve lipids and extract collagen from intratumoral septa and capsule that frequently contain viable cancer cells. Therefore, acetic acid is at least equally effective compared with ethanol in treating HCC.

Radiofrequency Ablation (RFA)

RFA for human HCC was first reported in the mid-1990s. The puncture needle (or probe) has an insulated shaft and a noninsulated tip, which is inserted into the lesion under ultrasound or computed tomography guidance. The patient is part of the electric circuit with grounding pads on the thighs or the back. The radiofrequency energy emitted from the needle tip induces ionic agitation and frictional heat. The surrounding tissue, rather than the electrode itself, is the source of heat that destroys the cancer cells. RFA has now become one of the very efficient local ablative therapies for HCC due to its excellent necrotizing effect. While many investigators consider RFA a safe procedure, a few reports found that the complication rate of RFA could be quite high. When the location of tumor nodule is close to the major blood vessels, the radiofrequency energy will be carried away by the blood flow (the "heat sink" phenomenon) and result in a suboptimal treatment response.

Microwave Coagulation Therapy (MCT)

As a thermal ablation method for HCC, MCT utilizes a microwave coagulator that generates and transmits microwave energy to a needle electrode which is inserted into the lesion. MCT has been studied in patients with HCC as well as in liver ►metastasis. It can be applied with percutaneous or laparoscopic approach to ablate unresectable HCC, and is useful to control tumor

Locoregional Therapy. Table 1 Comparison of various locoregional therapies for HCC

Treatment	Advantages	Disadvantages
TACE	Target multiple tumors in one treatment session	No effect for hypovascular tumors, may induce liver or renal failure
PEI	Minimally invasive	Limited to small lesions, need multiple treatment
PAI	Minimally invasive, probably more effective than PEI	Limited to small lesions, need multiple treatment
RFA	Effective for small and medium sized HCCs	Probably higher complication rate, more expensive
MCT	Effective for small to medium sized HCC	Probably higher complication rate, more expensive

TACE: transarterial chemoembolization; PEI: percutaneous ethanol injection; PAI: percutaneous acetic acid injection; RFA: radiofrequency ablation; MCT: microwave coagulation.

bleeding from ruptured HCC or prevent massive blood loss in liver surgery.

Comments

Locoregional therapy has also been applied to other cancers other than HCC, but the overall experience is relatively limited. The choice and application of various locoregional therapies for HCC and other cancers may vary from center to center and is likely to depend on the experience, preference and facility of the referral center. Long-term survival in patients with unresectable HCC may be achievable in selected patients provided various locoregional therapies can be appropriately performed.

Log-Kill Hypothesis

Tiffany A. Traina, Larry Norton
Breast Cancer Medicine Service, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY, USA

Synonyms

Skipper-Schabel-Wilcox model; Skipper-Schabel model

Definition

The ►log-kill hypothesis proposes a model for the effect of cytotoxic chemotherapy on tumor size. It states that a given dose of chemotherapy kills the same fraction of tumor cells regardless of the size of the tumor at the time of treatment.

Characteristics

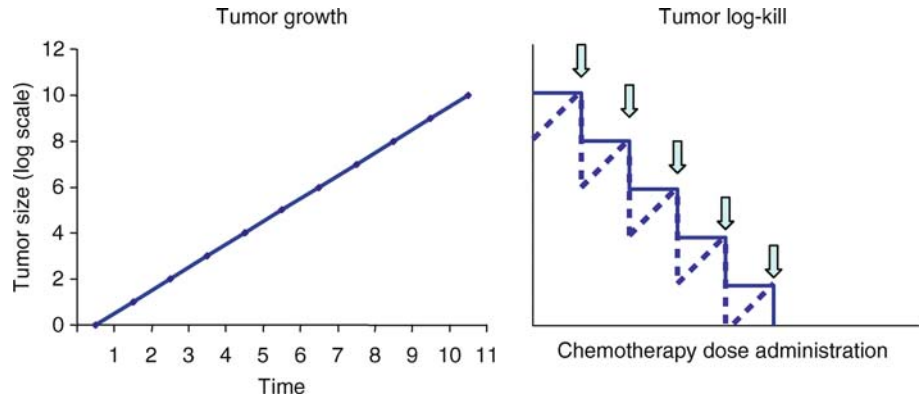
Experimental and mathematical models have attempted to describe the fundamentals of tumor cell growth and kinetics. From these systems arose an improved understanding of tumor growth characteristics, a foundation for the key principles of chemotherapy and eventually, recognition of the importance of dose scheduling. The Skipper-Schabel-Wilcox model is one of the most influential and pioneering experiments in the history of oncology.

Investigators at the Southern Research Institute developed a simple model of tumor growth using L1210 murine leukemia cells. This system had two notable features: a seemingly exponential growth pattern and the ability to spontaneously generate drug-resistant cells. These factors made it a reasonable reflection of the growth of rapidly fatal human malignancies and of the heterogeneity in drug sensitivity seen clinically in many cancers.

Leukemia in this murine model grows exponentially until it reaches a lethal volume of ~10^9 cells. A significant observation was that the doubling time remained constant regardless of the size of the tumor. This pattern of growth could be generalized to any fractional increase so that if it takes a certain amount of time (x) to grow from 10^3 cells to 10^4 cells, it will similarly take x amount of time for 10^7 cells to grow into 10^8 cells.

Building on the observations and assumptions above, the investigators hypothesized that when such a tumor is treated with chemotherapy, the fraction of cells killed is similarly constant. This fixed, relative cytoreduction suggests that a dose of drug active against a homogeneously sensitive population should always kill a constant proportion of the cells, regardless of the size of the tumor at the start of treatment. According to this model, if a dose of drug could improve survival by some period of time, then enough additional doses could delay death and lead to cure.

Graphically, when this fractional cell kill is expressed on a logarithmic scale, cytotoxicity occurs in the reverse of an exponential growth pattern (Fig. 1). Therefore, a drug dose that reduces 10^7 cells to 10^5 cells (a log-kill of 2) will also reduce the same tumor from 10^5 cells to 10^3 cells. Exponential cell growth is matched by exponential cell kill. Accordingly, enough cycles of enough drugs at high enough doses should be able to kill a high percentage of cells, if not all of them.



Log-Kill Hypothesis. Figure 1 The Skipper-Schabel-Wilcox "log-kill" model. Tumor growth appears exponential when plotted on a logarithmic scale (Left). With each dose of chemotherapy, a constant fraction of cells are killed (Right).

The log-kill model led to enthusiasm regarding the application of chemotherapy to the postoperative setting. ►Adjuvant therapy would theoretically cure patients of micrometastases as small volume tumors should be more easily eradicated as predicted by this model.

However, the Skipper-Schabel model does not accurately represent the entire clinical reality. The log-kill model presumes that growth is exponential between treatment doses and does not vary as a function of tumor size. Additionally, clinical experience with several solid tumors does not support this model. The observations that cure is rare for patients with advanced cancer, and that many patients with early stage cancer recur despite treatment suggest that this model does not completely predict or explain tumor cytokinetics.

Subsequent mathematical models based upon Gompertzian growth (►Gompertzian growth curve; ►Norton-Simon hypothesis) improved upon the concept established by the Skipper-Schabel-Wilcox model.

Loss-of-Function Mutation

Definition

Is any mutation of a gene that causes decreased or abolished function and/or activity of its encoded protein or of a protein that is directly or indirectly regulated by the mutated gene.

Loss of Heterozygosity

Definition

Synonym LOH; or allelic loss can be experimentally demonstrated in cases in which the two alleles differ. It is the loss of an allele in tumor DNA compared to matched normal DNA from the same individual. LOH is a very frequent somatic genetic change in human tumors. When LOH is found to occur at high frequency in a particular chromosome region, it is generally considered indicative of the location of a tumor suppressor gene whose loss/inactivation occurs by a 'two-hit' mechanism (i.e., physical loss of one copy of an allele and mutation or other genetic/epigenetic alteration of the other copy of the same allele). LOH can be identified in cancer cells by a number of technical approaches that all are make use of the fact that the two alleles on the two homologous parental chromosomes differ in their DNA sequence. Consequently, normal cells can be shown to be ►heterozygous for a given chromosomal region. If cancer cells of the same person lack this heterozygosity, one of the two alleles must have been lost. In essence, determining LOH in a cancer cell is a technical approach to show the deletion of chromosomal material from one of the homologous parental chromosomes.

Luciferase Reporter Gene Assays

Paul Bauer
Pfizer Research Technology Center, Cambridge, MA, USA

Synonyms
Bioluminescent reporter gene assays

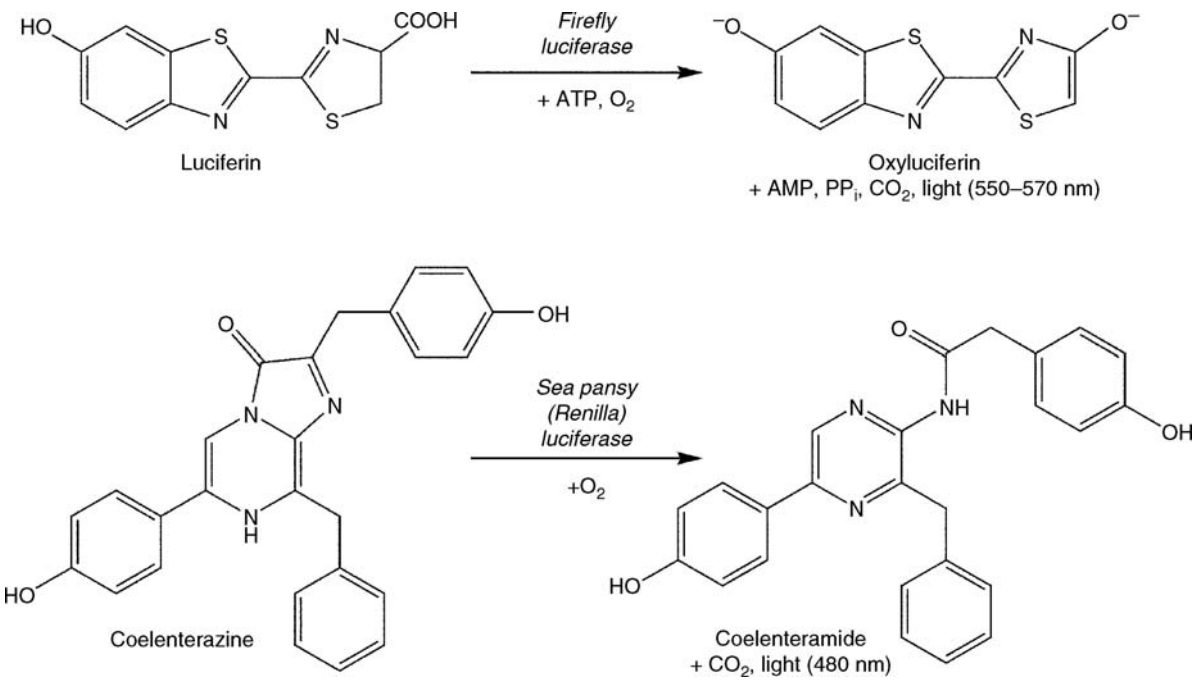
Definition
Luciferase ►reporter gene assays monitor the transcription of specific genes in cells and *in vivo* through the detection of light generated by the enzyme luciferase. Their primary uses are for mapping the control regions of genes, for measuring ►signal transduction pathways modulated by hormones or disease, as a tool in ►gene therapy and drug discovery, and for non-invasive whole-animal imaging.

Characteristics
Luciferase reporter gene assays are a type of reporter gene assay that utilize the light generated by one of a family of enzymes known as luciferases. Reporter genes are essential tools in the study of gene expression and regulation, as they are designed to function as surrogates for genes involved in key cellular processes and disease. To achieve this role, they are engineered

so that their expression is directly correlated with the expression of the gene to be studied, but they have the advantage that they are easier to measure. The characteristics of a good reporter gene include an easily measurable phenotype, low background activity in the cell under investigation, a large dynamic range, and high reliability and sensitivity. A number of such genes have been identified over the past 20 years, including members of the family of luciferases, β-galactosidase (β-Gal), chloramphenicol acetyltransferase (CAT), β-lactamase (β-lac), alkaline phosphatase (SEAP or SPAP), and green fluorescent protein (GFP) and derivatives. Each of these reporter genes has distinct advantages and disadvantages depending on the particular system being studied, but all are engineered in a similar way. The reporter gene is first cloned into an expression vector downstream of the regulatory elements of the cellular gene to be studied. The regulatory elements include the promoter, where specific transcription factors bind to modulate the gene's activity, and enhancers that can affect the promoter depending on the input from other signaling pathways in the cell. When this reporter gene expression vector is transfected into a cell, it becomes controlled by the same signals as the gene under study, and will function as a "reporter" of its transcriptional status. The proteins expressed by reporter genes can be measured directly by their intrinsic properties such as fluorescence, by enzymatic activities that generate fluorescent or luminescent products, or indirectly with antibodies. The primary advantages of reporter genes, as compared to direct measurements of gene transcription, are that they are easy to measure and allow for continuous monitoring of gene expression.

Luciferase is a general term for a family of enzymes that catalyze the oxidation of a number of substrates and in the process produce photons of visible light with emission spectra between 400 (purple) and 620 nm (orange). Luciferase genes have been cloned from a variety of bacteria, insects, and marine organisms, but the luciferases from firefly (*Photinus pyralis*), and sea pansy (*Renilla reniformis*), are most widely used as reporter genes in mammalian cells. The chemical reactions of the firefly and sea pansy luciferases are shown in Fig. 1.

Firefly luciferase is a monomeric protein of 61 kDa that produces an initial burst of light (seconds) followed by a sustained low level of luminescence (hours) when incubated with substrates. In the original assay, cell lysis was required prior to the addition of luciferin, but the development of membrane-permeable substrates has eliminated this step and also allowed imaging *in vivo*. Other improvements that have been introduced include modification of the reaction conditions to produce a stable luminescent output (important for applications that require consistent light output such as drug screening), and genetic changes that optimize expression and increase enzyme turnover. Light output is typically measured through the use of plate-based



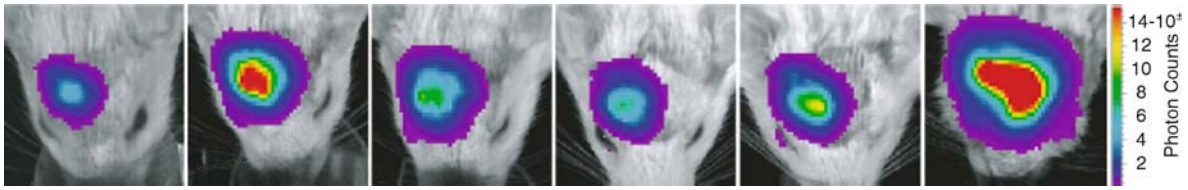
Luciferase Reporter Gene Assays. Figure 1 Chemical reactions catalyzed by (a) firefly (*Photinus pyralis*) and (b) sea pansy (*Renilla reniformis*) luciferases. The firefly luciferase reaction requires both ATP and O_2, while the sea pansy luciferase only requires O_2. The products of both luciferases include CO_2 and visible light.

luminometers or charged coupled device (CCD) cameras. Sea pansy luciferase (more commonly referenced as *Renilla*) is a monomeric protein of 36 kDa that uses the membrane-permeable substrate coelenterazine as a substrate and does not require ATP. While its structure is unrelated to firefly luciferase, it catalyzes a similar reaction and generates light of a shorter wavelength. The differences in substrate requirement and emitted wavelength have allowed the development of dual reporter systems that utilize both luciferase genes in a single assay. For example, cells have been transfected with firefly and *Renilla* reporter genes under the control of two separate signal transduction pathways, allowing the effects of compounds on each individual pathway to be monitored by the sequential addition of substrates. Similar dual reporter assays have been developed in living mice by taking advantage of the different emission wavelengths and kinetics of the two luciferases. Luciferases can also be utilized in ►protein-fragment complementation assays (PCAs) to measure the interaction between two proteins. In these assays, the luciferase gene is split into two parts, one of which is fused with the gene of the target protein and the other with its potential partner. The interaction of the target protein with its partner brings together the two fragments of luciferase and thus reconstitutes enzymatic activity. Such PCAs have been developed for a number of luciferases and function as highly sensitive detectors of protein–protein interactions in cells and *in vivo*. The primary advantages of either luciferase over the other reporter genes described above are their combination of high specific activity and low background (mammalian cells do not express light-generating enzymes), large and linear dynamic range (7–8 orders of magnitude), and the relatively rapid turnover of the enzyme. Highly stable reporter proteins can lead to a higher signal through accumulation, but their concentrations consequently become poorly linked to changes in transcription. The luciferase assay is also high-throughput, non-radioactive, non-toxic, relatively low cost, and easily adaptable to automation. The primary disadvantages of luciferase are the requirement for exogenous substrates and the 4–6 h delay from stimulus to response to allow transcription to occur.

Luciferase reporter gene assays have a number of important applications in biomedical science and cancer biology. Their initial uses were to map and characterize transcriptional control elements such as promoters, enhancers, silencers, and transcription factors, and these are still valuable applications today. In these experiments, an expression vector is developed with the control region of the gene to be studied inserted upstream of luciferase. Mutations or deletions are then made in the control region at different locations, and the effect of these changes on luciferase output are measured. Once the different regions are mapped in this way, they can be characterized further by removing them from the control region and inserting them immediately upstream of a constitutively active viral promoter driving luciferase. For example, tissue-specific enhancer elements inserted in either orientation should cause an increase in transcription only in the relevant cell types, and silencer elements should decrease expression. The contribution of individual transcription factors to the overall response can be characterized by monitoring the effect of the overexpression or ►siRNA-mediated inhibition of specific factors on the output of luciferase.

Another use of luciferase reporter gene assays is in the study of components of signaling pathways upstream of transcription. A wide variety of assays have been developed that can quantitate modifications of cell-surface proteins such as G-protein coupled receptors (GPCRs), signal transduction proteins such as protein kinases, and protein-protein signaling cascades. In the majority of cases, the particular protein to be studied is known and the assay is designed to respond to changes in its activation status. Specific examples include the site-directed mutagenesis of ►receptor tyrosine kinases, the identification of ligands for ►orphan GPCRs, and the involvement of particular proteins in different transcriptional activation pathways. One particularly important use for this type of assay is in the discovery of ►small molecule drugs. The sensitivity, convenience, and broad dynamic range of luciferase reporter gene assays make them especially suitable for cell-based high-throughput screening for inhibitors and activators of drug targets. Assays have been developed for nearly all classes of drug targets, including GPCRs, protein kinases, nuclear hormone receptors, and protein-protein interactions, and a number of successful drug discovery programs have been launched as a result. The assays are easily miniaturized to 384-well microtiter plate formats, and can be used to screen over 100,000 compounds a day with automated systems. Luciferase reporter gene assays also have applications in pathway identification and characterization when a specific target is not under study. These “black box” assays monitor the effect of a particular treatment on a cell which expresses a luciferase reporter gene linked to a general signaling cascade. Examples include their use in the identification of new drug targets through a ►chemical tool approach, and in genetic or chemical cytotoxicity screens for drug candidates or environmental pollutants.

An exciting and more recent use of luciferase reporter gene assays is in the visualization of gene expression *in vivo*, known as ►bioluminescent imaging. These assays allow the non-invasive, real-time monitoring of biological processes in living animals, and have already contributed to the development of better ways to diagnose and treat disease. The key observation that enabled these assays was that the light generated



Luciferase Reporter Gene Assays. Figure 2 The effect of chemotherapy on luciferase-expressing tumor cells implanted into mice. Tumor cells were implanted into the mice 16 days before the initiation of chemotherapy on day 0 (left panel), and luciferase activity was measured every 4 days thereafter (panels from left to right). Reference: Rehemtulla A, Stegman LD, Cardozo SJ, Gupta S, Hall DE, Contag CH, Ross BD (2000) Rapid and quantitative assessment of cancer treatment response using *in vivo* bioluminescent imaging. Neoplasia 2:491–495.

by luciferase could be transmitted through an animal's tissues and visualized by highly sensitive CCD cameras. Two general types of assays have been described: those where a normal animal is injected with cells or a virus engineered to contain a luciferase reporter gene, and those that utilize a luciferase reporter gene transgenic animal. The initial application for bioluminescent imaging was in animal models of bacterial infection. Pathogenic bacteria such as *Salmonella* and *Pseudomonas* were engineered to express bacterial luciferase without the need for exogenous substrate (other luciferases require the injection of luciferin or coelenterazine before imaging), and the process and distribution of infection was followed upon injection of the cells into an animal. This model has been used to identify those host cells that are important in defense against pathogens, and test possible treatments. A similar approach has been used to study the trafficking and fate of transplanted immune cells, carcinoma cells, or tumor xenografts that have been transfected with luciferase reporter genes. In these cases, the fate of the cells and the effects of different chemotherapeutic and immunotherapeutic regimens can be measured after injection (see Fig. 2). Finally, the effectiveness of viruses used for gene therapy can be monitored *in vivo* by engineering them to express luciferase reporter genes and measuring the degree and location of light output. This approach has been used to optimize the construction, delivery method, safety, and long-term efficacy of such viruses.

The use of transgenic animals in combination with luciferase reporter genes is another area of current development. For example, a number of groups have generated animals that express luciferase under the control of specific promoters (*e.g.* NFkB), or in particular tissues (*e.g.* pituitary). These animals are useful for determining the function of particular genes and the role of signal transduction pathways, for characterizing the effects of drug or other treatments on physiology and disease, and for measuring the tissue distribution and ►pharmacokinetics/pharmacodynamics of therapeutic drugs. One limitation of luciferase reporter gene assays *in vivo* is that they provide only a 2-dimensional view of expression patterns, but better detection technologies and the combination of bioluminescent imaging with other non-invasive technologies such as MRI or CT promise to improve resolution in the coming years.

Luciferase reporter gene assays are an essential *in vitro* and *in vivo* tool in the study of biology and medicine due to their simplicity, sensitivity, and ease-of-use. They have contributed greatly to the study of gene transcription and the elucidation of gene function, and are a valuable technology for drug discovery. Their application *in vivo* promises to facilitate the development of new treatments for cancer and other diseases.

Lugol Unstained Lesion

Kazuhiro Kaneko
Division of Digestive Endoscopy/Gastrointestinal Oncology, National Cancer Center Hospital East, Chiba, Japan

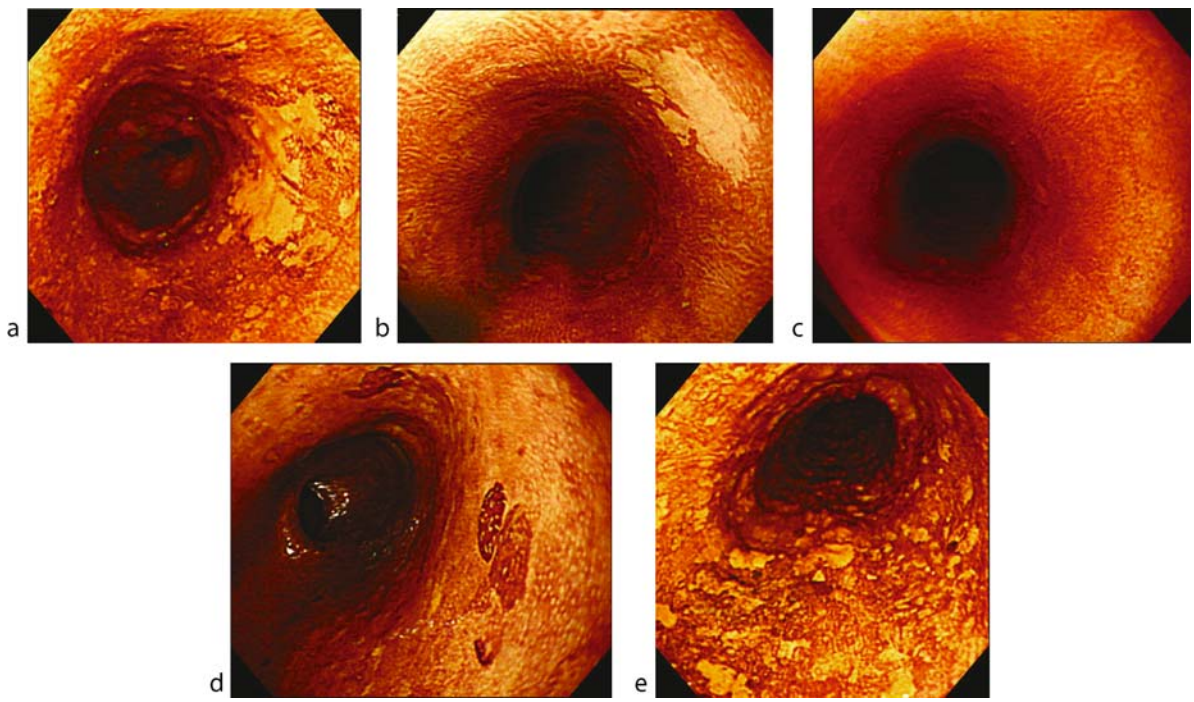
Definition

In 1933, the Lugol spraying method was introduced for the diagnosis of uterine cervical neoplasia using gynecologic colposcopy.

Since the 1980s, this technique has been used for screening of esophageal squamous cell carcinoma (ESCC) with Lugol chromoendoscopy. The Lugol spraying method has developed for early detection of ESCC from asymptomatic patients.

Characteristics

After ordinary endoscopic observation, 5–10 ml of 2.0% glycerin-free Lugol iodine solution, which is a brown liquid consisting of 2.0 g potassium iodine and 4.0 g iodine to 100 ml distilled water, is sprayed from the gastroesophageal junction to the upper esophagus using a plastic spray catheter passed through the biopsy channel of the endoscope. The whole esophagus is re-observed and epithelial areas are categorized as unstained (Fig.1a and b), normally stained (Fig. 1c), or overstained (Fig. 1d). Lugol unstained lesions (LULs) are defined as those areas either staining less intensely than normally stained epithelium, or completely unstained; this group of lesions includes carcinoma, dysplasia, and esophagitis. According to Lugol staining patterns, completely "unstained" areas are found in approximately 90% of high-grade dysplasia and carcinoma, while approximately 90% of areas, which stain less intensely than normally stained epithelium, represent non-dysplastic lesions and the remaining 10% are dysplastic. Therefore, LULs are detectable not only in dysplasias and carcinomas but also in non-dysplastic areas, for example with esophagitis, or in the setting of Barrett esophagus. Overstained areas represent glycogenic acanthosis (GA), which has been referred to as leukoplakia and hyperkeratosis of the esophagus. GA is a common benign lesion easily observed during ordinary endoscopic observations, usually varying in number and consisting of oval, slightly elevated, firm, gray-white plaques, measuring from 0.2 to a maximum of 1.5 cm in length. In addition, GAs stain a deep brown color when treated with Lugol solution. An iodine starch reaction occurs momentarily on esophageal epithelium when sprayed with Lugol solution. Therefore, since normal squamous epithelium contains glycogen that interacts with the iodine in the Lugol solution, normal esophageal epithelium becomes uniformly greenish-brown when stained (1). Dysplasia and esophagitis are not stained, since these regions have a reduced content or no glycogen. Therefore, these minute lesions that were not identifiable by conventional endoscopic observation, become visible when Lugol solution is used. Most individuals with LULs have only single or a few LULs, while multiple LULs (Fig. 1d) were found in some ESCC patients.



Lugol Unstained Lesion. Figure 1 (a) Endoscopic findings of a Lugol-unstained lesion, which was completely unstained. The lesion was 12 mm in diameter, and histologic finding was intraepithelial squamous cell carcinoma. (b) Endoscopic findings of a Lugol-unstained lesion, which was staining less intensely than normally stained epithelium. The lesion was 4 mm in diameter, and histologic finding was esophagitis. (c) Endoscopic findings of normally Lugol-staining epithelium without a Lugol-unstained lesion. (d) Endoscopic findings of an overstained lesion. (e) Endoscopic findings of multiple Lugol-unstained lesions. Many irregular lesions which were stained less intensely than normally Lugol-staining epithelium were located in one endoscopic view.

Carcinoma of the esophagus is considered to be a wide spread global disease estimated in 2000 to be responsible for 338,000 deaths worldwide ►(Squamous cell carcinoma). In Asia, some parts of Africa, South America, and South Europe, squamous cell carcinomas are the dominant form of esophageal cancer. Despite recent advances in the surgical treatment for ESCC, surgical outcome is not satisfactory, with an overall 5-year survival rate of 17–39% worldwide. In contrast, standard ►chemoradiotherapy has a curative potential for locally advanced ESCC, with inoperable cases having a 3-year survival rate of approximately 20%. The survival rate for advanced stage squamous cell carcinomas of the esophagus is poor, mainly due to their late detection and the poor efficacy of therapy containing surgery and chemoradiation. Conversely, the prognosis of patients treated endoscopically for carcinomas confined within the intraepithelium or proper mucosal layer is excellent ►(Tumor staging), with 5-year survival rates of 77–100% in Japan and Europe. These results indicate that endoscopically mucosal resection (EMR) for superficial ESCC can improve the prognosis of ESCC, highlighting the need to detect this disease at an early stage. Thus, the Lugol spraying method is a clinically important adjunct to endoscopic screening for ESCC, since two thirds of esophageal intraepithelial carcinomas are overlooked by conventional endoscopy alone. This simple technique of spraying Lugol solution in the esophagus is a highly sensitive tool for delineating areas of squamous dysplasia and carcinoma (1). In recent screening studies for ESCC, Lugol chromoendoscopy has been used worldwide.

Carcinogenesis (Precursor of ESCC)

Characterization of human esophageal precancerous lesions at the molecular level is of critical importance in our understanding of the etiology of ESCC and for the identification of useful ►biomarkers for prevention studies of this disease. The identification of ESCC precursors will ultimately lead to the prevention of poor-prognostic ESCC. Mutation analyses have demonstrated that *p53* gene mutations occur at an early stage of esophageal carcinogenesis, both in the setting of non-dysplastic lesions (i.e. basal cell hyperplasia (BCH), Lugol unstained lesions with non-dysplastic epithelium (LULs-NDE), chronic esophagitis) and in dysplastic lesions (i.e. low grade and high grade dysplasia, cancer in situ). Since *p53* mutations are frequently found in invasive ESCC, most of these lesions, both dysplastic and non-dysplastic, should be considered to be precancerous.

Mutations of the *p53* tumor suppressor gene ►(p53 protein, biological and clinical aspects) are the most common genetic abnormality in solid human cancers. Missense mutations are found in 78% of the 6,177 somatic *p53* mutations in exons 5–8, suggesting a correlation between the degree of evolutionary diversity and the structural or functional importance of individual amino acid residues. In contrast, *p53* gene mutations have been proposed to be concentrated in six hotspots (2). Based on the updated *p53* Gene Mutation Database containing 5,961 mutations, codons 175, 245, 248, 249, 273, and 282 have been identified as mutation hotspots in human cancers, and the incidence of the hotspot mutation is specific to the molecular alterations in solid human cancers (2). A hotspot can identify a relationship between the mutation, protein structure and function, and carcinogenesis. Furthermore, hotspot mutations in carcinomas represent protein alterations that provide a selective growth advantage to the cell, and missense mutations at six hotspots account for 25–30% of the mutations (2). In contrast, malignant transformation of human esophageal epithelium is a multistage progressive process from non-dysplastic lesions through dysplasia to carcinoma (3). The *p53* hotspot mutation was found in not only dysplasia or carcinoma but also Lugol unstained lesion with non-dysplastic epithelium (LUL-NDE) (4). Therefore, protein alterations that provide a selective growth advantage to the cell would have already occurred in cells of LULs-NDE before histologic transformation into dysplastic cells. Mutations at codon 175 and 273 have been shown to have transforming frequencies that are 22- and 8-fold, respectively, of the basal level for wild type p53 protein. The LUL-NDE or low-grade dysplasia containing mutations with high transforming activities, such as codon 175 and codon 273 mutations, might have growth advantages favoring progression to invasive ESCC with the acquisition of other genetic changes, and may acquire malignant potential before morphologically manifested cell proliferation at an early molecular level of carcinogenesis. In endoscopic biopsy samples, the *p53* missense mutation containing a hotspot mutation was found in NDE, which was identified as a LUL. No hotspot mutation was found in normal Lugol staining area or BCH. These findings suggest that some LULs-NDE may represent the earliest state of esophageal squamous cell carcinoma.

Multiple LULs

A single or few LULs were detected in one fifth of patients attending for routine endoscpy. Although subjects with multiple LULs (ten and more than ten LULs in one endoscopic view, Fig. 1d) were found in only 1% of the general population, dysplasia occurred frequently (60%) in these subjects. In contrast, multiple LULs were found in 27% of head and neck cancer patients, and secondary ESCCs were found in 72% of such cancer patients with multiple LULs (5). These results indicate essential information about field cancerization and malignant potential in respect of multiple LULs. The field cancerization phenomena

proposes that multiple squamous cell carcinomas occur either simultaneously with the primary lesion (synchronous) or after a period of time (metachronous) in the esophagus and the head and neck region. There is the possibility that widespread epithelial oncogenic alterations are found in patients with multiple LULs, indicating that esophageal epithelium with multiple LULs has unique characteristics in carcinogenesis.

Luminal Epithelial Cells

Definition

One of the two major epithelial cell types in the breast that are located in an inner cell layer surrounding the lumen of the gland and produce milk.

►Basal-like Breast Cancer

Lunasin

Blanca Hernandez-Ledesma, Ben O. de Lumen
Department of Nutritional Sciences and Toxicology, University of California, Berkeley, CA, USA

Definition

Lunasin is a novel seed peptide with ►cancer-preventive properties against chemical carcinogens and ►oncogenes.

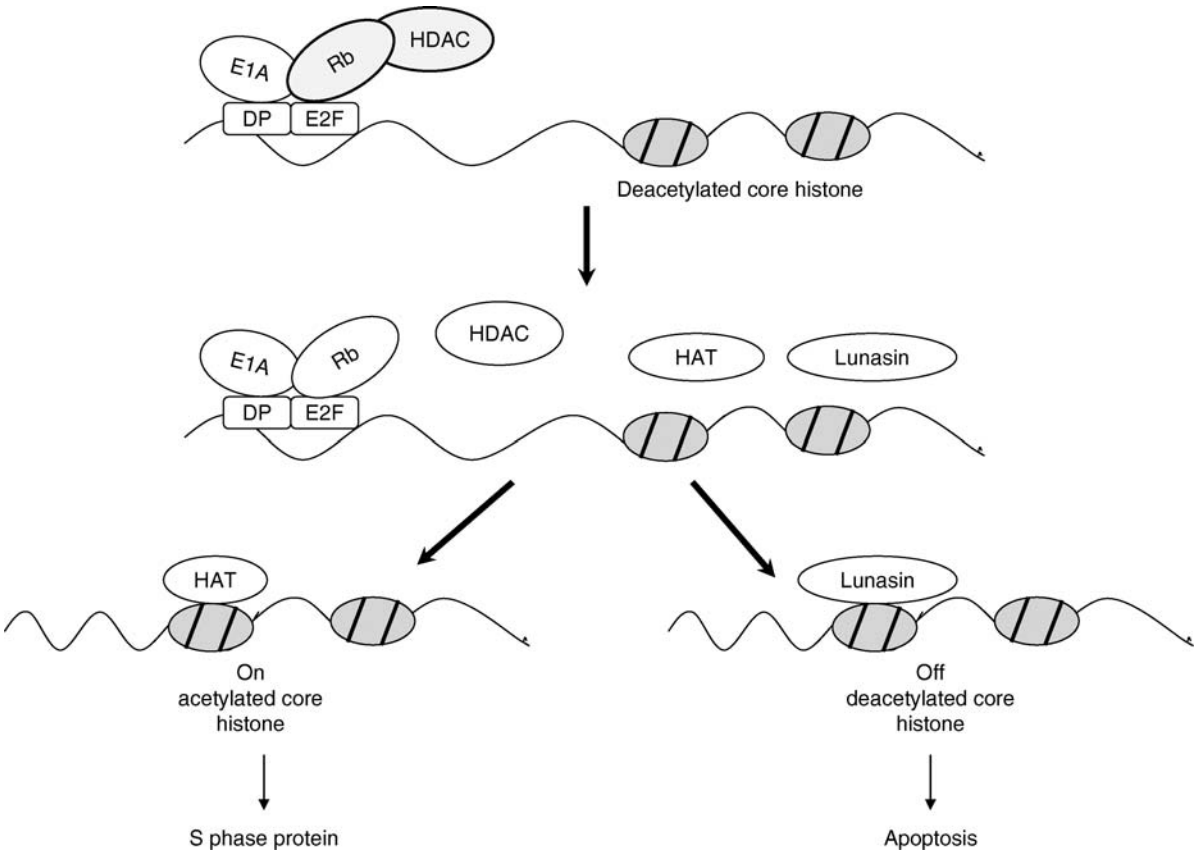
Characteristics

Lunasin is a unique 43-amino acid peptide that contains eight Asp (D) residues in its carboxyl end (bold) preceded by a cell adhesion motif Arg-Gly-Asp (RGD) (italics) and a predicted helix (underlined) with structural homology to a conserved region of chromatin-binding proteins: SKWQHQQDSCRKQKQGVNLTPC-EKHIMEKIQG-*RGD*-**DDDDDDDD**.

Initially identified in the soybean cotyledon, Lunasin has been recently found in barley, wheat, pepper, amaranth, and the *Solanaceae* family. It is likely that additional screening would reveal its presence in many other seeds. Lunasin has been demonstrated to have ►chemoprevention properties both *in vitro* and *in vivo*. In the absence of carcinogens, Lunasin does not seem to affect cell morphology and proliferation but prevents the transformation in the presence of carcinogens. At nanomolar concentrations, Lunasin added exogenously significantly suppresses chemical-carcinogen-induced (►DMBA and ►MCA) foci formation in mouse fibroblasts cells C3H10T1/2 (C3H). This effect is also produced by Lunasin in NIH3T3 cells, being fourfold more effective (on a molar basis) than the ►Bowman-Birk inhibitor (BBI), a known cancer-preventive agent from soy.

Lunasin also prevents transformation of mammalian cells by viral oncogenes. It inhibits, in a dose-dependent manner, foci formation in C3H cells and NIH3T3 cells transfected with the oncogene E1A, known to induce cell proliferation by inactivating the tumor suppressor protein Rb. Interestingly, Lunasin is effective even when added up to 15 days after transfection with E1A gene, suggesting its efficacy when applied even after the transformation event. Lunasin also suppresses colony formation induced by the ►RAS-oncogene in MCF-7 cells stably transfected with an inducible form of the oncogene.

►Chemical carcinogenesis and viral oncogenesis share common mechanism (s) involving changes in chromatin status that Lunasin disrupts to suppress cancer formation. Lunasin peptide added exogenously to mammalian cells treated with the ►histone deacetylases (HDAC) inhibitor sodium butyrate, internalizes into the cell and crosses the nuclear membrane, localizing in the nucleus. There, it binds specifically to deacetylated core histones H3 and H4, inhibiting their acetylation. The affinity of Lunasin for hypoacetylated chromatin and its inhibitory effect on histone acetylation is relevant to the proposed ►epigenetic mechanism of action (E1A-Rb-HDAC model; Fig. 1). This model stipulates that Lunasin selectively kills cells that are being transformed by disrupting the dynamics of histone acetylation-deacetylation when a transforming event occurs. The tumor suppressor protein Rb functions by interacting with E2F promoter and recruiting HDAC to keep the core histones in the deacetylated (repressed)



Lunasin. Figure 1 E1A-Rb-HDAC model to explain the ability of Lunasin to suppress E1A-induced transformation. *Top diagram*: Rb controls G1/S transcription by interacting with E2F promoter and recruiting HDAC to keep the core histones in the deacetylated (repressed) state. In a cell being transformed, E1A inactivates Rb and dissociates Rb-HDAC complex, exposing the deacetylated core histones in the E2F promoter (medium diagram). Lunasin competes with histone acetyltransferase (HAT) in binding to the deacetylated core histones. *Bottom diagram*: HAT binds and acetylates core histones, turning on E2F cell cycle transcription factors, leads to cell proliferation. Lunasin binds, turns off the transcription, perceived as abnormal by cell, results in apoptosis.

state. The inactivation of Rb by the oncoprotein E1A dissociates the Rb-HDAC complex, exposing the deacetylated core histones for acetylation by ►histone acetyltransferases (HATs). When this event occurs, Lunasin is triggered into action and binds to the deacetylated core histones, turning off transcription, which is perceived as abnormal by the cell and commits ►apoptosis. This epigenetic mechanism shows that Lunasin can influence regulatory pathways involving chromatin modifications that may be fundamental to carcinogenic pathways in general.

In the first animal model, Lunasin applied topically suppresses skin papilloma formation in SENCAR mice treated with DMBA and ►TPA. Tumor multiplicity is also reduced and the appearance of papilloma is delayed by this peptide.

Oral administration is an important feature of an ideal cancer preventive agent. To exert this effect, once orally ingested, the peptides have to survive degradation by gastrointestinal and serum proteinases and peptidases, reaching the target tissue or organ in an active form. Bioavailability studies have demonstrated that Lunasin, orally administered to rats, is protected from the gastrointestinal digestion by soy-naturally occurring protease inhibitors, such as BBI and ►Kunitz Trypsin inhibitor (KTI). Lunasin is absorbed and ends up in various tissues as an intact and bioactive peptide. This capacity and its *in vitro* demonstrated properties makes Lunasin the perfect candidate to exert an *in vivo* cancer-preventive activity. Animal studies demonstrating this preventive activity against different kinds of cancer, such as ►prostate, ►colon and ►breast cancer are currently being carried out.

Lung Cancer

Adi F. Gazdar, John D. Minna
Hamon Center for therapeutic Oncology Research and Departments of Pathology, Internal Medicine and Pharmacology, University of Texas Southwestern Medical Center, Dallas, Texas, USA

Synonyms

Lung carcinoma; Bronchogenic carcinoma

Definition

The term lung cancer is used for malignant epithelial tumors arising from the respiratory mucosa (bronchi, bronchioles, and alveoli). Mesotheliomas, lymphomas, and stromal tumors (sarcomas) are distinct from epithelial lung cancers.

Characteristics

Lung cancer is the leading cause of cancer death worldwide with over 1 million deaths each year. The disease is largely preventable as the majority of cases are attributable to smoking. However, global statistics estimate that 15% of lung cancer cases in men and 53% in women occur in never smokers.

The 5-year overall lung cancer survival rate (15%) has nearly doubled in the past 30 years as a result of advances in combined-modality treatment with surgery, radiotherapy, and chemotherapy. Thus, primary carcinoma of the lung is a major health problem with a generally poor prognosis.

Pathology

Four major cell types make up 88% of all primary lung neoplasms according to the World Health Organization classification. These are ►squamous cell carcinoma, ►small cell carcinoma, ►adenocarcinoma (including bronchioloalveolar), and ►large cell carcinoma. The remainder includes rarer tumor types including carcinoids. The various cell types have different natural histories and responses to therapy, and thus a correct histologic diagnosis is essential. In the past 25 years, adenocarcinoma has replaced squamous cell carcinoma as the most frequent histologic subtype, and the incidence of small cell carcinoma is on the decline. These dramatic histologic shifts may be due to changes in the composition of cigarettes.

Etiology

Most lung cancers are caused by ►carcinogens and tumor promoters inhaled via cigarette smoking. The relative risk of developing lung cancer is increased about 13-fold by active smoking and about 1.5-fold by long-term passive exposure to cigarette smoke. Exposure to industrial pollutants and chemicals including ►asbestos, ionizing radiation, ►radon etc. contribute to ►pathogenesis, often exacerbating the effects of ►tobacco carcinogensis.

Biology and Molecular Pathogenesis

Molecular genetic studies have shown the acquisition by lung cancer cells of a number of genetic lesions, including activation of dominant oncogenes and inactivation of ►tumor suppressor genes or recessive oncogenes. Lung cells may have to accumulate a large number (perhaps 20 or more) of such lesions before developing a fully invasive/metastatic phenotype.

Activation of Dominant Oncogenes

Changes in dominant oncogenes, include point mutations in the coding regions of the RAS family of oncogenes (especially ►KRAS gene in adenocarcinoma of the lung); mutations in the tyrosine kinase domain of the ►epidermal growth factor receptor (EGFR) found in non-smoking adenocarcinomas (~10% in Caucasioans, with much higher rates in East Asians) with rates >50% in non-smoking East Asian patients); occasional mutations in ►BRAF and ►PIK3CA or activation of the PIK3CA/AKT/►mTor pathway; amplification, rearrangement, and/or loss of transcriptional control of myc family oncogenes are found in non-small cell cancers, while changes in all myc family members are found in small cell lung cancer); overexpression of bcl-2 and other anti-apoptotic proteins; and overexpression of other EGFR family members such as ►Her-2/neu, and ERBB3; and activated expression of the telomerase gene in >90% of lung cancers. Genome wide approaches are identifying other amplified or mutated dominant oncogenes (such as MET) which could be important new therapeutic targets.

Inactivation of Tumor Suppressor Genes

Selected study and genome wide approaches have identified a large number of tumor suppressor genes

(recessive oncogenes) that are inactivated during the pathogenesis of lung cancer. This usually occurs by a tumor acquired inactivating mutation of one allele (seen for example in the ►*p53* and retinoblastoma, ►*RB1,* tumor suppressor gene) or tumor acquired inactivation of expression by tumor acquired promoter DNA ►methylation (seen for example in the case of the *p16* and *RASSF1A* tumor suppressor genes) which are then coupled with physical loss of the other parental allele ("►loss of heterozygosity"). This leaves the tumor cell with only the functionally inactive ►allele and thus loss of function of the growth regulatory tumor suppressor gene. Genome wide approaches have identified many such genes involved in lung cancer pathogenesis including *p53*, *Rb*, *RASSF1A*, *SEMA3B*, *SEMA3F*, *FUS1*, *p16*, *LKB1*, *RARβ,* and ►*FHIT*. Several tumor suppressor genes on chromosome 3p appear to be involved in nearly all lung cancers. Allelic lost for this region occurs very early in lung cancer pathogenesis, including in histologically normal smoking damaged lung epithelium.

Autocrine Growth Factors

The large number of genetic and epigenetic lesions indicate that lung cancer, like other common epithelial malignancies, is a multistep process that is likely to involve both carcinogens causing mutation ("initiation") and tumor promoters. Prevention can be directed at both processes. Lung cancer cells produce many peptide hormones and express receptors for these hormones, which can act to stimulate tumor cell growth in an "►autocrine" fashion.

Highly carcinogenic derivatives of ►nicotine are formed in cigarette smoke. Lung cancer cells of all histologic types (and the cells from which they are derived) express nicotinic acetylcholine receptors. Nicotine activates signaling pathways in tumor and normal cells that block ►apoptosis. Thus, nicotine itself could be directly involved in lung cancer pathogenesis both as a mutagen and tumor promoter.

Clinical Presentation

There are multiple ways by which lung cancer presents, including weight loss, chronic cough, persistent lung infection, malaise, chest pain, hemoptysis etc. ►SCLC, in particular, may present with a wide variety of paraneoplastic syndromes. With the advent of computer tomography (CT) screening programs, a modest number of mostly early stage cancers are being detected as asymptomatic tumors.

Treatment

Two important guiding principles in the treatment of lung cancer are: (i) histologic diagnosis (especially the distinction between small cell or ►non-small cell carcinomas, NSCLC) and (ii) staging. For early stages of NSCLC, complete resections offer relatively high 5-year survivals. Patients unsuitable for surgery may be offered curative intent radiotherapy. ►Adjuvant therapy may be given to more advanced resected cases. For late stage cases, chemotherapy with or without ►palliative radiotherapy are the conventional options, although the long term survival rates are very low.

Small cell lung cancer (SCLC) is considered a chemotherapy sensitive disease. Patients with limited stage disease have high response rates to chemotherapy (60–80%), including a 10–30% complete response rate, although the response rates in extensive disease patients is somewhat lower (50%), and almost always consists of partial responses. Tumor regressions usually occur quickly, within the first two cycles of treatment, and provide rapid palliation of tumor-related symptoms. Thus, chemotherapy is the backbone of treatment of patients with SCLC.

Given the poor prognosis of most patients with lung cancer, targeted therapies offer the best long term prospects. ►Tyrosine kinase inhibitors (►erlotinib and ►gefitinib) have been associated with responses and improved survival in specific subsets of NSCLC, specifically adenocarcinoma histology, female gender, East Asian ethnicity and never smoking status. The presence of EGFR mutations (and/or increased gene copy number in some studies) in the tumors are often associated with dramatic responses and lengthened good quality life, although most responders eventually relapse. Many other targeted therapies are currently undergoing clinical trial.

As lung cancer is one of the most preventable of diseases, anti-smoking campaigns have been initiated in many countries. Avoidance of smoking for never smokers and cessation for current smokers offer the best hopes for prevention, although these aims have proven more difficult to implement than expected. However, as pointed out earlier, about 15% of lung cancer occurs in lifetime never smokers. The very different molecular changes in cancers arising in smokers and never smokers suggests that ►environmental tobacco smoke ("passive smoking") can only account for a minority of cancers arising in never smokers. Thus lung cancer will remain an important cause of morbidity and mortality long after a complete ban on the use of tobacco products is implemented on a world wide scale.

Lymph

Definition

A transparent, slightly yellow fluid that carries lymphocytes, bathers the body tissues, and drains into to lymphatic vessels, which transport lymph to the immune organs and into the bloodstream.

►Lymphatic Vessels

Lymph Node

Definition

Is a component of the lymphatic system filtering the lymphatic fluid for bacteria, viruses, or foreign particles that can be recognized and eliminated by lymphocytes,

cells that rapidly multiple in response to infections in the highly specialized lymph node milleu.

►Sentinel Node

Lymph Node Metastases

Definition

Also known as nodal involvement, positive nodes, or regional disease. Cancer cells may spread to the regional lymph nodes near the primary tumor. Localized spread to regional lymph nodes is not normally counted as metastasis, but is a sign of worse prognosis.

►Endothelins

Lymphadenopathy

Definition

Enlarged lymph nodes.

Lymphangiogenesis

Judith A. Varner
Moores UCSD Cancer Center, University of California San Diego, La Jolla, CA, USA

Synonyms

Development of new lymphatic vessels; Growth of new lymphatic vessels

Definition

Lymphangiogenesis is the process whereby new lymphatic vessels develop within a tissue. Most commonly, lymphangiogenesis refers to the growth of lymphatic vessels by sprouting of new vessels from pre-existing lymphatic vessels. Additionally, lymphangiogenesis refers to the initial formation of the lymphatic system during embryonic development.

Characteristics

Lymphangiogenesis, the growth of new lymphatic vessels, occurs during embryonic development and in tumors and lymph nodes of tumor bearing animals. This key process also occurs in wounds and in inflamed tissues. Lymphangiogenesis in tumors has been linked to the formation of lymph node metastases. Importantly, lymph nodes are the initial or frequent sites of ►metastasis for many tumors, including human pancreatic, gastric, breast, and prostate carcinomas, ►melanomas and other tumors and recent studies indicate that lymphangiogenesis likely plays an important role in driving tumor metastasis.

The lymphatic system is comprised of a network of blind-ended, thin walled lymphatic capillaries, collecting vessels and specialized secondary immune organs, including lymph nodes, tonsils, Peyer's Patches and spleen. This system is connected to the vascular system through the thoracic duct. Lymphatic vessels drain protein-rich interstitial fluid and immune cells from tissues through lymph nodes. A thin network of lymphatic capillaries is found in the outer rim or capsule of the normal lymph node. Lymphatic capillaries are comprised of a single layer of lymphatic endothelial cells, which share many molecular characteristics with vascular endothelial cells. Collecting vessels in the lymphatic system are comprised of endothelia surrounded by a layer of ►pericytes. During early embryonic development, the lymphatic system forms by branching off of the cardinal vein and expanding into an alternate network of thin-walled vessels.

Lymphatic vessels differ from blood vessels in several ways. Large collecting lymphatic vessels contain vascular smooth muscle cells in their walls, as well as valves, which prevent the backflow of lymph. However, lymphatic capillaries, unlike typical blood capillaries, lack pericytes and a continuous basal lamina and contain large inter-endothelial valve-like openings. Lymphatic capillaries consist of loosely overlapping cells. Due to their greater permeability, lymphatic capillaries may be more effective than blood capillaries in allowing tumor cells to pass into the vessel lumen.

The recent identification of selective markers of lymphatic versus vascular endothelial cells has allowed identification of the mechanisms that regulate lymphangiogenesis. Lymphatic endothelia selectively express ►LYVE-1, a member of the ►CD44 hyaluronic acid receptor family, Prox-1, a lymphatic vessel specific homeobox transcription factor, ►podoplanin, a mucin-type glycoprotein, and ►VEGFR3, a receptor for ►VEGF-C and VEGF-D. Lymphatic capillaries, unlike typical blood capillaries, lack pericytes and a continuous basal lamina.

Tumor secreted factors such as VEGF-C and VEGF-A have been shown to promote lymphangiogenesis within tumors. These factors activate VEGFR3, a

tyrosine kinase VEGF family receptor that is expressed primarily on lymphatic endothelium. Expression of VEGF-C is correlated with increased lymph node metastasis and poor clinical outcome in a variety of tumors. Indeed, in animal models of metastasis, inhibitors of VEGF-C (soluble VEGFR3) inhibited tumor lymphangiogenesis and tumor metastasis to lymph nodes.

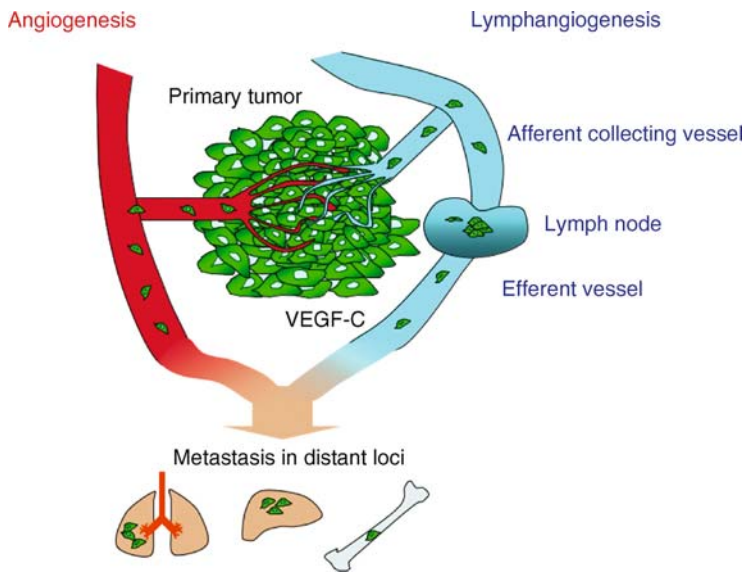
Tumors spread by lymphatic routes to lymph nodes but may also spread by hematogenous (vascular) or lymphatic routes to distant organs. Tumors secrete a number of factors including VEGF-C and others that induce both lymphangiogenesis and ►angiogenesis (Fig. 1).

Molecular Regulation

The molecular mechanisms that regulate lymphangiogenesis, the growth of lymphatic vessels, have recently begun to be understood. Two members of the VEGF family, VEGF-C and VEGF-D, stimulate lymphangiogenesis by binding to the receptors VEGFR-2 and VEGFR-3 on lymphatic endothelial cells. Indeed, homozygous deletion of VEGF-C genes in mice leads to a complete absence of the lymphatic system. VEGF-A, FGF and HGF can also stimulate lymphangiogenesis. The discovery of specific markers of lymphatic endothelium has facilitated analysis of the mechanisms regulating lymphangiogenesis. VEGFR3 is expressed only by quiescent lymphatic endothelial cells and not by quiescent vascular endothelial cells; however, both proliferating vascular and lymphatic endothelial cells express this protein. The homeodomain transcription factor Prox-1 is selectively expressed on lymphatic endothelium and not vascular endothelial cells. It is also expressed by developing neuronal cells in flies and mammals. Podoplanin, a mucin-type glycoprotein, is expressed by lymphatic endothelial cells and a few other cell types such as type I lung alveolar cells and kidney podocytes. Mice with genetic loss of podoplanin display paw lymphedema, or loss of fluid drainage from the paw. Importantly, the CD44 hyaluronic acid binding protein family member LYVE-1 is expressed only by lymphatic endothelium as well as liver and spleen sinusoidal endothelial cells. Interestingly, LYVE-1 is down regulated on pericyte-lined collecting vessels of the lymphatic system. Although the function of LYVE-1 is currently unknown, there is a clear association of the absence of LYVE-1 with the presence of pericytes. Expression of LYVE-1 is undetectable on lymphocytes, hematopoietic cells, or vascular endothelial cells. LYVE-1 is thus a useful marker to determine the localization of lymphatic endothelium by immunohistochemistry in vivo and to characterize and purify LEC in vitro.

While growth factors and their receptors play critical roles in angiogenesis and lymphangiogenesis, the integrin family of cell ►adhesion proteins controls cell attachment to the extracellular matrix and promotes the survival, proliferation and ►motility of many cell types. Angiogenesis, the development of new blood vessels, depends not only on soluble growth factors such as VEGF-A but also on survival and migratory signals transduced by the integrins αvβ3 αvβ5, α5β1 and/or α4β1. In contrast, only integrins α4β1 and α►9β1 have been shown to play roles in lymphatic vessel development, as animals lacking ►integrin α9β1 develop ►chylothorax and animals lacking α4β1in endothelia do not respond to VEGF-C.

Many tumors express VEGF-C and VEGF-D, growth factors that selectively regulate lymphangiogenesis.



Lymphangiogenesis. Figure 1 Model of tumor lymphangiogenesis.

While there are three known vascular endothelial growth factor receptors, VEGFR-1, VEGFR-2, and VEGFR-3, only one, VEGFR-3 is expressed predominantly on lymphatic vessel. Importantly, tumor-associated ►macrophages can release VEGF-C and can stimulate lymphangiogenesis in the absence of added growth factors. In fact, recent studies showed that macrophage secretion of VEGF-C and VEGF-D induces lymphangiogenesis, as well as lymphangiogenesis in tumors. Importantly, a number of studies have shown that antagonists of VEGF-C suppress tumor lymphangiogenesis and lymphatic metastases in animal models of tumor growth.

Clinical Relevance

Congenital or pathologically induced damage to the lymphatic system can result in lymphedema, a condition in which drainage of fluid from tissues is blocked, skin thickens and adipose tissue accumulates. Mutations in VEGFR3, the forkhead transcription factor ►FOXC2 and the transcription factor ►SOX18 each induce distinct forms of congenital or ►primary lymphedema. Recombinant VEGF-C was able to promote therapeutic lymphangiogenesis in animal models of lymphedema. Additionally, ►cancer surgery and radiation therapy, especially in breast cancer therapy, can induce ►secondary lymphedema by damaging the lymphatic system in normal tissues, such as the breast. Diseases of the lymphatic system include lymphedema, lymphangiosarcomas and lymph node metastasis. Primary lymphedema arises from congenital defects in molecules that regulate development of lymphatic vessels, such as VEGFR3, FOXC2 and SOX18. Secondary lymphedema arises as a consequence of surgery, infection (such as filariasis) or radiation therapy. In these disorders, the normal architecture of the lymphatic vessels and/or lymph nodes is disrupted. Removal of fluids from tissues can be disrupted in these disorders and tissue architecture is altered. An understanding of how lymphatic vessels grow and respond to environmental cues could help to develop therapies for these disorders. In over eighty percent of cancers, malignant tumor cells metastasize to the lymph nodes and travel through the lymphatic system. Tumor cell derived factors such as VEGF-C stimulate lymphangiogenesis in tumors and studies have shown that increased lymphatic vessel density is associated with increased metastasis. An understanding of the molecular mechanisms that regulate lymphangiogenesis may lead to new therapies for cancer metastasis and lymphedema.

Lymphangioleiomyomatosis

Definition

LAM; is a disorder seen almost exclusively in females and is characterized by bronchiolar smooth muscle infiltration and cystic changes in the lung parenchyma. LAM patients often have angiomyolipoma of the kidneys and/or abdominal and hilar lymph nodes.

Lymphangitic Carcinomatosis

Definition

Diffuse malignant infiltration of the lungs with obstruction of the lymphatic channels that occurs most commonly in patients with carcinoma of the breast, lung, stomach, pancreas, prostate, cervix, or thyroid as well as in patients with metastatic adenocarcinoma from an unknown primary site.

►Carcinomatosis

Lymphatic Mapping

Definition

The process in which a radio-labeled tracer is injected in or near a primary tumor site to outline the way lymph drains to its corresponding lymph nodes. This process is visualized on lymphoscintigrams and serves, with or without the use of blue dye, as an intraoperative guide during sentinel node biopsy.

►Sentinel Lymph Nodes

Lymphatic System

Definition

A circulatory network of lymph vessels that transports lymph fluid and filters it in the lymph nodes. Lymph fluid coming from the entire body is collected in several large trunks that eventually drain into the venous circulation.

►Sentinel Lymph Nodes

Lymphatic Vessels

Elizabeth D. Williams
Cancer Metastasis Laboratory, Monash Institute of Medical Research, Monash University, Clayton, VIC, Australia

Definition

Lymphatic vessels are the lymphatic capillaries, collecting vessels and ducts that form an integral part of the one-way, open-ended circulatory system known as the lymphatic system. In addition to lymphatic vessels, the lymphatic system consists of lymph nodes and other lymphoid organs.

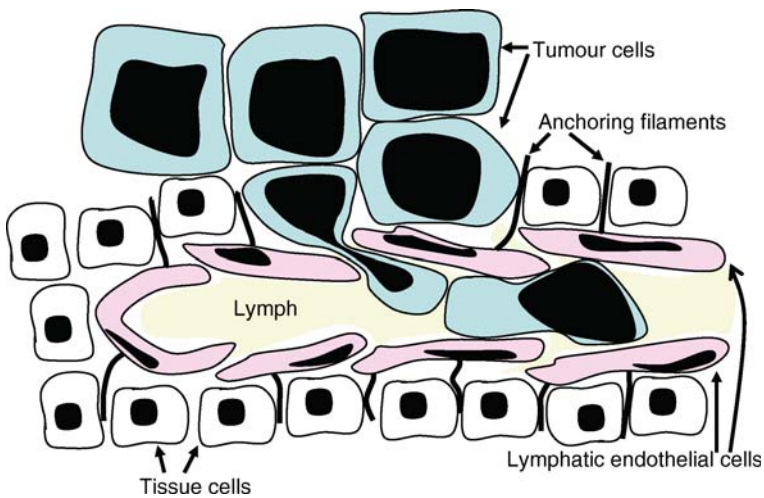
Lymphatic vessels have three interrelated physiological functions: (i) removal of excess fluids from body tissues, (ii) transportation of immune cells (including lymphocytes and dendritic cells) and, (iii) absorption of dietary fat and fat-soluble vitamins from the digestive system and the subsequent transport of fat (chyle) to the circulatory system.

Characteristics

Lymphatic capillaries are lined by a single layer of endothelial cells with overlapping intercellular junctional complexes (Fig. 1). They are devoid of ►pericytes and smooth muscle cells, and are surrounded by a discontinuous or absent basement membrane. Collecting lymphatic vessels typically possess a sparse smooth muscle cell layer, basement membrane and valves to facilitate unidirectional fluid transport. Lumen patency is maintained by anchoring filaments that connect the abluminal surface of the endothelial cells to the ►extracellular matrix. Lymphatic vessels are present in most organs, except avascular structures (such as epidermis and cartilage) and certain vascularized organs (the central nervous system and bone marrow).

Interstitial fluid in tissues drains into lymphatic capillaries and becomes ►lymph. It then flows into collecting lymphatic vessels away from tissues, passes through lymph nodes, and eventually reaches either the right lymphatic duct or the largest lymph vessel in the body, the thoracic duct. These vessels drain into the right and left subclavian veins respectively to return the processed lymph to the circulatory system.

The regulation of lymphatic vessel formation, growth and maturation is complex. The lymphatic system was first systematically described by Asellius in the seventeenth century (1627) as "milky veins" in the mesentery of a "well-fed" dog. The developmental origin of lymphatic vessels was first recognized by Sabin in the early twentieth century (1902), who proposed that endothelial cells bud off from veins in the jugular and



Lymphatic Vessels. Figure 1 Schematic representation of tumor cells invading a lymphatic capillary.

perimesonephric areas during early embryonic development and migrate to form primitive lymph sacs. Endothelial sprouting from these sacs subsequently forms lymphatic capillaries.

►Lymphangiogenesis is the *de novo* formation of lymphatic vessels, in a manner analogous to blood vessel ►angiogenesis. It plays an important physiological role in homeostasis, metabolism, immunity and wound healing. Aberrant lymphatic vessel formation has been implicated in a number of pathological conditions including tumor cell metastasis, edema, and inflammatory diseases.

Clinical Relevance

Defective lymphatic vessels result in a number of human pathologies. ►Congenital lymphedema is hereditary, and is often linked to mutation in the gene encoding vascular endothelial growth factor receptor-3, although other genes may also cause this condition. The hereditary disease ►lymphedema-distichiasis is caused by a mutation in the forkhead family transcription factor *FOXC2*. Lymphatic malformations are composed of defective cutaneous and subcutaneous lymphatic vessels. These lesions are not hereditary, and are thought to arise as a developmental defect where part of the developing lymphatic system becomes separated from the rest of the lymphatic system and subsequently becomes cystically dilated.

Secondary lymphedema occurs when the lymphatic system is damaged following trauma. Events that may cause damage include surgery and/or radiotherapy (typically during cancer treatment), infection, severe injury or burns. Secondary lymphedema may be transitory, recurring or a chronic condition.

Clinical findings have suggested that tumor-associated lymphatics play a key role in ►metastasis by providing a pathway for tumor cell dissemination, (Fig. 1). Indeed, the presence of metastatic tumor cells in regional lymph nodes is an important prognostic indicator for many human cancers.

Members of the ►vascular endothelial growth factor (VEGF) family, VEGF-A, VEGF-C and VEGF-D, signaling through VEGF receptors-2 and/or -3, have been shown to play a critical role in a number of *in vitro* and *in vivo* models of lymphangiogenesis. In cancer, the majority of clinical studies show positive correlations between VEGF-C and/or VEGF-D levels and tumor lymphatic vessel density, lymph node status and, in some instances, poor clinical outcome. In addition, several other growth factors, such as ►platelet-derived growth factors (PDFGs), hepatocyte growth factor (HGF), fibroblast growth factors (FGFs) angiopoietins, and ►insulin-like growth factors (IGFs), have been demonstrated to promote lymphangiogenesis.

It is currently unclear whether preexisting lymphatic vessels are sufficient to permit tumor cell dissemination, or whether this function requires *de novo* lymphatic formation or an increase in lymphatic size. The relative contribution of each of these processes may also vary with tumor type and subtype. Furthermore, as intratumoral lymphatic vessels are typically collapsed due to the high interstitial pressure found in tumors, it is likely that in the majority of tumors peri-tumoral lymphatic vessels play a key role in tumor dissemination to lymph nodes.

Lymphedema

Definition

Synonym lymphoedema; Refers to building up of lymphatic fluid in the soft tissues of the body, usually in an arm or leg, with the result of a swelling. As the fluid accumulates, the swelling continues. The lymphatic system consists of lymph vessels and lymph nodes that run through the body. Lymph vessels collect a fluid that is made up of protein, water, fats, and wastes from the cells of the body. Lymph vessels carry this fluid to the lymph nodes that filter waste materials and foreign products, and then return the fluid to the blood. If vessels or nodes become damaged or are missing, or when here is a blockage of the lymphatic system, the lymph fluid cannot move freely through the system. The fluids can then build up and cause swelling in the affected arms or legs.

Lymphedema-Distichiasis

Definition

Is an autosomal dominant disorder that classically presents as lymphedema of the limbs and double rows of eyelashes (distichiasis).

►Lymphatic Vessels

Lymphoblastoid Cell Lines

Definition

LCLs; ►Epstein Barr virus (EBV) immortalized B cell lines established by in vitro infection or culture of peripheral blood lymphocytes (PBL) from EBV-infected individuals. These cells are not tumorigenic in ►nude mice

Lymphocytes

Definition

All adaptive immune responses are mediated by lymphocytes. Lymphocytes are a class of white blood cells that bear variable cell-surface receptor for antigen. These receptors are encoded in rearranging gene segments. There are two main classes of lymphocyte – B lymphocytes (B cells) and T lymphocytes (T cells) – which mediate humoral and cell-mediated immunity, respectively. Small lymphocytes have little cytoplasm and condensed nuclear chromatin; on antigen recognition, the cell enlarges to form a lymphoblast and then proliferates and differentiates into an antigen-specific effector cell.

►Adaptive Immunity

Lymphocytic and Histiocytic Cells

Definition

L&H cells are the tumor cells in the lymphocyte predominant subtype of Hodgkin lymphoma. These are relatively large mononuclear lymphoma B cells, showing strong expression of the B cell maker CD20.

►Hodgkin and Reed/Sternberg Cell
►Hodgkin Disease

Lymphoepithelioma

►Nasopharyngeal Carcinoma

Lymphogenic Metastatic Spread

Definition

Small lymph capillaries surrounding or invading tumors may take up tumor cells and transport them via larger lymph vessels to regional lymph nodes.

►Senival Lymph Nodes

Lymphoid Organs

Definition

Are structured tissues where lymphocytes maturate, encounter their antigen and differentiate. They are divided into primary (bone marrow, thymus) and secondary (e.g., spleen, lymph nodes) lymphoid organs by providing sites for either lymphocyte maturation or activation and differentiation, respectively.

Lymphokine-Activated Killer

Definition

LAK cells are used in ►adoptive immunotherapy for the treatment of malignant diseases. The therapy involves the removal of peripheral blood from a patient, depletion of red blood cells from the blood to produce a lymphocyte-containing white blood cell fraction, incubating the blood fraction in culture medium with ►interleukin-2 (IL-2) to induce their transformation into tumor-destroying LAK cells, and injecting the LAK cells into the patient along with interleukin-2. LAK cells are thought to be similar to NK cells in that they lyse target cells in a non-major histocompatibility complex (►MHC)-restricted manner.

►Immunotherapy
►Activated Natural Killer Cells

Lymphokine-Activated Killer Cell

Definition

LAK; A white blood cell that is stimulated in a laboratory to kill tumor cells. If lymphocytes are

cultured in the presence of ►Interleukin 2, effector cells will develop that are ►cytotoxic to tumor cells.

Lymphokines

Definition

Soluble factors or cytokines that are produced by lymphocytes (mostly T cells), which have effects on the function of other cells expressing lymphokine receptors. Most common lymphokines belong to the interleukin family.

►Peptide Vaccines for Cancer

Lymphoma

Definition

Malignant lymphomas are defined as neoplasms consisting of cells of the lymphoid tissues. Contrary to most organs and tissues, and in spite of the fact that lymphomas show a wide range of aggressiveness from localized, indolent to highly aggressive, rapidly metastasizing tumors, no *bona fide* benign lymphomas have been defined. Distinct lymphoma entities in general show a characteristic clinical and biological behavior, but within these entities a broad spectrum of aggressiveness may be observed in individual cases, which is either due to disease progression in a multi-step process of lymphomagenesis and/or the involvement of specific risk factors.

►Malignant Lymphoma: Hallmarks and Concepts
►Hodgkin Disease

Lymphoscintigraphy

Definition

An imaging technique whereby a radio-labeled tracer is administered and its whereabouts in the lymphatic system are imaged using a gamma camera.

►Sentinel Lymph Nodes

Lymphotoxin

Definition

LT; Synonym tumor necrosis factor-β(TNF-β), a cytokine secreted by inflammatory CD4 T cells that is directly cytotoxic for some cells.

Lymphovascular Invasion

Definition

Presence of tumor cells invading blood or lymphatic vessel around the primary tumor.

►Adjuvant Chemoendocrine Therapy

Lymphovenous Shunt

Definition

Part of the lymphatic fluid entering the lymph node may be shunted to the blood capillaries without further transport in the serial system of lymph nodes. This direct access to the blood stream provides means of metastatic routes, where tumor cells may enter the blood stream at the site of the lymph node and spread by a hematogenously.

►Sentinel Node

Lynch Syndrome

Henry Lynch
Hereditary Cancer Institute, Creighton University, Omaha, NE, USA

Synonyms

Hereditary nonpolyposis colorectal cancer; HNPCC

Definition

Lynch syndrome is an autosomal dominantly inherited cancer susceptibility syndrome, characterized by cancers

of multiple anatomic sites, of which colorectal cancer (CRC) is the most common. Mismatch repair (MMR) genes, inclusive of hMSH2, hMLH1, hPMS1, hPMS2 and hMSH6, in their mutant form are causal for the cancer phenotype. Lynch syndrome appears to show genotypic and phenotypic heterogeneity. hMSH2 mutations may predispose to a greater frequency of extracolonic cancers while mutations in hMSH6 may result in a predominance of gynecologic cancer, particularly endometrial carcinoma, so that CRC may not pose the primary basis for Lynch syndrome diagnosis. Lynch syndrome is the most commonly occurring hereditary CRC disorder.

Molecular genetic findings have enabled hereditary CRC to be divided into two groups: (i) tumors that show microsatellite instability (MSI), occur more frequently in the right colon, have diploid DNA, harbor characteristic mutations such as transforming growth factor β Type II receptor and BAX26 and behave indolently, of which the Lynch syndrome is an example; (ii) tumors with chromosomal instability (CIN), which tend to be left-sided, show aneuploid DNA, harbor characteristic mutations such as K-ras, APC, p53), and behave aggressively, of which familial adenomatous polyposis is an example.

Characteristics

Characteristics (clinical, molecular and pathology): Affected individuals inherit a mutation in one of the MMR gene alleles. When a second mutation is acquired in the wild-type allele, the target cell is less able to repair DNA mismatch errors. Tumors composed of such cells characteristically manifest microsatellite instability and are said to have replication error phenotype (RER+). Most of the tumors arising in the Lynch syndrome are MSI+, while about 15% of apparently sporadic CRCs are MSI+. This is exceedingly interesting in that those sporadic MSI + tumors have clinical pathologic features similar to those observed in the Lynch syndrome (1–3).

Prior to molecular genetic breakthroughs, one was required to depend upon the cardinal features of the Lynch syndrome, since there were no premonitory signs or biomarkers to guide diagnosis. These cardinal features are as follows:

- The inheritance pattern is autosomal dominant
- Gene penetrance is ~85–90%
- Gene carriers develop colorectal carcinoma at an early age (~45 years)
- Most (~70%) cancers arise proximal to the splenic flexure
- Multiple CRCs, both synchronous and metachronous, are common
- Accelerated carcinogenesis is present
- The prognosis is better than for sporadic colon cancer
- The pathology features of CRC are often distinguishable (but not pathognomic) and include poor differentiation, increased signet cells, medullary features, peritumoral lymphocytic infiltration, Crohn's-like reaction, and an increased frequency of tumor infiltrating lymphocytes (TILs) admixed with tumor cells

These clinical features characterize Lynch syndrome I. Lynch syndrome II is characterized by all of these same features and, in addition, shows an increased risk for malignancy at certain extracolonic sites, including the endometrium, ovary, stomach, small bowel, hepatobiliary tract, pancreas, ureter, renal pelvis and breast.

History

The history of the Lynch syndrome dates to an observation of Dr. Aldred Warthin, pathologist at the University of Michigan School of Medicine. He became deeply moved when his seamstress, in 1895, told him that she would likely die of cancer of the colon, stomach or her female organs, because of the enormous proclivity to these cancers in her family. Warthin listened intently, developed her pedigree, and along with other similar cancer prone families published this work in 1913. He updated the family in 1925. The seamstress's family has since been known as Family G. Lynch et al. [4] described the natural history and genetics of two large Midwestern kindreds (Families N and M) which subsequently were found to have features similar to Family G. Dr. A. James French, Warthin's successor as chairman of pathology at the University of Michigan, heard about Families N and M and recalled that his predecessor, Aldred Warthin, had discovered a similar family in 1895. Dr. French invited Dr. Lynch to take custody of all the detailed documents and pathology specimens which the meticulous Dr. Warthin had investigated, catalogued and published over a span of more than 30 years. Family G was then updated and published in 1971 [5]. A detailed review of the history of the Lynch syndrome has been published by Lynch et al. [6].

Management of the Lynch syndrome is predicated upon the cardinal features of its natural history, discussed above. Most importantly, given the proximal predilection for CRC, colonoscopy is mandatory. In fact, evidence is already in hand that colonoscopy will significantly reduce morbidity and mortality in Lynch syndrome patients [7, 8]. Approximately one-third of the cancers occur in the cecum, so that colon cleanout is necessary for good visualization of the cecum. Given its early age of onset, and accelerated carcinogenesis, we recommend colonoscopy be initiated between ages 20 and 25 and repeated every 1–2 years. In the Lynch syndrome II variant, in addition to the colon, attention for screening is focused on the endometrium and ovary. At age 30, transvaginal ultrasound of the endometrium

and ovary is performed and endometrial aspiration is considered.

The search for a germ-line mutation should be performed only on families with substantial evidence of a hereditary cancer syndrome. Therefore, to establish a syndrome diagnosis, collecting the patient's cancer family history is mandatory and may potentially constitute the most cost-beneficial component of a patient's medical workup. Once the Lynch syndrome diagnosis is established, high-risk patients are then presented with opportunities to search for the germ-line cancer-prone mutation. Herein, genetic counseling prior to DNA collection and at the time of disclosure of DNA test results is recommended. Once a Lynch syndrome MMR germ-line mutation is identified within a family, those who are positive for the mutation are provided genetic counseling at the time of disclosure of results and are afforded an opportunity to follow highly targeted surveillance and management recommendations, while those who are negative for the mutation will revert to general population guidelines.

Lysolecithin

►Lysophosphatidylcholine

Lysophosphatidate

Definition

Lysophosphatidate (LPA) is a type of serum-derived lipid growth factor. This bioactive lipid phosphate is present outside the cell and signals through a series of cell surface receptors. LPA can be formed from phosphatidate by the action of phospholipase A1 or A2, or from circulating lysophosphatidylcholine by lysophospholipase D (autotaxin).

Synonyms

Lysolecithin

Definition

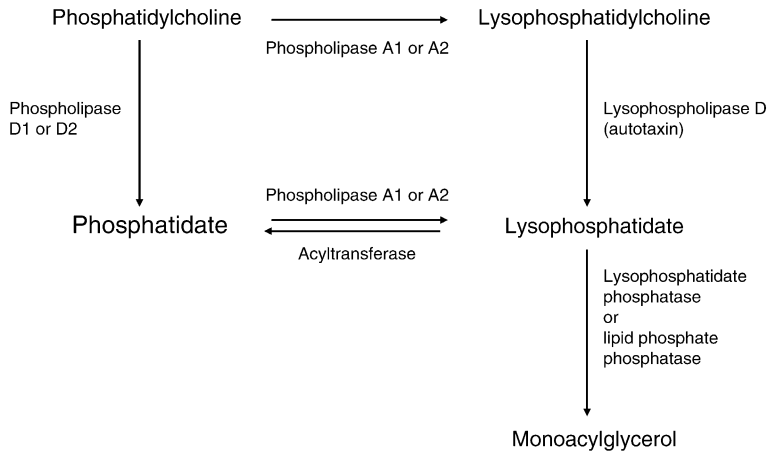
Lysophosphatidylcholine (LPC) is a major plasma lipid constituent that is produced from ►phosphatidylcholine (PC).

Characteristics

LPC is produced from PC under a variety of physiological and pathological conditions. LPC is present at high levels (about 100 μM) in plasma under normal conditions and exists mainly in albumin- or lipoprotein-bound forms. The biochemical conversion from PC to LPC is mediated by ►phospholipase A1 or ►phospholipase A2. Sequentially, LPC is converted to ►lysophosphatidate (LPA) by lysophospholipase D (autotaxin) (Fig. 1).

Signaling Mechanisms

LPC is a cell-signaling molecule. It acts as a ligand for a family of ►G-protein coupled receptors (GPCRs), e.g. G-protein coupled receptor 4 (GPR4) and G2A. Although our knowledge of LPC-sensitive GPCRs is



Lysophosphatidylcholine. Figure 1 Metabolism of lysophosphatidylcholine.

preliminary, circumstantial evidence suggests multiple roles in a variety of physiological and pathophysiological states, such as the development, regulation of the cardiovascular, immune and nervous systems, inflammation, arteriosclerosis and cancer.

GPR4 shows high-level expression in many tissues such as the lung, liver, kidney, ovary and lymph node. GPR4 has the Kd value for LPC = 159 nM in the binding experiments of GPR4-expressing cells. LPC induces transcriptional activation of the serum response element (SRE) in GPR4-transfected HEK293 cells. Gi and Rho (►Rho family proteins) signaling pathways are involved in SRE activation through GPR4. Rho-dependent activities induced by LPC also include actin rearrangement and cell migration. LPC-induced cell migration via GPR4 is sensitive to the C3-exoenzyme. GPR4 is also linked to the activation of the extracellular signal-regulated kinase (ERK) pathway in response to LPC, leading to the stimulation of DNA synthesis and cellular migration in Swiss 3T3 cells. In vascular endothelial cells, LPC upregulates adhesion molecules and growth factors and stimulates the secretion of chemokines and superoxide anions.

G2A is expressed in hematopoietic cells such as T- and B-lymphocytes, monocytes and macrophages and in tissues such as spleen and thymus. LPC activates the migration of T-lymphoid cell lines and peritoneal macrophages via a G2A/Rho dependent mechanism. G2A stimulates Rho via Ga13, resulting in actin rearrangement and SRE-dependent transcription activation. LPC-G2A activation also induces cell migration in Jurkat T cells. As a major component of oxidized low-density lipoprotein, LPC exerts a chemoattractive effect on T cells and macrophages in atherosclerosis and other chronic inflammatory diseases. G2A also displays distinct patterns of ERK activation.

As with other GPCRs, GPR4 and G2A induce ligand-dependent increase in $[Ca^{2+}]i$ (in particular, $[Ca^{2+}]i$ release from intracellular stores), by which they regulate cellular Ca^{2+} homoeostasis and the cytoskeleton, adhesion and migration, proliferation and survival.

Clinical Aspects

Although many lines of evidence support a causal relationship between LPC and atherosclerosis or other inflammatory diseases, its role in carcinogenesis has not yet been extensively investigated. The concentration of LPC (in particular, the ratios of palmitoyl-LPC to linoleoyl-LPC) is elevated in the sera of patients with ovarian cancer or multiple myeloma. In addition, LPC levels are elevated in the bile of patients with ►anomalous pancreaticobiliary ductal junction (APBDJ), which is one of the risk factors for biliary tract carcinomas, and that LPC inhibited cellular apoptosis by inducing ►cyclooxygenase-2 (COX-2) expression via a Raf-1 (►Raf kinase) dependent mechanism in human cholangiocytes. Therefore, LPC is considered to be involved in tumor development or progression, although this still needs to be clarified.

Lysosome

Definition

Is a catabolic organelle in the cytoplasm of eukaryotes. It is characterized by a membrane proto-ATPase that maintains the low pH of 5–6. Lysosomes contain hydrolytic enzymes like proteases, nucleases, phosphatases, glucosidases and lipases. Proteins and other cellular material that is to be degraded enter the lysosome by endocytosis or autophagy. Together with the ubiquitin/proteasome system, the lysosome is the main site of intracellular protein degradation and also fulfills storage functions for ions and small molecules.

Macrophage-Stimulating Protein

Alla Danilkovitch-Miagkova
National Cancer Institute-FCRDC, Frederick, MD, USA

Synonyms

Hepatocyte growth factor-like protein; HGFL; Macrophage stimulating protein; MSP; MST1; HGFL; DNF15S2

Definition

MSP is a plasminogen-related growth and motility serum protein that was discovered as a macrophage chemotactic factor (Fig. 1).

Characteristics

Structure

MSP is a heterodimeric protein (total mass 78 kD, 711 aa) composed of two chains, a 53 kD α and a 25 kD β chain that are linked together by a disulfide bond. Features of the α chain include an N-terminal domain corresponding to the plasminogen preactivating enzyme (PAP or hairpin loop), four kringle domains and a segment that terminates in the cleavage site for activation. The β chain has the serine protease-like domain that is devoid of enzymatic activity because of catalytic triad mutations. MSP is most closely related to hepatocyte growth factor/►scatter factor (HGF/SF), to which it has 45% sequence similarity, and the human gene maps to 3p21.

Biological Activities and Targets

- Murine resident peritoneal ►macrophages: involved in shape changes, ►chemotaxis and inhibition of inducible NO-synthase (iNOS).
- Epithelial cells: involved in enhanced ►adhesion to extracellular matrix, chemotaxis, proliferation, protection from ►apoptosis and increased beat frequency of ciliated epithelium.
- Hematopoetic cells: involved in proliferation, apoptosis and cytokine production.
- Osteoclast-like cells: involved in bone resorption.

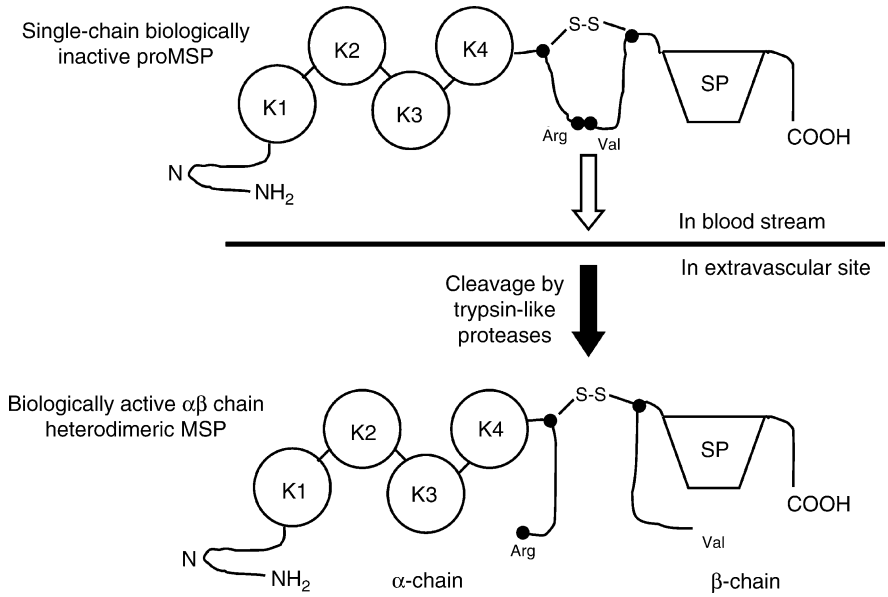
Cellular and Molecular Regulation

MSP is synthesized by hepatocytes as a biologically inactive single chain pro-MSP and is converted at extravascular sites to active MSP by trypsin-like proteases, which cleave at Arg483/Val484 to generate a disulfide-linked α/β chain heterodimer. The enzymes involved in the conversion of pro-MSP to MSP are:

- Purified coagulation system enzymes in vitro: factors XIa and XIIa, serum kallikrein;
- A trypsin-like proteolytic activity on the membrane of peritoneal macrophages;
- A trypsin-like protease in human wound fluid.

MSP Receptor Signaling

MSP mediates its biological activities by activating a cell receptor tyrosine kinase known as RON (Recepteur d'Origine Nantaise) in humans and STK (Stem cell-derived Tyrosine Kinase) in mice. RON/STK is a classical transmembrane receptor belonging to the Met-receptor tyrosine kinase family. The RON gene maps to 3p21, in close vicinity to the MSP gene. MSP-induced receptor activation involves, most likely, dimerization of receptors followed by autophosphorylation occurring in trans (between two receptors) of specific tyrosines in the cytoplasmic portion of the receptors. RON/STK receptors transmit a signal from the cell surface to the inside, which causes the cell to respond to MSP in a



Macrophage-Stimulating Protein. Figure 1 Structure and conversion of pro-MSP to MSP. MSP comprises an N-terminal domain (N) which includes a hairpin loop, four kringle domains (K1–K4) and a serine proteinase-like domain (SP). The interchain disulfide bridge is formed by the α chain Cys468 and the β chain Cys588 (*solid circles* connected by –S–S–). MSP circulates in the blood as single-chain biologically inactive pro-MSP. At extravascular sites, trypsin-like proteases convert pro-MSP to biologically active, disulfide-linked and αβ heterodimeric MSP by cleavage of the peptide bond between Arg483 and Val484 (shown as *solid circles*).

specific manner. MSP-activated signals and effects are cell type specific. MSP mitogenic effects are mediated via focal adhesion kinase (FAK), SRC and mitogen-activated protein kinase (MAPK). Phosphatidylinositol-3-kinase (PI-3K) mediates MSP-induced adhesion and motility. The PI-3K/AKT and the MAPK pathways transduce MSP anti-apoptotic effects, whereas activation of JUN N-terminal kinase (JNK) may induce apoptosis in selected hematopoietic cells.

Clinical Relevance

Active MSP is found in wound fluid, and a high level of RON receptor expression has been detected on the surface of epithelial cells in burn wound epidermis, suggesting a possible role for MSP in wound healing. Overexpression and constitutive ligand-independent RON activation are found in some breast carcinomas, suggesting a possible RON contribution to breast cancer progression. Transfection of a RON cDNA carrying activating mutations in the cytoplasmic domain at Asp 1232 or Met 1254 converts cells to tumorigenicity, raising the possibilty that mutated RON may contribute to tumor development in humans, although a primary role for mutated RON in causing human cancer has not been identified.

Macrophages

Jeffrey W. Pollard
Department of Developmental and Molecular Biology, Center for the Study of Reproductive Biology and Women's Health, Albert Einstein College of Medicine, Bronx, NY, USA

Definition

Mononuclear phagocytic cells differentiated from bone-marrow derived monocytes and found in tissue.

Characteristics

Macrophages originally defined by their phagocytic ability, hence their name (large eater), are one of the major cell types in the body and are found in all tissues where they often constitute 10–20% of the cells. These phagocytic cells were initially defined as the reticuloendothelial system but this definition appears to include cells with different origins and now macrophages are considered part of the mono-nuclear phagocytic system that also includes the more differentiated specialist cells such as the bone-remodeling, ►osteoclasts and the antigen-presenting, ►dendritic cells. These cells have various origins including primitive embryonic macrophages formed in the yolk sac, those derived later in embryogenesis from hematopoietic stem cells (HSC) in the fetal liver and during the post-natal period from the bone marrow. Except in very early embryos, HSCs differentiate through several steps into ►monocytes that circulate and that after extravasation into tissues mature into macrophages. Monocytes appear heterogenous and it is probable that different subsets of macrophages differentiate from different monocytic precursors. HSCs are directed down the mononuclear phagocytic lineage under the influence of several growth factors of which the major one is ►colony stimulating factor-1 (CSF-1; also known as macrophage-CSF), a homodimeric growth factor that activates a class three trans-membrane tyrosine kinase receptor the product of the *c-fms* proto-oncogene expressed on all cells of the lineage. Other growth factors can also promote macrophage colony formation including ►granulocyte-macrophage colony stimulating factor (GM-CSF) and IL-3.

Macrophages perform diverse roles and often have specialized names such as the ►Kupffer cells of the liver, the ►microglia in the brain and the Langerhans cells in the skin. Considerable focus has been paid to their role in the immune system where they are central players in the innate response and the transition of this response to an acquired one. Indeed, macrophages are recruited by a wide range of danger signals to orchestrate these immune activities. They are recruited in response to locally synthesized factors, including the growth factors CSF-1 and ►VEGF, chemokines such as CCL-2, and bacterial products. They are also have important roles in tissue remodeling and wound healing responding to any damage to produce matrix remodeling molecules and trophic and angiogenic factors. Studies on mutant mice depleted in macrophages, particularly the ►osteopetrotic mouse mutant that is homozygous for an inactivating mutation in gene for CSF-1 ($Csf1^{op}$), have confirmed these functions but have also revealed important roles for macrophages during development. These studies have shown that macrophages are essential for the full and timely development of many tissues including the mammary gland, skin, pancreas, brain and bone. For example, in the absence of CSF-1 signaling the mono-nuclear phagocyte derived osteoclasts fails to develop with the consequence that the bone laid down by osteoblasts is not remodeled causing an osteopetrotic phenotype after which the mutation is named. In these mice a bone cavity fails to form adequately and bone marrow hematopoiesis is compromised. Similar trophic and remodeling capacities of macrophages are found for many tissues and their deficiency results in a wide range of phenotypes including small size, reproductive compromise, neurological deficiencies and immune malfunction.

These diverse roles have led to a categorization of different states. Initially a "classically activated" macrophage was defined that showed enhanced antimicrobial activities in a stimulus dependent, but antigen-non-specific manner. These macrophages are activated largely by products of specifically-activated T helper (TH-1) cells particularly interferon γ and have also been referred to as M1 type macrophages. In addition to their ability to kill pathogens through the generation of reactive oxygen and nitrogen species, they can also behave as antigen-presenting cells. In contrast, exposure to cytokines such as ►IL-4 and IL-13 result in an alternatively activated class of macrophages that is produced in a Th-2 type responses and which are involved in allergic reactions and humoral responses to parasites. This class also overlaps with a trophic and remodeling macrophage sub-set that has been referred to as M2-macrophages. This M1/M2 dichotomy has been applied particularly in the tumor context (see below) and represents two extremes of function. It seems likely however, given the wide-range of macrophages phenotypes that there is a continuous spectrum of activities many of which are overlapping and that for our constraining definitions, may appear contradictory. Indeed macrophages may be continuously and reversibly educated by their micro-environment to perform specific tasks.

Macrophages are also found in all solid tumors. Although the original concepts were that these cells were attempting to reject the tumor through their cytocidal and antigen-processing capacities, a recent meta-analysis indicated that in over 80% of studies their density was positively correlated with poor prognosis. Similarly, over-expression of CSF-1 or the macrophage chemoattractant, ►CCL-2 (monocyte chemoattractant protein-1) is correlated with poor prognosis in a variety of cancers. These data suggest that ►tumor associated macrophages (TAM) predominantly, although not exclusively, act to enhance tumor progression and metastasis. In fact, macrophage may also play a causal role in cancer since there is a growing body of evidence that chronic, sometimes called smoldering inflammation, produced by infection for example by Hepatitis virus, ►*Helicobacter pylori* and *Schistosomiasis* or by chronic irritants such as asbestos

or cigarette smoke, can lead to cancer. Since macrophages are central to the inflammatory response their activities in producing growth factors, reactive oxygen and nitrogen species can create a mutagenic and growth promoting environment that both cause oncogenic mutations and promotes the outgrowth of malignant epithelial cells.

Detailed studies of the role of macrophages in mouse models of cancer support the clinical data. For example, genetic depletion of macrophages in a mouse model of breast cancer resulted in a slower rate of tumor progression to malignancy and a dramatic inhibition of metastasis. In contrast, premature recruitment of these cells enhanced these processes. Furthermore, therapeutic approaches using SiRNA or antisense oligonucleotides directed against CSF-1 or treatment with anti-CSF-1 antibodies reduced macrophage accumulation and inhibited tumor growth in xenograft models of human cancer.

TAMs have several activities that can enhance tumor progression and promote metastases. Firstly, they can stimulate angiogenesis and recently they have been found to be responsible for the ►angiogenic switch that is closely associated with the onset of malignancy *in vivo*. This is likely to be at least in part due to their ability to synthesize vascular ►endothelial growth factor (VEGF), a CSF-1 regulated gene in macrophages. Secondly, they can enhance tumor cell migration and invasion *in vivo* through a paracrine loop that requires EGF and CSF-1 signaling in the tumor cell and macrophage respectively with the cognate ligand being produced by the reciprocal cell. Tumor cells also show greater motility when they are in close apposition to macrophages *in vivo*. Macrophages are largely found in the stroma surrounding tumors but they also align in clusters along the abluminal side of vessels. Imaging of living tumors in mice using multi-photon microscopy has revealed that these macrophage foci are the major sites for tumor cell intravasation. Macrophages are also significant producers of proteases such as uPA and ►MMP9, both of which have been associated with tumor progression and metastasis. These proteases can remodel extra-cellular matrix thereby allowing escape of tumor cells from the basement membrane and access into the surrounding stroma and its associated vasculature. These proteases can also release matrix-bound growth factors such as VEGF, TGFβ1 and heparin-binding EGF, growth factors that have all been shown to play a causal role in tumor progression.

It has also been suggested that cells of the mononuclear phagocyte lineage form part of a niche that forms the "soil" for metastatic cells to grow. This is consistent with growing evidence of macrophages in the primary tumor migrating to distant sites where they promote the establishment of metastases. These niches allow tumor cell homing, growth and subsequent vascularization.

Macrophages can also be involved in the rejection of tumors through their cytocidal and antigen presenting properties and there are undoubtedly cases when this occurs. However, there is growing evidence that the tumor microenvironment directs macrophages away from these "activated" macrophage properties (M1) towards an alternative state (M2) that causes trophic and repair roles that are characteristic of their normal functions during development and in wound healing. These properties are enhanced by an environment that contains growth factors such as CSF-1 and the cytokines IL-4 and IL-10. There is also a growing body of evidence that the tumor microenvironment causes differentiation of a class of mononuclear phagocytes, referred to as ►myeloid suppressor cells, that block the development of cytotoxic T cells whose activities can reject tumors. Thus, macrophages may also play an important role in the ►immunoediting that allows tumors to escape immune destruction despite the expression of alloantigens.

In summary, the evidence both from clinical and experimental studies strongly suggests that in the majority of cases tumor associated macrophages are recruited to promote tumor progression and metastasis. It would appear that once in situ the tumor microenvironment educates the macrophages to perform many trophic functions that stimulate tumor growth, with its concurrent selection of epithelial cells with an increasing number of oncogenic mutations.

MAD

Definition

Encodes a nuclear protein (221 amino acids and 25 kDa) that belongs to the basic region helix-loop-helix (BHLH) family of proteins. It dimerizes with MAX and antagonizes transcriptional activity of the MYC protein; MAD/MAX dimers bind to DNA through the CAC GTG sequence (►E-box). MAD competes for MAX/MYC dimerization. The gene maps to chromosomal position 2p13. Mad family are a group of bHLH proteins comprising MAD, MAD3, MAD4, MNT and MXI1.

Mad (Mxd)

Definition

Max dimerization protein is a transcription factor of the Myc/Max/Mad(Mxd) network of basic region-helix-loop-helix-leucine zipper proteins. Mxd is primarily expressed in differentiated cells where it is considered to act as a transcriptional repressor, preventing transcription through recruitment of histone deacetylase-containing complexes. The four proteins Mxd1-4 were originally named Mad1, Mxi1, Mad3, and Mad4.

Magnetic Resonance Imaging

Definition

A basis of magnetic resonance imaging (MRI) method is the behavior of atomic nuclei of certain elements when subjected to a strong constant magnetic field plus superimposed weak variable magnetic fields and radio waves of a defined frequency. Hydrogen is the usual element investigated by MRI. Atoms of hydrogen make up about 65% of the body. Normally, the hydrogen nucleus (proton) spins around its own axis of rotation and a collection of protons within the patient's body has their individual axes spatially oriented at random. When the patient is placed inside a strong (constant) magnetic field, axes tend to line up parallel to the lines of magnetic field, but spin either clockwise or counter clockwise. Few unpaired atoms in the hydrogen assemblage inside the body can be "wobbled" by weak varying magnetic fields and radio waves producing signals of varying intensity. Through electronic and computer processing these varying signals are used to construct three-dimensional images of the various organs and tissues.

Major Histocompatibility Antigens

Definition

Polymorphic proteins between individuals of a given species or different species that can be directly recognized by recipient T lymphocytes, eventually leading to severe and rapid rejection reactions.

►Graft Acceptance and Rejection

Major Histocompatibility Complex

Definition

MHC; Is a cluster of genes on human chromosome 6 or mouse chromosome 17. It encodes a set of membrane glycoproteins called the MHC molecules. The MHC class I molecules present peptides generated in the cytosol to CD8 T cells, and the MHC class II molecules present peptides degraded in intracellular vesicles to CD4 T cells. The MHC also encodes proteins involved in antigen processing and other aspects of host defense. The MHC is the most polymorphic gene cluster in the human genome, having large numbers of alleles at several different loci. Because this polymorphism is usually detected by using antibodies or specific T cells, the MHC molecules are often called major histocompatibility antigens.

Major Histocompatibility Complex (MHC) Class I-related Chain Molecules

Definition

Major vault protein (MVP) is the major component of the vault complex, the largest ribonucleoprotein particle which is hypothesized to be a general carrier molecule for nucleocytoplasmic transport.

Characteristics

The Vault Complex

The vault complex is an evolutionarily conserved ribonucleoprotein particle with an estimated molecular mass of 13 MDa. The barrel-like structures of the vault, initially detected in preparations of clathrin-coated vesicles from rat liver in the mid 1980s, were named vaults due to their resemblance to the vaulted ceilings in cathedrals. The vault complex consists of two symmetrical halves which can unfold into flower-like structures, each consisting of eight distinct petals that are joined to a central ring. Cryoelectron-microscopic three-dimensional image reconstruction techniques revealed a smooth hollow barrel-like structure having an invaginated waist and two protruding caps. The entire mammalian vault complex is composed of ~96 molecules of the 100–110 kDa major vault protein (MVP), 8 molecules of the 193 kDa vault poly(ADP-ribose) polymerase (VPARP), 2 molecules of the 240 kDa telomerase-associated protein (TEP1), and at least six copies of a small untranslated RNA of 88–141 bases. Each petal of the two flower-like halves of vault is believed to consist of six MVP molecules, and the minor vault proteins; TEP1 and probably VPARP, as well as the vault RNAs were shown to be located in the two protruding caps.

The number of vaults per cell has been estimated to be 10,000–100,000 copies. Vaults are most numerous in ►macrophages and epithelial cells with secretory and excretory functions as well as cells chronically exposed to ►xenobiotics such as bronchial cells and cells lining the intestine. In mammalian cells, the vault complex is predominantly localized in the cytoplasm, but ~5% is localized to the cytoplasmic face of the nuclear membrane at or near ►nuclear pore complexes ►(NPC). Based on its typical structure and subcellular localization, the vault is hypothesized as a general carrier molecule for nuclear-cytoplasmic transport. Cryo-immunoelectron microscopy and immunogold staining have provided evidence for the passage of MVP/vaults through the NPC by locating MVP inside the NPC. Furthermore, immunofluorescence and ►immunohistochemistry experiments have demonstrated the association of vaults with cytoskeletal elements. In experiments using sea urchins, the caps of vaults were found to associate with microtubules *in vitro*. Another study demonstrated that β-►tubulin co-precipitated with MVP, and that destabilization of microtubules by nocodazole slowed down the vault mobility in fluorescence-recovery after photobleaching (FRAP) experiments. These data suggest that a subset of vaults move directionally, via microtubules towards the nucleus. Besides, the internal cavity of the vault complex is about 5×10^7 Å^3 in size, large enough to contain particles such as ribosomes or hundreds of proteins as cargoes. Indeed, the sea urchin MVP was demonstrated to copurify with ribosomes, and cryoelectron-microscopic images often show electron dense material within isolated vault particles. To date several proteins have been reported to interact with MVP making them potential cargoes for the vault. In stable transfectant MCF-7 cells, double-site mutations of bipartite ►nuclear localization signal (NLS)-like sequences in ►PTEN (phosphatase and tensin homolog deleted on chromosome 10) disrupted both the nuclear localization of PTEN and the interaction between PTEN and MVP, suggesting that MVP/vaults contribute to the nuclear transport of PTEN.

Major Vault Protein (MVP)

The main component of the vault complex is MVP, also known as ►lung resistance-related protein (LRP), which constitutes 75% of the total mass of the vault and determines its structure. The human MVP gene, located on the chromosome 16p, has 15 exons and encodes 893 amino acids. The human MVP protein contains two distinct domains: a coiled-coil domain at its C-terminal end responsible for the interaction between two MVP molecules and crucial for vault formation, and the N-terminal domain comprised of seven repeats of ~55 amino acids. Two, and possibly three, calcium-binding EF-hands have been identified in the N-terminal domain. The N-terminal part of MVP has been shown to interact with the C-terminus of VPARP.

Recent evidence, from many groups, suggests that MVP is involved in the regulation of signaling pathways including the ►PI3K (phosphatidylinositol 3-kinase)/Akt and ►Ras/►Raf/►MAPKs (mitogen-activated protein kinases) pathways, possibly by acting as a scaffold protein for signaling molecules. To date, several proteins have been reported to interact with MVP, including steroid receptors, PTEN, ►SHP-2, MAPKs, ►COP1 (constitutively photomorphogenic 1), and ►Src. MVP was coimmunoprecipitated with the estrogen receptor in MCF-7 cell nuclear extract. PTEN in HeLa cells was shown to interact with MVP *in vitro* in a Ca^{2+}-dependent manner. SHP-2 was shown to dephosphorylate MVP *in vitro*. Furthermore, in response to ►EGF (epidermal growth factor), SHP-2 associated with tyrosyl-phosphorylated MVP, MVP interacted with the activated MAPKs, and a constitutive complex between tyrosyl-phosphorylated MVP, SHP-2, and MAPKs was detected in MCF-7 cells. In MVP-deficient fibroblasts, MVP was shown to cooperate with Ras for optimal EGF-induced ►Elk-1 activation and

was required for cell survival. UV irradiation enhanced MVP's tyrosil phosphorylation, caused dissociation of COP1 from MVP, and attenuated the inhibitory activity of MVP on ►AP-1 (activator protein-1) transcription. The interaction between Src and MVP was shown to be dependent on EGF-induced Src activity and MVP tyrosil phosphorylation.

Accumulating data indicate that MVP plays a crucial role in cell survival. Serum deprivation significantly increased cell death of $MVP^{-/-}$ MEFs as compared to wild-type MEFs. Disruption of two MVP genes in the slime mold *Dictyostelium discoideum* resulted in growth defects under nutrient stress. Furthermore, anti-MVP polyclonal antiserum reduced viability of the mature monocyte-derived dendritic cells.

There are a couple lines of evidence that suggest the involvement of MVP in cell differentiation. Phorbol 12-myristate 13-acetate, lipopolysaccharide, and sodium butyrate (NaB), agents known to induce cell differentiation, up-regulate MVP in a variety of cell types. In addition, MVP is strongly up-regulated during dendritic cell (DC) maturation. In human DC cultures, antibodies against MVP reduced the expression of DC differentiation and maturation markers and impaired the capacity to induce antigen-specific T cell response. The exact role of MVP in DC maturation may be controversial as the MVP knockout mouse failed to substantiate the role of MVP in DC development and function.

During sea urchin embryogenesis, MVP accumulates in the nucleus at the mesenchyme blastula stage, the developmental stage marking the transition between proliferation and differentiation. This may suggest that MVP contributes to development through nuclear transport. This is further substantiated by the expression and distribution of MVP in mammalian oocytes and embryos at various stages of preimplantation development.

Taken together, these data implicate a role for MVP in cell survival, differentiation, and development through mediating cellular signaling pathways and/or nucleocytoplasmic transport.

Drug Resistance

Utilizing immunocytochemical methods in a screen of 61 human cancer cell lines, MVP was detected in 78% of the cell lines and expression levels predicted resistance against a variety of anticancer drugs. These data were confirmed in a study with eight cancer cell lines chosen from the panel which demonstrated a positive correlation between MVP mRNA level and broad chemoresistance. In astrocytic tumor cell cultures, a correlation between MVP expression and resistance against several drugs including anthracyclins, etoposide, and ►cisplatin was observed. In contrast, in ►non-small cell lung cancer (NSCLC) cells, basic MVP expression levels correlated with resistance to cisplatin, but not to several other drugs, including daunomycin, doxorubicin, etoposide, vinblastine and bleomycin. In pharyngeal epidermoid carcinoma KB-3–1 cells, however, elevated MVP levels correlated with decreased accumulation of doxorubicin in the nuclei.

Several studies have reported increased expression levels of MVP in drug-selected multidrug-resistant (MDR) cell models. Doxorubicin selected U-937 human leukemia cells have increased levels of both MVP mRNA and protein and acquired resistance against doxorubicin, etoposide, mitoxantrone and 5-FU, independent of several ►ABC transporters (ATP-binding cassette transporters). A selection of KB-3–1 cells with the carcinogen benzo[a]pyrene led to a selective up-regulation of MVP. In general, many drug-selected MDR cell lines have a 1.3–1.5-fold increase in MVP. The exact mechanism of MVP in MDR has not been elucidated, however recent findings suggest that MVP contributes to MDR by regulating nuclear drug export.

While MVP is thought to play a role in MDR, other studies indicate that MVP does not always play a role. For instance, in A2780 ovarian carcinoma cells, MVP overexpression did not confer drug resistance against doxorubicin, vincristine and etoposide, although these transfectants contained increased number of intact vault particles with increased levels of the minor vault components TEP1 and VPARP. In the MVP knockout mouse model, both embryonic stem cells and bone marrow cells did not show an increased sensitivity to a panel of cytostatic agents compared to wild-type cells. The activities of P-gp, MRP1 and BCRP1 were not altered in the vault-deficient cells, excluding the possibility of these ABC-transporters compensating for the loss of vaults. Moreover, both knockout and control mice responded similarly to the drug treatment. In a functional study, stable transfection of GFP-tagged MVP in the SW1573 NSCLC cell line did not alter daunorubicin efflux rate and intracellular distribution. No differences were detected in the handling of daunorubicin in MVP-knockout MEFs compared to wild-type MEFs. ►SiRNA-mediated inhibition of MVP in the drug resistant SW1573/2R120 NSCLC cell line did neither alter doxorubicin nuclear efflux, intracellular distribution, nor sensitivity to doxorubicin.

Altogether, while a direct role of MVP in MDR mainly by drug transport mechanisms was initially assumed, more recent findings suggest that MVP might be indirectly involved in drug resistance by modulating cellular signals for proliferation and survival. The interaction of MVP with key molecules in the PI3K/Akt and Ras/Raf/MAPK pathways may suggest a role as scaffold protein for signaling molecules, however this remains to be examined in great detail.

Prognostic Significance

The MVP expression has been detected in diverse types of human cancers, and numerous studies have been performed to examine the prognostic significance of MVP on chemotherapy response and patient prognosis. Overall, however, the current available data cannot provide any conclusive evidence regarding MVP's prognostic impact in human cancers mainly due to limited size of the patient groups and discrepancies among studies. Prospective clinical trials using larger size of cohorts and multivariate analyses are required to clarify the issue.

Malignancy-Associated Changes

Timon P. H. Buys, Wan L. Lam
Department of Cancer Genetics and Developmental Biology, British Columbia Cancer Research Centre, Vancouver, BC, Canada

Definition

Malignancy-associated changes (MACs) are subtle changes in the nuclear morphology and ►chromatin structure of seemingly normal cells located proximal or even distal to neoplastic or ►preneoplastic lesions.

Characteristics

MACs were first described nearly 100 years ago in the leukocytes of patients harboring malignant disease, though the term "MAC" was not applied until the 1950s when these features were observed in normal buccal mucosa. The hallmarks of MAC are a variety of changes in nuclear texture, including increases in the ratio of nucleus to cytoplasm, disappearance of nucleoli, emergence of specific arrangements for chromatin bands and nuclear proteins, and the presence of multinucleated cells.

Although MACs were observed in the nuclei of tumor-associated peripheral blood, sputum, bone marrow, uterus, pancreas, liver, and skin cells, the subjective approaches for determining these features limited their use in a clinical setting. The development of ►image cytometry techniques in the 1970s allowed objective measurement of this phenomenon, raising the potential for clinical application. ►Densitometric analysis of Feulgen-stained nuclei by a camera with a charge-coupled device was used to objectively assess MACs. This stain binds to DNA, allowing characterization of chromosomal features, while the camera's high resolution facilitates hundreds of precise independent measurements of nuclear size, shape, and volume. The spatial organization of genomic material within the nucleus is another metric for assessing MAC effect. This includes the assessment of whether DNA is dispersed to the edges of the nucleus or clumped at the center, the degree of contrast between condensed and non-condensed chromatin, and whether chromosomes are found in large irregular clumps or small uniform clumps. Ultimately, the development of high resolution imaging approaches has facilitated analysis of more than 60 different cell features – many of which cannot be detected by the human eye – to identify MACs.

Mechanisms

Two general mechanisms have been used to explain how MACs arise. The first is that MACs develop in normal tissue neighboring tumors due to exposure to the same carcinogens that induced the tumor. This "►field effect" explanation proposes that MACs arise independently from neighboring tumor tissue. The second proposed mechanism is that MACs arise in normal cells due to soluble factors that are released from tumor tissue. That is, the tumor induces changes in surrounding normal tissue.

One avenue of support for the second explanation is that the degree of MAC in normal cells escalates with increasing lesion severity (e.g. MACs in normal uterine cervical cells have been shown to increase with cancer ►progression). Further support for the idea that MACs arise in a tumor-dependent fashion is the fact that MACs in normal cells diminish after a tumor has been removed. Additional support for this tumor-dependent model can be found in the fact that MAC severity in normal cells can decrease depending on the distance from a given lesion and that ►*in vitro* experiments involving the maintenance of normal cells and tumor cells in the same culture flask show that the number of MACs in the normal cells increases when the concentration of co-cultured tumor cells increases.

Dysregulation of growth factors is well characterized in a variety of tumor types and ►autocrine signaling is understood to drive unchecked cell cycle progression. It is possible that neighboring normal cells are susceptible to the effects of this mode of activation; normal cells expressing growth factor receptors on their outer membrane could be susceptible to aberrant activation

through ►paracrine signaling. Redistribution of chromatin is also a hallmark of MAC. ►Chromatin remodelling in cancers has previously been described and is known to result in oncogenic activation. In normal cells exhibiting MACs, these changes may alter transcriptional activity in various parts of the genome, which may in turn lead to activation of genes that drive other observable MACs.

Clinical Aspects

High resolution genomic technologies have been used to uncover specific factors associated with MACs. For example, gene expression microarray studies of airway epithelial cells from smokers with and without lung cancer revealed specific changes associated with the presence of disease. Up-regulated genes were involved with ►inflammation and cell cycle progression processes, including multiple factors associated with the oncogenic ►*RAS* signalling pathway, suggesting that the presence of cancer mediates the behavior of normal airway tissue.

MACs could have utility as surrogate ►biomarkers in at-risk populations (e.g. smokers with risk of ►tobacco-related cancer). Where individuals are asymptomatic and have no detectable tumor mass, the presence of MACs may be used to identify patients requiring greater clinical vigilance, including regular screening for disease. For example, MACs have been shown to improve sensitivity for detecting early lung cancers when used in conjunction with conventional approaches to ►sputum cytology. (The ability to couple MACs with non-invasive diagnostic approaches also makes it an attractive tool for clinical application.) Discovery of additional MAC-associated factors will increase the likelihood that these changes will be adopted as screening tools in the clinic.

Malignant Lymphoma: Hallmarks and Concepts

H. K. Müller-Hermelink[1], G. Ott[2]
[1]Institute of Pathology, University of Würzburg, Würzburg, Germany
[2]Institute of Pathology, Robert-Bosch Krankenhaus, Stuttgart, Germany

Definition

Malignant lymphomas are defined as neoplasms consisting of cells of the lymphoid tissues. Contrary to most organs and tissues, and in spite of the fact that lymphomas show a wide range of aggressiveness from localized, indolent to highly aggressive, rapidly metastasizing tumors, no bona fide benign lymphomas have been defined. Distinct lymphoma entities in general show a characteristic clinical and biological behavior, but within these entities a broad spectrum of

aggressiveness may be observed in individual cases, which is either due to disease progression in a multistep process of lymphomagenesis and/or the involvement of specific risk factors.

Characteristics

Classification

The current WHO classification of the tumors of hematopoietic and lymphoid tissues greatly follows the rules of the REAL classification. According to morphological and biological criteria, Hodgkin lymphomas are distinguished from non-Hodgkin lymphomas, and neoplasias arising from immature precursor cells are set apart from those arising from peripheral mature cells. Distinct clinical and pathological entities are recognized by a combination of morphological, immunophenotypic, genetic and clinical features required for their specific diagnosis. Within each entity, morphological and clinical variants may be recognized that are important for diagnostic and/or prognostic reasons. Specific biological and/or clinical features may characterize distinct disease subtypes, e.g. mediastinal B cell lymphoma within the category of diffuse large B cell lymphoma.

The classification of lymphomas is organized primarily according to the functional differentiation pathways of lymphoid and immune-regulatory cell types and correlated to a suggested normal counterpart of lymphoma cells. The initially presenting clinical features, such as nodal or extranodal disease localization, and presence or absence of leukemic dissemination are important. Primary genetic abnormalities or specific etio-pathogenetic factors apply for only certain diseases.

Malignant non-Hodgkin lymphomas and their major variants are listed according to the main differentiated cell type as precursor or mature peripheral cell type tumors and their relationship to the B cell or NK/T cell systems (Tables 1 and 2).

In the Hodgkin lymphomas (HL), two entities are recognized: Nodular lymphocyte predominant HL and classical HL, with the latter harboring several variants (nodular sclerosis, mixed cellularity, lymphocyte-rich and lymphocyte-depleted (Table 3).

The Molecular Genetic Basis of NHL

Primary recurring genetic alterations have been defined in many B cell NHL and in some T cell NHL (Table 4). The likely primary transforming event represents constitutive activation of a proto-oncogene that has been translocated into strongly active or cell-specifically expressed cellular genes, forming fusion transcripts that retain the oncogenic or transcriptionally active part of the proto-oncogenes. Their functional consequence in some B cell lymphomas characterized by a protracted and indolent clinical course is to confer resistance to apoptosis (e.g. follicular lymphoma or marginal zone B cell lymphoma of MALT type), that is considered to represent the most important regulatory mechanism in the clonal evolution of B cells. It is activated in selection processes establishing anti-self tolerance during early development as well as during antigen-driven selection occurring in germinal centers of B cell follicles. Immunoglobulin rearrangements and heavy chain switching, as well as immunoglobulin gene related hypermutation processes during these steps of evolution, may cause a state of temporary active genomic destabilization that carries an increased risk for the formation of translocations involving the immunoglobulin heavy chain genes in the long arm of chromosome 14. Hereby, activated B cells destined to die may be rescued from apoptosis.

The transcriptional deregulation of some of these genes probably suffice to confer the fully malignant

phenotype (e.g. activation of the *MYC* gene in Burkitt lymphoma inferred by the translocation t(8;14)), whereas other translocations (e.g. the activation of the anti-apoptotic *BCL2* gene by the translocation t(14;18) in follicular lymphoma) seem to prolong the lifespan of the cells only, thus enabling the acquisition of secondary aberrations: Less than 10% of follicular lymphomas show this translocation as the sole genetic abnormality. Neoplastic transformation, therefore, in most cases is mediated as a multistep process involving loss or functional inactivation of important regulatory and/or tumor suppressor genes, and may in addition be responsible for the progression of indolent to highly aggressive lymphomas. Genes frequently targeted in the progression of malignant lymphomas are *TP53* in 17p, $p16^{INK4A}$ in 9p, and *MYC* in 8q.

Antigen Receptors in NHL

Signaling via the antigen receptor provides the most important pathway of lymphocyte differentiation and selection during ontogenesis and antigen related immune reactions, and is also of pivotal importance in the pathogenesis of malignant lymphomas.

Immunoglobulin Receptor of B Cells:

The unique clonal antigen receptor repertoire in B cells is formed by the rearrangement of VDJ and constant regions of the immunoglobulin heavy and light chain genes. The demonstration of a clonally rearranged, single receptor is the basis to determine the clonality of a lymphoproliferative process. V-gene usage and organization of VDJ genes provide important clues to aspects and differentiation of HL. For extranodal B cell lymphomas, a biased V-gene usage (with respect to the normal repertoire) and the demonstration and distribution of mutations in the complementary determining regions (CDR) and framework regions (FR) exemplifies the influence of antigen on the selection of neoplastic B cell populations. The presence of mutations in IG genes is an important clue to assess the pre-follicular B cell or follicular and post-follicular B cell origin of lymphoma cells. Whereas chronic lymphocytic leukemia and mantle cell lymphoma either show non-mutated or mutated Ig-receptors, most lymphomas show either non-mutated receptors (precursor B cell lymphoblastic lymphoma) or mutated receptors (follicular lymphoma, marginal zone B cell lymphoma and most aggressive B cell lymphomas including diffuse large B cell lymphoma and Burkitt lymphoma) exclusively. “Ongoing” somatic hypermutations indicating a still active process of immunoglobulin-related hypermutations were shown to represent the characteristic genetic fingerprint of follicular lymphoma, but also demonstrated in marginal zone B cell lymphoma and diffuse large B cell lymphoma. Therefore, most lymphomas originate in the antigen-driven germinal center cell reaction or by an extrafollicular post-germinal center lymphocyte activation process.

T Cell Receptors in Peripheral T Cell Lymphomas:

The specificity of α/β and γ/δ types of T cell receptors as well as the significance of the expression and functional activity of NK cell receptors in NK/T cell lymphomas is still poorly understood.

Gene Expression Profiling

The development of high throughput technologies and, in particular, of DNA microarrays led to a major advantage in the understanding of complex biological processes. They formed the basis towards a molecular

classification of lymphomas, and gene expression-based survival predictors are envisaged to become highly useful in guiding future treatment decisions.

In diffuse large B cell lymphoma, gene expression profiling (GEP) led to the recognition of two molecular subgroups, the germinal center-like type of DLBCL (GCB DLBCL) and the activated B-cell-like type of DLBCL (ABC DLBCL). GCB DLBCL are characterized by high expression of genes that are typically expressed in B-cells at the germinal center stage of B-cell differentiation, while ABC DLBCL express genes at a high level that are upregulated in B-cell in response to mitogenic activation. From a clinical point of view, the varying molecular features of DLBCL had a strong impact on the clinical course of the disease with strikingly different 5-year survival rates between GCB

and ABC DLBCL patients. Also, the molecularly defined DLBCL subtypes differ in their genetic constitution: The chromosomal translocation t(14;18) involving *BCL2* and amplifications of the *c-rel* locus on chromosome 2p were assigned to GCB-type DLBCL, while the genetic hallmark of ABC DLBCL are the constitutive activation of the NFκB-pathway, and genomic gains in 3q and 18q. In MCL, gene expression profiling led to the unequivocal definition of a new Cyclin D1-negative MCL subgroup. More important, a gene expression-based predictor of survival in MCL patients was constructed providing prognostic information at the time of diagnosis. In this approach, a 'proliferation signature' was defined encompassing genes required for DNA replication, cell cycle progression and metabolic processes required for the proliferation of tumor cells. Ranking of the MCL patients according to the proliferation signature score of their tumor specimens yielded four quartiles with median survival times differing by as much as 6 years. From a biological standpoint, the proliferation signature in MCL can be viewed as an integrator of various oncogenic events in these tumors. Results of GEP analyses in Follicular lymphoma led to the recognition of two gene signatures, Immune-response 1 (IR-1) and Immune-response 2 (IR-2) signatures with striking importance in defining the patient's individual risk. In this model, IR-1 over-expression was associated with a more favorable outcome, while IR-2 over-expression was pointing at an adverse prognosis. Most importantly, flow sorting of CD19 + and CD19-cell subpopulations from primary specimens suggested the expression of IR-1 and IR-2 signatures in the non-malignant cell population, thus providing evidence that expression signatures associated with survival in FL mainly reflect biological properties of non-malignant tumor-infiltrating cells.

Etiology

Among the etiological factors for malignant lymphoma, chronic viral and bacterial infections play a major role. Insertional mutagenesis, transcriptional activation by viral genes as well as viral homologues of cellular oncogenes and growth factors may cause lymphomatous transformation directly or indirectly by increasing the risk for further cellular mutagenic events.

The ►Epstein-Barr virus (EBV) plays a major role in the pathogenesis of Hodgkin lymphoma (HL), endemic Burkitt lymphoma and many immunodeficiency related malignant lymphomas. It is also found in a variety of peripheral T cell lymphomas, especially in angioimmunoblastic T cell lymphoma and extranodal NK/T cell lymphoma of nasal type, as well as in about 5% of diffuse large B cell lymphomas in the Western hemisphere. Epstein-Barr virus in all these cases is clonally integrated in lymphoma cells, suggesting that the virus was already present in the tumor stem cell. The transformation processes appear to be various in different lymphoma types and are still not completely understood.

HTLV-1 is invariably linked to Adult T cell Lymphoma/Leukemia, which is endemic in Southern Japan, the Caribbean and certain regions in Africa. The transformation is related to the transcriptional activation of cellular genes by the viral transcription factor TAX in CD4-positive T-helper lymphocytes and other mutagenic events.

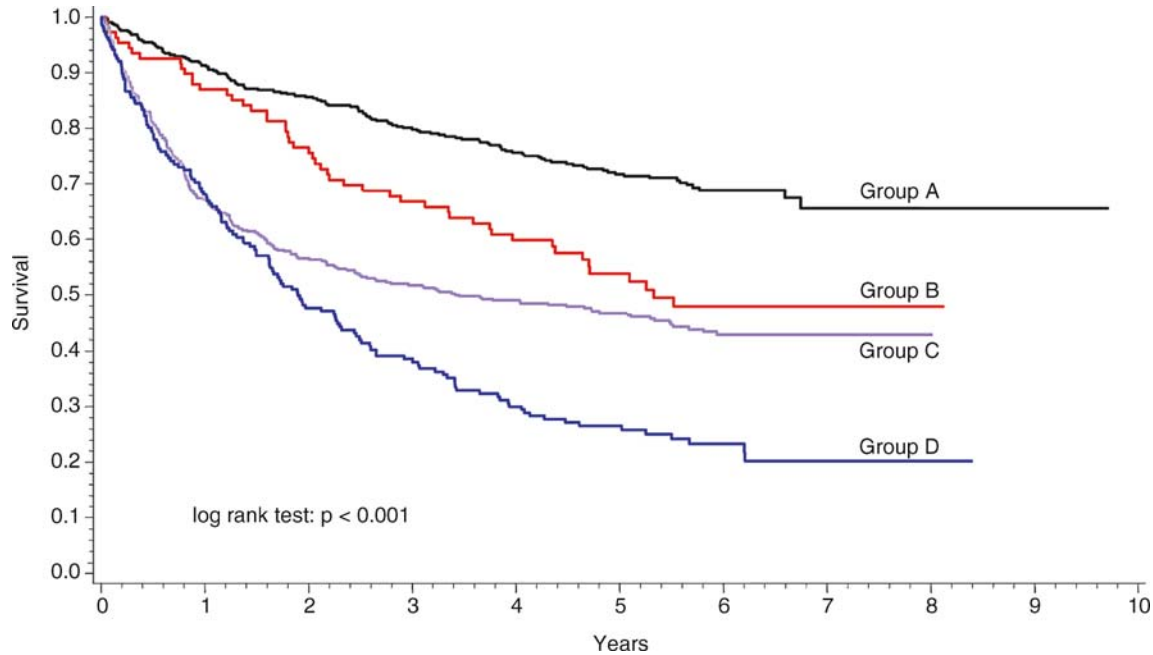
The human immunodeficiency virus (HIV) is associated with increased risk for aggressive B cell lymphomas, either of Burkitt lymphoma subtype or immunoblastic-plasmablastic lymphomas. 50% of Burkitt lymphomas and 80% of immunoblastic and plasmablastic diffuse large B cell lymphomas in HIV-infected individuals are caused by ►EBV, and its presence is related to the status of immunodeficiency. Rare specific subtypes of NHL seen in AIDS patients are the primary effusion lymphomas that are related to HHV8 (KSHV) frequently with co-infection of EBV. Whether HIV plays a direct role in EBV- and HHV8-negative lymphomas, or transformation in these cases is induced by other viruses or sporadic mutagenic events in hyperproliferative B lymphocytes, is unknown.

►Helicobacter pylori (H.p.) infection is a causative factor for extranodal marginal zone B cell lymphomas of MALT type in the stomach. Early stages of lymphoma development may be successfully treated by H.p. eradication. The molecular genetic analysis of H.p.-associated lymphomagenesis in the stomach shows that different factors are effective in the transformation processes.

- An indolent form of gastric MALT-type lymphoma does not show progression and is associated with the translocation t(11;18) (q21;q21). No transformation to high grade lymphomas and no further genetic imbalances are found in these cases.
- Low grade MALT type lymphomas show characteristic genetic imbalances in 3q;11q and 18q.
- Diffuse large B cell lymphomas show similar chromosomal imbalances but additional and more frequent changes in chromosomes 6q and 7q as well as ►LOH in the loci of the ►APC, ►$p16^{INK4A}$, the retinoblastoma ►RB1 and ►TP53 tumor suppressor genes.
- De novo diffuse large B cell lymphomas show genetic imbalances, losses and deletions as in the afore mentioned aggressive B cell lymphomas, but without the alterations seen in low grade tumors.

This scenario reflects the different pathways of lymphoma transformation: stable accumulative disease, a progressing genetically unstable disease

M



Malignant Lymphoma: Hallmarks and Concepts. Figure 1 Clinical groups of the International Lymphoma Classification Project according to different five year survival. Group A: 5 year Overall Survival > 70%: Indolent slow decline and/or few disease related deaths. (Anaplastic large cell lymphoma, marginal zone B cell lymphoma of MALT-type, follicular lymphoma).Group B: 5 year Overall Survival 50–70%: Continuous slow decline of survival. (Nodal marginal zone lymphoma, lymphoplasmacytoid lymphoma, small lymphocytic lymphoma). Group C: 5 year Overall Survival 30–50%: Rapid initial decline of survival plateau and few disease related deaths after 2 years. (Primary mediastinal large B cell lymphoma, diffuse large B cell lymphoma, Burkitt lymphoma, Burkitt-like lymphoma). Group D: 5 year Overall Survival < 30%: Rapid decline and low level plateau or rapid continuous decline. (Precursor T lymphoblastic lymphoma, peripheral T cell lymphoma, mantle cell lymphoma).

or aggressive de novo lymphomas, which are similar to sporadic non-H.p.-associated lymphomas of the B cell type.

Cell Biological Features of Hodgkin Lymphoma

All cases of Nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL) and 98% of classical Hodgkin lymphoma (CHL) are B lymphocyte derived monoclonal lymphoproliferative disorders of (frequently) young adults. For the pathological diagnosis, their unifying feature is that scattered tumor cells (called Hodgkin cells and Reed-Sternberg cells in CHL and L&H cells in NLPHL) are found in a non-neoplastic background infiltrate of various cell types forming the lymph node tumors. A rosette-like arrangement of T lymphocytes around tumor cells is often characteristic, suggesting the functional interaction of tumor cells and T lymphocytes in the production of multiple cytokines and chemokines, which are responsible for the pleomorphic histological picture and the paraneoplastic clinical features well-known in this disease (so-called B symptoms). The tumor cells of both NLPHL and HL correspond to germinal center-derived activated B lymphocytes, however, they markedly differ in their antigenic phenotype and receptor status. Rare cases of HL may show a T cell phenotype and genotype.

The B cell nature of L&H-, HD- and RS cells has been elucidated by single cell microdissection from tumor tissue. L&H cells show transcription of intact immunoglobulin receptor genes, whereas in HD and RS cells of CHL, the transcription of immunoglobulin genes is blocked. In an earlier hypothesis, it was postulated that this feature was due to 'crippled' immunoglobulin genes due to hypermutations occurring in the germinal center, often leading to stop codons and deletions. This view, however, has been challenged by the demonstration of defective co-activators of immunoglobulin gene transcription (i.e. Oct 2 and BOB 1), considered to be the basis of this cellular defect.

The constitutive activation of the NFκB pathway by different molecular events (i.e. inhibitor inactivation of IκBα-2, hyperexpression of TRAF-1 signaling and other, yet unknown reasons) appears to be a central defect of cell regulation in Hodgkin lymphoma. The hyperactivity of this important transcription factor leads to resistance of apoptosis and increased transactivation of cytokine and chemokine genes and their receptors, respectively, stimulating unrestrained growth. This may

result in the survival of activated germinal center cell populations normally destined to die by apoptosis.

Basic Clinical Features of Malignant Lymphoma

Malignant lymphomas occur at a frequency of about 12:100,000 per year in the Western population, equivalent to about 10,000 new cases in Germany per year. The incidence rate of Hodgkin lymphoma, with a frequency of 4:100,000 per year, has been stable over the last decades, whereas non-Hodgkin lymphomas show a continuous increase over time. This increase is still evident if absolute data are corrected for the increase of mean lifetime expectancies. The reason for the increase of non-Hodgkin lymphomas is unclear.

For most NHL and NLPHL, there is a slight to marked male predominance, whereas classical Hodgkin lymphoma and mediastinal large B cell lymphomas more frequently occur in young females. The age range of malignant lymphoma is broad, from young children to the highest age groups, with a characteristic predilection for certain subtypes in young patients (Burkitt lymphoma, precursor lymphoblastic lymphoma, diffuse large B cell lymphoma of centroblastic type and anaplastic large cell lymphoma of T type). Other lymphomas are more frequent in the young adult population (Hodgkin lymphoma, mediastinal B cell lymphoma, anaplastic large cell lymphoma T type, extranodal diffuse large B cell lymphoma) or in higher age groups (indolent lymphomas, which apparently do not exist under the age of 20, diffuse large B cell lymphomas, and peripheral T cell lymphomas).

With the introduction of modern multi-agent chemotherapy regimens, the prognosis of HL and aggressive non-Hodgkin lymphoma has greatly improved, whereas other non-Hodgkin lymphomas still show an incurable, indolent or aggressive course (Fig. 1). For the aggressive NHL, the use of anti-CD20 antibodies has resulted in an apparently dramatic improve of cure rates.

Modern and refined classifications of lymphoma entities including newer molecular genetic classification approaches may better define and find new and more specific treatment options for the incurable diseases. A better definition of molecular events in malignant lymphoma (e.g. by gene expression profiling) may also help to define specific risk factors and prognostic features that can be used to modify present treatment protocols on a rational basis and adapt more specific treatment regimens to individual diseases.

Malignant Peripheral Nerve Sheath Tumor

Definition

MPNST; Cancer that arises from the cells of connective tissue sheath of a peripheral nerve. Synonyms: malignant neurolemmoma, neurofibrosarcoma. About half the cases are diagonosed in people with neurofibromatosis 1.

►Neurofibromatosis 1

Malignant Pleural Effusion

Definition

MPE; Presence of fluid in the pleural cavity due to direct infiltration of the pleura by cancer or to a disturbance in the mechanisms that normally move the fluid across the pleural space and reabsorb it.

►Pleural Effusion

Malignant Progression

Definition

The change of cells from benign to malignant behavior is called malignant ►progression or transformation. Malignant progression is characterized by the acquisition of progressive and uncontrolled growth of tumor cells. Malignant tumors have the ability to invade adjacent tissues and spread to distant sites in the body. Although there can be many causes for malignant progression, an underlying commonality is genetic mutation either by inheritance or more commonly by acquiring mutations in one's DNA over time.

Malignant Salivary Gland Cancer

Mammalian Target of Rapamycin

Victoria A. Robb, Elizabeth Petri Henske
Fox Chase Cancer Center, Philadelphia, PA, USA

Synonyms

mTOR

Definition

Mammalian target of Rapamycin, commonly known as mTOR, is a central kinase that integrates signals from cellular cues to regulate many processes, including protein translation, cell survival, proliferation, metabolism, ►autophagy, and the cytoskeleton.

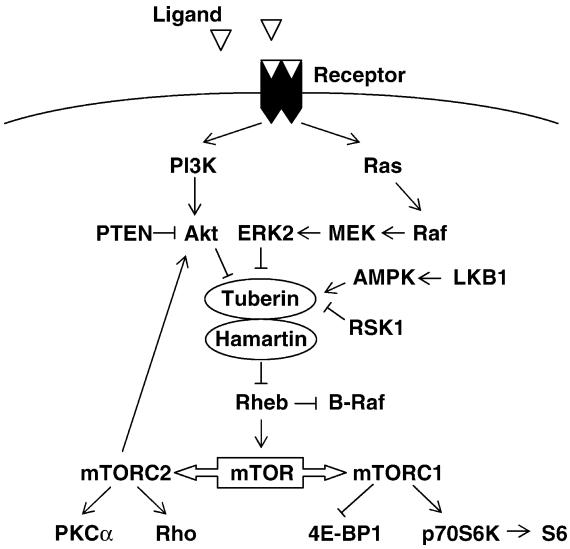
Characteristics

mTOR forms two functionally distinct protein complexes, mTOR complex 1 (mTORC1) and mTOR complex 2 (mTORC2). Both mTORC1 and mTORC2 are composed of mTOR and GβL. In addition, mTORC1 contains raptor while mTORC2 contains Sin1 and rictor. Functionally, the two complexes are very different. Activation of mTORC1 leads to the phosphorylation of downstream targets including p70 ribosomal protein S6 kinase (p70S6K), ribosomal protein S6 (S6), and eukaryotic initiation factor 4E-binding protein 1 (4E-BP1), that promote increased protein translation and cell growth. mTORC2 activation regulates Akt/PKB, PKCα, and Rho to control cell survival, proliferation, metabolism and the cytoskeleton.

Regulation

The mTOR signaling pathway is illustrated in Fig. 1. Upstream of mTOR are two ►tumor suppressor genes, *TSC1* and *TSC2*, that regulate mTOR activity via ►Rheb (Ras homologue enriched in brain). *TSC1* encodes hamartin, a 140 kDa protein that physically interacts with the protein product of *TSC2*, tuberin. Tuberin is a 200 kDa protein with a domain near the carboxyl terminus containing ►GTPase activating protein (GAP) homology. GAP proteins convert members of the Ras superfamily from their active, GTP-bound state to their inactive, GDP-bound state. Rheb, like other Ras family members, cycles between an active GTP-bound and an inactive GDP-bound state. Tuberin converts Rheb-GTP to Rheb-GDP, thereby inactivating Rheb and inhibiting mTOR. Conversely, loss of either tuberin or hamartin, or inactivation of tuberin by upstream regulators releases the brake on Rheb resulting in mTOR activation. At least three kinases are known to directly phosphorylate and inactivate tuberin: p90 ribosomal S6 kinase 1 (RSK1), Erk2 via the ►Ras signaling pathway, and Akt/PKB via the phosphatidylinositol 3 kinase (►PI_3K) signaling pathway. In addition, mTORC2 phosphorylates Akt/PKB on Serine 473, thereby activating Akt/PKB and inhibiting tuberin via a feedback mechanism. In contrast, LKB1/AMPK-mediated phosphorylation activates tuberin and inhibits Rheb-dependent mTOR activation.

The mTOR pathway is regulated by many intracellular and extracellular signals and integrates both positive and negative stimuli. mTOR is activated by insulin, growth factors, nutrients, and mitogens and inhibited by numerous stress conditions, such as cellular energy depletion and hypoxia. Pharmacologically, ►Rapamycin specifically inhibits mTORC1 thereby preventing phosphorylation of downstream effectors S6K and 4E-BP1 resulting in an inhibition of cell proliferation.



Mammalian Target of Rapamycin. Figure 1
Illustration of the mTOR signaling pathway. Tuberin and hamartin function as a complex to inactivate Rheb and inhibit mTOR. Inactivation of tuberin by upstream regulators, such as RSK1, Erk2 via the Ras signaling pathway, and Akt/PKB via the PI_3K signaling pathway, releases the brake on Rheb. In contrast, LKB1/AMPK-mediated phosphorylation activates tuberin. mTOR forms two functionally distinct protein complexes, mTORC1 and mTORC2. mTORC1 leads to the phosphorylation of p70S6K, S6, and 4E-BP1, that promote increased protein translation and cell growth. mTORC2 activation regulates Akt/PKB, PKCα, and Rho to control cell survival, proliferation, metabolism and the cytoskeleton. Arrowheads indicate activation and flat bars indicate inhibition of function.

Clinical Relevance

Unconstrained mTOR signaling has been noted in several human diseases. Inactivation of negative regulators of the AKT-mTOR pathway such as PTEN (associated with ►Cowden syndrome), TSC1 or TSC2 (►tuberous sclerosis complex), LKB1 (►Peutz–Jeghers syndrome), NF1 (►neurofibromatosis 1), and VHL (►von Hippel–Lindau disease), results in familial cancer syndromes (collectively called ►phakomatoses) with similar clinical features. In addition, Akt signaling is aberrant in many sporadic human cancers resulting in elevated mTOR activity. Collectively, these observations have provided a scientific basis for mTOR inhibition

using Rapamycin and its derivatives as a prospective treatment for these diseases.

Mammographic Breast Density and Cancer Risk

Elsebeth Lynge
Institute of Public Health, University of Copenhagen, Denmark, Copenhagen

Definition

The purpose of ►mammography screening is to reduce the mortality from breast cancer in the targeted population. Breast cancer is worldwide the most frequent cancer disease in women, and the highest incidence is found in countries with a high standard of living. Breast cancer is associated with the life long exposure to endogenous and exogenous hormones, and it is as such difficult to prevent. Mammography screening has therefore become an important tool in breast cancer control.

Screening is the examination of healthy people for the possible presence of diseases that has not given rise to symptoms. Screening might be undertaken in organized program targeting a given population at specified intervals, or opportunistically following the wish of a woman or advice from her physician. Mammography is a radiological examination of the breast for lumps and/or microcalcifications. Both invasive ►breast cancer and ►ductal carcinoma in situ (DCIS) can be detected by mammography. Mammography is used both as a diagnostic test for women with symptoms of breast cancer, and as a screening test for asymptomatic women. Mammography screening normally includes one- or two-view mammography of each breast at regular time intervals, and double reading may be recommended. Women testing positive are referred to assessment with clinical breast examination, additional mammography/ultrasound examination and needle biopsy, and in a small percentage of cases open biopsy may be needed to determine the final diagnosis.

Characteristics

Effect of Mammography Screening

With screening, the time of diagnosis of breast cancer patients is pushed forward. This period is called the lead time. The earlier diagnosis should allow for a better treatment, and a better prognosis. The effect of screening, however, cannot be measured by length of survival after diagnosis, as the survival time is by definition extended with the lead time. The effect of mammography screening can therefore only be measured by its effect on breast cancer mortality in the targeted population.

The effect of mammography screening has been studied in the 12 randomized controlled trials summarized in Table 1. Ten of the trials resulted in a reduced breast cancer mortality in the intervention group compared with that of the control group, but the reduction was statistically significant in only one of the trials. The size of the reduction varied depending on the targeted age group and the length of the follow-up period. The Two Canadian trials, both with a somewhat different design, formed an exception with no effect on breast cancer mortality. Following a detailed analysis of the data, the International Agency for Research on Cancer, IARC, concluded in 2002 that "There is sufficient evidence for the efficacy of screening women aged 50–69 years by mammography as the sole screening modality in reducing mortality from breast cancer." The calculated combined relative risk was 0.75 (95% confidence interval 0.67–0.85), and a 35% reduction was estimated for women accepting the invitation to screening. IARC further concluded that "There is limited evidence for the efficacy of screening women aged 40–49 years by mammography as the sole screening modality in reducing breast cancer mortality." The combined relative risk was 0.81 (95% confidence interval 0.65–1.01). Including data from the new UK trial, the combined estimate for all trials on women aged 40–49 is 0.84 (95% confidence interval 0.74–0.95). A 24% reduction in breast cancer mortality was estimated in the UK trial for women attending screening.

Mammographic Breast Density and Cancer Risk. Table 1 Randomized controlled trials of the effect of mammography screening on breast cancer mortality

Randomized trials are undertaken in dedicated centers with high quality equipment and quality assurance, and it is not a straightforward task to customize the trial results to routine health care. Continuous evaluation of the outcome of mammography service screening is therefore recommended. Such observational studies have been undertaken in England & Wales and the Netherlands using the population-based trends in breast cancer mortality. These studies indicated a 6% and 10%, respectively, reduction in breast cancer mortality following the introduction of organized mammography screening. A more rigid study design has been used in the Nordic countries where individual invitation and screening data can be linked with cancer register and death records. Following this methodology, a 25% reduction was seen in Denmark in women screened at age 50–69; a 27% reduction was seen in Sweden for women screened either at age 40–69 or at age 50–69; and a 42% reduction was seen in Finland for women screened at age 55–74. It should be noted that the participation rate in Finland was close to 90%, and the overall estimate for Finland is therefore expected to be close to the estimated effects for participants in Denmark and Sweden of 37% and 45%, respectively. The outcomes of the more rigid observational studies are well in agreement with the outcome of the combined estimated relative risk found in the randomized controlled trials. At present, both trial and observational data show that breast cancer mortality is reduced by about 25% in women offered screening at age 50–69, and trial data show that breast cancer mortality is reduced by about 16% in women offered screening at age 40–49. Modeling showed that both screening mammography and adjuvant therapy have helped to reduce the rate of death due to breast cancer in the United States from 1975 to 2000.

Benefits and Harms

Mammography screening is only a relevant tool in breast cancer control if it reduces breast cancer mortality. But mammography screening may also have other benefits and harms. The most important of these are summarized in Fig. 1.

On the benefit side, breast tumors are detected earlier by screening, which should allow for a more conservative treatment. Very accurate data on surgical procedures are needed to investigate this. Studies from Norway and Ireland indicate that an increasing proportion of breast cancer patients in screening regions have been treated with breast conserving surgery, but parallel developments took place in nonscreening regions.

On the harm side, the first thing to note is that patients with screen-detected cancers become cancer patients at an earlier point in time than if they have waited for their disease to become symptomatic. Two to three years of healthy life, depending on the length of the lead time, will be converted to life as a cancer patient.

Benefits	Harms
Reduced breast cancer mortality	Cancerpatient earlier in life
Conservative treatment	False positive/ false negative
	Overdiagnosis
	radiation

Mammographic Breast Density and Cancer Risk. Figure 1 Benefits and harms of mammography screening.

Mammography screening is not a perfect test. Some women will test positive but be declared disease free at assessment. The percent of false-positive tests depends on the cutoff point for abnormalities used by the radiologists. In the United States, about 45% of women undergoing ten rounds of screening will experience at least one false-positive test. In the Nordic countries, this percentage is 10–20%. Some breast cancers will also be missed at screening. As women with negative tests are not reexamined, this percentage of false-negative tests is not known. As a proxy, the proportional interval cancer rate is used, which is the number of breast cancer cases observed before the next scheduled screen in women with negative tests divided by the number of breast cancer cases expected in this cohort in the absence of screening. In European screening programs, the 2-year proportional interval cancer rates after first screen has varied from 0.34 to 0.49, clearly indicating that some breast cancers are missed at screening.

Overdiagnosis is screen detection of lesions that would otherwise not have become clinically manifest breast cancers in the women's life time. Overdiagnosis includes both invasive cancers and DCIS cases that if undetected would not have progressed to invasive cancer. Overdiagnosis is difficult to study because screening is intervention in the natural history of disease and therefore affects the incidence rate. As the time of diagnosis is pushed forward with screening, the incidence rate will go up when women start screening, the so-called prevalence peak. This peak is expected to be compensated by an incidence deficit when women stop screening, but this may not be easy to detect as it occurs at an older age where the background incidence is higher. Data from the randomized mammography screening trial in Malmö, Sweden, indicated a 16% overdiagnosis in women screened up to a maximum age of 78, whereas overdiagnosis was not seen in women screened up to the age of 70, but both estimated had broad confidence intervals. Data from the organized mammography screening program in Finland showed the same cumulative incidence of breast cancer at age 74 for women offered screening at age 50–59 as for women not offered screening. The cumulative incidence at age 74 was 8% higher in women offered screening at age 50–69, but a certain percentage of these women had probably continued screening after they left the organized program. Modeling data from the Netherlands estimated the life time cumulative risk to be 3% higher in women screened at age 50–74 than in nonscreened women. Based on the sparse data, overdiagnosis may in particular be an issue when screening is extended to women of older age.

Data from the UK mammography screening program showed an average radiation dose of 4.5 mGy to the glandular breast tissue from two-view mammography. Using this figure, it was estimated that a decade of annual screening starting at age 40 would result in 5 years of life lost from radiation-induced breast cancer per 1000 women screened. If screening led to a 20% reduction in breast cancer mortality among attendants, 25 years of life would be gained per 1000 women screened, giving a net gain of 20 years of life. The equivalent figures from a decade of screening every 3 years starting at the age 50 were estimated to be 1 year of life lost from radiation and 43 years of life gained from screening, resulting in a net gain of 42 years of life per 1000 women screened. The balance of benefit versus harm is thus considerably more favorable for screening starting at the age of 50 than for screening starting at the age of 40.

Public Health Screening Recommendations

The evidence for mammography screening benefits and harms form the basis for decisions at two levels. First, the individual woman has to decide whether or not she wants to undergo screening. Second, the health authorities have to decide whether or not mammography screening should be recommended as a public health policy. The first type of decision requires good information, but it is otherwise noncontroversial as it allows the individual woman to give different weights to benefits and harms. The second type of decision is much more complicated, because it involves responsibility for the life of other people, and for the allocation of public or health insurance resources.

The weighting of benefits and harms has resulted in two very different sets of screening recommendations from public health authorities. In the United States, the US Preventive Services Task Force recommends "screening mammography, with or without clinical breast examination, every 1–2 years for women aged 40 and older." In Europe, the Council of the European Union recommends "mammography screening for breast cancer in women aged 50—69 in accordance with European guidelines on quality assurance in mammography." The actual age range for screening varies across

European countries; for instance from age 40 to age 74 in parts of Sweden.

According to National Health Interview Survey data, 70% of US women aged 40 and above, and 79% of women aged 50–64, had a mammogram within the last 2 years. Statistics from the organized mammography screening program in England showed that 76% of women aged 53–64 had been screened at least once in the previous 3 years. Participation in the organized mammography screening programs in Europe has varied from about 90% in Finland and Northern Sweden to about 50% in Italy. There is overall an urban–rural gradient with higher screening participation in rural than in urban regions.

Mammographic Density

Norman Boyd
Campbell Family Institute for Breast Cancer Research, Ontario Cancer Institute, Toronto, ONT, Canada

Definition

Mammographic density refers to the radio-lucent (white) appearance of breast tissue as seen on a mammogram. It is often expressed as percentage of the total breast area. A greater percentage is associated with a greater risk of breast cancer.

Characteristics

Mammographic Density and Risk of Breast Cancer

The radiological appearance of the breast varies among women because of differences in breast tissue composition and the x-ray attenuation properties of breast tissue. Fat is radio-lucent and appears dark on a mammogram, while stroma and epithelium attenuate x-rays more and appear light. It is the appearance of light tissue in a mammogram that is referred to as "mammographic density," and often expressed as the proportion of the total breast area occupied by radiologically dense tissue. These variations are illustrated in Fig. 1.

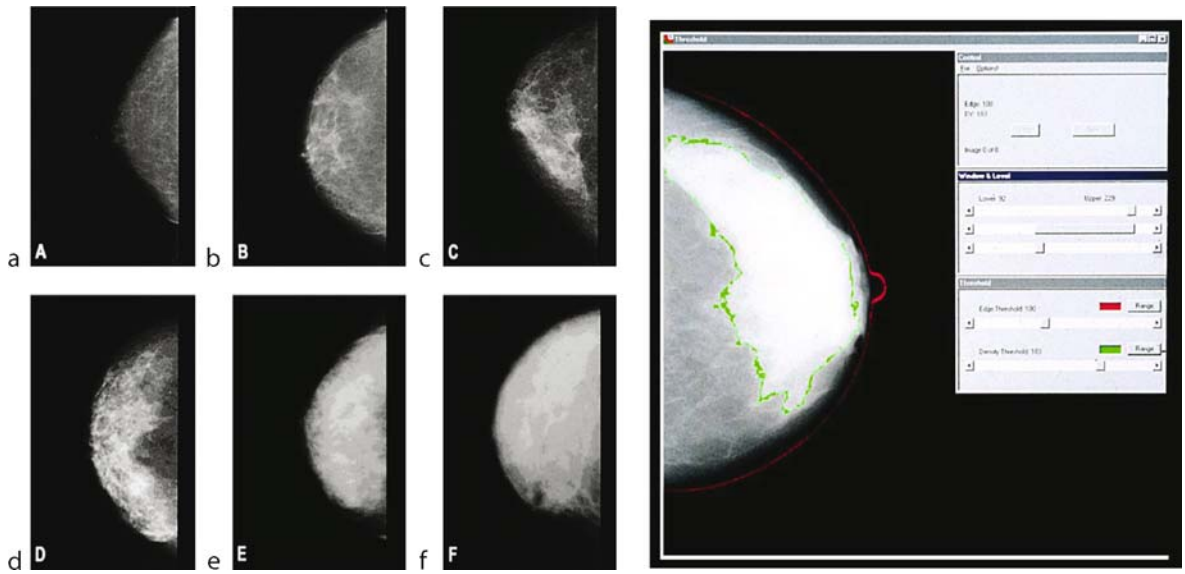
In 1976, Wolfe described a classification comprised of four categories: N1 in which the breast was mainly fat and risk of breast cancer lowest, DY in which the breast was mainly dense and risk of breast cancer highest, and P1 and P2 in which there were different degrees of linear density and cancer risk was intermediate. Most well designed epidemiological studies have found that this classification does identify women at different risks for breast cancer. The ▶Breast Imaging Reporting and Data System has described a qualitative method of classifying density.

Quantitative approaches that have been used to determine the proportion of the breast occupied by dense tissue include estimation by radiologists, planimetry, and computer assisted methods. Examples of the categories of the classification that have been used in estimation by radiologists are shown in Fig. 1, as is one of the computer-assisted methods. Planimetry and computer-assisted approaches have the advantage of generating a continuous measure that allows separate consideration of the dense and non-dense components of the image. Computer-assisted methods have also been shown to be highly reproducible.

In a systematic review of studies of mammographic features and breast cancer risk, McCormack and dos Santos Silva combined study specific data from more than 14,000 cases and 226,000 controls from 42 studies. Associations were stronger for studies in general populations than in symptomatic populations, and stronger for studies that used percent density than for those using Wolfe's classification or the Breast Imaging Reporting and Data System. Percent density in the prediagnostic mammogram was strongly associated with risk of breast cancer with a combined relative risk for incident breast cancer of 4.64 (95% confidence interval: 3.64, 5.91) in women with more than 75% of the breast occupied by density, compared to those with less than 5% density.

"Masking" of breast cancer by dense tissue does occur and is associated with an increased risk of breast cancer after a negative mammogram. Masking might inflate estimates of the risk of breast cancer estimates associated with mammographic density. However, the increased risk associated with density has been shown to persist for 10 years in one study, 8 years in another, and to increase risk of both screen detected and non-screen detected breast cancer. Masking does not therefore explain the increased risk of breast cancer associated with mammographic density. This risk factor both increases risk of the disease, and makes its detection by mammography more difficult.

All of the existing methods of assessing mammographic density have limitations. Non takes into account the thickness of the breast, and all are based on the



Mammographic Density. Figure 1 Examples of mammographic density and measurement. Left: examples of mammographic density; top left = 0% and bottom right = >75%. Right: illustrates computer assisted measurement.

projected area of the breast rather than volume. Current computer-assisted methods of measurement require that a dichotomous threshold be placed to distinguish dense from non-dense tissue, and do not allow for a gradual transition from one to the other, as is likely to exits in reality. Attempts to improve methods of measurement by addressing these and other limitations are in progress, and can be expected to improve risk prediction and to strengthen etiological associations.

Notwithstanding these limitations the relative risk of breast cancer associated with extensive mammographic density are larger than for almost all other risk factors for breast cancer. Although larger relative risks are associated with mutations in ►BRCA1 or ►BRCA2 genes, only a small proportion of the population carry these mutations, and the associated attributable risk is about 5%. By contrast, the attributable risk associated with mammographic density in 50% or more of the breast is about 30%.

Factors Associated with Variations in Mammographic Density

Mammographic density has consistently been found to be less extensive in older women, in women who are postmenopausal, in those who are parous and in those with a larger number of live births, and in those with greater body weight. Body weight and body mass index are strongly and positively correlated with the total area of the mammogram and the area of non-dense tissue, and weakly negatively correlated with the area of dense tissue, and it is therefore essential to adjust for measures of body size in analysis of the association between mammographic features and risk of breast cancer. Combined hormone therapy (HT) is associated with a small increase in risk of breast cancer, and increases mammographic density, effects that are not seen with estrogen alone. ►Tamoxifen, and a gonadotrophin hormone release agonist also reduce mammographic density.

Measurements of hormones and growth factors have shown that blood levels of growth hormone, ►IGF-I (in premenopausal women) and prolactin (in postmenopausal women), all mitogens in the breast, as well as sex-hormone binding globulin are associated with mammographic density. ►Estradiol has in general been found to be not associated, or associated inversely, with mammographic density in postmenopausal women. As levels of IGF-1 and prolactin have also been found to be associated with risk of breast cancer, respectively in premenopausal and postmenopausal women, they suggest potential mechanisms for the association of mammographic density with risk of breast cancer.

Heritability of Mammographic Density

The factors that are associated with mammographic density account for only 20–30% of the variation observed in the population. Early studies with limited numbers of mother-daughter sets, and a small twin study suggested that genetic factors might explain a proportion of the variation (i.e. the heritability) of mammographic density within a given population.

Twin pairs were aged 40–70 years and living in Australia or North America, and information was collected on the factors known to be associated with variations in mammographic density using the same questionnaires. Mammograms were obtained from each

member of each twin pair, digitized and percent density measured using the computer-assisted method shown above, by one observer blinded to zygosity and pairing. After adjusting for age, mammographic density had a symmetrical unimodal distribution, similar to that seen for other quantitative traits like height. After adjusting for age, age at menarche, parity, number of live births, menopausal status and body mass index, the variances in percent density were almost identical in both samples. The correlations between twin pairs in percent mammographic density in Australia and North America were, respectively, 0.61 and 0.67 for monozygotic twin pairs, and 0.25 and 0.27 for dizygotic twin pairs. The classic twin model assumes that variance for a given population can be partitioned into three components representing unmeasured effects, namely additive genetic effects, the effects of environmental factors that are shared by, or common to twin pairs, and individual specific environmental effects, that include measurement error. The proportion of the residual variation accounted for by additive genetic factors (heritability) was estimated to be 60% (95% confidence interval (CI): 54–66%) from Australian twins, 67% (95% CI: 59–75%) from North American twins, and 63% (95% CI: 59–67%) in the studies combined.

Analysis of the components of variance showed that the best fitting model included only components for the additive genetic factors, and person-specific environmental factors. Further details of the analysis, and additional references to the analysis of twin data, can be found in reference. These two twin studies thus replicate each other in providing compelling evidence that the wide variation in percent mammographic density among women aged 40–70 is strongly influenced by genetic factors.

Many of the factors associated with differences in mammographic density, including age at menarche and menopause, and BMI, are known to be at least in part heritable, but the estimates of heritability given for mammographic density were generated after adjusting for the effects of these factors. Heritability, however, refers to explaining variation within a population, and both twin studies were carried out in populations that are predominately European in origin, and living in "Western" environments, so our findings do not exclude the possibility of a greater influence of environmental factors at levels of exposure that lie outside the range usually seen in Western societies.

It is currently unknown whether, as with other quantitative traits, mammographic density variation at a given age, is determined by multiple genes, or variants in one or more major genes. Pankow et al. showed unadjusted sister-sister correlations in breast density of 0.27 ($p < 0.0002$), that are very similar to the correlation between DZ pairs seen in our twin studies. Segregation analysis of nuclear family data, assuming a single mode of inheritance of risk associated with one or more major genes, could not distinguish between dominant, recessive or co-dominant models.

Based on the relative risk of breast cancer associated with extensive mammographic density, and the observed correlation between dizygous twin sisters, we have estimated that the familial association in percent density would explain an increase in risk to first degree relatives by a factor of 1.05–1.08. Given that the increased risk to first-degree relatives of an affected woman is on average about twofold, this means that the genes that explain variation in mammographic density could explain 5–8% of familial aggregation on a population basis. Ziv et al. using a qualitative classification of density, have shown that subjects with first degree relatives with breast cancer do have greater amounts of density than those without such relatives.

Summary and Conclusions

There is now extensive evidence that mammographic density is a risk factor for breast cancer, independent of other risk factors, and associated with large relative and attributable risks for the disease. Mammographic density reflects variations in the tissue composition of the breast, and is positively associated with collagen and epithelium, and negatively associated with fat. Extensive mammographic density is relatively common, and estimates of attributable risk suggest that about a third of breast cancer may be attributable to density in 50% or more of the breast.

The epidemiology of mammographic density, notably the inverse association with age, is consistent with it being a marker of susceptibility to breast cancer, in a manner similar to the concept of "breast tissue age" in Pike's model of mammary carcinonogenesis. Cumulative exposure to mammographic density may thus be an important determinant of the age-specific incidence of breast cancer.

Mammographic density is a continuous quantitative trait that is highly heritable, and meets criteria for an intermediate phenotype. The genetic variants that influence mammographic density are now under investigation, and some of them may be associated with breast cancer risk.

Mantle Cell Lymphoma

Christian Geisler
Department of Hematology, The Finsen Centre, Rigshospitalet, Copenhagen, Denmark

Synonyms

MCL; Centrocytic (mantle cell) lymphoma; Diffuse, small cleaved cell lymphoma; Intermediately or poorly differentiated lymphocytic lymphoma, diffuse or nodular

Definition

Mantle cell lymphoma is a B-cell neoplasia of monomorphic small to medium-sized lymphoid cells with irregular nuclei, morphologically most resembling centrocytes (According to WHO).

Characteristics

Incidence. MCL comprises ~6% of ►non-Hodgkin lymphoma.

Epidemiology. The majority of patients (2/3) are male, and the median age at diagnosis is 70 years. The etiology is unknown.

Pathogenesis. The causal molecular lesion is a ►reciprocal translocation t(11;14)(q13;q32), translocating the *CCND1* gene from chromosome 11 to chromosome 14, where it is brought under the control of the promoter of the constitutionally activated IgH gene. Therefore, overexpression of cyclinD1 is present in virtually all cases of MCL. A characteristic ►gene expression profile, however, allows the recognition of rare t(11;14)-negative, cyclin D1-neg. cases that in stead overexpress cyclinD2. More complicated cytogenetic changes occur, such as del13q14 and del17p. Also inactivation of the ATM gene on chromosome 11q22 may occur, leading to inhibition of the DNA-damage repair pathway.

Pathology. The normal architecture of the lymph node is replaced by a monomorphic lymphoproliferative process with a vaguely nodular, diffuse, or mantle-zone growth pattern. Two blastoid variants are recognized, the classical blastoid and the pleomorphic, both associated with high proliferation rate and poor prognosis. Transformation to diffuse large B cell lymphoma does not occur. Immunophenotype: The lymphoma cells are CD5+ B cells (CD19+, CD20+), which are CD23-negative, FMC7+, and strongly IgM+ often also IgD+.

Symptoms and Clinical Findings. The majority of patients have advanced disease with bone marrow involvement (Ann Arbor stage IV) (►Ann Arbor staging system) at diagnosis, often also with other extranodal involvement, typically of the gastrointestinal tract. The spleen is often enlarged. General symptoms as weight loss, night sweats, and fatigue are frequent.

Paraclinical Findings. The bone marrow involvement may lead to pancytopenia, and a minority of MCL cases are leukemic. LDH is often increased and some patients present with tumor lysis already at diagnosis.

Diagnosis and Differential Diagnosis. The first step of the diagnosis is the documentation of CD5+, CD23-neg. B-cell disease, but the hallmark of the disease is cyclinD1 overexpression or the t(11;14). The rare CD5-neg. or cyclinD1-neg. cases are always problematic to diagnose if gene-expression profile analysis is not available. The most important differential diagnosis to small-cell MCL is CLL, and to blastoid MCL, lymphoblastic lymphoma. CLL will be CD23+ with weak surface immunoglobulin expression, both CLL and lymphoblastic lymphoma will be t(11;14)-neg. and cyclinD1-neg., and in addition, lymphoblastic lymphoma will be TdT+. It was previously believed that some marginal-zone lymphomas could be t(11;14) pos., but such cases are now considered MCL.

Disease Staging. Standard work-up comprises physical examination including ear–nose–throat examination, CT scan of neck, chest, abdomen, and pelvis, bone marrow examination with flow cytometry and immunocytochemistry for cyclinD1 and ►fluorescent in situ hybridization (FISH) for t(11;14). There is increasing evidence that most cases of MCL are ►PET positive with intermediary specific uptake value, and particularly in this disease with frequent extranodal involvement this method may prove useful. Upper and lower endoscopy of the gastrointestinal tract is not indicated unless there are specific symptoms that require management, and will rarely have therapeutic consequences.

Prognostic Factors. Practically feasible prognostic factors are International prognostic Index (IPI), the proliferative index (proportion of Ki-67-pos. cells), and the cytomorphological subtype.

Course of Disease. Although MCL with indolent course of disease has been identified, both clinically and by proliferation-gene-profile studies, MCL generally presents itself with aggressive disease and symptoms of rapid tumor growth, and MCL has, until recently, been considered one of the lymphoma subtypes with the worst prognosis, with an expected median survival of 3½ years from the time of diagnosis following conventional anthracyclin-based chemotherapy. Newer results, however, suggest that long-term disease-free survival may be achieved by modern intensive immunochemotherapy with stem cell support at least in younger patients (<65 years).

Treatment. The choice of treatment must match the patients' age and performance status. In younger patients, induction therapy followed by stem cell harvest and ►high-dose therapy with stem-cell support is now standard treatment. CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone) was for many years been considered the standard induction therapy, in spite of rather poor results (response and CR rates 75 and 25% respectively). Mantle cells are invariably CD20+ and the addition of rituximab to CHOP (R-CHOP) increases the complete and overall response rates to 35 and 95% respectively. The preferred 1st line induction treatment will often be R-CHOP that can be tolerated also by elderly patients. High-dose Ara-C has documented effect in MCL, and many consider it to be the most important drug in the treatment of MCL. Controlled trials are presently comparing R-CHOP with R-Ara-C in younger patients and with R-FC (Rituximab + Fludarabine + cyclophosphamide) in elderly patients.

►*Stem-Cell Harvest and Purging*. As most patients with MCL have bone marrow involvement, tumor-cell contamination of stem cell harvests from the bone marrow or the blood was previously considered a major problem and attempts to in vitro purge the autografts were not successful. However, intensive stem-cell mobilization with high-dose ara-C + concomitant rituximab (in vivo purging) has turned out to be highly effective leading to 90–100% PCR-negative grafts. Reinfusion of tumor cells with the autograft is therefore no longer of any significant concern.

High-Dose Therapy with Stem-Cell Support. Following induction therapy with CHOP, high-dose radiochemotherapy (TBI-CTX) leads to documented prolongation of progression-free survival. Intensive induction (R-hyperCVAD-MTX/Ara-C) without stem cell support is feasible but quite toxic, and, with the reduced risk of tumor-cell reinfusion with the graft, there seems to be no reason not to give the patients stem-cell support.

Total Body Irradiation (*TBI*). The importance of TBI in the conditioning regimen is disputed, and results based on pure chemotherapy, e.g., BEAM (BCNU, etoposide, Ara-C, and Melphalan) and HDS (high-dose sequential therapy with cyclophosphamide, Ara-C, melphalan, and mitoxantrone) leading to high proportion of long-term progression-free survival, contradict the necessity of TBI.

2nd-Line Treatment. Following relapse, systemic treatment with R-FC or R-Ara-C or involved field radiotherapy have proven efficacy, but all treatment will be palliative. Newer promising therapy modalities include proteasome inhibitors and, if the bone marrow is not too heavily infiltrated, radioimmunotherapy. In 2nd or later remission, autografting is not effective in MCL. ►Reduced intensity conditioning (RIC) allogeneic stem-cell transplantation is still experimental in this disease, but graft-versus-lymphoma has been documented and single-center reports on this modality in MCL have shown long-term disease-free survival.

Summary. A paradigm-shift is occurring in MCL, where – at least in younger patients – intensive immunochemotherapy with stem-cell support, in parallel with increasing biologic knowledge, may improve dramatically the poor prognosis traditionally associated with this disease.

MAP Kinase

Rony Seger
Department of Biological Regulation, Weizmann Institute of Science, Rehovot, Israel

Definition

Mitogen-activated protein (MAP) kinases are a family of protein kinases that mediate the transfer of phosphate from ATP to various proteins. They are evolutionarily conserved from yeast to mammals, and are expressed in nematodes, insects, slime molds and plants as well. Moreover, the MAP Kinases are ubiquitous enzymes, which are highly expressed in all cells of eukaryotic organisms. These kinases, operating within intracellular signaling pathways, play a key role in the transmission of extracellular signals from the plasma membrane to the nucleus. The MAP Kinases respond to a wide array of extracellular agents, including mitogens, hormones and cytokines, to regulate a variety of cellular responses such as proliferation, differentiation, ►adhesion, stress response and ►apoptosis.

Characteristics

In order to survive and perform their functions, cells need to respond to many extracellular signals such as mitogens, hormones, cytokines, physical changes of the environment and stress. These extracellular signals induce various distinct cellular processes, which are largely executed by induction of de-novo gene expression. Most of the extracellular agents bind to membranal receptors, and do not penetrate the cells in order to activate transcription. Rather, the extracellular signals are transferred from the membranes to the genes in the nucleus via several communication lines known as intracellular signaling pathways, which operate within a complex network. In many cases, the transmission of signals through these pathways involves sequential phosphorylation events by protein kinases, which are termed kinase cascades. Central building blocks in the signaling network are the MAP Kinases, which usually operate within signaling kinase cascades to connect receptors in the plasma membranes to nuclear transcription factors and other regulatory targets. They all respond to various extracellular factors and consequently regulate diverse cellular processes such as proliferation, differentiation, stress response, and apoptosis. These proteins, their mode of action and role in cancer are the subjects of this essay (►DNA damage response; G-protein; Insulin receptor; Integrin signaling and cancer).

Members of the MAP Kinase Family

The first MAP Kinases to be elucidated are the extracellular signal-regulated kinases 1 and 2 (ERK1/2) that have been identified as key components in growth factor signaling. Early studies on these kinases revealed that they are activated by upstream kinases, termed MAP Kinase/ERK kinases (MEKs). The activation occurs by phosphorylation of Thr and Tyr residues within a distinctive sequence known as Thr-Xaa-Tyr (TXY) motif, located in their activation loop. Subsequently, other protein kinases with a significant sequence homology to ERK1/2 (30–50%) were identified. Among them, the proteins that contain a TXY motif, and are activated by upstream kinases similar to MEKs, were grouped to the MAP Kinase family. Other protein kinases, demonstrating only some of the features, such as high sequence homology without activation by TXY phosphorylation downstream of a kinase cascade, or existence of a TXY motif without a sequence homology, are often considered as MAP Kinase-like proteins, and are not genuine members of the MAP Kinase family.

Presently, ten genuine MAP Kinases have been identified in mammals: ERK 1/2, c-Jun N-terminal kinase ►(JNK)1–3 (►JNK subfamily and cancer), p38 α–δ, and ERK5 (BMK1). Unfortunately, many names and acronyms have been attributed to each of the MAP Kinases over the years, and the terminology used in the field is still not unified. Details on the nomenclature and properties of the various MAP Kinases are summarized in Table 1. It should be noted that aside from the main gene products, many of the MAP Kinase genes encode for alternatively spliced forms that are designated by the addition of a letter after their name (e.g. ERK1b). Finally, the group of MAP Kinase-like proteins include: (i) ERK7 (ERK8 in human) that demonstrates a high homology to the other MAP Kinases, has a TXY motif, and yet is probably not activated by a kinase cascade. (ii) ERK3 and ERK4 that have high homology to other MAPKs but no TXY motif, and their mechanism of activation is not yet fully understood. (iii) Several other protein kinases, previously termed "cousins of MAPK," which do contain a TXY in their activation loop, but are not activated by kinase cascades. However, these kinases are functionally and structurally very different from genuine MAP Kinases, and therefore are currently regarded as a separate group of kinases.

Structure of MAP Kinase Cascades

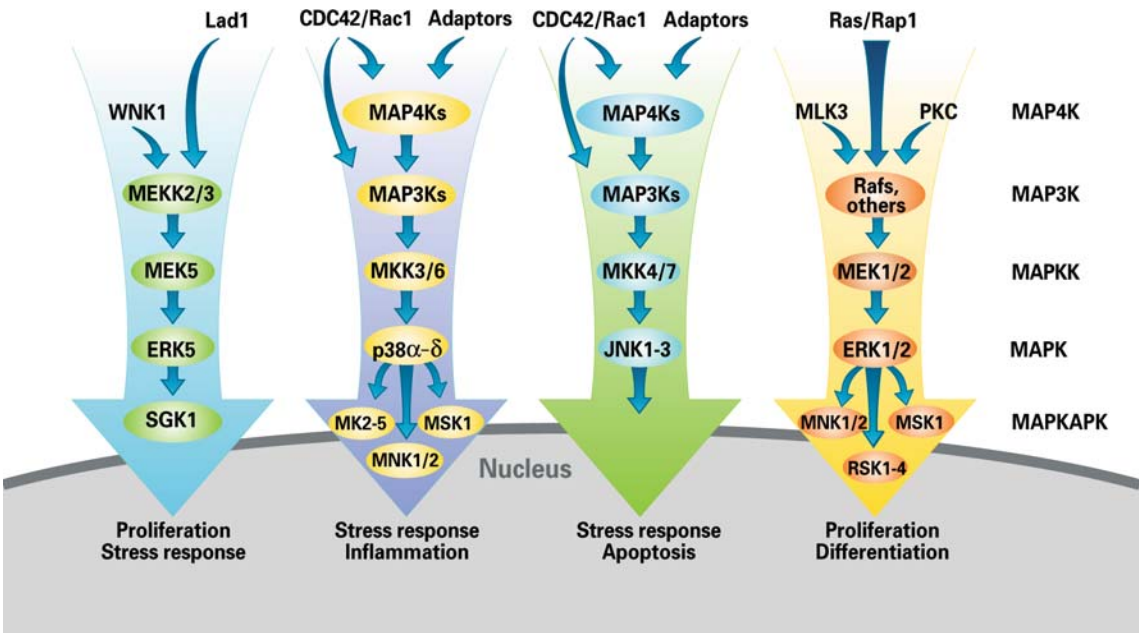
Transmission of signals via the MAP Kinase cascades is initiated by several mechanisms, including activation

of a small G protein (e.g. ►Ras), or interaction with adaptor proteins, which in turn, activate the upstream kinases of the cascades. Then, the signal is transmitted by three to five tiers of protein kinases in each cascade (Fig. 1):

- MAP4K (also termed MKKKK or STE20-like kinase), directly phosphorylates MAP3Ks
- MAP3K (also termed MKKK or MEKK), directly phosphorylates MAPKKs
- MAPKK (also termed MKK or MEK), directly and specifically phosphorylates MAP Kinases
- MAP Kinase (also termed MAPK) phosphorylates many targets including MAPKAPKs
- MAPKAPK (MAPK activated protein kinase, also termed MK).

MAP Kinase. Table 1 Nomenclature of members of the MAP kinase family

Name	Full name	Gene name	MW	Synonyms
MAP kinase				
ERK1	Extracellular signal-regulated kinase1	MAPK3	44 kDa	P44MAPK
ERK2	Extracellular signal-regulated kinase2	MAPK1	42 kDa	P42MAPK
P38α	P38αMAPK	MAPK14	43 kDa	SAPK2α, SAPK2A, CSBP1/2
P38β	P38βMAPK	MAPK11	42 kDa	SAPK2β, SAPK2B
P38γ	P38γMAPK	MAPK12	47 kDa	SAPK3, ERK6,
P38δ	P38δMAPK	MAPK13	46 kDa	SAPK4, Serk4
JNK1	c-Jun-N-terminal kinase1	MAPK8	46 kDa	SAPK1χ, SAPKχ, SAPK1
JNK2	c-Jun-N-terminal kinase2	MAPK9	54 kDa	SAPK1α, SAPKα, SAPK2
JNK3	c-Jun-N-terminal kinase3	MAPK10	49 kDa	SAPK1β, SAPKβ, Serk2
ERK5	Extracellular signal-regulated kinase5	MAPK7	110 kDa	BMK1
MAP Kinase-like				
ERK7	Extracellular signal-regulated kinase7	MAPK15	63 kDa	ERK8 in human (but only 69% identity)
ERK3	Extracellular signal-regulated kinase3	MAPK6	62/97 kDa	P97Mapk, ERK3α
ERK4	Extracellular signal-regulated kinase4	MAPK4	63 kDa	ERK3β, p63MAPK



MAP Kinase. Figure 1 Schematic representation of the MAP kinase signaling cascades. Activating phosphorylations are denoted by arrows.

Although MAPKAPKs can further phosphorylate and activate downstream protein kinases, these are usually not considered as components of the MAPK cascades. The three central tiers MAP3K, MAPKK, and MAPK are in fact the core signaling modules, whereas MAP4Ks and MAPKAPKs participate only in some instances. One or more kinase component in each of the tiers phosphorylates and activates components in the next tier, in order to transmit the signal downstream the cascade. Finally, a downstream component (MAP Kinases or MAPKAPKs) phosphorylates target regulatory molecules, either in the cytoplasm or the nucleus. This phosphorylation triggers changes in conformation and/or in molecular recognition of the target proteins, which lead to modulation of their activity, and consequently, initiation of the required physiological processes. Four distinct MAPK cascades have been elucidated thus far in mammals and those are named after their MAP Kinase components (ERK1/2, JNK, p38 and ERK5). The number of cascades, however, can be increased due to the existence of MAP Kinases that are not yet specified to any known pathway (e.g. ERK7/8). The components at the MAPKK are limited in number and usually selective to their cognate MAP Kinases. However, the upstream tiers contain many distinct components, and those can usually play a role in the activation of more than one cascade (e.g. Tpl2 was implicated in all MAP Kinase cascades). The cascades cooperate with each other, and along with other signaling components form a signaling network that determines the cell's fate upon distinct extracellular stimulations.

Signaling Via the MAP Kinase Cascades

The ERK1/2 Cascade

This cascade is a prototype of the MAP Kinase cascades, which is activated mainly by mitogens, hormones and differentiation factors. The extracellular factors stimulate cells by binding to their cognate membranal receptors that, via various mechanisms, induce activation of small ►GTPases (*e.g.,* Ras). These regulating proteins further transmit the signal to the MAP3K tier of the cascade that includes mostly ►Raf-1 (Raf kinase) and ►B-Raf (B-Raf signaling). Several other MAP3Ks of the ERK cascade (A-Raf, Tpl2, MOS and MEKK1) function under more specific conditions such as MEKK1 in stress. Although the MAP3K activation does not always require a phosphorylation by MAP4K, under some conditions ►protein kinase C and MLK3 can act at that tier to facilitate Rafs activation by phosphorylation. Thereafter, the signal is transmitted down the cascade through the MAPKKs MEK1 and MEK2, which are activated by phosphorylation of Ser residues in their activation loop. The activated MEKs are dual specificity protein kinases that demonstrate a high selectivity towards ERK1/2 in the MAP Kinase tier, activating them by phosphorylating their Thr-Glu-Tyr motif. ERK1/2, in turn, phosphorylate hundreds of regulatory proteins, either in the cytoplasm [e.g. ►PLA_2 (Phospholipase A2) and MAPKAPKs], or upon translocation they activate transcription factors such as Elk1 or ►c-Myc (Myc oncogene) in the nucleus. The MAPKAPK tier of the ERK cascade includes RSK1–4, which are specific to ERK1/2, and also MSK1, MNK1/2 and possibly MK3/5, which are activated by p38 as well.

The p38 and JNK Cascades

These cascades are also known as stress-activated protein kinase cascades and they posses considerable cross-talk between them. Their activation can be triggered not only by small GTPases but also by adaptor proteins, and both types of activators lead the signals to the MAP3K tier, either directly or via MAP4Ks. The kinases at these tiers seem to be common for the two cascades. There are at least 16 proteins at the MAP4K (e.g. GCK), and about 20 distinct proteins at the MAP3K (e.g. MEKKs, MLKs, ASKs) tiers. The funneling of the signals in these tiers towards the appropriate MAP Kinases is regulated mainly by scaffold proteins as described below. At the MAPKK tier, MKK3 and MKK6 are the main components of the p38 cascade, while MKK4 and MKK7 are the components of the JNK cascade, although some crosstalk between these components may occur. The MAPK tier of p38 is composed of products of four main gene products (p38α,β,γ,δ), all containing Thr-Gly-Tyr motif in their activation loop. Once activated, they either transmit the signal to the MAPKAPK tier (e.g. MK2), or phosphorylate regulatory proteins, such as transcription factors. On the other hand, three genes (JNK1–3) encode the JNK isoforms, which all contain a Thr-Pro-Tyr motif in their activation loop. Only a few cytosoplasmic targets, and no clear MAPKAPK, were identified for JNKs, but these kinases are considered to be major regulators of transcription, as they phosphorylate transcription factors such as c-Jun, and ATF (►Rho Family proteins).

The ERK5 Cascade

Another MAPK cascade is that of ERK5 (Big MAPK, BMK1), which is a 110 kDa protein that is activated by both mitogenic and stress signals. The mechanism of upstream activation of the cascade has not been fully elucidated as yet, but can involve either adaptor proteins (e.g. Lad), or MAP4K (e.g. WNK1). Those components activate the kinases at the MAP3K tier, consisting mainly of MEKK2/3. These kinases activate the only component in the MAPKK tier, MEK5, by phosphorylating Ser and Thr in its activation loop. MEK5 then activates ERK5 by phosphorylating both Thr and Tyr residues within its Thr-Glu-Tyr motif. Although this motif is identical to that of ERK1/2, there is no crosstalk between these cascades. Upon stimulation, ERK5 phosphorylates

several transcription factors (e.g. c-Myc), and one MAPKAPK, SGK, was identified thus far. Interestingly, ERK5 is unique in influencing transcription also through stabilization of transcription factors, and by a direct transcriptional activity mediated by its non-catalytic region.

Regulation and Specificity Determination of MAP Kinases

The activation of all MAP Kinases is reversible, as their activity peaks a few minutes (4 to 30) after stimulation and then declines back to basal levels. Fast decline (within 15–40 min) gives rise to an activation kinetics named "transient activation," while a slower decrease back to basal levels (40–180 min) is termed "sustained activation." These differences in signal duration often dictate the specificity and fate of the signals as described below. The main enzymes that regulate the duration as well as strength of the signals are protein phosphatases that counterbalance various activating signals. Because simultaneous phosphorylation of Tyr and Thr residues is required for the activity of MAP Kinases, their full inactivation can be achieved by the removal of phosphates from either one of the regulatory residues, or from both of them together. Thus, protein Ser/Thr phosphatases, protein Tyr phosphatases and dual specificity phosphatases all act as MAP Kinase phosphatases. One important group of regulatory phosphatases is the MAP Kinase dual specificity phosphatases (MKPs). The members of this group are products of induced genes and are rarely expressed in quiescent cells. Therefore, the immediate inactivation of MAP Kinases, 5–45 min after stimulation, is mainly regulated by Tyr phosphtases, and the MKPs take over at later stages after stimulation.

Another mechanism that participates in the regulation of MAP Kinases is the formation of multi-protein complexes, primarily due to interaction with scaffold proteins. The importance of scaffolds for MAP Kinase signaling was first demonstrated in yeast, whereby different scaffolds direct signaling components to regulate distinct processes. A similar mechanism is now known in mammals whereby scaffolds, such as KSR1 or ►IQGAP1 (IQGAP protein) for ERK, or JIP1 for JNKs facilitate the rate of MAP Kinase activation by bringing distinct components of the cascade to close proximity. In addition, the scaffolds may direct MAP Kinases to their proper subcellular localization, allowing interaction with proper target molecules upon distinct upstream signals, thereby securing their proper mode of action.

The ability of MAP Kinases to transmit different, and even opposing signals in the same cells raises the question as to how the specificity of the different signals transmitted by the MAP Kinase cascade is regulated. The duration and strength of the signal, as well as scaffolding with proper activators and targets, are two mechanisms suggested for the specificity determination. However, not less important are (i) subcellular localization of the cascade components that directs the signals to their proper destinations; (ii) presence of several similar isoforms in each tier of the cascade, each of which may possess distinct properties; (iii) extensive cross-talk and interplay between the MAP Kinases and other intracellular signaling pathways that modulate the output of each cascade, and (iv) combinatorial integration of the MAP Kinase signals at downstream levels. Although these mechanisms can independently determine signaling specificity, they often cooperate with each other in order to induce proper downstream effects.

Involvement of MAP Kinases in Cancer

MAP Kinase cascades provide viable targets for pharmaceutical intervention in various human diseases including cancer. All four MAP Kinase cascdes have been implicated to varying extents in the induction and progression of oncogenic ►cell transformation. Indeed, elevated phosphorylation and activity of the MAP Kinases is detected in many (but not all) cancers and metastasis. However, while ERK1/2 seem to be involved in the transformation of most cell types, the involvement of the other cascades is limited to specific cancers. The involvement of ERK1/2 in cancer is not surprising since this MAP Kinase lies downstream to many ►oncogene products such as Her2, ►v-Ras (RAS transformation targets) and B-Raf. In addition, ERK1/2 are key regulators of cellular proliferation, and therefore, the activation of ERK1/2 is usually required for the enhanced proliferation observed in cancer. These observations led to the development of MEKs and Rafs inhibitors that completely inhibit ERK1/2 activity. These inhibitors are now in clinical trials for several cancer types, and in spite of the wide range of ERK1/2 activity, it seems that these agents can become specific and potent anti cancer drugs.

Phosphorylation of c-Jun, which is induced primarily by JNKs, has been reported to play a critical role in Ras-induced tumorigenesis. In addition, JNKs and c-Jun appear to repress p53 gene expression and, thereby, induce mitogenicity in cancer cells. Therefore, JNKs may be involved in cancers induced by Ras and other oncogenes. However, in other cancers JNKs play a role in the induction of apoptosis, and therefore may have a tumor suppressive function. ERK5 can play a role in the regulation of proliferation as well, and it was shown that this kinase cooperates with ERK1/2 in ►oncogenesis, although very little is known today regarding its involvement in human cancer. Finally, p38 was implicated in the progression of only a few cancers, and is in fact considered to be a tumor suppressor in many cancer types. In view of the above information, it is likely that better understanding of

MAP Kinase role in oncogenic transformation and ►metastasis (Metastasis signaling) will lead to novel drugs and therapeutic strategies in combating cancer.

Mapatumumab

Definition

Mapatumumab is a fully ►humanized antibody. The antibody exerts anti-tumour activity in diverse preclinical tumours models including breast, gastrointestinal, lymphoma, ovarial carcinoma, and uterine cancers. Mapatumumab was shown to specifically recognize the TRAIL-Receptor 1 protein without any relevant interactions with the ►TRAIL decoy receptors. The efficacy of mapatumumab is increased by combinations with various cytostatic drugs including carboplatinum, cisplatin, camptothecin, topotecan, ►paclitaxel as well as radiation. ►Xenograft models for breast, colorectal, non-small cell lung cancer as well as uterine cancer revealed a high activity of either the drug alone or in combination with other cytotoxic treatment approaches including radiation.

►TRAIL-Receptor Antibodies

MAPK

Definition

Mitogen-activated protein kinases operate within signaling cascades, which consist of up to six tiers of protein kinases, which sequentially activate each other by phosphorylation. Four major MAPK cascades are known in mammals: ERK1-2, JNK1-3, p38 α-δ, and ERK5. The MAPK cascades are activated by growth factors, hormones, cytokines, and stress. The hallmark of the MAPK family is their ability to translocate to the nucleus and activate transcription factors. MAPKs are involved in growth, differentiation, development, transformation, metabolism, learning, survival, apoptosis, cell cycle control, and gene expression. MAPK inhibitors are being developed mainly for cancer therapy.

Definition

Marginal zone lymphomas (MZL) represent the neoplastic counterpart of the marginal zone. The latter is a distinct micro-anatomic compartment of the B-follicle, well developed in those lymphoid organs where an abundant influx of antigens is known to occur (spleen, mesenteric lymph nodes, and mucosa-associated lymphoid tissue or MALT). MZL account for approximately 10% of all non-Hodgkin lymphomas, being the third most frequent subtype after diffuse large B-cell lymphoma (DLBCL) and follicular lymphoma. They are subdivided into three entities by the World Health Organisation (WHO): splenic MZL, nodal MZL, and MALT lymphoma (or extranodal MZL). Despite histologic and genetic similarities, clinical differences were the main reason to consider these three MZL subtypes as distinct clinicopathological entities.

Characteristics

Histology

Diagnosis of an MZL is always made on a ►biopsy. Residual reactive ►germinal centers are a constant finding in all MZL occurring at any site. The architecture of a lymph node involved by primary nodal MZL is most frequently preserved, with the neoplastic proliferation extending into the interfollicular area and surrounding residual reactive germinal centers as distinct rings. In splenic MZCL, the white pulp is hyperplastic with broad marginal zones and variable invasion into the red pulp, resulting in a massive expansion of the spleen. In ►MALT lymphomas, the neoplastic cells may invade and destroy the epithelium, resulting in so-called lymphoepithelial lesions. The neoplastic proliferation itself may be predominantly composed of marginal zone B-cells ("centrocyte-like cells"), but is most frequently heterogeneous in cell composition. A polymorphous mixture of centrocyte-like cells, small lymphocytes, plasma cells and scattered large blast cells may be found in all MZL, regardless of the site. The immunophenotypes of extranodal, nodal and splenic MZL are almost completely similar and homologous to that of normal MZ B-cells. There is positivity for surface Ig (IgM > IgA, IgG), pan B-cell markers (CD20, CD19, CD79a) and complement receptors (CD21, CD35). IgD expression may be variable but has been considered by some authors as an important difference between nodal/extranodal MZL and splenic MZL, as they observed positivity in the latter and no expression in the former. In the differential diagnosis with other small B-cell lymphomas, absence of characteristic markers for those neoplasms is important: lack of CD5 is useful in distinction from mantle cell and small lymphocytic lymphomas, and lack of cyclin D1 in differential diagnosis with mantle cell lymphomas.

Pathogenesis

Growing evidence indicates that MZL, and MALT lymphomas in particular, are proceeded by chronic antigenic stimulation (chronic infection or autoimmune diseases) and involve deregulation of the ►nuclear factor κB (NF-κB) pathway. Long-standing (auto)antigenic stimulation explains how lymphoid infiltrates may appear in extranodal sites that are normally devoid of lymphoid tissue (e.g. the stomach, lung, the salivary and lachrymal glands). The list of microbial species associated with MZ lymphoproliferations now comprises at least five distinct members: ►*Helicobacter pylori*, *Campylobacter jejuni*, *Borrelia burgdorferi*, *Chlamydia psittaci*, and ►hepatitis C virus (HCV), which have been associated with gastric MALT lymphoma, immunoproliferative small intestinal disease (IPSID), cutaneous MALT lymphoma, orbital MALT lymphoma, and splenic MZL, respectively. Furthermore, some autoimmune diseases may also favor the development of a MALT lymphoma: patients with ►Sjögren syndrome have a 44-fold increased risk of developing a lymphoma and patients with ►Hashimoto thyroiditis have a 70-fold increased risk of thyroid lymphoma.

Besides inducing an initially polyclonal B-cell proliferation, sustained (auto)antigenic stimulation may also trigger inflammatory responses by attracting neutrophils, which release reactive oxygen species. The latter are genotoxic and cause a wide range of genetic abnormalities (see genetics). Remarkably, the genes targeted by most of these abnormalities are

involved in one and the same pathway leading to the activation of nuclear factor κB (NF-κB). The latter is a key transcription factor in the immune response as it regulates the expression of a number of survival- and proliferation-related genes in B-cells. As such, its constitutive activation by MALT lymphoma-related genetic abnormalities results in uncontrolled B-cell proliferation and thus subsequent neoplastic transformation of the B-cell clone.

In splenic and nodal MZ, the mechanisms determining lymphomagenesis are not clear yet.

Genetics

►Trisomy 3 and 18 have been detected at similar frequencies, ranging from 15% to 60%, in extranodal, nodal and splenic MZL. Other trisomies, such as trisomy 7 and 12 are less common.

The chromosomal translocations t(11;18)(q21;q21), t(1;14)(p22;q32), t(14;18)(q32;q21) and t(3;14)(p13;q32) are all known to occur with variable frequencies in MALT lymphomas, resulting in *API2-MALT1*, *IGH-BCL10*, *IGH-MALT1* and *IGH-FOXP1* rearrangements respectively. The t(11;18)(q21;q21) is the most common structural chromosomal abnormality in MALT lymphomas. It is demonstrated in 10–50% of gastric MALT lymphomas, whereas this translocation rarely occurs in nongastric MALT lymphomas, with the exception of pulmonary MALT lymphomas. MALT lymphomas marked by t(11;18)(q21;q21) are resistant to *H. pylori* eradication treatment and only rarely evolve to a DLBCL. The t(11;18)(q21;q21) fuses the amino-terminus of the *API2*-gene (located at 11q21) to the carboxyl-terminus of the *MALT1*-gene (located at 18q21), hereby generating the fusion-protein API2-MALT1. The t(11;18)(q21;q21) has never been found in other lymphoma types and its presence in MALT lymphoma correlates with the absence of any further genetic aberrations. The t(1;14)(p22;q32) and t(14;18)(q32;q21) occur in a small minority of almost exclusively non-gastric MALT lymphomas, which typically display additional genomic aberrations and tend to be at advanced stage of disease at presentation. These translocations are both mediated by the *IGH*-gene enhancer and result in overexpression of the *BCL10*-gene (located at 1p22) and *MALT1*-gene (located at 18q21) respectively. Both BCL10 and MALT1 play a key role in the antigen-receptor signaling to NF-κB. The t(11;18)(q21;q21)- and (1;14)(p22;q32)-positive MALT lymphomas are marked by a respectively moderate to strong nuclear BCL10 expression while t(14;18)(q32;q21)-positive MALT lymphomas are characterized by a perinuclear BCL10 immunohistochemical staining pattern. Recently, *FOXP1* (located at 3p13) was identified as a new translocation partner of *IGH* at low frequency, not only in MALT lymphomas, but also in DLBCL with mainly extranodal location. Remarkably, a significant number of t(3;14)(p13;q32)-negative MALT lymphomas and DLBCLs harbors strong nuclear FOXP1 expression, suggesting that mechanisms other than underlying *FOXP1* rearrangements can upregulate FOXP1 expression. The significance of this nuclear FOXP1 overexpression in MALT lymphomas is still debated; one study found strong nuclear FOXP1 expression to be confined to MALT lymphomas that are at risk of transforming into a DLBCL with poor clinical outcome. So far, it is not clear yet how FOXP1 mediates MALT lymphomagenesis.

Except for trisomy 3 and 18, cytogenetic findings in both splenic and nodal MZL are rather heterogeneous and complex, and no unique abnormalities have been documented so far. Of interest, chromosome 7 is most frequently altered in splenic MZL, with a loss of 7q31–q32 in 40% of cases. In addition, cases with 7q loss behave more aggressively and display more frequent tumoral progression.

Deregulation of NF-κB: The Unifying Concept for MALT Lymphomagenesis?

Mounting evidence links the oncogenic activity of t(11;18)(q12;q21), t(1;14)(p22;q32) and t(14;18)(q32;q21) to aberrant activation of the canonical NF-κB pathway by API2-MALT1, BCL10 and MALT1 respectively. The NF-κB family is composed of five proteins that share a conserved REL homology domain for DNA binding: NF-κB1 (p105/p50), NF-κB2 (p100/p52), RelA (p65), RelB and ►REL. In unstimulated B-cells, the NF-κB molecules RelA and p50 are sequestered in the cytoplasm as latent complexes through binding with inhibitory κB (IκB) proteins. However, upon antigen encounter, CARMA1 interacts with the antigen-activated B-cell receptor in the lipid-rafts and induces the oligomerization of its downstream components BCL10 and MALT1 with TRAF6. The latter elicits its ubiquitin ligase activity, resulting in ►ubiquitination of IκB kinase-γ (IKKγ or NEMO), which in turn phosporylates IκB, hereby targeting IκB for phosphorylation and proteasomal degradation. This allows the RELA/p50 dimers to enter the nucleus and mediate transcription of NF-κB-responsive genes, such as the pro-proliferative gene *cyclin D2* and the anti-apoptotic genes BCL-X_L and ►*BCL-2*.

In MALT lymphomas, the overexpression of BCL10 and MALT1 induced by fusion with the *IGH*-enhancer in t(1;14)(p22;q32) and t(14;18)(q32;q32) respectively hints at a role for NF-κB deregulation in lymphomagenesis. In t(1;14)(p22;q32)-positive MALT lymphomas, in which BCL10 is overexpressed, BCL10 is believed to form oligomers without the need for upstream signaling, hereby triggering MALT1 oligomerization and aberrant NF-κB activation. In t(14;18)(q32;q21)-positive MALT lymphomas, in which MALT1 is overexpressed, the oligomerization of MALT1 with

subsequent NF-κB activation is thought to be dependent on BCL10, as MALT1 does not have a structural domain to mediate self-oligomerization, nor does its overexpression alone activate NF-κB *in vitro*. In t(11;18)(q21;q21)-positive MALT lymphomas, it is believed that the fusion-protein API2-MALT1 activates NF-κB directly by constitutively increased IKKγ polyubiquitination, as shown *in vitro* and in mice models. Also, the API2-MALT1 fusion protein was reported to reside in the lipid-rafts. This raft association facilitates oligomerization of the API2-MALT1 fusion-protein and/or its interaction with its downstream signaling components (e.g. TRAF6), in this way bypassing the normal antigen requirement for formation of MALT1-TRAF6 oligomers and resulting in constitutive NF-κB activation. In addition, it was shown that API2-MALT1 induces transactivation of the *API2*-gene through NF-κB activation, hereby creating a positive feedback-loop mechanism of self-activation by upregulating its own expression in t(11;18)(q21;q21)-positive MALT lymphomas.

Clinical Features, Prognosis and Therapy

MALT lymphomas mostly present as Ann-Arbor stage IE disease (extranodal disease limited to the site of origin) as bone marrow and peripheral lymph node involvement are rather uncommon. It is nowadays generally accepted that *H. pylori* eradication with antibiotics is the first choice of therapy for localized gastric MALT lymphoma. The use of anti-infectious treatment in non-gastric MALT lymphomas is still under investigation, although recent reports discourage the use of antibiotics in patients suffering from non-gastric MALT lymphomas. Other effective treatment approaches include radiotherapy, chemotherapy, and anti-CD20 monoclonal antibody.

Splenic MZL is characterized by an enlarged spleen and often presents with peripheral blood and bone marrow involvement. The clinical course is indolent, even with bone marrow involvement, and splenectomy may be followed by a prolonged remission. Chemotherapy is only employed for patients with progression after splenectomy or when surgery is contraindicated. Alkylating agents (chlorambucil or cyclophosphamide) or purine analogues (fludarabine) have been reported as being effective treatments.

Finally, the typical clinical presentation of nodal MZL, without extranodal involvement, is that of a middle-aged individual with peripheral and para-aortic lymphadenopathy and advanced stage disease with bone marrow involvement. This presentation is similar to other low-grade nodal ►non-Hodgkin lymphomas, such as follicular lymphocytic lymphomas. Nodal MZL represents a therapeutic dilemma, since no studies of large series have been published so far. In addition, the 5-year overall survival as well as the failure-free survival of patients with nodal MZL was found to be lower than that of patients with extranodal MZL (56% vs. 81% and 28% vs. 65%, respectively).

Maspin

Shijie Sheng
Department of Pathology, Wayne State University School of Medicine, Karmanos Cancer Institute, Detroit, MI, USA

Definition

Maspin is a 42 kDa clade B ►serpin. The human maspin gene has been mapped to a cluster of serpins at chromosome 18q21.3–q23.

Characteristics

Maspin is one of 13 human clade B serpins that share high homologies with chick ovalbumin (ov-serpins).

Inhibitory serpins are known for their conformational changes in which the reactive site loop (RSL) is engaged in a covalent bond with the catalytic site of the protease. Eventually the pseudo substrate p_1p_1-bond in RSL is cleaved, and the cleaved RSL is inserted into the β-pleated sheets as strand 4A. This conformation change, also known as loop insertion, is viewed as the most critical trait for inhibitory serpins. The polypeptide sequence of maspin is the most divergent from other ov-serpins. Crystallized maspin has a hydrophilic Asn (Asn^{113}) in the shutter region at the base of the β-pleated sheets. In addition, the exposed RSL may directly interact with β-pleated sheet C1 but does not have significant flexibility. These structural features may prevent the protease-induced loop insertion. The exposed G-helix has two different conformations (closed and open).

The Role of Maspin in Epithelial Pathophysiology

Maspin is differentially expressed: The human maspin gene is expressed by epithelial cells in several types of tissues including breast, prostate, placenta, testis, colon, small intestine, tongue, thymus, and skin. Mouse maspin (mMaspin) is found to have a similar tissue expression pattern as human maspin. The epithelial-specific expression of maspin in normal somatic tissues is controlled by the DNA ►methylation mechanism. The level of mMaspin mRNA is altered at different developmental stages of the mammary gland; low in virgin mouse breast and during involution, but high in late pregnancy and lactation. Maspin expression can be induced by pathophysioloigcal stress stimuli, including ►DNA-damaging agents, cytotoxic drugs, peroxisome proliferator-activated receptor-gamma, nitric oxide, and manganese superoxide dismutase (MnSOD). The Maspin transcription may be positively regulated by ►tumor suppressor, ►p53 and negatively regulated by a cis-acting ►hormone responsive element. The Maspin protein isolated from biological sources is a monomer which may be present as a secreted, a cytoplasmic, a nuclear, as well as a cell surface-associated protein. Changes of the subcellular localization pattern of maspin have been noted in tumor progression. In ►breast cancer, ►prostate cancer, ovarian, and ►lung cancer, nuclear maspin correlates with better differentiate phenotypes, whereas cytoplasmic maspin is associated with poor prognoses. Maspin is generally downregulated or lost as tumor progresses to invasive and metastatic stages.

Maspin acts as a ►tumor suppressor: Despite the evidence that systematic maspin knockout is lethal at embryogenesis, the biological function of maspin in development remains elusive. In the meantime, accumulated evidence supports a tumor suppressive role of maspin, acting at the levels of ►invasion, ►angiogenesis, and ►metastasis. Orthotopic explants of mammary carcinoma cells transfected with maspin-coding cDNA are inhibited in tumor growth and metastasis in nude mice. In a novel intraosseous SCID-Hu model that reproduces the organ and species-specific prostate–bone interaction, maspin overexpression in prostate carcinoma cells decreased tumor growth, tumor-induced osteolysis, and tumor angiogenesis. Maspin expression also led to redifferentiation of prostate tumor cells in vivo. These findings are further supported by several in vivo experiments using genetically modified mouse models. For example, in a syngeneic mammary tumor model, maspin overexpression in TM40D mammary tumor cells blocked tumor invasiveness, angiogenesis, and metastasis.

Maspin transfected breast and prostate tumor cells are significantly inhibited in in vitro invasion and ►motility assays. Similarly, induced reexpression of maspin by γ-linolenic acid has been shown to correlate with a marked reduction of the spreading and ►migration of breast tumor cell lines. Secreted maspin sequestered by extracellular matrix inhibits tumor cell invasion. Purified recombinant human maspin exhibits potent inhibitory activities on the invasion and motility of an array of human carcinoma cell lines. Recombinant maspin is also shown to directly block endothelial cell migration toward basic fibroblast growth factor and vascular endothelial growth factor, and inhibited endothelial tube formation in vitro. A current consensus suggests that the inhibitory effects of maspin on tumor cell motility and invasion is localized to the cell surface, depends on cell interaction with extracellular matrix-extracellular matrix, and depends on maspin RSL. Maspin inhibits tumor-induced extracellular matrix degradation. In addition, maspin enhances cell ►adhesion with increased focal adhesion contacts in vitro. It has been recently shown that maspin stabilizes the mature focal adhesion contacts and retard cell detachment.

Maspin enhances tumor cell apoptotic sensitivity: Maspin protein does not induce spontaneous cell death in vitro. However, overexpression of maspin in ►cancer cells always results in growth inhibition in various in vivo tumor models. These in vivo maspin effects are associated with increased tumor cell ►apoptosis. Consistently, a recent clinical study revealed a positive correlation between maspin and drug sensitivity of ►colon cancer patients. Experimental evidence indicates that intracellular, but not extracellular, maspin significantly increases the sensitivity of breast and prostate carcinoma cells to various drugs, ranging from extrinsic death ligands to endoplasmic reticulum stress. The proapoptotic effect of maspin appears to be tumor specific since normal epithelial cells that express maspin at a high level are not sensitized to drug-induced apoptosis. Thus far, maspin is the only proapoptotic clade B serpin among all serpins implicated in apoptosis regulation.

The Molecular Mechanisms of Maspin

Maspin does not directly inhibit active serine proteases. Efforts to delineate the underlying molecular mechanisms of maspin led to the identification of several candidate extracellular maspin partners/targets: tissue-type ►plasminogen activator, α2-chain collagen type I, ►uPA zymogen (pro-uPA). Interestingly, maspin prefers pro-uPA and inhibit the proteolytic activation of pro-uPA to active uPA. Furthermore, maspin has been shown to trigger robust ►endocytosis of uPA/uPAR. uPA is thought to be responsible for initiating a powerful proteolytic cascade, by converting plasminogen to plasmin. Plasmin can directly degrade nonfibrillar extracellular matrix proteins or indirectly degrade fibrillar extracellular matrix proteins by activating members in the ►matrix metalloproteinase (MMPs) family. Plasmin and active MMPs are also implicated in the proteolytic activation and/or release of growth factors. All these consequences increase ►extracellular matrix remodeling and the vicious paracrine communication between tumor cells and tumor stroma.

Yeast two-hybrid screening method pulled out ►histone deacetylase 1 (HDAC1) glutathione s-transferase (GST), ►Hsp90, and interferon regulatory factor 6 (IRF6) as candidate intracellular maspin-binding proteins. The interaction of maspin with HDAC1, GST, and IRF6 has been confirmed. Although the biochemical reactions involved are subjects of further investigation, accumulative evidence suggests that maspin may regulate stress-responsive pathways involved in epithelial homeostasis. For example, GSTs are major glutathione-based reductases. The interaction of maspin with GST correlates with increased cellular GST activity and cell resistance to ►oxidative stress-induced generation of ►reactive oxygen species.

The interaction of maspin with HDAC1 leads to specific HDAC1 inhibition. HDAC1 is a major class I ►HDAC that hydrolyzes the ε-acetyl lysine residues in histone and other proteins. HDAC1-mediated histone deacetylation leads to chromatin condensation, preventing the access of transcription factors to DNA and repressing gene expression. HDAC1 target genes such as Bax, $p21^{WAF1/CIP1}$, $p27^{KIP1}$, and cytokeratin 18 play important roles in proliferation, apoptosis, and differentiation. Consistently, maspin expression in cancer cells correlates with increased expression of Bax. Furthermore, the effect of maspin in sensitizing cells to induced apoptosis depends on the Bax-mediated mitochondrial pathway.

This inhibitory interaction of maspin with HDAC1 may depend on the novel serpin conformation of maspin as well as the serine protease-like conformation of HDAC1. HDAC1 crystallized with synthetic inhibitor trichostatin A shows a catalytic pocket similar to that of a serine protease. However, this pocket has a unique narrow "tunnel" extending into the center of the molecule. At the bottom of the "tunnel" is a Zn^{2+} ion chelated by two Asp-His charge-relay systems. In HDAC1-mediated protein deacetylation, a H_2O and a ε-acetyl-lysine side chain bind to Zn^{2+}, leading to a series of proton transfer and lysine deacetylation. Coincidentally, maspin RSL p_1 residue $Arginine^{340}$ has a similar structure as ε-acetyl-lysine. The exposed maspin RSL with $Arginine^{340}$ at the center seems a natural cap to block the entry of HDAC1 substrates.

Taken together, maspin may act as a serpin-like regulator of serine protease-like targets. Maspin is one of loneliest and the most ancient ov-serpins. From an evolution point of view, the conservation of a serine protease-like catalytic center in many molecules (such as pro-uPA and HDAC1) should require the coexistence of endogenous antagonists. It is likely that the activity of maspin to target serine protease-like molecules may not be substituted by other serpins that have evolved to acquire higher target specificities.

Mass Spectrometry

Definition

Mass spectrometry is an analytical technique in which molecules are ionized and their mass-to-charge ratio is measured in order to determine the exact mass. If the mass is measured with precision, then the composition of the molecule can be identified. In the case of proteins, the sequence can be identified. It is most generally used to find the composition of a physical sample by

generating a mass spectrum representing the masses of sample components. The mass spectrum is measured by a mass spectrometer to give the mass-to-charge ratio of all compounds in the sample.

Definition

A large cell in connective tissues with many coarse cytoplasmic granules, containing several chemical mediators, which are released during allergic responses, inflammation, and tumor growth.

Characteristics

Mammalian mast cells (MC) express common characteristics, including high affinity plasma membrane receptors (FcεRI) binding IgE antibodies and cytoplasmic granules storing biogenic amines, proteoglycans, cytokines, and neutral serine proteases. However, MC populations show marked differences in their phenotypic expression in different species as well as distinct anatomical sites, a phenomenon called "MC heterogeneity."

MC arise from multipotential precursors in the bone marrow, circulate as mononuclear agranular cells, then traverse the vascular space and enter the tissues where they complete their development. In humans, MC derive from $CD34^+$, $FcεRI^-$, c-kit^+ progenitors. Differentiation and maturation of MC are most likely regulated by local microenvironmental factors, in particular the c-kit ligand (stem cell factor, SCF) secreted by fibroblasts, stromal cells, and endothelial cells, which represents the most important cytokine involved in MC development. In humans, tissue MC survival and differentiation are also enhanced by other cytokines including interleukin-4 (IL-4) and IL-6.

MC are found in almost all of the major organs and tissues of the body, particularly in association with connective tissue structures such as blood vessels, lymphatic vessels, and nerves, and in proximity to surfaces that interface the external environment, such as those of the respiratory and gastrointestinal system and the skin. Human MC are conventionally divided into two types depending on the expression of different proteases in their granules. MC tryptase (MCT) cells contain tryptase and are predominantly located in the respiratory and intestinal mucosa, where they colocalize around T lymphocytes. MC tryptase–chymase (MCTC) cells contain both tryptase and chymase, along with other proteases such as carboxypeptidase A and cathepsin G. They are predominantly found in connective tissue areas, such as skin, submucosa of stomach and intestine, breast parenchyma, myocardium, lymph nodes, conjunctiva, and synovium. A third type of MC, MC chymase (MCC) cell has been identified: this MC expresses chymase without tryptase and resides mainly in the submucosa and mucosa of the stomach, small intestinal submucosa, and colonic mucosa.

Human MC are usually described as round or elongated cells with a diameter ranging between 8 and 20 μm, depending on the organ examined. They present a single round or oval nucleus and numerous cytoplasmic granules that stain metachromatically with thiazine dyes such as toluidine blue. Ultrastructurally, these cells exhibit a nonsegmented monolobed nucleus with peripherally condensed chromatin. The cytoplasm contains a few mitochondria, short profiles of the rough endoplasmic reticulum, and numerous free ribosomes.

The most characteristic cytoplasmic organelle in human MC is the membrane-bound, moderately electron-dense secretory granule. Secretory granules are much abundant and correspond to the metachromatic granules of the light microscopy. They have an average diameter of 1.5 μm and present different types of substructural patterns: homogeneous, crystalline, scroll, particle or thread-like or a combination of them. Granules with the chymase protease preferentially exhibit homogeneous or crystalline substructures whereas granules lacking this protease show mainly a scroll pattern. However, significant granule heterogeneity can be found in any particular tissue and even between granules of a single MC. Besides the typical secretory granules, human MC also contain nonmembrane-bound, highly osmiophilic granules, called lipid bodies. They are fewer in number and generally larger than secretory granules, and serve as a significant storage site for arachidonic acid. Release

of preformed and lipid mediators, cytokines and chemokines (histamine, tryptase, chymase, cathepsin, carboxypeptidase A, PAF, LTC-4, PGD-2, SCF, IL-3, IL-5, IL-6, IL-8, IL-13, IL-16, IL-18, IL-25, TGF-β, GM-CSF, TNF-α, VEGF, NGF, I-309/CCL-1, MCP/CCL-2, MIP-1α/CCL-3) stored in the secretory granules can be accomplished by two morphologically distinct secretory pathways, referred to as exocytosis (also called "anaphylactic degranulation") and piecemeal degranulation. The former consists of a rapid and massive secretory process, occurring during IgE-dependent hypersensitivity reactions. In exocytosis, cytoplasmic granule membranes fuse with each other and with the plasma membrane, giving rise to open secretory channels which allow the release of granule contents into the local extracellular environment. Piecemeal degranulation, conversely, represents a slow and particulate mode of MC secretion, characterized by granule content release in a "piecemeal" fashion, not accompanied by membrane fusion events and granule opening to the cell exterior. This degranulation pattern has been observed in MC infiltrating areas of chronic inflammation or tumors.

MC and Tumor Growth

Since the first recognition by Ehrlich in 1878, MC have often been observed at different sites of neoplasms. MC are commonly recognized at the margins of diverse tumors in human and rodents. MC are prominent in the tumor ►microenvironment, are thought to provide a host response of the innate immunity to neoplasia and could either promote or inhibit tumor growth depending on the local stromal conditions.

It is now well documented that neoplastic cells are influenced by their microenvironment and vice versa. The specific organ microenvironment determines the extent of ►cancer cell proliferation, ►angiogenesis, invasion, and survival. This indicates that a permissive stromal environment is important in supporting tumor progression in combination with genetic alterations. Tumor cells are surrounded by an infiltrate of inflammatory cells, namely lymphocytes, neutrophils, macrophages, and MC, which communicate via a complex network of intercellular signaling pathways, mediated by surface adhesion molecules, cytokines and their receptors.

MC deficient mouse had an increased tumor incidence compared with normal and in a study evaluating growth of pulmonary metastases of B16 melanoma, lung metastases were significantly decreased in controls, compared to MC deficient mice. In a murine model of squamous epithelial carcinogenesis, MC in conjunction with neutrophils and other inflammatory cells contribute to tumor growth, in part through the production of the protease matrix metalloproteinase-9 (MMP-9).

MC accumulate at sites of tumor growth in response to numerous chemoattractants, such as tumor-derived peptides, RANTES, or monocyte chemotactic protein (MCP-1). Melanoma cells recruit MC in vivo by producing MC chemotactic and mitogenic factors, such as IL-3. MC secrete histamine that could induce tumor cell proliferation through H1 receptors identified in human malignant carcinoma, whereas MCC induces the accumulation of tumor-associated macrophages, neutrophils, and other inflammatory cells in vivo.

The most aggressive human cancers, namely malignant melanoma, breast carcinoma, and colorectal adenocarcinoma, are associated with a dramatic host response composed of various inflammatory cells, especially MC at the tumor periphery. MC infiltrate hyperplasias, dysplasias, and invasive fronts of carcinomas, where they degranulate in close apposition to capillaries and epithelial basement membranes.

MC increase at sites of breast cancer and in associated lymph nodes in reaction to the tumor and might participate in tumor rejection. Perivascular tumor-associated MC in mammary adenocarcinoma could secrete several cytokines and proteolytic enzymes that could be detrimental to the tumor cells. MC are present in area of intense tumor infiltration, whereas MC in an area of marginal tumor growth appear to be degranulated. Patients with longer survival have a significantly higher number of MC in their axillary lymph nodes.

MC accumulation has also been noted around melanomas, especially invasive melanoma, where MC accumulate around the margin of the malignancies. Among the mediators released by MC, fibroblast growth factor-2 (FGF-2) and IL-8 are directly mitogenic to melanoma cells, whereas certain other mediators including tumor necrosis factor alpha (TNF-α), IL-1, IL-6, and interferon gamma suppress melanoma cell growth.

Among the localized benign tumors of mesenchymal origin, increased number of MC have been encountered in Schwannomas, hemangiomas, and dermatofibromas. MC have been noted around peripheral nerves and nerve tumors, and an increased number of MC has been reported around neurofibromatosis type 1 lesions, in which c-kit and SCF have been implicated in MC proliferation.

Mastocytosis is characterized by abnormal growth and accumulation of MC in one or multiple organs. Two groups of patients can be distinguished, namely patients with cutaneous mastocytosis (CM) and those with systemic mastocytosis (SM). Usually, CM manifests in childhood and presents as urticaria pigmentosa. The clinical course of CM is benign and in many cases skin lesions disappear during puberty. SM is usually diagnosed in adulthood and is characterized by multiorgan involvement and disease persistence. Indolent

variants as well as aggressive variants (aggressive systemic mastocytosis) have been reported. MC leukemia (MCL) is a rare subtype of SM defined by circulating MC and a rapidly deteriorating clinical course in most cases.

MC may support tumor cell expansion in Waldenstrom's macroglobulinemia through constitutive CD154–CD40 signaling and therefore may provide a framework for therapeutic targeting of MC.

MC and Tumor Angiogenesis

Tumors are endowed with an angiogenic capability and their growth, invasion and metastasis are angiogenesis-dependent. After the initial transformation and growth of cells, vascularization must occur if a tumor mass is to exceed 1 mm^3 in diameter. The synthesis and secretion of several proangiogenic factors by tumor and host cells plays a key role in establishing a vascular network from the surrounding stroma.

Several MC-dependent mediators are involved in angiogenesis. Heparin stimulates endothelial cell proliferation and migration in vitro. In vivo, however, it stimulates, inhibits, or has no effect. These differences seem to be related to its molecular size and degree of sulfation. Heparin acts as a soluble form of the low-affinity FGF-2 receptor, which displaces FGF-2 in the biologically active form, and allows its rapid interaction with endothelial cells. Histamine has an angiogenic effect through both H1 and H2 receptors. It may also increase the permeability of newly formed microvessels during tumor angiogenesis, and hence increase the leakage of plasma proteins and deposition of fibrin. Degradation products of fibrin are angiogenic in vivo. MC synthesize and store large amounts of MMP-2, MMP-9, and serine-proteinases of two subclasses: tryptase and chymase. Given the ability of MMP-2 and MMP-9 to degrade type IV, V, VII, and X collagens, as well as fibronectin, namely the major components of the interstitial stroma and subendothelial basement membrane, the findings suggest that MC may contribute to the progression from in situ to invasive and metastatic solid tumors, characterized by an enhanced angiogenesis and secretion of proteolytic enzymes. Tryptase added to microvascular endothelial cells cultured on Matrigel caused a pronounced increase in capillary growth, and this was suppressed by specific tryptase inhibitors. Moreover, tryptase directly induced endothelial cell proliferation in a dose-dependent fashion. MC release several polypeptide growth factors, including FGF-2, vascular endothelial growth factor (VEGF), transforming growth factor beta (TGF-β), TNF-α, and IL-8. These cytokines are involved both in normal as well as tumor-associated angiogenesis. The spectrum of cytokines expressed appears to vary depending on the maturity state of the MC and of the tissue of residence. Nerve growth factor (NGF), also contained in MC secretory granules, induces endothelial cell proliferation in vitro and angiogenesis in vivo in the chick embryo chorioallantoic membrane (CAM) assay.

Isolated MC and their secretory granules, but not degranulated MC, induce an angiogenic response in the CAM assay. Addition of anti-FGF-2 or anti-VEGF antibodies reduced the angiogenic response of both MC and their secretory granules by 50 and 30%, respectively. These data support the evidence that the angiogenic properties of MC depend on the angiogenic molecules contained in their secretory granules, and indicate that FGF-2 and VEGF are the angiogenic cytokines primarily and perhaps synergistically responsible for this vasoproliferative activity.

Tryptase-positive MC increased in number and vascularization increased in a linear fashion from dysplasia to invasive cancer of the uterine cervix. An association of VEGF and MC with angiogenesis has been demonstrated in laryngeal carcinoma, in small lung carcinoma, where most intratumoral MC express VEGF, and in melanoma, where MC express both VEGF and FGF-2. Lastly, a prognostic significance has been attributed to MC and microvascular density in squamous cell cancer of the esophagus and in melanoma.

Bone marrow angiogenesis, evaluated as microvessel area, and MC counts are highly correlated in patients with inactive and active multiple myeloma (MM) and in those with monoclonal gammopathies of undetermined significance (MGUS). Both parameters increase simultaneously in active MM. A significant correlation has been demonstrated in non Hodgkin's lymphoma (NHL) between vessel count and the number of both MC and VEGF-expressing cells. Double fluorescence staining of VEGF mRNA and MCT revealed that MC expressed VEGF mRNA. In both B-NHL and MM, MC rest near or around blood or lymphatic capillaries. Their ultrastructural picture includes a typical morphological semilunar feature, or "piecemeal" partial degranulation of their secretory granules, unlike the IgE-mediated massive degranulation that occurs during immediate hypersensitivity reactions. This morphology is typical of the slow degranulation that takes place in delayed hypersensitivity reactions and chronic inflammation. Semilunar appearance may reflect slow but progressive release of angiogenic factors favoring chronic and progressive stimulation of MC degranulation.

Bone marrow samples of patients with myelodysplastic syndromes display a high correlation between microvessel counts and both total and tryptase-positive MC, and that both parameters increase simultaneously with tumor progression. There is also a correlation between the extent of angiogenesis and the number of tryptase-positive MC in patients with early B-cell

chronic lymphocytic leukemia and tryptase-positive MC predict their clinical outcome.

Conclusions

Inhibition or destruction of tumor cells has long been the prime goal of cancer therapy. Treatment of these cells and modulation of their microenvironment may prove a better approach. The balance or imbalance of inducers and inhibitors of angiogenesis secreted by inflammatory cells may favor a tumor's progression or regression. The circumstances in which MC are a critical source of angiogenic factors in vivo, and in such cases, what signals regulate their production and secretion are all matters that need to be determined as a prelude to the elaboration of new therapeutic strategies associated with their presence and activation. Finally, a more accurate insight into the role of MC may be obtained from the use of activation markers, along with consideration of local, microenvironmental stimuli in the regulation of their functions.

[2]University of Michigan, Ann Arbor, MI, USA

Definition

Mastocytosis, a ►hematopoietic neoplasm, is a clonal disorder of the mast cell and its progenitor resulting in the presence of excessive numbers of mast cells in the skin, bone marrow, and internal organs such as the liver, spleen, and lymph nodes.

Characteristics

Most patients with mastocytosis present with symptoms due to the release of mediators from activated mast cells in various tissues. The activation of mast cells can be caused by triggers such as temperature changes, emotional or physical stress, exercise, ingestion of alcohol, spicy foods, or mast cell degranulating drugs, insect venom, and allergens, but may also occur without an apparent stimulus. Patients with mastocytosis display a wide range of clinical presentations, ranging from no symptoms to severe life-threatening syncopal episodes or hematologic abnormalities. The most common symptoms of mast cell degranulation are itching, flushing, gastrointestinal symptoms such as heartburn and diarrhea, lightheadedness, and palpitations. These symptoms usually occur in well-defined episodes generally lasting from a few minutes to several hours. Other mast cell degranulation symptoms, such as angioedema, hives, and wheezing, are unusual but may be occasionally encountered, especially if the patient has co-existing allergic disease or asthma. Physical examination at the time of a symptomatic mast cell degranulation event may reveal flushing of the skin, conjunctival injection, nasal turbinate edema, hypotension, and tachycardia. Between episodes, the patient may be asymptomatic or may have constitutional symptoms such as fatigue, musculoskeletal pain, and cognitive difficulties.

Approximately 10–20% of patients with mastocytosis will be diagnosed with a non-mast-cell clonal hematologic disorder, and the clinical presentation will reflect that of the associated ►hematologic disorder. Myeloid neoplasms such as chronic myeloproliferative disorders and myelodysplastic syndromes are the most common hematologic disorders encountered in the context of mastocytosis, but ►acute leukemias and ►chronic lymphoproliferative disorders have also been reported.

Although mastocytosis generally follows an indolent course, mast cell infiltration of the bone marrow and internal organs may take an aggressive turn in a small

number of patients. These patients may suffer from bone marrow failure, liver failure with ascites, severe diarrhea and malabsorption, and pathologic bone fractures.

Mastocytosis affects both children and adults. In children, the disease commonly presents in the first year of life as characteristic skin lesions of ►urticaria pigmentosa (UP). These are fixed, hyperpigmented, and vascular maculopapular lesions, generally a few centimeters in diameter, which may urticate when rubbed or irritated (►Darier's sign). Mastocytosis is generally limited to the skin in children, who commonly experience resolution or improvement of symptoms by adolescence. In contrast, pathologic mast cell accumulation occurs in the bone marrow and other extracutaneous sites in most adult patients. Mastocytosis has been observed in patients of all ethnic backgrounds.

A somatic point mutation in codon 816 of the *KIT* gene occurs in more than 90% of patients with mastocytosis. *KIT* gene encodes for KIT, a membrane receptor with intrinsic ►tyrosine kinase activity, which is critically involved in mast cell growth, differentiation, survival, and functional activation, upon binding its ligand ►stem cell factor. In mastocytosis the D816V mutation in KIT results in this tyrosine kinase being constitutively active without the need for stem cell factor. This is thought to be a critical step in the pathogenesis of mastocytosis.

Diagnosis

Cutaneous Disease: Urticaria pigmentosa (UP) is the most common finding upon physical examination in patients with mastocytosis. UP is the initial finding that leads to diagnosis in most patients with childhood-onset disease and is present in up to 80% of patients with adult-onset disease. Other less common forms of cutaneous mastocytosis are mastocytomas and diffuse cutaneous mastocytosis (DCM) in children and ►telangiectasia macularis eruptive perstans (TMEP) in adults. Mastocytomas are benign solid mast cell tumors that can be solitary or occur with UP. Rubbing or physical irritation of the mastocytoma may lead to generalized symptoms such as flushing and itching due to mast cell mediator release. Children with DCM have diffuse involvement of the skin, which may have a coarse and thickened appearance with a yellowish hue. TMEP is a rare form of cutaneous mastocytosis presenting with generalized telangiectatic macules with or without systemic bone marrow involvement. Although experienced physicians may be able to diagnose UP by its characteristic appearance, a skin biopsy is recommended if any doubts exist. If UP is present, the biopsy will show increased mast cells in the upper dermis, particularly around blood vessels, not accompanied by other inflammatory cells. Immunohistochemical staining for ►tryptase is recommended over metachromatic stains to visualize mast cells in tissue biopsy sections.

Systemic Mastocytosis. The pathologic increase of mast cells in extracutaneous sites is termed systemic mastocytosis. Bone marrow, the site of mast cell production, almost always demonstrates pathologic changes in systemic mastocytosis. Examination of the bone marrow in patients with systemic mastocytosis provides valuable information about the extent of the disease and the presence or absence of a non-mast-cell hematologic disorder. It also helps the physician to counsel the patient about prognosis. Therefore, a bone marrow biopsy and aspirate is the diagnostic method of choice in the evaluation of patients with suspected systemic mastocytosis.

The diagnosis of systemic mastocytosis should be based on the World Health Organization's criteria (Table 1). These criteria consider not only the quantitative increase in mast cells but also qualitative abnormalities such as morphologic changes and expression of aberrant surface markers. Serum or plasma tryptase levels generally correlate with mast cell burden and are elevated in most patients with systemic mastocytosis. The normal median tryptase level in the general population is approximately 5 ng/mL, and a tryptase level greater than 20 ng/mL should raise suspicion for the diagnosis of systemic mastocytosis. Tryptase levels may be transiently elevated after acute allergic and anaphylactic reactions, even in the absence of mastocytosis. Other diagnostic evaluations in cases of suspected mastocytosis generally include a complete blood count with differential and liver function tests. Bone densitometry is also recommended as a baseline test for many patients, as mastocytosis may accelerate osteoporosis. Other tests such as gastrointestinal endoscopies, skeletal X-rays, and imaging of the chest and abdomen may be necessary depending on the presenting symptoms.

Classification

Mastocytosis is a hematopoietic neoplasm classified according to the World Health Organization into seven categories on the basis of the site of involvement and aggressiveness of the disease (Table 2).

Therapy

Treatments for mastocytosis can be divided into two broad categories: (i) those intended to control symptoms due to mediators released from mast cells and (ii) those intended to reduce the mast cell burden. Treatment of mastocytosis aimed at controlling mast cell mediator symptoms is offered in all categories of mastocytosis. Mast cell cytoreductive therapies are generally reserved for patients with aggressive systemic mastocytosis (ASM), mast-cell leukemia (MCL), and mast-cell sarcoma (MCS). However, none of the current

Mastocytosis. Table 1 WHO diagnostic criteria for systemic mastocytosis*

Major criterion	Demonstration of multifocal aggregates of 15 or more mast cells in bone marrow or another extracutaneous site by a mast cell stain such as tryptase or CD117 immunohistochemistry
Minor criteria	Serum tryptase level greater than 20 ng/mL (not applicable if the patient has a non-mast-cell clonal myeloid disease)
	Surface expression of CD25 and/or CD2 on mast cells, as detected by flow cytometry or immunohistochemistry
	Morphologic aberrancy, such as hypogranulation, elongation (spindle-shape), cytoplasmic projections, and off-centered or lobulated nucleus, in greater than 25% of mast cells in tissue sections or bone marrow aspirate smears
	Presence of a codon 816 point mutation in the *KIT* gene in bone marrow, peripheral blood, or other lesional tissue specimens

* Either the major criterion + 1 minor criteria or 3 minor criteria are needed to establish the diagnosis

Mastocytosis. Table 2 Diagnostic features and prognosis of mastocytosis

Category	Diagnostic features	Prognosis
Cutaneous mastocytosis	Lack of systemic (bone marrow) involvement. Most common category in children, rare in adults	Good. Resolves or improves by adolescence in most children
Indolent systemic mastocytosis (ISM)	Benign, multifocal collections of mast cells in bone marrow. Symptoms of mast cell mediator release. Lack of organ dysfunction due to mast cell infiltration. Most common category in adult-onset disease	Good. Inadequate control of mast cell mediator symptoms may lead to poor quality of life
Systemic mastocytosis with associated clonal hematological non-mast-cell-lineage disease (SM-AHNMD)	Commonly associated with myelodysplastic or myeloproliferative disorders; occasionally seen with acute leukemias and lymphomas	Poor. Determined by the progression of non-mast-cell hematologic disorder
Aggressive systemic mastocytosis (ASM)	Findings of end-organ dysfunction due to mast-cell infiltration, such as bone marrow failure, liver dysfunction with ascites, splenomegaly, skeletal osteolytes with pathologic fractures, gastrointestinal involvement with malabsorption, and weight loss	Poor. Average survival 3–5 years
Mast-cell leukemia (MCL)	Mast cells with high-grade morphology (multilobular or multiple nuclei), >10% mast cells in peripheral blood, or >20% mast cells in bone marrow aspirate smears. Very rare	Poor. Average survival 3–9 months
Mast-cell sarcoma (MCS)	Local destructive (sarcoma-like) growth of a tumor consisting of highly atypical immature mast cells, similar in morphology to those seen in MCL. Very rare	Poor. Average survival 3–9 months
Extracutaneous mastocytoma	Benign extramedullary mast cell tumor in extracutaneous tissue such as lungs. Mast cells are mature with non-aggressive growth pattern. Very rare	Good

cytoreductive approaches has resulted in the cure of mastocytosis.

Because there is no therapy proven to cure mast cell disease, symptom control is an important aspect of the treatment strategy. Symptom control may be accomplished through the use of anti-histamines (H1 and H2 receptor blockers), leukotriene antagonists, and mast cell stabilizers such as sodium cromoglycate.

Patients with malabsorption, ascites, or recurrent anaphylactoid (syncopal) episodes are generally managed with glucocorticoids. Calcium and vitamin D supplementation and bisphosphonates are useful in the treatment of patients with osteoporosis. Self-injectable epinephrine should be prescribed to patients with life-threatening episodes of generalized mast cell mediator release resulting in cardiovascular collapse or respiratory compromise. The avoidance of known triggers of mast cell mediator release is an important non-medical management strategy. The potential of certain medications to stimulate mast cell mediator release should be considered in the overall medical management of the patient. These medications include, but are not limited to, opioid analgesics, non-steroidal anti-inflammatory drugs, muscle relaxants, general anesthetics, and medications that were not tolerated by the patient in the past. Despite symptomatic treatment with available anti-mediator drugs, some patients continue to have a poor quality of life, probably because of the drugs' inability to block all mast cell mediators.

Patients with ASM, MCL, and MCS and selected patients with indolent systemic mastocytosis (ISM) who have a high mast cell burden and/or poor quality of life may be candidates for several approaches that aim to control the mast cell burden. ►Interferon-alpha (IFN-α) has been the subject of most of the research in this area. Due to rarity of the disease, however, most of the reports on the use of IFN-α (with or without prednisolone) are limited in the number of patients reported. For example, a recent review of the literature identified 14 well-documented patients with aggressive mast cell disease treated with IFN-α (with or without prednisolone); three (21%) had a major response, with dissolution of signs and symptoms of the disease, and five patients (36%) had a partial response. ►Clinical trial experience with IFN-α is less favorable, however. The largest phase II trial of IFN-α in 20 adult patients with systemic mastocytosis resulted in seven (35%) partial responses and no major response. Although given primarily to patients with aggressive forms of mastocytosis, IFN-α may also be considered in patients with ISM when they present with severe osteoporosis or when symptomatic therapy fails to control anaphylactic episodes. Patients with ISM who have a high mast cell burden and progressive disease (i.e., involvement of the organs but with preserved organ function) may also benefit from biological cytoreductive therapy with IFN-α.

Patients with systemic mastocytosis with associated clonal hematological non-mast-cell-lineage disease (SM-AHNMD) may have an indolent or aggressive mast cell disease component independent of the AHNMD, and therapy depends on the severity of the individual disorders. In most cases, treatment of the latter usually takes precedence and should follow standard guidelines for the associated hematologic disease. When the SM component is clinically more prominent, therapy with IFN-α (with or without the addition of corticosteroids) or chemotherapy can be beneficial. Patients with ASM have poor quality of life and shortened life expectancy and are therefore treated with cytoreductive therapy (usually IFN-α ± corticosteroids as first-line therapy). Recent experience suggests that there exists a subpopulation of patients with ASM who respond to 2-chlorodeoxyadenosine (►cladribine; 2-CDA). One report of four patients with ASM treated with cladribine noted a major response in 2 patients and a partial response in a third patient. Another report documented improvement in symptoms (partial response) in 10 of 10 patients treated with cladribine, although no major responses were observed. Some patients with ASM may benefit from hematopoietic stem cell transplantation. Patients with MCL traditionally have been treated with polychemotherapy regimens similar to those employed in patients with acute myeloid leukemia. While these modalities can render significant mast cell reduction and symptom control in some patients, responses are transient and the prognosis remains very poor.

The discovery of activating point mutations near the activation loop of the KIT tyrosine kinase domain has driven recent investigative efforts to identify suitable drugs that inhibit this target. The therapeutic potential of many target-specific small molecules in systemic mastocytosis, including ►imatinib, dasatinib, and ►nilotinib, is currently being evaluated in clinical trials. The first such medication to be tried in patients with systemic mastocytosis was imatinib mesylate. Imatinib is a potent competitive inhibitor of Abl, ►platelet derived growth factor receptor (PDGFR), and KIT tyrosine kinases and is the standard first-line therapy for chronic myeloid leukemia associated with the ►Bcr-Abl oncoprotein. Because of its inhibitory effect on wild-type (non-mutated) KIT, some investigators have utilized imatinib mesylate in patients with systemic mastocytosis, and responses were seen in selected patients. Unfortunately, the mutated D816V KIT found in the great majority of systemic mastocytosis patients is not sensitive to imatinib, as shown by in vitro laboratory studies. Therefore, the initial high expectations for imatinib treatment have diminished significantly. A review of all experience with imatinib confirmed, however, its potential to improve signs and symptoms of the disease in some patients. This led the US Food and Drug Administration to approve imatinib in the USA, as therapy for adult patients with ASM without the D816V KIT mutation or with unknown KIT mutational status. Another indication for therapy with imatinib is systemic mastocytosis associated with chronic eosinophilic leukemia characterized by the presence of the FIP1L1-PDGFRα

►fusion gene. Approximately 20% of cases of systemic mastocytosis present with persistent peripheral blood eosinophilia, and clonality can be demonstrated in a significant proportion of them. Some of these cases express the imatinib-sensitive FIP1L1-PDGFRα oncogene, which results from an interstitial deletion of chromosome 4q12, leading to the constitutive activation of the PDGFRα tyrosine kinase. For this subset of patients, imatinib must be considered first-line therapy, as it eliminates the disease in the great majority of cases. Other targets for therapy that are involved in neoplastic mast cell survival and activation are currently being investigated.

Matricellular Proteins

Definition

Introduced in 1995 by Paul Bornstein, the term refers to a group of soluble, non-structural ►extracellular matrix (ECM) proteins, that regulate the interaction of cells with their environment by binding and modulating the function of matrix proteins, growth factors and cell surface receptors.

►SPARC

Matrigel

Definition

Is a basement membrane extract that includes many ►extracellular matrix components such as laminin, type IV collagen, proteoglygans and growth factors. It promotes tissue like differentiation in many cell types. Matrigel is a mixture of proteins of the extracellular matrix extracted from a mouse sarcoma cell line. Matrigel provides a physiological environment to cells grown in vitro.

►Three-Dimensional Tissue Cultures

Matriptase

Definition

Is an epithelial-derived, type 2, plasma membrane spanning serine protease. Is an endopeptidase that hydrolyses peptide bonds after arginine or lysine residues. These cleavage reactions, which take place on the cell surface, activate specific growth factors and ►G-protein-coupled receptors. ►Serine proteases (Type II) spanning the plasma membrane; ►TMPRSS2/ERG Fusions.

►TMPRSS2

Matriptase: Epithin, MT-SP1, suppression of tumorigenicity 14

►Serine Proteases (Type II) Spanning the Plasma Membrane

Matrix-Assisted Laser Desorption/Ionization

Definition

Matrix-assisted laser desorption/ionization (MALDI) is a soft ionization technique used in mass spectrometry, allowing the analysis of biomolecules (such as proteins, peptides, and carbohydrates) and large organic molecules (such as polymer, dendrimer, and other macromolecules). It is based on the usage of matrix complex with a given sample molecule that is bombarded with a laser in order for the sample molecule to form a sample

ionization. A matrix is used to protect the biomolecules from being destroyed by direct laser beam and to facilitate vaporization and ionization. Most commercially available MALDI mass spectrometers are pulsed nitrogen laser. This technique is normally coupled with a time-of-flight detector in order to obtain proper mass-to-charge ratios and generate a mass spectrum.

►Proteinchip

Matrix-Assisted Laser Desorption/Ionization-Time of Flight (MALDI-TOF)

Definition

One of the "soft ionization" methods used in mass spectrometry, leading to the generation of singly charged ions formed by protonation of the basic residues such as the side chains of arginine, lysine, histidine and the free α-amino group. MALDI-TOF technique is useful for the analysis of peptides, proteins, or polymers. This technique is not suitable for the measurement of small molecules (<500 Da), however is extraordinarily tolerant to the presence of non-volatile buffer components and detergents.

►Surface Plasmon Resonance

Matrix Metalloproteinase

A zinc-dependent endopeptidase that cleaves extracellular matrix proteins, cell surface receptors and other biomolecules.

►Genistein

Matrix Metalloproteinase 2

Definition

MMP2 is a metalloproteinase (►Matrix metalloproteinases) that cleaves type IV collagen, a component of the basement membrane, and has been implicated in tumor cell invasion and ►metastasis.

►Gelatinase
►Collagenase Type IV
►Securin

Matrix Metalloproteinase 3

►Stromelysin-1

Matrix Metalloproteinase-7, -9

Definition

MMP-7, or -9; Proteolytic activity is important for tumor invasion, tissue remodeling, and angiogenesis. Latent precursors have to be proteolytically cleaved to produce the active form. Can exist in soluble or bound form (e.g., to ►CD44). Potent tissue inhibitors of MMPs (TIMP) can block their activity.

►CD44

Matrix Metalloproteinase Inhibitor

►RECK Glycoprotein

Matrix Metalloproteinases

M. Sharon Stack
Northwestern University Medical School, Chicago, IL, USA

Synonyms

Matrixins; MMPs

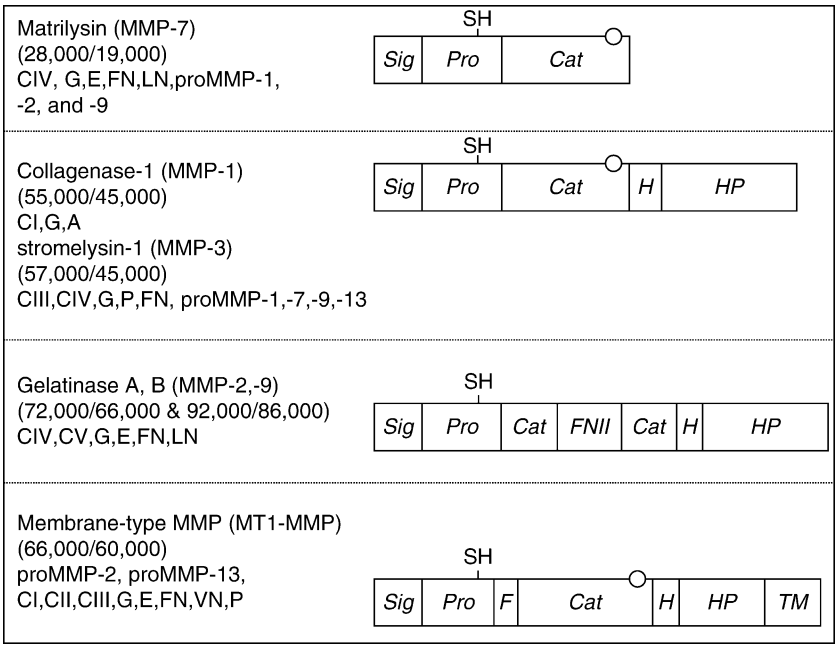
Definition

The matrix metalloproteinases (MMPs), or matrixins, are a family of zinc-dependent metalloendopeptidases that are widely expressed. They cleave a variety of extracellular substrates including, but not limited to, protein and proteoglycan components of the extracellular matrix (ECM). MMPs belong to the metzincin family of endopeptidases, characterized by the presence of three zinc-binding histidine residues within the active site (HexxHxxGxxH). MMPs are believed to catalyze localized hydrolysis of extracellular matrix proteins including collagens, fibronectin, laminins and proteoglycans, thereby modifying the integrity of the connective tissue.

Characteristics

Domain Structure

MMPs are synthesized as prepro-enzymes and, following removal of the signal peptide, are generally secreted in proenzyme or zymogen form. The latency of the zymogen is maintained by the presence of an unpaired cysteine residue in the propeptide domain (Fig. 1), contained within the conserved sequence PRCG(V/N)PD. This cysteine residue ligates the catalytically essential zinc atom in the enzyme active site, thereby preventing enzymatic activity. Exceptions exist including stromelysin 3 (MMP-11) and membrane-type MMPs (MT-MMPs), which contain a conserved RX(K/R)R sequence within the propeptide and can be activated intracellularly by proprotein processing enzymes of the PACE family, such as furin. In addition to the catalytic zinc atom described above, an additional zinc and two calcium ions provide structural stability. Inserted into the active site of the gelatinases (MMP-2 [gelatinase A] and MMP-9 [gelatinase B]) are a series of three fibronectin type II repeats that function in substrate recognition. The catalytic domain is followed by a short connecting (hinge) region and, with the exception of MMP-7 (matrilysin), a hemopexin-like domain. The role of the hemopexin-like domain is the subject of current investigation, and recent studies have demonstrated that this region participates in cell surface association (MMP-2) and collagen recognition and cleavage (MMP-1). The MT-MMPs also contain an hydrophobic transmembrane sequence and a short (20 amino acids) cytoplasmic tail. Like the hemopexin domain, the cytoplasmic tail of MT-MMPs is also currently under active investigation to evaluate the potential for association with other cytoplasmic proteins that may regulate MT-MMP localization or



Matrix Metalloproteinases. Figure 1 Domain structure of selected tumor-associated MMPs. The common name and MMP number are listed, followed by the approximate molecular weight of the latent and active species, respectively. Reported substrates are summarized as follows: CI, CII, CIII, CIV, CV – collagen types I, II, III, IV, and V, respectively; G – gelatin; E – elastin; FN – fibronectin; LN – laminin-1; A – aggrecan; P – proteoglycan; VN – vitronectin. Structural/functional domains are denoted as follows: Sig – signal peptide; pro- propeptide domain containing unpaired Cys residue denoted by -SH; Cat – catalytic domain containing the zinc binding consensus sequence that chelates the catalytically essential zinc atom (circle); H – hinge region; HP – hemopexin-like domain; FNII – fibronectin type II-like repeats; F – furin cleavage site; TM – transmembrane and cytoplasmic domain.

function. The domain structures of the MMPs most widely expressed in tumor tissues are summarized in Fig. 1.

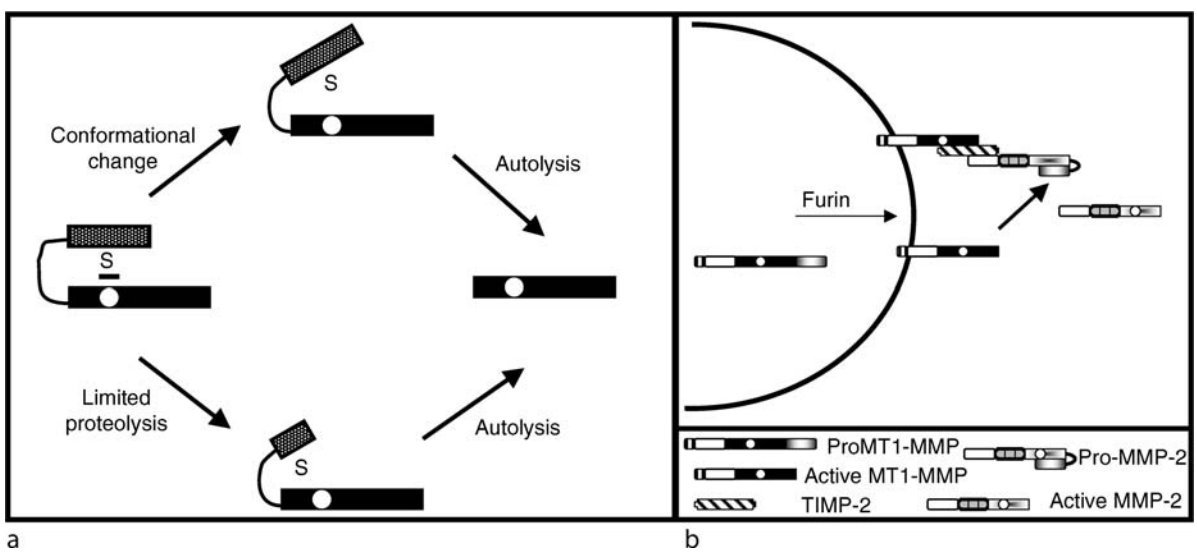
Zymogen Activation

In addition to regulation of MMP gene expression by a number of growth factors and cytokines, the activity of MMPs is stringently regulated by post-translational mechanisms, predominantly zymogen activation and enzyme/inhibitor binding. Proteolytic activation of proMMP zymogens functions primarily via a cysteine switch mechanism (Fig. 2a) and involves cleavage of the propeptide, thus destabilizing the cysteine-zinc interaction and generating catalytically active enzyme. The initial cleavage in many MMP propeptides can be carried out by proteinases of other mechanistic classes, predominantly serine proteinases such as plasmin. Following the initial proteolytic event, the partially active enzymes often undergo further inter- or intramolecular cleavages, resulting in complete removal of the prodomain and generation of fully active enzyme. Proteinase activity is frequently regulated by zymogen activation cascades, such that an initial event will generate an active proteinase that processes a downstream zymogen (Fig. 3). Many studies suggest that coupling of serine and MMP zymogen activation pathways may function to promote pericellular proteolysis during tumor invasion and metastasis.

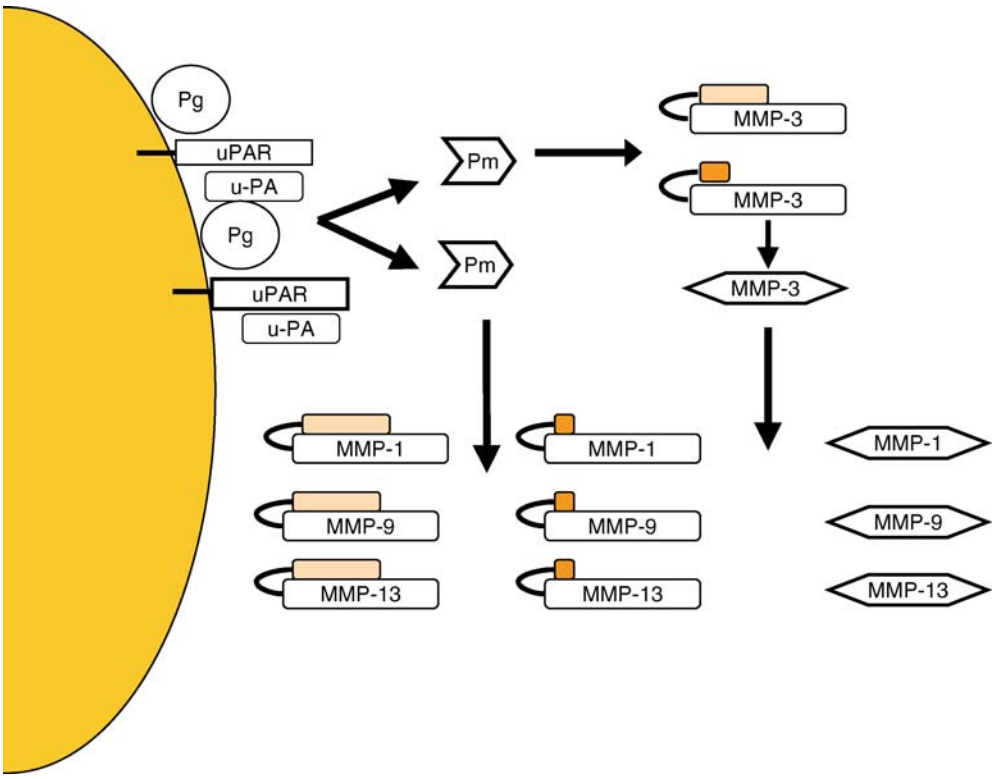
proMMP-2 (gelatinase A) is an exception to serine proteinase activation of proMMPs. Detailed biochemical studies from a number of laboratories have demonstrated that proMMP-2 is activated on the surface of many neoplastic cells following formation of a trimeric complex containing the transmembrane proteinase MT1-MMP and a molecule of tissue inhibitor of metalloproteinases 2 (TIMP-2). The MT1-MMP/TIMP-2 complex forms a binding site for proMMP-2, which is then proteolytically processed by a second MT1-MMP molecule (Fig. 2b). This is an interesting example of a reaction in which a proteinase inhibitor (TIMP-2) is also required for zymogen activation. Activation of proMT1-MMP is believed to occur intracellularly, as the zymogen contains a dibasic recognition motif (Arg108-Arg-Lys-Arg) in the propeptide region that may be cleaved by proprotein processing enzymes including the PACE family serine proteinase furin.

Inhibition

Aside from zymogen activation, a predominant mechanism for post-translational control of MMP enzymatic



Matrix Metalloproteinases. Figure 2 Activation of proMMPs. (a) Cysteine switch mechanism for proMMP activation. The latency of MMP zymogens is maintained by an interaction between an unpaired cysteine residue in the propeptide region (S) and the catalytically essential zinc atom (circle). Following conformational perturbation via the action of agents such as SDS, the Cys-Zn2+ interaction is disrupted, leading to autolytic activation characterized by propeptide cleavage. Alternatively, limited proteolysis of the propeptide initiated by serine or metalloproteinases may result in partial propeptide processing and disruption of the Cys-Zn2+ interaction, followed by autolytic processing to generate the fully active specie. (b) Cell surface activation of proMMP-2 by MT1-MMP. ProMT1-MMP is processed intracellularly by proprotein convertases, such as furin, and active enzyme is inserted in the plasma membrane. A ternary "activation complex" form, comprised of MT1-MMP/TIMP-2/proMMP-2. ProMMP-2 in the "activation complex" is proteolytically processed by a neighboring MT1-MMP molecule, followed by additional autolytic activation and release of the fully active proteinase.



Matrix Metalloproteinases. Figure 3 Cell surface-initiated zymogen activation cascade. Interaction of the serine proteinase uPA with its cell surface glycosyl phosphatidyl inositol-anchored receptor (uPAR) initiates activation of cell-associated plasminogen (Pg), forming the broad-spectrum serine proteinase plasmin (Pm). Plasmin can initiate propeptide processing of MMP-1, -3, -9, or -13. This is followed by additional autolytic cleavages or MMP-3 processing events, leading to the generation of fully activated MMPs.

activity is via interaction with protein inhibitors. Tissue inhibitors of metalloproteinases (TIMPs) inhibit MMP activity via the formation of a tight, non-covalent enzyme/inhibitor complex in a 1:1 molar ratio. Four TIMPs (TIMPs 1–4) have been identified, although the function of TIMP-1 and TIMP-2 are the most well characterized. Recent studies have demonstrated that the amino terminal cysteine residue in TIMPs is required for inhibitory activity, functioning by coordinating the catalytically essential zinc ion. Additional contact sites have been described that may interfere with substrate binding or other proteinase functions, suggesting that the inhibitor presents an extended contact surface to the enzyme. In addition to TIMPs, MMPs are also inhibited by the non-specific plasma proteinase inhibitor α-2-macroglobulin. Substantial research efforts have also been directed toward generation of synthetic MMP inhibitors to prevent pathologic proteolysis prevalent in diseases such as cancer and arthritis. These compounds contain a zinc binding functionality such as an hydroxamic acid group coupled with a peptide or peptidomimetic sequence designed to target the inhibitor to the enzyme active site. Most synthetic inhibitors are broad spectrum, blocking the activity of a wide range of MMPs. However, a current alternative strategy in inhibitor design is the generation of more specific compounds that target only a specific subset of MMPs (for example, gelatinase inhibitors that do no alter collagenase function).

Substrate Cleavage

Although it is widely believed that MMPs function in vivo to process extracellular matrix macromolecules, the precise substrates for the majority of MMPs remain unclear. In vitro experiments have demonstrated a wide range of substrates for MMPs including native and denatured collagens, adhesive glycoproteins such as fibronectin, laminins, and vitronectin, and proteoglycans. Substrate gel electrophoresis, or zymography, is a commonly utilized method to evaluate relative MMP activity levels in tissue extracts or tumor cell conditioned media. Although not quantitative, this method provides a rapid and sensitive initial evaluation of cellular MMP profiles. However, data obtained using zymography are frequently misinterpreted as

- MMP zymogens attain proteolytic activity in the presence of sodium dodecyl sulfate without propeptide cleavage;
- MMP/TIMP complexes are non-covalent and are thus dissociated during electrophoresis, leading to the potential for over-estimation of enzymatic activity.

Preliminary results obtained using zymography should be confirmed by other methods such as those based on solution interaction of the MMP and its potential target substrate such as collagen, gelatin or other matrix macromolecules. Cleavage may then be assessed by electrophoretic examination of reaction products or other methods. Alternatively, a number of quenched fluorescent peptide MMP substrates have been described that have broad utility for continuous kinetic monitoring of peptidase activity. These synthetic substrates have proven useful for comparative evaluation of synthetic MMP inhibitors. A more complex approach for elucidation of MMP substrates in vivo involves generation of mice genetically engineered for a specific MMP deficiency by targeted gene inactivation (MMP "knockouts"). The majority of these animals display relatively mild phenotypes, with the exception of animals deficient in MT1-MMP expression. These mice display severe connective tissue abnormalities characterized by dwarfism, osteopenia and arthritis, suggesting that MT1-MMP is required for pericellular collagenolysis in vivo.

Control of MMP Gene Expression

MMP gene expression is tightly regulated and transcription of many MMP genes is inducible by a wide variety of effectors including hormones, growth factors, cytokines and tumor promoters. In addition to soluble mediators, recent studies have demonstrated changes in MMP expression or activity associated with physical factors such as alterations in cell/cell or cell/matrix contact, or changes in cell shape associated with conditions such as physical stress that induce cytoskeletal rearrangement.

Clinical Relevance

MMPs have been implicated in a wide variety of pathologic processes including arthritis, cardiovascular disease, periodontal disease, emphysema and cancer. In tumor tissues, enhanced or de novo expression of MMPs is often correlated with disease progression. Conversely, experimental manipulation of TIMP levels has been shown to decrease tumor invasion and metastasis in many experimental models. MMP production in malignant tissues is not necessarily limited to neoplastic cells, as several studies have demonstrated that tumor cells can "recruit" stromally produced enzymes to promote pericellular proteolysis. Furthermore, MMPs have also been implicated in tumor-associated angiogenesis, suggesting an additional mechanism whereby MMPs can contribute to tumor progression. Therapeutic administration of MMP inhibitors is currently under investigation as a potential strategy to prevent tumor invasion and metastasis, and several synthetic MMP inhibitors have demonstrated efficacy in preclinical models of human cancers including colon, breast, and lung carcinoma and melanoma. The observed inhibition of tumor growth may be due in part to inhibition of tumor angiogenesis. In human trials, a decrease in the rate of rise in cancer antigens was observed in patients with prostate, ovarian, colorectal and pancreatic cancer. However treatment was associated with musculoskeletal pain and inflammation. Additional studies are necessary using MMP inhibitors alone or in combination with cytotoxic chemotherapies to assess the efficacy of these compounds in inhibition of tumor growth, metastasis and angiogenesis.

Mature B-cell Tumors

Definition

In the scheme of Revised European-American Classification of Lymphoid Neoplasm (REAL), ►B-cell tumors are divided into those arising from immature cells and those representing more mature B-cell phenotype. The latter group consists of 11 subcategories, most of which are included in the more widely used clinical term, non-Hodgkin lymphoma (NHL). Immunoglobulin genes of the neoplastic cells are rearranged, and the cells express 'pan-B' markers as well as immunoglobulin molecules on their cell surface. Oncogene rearrangement, clinical features and response to treatment vary among the subcategories.

Max

Definition

Myc-associated protein X; Is a transcription factor of the Myc/Max/Mad(Mxd) network of basic region-helix-loop-helix-leucine zipper proteins. Max is ubiquitously expressed throughout the cell cycle and is required for the DNA binding and activity of additional network members. In addition to heterodimer formation with Myc, Mnt, and Mxd, Max can also form homodimers with an unclear physiological role, as well as heterodimers with the related protein Mga.

►*Myc* Oncogene

Maximum Tolerable Dose

Definition

MTD; The highest quantity of a drug, typically determined in a phase I clinical trial, that can be administered without causing unacceptable harm to patients. The MTD has traditionally been used to design phase II and phase III clinical cancer trials based on the assumption that the adverse toxicities arising from the effect of the drug(s) on normal rapidly dividing cells are related to the cytotoxic effect of the drug(s) on cancerous cells.

Mcl Family

Shinichi Kitada
Burnham Institute for Medical Research, La Jolla, CA, USA

Synonyms

Mcl-1, Myeloid cell leukemia sequence 1

Definition

Mcl family is a subfamily of the ►Bcl-2 (B-cell leukemia/lymphoma 2) family proteins involved in the regulation of ►apoptosis (programmed cell death), as represented by Mcl-1 (homo sapience myeloid cell leukemia sequence 1).

Characteristics

Mcl-1, a member of the Bcl-2 family proteins (where Bcl-2-family proteins include both anti-apoptotic and pro-apoptotic members) was originally cloned as an early response gene up-regulated in the ML-1 human myeloblastic leukemia cell line following addition of cytokines. It is a mitochondrial protein of 350 amino acids (its molecular weight is 42/40 kDa), and the gene maps to chromosome 1, q21.2.

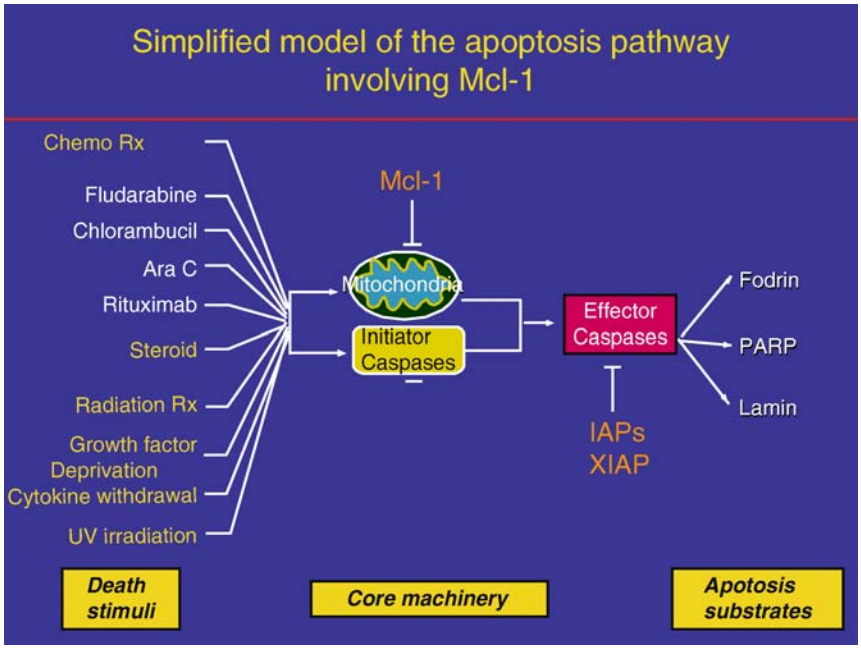
Mcl-1 contains BH-1 (Bcl-2 homology domain-1), BH-2, ►BH-3 (one helix only) but not BH-4. Mcl-1 preferentially ►heterodimerizes with Bak (a pro-apoptotic member of Bcl-2 family proteins) via ►BH-3 binding pocket which represents hydrophobic grooves, in contrast to Bcl-2 which preferentially heterodimerizes with Bax. The BH3 binding pocket is a crucial domain for functions of Mcl-1 and Bcl-2.

Imbalances in the levels or activities of these proteins are commonly associated with malignancy, including lymphocytic malignancies such as non-Hodgkin's lymphomas where the founding member of the family, Bcl-2, was first discovered nearly two decades ago by virtue of involvement of its encoding gene in chromosomal translocations, including ►t(14:18) translocations. Analogously, transgenic mice over-expressing Mcl-1 protein in lymphocytes frequently develop lymphomas, attesting to the in vivo importance of this anti-apoptotic protein for B-cell neoplasia.

The carboxyl regions of Mcl-1 and Bcl-2 share significant sequence homology, as is the case for other members of the Bcl-2 family. Like Bcl-2, Mcl-1 elicits and enhances cell viability under apoptotic conditions. Unlike Bcl-2, Mcl-1 is very labile (its half-life = 2 h), presumably because of its ►PEST sequences that target it for rapid degradation. In addition, Mcl-1 resembles Bcl-2 in that both proteins are found in the outer-membrane of mitochondria. Differentiated cells lose their proliferative capacity, but remain viable and capable of carrying out normal physiological functions. Physiologically, Mcl-1 is important in keeping cells viable during the early induction of differentiation.

Regulation

A simplified model of cell survival and cell death pathways, involving Mcl-1, is presented in Fig. 1. Cell numbers in the body are governed not only by cell division, which determines the rate of cell production, but also by cell death, which sets the rate of cell loss. Normally, these two processes of cell division and cell death are tightly coupled so that no net increase in cell numbers occurs. However, alterations in the expression or function of genes that control programmed cell death (PCD) can upset this delicate balance, contributing to the expansion of neoplastic cells. As shown in Fig. 1, Mcl-1 is located in the outer membrane of mitochondria and inhibits apoptotic process in core machinery of PCD, involving mitochondria. ►CLL (chronic lymphocytic leukemia) (B-CLL) is one of representative diseases caused by defect in programmed cell death primarily as a result of over-expression of Bcl-2. As shown in Fig. 1, chemotherapeutic agents, such as ►fludarabine, chlorambucil, cytosine arabinoside (ara C), ►Rituximab (chimeric anti-CD20 monoclonal antibody), ►Campath-1H, ►Hu1D10 and steroid as well as radiation therapy are believed to induce programmed cell death via mitochondrial pathway, and Mcl-1 inhibits this ►core machinery of programmed cell death. Therefore,



Mcl Family. Figure 1 Simplified model of the apoptosis pathway involving Mcl-1.

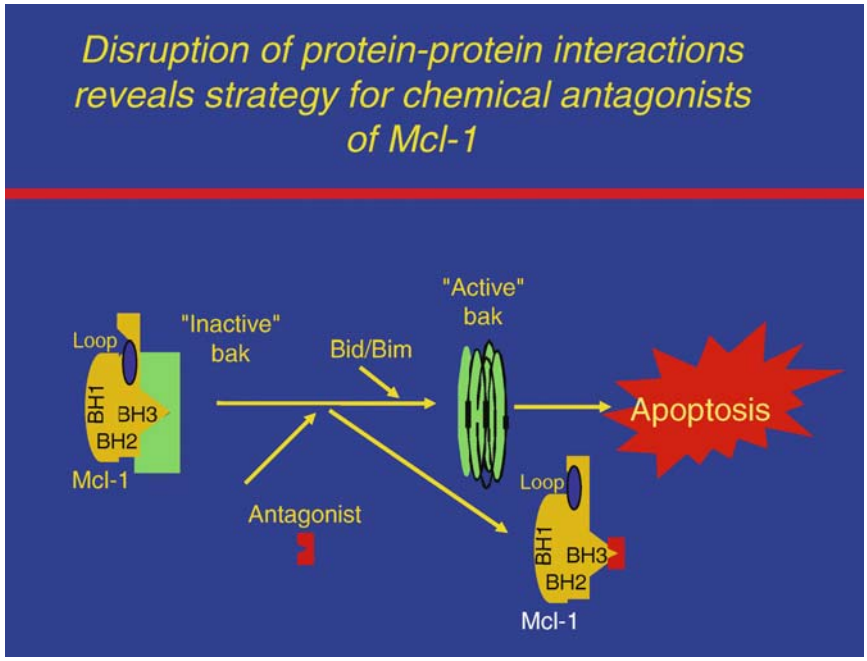
over-expression of Mcl-1 accounts for chemoresistance commonly seen in patients with CLL and AML (acute myeloblastic leukemia), at least in part. Under physiological conditions, Mcl-1 is regulated at multiple levels. In many hematopoietic cells, growth factors promote cell survival by triggering Mcl-1 transcription and stabilizing Mcl-1 protein. Conversely, cytokine withdrawal and other stress signals such as UV-irradiation initiate cell death by promoting Mcl-1 degradation.

Clinical Relevance

Previous studies documented high levels of anti-apoptotic Bcl-2 relative to pro-apoptotic Bax protein in CLL, with higher Bcl-2:Bax ratios often correlating with aggressive disease or poor response to therapy. The mechanisms responsible for the high levels of Bcl-2 in CLL are poorly understood, but gene hypomethylation has been reported. Occasionally chromosomal translocations activate the Bcl-2 gene in CLL, but these are relevant to only a few percent of cases. Thus, the reasons for elevated Bcl-2 expression in CLL are incompletely resolved. Also, Bcl-2:Bax ratios are insufficient to explain differences among CLL patients with respect to progression and chemoresponses.

Searches for other prognostic determinants of outcome and response have uncovered Mcl-1 as a candidate predictor of more aggressive disease. Roughly one-half of CLLs contain higher levels of Mcl-1 protein, as measured by immunoblotting using peripheral blood B-cells. Though cohort sizes are small, correlations have been noted for higher Mcl-1 and failure to achieve complete remission (CR) following single agent chemotherapy (either fludarabine or chlorambucil). In fact, in two independent clinical studies conducted in North America, not a single patient with higher Mcl-1 protein achieved complete remission. Thus, while larger cohorts of patients must be analyzed before firm conclusions are reached, higher Mcl-1 protein may represent an indicator of adverse outcome for patients with CLL. Interestingly, comparisons of matched pairs of untreated and relapsed specimens from acute leukemia patients have revealed elevations in Mcl-1 during progression to chemorefractory disease, further supporting a role for this anti-apoptotic protein in chemoresistance.

The unique requirement for Mcl-1 for survival of lymphoid cells in vivo suggests it might make a good target for treatment of lymphoid malignancies such as CLL and B-lymphoma. Strategies for targeting Mcl-1 include reducing its expression using antisense oligonucleotides recognizing its mRNA, kinase inhibitors such as flavopiridol and therapeutic monoclonal antibodies such as anti-CD20 (Rituximab), which have been shown to interfere with signaling events necessary for maintaining expression of Mcl-1 protein in CLL, and small-molecule compounds that mimic the inhibitory BH3 domain of endogenous Mcl-1 antagonists. Currently, a number of investigators in academia and industries are making efforts to develop small molecule inhibitors targeted on the BH3 binding pocket of Mcl-1 and other anti-apoptotic Bcl-2 family proteins, and strategies for development of chemical antagonists of Mcl-1 are illustrated in Fig. 2. As shown in this figure, disruption of protein-protein interactions, in



Mcl Family. Figure 2 Disruption of protein–protein interactions reveals strategy for chemical antagonists of Mcl-1.

particular, disruption of Mcl-1-Bak interactions has been employed as strategies for development of chemical antagonists of Mcl-1. Mcl-1 consists of three major domains, BH-1, BH-2 and BH-3, and Mcl-1 hetero-dimerizes preferentially with Bak, a pro-apoptotic member of Bcl-2 family proteins through the BH3 binding pocket, thereby neutralizing pro-apoptotic activity of Bak. Small molecule antagonist of Mcl-1 binds to BH3 binding pocket of Mcl-1 and displaces Bak. Initially, Bak is inactive, but Bid or Bim binds to inactive Bak subsequently and induces conformational changes in Bak protein, resulting in activation of Bak, leading to apoptosis. At present, a number of investigators in academia and industries have been screening natural compounds, semi-synthetic compounds and fully synthetic compounds to identify chemical antagonists of Mcl-1. Among them, GX15–070 (Gemin X Pharmaceuticals Inc. Montreal, Canada) is the first small molecule antagonist of Mcl-1 that has been under clinical development (►small molecule drugs). At present, GX15–070 has entered phase I clinical trials, using patients with CLL (chronic lymphocytic leukemia) and solid tumors, although no results are yet available. Gossypol (from cotton seeds) has been reported to occupy the BH3-binding site on Bcl-2 and Bcl-XL, and tested clinically and shown to have bioactivities against refractory cancers. An enantiomer with superior affinity for Bcl-2, (−)-gossypol, termed "AT-101," is currently being developed by Ascenta Pharmaceuticals Inc. (San Diego, CA) in collaboration with the DTP (Developmental Therapeutics Programs) at the NCI (National Cancer Institute). AT-101 has been shown to be a broad-spectrum inhibitor of Bcl-2 family proteins, including Mcl-1, Bcl-2, Bcl-xl, and Bcl-w. Clinical trials of AT-101 have been currently conducted in patients with CLL and B-lymphoma, and anti-tumor activities of AT-101 have been reported. Selective inhibition of Mcl-1 and Bcl-2 may represent a useful strategy for leukemia and cancers (►chemosensitization), including CLL (chronic lymphocytic leukemia), AML (acute myeloblastic leukemia) and small cell lung cancer. However, conditional gene ablation studies in mice indicate that Mcl-1 is also required for survival of hematopoietic progenitor cells, raising the specter of toxicities that might limit utility.

MCT-1 Oncogene

Ronald B. Gartenhaus
The University of Maryland Marlene and Stewart Greenebaum Cancer Center, Baltimore, MD, USA

Synonyms

MCTS1

Definition

MCT-1 is an oncogene initially identified in a human T-cell lymphoma and has been shown to induce cell proliferation as well as activate survival-related pathways. The MCT-1 protein MCT-1 contains a PUA domain, which is a recently described RNA binding domain. MCT-1 interacts with the ►cap-binding complex and modulates the translation profiles of a subset of mRNAs.

Characteristics

The MCT-1 oncogene is mapped to chromosome Xq22–24. MCT-1 was shown to interact with the density-regulated protein (DENR/DRP), a protein whose expression is increased in cultured cells grown at high density. DENR has a ►SUI1 domain which is involved in recognition of the ►initiation codon by the eIF2-GTP-Met-tRNAi ternary complex. Together MCT-1 and DENR form a functional unit which binds to the cap binding complex either directly or indirectly through interaction with ►eIF4E.

Regulation

Expression analysis of a variety of normal human tissues revealed low level ubiquitous expression of MCT-1 message. Levels of MCT-1 protein were shown to be increased after exposure to DNA damaging agents; this increase did not require new protein synthesis. Phosphorylation of MCT-1 protein by ►p44/p42 MAPK is critical for stabilization of MCT-1 protein and for its ability to promote cell proliferation.

Clinical Relevance

A subset of primary diffuse large B-cell lymphomas exhibited significantly elevated levels of MCT-1 protein compared with normal lymphoid tissue. The region of chromosome Xq22–24 has been shown to contain amplified DNA in a variety of primary B-cell lymphoid neoplasms using ►comparative genomic hybridization, suggesting that increased copy number of a gene(s) located in this region confers a growth advantage. The signaling pathways that regulate the translational machinery are abnormally active in many human cancers and are causally related to tumor formation in mouse models. The MCT-1 protein interacts with the cap-binding complex and modulates mRNA ►translational profiles through its binding to DENR. Using a ►comparative genomics approach, a homolog of MCT-1 was identified in the ►archaea *Pyrococcus abyssi*. MCT-1 is the only known oncogene homolog in archaea and highlights that MCT-1 is a highly conserved gene with critical biological function. Further underscoring the functional relevance of MCT-1 is the observation that the human MCT-1 gene can complement in yeast the translation defects

observed by the loss of the yeast gene TMA20, having significant homology (48%) to MCT-1. It is clear that MCT-1 plays a role in translational regulation, and further supports the linkage between translational control and oncogenesis. Many human malignancies gain a selective advantage through the abnormal activation of this pathway, and its selective inhibition may provide a potential therapeutic approach in malignancies that exhibit high levels of MCT-1 protein.

►BRIT1 Gene

MDM2

Definition

Human homolog of mouse double minute 2 (MDM2); the protein was first identified as the product of the mdm2 gene amplified in transformed murine cells. It is a p53-binding nuclear protein that antagonizes and down-regulates p53 activity. The gene maps to 12q14–q15 and is amplified in certain human tumors, including sarcomas, glioblastomas and astrocytomas.

Synonyms

Mouse double minute gene; HDM

Definition

The *MDM* are two genes, *MDM2* and *MDM4*, found ►amplified in different human tumors. Their main activity is the binding and regulation of the oncosuppressor p53.

Characteristics

The *MDM* gene family is comprised of *MDM2* and *MDM4* (also called *MDMX*), identified in 1992 and 1997 respectively. The first identified gene, *MDM2*, derives its name from having been isolated from small, extrachromosomal bodies present in a mouse cell line and called mouse double minute. On the same double minute, *MDM1* and *MDM3* were also isolated but they resulted completely unrelated to *MDM2*.

MDM2 and *MDM4* show high similarity at the level of gene sequence and structure and may be considered ►paralogs. Orthologs of *MDM2* and *MDM4* have been described in different animal species across evolution, from Homo sapiens to the zebra fish, Danio Rerio, and the frog Xenopus Laevis, suggesting an ancient origin of these genes. *MDM2* and *MDM4* are indeed essential genes for mouse development and viability, as demonstrated by the embryonic lethal

phenotype of the mice lacking both alleles of each gene (*MDM2* or *MDM4* ►knock-out mouse, usually indicated as $MDM2^{-/-}$ or $MDM4^{-/-}$ KO mouse).

MDM2 and MDM4 are mostly studied for their ability to bind and regulate the ►oncosuppressor p53 protein. Their structure, depicted in Fig. 1 is composed of a p53-binding domain at their amino-terminus, with a structure similarity of 54% between the two proteins; by a ►Zinc finger motif with 42% of structural similarity whose activity has not been defined, and a ►Ring finger domain at their carboxy-terminus, with a structure similarity of 53%. Through this last domain MDM2 and MDM4 interact with each other forming a functional heterodimer. The central part of the two proteins is the most divergent region. Despite their similarity, the two proteins are not redundant and play different roles in the cell and during mouse development. Indeed, their loss in knock-out mice causes a different lethal phenotype, regardless of the presence of the other gene. Notably, both mice are viable when p53 is simultaneously deleted, indicating that MDM2 and MDM4 lethality is closely related to deregulation of p53 activity.

MDM2

The human ortholog of the *MDM2* gene (Also indicated as *Hdm2* or *hMDM2*) is located on chromosome 12q13-14. It codes for a protein composed of 491 aminoacids, indicated also as $MDM2^{p90}$. In addition, a short protein, called $MDM2^{p76}$ (or $MDM2^{p75}$), derived from the initiation of translation at two internal ATG, has been detected. $MDM2^{p90}$ is present in all tissues with varying levels in response to cellular behavior.

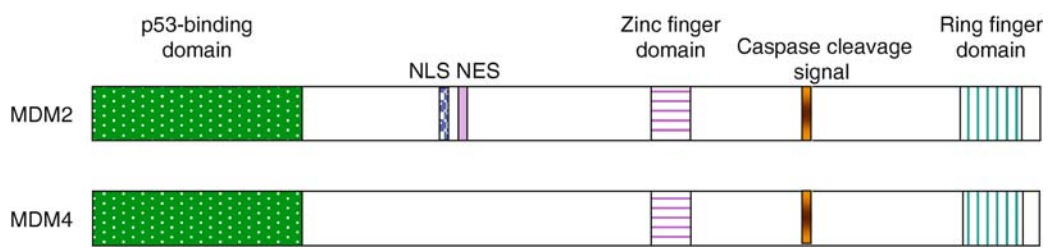
MDM2 is an E3-type ►ubiquitin ligase, able to covalently bind ubiquitin moieties to specific targets through its Ring finger domain. Multiubiquitin chains are a signal that brings proteins to degradation through the proteasome system. The main target of MDM2 is p53 but other targets have been described, many of which are►proapoptotic molecules. Degradative activity of MDM2 independent of its ubiquitination function has been also reported (i.e., toward the oncosuppressor ►Rb).

Biologically, the MDM2 most relevant activities are those exerted toward p53. To date, all studies targeting inactivation of MDM2 in different mouse tissues yielded a severe phenotype, recovered by simultaneous knocking down of p53, thus pointing to an essential role of MDM2 in the regulation of p53. MDM2 function on p53 can be summarized in two kinds of actions:

1. MDM2 controls p53 protein levels through its degradative function.
2. MDM2 inhibits p53 transcriptional activity. This function takes place through different mechanisms: by binding p53 in the same region through which p53 binds basal transcription factors, thereby preventing such interaction; by promoting a modification of p53 (►NEDDylation) that inhibits its transcriptional activity; by ubiquitinating histones surrounding the DNA p53-binding regions and inducing gene silencing.

It is still a matter of debate if and which activity prevails over the other. MDM2 activities not related to p53 regulation have also been described. Many of them confer on MDM2 a further prooncogenic role: degradation of the oncosuppressor Rb, of ►E-cadherins (a component of cell–cell junction), and the activation of the ►E2F1 transcription factor are representatives of these activities. Although these MDM2 activities do not seem to be essential for mouse development and viability, they might play a relevant role in tumor promotion. Notably, two independent ►transgenic studies targeting MDM overexpression in all tissues or specifically in mammary gland have evidenced MDM2 tumorigenic properties independent of p53. Conversely, MDM2 growth inhibitory activity in normal cells has also been described. In agreement with this function, MDM2 is expressed at high levels in terminally differentiated "growth-arrested" tissues such as brain, muscle, and skin.

Several studies have investigated the regulation of MDM2 function. What is particularly interesting is the transcriptional regulation of its levels by p53. This establishes a negative feedback loop between MDM2 and its target p53. When p53 activity raises, levels of MDM2 raise too and this in turn ensures shut down



MDM Genes. Figure 1 Scheme of MDM proteins. The main regions are indicated. NLS indicates nuclear localization signal, NES indicates nuclear export signal, Caspase cleavage signal indicates a tetrapeptide that mediates cleavage of the entire protein at this site.

M

of p53 activity, thus limiting the duration of the ►stress response. Other proteins that regulate MDM2 activity include: (i) ►kinases and ►phosphatases that modify its interactions by phosphorylating or dephosphorylating different MDM2 residues; (ii) proteins that delocalize MDM2 in different cell compartments; (iii) proteins that inhibit MDM2 degradative activity. Interestingly, some posttranslational modifications trigger MDM2 degradative activity toward itself, thereby favoring an autocontrol of its levels.

MDM2 and Human Tumors

Direct mutation of the *p53* gene that results in abrogation of the p53 oncosuppressive function is present in ~50% of human cancers. Deregulation of p53 is supposed to exist in the remaining 50% of cancers. Alterations of p53-regulators, particularly of *MDM* genes, represent a good way to achieve it.

Indeed, *MDM2* is amplified in many different human tumors that harbor wild-type *p53*, with the highest frequency in human sarcomas. Analysis of data obtained from 3,889 tumor samples from 28 tumor histotypes revealed an overall *MDM2* ►amplification frequency of 7%. In addition to gene amplification, overexpression of the protein caused by different molecular mechanisms has also been described in human tumors, indicating that the previous frequency underestimates the incidence of *MDM2* deregulation in human cancer. Moreover, a ►polymorphism in the promoter region of *MDM2* gene (SNP309) has been identified. This polymorphism causes an increased MDM2 expression that in turn should lead to attenuation of p53 oncosuppressive function. Indeed, a survey of the presence of this polymorphism in different human tumors has shown a significant earlier age of onset of several tumors, both hereditary and sporadic. It has to be mentioned that the genetic background is a strong determinant for MDM2-SNP309 activity, as it accelerates tumor formation in a gender-specific and hormonal-dependent manner.

Some studies have pointed to the worse prognosis of the tumors harboring p53 mutation and MDM2 overexpression, in respect to the tumors harboring only one of these alterations. These data confirm that MDM2 possesses tumorigenic properties also independently of p53.

Despite wide characterization of MDM2 molecular functions, the predictive value of MDM2 overexpression on cancer features is still controversial. It probably relies on additional factors as tumor type and genetic alterations that need to be comparatively evaluated to obtain significant predictive ►biomarkers. The relevance of the genetic background in the activity of MDM2-SNP309 is a good example in this respect.

In addition to full-length protein, different forms of MDM2 have been found in human tumors. Some of these forms arise from ►alternative splicing, others from ►aberrant splicing of full-length mRNA. Some of these forms are considered ►oncogenic and their activity has been evaluated by in vitro studies. However, the genetic background in which they work seems to strongly affect the biological outcome they cause. Therefore, further studies are necessary to define their function and tumorigenic potential.

In agreement with its protooncogenic function, different strategies aimed at inhibiting MDM2 have been set up. They can be essentially summarized in two types:

1. Downregulation of its levels by ►antisense nucleotides and ►siRNA.
2. Molecules that prevent its activity, mainly the binding to p53. To this group belong synthetic peptides that compete for MDM2–p53 binding. More recently, new tools represented by "low molecular weight compound" have come to light. This new group consists of: (i) Nutlin-3a (a *cis*-imidazoline analog) that disrupts p53–Mdm2 interaction by binding to the p53-binding pocket of MDM2; (ii) RITA (a furan-derived compound) that binds to p53 and alleviates its inhibition by MDM2.

Many of these approaches have shown antitumor activity in in vitro and in vivo human cancer models, used alone or in combination with chemotherapy and radiation therapy. Testing of these MDM2 antagonists in ►clinical trials is needed to ensure their effectiveness and toxicity.

MDM4

Human *MDM4* (also called *HDMX*) is located on chromosome 1q32, and codes for a protein of 490 aminoacids. Its mRNA is expressed in all human tissues, with particularly high levels in brain and thymus. Despite structure similarity with MDM2, MDM4 molecular activities are not yet completely understood. MDM4 does not function as an E3 ubiquitin ligase in vivo, in spite of the similarity with MDM2 at the level of the Ring finger domain. However, contribution of MDM4 in the regulation of MDM2-mediated p53 stability is considered. More consistently, MDM4 inhibits p53-transcriptional function especially the activation of growth arrest genes. Interaction of MDM4 with other proteins has been described too but the biological relevance is not completely defined.

Biologically, the recovery of *MDM4* KO mouse lethality by simultaneous *p53* deletion clearly indicates an essential function of MDM4 in the regulation of p53 during mouse development. In contrast to MDM2, loss of MDM4 in different cell types leads to different phenotypes, in some cases with no apparent defects, indicating that its function is more cell-type specific than that of MDM2.

Different studies have concurred to characterize regulation of MDM4. In contrast to MDM2, MDM4 transcriptional levels are not modulated by p53. At present, mainly posttranslational modifications (such as phosphorylation, ubiquitination, and ►SUMOylation) have been identified that regulate MDM4 stability and activity. Interestingly, MDM4 levels are also controlled by MDM2 during cell stress response, highlighting the complexity of the p53–MDM2–MDM4 interplay.

MDM4 and Human Tumors

To date, analysis of *MDM4* in human tumors has been performed in few studies. In analogy to *MDM2*, amplification of *MDM4* gene in human tumors characterized by wild-type *p53* has been observed in gliomas, as well as in breast carcinomas and in pediatric retinoblastoma with different percentages. Overexpression has been observed in lung and colon tumors too. These data concur to define MDM4 as a protooncogene, similar to MDM2. However, a detailed analysis of MDM4 role during tumor progression is still lacking. In fact, some studies reported down-regulation of MDM4 in some cases associated with advanced ►stage tumors, leading to the hypothesis that the presence of MDM4 might be detrimental to tumor progression. These findings need to be confirmed and further investigated.

In analogy to MDM2, ►splicing forms of MDM4 deriving from alternative or aberrant splicing events have been described and the oncogenic properties of these spliced forms are shown in vitro. Their presence coexists with that of the full-length protein, raising the question of the extent to which gene amplification contributes to their expression and of their relevance with respect to full-length protein.

Strategies aimed at counteracting MDM4 inhibitory function and reactivating p53 oncosuppression have been proposed. However, despite structural similarity between the MDM2 and MDM4 p53-binding domain, strategies that work with MDM2 appear to be not effective with MDM4, indicating the need to search for optimal MDM4 antagonists.

Mechanical Properties

Definition

Of cells are the measures of cellular deformation induced by the externally applied forces, and thus are the main parameters indicative of the mechanical balance between the external and intracellular forces. The mechanical response of the cells during deformation can be expressed in viscoelastic properties, such as stiffness or elastic modulus, and viscosity. The deformation of cells induced by external forces can be elastic if the cells deform immediately upon applying forces and fully restore to its original shape after the applied force is removed. Cellular deformation can be viscous if there is a resistance to deform in the short term which relaxes over time allowing the materials to "flow." The elastic response of the materials is measured by stiffness, which is the ratio of the applied force to the deformation or elastic modulus, which is the ratio of stress defined by force per area to strain defined by deformed length over original length. The viscosity is usually defined as a fluid's resistance to flow. Dynamic mechanical analysis measures the viscoelastic properties in which a small oscillatory strain is applied and the resulting stress is measured. Purely elastic materials will have no lag between stress and strain, so that the response of one caused by the other is immediate while viscous materials will exhibit lag. The elastic and viscous response of the material is expressed in storage and loss modulus, respectively. Storage modulus represents the stored energy in the material during elastic deformation and loss modulus corresponds to the energy dissipated as heat due to viscous flow.

►Tensional Homeostasis

Mechanical Stress

Definition

Is defined as force per area and is expressed in terms of Newtons per meter square (N/m^2) which is equal to Pascals (Pa), or dynes per square centimeter (dyn/cm^2). The types of stress include compressive or tensile stress, which is applied perpendicular to the surface, and shear stress, which is applied parallel to the surface.

►Tensional Homeostasis

Mechanosensor

Definition

The apparatus within cells which detects mechanical ►microenvironment such as applied force or extracellular matrix (ECM) stiffness.

Medullary Breast Carcinoma

Definition

Accounts for approximately 5% of ►breast cancer. The tumors have unusual histologic features, they are circumscribed but anaplastic and high grade, formed by large cells with abundant cytoplasm, numerous mitoses, and a diagnostic plasmacytic infiltrate. Despite these features, patients with medullary breast carcinoma have improved survival in comparison to matched cases of infiltrating ductal carcinoma of the breast and long-term survival of individual patients correlates with the degree of tumor infiltration.

Medullary Thyroid Carcinoma

Definition

MTC; derives from the parafollicular C-cells. C-cells produce calcitonin, which can be used as a sensitive tumor marker for MTC. About 75% of all MTCs are believed to be sporadic while 25% have a hereditary background and are part of the ►Multiple Endocrine Neoplasia Type (MEN 2) syndromes. Germline mutations in the proto-oncogene *RET* are found in more than 95% of all patients with hereditary MTC. Somatic *RET* mutations are found in about 50% of sporadic MTCs but their role in the pathogenesis of MTC is unknown.

►RB1/pTP53 ►knockoutmouse shows a high incidence (about 40%) of MTC. Some of the mice acquire a somatic *RET* mutation, analogous to activating mutations seen in humans with MEN 2A and FMTC. However, ►*RB1* mutations have not yet been described in human MTC, and ►pTP53 mutations are only found in a minority of cases of this tumor.

►RET
►Thyroid Carcinogenesis

Medulloblastoma

Michael C. Frühwald
Department of Pediatric Hematology and Oncology, University Children's Hospital Muenster, Muenster, Germany

Synonyms

Infratentorial primitive neuroectodermal tumor; PNET

Definition

An embryonal tumor originating from the cerebellum, composed of densely packed small cells with round to oval nuclei and scanty cytoplasm. These tumors exhibit a pronounced tendency to metastasize along the subarachnoid space throughout the central nervous system (CNS).

Molecular and morphologic analyses classify medulloblastomas (MB) into five distinct histological subtypes (frequencies vary between published series):

1. Classic medulloblastoma (~65–90%)
2. Desmoplastic, nodular medulloblastoma (► Desmoplastic medulloblastoma) (~10–25%)
3. Medulloblastoma with extensive nodularity (~5%, mostly <3years)
4. ►Large cell medulloblastoma (~5%)
5. Anaplastic medulloblastoma (~25%)

Some authors suggest the presence of a defined entity of large cell, anaplastic medulloblastoma (LC/A), however, signs of anaplasia may be present in up to 24% of medulloblastomas. Thus anaplastic medulloblastoma

M

likely represents a progressed malignant variant of MB that arises on the background of other histologic subtypes. The formerly individually listed ►melanotic medulloblastoma and ►medullomyoblastoma are now viewed as extremely rare forms with markers of melanotic or myocytic differentiation but similar genetic mutations as other MB. On immunohistochemistry, MB cells predominantly express neuronal marker proteins (e.g., synaptophysin, neurofilaments). Occasionally, astrocytic differentiation (expression of GFAP) and, rarely, ependymal features are seen.

Characteristics

Clinical Significance

MB constitute the most common malignant ►brain tumors of childhood, affecting each year approximately seven in one million children (<21 years) in the Western World, amounting to an annual rate of 540 cases per year in the US. Two age peaks at 3–4 and 8–9 years and a male predominance ranging from 1.4 to 2.1 have been reported. MB have been described in neonates and in ~1% of primary adult CNS tumors. These tumors are rarely observed beyond the fifth decade.

MB commonly (≥75%) arise in the midline (the vermis) of the cerebellum, projecting and obstructing the fourth ventricle. A hemispheric location is more commonly found in the desmoplastic variant and also with increasing age (~50% of adult medulloblastomas are desmoplastic). Approximately 30% of medulloblastomas have metastasized to the cerebrospinal fluid (CSF) at the time of diagnosis; metastases outside the CNS to bone, bone marrow, peritoneum, liver, and lung have been reported in children with ventriculoperitoneal shunts but also rarely in children without any extraanatomical connections. Clinical symptoms consist of truncal ataxia, gait disturbances and, due to increased intracranial pressure, headache, lethargy, and morning vomiting. In infants, increased excitability, inadequate growth of the head, and/or lethargy may be the only clinical signs. On computed tomography (CT) and magnetic resonance imaging (MRI), MB usually present as solid, homogeneously contrast-enhancing masses. CT shows a hyperdense and T1-MRI an iso- to hypointense mass owing to the dense cellularity of the tumor (Fig. 1). Imaging modalities such as diffusion-weighted imaging, spectroscopy, and nuclear medicine techniques (e.g., ^{111}In-Pentetreotide scintigraphy) are currently restricted to selected clinical indications and clinical studies. Diagnosis and staging are established by clinical examination, imaging studies (CT and MRI), and analysis of the CSF from a lumbar puncture site. For stratification and prognostic evaluation, patients are broadly divided into two groups:

1. Standard-risk patients are ≥3 years, have a localized tumor, which can be totally or near totally resected (residual no more than 1.5 cm^2) and no CSF metastases.
2. High-risk patients exhibit metastasis on CSF examination or macrometastasis to the supratentorial or lumbar space on imaging, or a residual tumor of more than 1.5 cm^2.

Patients below the age of 3 years often exhibit a high-risk profile due to a propensity for metastasis, commonly large postoperative residuals, low tolerance of chemotherapy, and a high risk for radiotherapy-associated side effects.

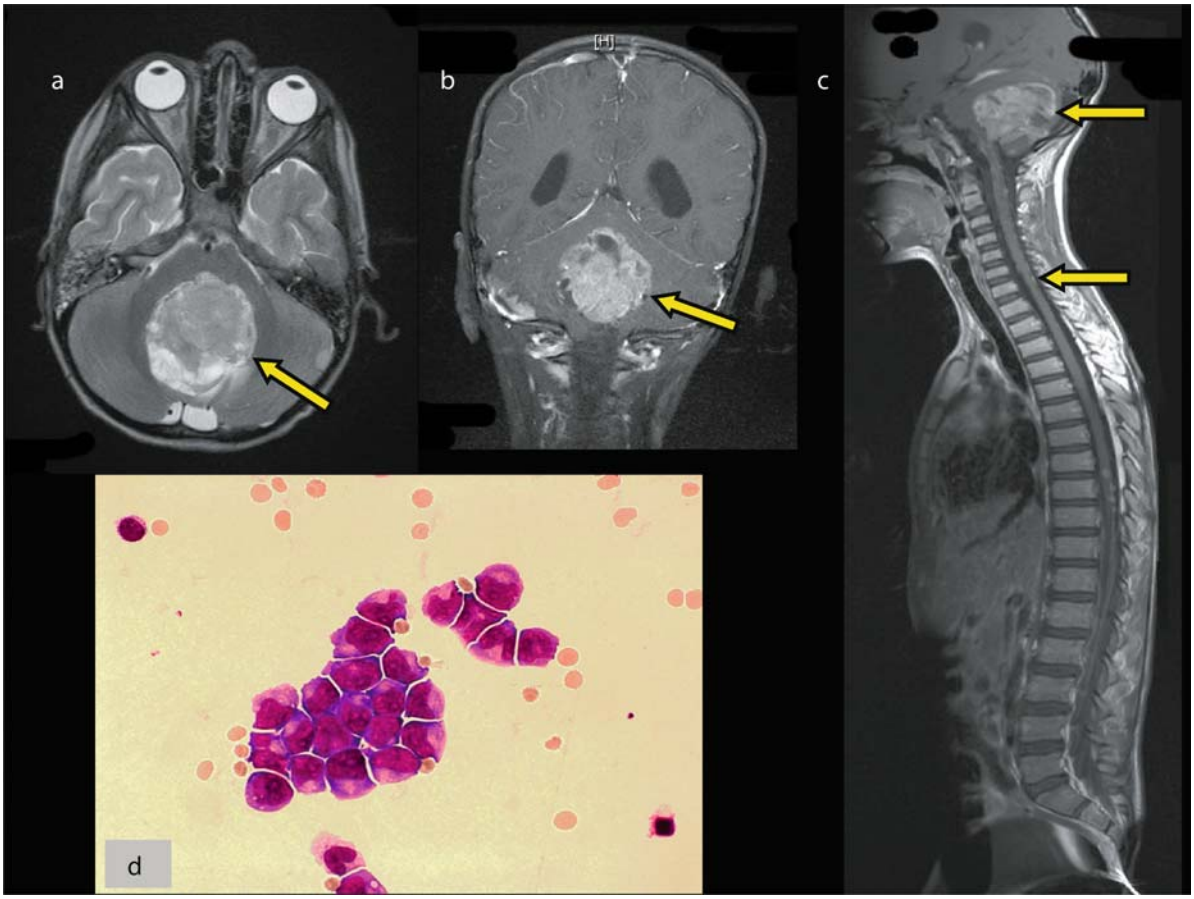
Correlational studies have demonstrated overexpression of the ►*MYC* gene (detected in ~40%) as a negative prognostic factor and high levels of the Neurotrophin 3 (►Neurotrophin) receptor ►*TRKC* (~45%) as a positive prognosticator. Furthermore stabilization of the gene *β-catenin* (~25%) seems to impose a better prognosis, while isolated studies show high expression of the *EGFR* receptor *erbB-2* (►*HER2*) (~80%) as an indicator of a bad prognosis. The prognostic value of the most common cytogenetic lesion in MB (~50%) loss of heterozygosity (►LOH) for 17p remains unclear. Some studies demonstrate a negative correlation and some deny it. Clinical trials employing molecular markers for stratification are in the planning stages. As desmoplastic, nodular histology appears to confer a rather good prognosis signs of nodular histology along with molecular markers such as *TRKC* overexpression may constitute a therapeutic stratum by itself in future trials.

Current treatment protocols consist of radio- and chemotherapy attempting to delay radiotherapy in children ≤3 years to avoid damage to the developing CNS. Using a regimen of cyclophosphamide, vincristine, etoposide high-dose, and intraventricular methotrexate, 5-year event-free survival rates of up to 82% have been achieved in children ≤3 years without using radiotherapy. Older children with standard-risk disease receive radiotherapy at doses of 23.4–36 Gy to the craniospinal axis (CSI) and a boost to the posterior fossa or tumor site up to 55.8 Gy. Further dose reductions to 18.0 Gy CSI in standard-risk patients are evaluated in ongoing studies. Current trials for high-risk patients include radiochemotherapy and high-dose chemotherapy regimens followed by autologous stem cell support.

The 5-year survival rates of 74–83% in the average-risk group have consistently been achieved. For patients with a high-risk profile, cure rates remain disappointing approaching 32–38%. The long-term survival of patients with relapse after radiotherapy remains a rare event.

Medulloblastoma Stem Cells

Experimental evidence and identification of genetic mutations restricted to individual histological subtypes



Medulloblastoma. Figure 1 (a–c) Neuroradiology of metastatic medulloblastoma. (a) Axial T2-weighted image of a typical vermal tumor with pronounced peritumoral edema; (b) coronal T1 MRI demonstrating a large midline tumor, which has caused enlargement of both ventricles (internal hydrocephalus); (c) sagittal T1 MRI of the craniospinal axis indicating the primary in the cerebellum as well as leptomeningeal metastases (yellow arrows). (d) Cytospin of a CSF specimen demonstrating a large nest of tumor cells some small erythrocytes and one lymphocyte.

suggest the presence of at least two groups of progenitor cells that fit into the paradigm of a cancer stem cell hypothesis. One progenitor cell for MB (classic histology) appears to be derived from the periventricular matrix, may demonstrate LOH of 17p, amplification of the *MYC* gene, mutations within the *WNT/WG* pathway, and epigenetic inactivation of the gene *HIC1*. Another progenitor (desmoplastic, nodular variant, and variant with extensive nodularity) is derived from the external germinal layer (►External granular layer (EGL)) of the cerebellum and is characterized by mutations in components of the *SHH* pathway and deletions of chromosome 9q22.3.

Molecular Genetics and Biology

Many clues to an improved understanding of the molecular biology of MB are derived from the study of hereditary tumor syndromes. "Turcot's syndrome," also called "brain tumor polyposis syndrome type II," is characterized by the synchronous occurrence of adenomatous polyps or carcinomas of the colon. There, as well as in the associated brain tumors, primarily glioblastomas and MB, germline mutations of the ►*APC* gene can be detected. Rarely, MB have been seen in patients with Li-Fraumeni syndrome or in neurofibromatosis. Sporadic medulloblastomas rarely carry mutations of *TP53* and *NF1* respectively, causing these syndromes. In the ►basal cell nevus syndrome (BCNS) or ►Gorlin syndrome, patients are affected by basal cell carcinomas, ovarian fibromas, keratocysts of the jaw, palmar and plantar pits, skeletal abnormalities, and MB, mainly of the desmoplastic, nodular variant. In such patients and in about 10% of the cases with sporadic MB, mutations of the human homologue of the drosophila melanogaster segment polarity gene *PTCH1* in 9q22.3 have been described. Transgenic mice, heterozygous for *PTCH1*, develop tumors intriguingly similar to MB.

Commonly detected cytogenetic abnormalities in MB include isochromosomes 17q (up to 50%), trisomy

M

7, extra copies of 1q, monosomy 8 and 22, and deletions on 10q and 4q. Comparative Genome Hybridization studies demonstrated loss of genetic material from chromosomes 10q, 11, 16q, 17p, and 8p; gains were found for 17q and 7 and amplifications were detected in 5p15.3 and 11q22.3.

On gene expression profiles, MB can be readily differentiated from other embryonal tumors of the CNS such as ►sPNET or ►AT/RT, but also desmoplastic, nodular subtypes from classic. Metastatic MB have an individual expression signature, which among others demonstrates ►*PDGFRα* as a marker for invasion and adhesion.

Analyses of pathways involved in the normal development of the cerebellum have found several targets for mutations in sporadic nonhereditary MB. Mutations have thus been detected in key protein components of the *SHH* pathway: *PTCH1* and *SUFU* are mutated in ∼10% and *SMO* in ∼5% of sporadic MB. Components of the *WNT/WG* pathway (wingless) are less commonly found mutated. β-*catenin* exhibits mutations in ∼6% and *APC* in ∼2.5% of the cases. However, stabilization of the β-catenin protein can be seen in up to 25%. Another component of the WNT pathway, the gene *AXIN1*, has also been found mutated in isolated cases.

In molecular genetic studies, LOH for the short arm of chromosome 17 (17p) was demonstrated in up to 50% of sporadic medulloblastomas and the chromosomal breakpoint has been narrowed down to a region in 17p11.2. The search for a tumor suppressor gene distal to the locus of 17p13.3 is ongoing, even though several genes are under scrutiny. Aberrant methylation of *HIC1* (17p13.3) has been described in limited series just as deletion of *REN(KCTD11)* (17p13.2), an antagonist of SHH signaling. Loss of genetic material from chromosome 10q is in some MB associated with homozygous deletions of the gene *DMBT1*. The combined incidence for amplifications of the genes *MYC*, ►*MYCN*, and *EGFR* in MB is ~10%. A multitude of other loci have been implied in the tumorigenesis of MB as they show expression differences between the tumors and normal cerebellum. Among many others are the transcription factor genes *PAX5, NEUROD3/neurogenin*, and *ZIC*, the neuropeptides somatostatin and VIP as well as the growth factor receptor genes *HER2* and *HER4*. Epigenetic changes and foremost aberrant methylation has been detected in a series of genes including *RASSF1A*, *ZIC2*, *SGNE1/7B2*, $p16^{INK4A}$, *MCJ*, *EMP3*, and *HIC1*. Many more genes are affected by epigenetic changes.

Melanin

Definition

A number of closely related brown-black pigments produced in melanosomes from the primary substrate, tyrosin.

►Melanocytic Tumors

Melanocortin Receptor

Definition

Cell surface glycoprotein. Receptor for ►Melanocyte-Stimulating Hormone (MSH), a polypeptide with homology to other pituitary hormones. It is produced by the pituitary, and also by keratinocytes in response to ►UV radiation. A principal downstream target is tyrosinase, the rate-limiting enzyme in melanin production.

►Melanoma

Melanocyte

Definition

A nonepithelial cell type specifically dedicated to the production of melanin. Most melanocytes reside in the skin, but smaller numbers populate some mucous membranes, the eye, the meninges and inner ear.

►Melanocytic Tumors

Melanocyte-Stimulating Hormone

Definition

MSH; derives its name because of its effect on melanocyte, which are skin cells that contain the black pigment melanin. MSH is a member of the group of melanocortins, which are pituitary peptide hormones that include adrenocorticotropin (ACTH) and the alpha, beta and gamma melanocyte-stimulating hormones (MSH). In humans, melanocytes are responsible for moles, freckles, and suntan and, if they turn cancerous, melanoma. In most vertebrates, MSH is produced by an intermediate lobe of the pituitary gland.

Melanocytic Nevus

Synonyms

Nevus; Nevocellular nevus; Melanocytic nevus; Mole; Melanoma; Melanocytoma

Definition

Melanocytic tumors are neoplastic proliferations of cells featuring phenotypic characteristics of ►melanocytes. The large majority originates in the skin. Benign melanocytic tumors are melanocytic nevi (or nevocellular nevi or, briefly, nevi, or "moles"), malignant ones are ►melanomas.

Characteristics

Melanocytic tumors are neoplasms of cells showing the features of melanocytic differentiation, the most distinctive of which is the production of ►melanin. With few exceptions, this phenotype is thought to reflect their origin from a melanocyte. In mammals, most melanocytes reside in the basal epidermal cell layer and in the hair follicle. Smaller numbers are located in the dermal connective tissue, the uvea, the meninges and the inner ear. In poikilotherms such as reptiles and fish, most melanocytes reside in the dermis.

Cutaneous and extracutaneous melanocytic tumors are subdivided into melanocytic nevi (or nevocellular nevi, nevi, or "moles"), which are benign, and melanomas, which are malignant. Melanocytic nevi can be classified into congenital and acquired ones, the latter outnumbering the former by at least three orders of magnitude.

Congenital nevi manifest at birth as a macule or larger patch of increased pigmentation. The largest examples, giant congenital nevi, may cover a substantial part of the body. The congenital ►nevus grows more or less in accordance with body growth, and it becomes somewhat raised and sometimes covered with hair. Melanoma arises in some congenital nevi, but this is uncommon: the available evidence suggests that the chance of melanoma is a few percent or less, and is highest in large examples. Surgical removal of the nevus, or of its superficial part, improves cosmesis and may reduce melanoma risk, although the latter has not been established. Most surgeons prefer to operate large congenital nevi in the early infantile period.

Acquired nevi tend to arise in childhood and adolescence, but some emerge later in life. Most start out as a small pigmented flat macule, which slowly increases in size and becomes raised, producing a papule. This initial growth phase is soon followed by stabilization of size and appearance. Most nevi are less than 6 mm across. Nevi are generally symmetrical, sharply defined, are covered by an intact epidermis, and lack variations in color or degree of pigmentation. In case of doubt, an excisional biopsy (total surgical removal, with narrow margins) of the lesion allows histopathologic investigation, which usually, but not always, clinches the diagnosis.

Nevus numbers are correlated with skin type, caucasians with a fair skin generally having larger numbers than dark-haired caucasians and noncaucasians. Heavy exposure to ►UV Radiation of sunlight, especially in early childhood, is correlated with increased nevus counts. In some families with an increased melanoma risk, nevi are very numerous and more irregular, clinically as well as histologically (dysplastic nevus syndrome; familial atypical multiple mole melanoma syndrome).

Most melanocytic nevi harbor an activating ►B-RAF mutation, which results in increased signaling through the RAS-ERK pathway, which presumably drives, or contributes to, increased proliferation. Some variants, such as Spitz nevi (which are characterized by a large cell

type) instead may have an activating HRAS mutation, while large congenital nevi tend to harbor and activating NRAS mutation. These mutations are mutually exclusive. In aggregate, these findings suggest that dysregulated RAS-ERK signaling is an important factor in the pathogenesis of a nevus. The characteristic cessation of nevus growth, which is caused by loss of proliferative activity, exhibits the central characteristics of ►cellular senescence, with upregulation of $p16^{INK4A}$, activation of senescence-associated β-galactosidase, and loss of proliferative activity. Germline inactivating mutations of INK4A or of the sequence coding for the $p16^{INK4A}$ binding site of CDK4 result in the melanoma-proneness familial dysplastic nevus syndrome mentioned above, whereas somatic mutations of INK4A or amplifications of CYCLIN-D1 are common in melanoma. In aggregate, these data suggest that unscheduled pRB-inactivation and inability to mount an ►oncogene-induced senescence response play an important role in melanomagenesis.

►Melanoma is a malignant tumor of melanocytes. Epidemiologic studies indicate that exposure to sunlight is an important factor in their pathogenesis. Fair skinned and blonde or red-haired individuals are especially at risk; melanoma is uncommon in non-caucasians. Most arise in the skin and are detected when still relatively small, with a thickness of a few millimeters or less. Macroscopically, melanoma is often irregular in shape and color, and may ulcerate or produce an itching or burning sensation. Melanoma may arise in a nevus; a change in a previously stable mole is suspicious of such malignant transformation. At the earliest phase, melanoma is confined to the epithelial compartment of the skin but it subsequently invades into the dermis and underlying tissues; at this invasive phase it may disseminate through the lymphatics and blood vessels. Lymphogenous metastases manifest in the skin and subcutis of the same body region (in-transit metastases) and in regional lymph nodes. Hematogenous metastases arise in a wide variety of sites, including some that are uncommonly affected by other tumors, such as the heart, intestines and spleen. Primary melanoma is treated by wide local excision, usually with a margin of 1 cm of apparently uninvolved skin, in order to minimize the risk of local recurrence. Metastases to regional lymph nodes, manifest clinically or detected by ►sentinel node biopsy, are generally treated by regional lymph node dissection. This procedure still offers a significant chance of cure. Distant, hematogenous metastasis is not amenable to curative surgery, but a selected group of patients benefits from surgical removal of solitary metastases. The response to radiation therapy and chemotherapy is usually modest. Much clinical interest focuses on innovative immunotherapeutic strategies (►immunotherapy), which aim to capitalize on the antitumor immune response that is often evident histologically in primary melanomas, and which effaces the primary tumor (but, unfortunately, not the metastases) in some patients.

Synonyms

Malignant melanoma

Definition

Melanoma is a tumor arising from melanocytes. Melanocytes are dendritic cells that migrate from the neuroectoderm to lodge at the base of the epidermis, and in other epithelial sites, including the eye, gastrointestinal tract, and vagina. Melanoma can arise at any of these sites, but most commonly arises in the epidermis (cutaneous melanoma, CM), where the function of melanocytes is normally to produce melanin, a protective skin pigment, in response to ultraviolet radiation (UV radiation). Ocular melanoma (OM) arises from melanocytes in the uveal stroma. Melanoma may or may not develop in a preexisting ►nevus.

Characteristics

The incidence of CM is highest in fair-skinned people living in areas of high sunlight exposure. High incidence countries (>20/100,000) include Australia,

Hawaii, and New Zealand. Incidence rates are beginning to fall in younger age groups in some of these countries, attributed in part to intensive public health sun protection programs. Countries of intermediate incidence (5–15/100,000) include northern Europe, and mainland USA. The incidence continues to rise at a rate of approximately 1.8% per year in US Whites, and increased by as much as 40–80% in the UK, France, and Spain between the early 1980s and the early 1990s. A low incidence (<2/100,000) is found in Africa and South-East Asia. Five-year survival has steadily improved since the 1970s, and is now greater than 85%, but melanoma takes a high toll on younger people, such that an average of 18.6 years of potential life is lost for each melanoma death in the USA, one of the highest rates for adult-onset cancers. The world-wide burden of CM is likely to increase well into this century, due to the aging population, continued high recreational sun exposure habits, and changing climate patterns which may increase ambient UV radiation.

Although the most common form of intraocular tumor, OM incidence is less than 0.7/100,000.

Risk factors for the development of CM include the presence of multiple ►nevi, family history of CM, history of a previous primary CM, fair skin that tans rather than burns, freckling, red hair, and blue eyes. Individuals with multiple ►atypical nevi (dysplastic nevi) are at particularly high risk. The fact that CM frequently develops de novo, even in those with multiple atypical nevi, suggests that these nevi are a marker of melanocytic stability, rather than being obligatory precursor lesions. It has been estimated that approximately 65% of all CM world-wide is due to sun exposure, and as much as 90% in the USA and Oceania. Epidemiological data best fit the hypothesis that CM is related to pattern as well as amount of sun exposure, with increasing intermittency of exposure being associated with increasing risk.

CM presents most commonly as change in a nevus, the majority, but not all, of which are pigmented. Suspicion of malignant change is raised by the presence in a nevus of asymmetry, border irregularity, distinguishing color, including areas of red, blue, or white, and diameter >5 mm. None of these features is invariable. Particular difficulty is presented by amelanotic primary CM. Approximately 15% of CM presenting to Sydney Melanoma Unit presents as metastatic disease with an occult primary, presumed in many cases to have regressed.

CM progresses through an in situ stage to *radial* growth phase and final *vertical* growth phase. Once cells penetrate the dermis, invasion of blood and lymphatic vessels leads to dissemination. The patterns of dissemination are highly varied and unpredictable. In typical cases, the draining lymph nodes are the first sites of apparent metastasis. In other cases, hematological dissemination occurs early. The skin, (Fig. 1), subcutis, and lungs are particularly common sites for metastases, but in later stages nearly every organ and tissue can be involved. Cerebral metastases are present in over 80% of autopsy cases.

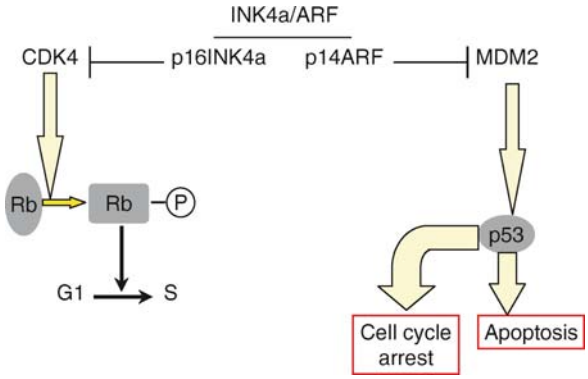
OM metastasizes hematogenously, with a particular affinity for the liver, which may remain the only site of indolent metastatic disease until preterminal stage, when lung, brain, and distant lymph node sites are also often involved.

The prognosis of primary CM is linearly correlated with the thickness of the lesion (*Breslow* depth) and the presence of melanoma cells in the initial draining lymph node (sentinel lymph node). More than 85% of patients with primary CM<1.5 mm in depth survive 5 years. Fewer than 10% of patients with hematogenous metastases survive 2 years.

Genetics of Melanoma Susceptibility (Genetic Disorders Associated with Cancer Predisposition and Chromosomal Instability)

Approximately 5–10% of CM patients have a positive family history of the disease. In 20–40% of multiple (≥3 case) families the cause is an inherited mutation in the CDKN2A gene, which codes for two tumor suppressor (►tumor suppressor genes) proteins, $p16^{INK4A}$ and p14ARF (Fig. 2). Certain kindreds with CDKN2A mutations also show a propensity for pancreatic cancer. CM-associated mutations in the CDKN2A gene prevent $p16^{INK4A}$ from binding to cyclin-dependent kinase 4 (CDK4). The consequence is phosphorylation of the retinoblastoma protein, release of the E2F transcriptional regulator, and unrestricted passage of cells through the G1-S restriction point (Fig. 2). $p14^{ARF}$ stabilizes p53 levels through interaction

Melanoma. Figure 1 Multiple intracutaneous melanoma metastases.



Melanoma. Figure 2 Functions of the INK4a/ARF locus on chromosome 9p. Alternate splicing produces two proteins. p16INK4A inhibits CDK4, preventing phosphorylation of Rb, and restricting the cell cycle at the G1-S interface. p14ARF binds to MDM2, preventing degradation of p53, and permitting p53 to carry out its functions of cell cycle arrest or promotion of apoptosis.

with MDM2 (Fig. 2). The location of other CM susceptibility genes is the subject of intense research by GenoMel, the international Melanoma Genetics Consortium, and genome screening has revealed several promising new melanoma susceptibility loci, including one on chromosome 1p22. Potential modifier genes include those that determine skin color, including the melanocortin-1 receptor (►melanocortin receptor), MC1R. The ►penetrance of CDKN2A mutations is higher at earlier ages in areas of high sun exposure, demonstrating a clear synergy between environment and genetic susceptibility in the induction of a human cancer. The use of genotyping to influence clinical management of those at high risk of CM is currently discouraged because of the lack of clarity concerning penetrance, the absence of functional data on many CDKN2A mutations, and the demonstrated high risk of CM in nongene carriers in hereditary CM families. The current best strategy is for all at high risk to be subject to the same high standards of sun protection and skin surveillance.

Twin studies have shown a strong genetic basis for nevus number, although sun exposure also clearly has a strong influence. Neither nevus count nor presence of atypical nevi correlates well with genotype in CM families with CDKN2A mutations, suggesting that other genes may be involved. However, segregation studies suggest that CDKN2A, or another gene close to it, are important regulators of nevus number.

Molecular Abnormalities in Melanoma

Activating mutations in the BRAF and NRAS oncogenes are the most common oncogene mutations in CM indicating the importance of this pathway in the deregulation of melanocyte growth. There is complementarity between the presence of NRAS and BRAF mutations in any individual melanoma as each has the same effect of causing unrestrained cell proliferation. cKit mutations occur in approximately 30% of melanomas arising in chronic sun-damaged skin.

BRAF mutations are also seen in 60–80% of benign melanocytic nevi. This suggests that the complex molecular machinery providing checks and balances in the cell normally protects against the unrestrained growth stimuli propagated through such abnormalities in the Ras/RAF pathways, possibly preventing the vast majority of benign nevi from undergoing malignant change.

Immunology

There continues to be keen interest in the potential for immunological strategies in the treatment of CM (►immunotherapy). This is based on the following observations: (i) Regression is common in primary CMs, and a predominantly CD4 T-cell lymphocytic infiltration is commonly seen. (ii) Well-documented instances of spontaneous regression have been reported in metastatic melanoma. (iii) In vitro and animal evidence for a cell-mediated immune response to melanoma cell surface antigens. (iv) There is an increased incidence of CM in immunosuppressed patients.

Immunotherapies under investigation include vaccination against melanoma cell-surface membranes or purified peptide components of common melanoma cell-surface antigens. These antigens are derived either from differentiation antigens in melanoma, such as tyrosinase, MART-1, gp100, or from tumor specific gene products, such as MAGE, BAGE, and GAGE proteins. The latter are expressed normally only in the testes but become expressed in melanoma and other tumors because of demethylation of the genes. The third group of antigens is specific to individual tumors and is usually due to mutations in the gene concerned, such as CDK4 or β-catenin. Recent advances on these strategies include the use of peptide-primed autologous dendritic cells as antigen-presenting cells, the use of improved adjuvants, and the addition of cytokines, such as GM-CSF, IL2, or interferon-α. Cytokines may be administered systemically by subcutaneous infusion, or locally in the site of vaccination utilizing autologous melanoma cells or tumor-infiltrating lymphocytes (TILs) transduced with a transgene constructs containing the cytokine gene. Recent immunotherapy approaches include the use of immunotoxins to eliminate regulatory T-cells (thereby allowing tumor-specific T-cells to be activated), and the use of monoclonal antibodies such as Mipilimumab and tremelimumab against the T-cell surface protein CTLA4, to inhibit immunosuppressive cell signaling.

Rational Therapies

Surgery remains the mainstay of treatment for melanoma, and the screening and early detection of high risk groups remains a principle of melanoma control. Metastatic melanoma is relatively resistant to treatment with existing cytotoxic drugs, and there is no evidence that any form of chemotherapy prolongs survival. The reason for this is probably the evolution within the tumor of robust and redundant mechanisms of inhibition of the apoptotic pathway. Partial responses to single agent chemotherapy occur only 10% of treated patients in prospective Phase III clinical trials and most of these last only months. The single agent with the highest reproducible response rate is the alkylating agent dacarbazine (DTIC).

Biochemical pathways of particular interest in the development of future rational and specific therapies for CM include receptor signaling pathways, cell cycle regulation, angiogenesis, integrin expression and regulation of apoptosis. For example, the use of the antisense molecule to bcl-2, oblimersen, increases clinical sensitivity to DTIC in a subset of patients.

Melanoma Antigens

Tobias Peikert, Ulrich Specks
Division of Pulmonary and Critical Care Medicine, Department of Internal Medicine, Mayo Clinic College of Medicine, Rochester, USA

Synonyms

Melanoma associated antigens

Definition

►Melanoma antigens are a group of tumor antigens. ►Proteasomal cleavage of these intracellular proteins generates small antigenic peptides. The presentation of these peptides in conjunction with ►Major Histocompatibility Complex-MHC molecules facilitates an immune response promoting the destruction of the melanoma antigen expressing cancer cells.

Characteristics

Background

Over the years several reports have documented cancer patients mounting immune responses against their malignancies. Most of these cases are characterized by massive lymphocytic infiltration of the tumor tissue, which leads to the destruction of the malignant cells and eventually to either partial or complete disease remission. Compared to other human malignancies these immunologic phenomena are most frequently observed in malignant ►melanomas. This observation led researchers to focus their investigations on this particular tumor. Following experiments documenting the presence of tumor specific cytotoxic T-lymphocytes among the mononuclear cells infiltrating the tumor, investigators identified the first group of melanoma antigens as possible target antigens of these immune responses. Shortly thereafter it became clear that most of these proteins are not specific for melanomas but are also present in a broad range of other malignancies. ►Proteasomal degradation of these proteins produces several small unique 8–10 amino acid long peptides. Before being displayed on the cell surface in association with class I ►MHC molecules, these peptides are processed in the endoplasmic reticulum. Their subsequent presentation on the cell membrane of cancer cells results in the activation and proliferation of tumor specific cytotoxic T-lymphocytes ($CD8^+$), mediating the destruction of these melanoma antigen expressing cells.

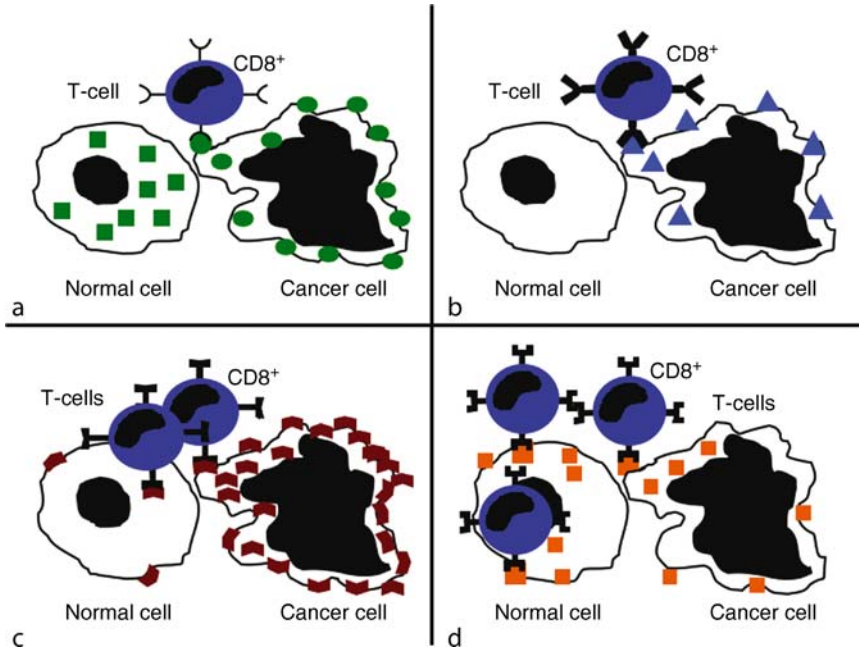
Classification

Based on how these antigens are generated, the presence of tumor cell specific gene expression, the gene expression level and whether the protein encoding the antigen represents a cell type specific differentiation gene, melanoma antigens are classified into Fig. 1:

- Tumor specific antigens
- Tumor specific shared antigens (►Cancer/►Testis antigens, ►CTA)
- Antigens encoded by genes overexpressed in tumor cells
- Antigens encoded by differentiation genes

Tumor Specific Antigens

Tumor specific melanoma antigens are the result of genetic alterations during carcinogenesis. Modifications of the structure and/or function of various physiologically expressed intracellular proteins due to



Melanoma Antigens. Figure 1 Melanoma antigens: (a) Tumor specific antigens: carcinogenesis generates genetically altered proteins which are recognized by cytotoxic T-cells; (b) Tumor specific shared antigens (Cancer/Testis antigens) represent self-antigens with restricted gene expression in cancer cells and immunologically silent male germ cells; (c) Antigens encoded by genes overexpressed in tumor cells; and (d) Antigens encoded by differentiation genes. Immune responses targeting antigens encoded by genes overexpressed in tumor cell and differentiation genes may lead to serious autoimmune reactions.

these mutations can generate novel antigenic epitopes and/or new MHC binding sites. Presentation of these new tumor specific antigens on the cell surface together with the appropriate MHC molecules can trigger an anti-tumor immune response. This immune response typically begins with the binding of T-cell receptors to the antigen and is followed by the clonal expansion of tumor specific cytotoxic ($CD8^+$) T-lymphocytes, which ultimately eliminate the melanoma antigen expressing tumor cells. Rather than being universally expressed in all patients with certain malignancies, most of these novel tumor antigens are the result of specific mutations restricted to the tumor cells of individual patients. Therefore, most of these tumor specific antigens do not represent unanimously applicable targets for cancer immunotherapy. However, some are present in a wide variety of patients. A good example for this phenomenon is the oncogenic ►tyrosine kinase, ►BCR-ABL1 which is generated as the result of a ►translocation between chromosomes 9 and 22, t(9;22)(q34;q11), also known as the "►Philadelphia Chromosome." This genetic abnormality is found in 95% of patients with ►chronic myelogenous leukemia (CML). Beside its role as an oncogenic tyrosine kinase, BCR-ABL1 also represents a tumor specific antigen which is recognized by tumor specific cytotoxic ($CD8^+$) T-lymphocytes.

Tumor Specific Shared Antigens (CTA)

The second category of melanoma antigens are genes commonly found in a wide variety of malignancies, including melanomas, but absent in most adult tissues other than male germ cells and placental tissue. The genes are also known as ►CTA. Gene expression of CTA is almost exclusively restricted to tumor cells and male germ cells. The absence of gene expression and the lack of human leukocyte antigens in CTA expressing germ cells preclude recognition of these antigens by cytotoxic T-lymphocytes outside of CTA expressing malignancies. Therefore, even though they represent self-antigens, CTA are considered to be tumor specific.

The prototype of the CTA is the Melanoma AntiGEn (►MAGE) gene family. The first members of this gene family were characterized in 1991 during efforts to identify the immunological targets of cytotoxic T-lymphocytes attacking the cells of the melanoma cell line MZ-2. Subsequently, many more members of this gene family have been identified. Up to date three subfamilies with numerous genes (MAGE-A (1–15), -B (1–17) and C (1–7)) are known. Interestingly, all these genes are localized on the X chromosome. Their messenger RNA is assembled of three exons, and the entire open reading frame is localized on the third exon. A large area (65–85%) of the gene sequence is

preserved between the different members of the MAGE gene family. This area, the MAGE-homology domain, encodes ~170 amino acids and is positioned at the carboxyl-terminal end of the MAGE proteins.

Based on the remarkable structural resemblance and the frequent co-expression of various members of the MAGE family within the same cell, it has been speculated that these proteins are involved in similar cellular pathways. However, the exact physiologic function of MAGE remains not fully understood. Several MAGE proteins have been shown to be involved in the regulation of the cell cycle and control of apoptotic pathways. In addition the unique gene expression pattern of MAGE suggests that the physiologic role of the MAGE proteins is limited to pathways active during germ cell development and carcinogenesis.

The silencing of MAGE gene expression in the majority of tissues is not attributable to a lack of the required transcription factors (Sp1 and ►Ets). These transcription factors are universally present in most cells, however methylation of their binding sites at the gene promoter inhibits gene transcription. In contrast, DNA hypomethylation as frequently seen during carcinogenesis, induces gene transcription by allowing transcription factor binding to the gene promoter. Alternatively, gene transcription can also be induced by inhibition of the ►DNA-methyl-transferase caused for example by ►5-Azacytidine. Other mechanisms potentially involved in the regulation of MAGE gene expression are genetic ►imprinting, suggested by the X chromosomal gene localization, and the presence of alternatively spliced promoters with variable transcription efficiency for some MAGE genes.

Besides MAGE-A, -B and -C (also called Type I MAGE genes) several additional MAGE gene subfamilies (MAGE-D to L) have been described (Type II MAGE genes). In contrast to Type I MAGE genes, Type II genes are almost universally expressed in normal tissues. However, due to a lack of similarity between Type I and Type II MAGE genes none of the antigenic peptides encoded by the Type I genes is present in Type II genes. This preserves the tumor specificity of the Type I MAGE genes.

Other members of the ►Cancer/Testis antigens include the B melanoma antigens (BAGE), G antigens (►GAGE), Cancer/Testis antigen 2 (LAGE-1), the New York esophageal squamous cell carcinoma 1 (NY-ESO-1) gene and the synovial sarcoma X (SSX) breakpoint genes.

Antigens Encoded by Genes Overexpressed in Tumor Cells

During carcinogenesis there are numerous modifications to the cellular gene expression profile. Besides the activation of oncogenes and the silencing or mutation of tumor suppressor genes, cancer cells frequently overexpress genes that provide them with a selection advantage. These genes commonly enhance cell proliferation or inhibit apoptosis. Furthermore, these genes can also encode antigens, which are capable of triggering a cytotoxic T-lymphocyte mediated immune response against the tumor. Examples for these antigens include ►survivin (inhibitor of apoptosis), ►telomerase (stabilizes chromosomes) and ►HER2/neu (Epidermal growth factor receptor, cell membrane bound tyrosine kinase involved in cell growth and differentiation). HER2/neu is overexpressed in 20–40% of all breast cancers. Given that these antigens represent self-proteins, the resulting immune response represents a breach of self-tolerance and is not tumor cell specific.

Antigens Encoded by Differentiation Genes

The last group of melanoma antigens includes proteins encoded by cell type specific differentiation genes. For melanoma cells this includes tyrosinase, Melan-A, gp100 and tyrosinase-related proteins 1 and 2. An effective immune response targeting these antigens also results in the elimination of normal melanocytes and may present as ►vitiligo. Other tumor antigens encoded by differentiation genes include the ►prostate specific antigen (PSA) and the ►carcinoembryonic antigen (CEA).

Clinical Implications

The elimination of cancer cells by the immune system represents an important defense mechanism against the development of malignancies. It has been well documented that immunocompromised individuals and patients receiving immunosuppressive medications are at an increased risk to develop certain types of cancer. In patients with established malignancies the presence of tumor infiltrating lymphocytes has been associated with better outcomes for several malignancies. Peptides derived from Melanoma antigens represent some of the immunological targets of these anti-tumor T-lymphocytes. Occasionally, this vigorous immune response results in spontaneous tumor regression and remission. Unfortunately, these dramatic responses are only seen in very few individuals; more commonly disease progression occurs despite the presence of anti-tumor T-lymphocytes. The mechanisms by which the majority of malignancies escape the immune system are incompletely understood. It is possible that the loss of antigen or MHC class I expression by tumor cells and/or alterations in the local milieu of inflammatory cytokines leads to local anergy and allows tumor cells to proliferate despite the presence of anti-tumor T-lymphocytes.

Not surprisingly, melanoma antigens have been of great interest as targets for the development of anti-cancer vaccines. Prior to the characterization of the melanoma antigens it has been shown that the adoptive

transfer of anti-tumor lymphocytes results in a response of the tumor in ~30% of recipients. In addition, there was some success using either allogenic or autologous tumor cell vaccines. Following the characterization of the antigenic peptides contained in various melanoma antigens investigators developed various strategies to improve the immunogenic effects of these vaccines. These approaches include the use of peptide vaccines with or without immunogenic adjuvants, genetically altered antigenic peptides to increase MHC class I binding, transfer of antigen transfected dentritic cells as well as virus and DNA vaccines. Despite these efforts, clinical response rates remain suboptimal (20–30%), and further innovations are needed. Some of the problems to be resolved include the heterogeneous expression of melanoma antigens, local anergy and the development of autoimmune phenomena.

Melanoma Associated Antigens

►Melanoma Antigens

Melanoma-Associated Retinopathy

Claudia Pföhler
Department of Dermatology, Saarland University Medical School, Homburg/Saar, Germany

Synonyms

MAR; MAR-syndrome

Definition

Paraneoplastic syndrome in ►melanoma patients characterized by different visual signs and symptoms, a reduced b-wave in the electroretinogram, and serum antibodies against retinal proteins.

Characteristics

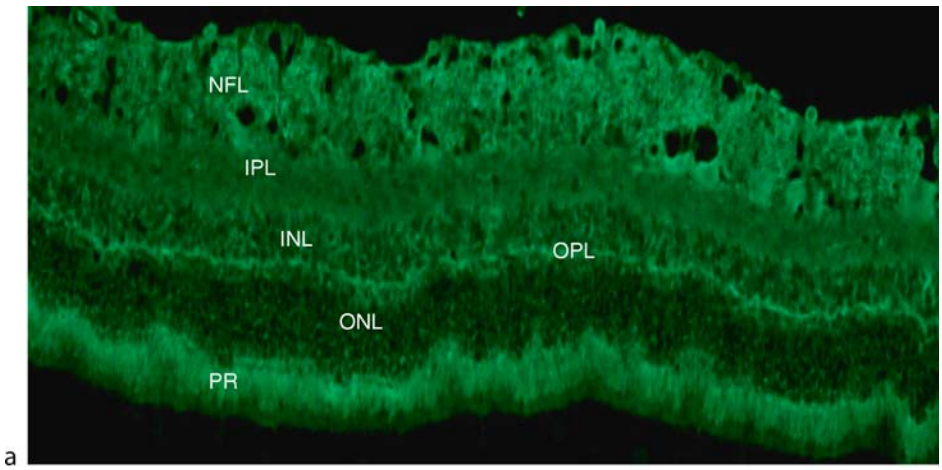
Pathogenesis

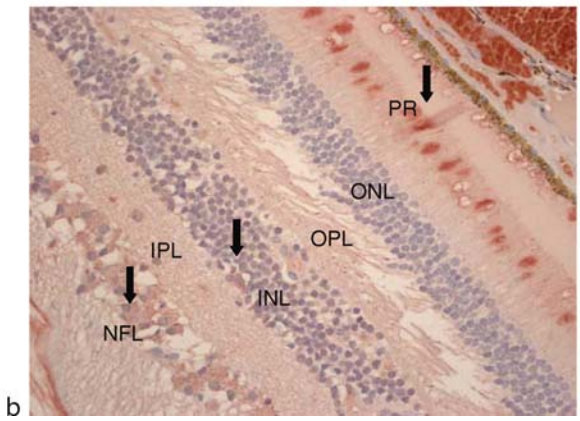
Formerly, melanoma-associated retinopathy (MAR) was supposed to result exclusively from antibody production against ►melanoma antigens that are also expressed in retinal tissue, leading to the destruction of retinal cells and resulting in defective signal transduction. Indirect immunohistochemical investigation of serum samples from MAR patients on retinal tissue lead to the detection of these antibodies (Fig. 1). In some cases, a diffuse antibody involvement with a variety of different cell populations such as optic nerve, nerve fiber layers, photoreceptors, and bipolar cells could be observed. In single cases, a 35 kDa protein in Müller glial cells, a 22 kDa neuronal antigen, and retinal transducin could be identified as antigens possibly involved in the development of MAR. Recently performed experimental investigations of serum samples from patients with MAR using ►SEREX were able to identify mitofilin and titin as further target antigens. The fact that none of these MAR-associated antigens detected to date by their capacity to elicit a humoral immune response is located on the cell surface questions a major pathogenetic role of the respective antibodies. Rather, it is probable that cellular, T cell-mediated processes are operative in the primary immune attack against the retina.

Clinical Aspects

Patients with MAR develop, often within a very short time period or even overnight, a multiplicity of visual disturbances. Patients describe frequently sudden onset shimmering, flickering, or pulsating photopsias in combination with difficulty seeing in the dark or night blindness. These first signs are often followed by progressive visual loss over months. Further, some patients develop color vision deficiencies. The electroretinogram in MAR patients reveals a characteristic pattern of a markedly reduced b-wave in the presence of a normal dark-adapted a-wave, resembling that seen in patients with stationary night blindness.

In most cases, patients have an established diagnosis of previous cutaneous melanoma and develop vision problems years later. Only in single cases, MAR symptoms preceded the diagnosis of melanoma in terms of a monitoric paraneoplastic syndrome. More often than not, the onset of MAR symptoms is associated with progression of disease and occurrence of metastases.





Melanoma-Associated Retinopathy. Figure 1 Immunofluorescence (a) and immunohistochemistry (b) using serum from different MAR patients on retinal tissue. Antibodies bind to photoreceptor cells (PR), cells of the inner and outer plexiform layer (IPL and OPL), as well as on cells of the inner nuclear layer (INL) and the nerve fiber layer (NFL).

The MAR syndrome with all its clinically apparent symptoms is very rare and to date only about 100 cases have been reported in the literature. However, recently performed clinical investigations including melanoma patients without visual disturbances could prove that subclinical MAR signs and symptoms appear more common than previously suspected. These subclinical symptoms are stage-dependent and are predominantly found in patients with advanced disease. These clinical observations are confirmed by further experimental investigations. Antibody activity similar to that ascribed to the MAR syndrome appears frequently in patients with melanoma who have no MAR-like retinopathy, but are potentially patients with a subclinical form of MAR.

Diagnostic Procedure

If clinical symptoms in a melanoma patient arise suspicion of MAR, the following ophthalmological examinations should be performed:

- Slit lamp and fundus examination
- Scotopic electroretinography
- Static and kinetic perimetry
- Nyctometry
- Color vision test (optional)

Serum samples from the individual patient should be investigated using indirect ▶immunohistochemistry or immunofluorescence on retinal tissue. However, one should be aware that the presence of antiretinal antibodies alone is not sufficient to diagnose MAR, as antiretinal antibodies are also found in sera derived from healthy human subjects or patients with different ocular or nonocular inflammatory diseases.

Therapy

Reports about successful MAR therapy are very rare. The use of immunosuppressive agents was ineffective in most cases. However, in single cases the administra-

tion of corticosteroids, corticosteroids in combination with azathioprine and plasmapheresis or the intravenous application of immunoglobulins could achieve improvement of vision disturbances. In addition, operative debulking of tumor masses or their irradiation could positively influence on MAR symptoms.

Prognostic Relevance

The prognostic relevance ►(autoimmunity and prognosis) of MAR symptoms remains unclear. Although the appearance of MAR symptoms is mostly associated with progression of disease, retrospective analyses did not find significant differences between the overall survival rates of melanoma patients with or without MAR. Further, it is still unclear if the antiretinal antibodies found in the serum from MAR patients have a protective effect for the individual patient. Background of this speculation is the observation of patients with non-small cell lung cancer or breast cancer who show extended overall survival if antitumoral antibodies are detected. However, it must be speculated that immunosuppressive therapy of MAR symptoms is associated with increased mortality. The comparison of melanoma patients with or without MAR concerning 5-year survival rates is not possible, as the number of MAR patients worldwide is too small for such analyses.

Melanoma Vaccines

Thomas Tüting
Laboratory for Experimental Dermatology, Department of Dermatology, University of Bonn, Bonn, Germany

Synonyms

Active; Specific immunotherapy for melanoma

Definition

Melanoma vaccines aim at inducing or enhancing cellular and humoral immune responses specifically against melanoma cells.

Characteristics

Historical Background

The earliest concepts for immunotherapy of malignant tumors were developed at the beginning of the twentieth century, when Paul Ehrlich suggested that the newly discovered antibodies be directed as "magic bullets" specifically against cancer cells. Various approaches to stimulate tumor immune defence have been experimentally developed in the last few decades. Patients with malignant melanoma have been of particular interest in the field of tumor immunology because clinical observations such as spontaneous regressions of primary tumors in the skin supported the idea that the immune system is capable of recognizing and eliminating melanoma cells. Immunological approaches were believed to be particularly suited to prevent the early metastatic spread of melanoma cells, which is associated with high mortality. Initial clinical studies performed with bacterial extracts derived from Corynebacterium parvum or Bacillus Calmette-Guérin as an adjuvant immunotherapy were initiated in the 1970s but were largely unsuccessful. Recombinant cytokines such as interferon-alpha (IFNα) and interleukin-2 (IL-2) were introduced for immunotherapy of melanoma in the 1980s. Encouraging results were noted in some patients with inoperable metastatic melanoma, which showed complete and long-lasting remissions following treatment with high-dose IL-2. The occurrence of vitiligo-like depigmentation and other autoimmune phenomena in patients treated with IFNα or IL-2 appear to correlate with a favorable clinical course, suggesting that an activation of the immune system against pigment cells is involved.

Tumor Immune Defence against Transplantable Tumors in Mouse Models

MacFarlane Burnet proposed in the 1950s that the immune system is principally able to recognize and eliminate cancer cells. This "immunosurveillance hypothesis" was controversially discussed for many years. The biologic understanding of immune defence against malignant tumor cells was widely studied in experimental mouse models involving the transplantation of chemically or virally transformed tumor cells. The analysis of humoral immunity against transplanted carcinogen-induced sarcomas revealed that the immune system is in principle capable of detecting molecular events associated with transformation such as the aberrant expression of p53. Adoptive transfer experiments showed that cellular components of the immune system were responsible for the rejection of transplanted tumor cells. In the 1980s it was discovered that cytotoxic T cells (CTL) recognize peptide fragments derived from intracellularly synthesized proteins bound to major histocompatibility (MHC) class I molecules on the cell surface and are able to specifically detect and destroy not only virus-infected

but also tumor cells. Various experimental studies using well-characterized model antigens showed that recombinant vaccines were able to induce immunity against viral infection and transplanted tumor cells, provided that the tumor cells express the model antigen themselves.

Culture of Melanoma-Specific Human T Cells and Identification of Melanoma Antigens

In the 1980s melanoma-specific CTL could be isolated from peripheral blood or tumor tissue of melanoma patients and propagated in vitro with the help of recombinant IL-2, a T cell growth factor. In the 1990s a number of melanoma-antigens recognized by these melanoma-specific CTL could be identified on the molecular level. These belonged to three principal categories: (i) tumor-specific antigens such as the MAGE family of proteins which were termed "►cancer-testis-antigens" because they are expressed by tumor cells as well as by germ cells in the testes; (ii) ►lineage differentiation tumor antigens such as the tyrosinase family of enzymes, gp100 or MART/MelanA which are expressed by melanoma cells as well as melanocytes; and (iii) ►individually mutated tumor antigens which in some cases even participated in malignant transformation. The identification of melanoma antigens recognized by T cells provided the scientific basis for the development of T cell-directed melanoma vaccines.

Rational Development of Melanoma Vaccine Strategies in Animal Models

Strategies for melanoma vaccination were experimentally developed over many years using the transplantable mouse B16 melanoma cell line in the syngeneic, inbred C57BL/6 mouse strain. Unlike experiments with carcinogen-induced sarcomas, vaccinations with irradiated B16 melanoma cells were not able to protect mice against a subsequent challenge with viable B16 melanoma cells showing that these melanoma cells were poorly immunogenic. Cytokine gene transfer such as the transduction of B16 melanoma cells with GM-CSF significantly improved their immunogenicity. This was later shown to be due to the ability of GM-CSF to recruit and activate antigen-presenting dendritic cells (DC) which are critical for the induction of an effective cellular anti-tumor immune response. The establishment of protocols for the ex vivo culture of DC from precursors in bone marrow or peripheral blood with the help of recombinant GM-CSF enabled their use as a biologic vaccine adjuvant. Injections with GM-CSF-derived DC pulsed with B16 tumor cell lysates were also able to promote protective immunity against a subsequent challenge with viable B16 melanoma cells. With the discovery of MHC class I-restricted antigen-recognition by T cells and the molecular identification of different melanoma antigens, active specific approaches for melanoma vaccination were developed using well-characterized model antigens. Vaccines employing defined synthetic MHC class I-binding peptides with appropriate adjuvants, recombinant plasmid DNA or recombinant viral vectors were able to successfully protect against a subsequent challenge with antigen-transduced B16 melanoma cells. Cultured DC and stimulation of Toll-like receptors (TLR) with synthetic oligonucleotides, which activate the innate immune system, were required for the induction of an effective tumor-immune response against lineage-specific differentiation antigens in a therapeutic experimental setting.

Efficacy of Melanoma Vaccines in Clinical Trials

Different strategies for therapeutic melanoma vaccination have been tested in clinical trials in the last 20 years. They can be grouped into vaccines on the basis of

1. Autologous tumor cells
2. Allogeneic tumor cells
3. Synthetic or recombinant molecules

The use of autologous tumor cells has the principal advantage that immune responses can potentially be stimulated against a broad spectrum of (unknown) tumor-antigens. This includes the mutated proteins of the individual tumor. Both the generation of adequate amounts of autologous tumor cell lysates as well as the in vitro establishment of autologous melanoma cell lines requires the acquisition of sufficient tumor material. This is only possible for patients with disseminated disease where tumor metastases can be easily excised. Clinical vaccine trials using autologous GM-CSF-transduced melanoma cells, cultured DC pulsed with autologous melanoma cell lysate or purified heat-shock protein-preparations have all shown that this strategy can successfully induce objective tumor regressions and long-lasting remissions in a small subset of patients. Unfortunately, most patients did not profit from the vaccine but it needs to be considered that these trials were largely performed in patients with advanced disease.

The idea of inducing a tumor-specific immune response using a vaccine approach appears to be particularly attractive in patients with clinical stage III melanoma after complete operative elimination of all detectable locoregional metastases. Autologous melanoma is usually not available in this situation. Therefore, well-characterized allogeneic melanoma cell lines derived from other patients have been used for vaccine purposes. This approach is potentially able to induce immune responses against cancer-testis antigens and lineage-specific differentiation antigens. Clinical trials involving large numbers of patients have been performed over many years. The results of these trials, reported in the last couple of years, claimed that this type of melanoma vaccine can be as effective as adjuvant treatment with recombinant IFNα.

The molecular identification of melanoma antigens and the fact that many melanoma patients spontaneously show ►tumor antigen-specific cellular immunity have also promoted the development of vaccine strategies with synthetic peptides and recombinant viral vectors. Peptide-based vaccines could be made increasingly efficient with the help of recombinant cytokines (such as GM-CSF, IFNα or IL-12), cultured DC or synthetic CpG oligonucleotides as a TLR9 agonist. Various recombinant viral vectors including adenovirus, vaccinia virus or canarypox virus carrying cDNA for defined melanoma antigens were also successfully used in clinical trials. Optimized melanoma vaccine strategies could effectively induce or enhance specific immune responses against the MAGE-family of cancer-testis antigens or against melanocyte differentiation antigens like tyrosinase, gp100 or MART/Melan-A *in vivo*. However, despite objectively measurable vaccine effects, only very few patients responded clinically with tumor regression and a longer-lasting remission.

Barriers for the Successful Implementation of Therapeutic Melanoma Vaccines

Current research is directed towards understanding the reasons why melanoma vaccines are not as effective as expected in the clinical situation. Sensitive and reproducible procedures for the measurement of spontaneous and vaccine-induced immune responses against defined as well as unknown melanoma antigens were developed in the last decade. These include, for example, flow cytometric enumeration of specific CTL with recombinant MHC class I-peptide tetramers and evaluation of their ability to produce IFNγ using intracellular cytokine staining or the Enzyme-Linked-Immuno-Spot (ELISPOT) technique. The detection of melanoma-specific CTL present in very low numbers in blood or tumor tissue in vivo could be achieved by in vitro expansion in limiting dilution assays.

Insights into the molecular and cellular mechanisms underlying the control of immune reactions and the maintenance of peripheral tolerance in recent years have also advanced the development of vaccines. It has become clear that the induction of CD8 + CTL is tightly controlled by regulatory lymphocyte populations via specific cell surface molecules and transcription factors such as CTLA-4 and FoxP3, respectively. In mice, selective elimination of regulatory T cells or blockade of CTLA-4 is able to circumvent peripheral tolerance mechanisms and enhance the induction of melanoma-specific cellular immunity in vivo. Stimulation of TLR was also shown to transiently suppress regulatory control and enhance vaccine responses.

Further important insights could be gained with a detailed analysis of cellular immune responses in blood and tumor tissue of individual melanoma patients, which showed remarkable clinical regressions following melanoma vaccination. Injections of autologous tumor cells together with cultured DC as an adjuvant could enhance existing spontaneous CTL-responses against various melanoma antigens. Vaccinations against the MAGE family of antigens were able to induce MAGE-specific CTL, which appeared to support the functional reactivation of preexisting CTL in the tumor tissue with other specificities. This observation demonstrated the importance of mechanisms regulating immune cell function within the tumor microenvironment, which is still not completely understood.

Tumor cells need to communicate with endothelial cells, fibroblasts and immune cells to support progressive tumor growth, invasive spread and angiogenesis. The interaction between tumor growth control, inflammatory responses and cytotoxic immunity in the pathogenesis of cancer is actively studied by many groups in the field. For example, the production of cytokines such as IL-6 and TGFβ in tumor tissue is able to stimulate cell proliferation and simultaneously suppress the function of CTL. Various mechanisms contribute to the escape of melanoma cells from recognition and destruction by the cellular immune system. For example, melanoma cells are able to impair the function of DC and T cells and can down-regulate MHC class I-restricted processing and presentation of antigens. Novel experimental mouse models have been generated in the last few years where melanomas can be induced in the skin by UV and spontaneously metastasize in lymph nodes and visceral organs on the basis of defined genetic alterations in the germline. These genetically engineered mouse melanoma models, which portray the clinical situation in patients much more closely than the transplantion of melanoma cell lines, may help to understand the role of molecular and cellular mechanisms regulating immune cell function in the pathogenesis of melanoma and find ways to improve the therapeutic efficacy of melanoma vaccines.

Summary and Future Perspective

Various strategies for melanoma vaccination have been evaluated in clinical trials in the last 10–20 years. Several approaches, which had been rationally developed in experimental animal models, were clearly able to induce melanoma antigen-specific cellular and humoral immunity in patients. A favorable influence on the clinical course of the disease could only be achieved in a small minority of patients. Melanoma vaccines have disappointed the expectations. Most vaccine approaches have been evaluated in patients with advanced metastatic disease that had failed standard treatment options. Conceptually, melanoma vaccines should be much more effective in the adjuvant setting where the immune system can specifically detect and eradicate melanoma micrometastases in patients at high risk of recurrent disease. Melanoma

vaccines may also become part of future treatment regimens for inoperable metastases which combine novel targeted anti-proliferative, anti-angiogenic and immunostimulatory measures in order to attack tumors simultaneously from several sides. These approaches will have to aim at supporting the efficacy of melanoma-specific CTL in tumor tissue, for example by creating the cytokine milieu associated with viral infections using appropriate synthetic oligonucleotides and by blocking regulatory mechanisms at the molecular or cellular level. Futuristic concepts include the adoptive transfer of ex vivo genetically engineered DC and CTL which are optimized for tumor cell destruction and may represent the "magic bullets" of the twentieth century.

Melanosomes

Definition

A membrane-bound cytoplasmic organelle in which melanin is produced. Melanosomes are found in cutaneous and extracutaneous melanocytes, and in the pigment epithelium of the eye.

►Melanocytic Tumors
►Melanoma

Melanotic Medulloblastoma

Definition

Rare variant of ►medulloblastoma containing focal accumulations of melanin-containing epithelial next to typical medulloblastoma cells.

Melanotic Schwannoma

Definition

Is a rare pigmented nerve cell tumor most commonly occurring in the paraspinal region, but may also be located in the skin and express local aggressivity. This tumor may occur singly, but it may also appear as part of the ►Carney complex, which consists of various but specific tumors.

Melatonin

David E. Blask[1], Richard G. Stevens[2]
[1]Bassett Research Institute, The Mary Imogene Bassett Hospital, Cooperstown, NY, USA
[2]University of Connecticut Health Center, Farmington, CT, USA

Definition

►Melatonin is an ►indoleamine synthesized from tryptophan and secreted from the ►pineal gland during the night. Peak concentrations in blood reach 60–80 pg/mL at around 2–3 a.m. in humans, whereas daytime levels are barely detectable. The half-life of melatonin in the blood is ~50–60 min. As a result of first-pass metabolism in the liver, 90% of melatonin is catabolized to ►6-sulfatoxymelatonin, which is excreted in the urine. Most of the melatonin (e.g., 70%) circulating in the bloodstream is bound to albumin. The absolute oral bioavailability of melatonin (2–4 mg) is 15% with peak levels (2–4 ng/mL) being reached within ~1 h of ingestion. The bioavailability of lower amounts (i.e., micrograms) of oral melatonin varies widely. Melatonin is regularly consumed from commercially available nutritional supplements by millions of people throughout the world primarily for sleep problems and/or jet lag. The long term health implications of this are unknown.

Characteristics

Melatonin is among the most phylogenetically old (e.g., 3–4 billion years) and fundamental biological signaling molecules (►Hormones and Cancer) found in a wide range of organisms as simple as bacteria and as complex as man. This compound is often present in high concentrations in many flowering and edible plants as well as in medicinal herbs; in this context it is referred to as phytomelatonin. In humans, melatonin is produced during the night primarily by the pineal gland, a pea-sized ►neuroendocrine gland located deep within the center of the brain. Nighttime melatonin

production follows a circadian (e.g., daily) rhythm that is synchronized by the light/dark cycle. Light reaching specialized photoreceptors in the retina of the eye stimulates nerve impulses that are transmitted to a central ►biological clock mechanism residing in a small cluster of cells called the ►suprachiasmatic nucleus (SCN). The SCN is located in the brainstem, below the cerebral cortex, in a structure called the hypothalamus. The SCN is a central pacemaker or biological clock driving the ►circadian rhythm of nocturnal pineal melatonin production. Daylight resets the central biological clock in the SCN, whereas light, of sufficient intensity, wavelength, and duration, present during the night suppresses melatonin production. Although darkness is absolutely necessary for melatonin production to occur during the night, it is not sufficient to stimulate melatonin production during the day.

Melatonin is soluble in both lipid and water compartments of living cells and thus has the ability to easily pass through all morphophysiological barriers including cell membranes. This pleiotropic molecule is involved in myriad functions including phase-shifting of circadian rhythms, sleep/activity cycles, body temperature, seasonal reproductive rhythms, retinal physiology, immune activity, vascular tone, intermediary metabolism, free radical/antioxidant mechanisms, mitochondrial activity, and cancer development and growth. Melatonin mechanism of action in the regulation of many of these processes is thought to involve membrane-associated, inhibitory G protein-coupled ►melatonin receptors (MT_1 and MT_2) the activation of which lead to the suppression of production of the second messenger molecule, 3′, 5′ - cyclic adenosine monophosphate (cAMP). As the neurohormonal expression of darkness, the timing and duration of circadian melatonin signal in essence "tells" all the cells, tissues and organs of the body not only that it is dark, but the length of the dark period as well. In this way, melatonin acts as one of the hands of the central circadian pacemaker to help coordinate physiological and metabolic activities in synchronization with the 24-h solar day.

Melatonin Anticancer Action and Mechanisms

Both the physiological melatonin signal as well as the administration of exogenous melatonin near the beginning of or during the dark phase suppress the initiation phase of tumorigenesis in experimental rat models of chemical ►carcinogenesis. This may be accomplished via melatonin ability to suppress the accumulation of DNA adducts (the resulting complex when chemicals bind to DNA) formed by carcinogens that cause damage to and permanent alterations in DNA (i.e., mutations and amplifications), which lead to neoplastic transformation. The inhibition of DNA adduct formation appears to relate to melatonin's potent and direct free radical scavenging action (►Oxidative Stress). It may also indirectly detoxify carcinogens via activation of the glutathione and related antioxidative pathways. In addition to protecting cells from DNA damage, melatonin may also promote the repair of DNA once damage has occurred.

Melatonin inhibits the proliferation of a number of human cancer cell lines *in vitro* such as breast, prostate, ovarian, liver, endometrial, choriocarcinoma, melanoma, colon, and bladder cancer cells. At pharmacological levels, melatonin exerts cytotoxic effects on cancer cells whereas nocturnal, physiological levels induce oncostatic effects. One of melatonin important antiproliferative mechanisms is to delay the progression of cells from the $G_{1/0}$ to the S phase of the cell cycle (►Cell-cycle Targets for Cancer Therapy). Either alone or in combination with other agents, melatonin induces apoptotic cancer cell death (►Apoptosis). In some neoplastic cells, this indoleamine acts as a differentiating agent and diminishes their invasive/metastatic potential via alterations in adhesion molecule expression and the support of mechanisms responsible for gap junctional intercellular communication. A wide array of biochemical and molecular mechanisms of melatonin's oncostatic action *in vitro* have been reported including the regulation of estrogen receptor expression and transactivation, calcium/calmodulin activity, protein kinase C activity, cytoskeletal architecture and function, intracellular redox status, melatonin receptor-mediated signal transduction cascades, aromatase and telomerase activity, and fatty acid transport and metabolism.

A key to melatonin cancer inhibitory action on tumor growth *in vivo* involves the essential omega-6 ►polyunsaturated fatty acid (PUFA), ►linoleic acid (LA). As the most prevalent PUFA in the Western diet, LA levels greatly exceed those required to prevent essential FA deficiency (i.e., 1% of total calories). As a potent promoter of both murine and human tumorigenesis, LA exerts actions on cancer cells that are diametrically opposed to many of the oncostatic actions of melatonin listed above. Its oncogenic effects are related to its ability to upregulate the expression of genes involved in estrogen receptor (ERα) expression, cell cycle progression, G protein signaling, and the mitogen-activated protein kinase (MAPK) growth cascade. In both tissue-isolated ERα (+and−) human ►breast cancer xenografts, melatonin acts via melatonin receptors to suppress tumor cAMP formation leading to a suppression of LA uptake and its metabolism to the mitogenic signaling molecule ►13-hydroxyoctadecadienoic acid (13-HODE). Down-regulation of LA uptake and metabolism reduces the activation of the epidermal growth factor receptor/MAPK pathway, culminating in tumor growth inhibition. The fact that LA up-regulates whereas melatonin down-regulates transcriptional regulation of ERα in human breast cancer cells via a melatonin receptor-mediated inhibition of cAMP in these cells would potentially

provide ample opportunity for cross-talk among these pathways. Like rat hepatomas, human breast cancer xenografts exhibit a circadian rhythm of tumor proliferative activity, LA uptake, and metabolism and signal transduction activity that is driven by the nocturnal, circadian melatonin signal.

Nocturnal Melatonin Suppresson by Light at Night and Human Breast Cancer Risk

The risk of developing breast cancer is up to five times higher in industrialized nations than in underdeveloped countries. Overall, nearly 50% of breast cancers cannot be accounted for by conventional risk factors. Westernized nations have increasingly become 24-h per day societies with greater numbers of people being exposed to more artificial light during the night both at home and particularly in the workplace. It has been postulated that light exposure at night may represent a unique risk factor for breast cancer in industrialized societies via its ability to suppress the nocturnal production of melatonin by the pineal gland. This hypothesis is based on studies showing that melatonin inhibits the development and growth of experimental models of breast cancer whereas either surgical removal of the pineal gland or exposure to constant light stimulates mammary tumorigenesis in rodents. This postulate is further strengthened by recent epidemiological studies demonstrating that women working night shifts have a significantly elevated risk of breast cancer presumably due to their increased exposure to light at night (►Cancer Epidemiology). A similar observation has been made for prostate cancer in men (►Prostate Cancer – Basic Characteristics and Experimental Models).

Experimental studies have uncovered important new relationships between circadian biology, the endogenous nocturnal melatonin signal, and its suppression by light at night, relative to human breast cancer risk. The proliferative and metabolic activity of human breast cancer tissue, growing in a nude rat, perfused *in situ* with blood collected during completely dark nights from premenopausal female subjects (i.e., high melatonin), is markedly reduced as compared to when the tissue is perfused with daytime blood (i.e., low melatonin). Subsequent exposure of the subjects to bright, fluorescent light during the night completely extinguishes the tumor inhibitory activity of their blood by lowering melatonin levels. Therefore, melatonin is the first soluble, nocturnal anticancer signal to be identified in humans that directly links the central circadian clock with some of the important mechanisms regulating breast carcinogenesis. These findings also provide the first definitive nexus between the exposure of healthy premenopausal female human subjects to bright, white light at night and the enhancement of human breast oncogenesis via ►circadian disruption (i.e., suppression) of the nocturnal, oncostatic melatonin signal. The suppression of circadian melatonin production by ocular exposure to bright white light at night, leading to augmented nocturnal tumor uptake of dietary LA and its conversion to mitogenically active 13-HODE, can now be afforded serious consideration as a new risk factor for human breast cancer.

In non-shift working women, evidence suggests a decreased breast cancer risk associated with higher, first morning urine levels of 6-sulfatoxymelatonin or sleep duration ≥9 h per night (longer melatonin duration?). In some cancer patients, the nocturnal amplitude of circulating melatonin levels is reduced to various degrees. In breast cancer patients in particular, nocturnal circulating levels of melatonin are negatively correlated with breast cancer ERα content while tissue levels of melatonin correlate positively with tumor ERα status and negatively with the nuclear grade and proliferative index. These findings suggest that cancer cells elaborate soluble factors that negatively feedback on the mechanisms regulating nocturnal melatonin production.

Clinical Cancer Trials with Melatonin

Over the past three decades, nearly 50 small clinical trials have been performed by a single group in Italy to test melatonin clinical efficacy in cancer patients. In a minority of these studies, melatonin was given as a single agent while in most cases it was administered in combination with other standard therapies, including chemotherapy, immunotherapy or radiation therapy, exclusively to patients with advanced stage solid tumors that had become refractory to standard therapy alone. More than half of these trials consisted primarily of non-randomized broad phase II trials in which melatonin therapy was administered to patients with a wide range of malignancies; the remainder were randomized, controlled phase II trials that were disease-specific for lung cancer, colorectal cancer, breast cancer, glioblastoma, and brain metastases from solid tumors. In no case were the trials double-blind and/or placebo-controlled. An oral dose of anywhere from 10 to 50 mg of melatonin (usually 20 mg) was administered to cancer patients in the early evening either alone or concurrently with chemo- or radiation therapy. Although an objective partial tumor response was observed in a small percentage of patients receiving melatonin, the majority of tumor responses consisted of disease stabilization. Probably the most dramatic effect of melatonin treatment was a markedly improved 1-year survival in these patients compared with those receiving supportive care, chemotherapy, or radiotherapy alone.

Other benefits that accrue from melatonin therapy as reported in these clinical trials are a reduction in the toxicities associated with chemotherapy including myelotoxicity, nephrotoxicity, thrombocytopenia, lymphocytopenia, stomatitis, neuropathy, and cancer

cachexia. Probably the most clinically important aspect of these trials is that melatonin-treated cancer patients apparently achieve and maintain better performance status and experience less anxiety than those individuals not receiving the indoleamine. Performance status represents the general well being and quality of life of the patient. In fact, patients who have a better performance status at the outset usually respond more favorably to melatonin alone or in combination with other more conventional therapies.

The most common reported side effects of therapeutic (milligram) doses of melatonin include sedation, drowsiness, and mild hypothermia. In a recent randomized, double-blind, placebo-controlled trial, oral melatonin (10 mg) administered prior to sleep for 1 month was found to exert no toxic effects in on a wide range of physiological and neurological parameters in healthy individuals. In the clinical cancer trials, in which up to 50 mg of melatonin was administered daily for 1–3 years, no adverse side effects warranting its discontinuation were reported.

Summary and Conclusions

The nocturnal, circadian melatonin signal is a newly identified inhibitory link between the central circadian pacemaker in the brain and the processes governing cancer development and growth in both experimental animals and humans. This anticancer signal in essence organizes the processes controlling oncogenesis within biological time structure and in doing so, provides the body with a degree of protection from the development and growth of cancer cells during each night. Melatonin blocks the ability of cancer cells to take-up linoleic acid and convert it to the mitogenic signaling molecule 13-HODE. Bright light at night, which suppresses this onocostatic signal, represents a newly identified risk factor for breast cancer in night-shift workers. Clinical trials indicate that nighttime melatonin supplementation may offer a promising new approach in the treatment of advanced stage malignancies and reduction in the toxicity of chemotherapy, immunotherapy and/or radiation. Pharmacological doses of melatonin appear to be safe and generally well tolerated in cancer patients. The role of melatonin in human cancer prevention remains to be explored.

Melatonin Receptors

Definition

A superfamily of membrane associated ►G-protein coupled receptor proteins containing seven transmembrane domains that recognize and mediate major actions of ►melatonin.

Melphalan

Definition

Also known as L-PAM, L-Sarcolysin, Phenylalanine Mustard, or Phenylalanine Nitrogen Mustard, and by the brand name Alkeran. Melphalan is classified as a nitrogen mustard-derivative alkylating agent and a cytotoxic for use in chemotherapy. Melphalan inhibits DNA and RNA synthesis through the formation of interstrand DNA cross-links. Melphalan is non-specific for cell cycle phase and also exhibits immunosuppressive properties.

►Alkylating Agents
►Hyperthermia

Melting Point Analysis

Definition

Identification of molecular mutations based on melting of mutated alleles at lower temperatures compared to unmutated alleles.

►Leukemia Diagnostics

Membrane Fluidity

Definition

This property of membranes is associated with lipid mobility, necessary for the correct distribution and

function of certain proteins. Viscosity is an antonymous term often used to refer to the same physical property.

Membrane-Linked Docking Protein

Noriko Gotoh[1], Nobuo Tsuchida[2]
[1]Divisions of Systems Biomedical Technology, Institute of Medical Sciences, The University of Tokyo, Minatoku, Tokyo, Japan
[2]Department of Molecular Cellular Oncology and Microbiology, Tokyo Medical and Dental University, Bunkyo-ku, Tokyo, Japan

Definition

Membrane-linked docking protein (MLDP) is a signal-transducing molecule, and consists of the following family members: (i) FRS2/SNT (fibroblast growth factor receptor substrate 2/suc1-associated neurotrophic factor target) (ii) Dok (docking protein), (iii) TRAP (transmembrane adaptor protein), (iv) Gab (Grb2-associated binder), and (v) IRS (insulin receptor substrate). The protein has the following structural motifs: (i) membrane-linking function and (ii) scaffolding or adaptor function, and (iii) multiple tyrosine residues capable of being phosphorylated by tyrosine kinases. However, the protein itself has no enzymatic activity, as well as no or very short (less than 40 amino acid residues) extracellular domain.

Although MLDP works as a mediator of signal transduction, the protein families represent groups of adaptor proteins N-termini of which are anchored in the membrane and the rest of which in the cytoplasm.

Characteristics

Mechanism of Signal Transduction by MLDP

MLDP is localized on the inner side of membrane, since the protein contains (i) ►PH (Pleckstrin homology) domain, (ii) membrane-anchor domain of a stretch of hydrophobic amino acid residues, or (iii) a palmitylation/myristylation site at or close to N-terminus of MLDP. The upstream signals are received by MLDP with two steps (Fig. 1). The first step is the docking at the inner side with transmembrane receptors. Growth factors, cytokines, or antigens bind to transmembrane receptors, resulting in dimerization or oligomerization. The receptors are phosphorylated by elevated tyrosine kinase activity themselves or by activated cytoplasmic tyrosine kinases. MLDP binds to the phosphorylated tyrosine site on the receptors using ►PTB (Phosphotyrosine binding) domain. Once docked, several tyrosine residues of MLDP are phosphorylated by the activated ►receptor tyrosine kinase. In turn, MLDP provides with Tyr-phosphorylation sites as a platform to downstream effector proteins for their binding, such as to SHP2 (phosphotyrosine phosphatase = PTP) containing two ►SH2 domains. When inactive SHP2 is recruited to MLDP for its binding, conformational changes of SHP2 take place, thus resulting in the activation of phosphatase of SHP2. SHP2 subsequently activates ERK (one of the ►MAP kinases) pathway, resulting in cell proliferation. Another MLDP-binding protein, p85, regulatory subunit of ►phosphatidyl inositol (PI) 3-kinase, is also recruited after tyrosyl phosphorylation of MLDP, leading to activation of ►AKT survival pathway.

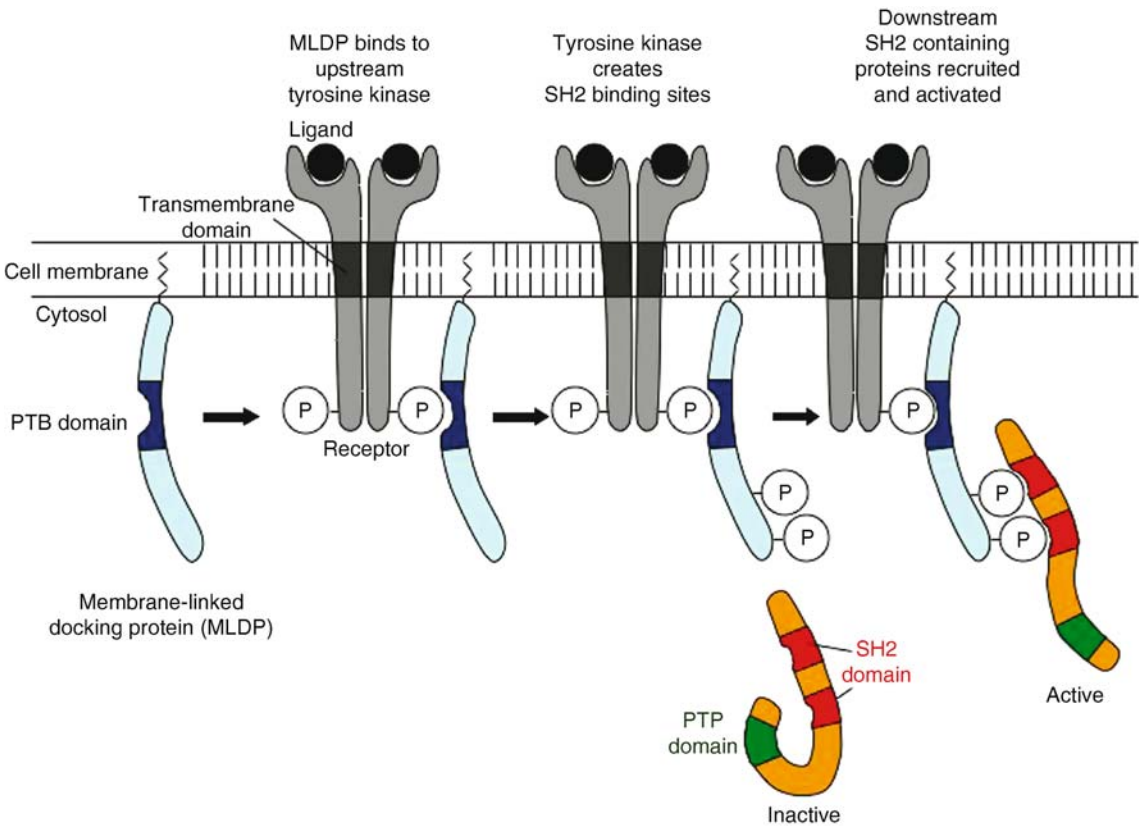
Roles of Individual MLDP Family in Normal and Cancer Cells

Five families of MLDPs, binding proteins to the ►PTB domain, and the binding molecules to the phosphorylated tyrosine residues exist (Fig. 2).

FRS2/SNT

FRS2/SNT family consists of two members: FRS2α/SNT-1 and FRS2β/SNT-2/FRS3. Each protein consists of a membrane-anchoring N-myristylation signal, a PTB domain, and a C-terminal side region containing tyrosine residues which serve as the binding sites, when phosphorylated, for the SH2 domains of ►Grb2 adaptor protein and SHP2 tyrosine phosphatase. Although both FRS2 family members are highly homologous, their different expression patterns point to the presence of specific roles for each member. *Frs2α/Snt-1* is ubiquitously expressed at every developmental stage of the mouse, whereas high levels of expression of *Frs2β/Snt-2* are confined to several tissues of neuronal or epithelial origin.

Tyrosine phosphorylated FRS2/SNT proteins serve as a platform for multiprotein complexes induced by activation of several receptor tyrosine kinases with their corresponding ligands, such as ►fibroblast growth factor (FGF), nerve growth factor (NGF), brain-derived growth factor (BDNF), and glial cell-derived growth factor (GDNF). The PTB domain of FRS2/SNT binds to phosphorylated tyrosine residues on ►TrkA, TrkB, and ►RET, although in the case of ►FGF, it binds to both phosphorylated and unphosphorylated forms of FGF receptor. The SHP2 binding sites on FRS2α/SNT-1 play a primary role for ►Ras-ERK activation and the Grb2 binding sites on FRS2α/SNT-1 recruit Gab1 and ubiquitin ligase Cbl; tyrosine phosphorylated Gab1 recruits and activates ►PI3-kinase, whereas Cbl activates the ubiquitination, leading to degradation pathway.



Membrane-Linked Docking Protein. Figure 1 Model of signaling through membrane-linked docking protein (MLDP).

RET gene rearrangements lead to generation of chimeric oncoprotein, RET-PTC, in papillary thyroid carcinomas. Point mutations on *RET* gene result in the expression of constitutively active RET in inherited ►multiple endocrine neoplasia types 2A and 2B (MEN 2A and MEN 2B) and familial medullary thyroid carcinoma. FRS2α/SNT-1 couples these oncogenic forms of RET with Ras-ERK activation and is implicated in oncogenesis. FRS2/SNT protein is also implicated in oncogenesis of another chimeric oncoprotein, nucleophosmin (NPM)-anaplastic lymphoma kinase (►ALK), which was identified in anaplastic large-cell lymphoma with the t(2:5) ►chromosomal translocation.

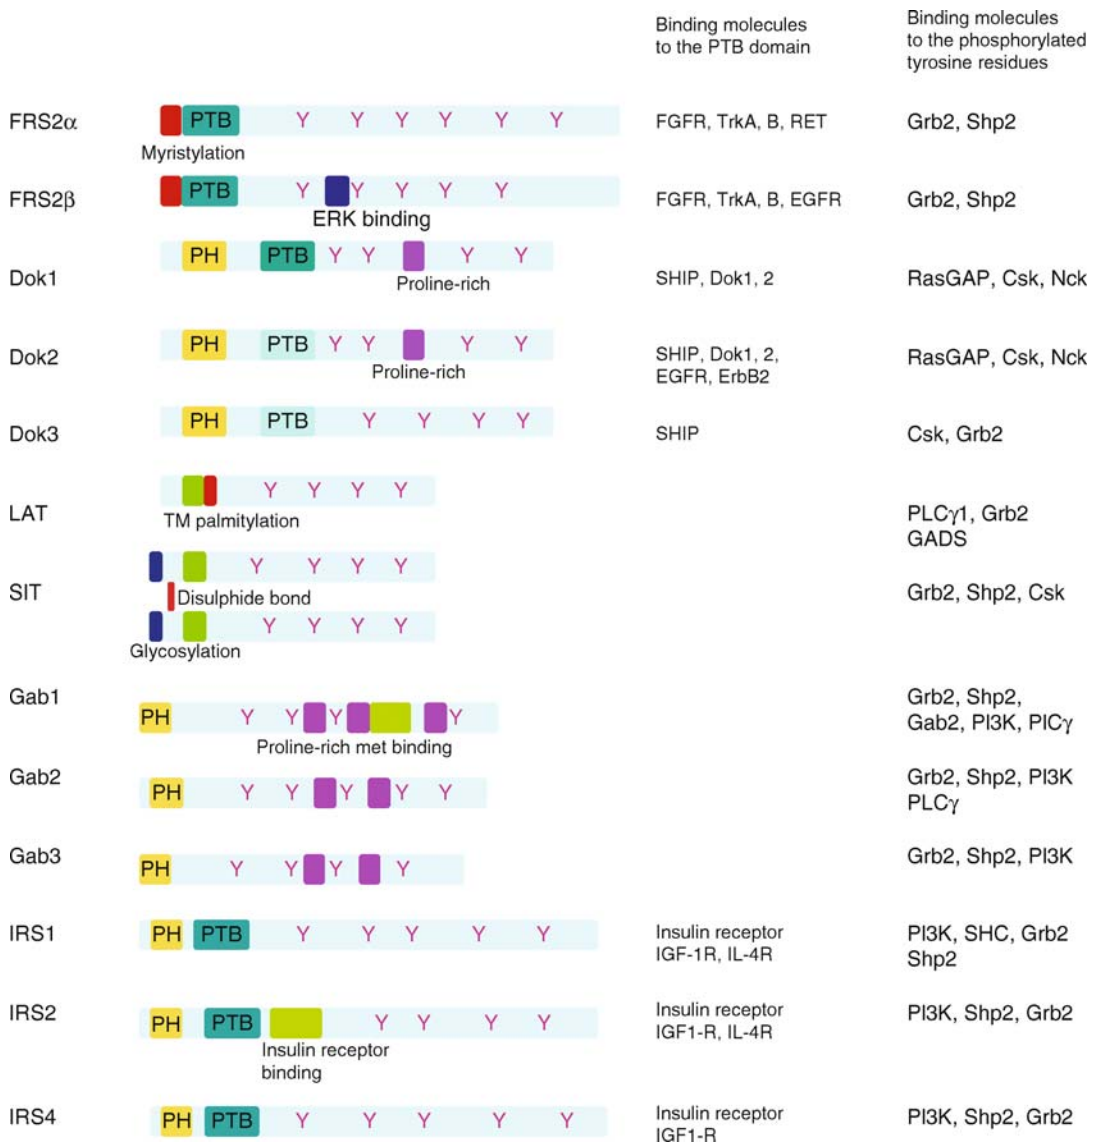
Contrary to the case of FRS2α/SNT-1, FRS2β/SNT-2 is not tyrosine-phosphorylated significantly in response to epidermal growth factor (EGF) (one of the ►epidermal growth factor receptor ligands) but it inhibits EGF signaling and cell transformation via forming a complex with ERK2. FRS2β thus acts as an adaptor protein for negative regulation of EGF receptor tyrosine kinase signaling pathways.

Dok

Dok family consists of seven members: Dok1/p62^{dok},Dok2/Dok-R/FRIP/p56^{dok}, Dok3/Dok-L, Dok4/IRS5,Dok5/IRS6, Dok6, and Dok7. Among them, Dok1–3 or Dok4 and 5 comprise a subfamily based on their structural similarity. They are typical docking proteins with an N-terminal module composed of tandem PH-PTB domains followed by a region with binding motifs for SH2 domain. Dok1 and 2 also possess proline-rich sequences within their C-terminal tails that are for binding to ►SH3 domain. The PH domain of Dok1 binds to both PI-4,5-biphosphate (PIP_2) and PI-3,4,5-triphosphate (PIP_3) in the plasma membrane. Phospholipase C (PLC) γ and PI3-kinase are also recruited to the plasma membrane where PIP_3 is synthesized from PIP_2.

Dok1 is first identified as a tyrosine-phosphorylated protein of 62 kDa (pp62) in leukemic cells isolated from patients of chronic myelogenous leukemia (CML) carrying a t(9;22) chromosomal translocation as a complex with a chimeric p210 (►Bcr-Abl) protein with elevated tyrosine kinase activity. Since *Dok1* and *Dok2* double knockout mice display CML-like disease and lymphoma, Dok proteins are considered essential for homeostatic control of activation and proliferation of hematopoietic cells.

Dok 1, 2, and 3 proteins are key negative regulators to nonreceptor tyrosine-kinases, forming multiprotein



Membrane-Linked Docking Protein. Figure 2 Schematic structures of several members of MLDPs. The phosphotyrosine binding domain (PTB) binds to phosphorylated tyrosine residues on receptors or signaling proteins. The PH domain binds to phospholipids such as phosphatidyl inositol (PI)-3 phosphate. The proline-rich domains are important for binding to SH3 containing proteins such as Src family tyrosine kinases or Grb2. Y designates potential tyrosine (Y) phosphorylation sites. The ERK binding domain in FRS2β, Met binding domain in Gab1, or insulin receptor binding domain in IRS1 contain a unique sequence for binding to ERK, Met, or insulin receptor.

complexes in response to cytokines, growth factors, and immunogens, thus controlling the delicate balance between positive and negative signals. Dok1 and 2 constitutively bind to SH3 domains of ►Src family tyrosine kinases or c-Abl. Coaggregation of B cell receptor with FcγRIIB1 or T cell receptor stimulation induces tyrosine-phosphorylation on Dok. The PTB domain of Dok binds to tyrosine-phosphorylated SHIP1 (the SH2 domain-containing inositol polyphosphate 5′-phosphatase), a negative regulator for B cell and ►T cell receptor signaling. The phosphorylated Dok1 and 2 bind to SH2 domains of Ras-GAP (►GTPase activating protein for Ras) and Csk, negative regulators for Ras and ►Src family kinases, respectively. Tyrosine-phosphorylated Dok1 and 2 also bind to SH2 domain of Nck adaptor protein, whereas Dok3 binds to Csk and Grb2 but not Ras-GAP.

Dok also regulates signaling through ►receptor type tyrosine kinases. Dok1 and 2 negatively regulate platelet-derived growth factor (PDGF), EGF, or insulin signaling. Upon EGF treatment, the PTB domain of Dok2 binds to tyrosine phosphorylated EGF receptor, and subsequently

M

Dok2 is phosphorylated, and then the phosphorylated Dok2 inhibits activation of downstream effectors. On the other hand, Dok4, 5, and 6 have positive effects on neurite outgrowth stimulated by activation of RET, TrkB, or TrkC receptor tyrosine kinases. In addition, Dok7 binds to muscle-specific receptor kinase (MuSK) via the PTB domain and induces activation of MuSK for neuromuscular synaptogenesis. Mutations in *DOK7* cause a congenital limb-girdle myasthenic syndrome with a characteristic pattern of weakness, particularly affecting the proximal muscle groups.

Transmembrane Adaptor Proteins (TRAPs)

TRAPs are membrane-associated molecules that are capable of binding with different SH2 domains after the tyrosyl phosphorylation and are key mediators of immunoreceptor-mediated signaling. They are divided into two groups: raft-associated TRAPs such as LAT (linker for activation of T cells), PAG (phosphoprotein associated with glycolipid-enriched membranes)/CBP (Csk-binding protein) and LAB (linker for activation of B cells)/LAT2 and nonraft associated TRAPs such as SIT (SHP2-interacting transmembrane adaptor protein). Lipid rafts are submicroscopic regions enriched in sphingolipids and cholesterol in the plasma membrane and contain several signaling proteins including Src family tyrosine kinases. The raft-associated TRAPs but not nonraft associated TRAPs have CXXC palmitylation motif in the juxtamembrane region for targeting the lipid raft. Each TRAP has a short extracellular domain, typical transmembrane domain, and a long cytoplasmic tail that has up to nine potential tyrosyl phosphorylation sites.

LAT can be considered the master switch of T cell and mast cell activation. Stimulation of T cell receptor or high-affinity receptor for IgE (FcεRI) on mast cells leads to tyrosine phosphorylation on LAT. Then LAT binds to SH2 domains of PLCγ1, Grb2, and GADS, the Grb2-related adaptor protein. PLCγ then hydrolyses PIP_2, producing the second messengers IP_3 and diacylglycerol. Grb2 binds to Ras activator SOS. GADS binds to SLP76, another adaptor protein, leading to activation of Itk cytoplasmic tyrosine kinase and Vav, an activator for Rac.

NTAL is a LAT-like protein in non-T cells and tyrosine phosphorylated PAG inhibits Src family tyrosine kinases via binding to SH2 domain of Csk. Tyrosine phosphorylated SIT binds to Grb2, an SH2 domain-containing phosphatase Shp2 and Csk and negatively regulate T cell signaling.

Gab

Gab family consists of Gab1, Gab2, and Gab3, has PH domain at N-terminus, and phosphotyrosine sites which, upon stimulation with growth factors, cytokines, or antigens, provide binding sites for ►SH2-containing proteins (SHP2, p85 subunit of PI3-kinase, Grb2, PLCγ, or Crk). For tyrosine-phosphorylation, Gab1 directly or indirectly binds to growth factor receptors for hepatocyte growth factor (HGF)(►MET), EGF, vascular endothelial cell growth factor (VEGF), and PDGF, in addition to Src family and JAK, though tyrosine kinases involved depend on cell types and ligands. Exact mechanisms are still to be clarified for signaling from activated tyrosine-kinase to Gab proteins which contain no PTB domain, though Gab1 has direct HGF-receptor (MET)-binding domain. It has been suggested that Grb2 and/or Cbl is involved in coupling tyrosine kinase with Gab family. Gab proteins contain several proline-rich motifs that can mediate constitutive binding to the SH3 domain of Grb2. The Grb2–Gab complex targets the receptors containing Grb2 SH2 domain binding sites. In addition, tyrosine phosphorylated FRS2α/SNT-1 docking protein binds to SH2 domain of Grb2, serving as another intermediate protein for coupling Gab to the receptors. Gab1 and Gab 2 are tyrosine-phosphorylated by antigen receptors of B and T cells upon stimulation with various cytokines and antigens, whereas M-CSF stimulates Gab2 and Gab3. SHP2 activated by Gab family leads to cell proliferation by activating ERK, whereas PI3-kinase activation to cell survival by activating AKT.

Overexpression of tyrosine kinase receptors that are often detected in cancer cells leads to enhanced tyrosine phosphorylation of Gab1, which stimulates proliferation and survival through SHP2-ERK, PI3-kinase-AKT, or Crk-Rac signal transduction pathway. Constitutive activation by in-frame fusion of RET tyrosine kinase, RET-TPC phosphorylate Gab1, leading to BRAF and ERK kinase stimulation. Trp-MET oncoprotein also stimulates tyrosyl phosphorylation of Gab1.

Roles of Gab 2 in tumorigenicity have been reported: (i) frequent *Gab2* amplification was reported in ►breast cancer and (ii) Gab2-signaling pathway is used upon transformation by Bcr-Abl. In the former case, receptor activation of ERB2/►HER2/neu enhanced further Gab2 signaling.

IRS

The protein family of IRS1, IRS2, IRS3, and IRS4 has been identified originally as proteins transducing insulin signals to intracellular effectors for the glucose homeostasis. This family commonly contain PH domain near N-terminus and PTB at the following position. IRS3 may not be expressed in human. Activated insulin receptor (IR) or IGF-1 receptor binds to IRSs by its PTB domain and subsequently induces phosphorylation on multiple tyrosine sites of each IRS, which are binding sites for PI3-kinase, SHC, an adaptor protein, and also for Grb2. IRS2 is unique in that it carries insulin receptor binding domain. IRS1 has a higher binding affinity to Grb2 when compared to IRS2, thus segregating IRS1 with mitogenic and IRS2 with metabolic outcomes.

Oncogenic SV40 T antigen gene transforms human cells through IRS1 signaling, as the transforming ability was suppressed in several human cancer cell lines which do not express IRS1or at low levels. Constitutive phosphorylation of IRS1 and IRS2 appears to stimulate proliferation and motility in mammary cancer cells. IRS4 binds to nonreceptor tyrosine kinase, Brk (breast tumor kinase) which is overexpressed in a high percentage of breast cancers.

Membrane Lipid Structure

Definition

Term used to describe the types of organizations adopted by lipids in membranes, either *in vivo* or *in vitro*, and that usually refers to the secondary structure formed by lipids.

►Membrane-Lipid Therapy

Membrane-Lipid Therapy

Pablo V. Escribá
Department of Biology-IUNICS, University of the Balearic Islands, Palma de Mallorca, Spain

Synonyms

Lipid therapy

Definition

Clinical drugs that interact with membrane lipids and that modify the composition and structure of cell membranes can change the localization and/or activity of membrane proteins. Several drugs used to combat cancer and other pathologies, both in cell and animal models or in humans, regulate ►membrane lipid structure and they produce a concomitant alteration in the localization and activity of signaling proteins. The net result of these effects is the modulation of certain signaling pathways that reverse the pathological state. Indeed, ►G proteins, ►protein kinase C (PKC) and heat shock proteins (HSPs) are among the proteins regulated by ►membrane-lipid therapy and the therapeutic agents used can inhibit cell proliferation or induce ►apoptosis and cell differentiation.

Characteristics

Heterogeneity of Membrane Lipids and Lipid Structures

Membranes are composed of thousands of different lipid molecules that interact dynamically to form the transient or stable structures used by many proteins as platforms for their activity and for their interactions with other proteins. Usually, integral (transmembrane) (►Integral membrane protein) and peripheral (amphitropic) (►Peripheral membrane proteins) proteins show important specificities in their interactions with lipids. These preferences may be associated either with a defined type of membrane lipid or a given membrane lipid structure. Most proteins are sensitive to their lipid environment, so that their activity can be modified by changes in membrane lipid composition and structure. These changes in membrane lipid composition and structure may have a physiological basis or they may be a response to external stimuli. An example of the former is the change in cell membrane lipids in response to important changes in water temperature in cold-adapted fishes, a topic widely studied by Tibor Farkas and colleagues. Alternatively, one example of the latter is the variation observed in membrane lipids after the intake of a given substance (drug, food, toxin, etc.).

Membrane lipids can organize into many more secondary structures than proteins and nucleic acids *in vitro*. Moreover, the number of lipid species exceeds the number of different amino acids and nucleic acid bases by various orders of magnitude. In contrast with proteins and nucleic acids, the spatial relationship between the lipids that form membranes is not defined by covalent bonds, they usually move freely in this environment. Furthermore, since some structural aspects related to membranes still remain unclear, the behavior of lipids is less predictable. However, this does not mean that structure-function relationships are not established in membranes and that bulk thermodynamics can explain all physico-chemical properties of membranes. In fact, changes in the structure of lipids influence not only the physical behavior of membrane lipids (membrane structure) but also the activity of

certain associated proteins (membrane function). In general, modifications in membrane lipid structure are reflected in changes in membrane lipid function. Thus, oleic acid (18:1 cisΔ9) induces a large increase in the non-lamellar (H_{II}) phase propensity of membranes and it alters the interaction and activity of G proteins. In contrast, neither the trans analogue of oleic acid (elaidic acid) nor stearic acid (18:0) markedly influence the ►lamellar phase of membranes and accordingly, they do not influence G protein activity.

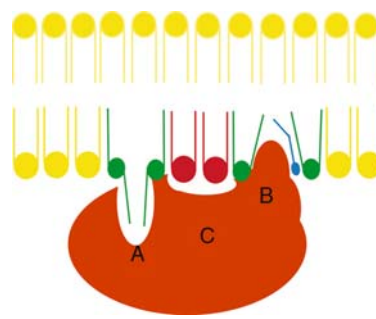
During recent years it has become accepted that the fluid mosaic model of membranes described more than 30 years ago by Singer and Nicolson is a somewhat simplified model which fails to take into account the presence of large membrane domains (e.g. the basal, lateral and apical membrane regions of polarized cells, such as glandular, endothelial and epithelial cells), as well as the smaller yet highly abundant membrane structures (lipid rafts, synaptosomes, ►caveolin domains (caveolae), coated pits, receptor clusters, etc.). These domains and structures are characterized by their characteristic lipid and protein composition. In this sense, while the membrane lipid composition most likely defines the presence of specific proteins, proteins may also influence the lipid composition of these domains.

Lipid-Protein Interactions in Membranes

Membrane proteins are classified as integral (transmembrane, intrinsic) and peripheral (amphitropic, extrinsic) proteins and both these types of proteins are very sensitive to changes in their lipid environment. For example, the exchange of sodium ions through the nicotinic acetylcholine receptor (►Integral protein) is modified by changes in ►membrane fluidity that can be achieved by altering the membrane lipid composition. On the other hand, PKCα (a ►peripheral protein) translocates from the cytosol to the membrane upon different types of stimuli. One such stimulus is an increase in the ►non-lamellar phase propensity of membranes. Thus, a high non-lamellar H_{II}-phase propensity (i.e. elevated negative curvature strain) favors the binding of PKC to membranes and its subsequent activation. Diacylglycerol induces PKC activation not only by binding to the enzyme but also by promoting the H_{II}-phase. In line with this, phorbol esters, which induce a marked activation of PKC enzyme and that are tumor promoters, also induce these non-lamellar phases. For this reason, it has been suggested that inhibitors of PKC could potentially behave as anticancer compounds. However, the anticancer drug ►minerval (►2-Hydroxyoleic acid) also increases the non-lamellar propensity of membrane lipids, activating PKC. An explanation for this apparently paradoxical behavior is that phorbol esters induce massive activation of PKC, followed by rapid enzyme depletion within minutes of the treatment. In contrast, minerval produces a mild (about two-fold) and sustained activation and overexpression of PKC. Likewise, some signaling pathways regulated by G proteins are also involved in the control of cell proliferation. In this context, the localization and activity of G proteins is also regulated by the non-lamellar propensity of membranes.

One important question regarding the regulation of protein-lipid interactions is how lipid structure can control the membrane translocation, cellular localization and the membrane sorting of these and other ►peripheral signaling proteins. Different mechanisms could be involved in these phenomena based on the formation of membrane "defects". Non-lamellar prone lipids (e.g. phosphatidylethanolamine and minerval, Fig. 1) reduce phospholipid surface packing (i.e. the lateral pressure) at the interface and the polar regions of the lipid bilayer. This allows hydrophobic domains of peripheral proteins to interact with deep hydrophobic regions of the membrane and/or fatty acid moieties of phospholipids that exit out of the bilayer plane (Fig. 1). In addition, electrostatic interactions with phospholipid headgroups and interactions with other proteins also participate in the binding of peripheral proteins to membranes. The effect of lipids in regulating the interaction of these proteins with membranes has been demonstrated using synthetic lipids and purified proteins (G proteins, PKC).

Changes in membrane lipid composition have been reported in several pathologies, including cancer. These alterations may be associated with the etiology of the



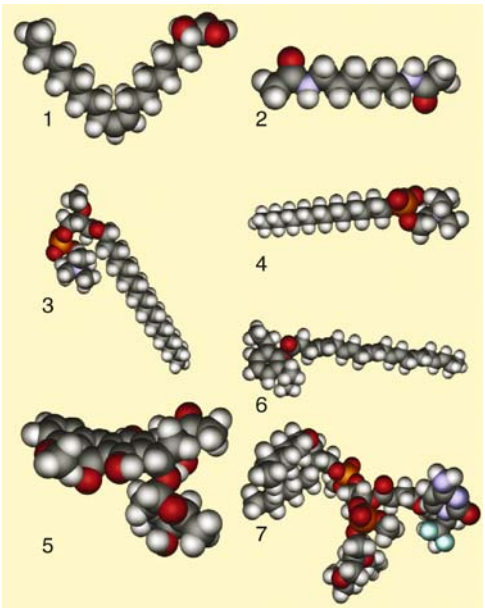
Membrane-Lipid Therapy. Figure 1 Lipids with bulky polar head, like phosphatidylcholine (yellow) and phosphatidylserine (red), have a ►molecular shape similar to a cylinder. In turn, phosphatidylethanolamine (green) has a small polar head and increases the negative curvature strain (hexagonal phase propensity) of membranes. Minerval (blue) also favors non-lamellar phases. The scheme also shows a peripheral (amphitropic) protein interacting with fatty acid moieties of phospholipids (A) or deep hydrophobic regions of the membrane (B) in non-lamellar prone regions. Electrostatic interactions with the polar head of charged phospholipids (C) also participate in the binding of this protein to membrane.

disease or they may reflect an adaptive response. Therefore, lipid interventions could be effective in reversing pathological processes. Despite the potential use of this new therapeutic approach, three important issues will require further study during the following years. First, an in-depth study of the molecular basis underlying the interaction of numerous relevant proteins with membranes will be necessary. Second, the influence of lipid changes on protein activity, pathophysiological processes and therapeutic actions must be defined. Finally, the specificity of clinical strategies based on this principle will have to be assessed. Conventional chemotherapy is based on the design of drugs to target specific proteins and the elucidation of their structure. From the molecular point of view, conventional chemotherapy and membrane-lipid therapy are quite different, although the final result is the regulation of protein activity. The fact that all membranes contain lipids could question the potential specificity of this therapy. However, there is a huge diversity of membrane lipids, a wide variety of membrane lipid compositions and structures, and tremendous variety among the protein-lipid interactions, which establishes a suitable context to design specific therapies (see above). Obviously, drugs acting through membrane-lipid therapy not only reach pathological cells but also healthy cells, as do drugs acting on a given protein through conventional chemotherapy. However, compounds used in conventional chemotherapy often interact with proteins other than their original target, causing side effects of diverse importance. Thus, the degree of specificity of both approaches could be similar. In this context, the specificity of membrane-lipid therapy is more directly associated with the effects promoted in cancer and other types of pathological cells than with its interaction with a given cell. An example of this is the activity of minerval in tumor cells where its inhibitory effects display an IC_{50} in the range of 50–100 μM in comparison with the IC_{50} value of >5,000 μM in non-tumor human fibroblasts (IMR90 cells). In addition, it has been found that minerval strongly induces the expression or repression of fewer genes than most drugs, further supporting the specificity of membrane-lipid therapy.

Development

It was proposed that the cytotoxic effects of anthracyclines on cancer cells may be exclusively exerted through their interaction with membranes. Indeed, it was later demonstrated that they acted by regulating membrane lipid structure which altered the interaction between peripheral signaling proteins and the plasma membrane. Subsequently, a potential anticancer drug under study, hexamethylene bisacetamide, was found to have a very similar effect on cell membranes, which was associated with the regulation of gene expression. In the knowledge that the mechanism of action was based on the regulation of membrane lipid structure, a number of lipid-interacting molecules were subsequently studied and accordingly, it was demonstrated that oleic acid and its derivatives are potent regulators of the membrane structure. Subsequently, minerval (the α-hydroxyl-derivative of oleic acid) was found to be a potent antitumor agent without displaying any relevant side effects.

Minerval is not the only drug used against cancer that interacts with membranes. As mentioned above, anthracyclines and hexamethylene bisacetamide also regulate membrane structure and peripheral protein-associated signaling. In addition, certain molecules that readily bind to membranes have been shown to have important anticancer effects. For instance, edelfosine (Et-18-OCH_3 (1-O-octadecyl-2-O-methyl-rac-glycero-3-phosphocholine)) and miltefosine (HePC (hexadecyl phosphocholine)) have an important hydrophobic moiety with long hydrocarbon chains (18 and 16 C atoms, respectively), and a polar region comprised of a phosphate group and a choline moiety (Fig. 2). This polar-apolar hybrid structure appears to be a common feature of these anticancer drugs that appear to be active in membrane-lipid therapy. This physico-chemical property of these drugs may allow them to interact with both the surface-interface of the membrane and with the hydrophobic core, facilitating more stable and long-lasting



Membrane-Lipid Therapy. Figure 2 Structures of the semi-empirical RHF calculations for minerval (1), HMBA (2), edelfosine (3), miltefosine (4), ►daunorubicin (5), propofol-DHA (6) and NEO6002 in gas phase. Carbon atoms are shown in gray, hydrogen in light gray, phosphorus in orange, oxygen in red, nitrogen in light blue and fluorine.

interactions, as well as inducing the relevant effects on membrane lipid structure. Thus, an interesting class of new anticancer drugs are those compounds known to bind to lipid molecules, such as the molecule NEO6002 (Fig. 2). This drug results from the combination of ►gemcitabine with cardiolipin, a phospholipid typical of mitochondrial membranes, and it appears to be less toxic and more effective than gemcitabine alone. The lipid modification of gemcitabine induces the membrane-mediated internalization of the compound, which is not blocked by nucleoside transporter inhibitors. Another type of lipid-interacting compound is propofol-DHA (Fig. 2), which combines a well-known anesthetic (propofol) with a polyunsaturated fatty acid (docosahexaenoic acid, DHA) that is present in membranes. The resulting compound has been shown to induce apoptosis in MDA-MB-231 breast cancer cells.

Most cell functions are localized in or around membranes, and lipids control the interaction and activity of many proteins. The relevance of lipids in the treatment of cancer is also highlighted by the lipid abnormalities identified in the membranes of patients with cancer. Thus, changes in the type or abundance of lipids and other types of membrane components may produce either positive or negative effects on health. Hence, membrane-lipid therapy is a new therapeutic approach that could be used in the treatment of cancer and other pathologies.

Membrane Permeability Transition

Definition

MPT; Increase of permeability of the inner mitochondrial membrane to solutes with a molecular mass of less than 1,500 Da. The rapid increase of permeability quickly causes depolarization, uncoupling of oxidative phosphorylation, and large-amplitude mitochondrial swelling. Onset of the MPT is caused by the opening of a very large conductance channel or pore in the inner mitochondrial membrane and can trigger the intrinsic proapoptotic pathway.

►Amine Oxidases

Membrane Potential

Definition

Is the voltage difference between the internal and the external part of the cell, in most cases ranging from −30 to −70 millivolts at rest. Membrane potential influences ion movement, for example, promotes calcium influx needed for several functions and favors potassium loss required for ►apoptosis.

Membrane transport proteins

Definition

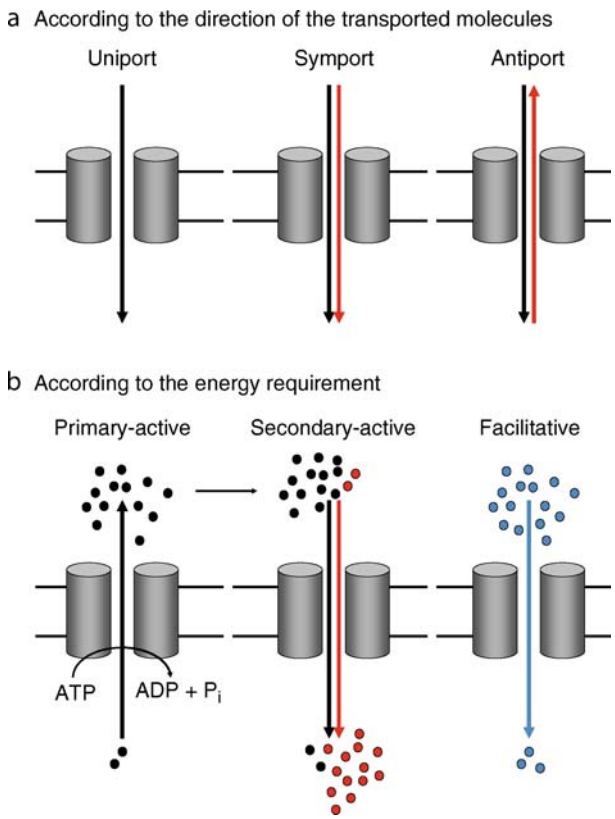
Membrane transport proteins are embedded in the lipid bilayer of biological membranes and transfer ions and small molecules across these biological membranes. Several membrane transporters contribute to the resistance of tumor cells against anticancer drugs.

Characteristics

General Features

Membrane transporters mediate the movement of ions and small molecules across the plasma membrane and the membranes of intracellular compartments such as mitochondria, lysosomes, and vesicles. The human genome comprises at least 530 genes for plasma membrane transporters (1.7% of total genes) and 350 genes for intracellular membrane transporters (1.1% of total genes). Membrane transporters typically have several transmembrane segments, each consisting of a stretch of 20–25 hydrophobic amino acids that spans the lipid bilayer of a biological membrane.

According to the direction of the transported molecules, membrane transport can be classified as uniport (one type of molecules is transported in one direction), symport (two different types of molecules are transported in the same direction), and antiport (two different types of molecules are transported in exchange with each other) (Fig. 1). Membrane transporters can also be classified as active (energy-dependent) or passive (energy-independent) (Fig. 1). Primary-active transporters are able to build up ion or solute gradients across membranes by directly utilizing the energy released during adenosine triphosphate (ATP) hydrolysis. They either belong to the ►ATP-binding cassette (ABC) transporter family or they are ion pumps (ATPases). ABC family members transport a large variety of small molecules including peptides, lipids, endogenous and ►xenobiotic organic anions and organic cations, including drugs. ATPases pump ions such as Na^+, K^+, H^+(protons), Ca^{2+}, and Cu^{2+} and contribute to maintain ion gradients across biological membranes. The Na^+ gradient is preferentially used by the so-called secondary-active transporters that can couple the flow of Na^+ down its concentration gradient with the transport of small molecules against their concentration gradients. One example is the Na^+/glucose symporter in the ►brush border membrane of enterocytes in the small intestine that mediates the uptake of glucose into the body. Passive (facilitative) transporters mediate the movement of molecules down their concentration gradients. Most of the currently known secondary-active and passive transporters are subsumed into the ►solute



Membrane Transporters. Figure 1 Classification of membrane transporters. (a) According to the direction of the transported molecules one can differentiate between uniport, symport (coupled transport), and antiport (exchanger). (b) Transporters can also be classified as primary-active, secondary-active, and facilitative. See text for details.

M

carrier (SLC) group that comprises more than 360 members in 46 families.

Similar to passive transporters, channels also mediate the movement of ions and small molecules down their concentration gradients. However, several features clearly discriminate channels from membrane transporters. Channels are pores in biological membranes that have a rather limited specificity. Substance flow through channels is controlled by the channels' open probability so that high transport rates of 10^7–10^9 molecules per second can be achieved. In contrast, transporters are able to specifically bind a substrate, but this high precision is traded in for slow transport rates of about 10^3–10^5 molecules per second. Evidently, no sugar channels have evolved, but different sugar transporters exist that can discriminate between sugars of the same size and selectively transport e.g., glucose, but not fructose.

Pharmacological Relevance of Membrane Transporters

Especially the plasma membrane transporters decisively determine which substances enter or leave a cell at sufficient rates, because it is virtually impossible for ions and most small molecules to cross the lipid bilayer of a biological membrane at a sufficient rate by simple diffusion. A number of ►SLC transporters serve as uptake transporters for nutrients and vitamins. ABC efflux pumps transport a wide variety of endogenous compounds out of cells and are localized in gastrointestinal and renal epithelia, hepatocytes, and blood–tissue barriers. The localization patterns underline that membrane transporters are essential for many physiological processes such as intestinal absorption, renal and hepatobiliary elimination and detoxification, and protection against toxins. Many SLC transporters and ABC efflux pumps transport ►xenobiotics so that they also decisively determine absorption, distribution, and elimination of drugs. They are, therefore, of important pharmacological relevance and can either be used as drug delivery systems or serve as drug targets.

Role of Membrane Transporters in Drug Resistance

Cancer cells are often resistant against a large variety of structurally diverse anticancer drugs. Two major mechanisms have been recognized that may cause this phenomenon of ►multidrug resistance, i.e., (i) an insufficient accumulation of anticancer drugs in the cancer cells and (ii) intracellular changes that impair the capability of drugs to kill the cancer cells, e.g., alterations in ►cell-cycle targets for cancer therapy, an increased repair of ►DNA damage, an inhibition of ►apoptosis, and an altered drug metabolism.

The intracellular accumulation of anticancer drugs is decisively controlled by plasma membrane transporters. Cellular drug resistance can occur either by decreased drug uptake, typically via uptake transporters, or by enhanced drug efflux, typically via primary-active transporters. Several uptake transporters that transport nutrients as physiological substrates have been implicated in the sensitivity of cells to certain drugs. For example, the presence of nucleoside transporters (SLC28 and SLC29 families) and folate transporters (SLC19 family) sensitizes cells to nucleoside analogs (e.g., ►cladribine, ►fludarabine, ►gemcitabine and ►methotrexate, respectively. Sensitivity of cells to ►platinum drugs may be due to the presence of copper transporters (SLC31 family) and organic cation transporters of the SLC22 family in the plasma membrane. The relevance of uptake transporters for the sensitivity of cells to other anticancer drugs is incompletely understood and currently intensively investigated. In addition to plasma membrane transporters, some drugs may enter cells via ►endocytosis. This pathway is e.g., utilized by some novel anticancer agents, the ►immunotoxins.

Cellular resistance resulting from enhanced drug efflux is most often mediated by members of the ABC transporter family, namely MDR1 ►P-glycoprotein (ABCB1), the ►multidrug resistance proteins (MRPs) of the ABCC subfamily, and ►breast cancer resistance protein (►BCRP; ►MXR; ABCG2). Drug substrates include methotrexate, ►vinca alkaloids, ►anthracyclines (e.g., ►adriamycin), ►podophyllotoxins, ►taxanes (e.g., ►paclitaxel), inhibitors of ►receptor tyrosine kinases (e.g., ►imatinib), and ►camptothecins (e.g., ►irinotecan). These drug efflux pumps have been identified in many human cancers so that they may contribute to drug resistance, although their precise role in establishing clinical drug resistance is still under investigation. Strategies to overcome multidrug resistance include its reversal by small molecules that function as inhibitors of ABC efflux pumps. Although already in their third generation, these reversal agents have so far not been beneficial in reversing drug resistance. Reasons for failure include the overlapping substrate specificities of several ABC drug efflux pumps and toxicity which is often caused because important physiological functions of the ABC efflux pumps are blocked by the reversal agents.

[3]School of Women's and Infants' Health, University of Western Australia, Crawley, WA, Australia

Definition

►Menopause is the permanent cessation of menstruation resulting from loss of ovarian activity. Natural menopause is diagnosed following 12 months of amenorrhea, which is not due to a pathological cause. Menopause Secondary amenorrhea (►Early menopause, ►surgical menopause) can also be induced by surgery, chemotherapy, and radiotherapy.

Characteristics

Introduction

►Breast cancer is one of the most common causes of morbidity and mortality in women of middle years in western world. There has been a reduction in annual breast cancer death rates in almost all western countries, which may be due to the increasing use of breast screening and adjuvant systemic therapy (►Adjuvant treatment). As a result, more women are becoming long-term breast cancer survivors.

A common side effect of breast cancer treatment is the earlier onset of menopause or menopausal symptoms. Many women who are premenopausal at diagnosis will develop ►premature menopause resulting from chemotherapy, endocrine therapy, bilateral oophorectomy, or ovarian radiation, and may experience severe and long lasting menopausal symptoms. All endocrine therapy will generally induce menopausal symptoms, often for the

duration of its use. This can occur in women at any age, regardless of menopausal status. Premenopausal women who are older at the time of chemotherapy are more likely to experience chemotherapy-induced ovarian failure leading to permanent menopause. Those who do not have ovarian failure may subsequently go through menopause at a younger age. Younger patients require higher cumulative dosage of chemotherapy to induce ovarian failure and may have temporary menopausal symptoms. However, it is not possible to predict reliably whether an individual woman will go through menopause as a result of her chemotherapy treatment.

A significant number of peri- and postmenopausal women are taking hormone replacement therapy (HRT) when they are diagnosed with breast cancer. Cessation of HRT commonly leads to a return of menopausal symptoms.

Recurrence of menopausal symptoms and premature menopause in breast cancer patients can have significant negative impact on quality of life, body image, sexual function, and self-esteem. The clinical challenge lies in providing safe and effective therapy to these patients. The safety of conventional hormonal treatments for menopausal symptoms has not been established following breast cancer. Furthermore, many women will have hormone receptor positive tumors and endocrine therapy aims to reduce circulating estrogen and/or suppress ovarian activity. HRT may undermine the efficacy of these treatments. Hence, there is an urgent need to provide some alternative form of treatment to alleviate menopausal symptoms in breast cancer patients.

Treatment Options

Menopausal symptoms are variable in nature and severity, and each woman requires careful individual assessment. This should include an assessment of the likely cause, nature, frequency, severity of symptoms, and impact on quality of life of these symptoms. For some women, reassurance that her symptoms are normal and are likely to reduce over time, combined with practical suggestions for minimizing their impact is sufficient management. Available treatment interventions fall into two main groups:

Synthetic Hormonal Compound

Tibolone has weak estrogenic, progestogenic, and androgenic actions. It shows similar efficacy to HRT in reducing hot flushes and vaginal dryness, and may improve sexual function more effectively than HRT. It improves bone density but its impact on fracture rates is not known. Unwanted side effects of tibolone include a reduction in circulating high-density lipoproteins, uterine bleeding, body pain, and headache. The safety of tibolone in women with a prior history of breast cancer is subject of a large randomized controlled trial (the LIBERATE study) due to be reported at the end of 2007.

Nonhormonal Therapies

A variety of nonhormonal therapies aimed at reducing vasomotor symptoms or urogenital atrophy have been subjected to randomized controlled trials. The most common vasomotor symptom is hot flushes. However, the basic physiology underlying hot flushes is poorly understood. It is hypothesized that reduced estrogen levels cause an induction of noradrenergic activity leading to the feeling of warmth, heat loss, and sweating. Because the ►placebo effect is profound and prolonged in treatments for hot flushes, it is essential that new therapies should be tested for adequate durations (at least 12 weeks) in randomized placebo controlled trials.

Phytoestrogens. Phytoestrogens are plant derivatives either in the form of ►isoflavones found in soy products or lignans found in flax seeds. They exhibit both estrogenic and antiestrogenic effects, depending on their concentration. Although some studies have shown small benefits in hot flushes from using phytoestrogens, a recent metanalysis failed to demonstrate any benefit over placebo. Their safety in women with a history of breast cancer is unknown.

Black Cohosh (*Cimicifuga Racemosa*). It was traditionally used by native North Americans for treating range of menstrual problems. It appears to act by competing for the ►estrogen receptor, and binds to Gamma amino butyric acid (GABA), serotonin, and dopamine receptors. Again, results have been conflicting with some studies finding black cohosh mildly effective in decreasing severity and frequency of hot flushes, genitourinary symptoms, and mood disturbances in few studies. However, a metanalysis of randomized controlled trials has shown no overall benefit of black cohosh over placebo. Black cohosh has recently been associated with several episodes of hepatotoxicity and liver failure.

Neuroendocrine Agents. (i) Clonidine – It is a central alpha-adrenergic agonist, found to be moderately more effective than placebo in treating hot flushes. Some studies have also shown improved quality of life in breast cancer patients treated with clonidine for hot flushes. Clonidine is one of the very few nonhormonal therapies licensed for the treatment of hot flushes. There are no safety data regarding clonidine and breast cancer. (ii) Selective serotonin and noradrenaline reuptake inhibitors (SSRI/SNRI) – Over the menopause transition, serum serotonin levels fall and monoamine oxidase activity increases. Venlafaxine is an SNRI, which has demonstrated short-term (up to 6 weeks) superiority over placebo in reducing hot flushes. Side effects of venlafaxine are largely dose related and include nausea, constipation, dry mouth, and decreased

appetite. Other SSRI including paroxetine, fluoxetine, and citalopram have also demonstrated short-term efficacy in reducing hot flushes although their safety in some breast cancer patients has been questioned due to their interactions with the metabolism of Tamoxifen.

The GABA analogue gabapentin may be more effective than SSRI/SNRI and is well tolerated by most women, though side effects may include somnolence, dry mouth, heart palpitations, and dizziness. Gabapentin effectively reduced hot flushes for at least 12 weeks in randomized placebo controlled trials of women some of whom have had a personal history of breast cancer.

Treatment of Urogenital Atrophy and Related Symptoms

Lack of estrogen results in vaginal atrophy, urinary frequency, dysuria, and incontinence. In breast cancer patients, urogenital atrophy is relatively uncommon in tamoxifen users, due to the estrogenic effects of tamoxifen in the vagina. Urogenital atrophy is more common in those using ►aromatase inhibitors. Topical estrogens are more effective than nonhormonal preparations in the treatment of urogenital atrophy. They have been widely used following breast cancer but recent reports, which state that topical estradiol may increase circulating estrogen levels in women using aromatase inhibitors, have raised some concern. Topical estradiol is also available and may be a safer choice following breast cancer.

Sexual dysfunction is often multifactorial, and the management of urogenital atrophy should include a discussion of relationship problems, loss of libido, and depression. Physiotherapy and lubricants such as olive or almond oil may also be helpful for some women.

Treatment of Bone Loss

►Osteoporosis is a common condition seen in older postmenopausal women. Endocrine therapy for breast cancer may increase the risk of osteoporosis. Abrupt withdrawal of circulating estrogens occurs following chemotherapy-induced ovarian failure, oophorectomy, or gonadotrophin-releasing hormone (GnRH), or following treatment with an aromatase inhibitor (AI) in the postmenopausal setting. Chemotherapy alone does not cause osteoporosis if not associated with ovarian failure.

Bone loss, increased fracture risk (especially nonhip fractures) are major concerns for long-term breast cancer survivors. Tamoxifen shows agonistic estrogenic activity in bone and reduces risk of fracture in postmenopausal but not in premenopausal women.

In postmenopausal women, AIs have a deleterious effect on bone density and may increase the risk of fracture. A base line bone mineral density to be repeated up to annually is advised. A bisphosphonate in conjunction with AI may mitigate the deleterious effect of AI on bone.

Lifestyle modifications to minimize bone loss including diet, supplementary calcium weight bearing exercise, stopping smoking, and minimizing alcohol consumption should be encouraged. Calcium and Vitamin D supplements should also be advised to any women at risk.

Cardiovascular Complications

In women with early breast cancer, one of major reported causes of deaths are cardiovascular diseases. The American Heart Association guidelines stratify women in three groups based on their 10-year probability of having a coronary event. Universal recommendations for all groups are moderate exercise, cessation of smoking, body weight aimed at less than 25 BMI (body mass index), and waist circumference less than 35 in., limited intake of saturated fat and cholesterol, and dietary modification to include grains, fruits and vegetables, and fish.

Some drugs used in the treatment of breast cancer can have adverse cardiovascular effects. Tamoxifen increases the incidence of thromboembolic events and may increase triglyceride levels and lower low-density lipoproteins (LDLs). AIs have less impact on lipid profile, but their long-term effects on cardiovascular disease are not yet known. Tibolone may also have an adverse effect on LDLs in some women.

Conclusion

Menopausal symptoms are common in women treated for breast cancer. Estrogen containing HRT is the most effective treatment for menopausal symptoms, but is not recommended following breast cancer, even for those with estrogen receptor negative disease. There is an urgent need for safe and effective nonhormonal treatments. Several nonhormonal treatments have been studied with varied results and outcomes. Life style modifications are an integral part of treatment especially for osteoporosis and cardiovascular diseases. Younger women who develop premature menopause often need psychological assessment and support. Topical estrogens are effective for vaginal atrophy but their safety in women using aromatase inhibitors is not established. Gabapentin and clonidine appear effective for hot flushes but have significant side effects. Several short studies support the efficacy of SNRI and SSRI but their medium to long-term efficacy is not established. Very few studies have addressed effective nonhormonal treatments for symptoms other than hot flushes. Because of the complexity of these cases, management of menopausal symptoms following breast cancer is best conducted within a multidisciplinary environment and with individualized care.

Merlin

Guang-Hui Xiao, Joseph R. Testa
Fox Chase Cancer Center, Philadelphia, PA, USA

Synonyms

Schwannomin; NF2 gene product

Definition

Merlin is the protein product of the *NF2* ►tumor suppressor gene. Germline mutations of the *NF2* gene predispose individuals to the development of ►neurofibromatosis 2, an autosomal dominant disorder affecting one in 33,000–40,000 people. Biallelic inactivation of the *NF2* gene has been reported in nearly all sporadic vestibular schwannomas and in 50–70% of sporadic meningiomas. In addition, somatic genetic changes resulting in biallelic inactivation of *NF2* occur in about 50% of ►mesothelioma tumors, which are mesodermally derived, primarily pleural tumors unrelated to the NF2 syndrome. Development of bilateral vestibular schwannomas is a hallmark of the NF2 syndrome. Because the NF2 gene product exhibits significant homology to the highly conserved ezrin-radixin-moesin (ERM) family proteins, it was dubbed merlin (moesin-ezrin-radixin like protein). It has also been referred to as schwannomin for its suppressive effect against schwannoma formation.

Characteristics

Merlin is a 595-amino-acid protein consisting of three structural domains: an N-terminal domain that exhibits highest homology to ►ERM proteins, an α-helical region, and a unique C-terminal domain. Intramolecular self-association of the N- and C-termini causes merlin to adopt a closed conformation, which is functionally active.

Like ERM proteins, but distinct from all known tumor suppressors, merlin is cytoskeleton-associated and localizes at the cell membrane. Immunofluorescence studies have revealed that merlin predominates at membrane ruffling edges. Merlin binds directly to the actin cytoskeleton via two actin-binding sites located in its N-terminal domain. Merlin also interacts with the cytoskeleton indirectly through other cytoskeleton proteins such as ERM, βII-spectrin, and paxillin.

Merlin plays a critical role in regulating cytoskeletal organization and cell motility. In schwannoma cells, loss of merlin function results in increased membrane ruffling, disorganized stress fibers, and altered spreading. Restoration of merlin expression in these *NF2*-deficient cells has been shown to impair cell motility and rescue the aberrant cytoskeletal morphology. Cell motility is critical for tumor invasiveness and metastasis, and merlin loss-of-function has been implicated in these stages of tumor progression in a mouse model. Primary mouse embryonic fibroblasts from $Nf2^{+/-}$ mice are very motile, and tumors arising in these mice are highly metastatic. However, this feature is distinct from the situation observed in benign tumors of NF2 patients.

Consistent with its role as a tumor suppressor, merlin has been shown to play an important role in regulating cell proliferation in a variety of cell types. Overexpression of merlin in both *NF2*-negative and -positive cells led to growth suppression, G0/G1 arrest, pRB phosphorylation, and decreased cyclin D1 expression. On the other hand, knockdown experiments with *NF2* siRNA accelerated S-phase entry and cyclin D1 accumulation of *NF2*-positive cells. The tumor suppressor function of merlin has also been demonstrated in targeted mutant mouse strains. Heterozygous $Nf2^{+/-}$ mice develop osteosarcomas, fibrosarcomas and hepatocellular carcinomas, and biallelic inactivation of *Nf2* occurred in all of the tumors. In a conditional homozygous knockout mouse model, however, Cre-mediated biallelic excision of *Nf2* exon 2 specifically in Schwann cells resulted in a high incidence of benign and malignant schwannomas. Intriguingly, two mesotheliomas were also found in this mouse strain.

The growth-suppressing function of merlin has also been connected to its role in contact-dependent inhibition of cell proliferation. The primary phenotypic consequence of Nf2 deficiency in mouse primary cells is loss of contact-dependent inhibition, which is accompanied by a lack of ►adherens junction formation. In agreement with this conclusion, phosphorylation and expression levels of merlin are regulated by cell density.

Merlin also plays a role in regulating signaling by ►Rho family proteins known as Rho GTPases that participate in actin cytoskeletal remodeling. Merlin physically localizes at membrane ruffles, which can be induced by Rac activity. Extensive membrane ruffling and aberrant stress fibers characteristic of schwannoma cells were similar to those observed in other cells with active Rac or Rho A, and could be reversed by inhibition of Rac1 or RhoA signaling, respectively. Biochemical experiments have connected merlin mechanistically to Rho GTPase signaling. In response to active Rac or Cdc42, but not active Rho, merlin is phosphorylated on S518, and this phosphorylation is mediated by p21-activated kinase (Pak), a common downstream target of both Rac and Cdc42. Phosphorylation of merlin by Rac/Pak signaling weakens its intramolecular binding, resulting in an open, functionally inactive protein. Indeed, a phosphomimic mutant merlin S518D impairs merlin's ability to suppress cell cycle progression and motility, whereas a S518A phosphorylation-defective form of merlin can act as a constitutively active form of the tumor suppressor in modulating cell proliferation. Intriguingly, wild-type merlin and Pak appear to operate in a negative feedback loop, because unphosphorylated merlin can directly bind Pak and inhibit its activity.

Mesalazine

Definition

5-Aminosalicylic acid (5-ASA) has long-term clinical experience in the treatment of patients with ►inflammatory bowel disease (IBD), is well tolerated, has limited systemic side effects, and has no gastrointestinal toxicity. In a rodent model of colorectal cancer, mesalazine inhibits tumor growth and reduces the number of aberrant crypt foci whereas in patients with sporadic polyps or cancer of the large bowel mesalazine induces apoptosis and decreases proliferation in the colorectal mucosa. Epidemiological data strongly supports a chemopreventive role for mesalazine in ►ulcerative colitis associated colorectal cancer.

Mesenchymal Stem Cells

Definition

MSCs; A type of stem cell found in bone marrow (marrow stromal cells) and many other locations e.g. adipose tissue. Defined by their ability to adhere to plastic when cultured, and of trilineage differentiation into fat, cartilage and bone. Found to be highly malleable, and can be switched to many other different cell types. Possess an extensive proliferative potential and ability to differentiate into various cell types, including: osteocytes, adipocytes, chondrocytes, myocytes, cardiomyocytes and neurons.

Mesna

Definition

A sulfhydryl compound that is used to reduce the incidence of hemorrhagic cystitis associated with certain chemotherapeutic agents. Mesna is converted to a free thiol compound in the kidney, where it binds to and inactivates acrolein and other urotoxic metabolites of ifosfamide and cyclophosphamide, thereby reducing their toxic effects on the urinary tract during urinary excretion.

►Chemoprotectants

Mesoblastic Nephroma

Rhoikos Furtwängler
Division of Pediatric Hematology and Oncology, Saarland University Hospital, Homburg/Saar, Germany

Synonyms

Congenital mesoblastic nephroma; Atypical congenital mesoblastic nephroma; Leiomymatous harmatoma of the kidney; Fetal hamartoma of the kidney; Malignant mesenchymal nephroma of infancy

Definition

Mesoblastic nephroma is a rare mesenchymal tumor of the kidney, which typically occurs in neonates and young infants and constitutes the most frequent renal tumor in the first three months of life.

Characteristics

Mesoblastic nephroma (MN) is a rare malignant tumor of the kidney, which originates from the mesenchymal anlage ►(metanephrogenic blastema). The typical patient is a neonate or young infant. In the first 3 months of life MN is the most frequent renal tumor, hence preoperative chemotherapy is not recommended for renal tumors in this age group. It accounts for 5% of all childhood renal tumors. According to the ►German Childhood Cancer Registry the cumulative incidence of MN is estimated at 1 in 150,000 children (0–14 years) in Germany. Contrary to ►nephroblastoma, MN has a 2 to 1 male preponderance. Metastatic disease at diagnosis is an extreme rarity.

Diagnosis

The clinical course of the MN even in the connatal or neonatal period is mainly indolent. Incidental diagnosis because of a palpable abdominal mass or a routine ultrasound scan is frequent. Abdominal protrusion, pain, emesis, hypertension, and hematuria can be clinical symptoms of MN forcing parents to contact a pediatrician. A growing number of MNs are diagnosed even antenatally, as prenatal ultrasound scans become more and more standard care. Nevertheless MN can be the reason for preterm deliveries and in reports throughout the seventies and eighties a remarkable number of MNs had been found in stillbirths.

Ultrasound scan and MRI scan are the gold standard in the diagnosis of childhood renal tumors. Differential diagnosis includes ►neuroblastoma, ►nephroblastoma, ►nephroblastomatosis, ►cystic nephroma, ►rhabdoid tumor (RT), ►clear cell sarcoma of the kidney (CCSK), and other rarer renal tumors. In ultrasound scan MN usually appears as a solid, intrarenal heterogeneous structure of mixed echotexture with circumferential echopoor areas. Furthermore a so-called "vascular ring sign" can be seen in color-coded duplexsonography. The latter corresponds to a heterogeneous circumferential contrast enhancement in MRI scan. A pseudocapsule, often seen in case of nephroblastoma, is normally not visualized in MN. However nephroblastoma can not be distinguished from MN by imaging alone, contrary to the typical neuroblastoma (retroperitoneal and extrarenal mass with calcifications that often involves vena cava and/or aorta and displaces the kidney). Unfortunately there is no specific MN-marker yet, but catecholamines in urine and blood, NSE, mIBG scan and fine needle aspiration can be of additional use in distinguishing neuroblastoma from MN. Final diagnosis, especially differing MN from other renal tumors, can only be made by histology, therefore primary surgery is the next step in diagnosis.

Histology and Genetics

MN histology can be polymorphic and challenging. This has been the reason for a variety of synonyms for MN over the years. However classical mesoblastic nephroma is actually distinguished from a cellular and a

mixed type mesoblastic nephroma. The classical type MN is characterized by leiomyomatous histology with spindle cells in bundles, absence of necrosis, and rare mitoses. It grows in a rather displacing than infiltrative manner, but tends to develop finger-shaped projections thereby trapping normal renal tissue. The cellular type MN shows contrary to the classic type MN a high cellularity and mitotic index and an atypical growth pattern (invasion of other adjacent structures other than connective tissue, hemorrhage, necrosis, and fleshy areas), thus it can infiltrate the adipose capsule of the kidney and beyond. Earlier, this MN subtype had also been called atypical congenital MN. The mixed type MN has a predominantly classic histological pattern but with some islets of cellular type MN within.

The local tumor extension is staged according to the Children's Oncology Group (COG) or ►Society of Pediatric Oncology (SIOP) working classification of renal tumors of childhood. Macroscopic residual tumor, rupture, and positive resection margins are reasons for a local stage III.

Recent studies have shown that cellular and occasionally mixed type MN differs genetically from classic MN. The translocation t(12;15) (p13;q25), detectable in most cellular and occasionally in mixed type MN, gives rise to an ETV6-NTRK3 gene fusion. Moreover trisomy 11 is found in those MN too. The translocation t(12;15) (p13;q25) can be of use to differ cellular MN from the sometimes histologically similar clear cell sarcoma of the kidney. This translocation has also been proven in congenital fibrosarcoma, suggesting a genetical link between those two histologically similar lesions.

Treatment

Primary surgery is the gold standard in MN treatment, leading to high cure rates by complete resection. Complete nephrectomy including the adipose capsule is recommended, since MN's finger-shaped projections easily can be inadvertently left behind in case of partial nephrectomy. Furthermore, sometimes cystic growth pattern, especially in cellular type MN, makes the tumor vulnerable and can cause rupture during surgery.

MN is susceptible to chemotherapy which is indicated in case of nonresectable tumor or relapse. Adjuvant chemotherapy is discussed controversially in patients with stage III cellular type MN and older age. Standard nephroblastoma and sarcoma treatment regimens are effective in the treatment of MN (dactinomycin, vincristine, cyclophosphamide, doxorubicin, ifosfamide, etoposide and carboplatin). As MN can be treated by surgery and chemotherapy, radiation therapy is not indicated in these very young patients.

Prognosis

Though MN, if completely resected, has an excellent prognosis (overall and event-free survival rate >95%) metastatic and local relapses occur, but almost exclusively in cellular type MN. Contrary classical and mixed type MN may be followed even in case of positive surgical margins or local spillage. Second look surgery can be indicated to achieve downstaging. Relapsed patients can develop metastasis to the lung, more seldom to the liver or the brain. Incomplete resection, cellular type MN, and older age correlate with relapse but are probably not independent risk factors.

Mesothelin

Nathalie Scholler
Center for Research on Early Detection and cure of Ovarian Cancer School of Medicine, University of Pennsylvania, Philadelphia, PA, USA

Synonyms

CAK1 antigen; SMR (soluble mesothelin-related proteins); MPF

Definition

The name Mesothelin was given by K. Chang and I. Pastan to a 40 kDa, GPI-anchored ►glycoprotein ►(GPI-anchored protein) that is physiologically expressed at the cell surface of mesothelial cells lining the pleura, pericardium and peritoneum [1]. Mesothelin is an epithelial marker highly expressed by ►cancer cells from diverse origins, including ►ovarian adenocarcinomas, pancreatic adenocarcinomas, and ►mesotheliomas. Soluble forms of mesothelin can be found in fluids from patients affected by these cancers.

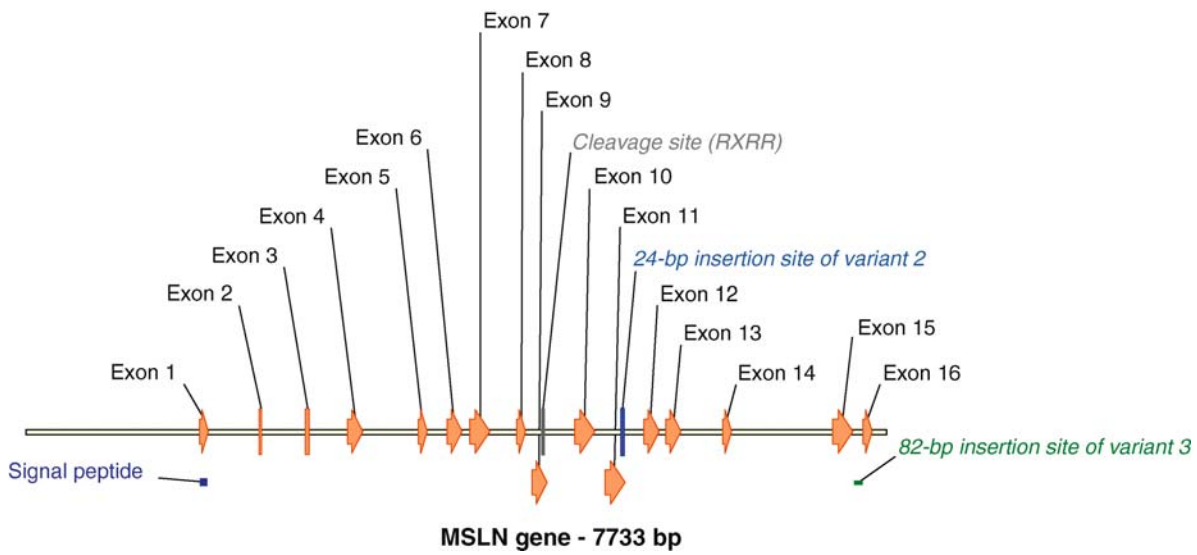
Characteristics

Mesothelin results from the cleavage of a 69 kDa preproprotein encoded by the human MSLN gene (NC_000016) that spans over 16 exons and occupies about 8 kb of human chromosome 16 (Fig. 1). The alternative splicing of MSLN gene results in at least two mesothelin transcript variants, variant 1 encoded by MSLN1 (NM_005823) and variant 2 encoded by MLSN2 (NM_013404) (Fig. 2). The variant 1 is predominant and variant 2 differs from variant 1 by 24 bp inserted in exon 11. The cleavage of MSLN-encoded preproprotein at the cationic motif TILRPRFRREVE in exon 9 releases the ►megakaryocyte potentiating factor (MPF), a 31 kDa soluble protein, while mesothelin remains membrane-bound.

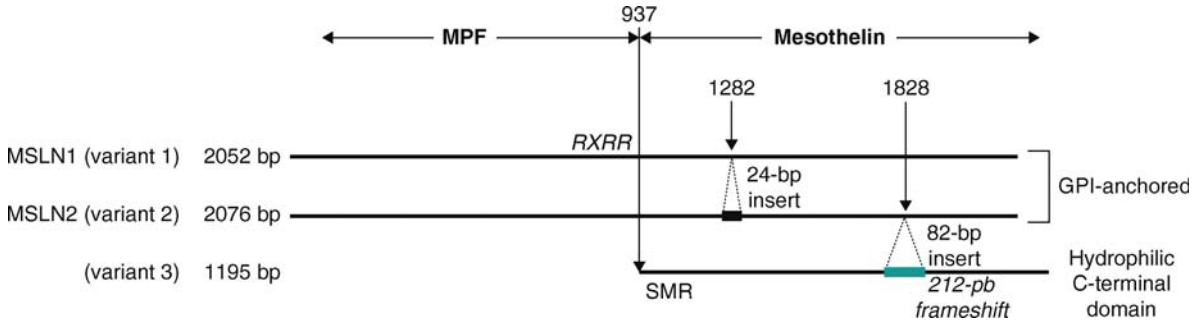
MSLN gene is composed of 16 exons spanned over 7733 bp. In human, MSLN gene is located in 16p13.3. MSLN1 and 2 gene variants encode a 69 kDa preproprotein that is cleaved in position 937 after the cationic motif *RXRR,* into two mature proteins, MPF and mesothelin. MSLN1 encodes mesothelin variant 1 and MSLN2 encodes variant 2, a less abundant, alternate splice with a 24-bp insertion in position 1282. Soluble mesothelins arise through a cleavage of GPI-anchored variants 1 or 2, or less frequently, an 82-bp insertion in position 1828 of MSLN1 resulting in a 212-bp ►frameshift mutation that transforms the GPI anchor motif into a hydrophilic domain (SMR or variant 3). The insertion of an 82-bp fragment results probably from a lack of splicing of the last intron (Figs. 1 and 2).

The core of a GPI anchor is composed of a hydrophobic phosphatidyl-inositol group and a carbohydrate-containing linker made of glucosamines and mannoses linked to a phosphoryl-ethanolamine residue (Fig. 3). The GPI anchor is linked to the C-terminal amino acid of a mature protein *via* the phosphoryl-ethanolamine residue. R1 and R2 fatty acids anchor the protein to cell membranes.

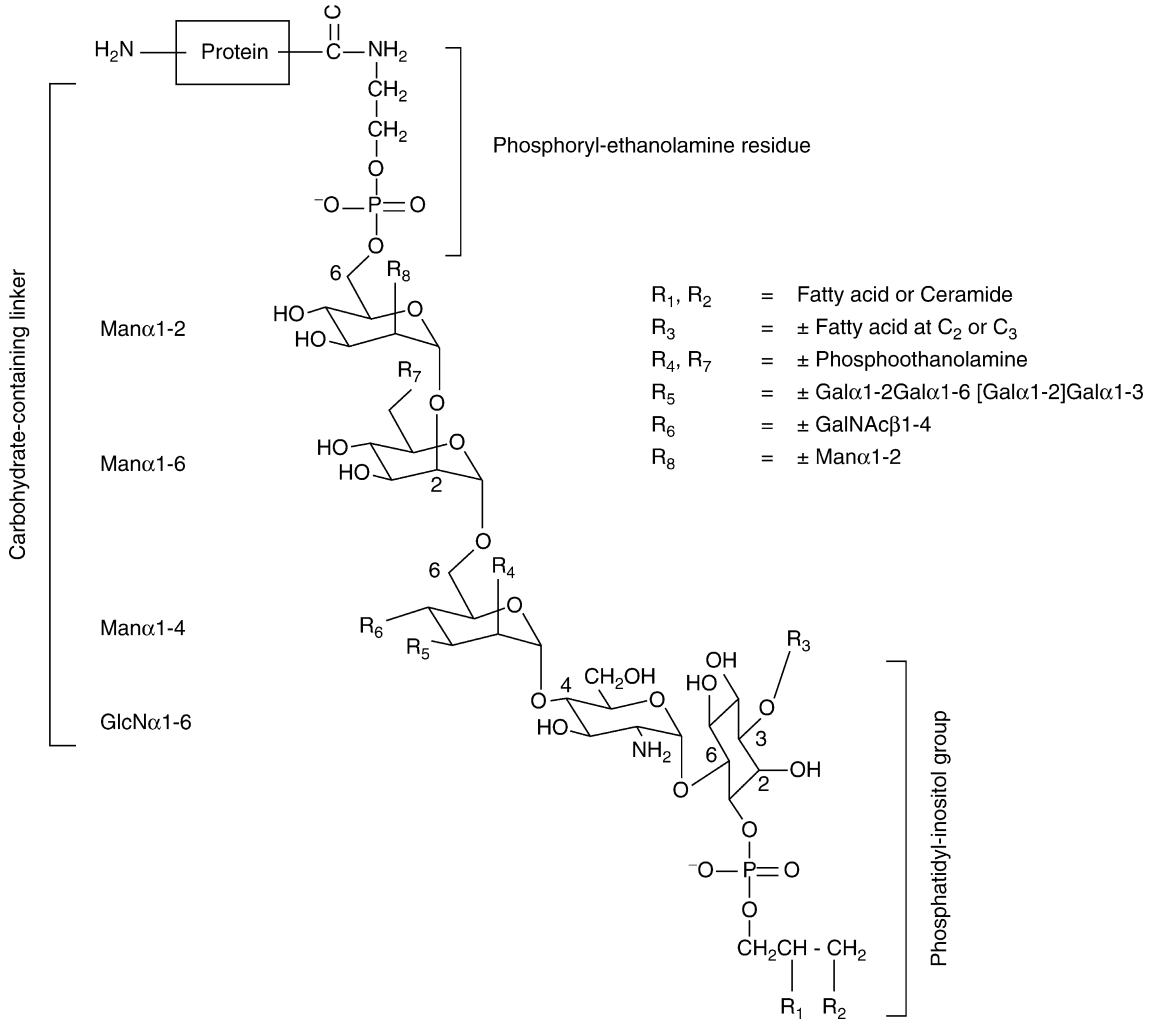
Mesothelin homologues were described for chimpanzees (MSLN gene, *Pan troglodytes*, accession DQ052446), macaque (LOC698095 gene, *Macaca mulatta,* accession XM_001087333), bovine (LOC516237 gene, *Bos Taurus,* accession XM_594389), dog (LOC611363 gene, *Canis familiaris*, accession XM_849019), rat (Msln gene, *Rattus norvegicus*,



Mesothelin. Figure 1 Exon map of MSLN gene.



Mesothelin. Figure 2 MSLN variants.



Mesothelin. Figure 3 Glycosylphosphatidylinositol (GPI) anchor.

accession NM_031658), mouse (Msln gene, *Mus musculus*, accession NM_018857) and chicken (LOC416534 gene, *Gallus gallus*, accession XM_414835). Mouse mesothelin is 55% homologous to its human counterpart and its protease target sequence TVIHPRFRRDAE is conserved.

Tissue Expression

Serial analysis of gene expression (SAGE), oligonucleotide and cDNA arrays have been used by independent laboratories to identify large sets of genes expressed at higher levels in cancer tissues compared with normal tissues. MSLN transcripts were found consistently highly

over-expressed in non-mucinous ovarian carcinomas and invasive ductal adenocarcinoma (►Pancreatic ductal adenocarcinoma (DA)) and significantly over-expressed in mesotheliomas and pulmonary, gastric/esophageal and colorectal adenocarcinomas. By real time PCR-based analysis, normal transcript levels of MSLN and CCL23, GAGED2, SPAG6, ST18, WT1 and PRAME genes were found to be associated with continuous complete remission of pediatric acute myeloid leukemia, while elevated levels of at least one of these genes were found prior to relapse in most patients.

The up-regulation of MSLN transcripts correlates well with mesothelin cell-surface expression. Studies by immuno-histochemistry (IHC) confirm that mesothelin is significantly more expressed by pancreatic cancer cells as compared to very weak or no expression in chronic pancreatitis or normal pancreatic ducts; mesothelin is found with a higher frequency in invasive intraductal papillary mucinous neoplasms (IPMN) than in non-invasive. Comparative analyses with tissue microarrays showed that the mesothelin protein expression in ovarian cancer depends on the histological type (75% of expression in serous papillary tumors, 30% in endometrioid and less than 20% in mucinous). Diffuse mesothelin staining in primary high grade ovarian serous carcinomas may be correlated with prolonged survival. Finally, mesothelin was also found to be expressed at a low level by a variety of adenocarcinomas, including endometrium, stomach/esophagus, pulmonary, ►breast and colorectal. None or very rare mesothelin expressions (less than 5%) were reported for carcinomas of ►prostate, bladder/ureter, liver, kidney and ►thyroid.

Regulation

Mechanisms that regulate MSLN transcription levels and mesothelin cell-surface expression or release as a soluble form in patient fluids are not well understood. Several pathways have been explored. MSLN gene was found ►hypomethylated in pancreatic ductal adenocarcinoma, consistently with the inverse correlation between mRNA expression and ►DNA methylation described in numerous cancers. Also, mesothelin up-regulation in carcinomas has been associated with a misregulation of ►Wnt signal transduction pathway. In mouse mammary epithelial cells, Wnt-5a down-regulates mesothelin expression, perhaps through antagonism of the ►Wnt/beta-catenin pathway, while in human ►colon cancer cells the forced expression of an N-terminal β-catenin binding site-deficient high mobility group (HMG)-box T-cell factor 1 is associated with the up-regulation of several GPI-anchored adhesion molecules, including mesothelin. Furthermore, the overexpression of mesothelin in exon 9 ►GISTs suggests that mesothelin regulation could be linked to the intracellular signaling cascade triggered by ligand-independent activation of ►KIT receptor tyrosine kinase. Finally, the presence of soluble mesothelin derived from GPI-anchored forms in ovarian and mesothelioma patient fluids could also be related to the over-expression of ►GPI PLD observed in some cancer cells.

Function

Mesothelin ►knock-out mice have no obvious phenotype and produce normal offspring without anatomical or histological abnormalities, which suggests that mesothelin is a non-essential protein. However, mesothelin binds to ►CA125 in a specific and N-linked glycan-dependent manner, thus CA125-expressing tumor cells could bind specifically to mesothelin-expressing peritoneal lining. Consequently, CA125/mesothelin-dependent cell attachment may play an important role in the peritoneal implantation of ovarian tumor cells.

Some indirect experimental evidences suggest that mesothelin could also have a role in neoplastic progression. First mesothelin up-regulation in pancreatic cancer corresponds to the transition from carcinoma *in situ* to DA. Second, mesothelin expression was found to be up-regulated after carcinogenic treatment in rats and its expression correlated with the risk of cancer development. Virgin and parous rats were compared for breast cancer incidence and mesothelin expression, before and after carcinogen exposure. Mesothelin was down-regulated before and after treatment in parous rats but only before treatment in virgin rats. It was increased after treatment in virgin rats, as were their cancer development risks.

Finally mesothelin is an immunogenic molecule. This observation is consistent with mesothelin GPI-anchor but puzzling considering its overexpression by cancer cells. In fact, most tumor antigens are weak immunogens and this has been a burden for the development of ►cancer vaccines. Nevertheless, anti-mesothelin autoantibodies have been found in about 40% of mesothelioma and epithelial ovarian cancer patients, and in some patients with pharynx/larynx ►squamous cell carcinoma. In addition, mesothelin-specific CD8-T cell responses are identifiable with a ►HLA-A2 mesothelin epitope in both normal and cancer patients, and have been reported to be increased after vaccination with pancreatic cancer lines in presence of GM-CSF.

Diagnostic Marker

The differential expression of mesothelin at the cell surface of some cancer cells and in patient fluids makes it suitable as a cancer marker. Mouse monoclonal antibodies (mAb) are commercially available for immunohistochemistry (IHC) staining, for example K1 mAb from Abcam and 5B2 mAb from BioGenex, and for ►ELISA assay (Mesomark™ kit from Fujirebio

Diagnostics, Inc., corresponding to the assay described by Scholler et al. [2]).

Anti-mesothelin mAbs stain mesotheliomas with a high sensitivity and a specificity of 75%. Several studies suggest than mesothelin can be useful for differential diagnostics, alone or combined with a biomarker panel. For example, mesothelin staining can help to identify the origin of mucinous tumors or metastatic adenocarcinomas. Mesothelin staining is much less frequent (less than 20%) in primary ovarian mucinous tumors than in metastatic pancreatic mucinous carcinomas (more than 70%). Used with PSCA, mesothelin appears highly specific for pancreatic adenocarcinoma in fine needle aspirate (FNA) specimens thus useful in categorizing suspicious lesions. In combination with p53, TAG-72, mCEA and loss of Dpc4, mesothelin staining distinguishes well differentiated liver metastasis of DA from bile duct adenomas (BDA) or hamartoma of the liver. Mesothelin, calretinin and cytokeratin 5/6 were reported to be the best positive mesothelioma markers for differentiating epithelioid mesotheliomas from renal cell carcinomas; mesothelin, WT1, p63 and MOC31 distinguish between epithelioid mesotheliomas and squamous carcinomas of the ►lung; mesothelin, calretinin, BG8 and MOC 31 distinguish between epithelioid mesothelioma and adenocarcinoma. Finally, a larger panel including mesothelin, CA125, CDX2, cytokeratins 7/20, ►estrogen receptor, gross cystic disease fluid protein 15, lysozyme, prostate specific antigen and thyroid transcription factor 1 was reported to correctly classify 88% of breast, colon, lung, ovary, ►pancreas, prostate and stomach adenocarcinomas.

Mesothelin measured in fluids is a promising marker for ovarian carcinomas and mesotheliomas. Mesothelin serum levels are elevated in most late stage ovarian cancer patients and in most patients with malignant mesotheliomas (MM) at diagnosis, and serum levels correlate with tumor size and increase during tumor progression. This suggests that mesothelin serum levels could be helpful to monitor disease progression and to screen asbestos-exposed individuals for early MM. In addition, the presence of mesothelin in MM pleural fluid can help to better discriminate mesothelioma from pleural metastasis. Recent results, taken together with mesothelin cell surface expression on pancreatic tumor, suggest that mesothelin could also be a serum marker for some pancreas cancers. A pancreatic tumor cell line was reported to release soluble mesothelin in culture supernatant using an acoustic wave device immunosensor, and mesothelin mRNA was isolated from pure pancreatic juice of pancreatic tumors and was found more abundantly in DA than in IPMN. Finally, various studies combined mesothelin with other biomarkers to form a composite marker (CM) and demonstrated that the use of CM can improve diagnostic test sensitivity. For ovarian carcinoma diagnostic, mesothelin titers have been evaluated in combination with CA125, HE4, M-CSF, ►kallikrein and/or soluble EGF receptor; for mesothelioma diagnostic, mesothelin has been combined with ►osteopontin.

Interestingly, mesothelin tumor cell expression and serum levels do not strictly correlate. Although mesothelin serum levels are more frequently increased in both MM and ovarian cancer patients whose tumor expressed mesothelin (≥30% expression by tumor cells), some patients without detectable mesothelin expression on tumor cells have elevated titers of serum mesothelin. The absence of detectable mesothelin by IHC could be due to technical artifact, or alternatively, in some cases soluble mesothelin might be mainly released from normal mesothelial cells that are in contact with the tumor microenvironment, such as in ►pleural effusion or peritoneal fluid.

Therapeutic Applications

Because of its high expression in mesothelioma, ovarian and pancreatic carcinomas, its immunogenicity and its non-essential function, mesothelin is an antigen of choice for targeted therapies and cancer vaccines. Anti-mesothelin natural and recombinant antibodies have been generated and conjugated to Pseudomonas exotoxin A (SS1P), 125I or 111In, and used alone or in combination with ►Taxol *in vitro* and *in vivo* in mouse model systems. Recent results demonstrated that SS1P synergizes with Taxol *in vivo* but not *in vitro* which underlines the importance of the tumor microenvironment for therapeutic strategies. Phase I trials with recombinant anti-mesothelin immunotoxin were completed in patients with mesothelin-expressing tumors without evidence of non-manageable side effects; about a fourth of the treated patients developed anti-SS1P antibodies. In addition, a DNA vaccine with a single-chain trimer of HLA-A2 linked to human mesothelin peptides has been successfully used to prevent the growth *in vivo* of HLA-A2 positive human mesothelin-expressing tumor cell lines in HLA-A2 transgenic mice. These results suggest possible clinical translation of mesothelin-targeted therapy and ►DNA vaccines for immunotherapy of gynecologic cancers against mesothelin.

Finally, the specific binding of mesothelin to CA125 suggests that agents able to compete with or to block CA125/mesothelin-dependent cell attachment could prevent or delay the development of peritoneal metastasis.

Synonyms

Malignant mesothelioma

Definition

Mesotheliomas are tumors derived from mesothelial cells that form the membranes surrounding the lungs, pericardium and peritoneum. Mesotheliomas are highly aggressive malignancies, with a median survival of 9 months from diagnosis. The incidence of mesothelioma is higher in men than in women (8:1) and these tumors usually occur during the seventh and eighth decades of life. Mesothelioma is usually associated with occupational ►asbestos exposure, or to exposure to erionite, a mineral fiber that shares some physical characteristics with crocidolite asbestos. Studies have also linked this disease with a DNA tumor virus known as ►SV40, although this remains controversial. Moreover, genetic predisposition to mineral fiber carcinogenesis may contribute to multiple cases of mesothelioma within the same family. There are 2,000–3,000 cases of mesothelioma per year in the USA and more than 1,000 in England and Italy. The incidence of mesothelioma continues to increase in spite of measures adopted in the 1970s and 1980s to eliminate (Italy) or reduce (USA) the use of products containing asbestos.

Characteristics

Pathogenesis

Asbestos

►Cancer epidemiology studies and experiments performed in vitro and in animals have clearly linked exposure to crocidolite asbestos, a form of amphibole asbestos, and to ►erionite, a type of ►zeolite, to the development of mesothelioma. Other forms of amphibole asbestos, such as ►tremolite have also been linked to mesothelioma, but some studies suggest that the risk may be lower compared to ►crocidolite. Whether other forms of asbestos, such as antophyllite or chrysotile (the latter is also known as serpentine asbestos) cause mesothelioma is controversial. The mechanisms responsible for asbestos carcinogenicity have been recently linked to the secretion of ►TNF-alpha by mesothelial cells and ►macrophages exposed to asbestos, which in turn leads to ►NFκB activation. The activation of the NFκB pathway in mesothelial cells appears to allow these cells to survive the cytotoxicity and genetic damage caused by asbestos, and these damaged cells may proliferate into a mesothelioma.

Asbestos has been shown to induce the proto-oncogenes ►Fos and ►Jun, which encode ►AP-1 transcription factors that activate various genes critical in the initiation of DNA synthesis. The persistent induction of these transcription activators following asbestos exposure may enhance cell division and favor malignant growth. AP-1 activation is enhanced in mesothelial cells infected experimentally with SV40 and exposed to asbestos, and animal studies have confirmed that asbestos and SV40 can act as co-carcinogens in causing mesothelioma. Asbestos is a ubiquitous carcinogen. Therefore, virtually everyone may have some level of exposure. It is hypothesized that there is a threshold level of exposure above which the risk of developing mesothelioma increases. But the threshold is unknown, and individual genetic susceptibility and/or infection with SV40 may influence this threshold.

SV40

100% of hamsters injected in the pleural space develop and die of mesothelioma within 6 months, compared to 20% of those injected with asbestos, which develop mesotheliomas after about 2 years. SV40 can transform human cells in tissue culture, and mesothelial cells are transformed at a rate that is much higher than in other cell types tested. This effect appears to be related to the unusually high levels of the ►p53 tumor suppressor normally present in mesothelial cells. p53 binds and inhibits the SV40 oncoprotein large T antigen (Tag), thereby limiting viral replication. Thus, in these cells infection is not lytic, as observed in other human cell types. Instead, mesothelial cells are infected, and SV40 establishes a "parasitic" relationship within mesothelial cells, i.e., replicating without lysing the cells. SV40 has been detected in 6–60% of human mesotheliomas, and Tag has been shown to bind and inhibit the tumor suppressors p53 and the ►retinoblastoma protein, pRb. Microdissection, ►immunohistochemistry and in situ hybridization experiments have shown that SV40 is present in tumor cells and not in nearby stromal cells. Because different groups have reported different percentages of mesotheliomas containing SV40, and

some have failed to detect it at all, the overall contribution of SV40 to the incidence of mesothelioma remains unknown. In vitro and animal experiments have shown that asbestos and SV40 can be co-carcinogens and that SV40 infection may lower the threshold level of asbestos required for oncogenesis.

Although asbestos fibers induce cytotoxicity in mesothelial cells, cell survival activated by key signaling pathways may promote transformation. Activation of the ►AKT signal transduction pathway is one of the major ways in which cell survival is promoted, and SV40 has been shown to inhibit programmed cell death via AKT kinase activation in mesothelial cells exposed to asbestos. Activation of AKT has been observed in about 65% of mesotheliomas, which has therapeutic implications, because AKT signaling contributes to tumor aggressiveness, in part by mediating cell survival and reducing sensitivity to chemo- or radiotherapy. Thus, the AKT signaling pathway has been proposed as a novel therapeutic target to overcome mesothelioma resistance to conventional therapies.

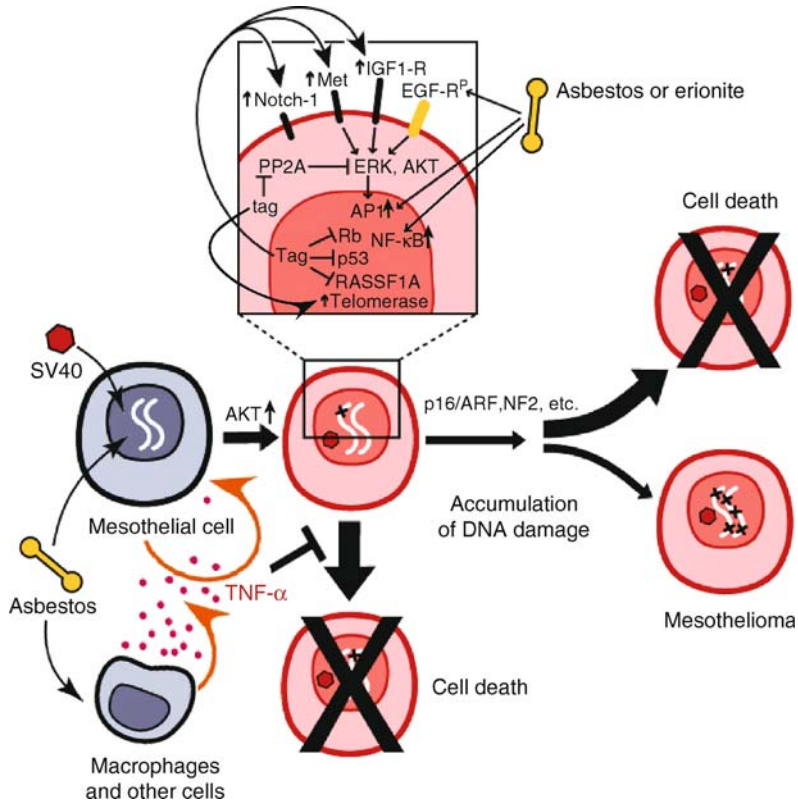
Chromosome Changes

In vitro studies have shown that human mesothelial cells acquire extensive numerical and structural chromosomal abnormalities shortly after exposure to low concentrations of asbestos fibers. SV40 can also cause genetic damage. SV40 Tag is known to be mutagenic and can cause point mutations, chromosome rearrangements and ►aneuploidy. While many of the DNA alterations caused by asbestos or SV40 will either be of no significance or lead to cell death, a few cells may develop perturbations of key cell cycle regulatory genes, leading to tumor formation and/or progression. Cytogenetic analysis has revealed multiple chromosome alterations in most human mesotheliomas. Although a specific chromosomal change is not shared by all mesotheliomas, several prominent sites of chromosomal loss have been identified. Deletions of specific regions in the short (p) arms of chromosomes 1, 3 and 9 and long (q) arm of 6, 13 and 15 are repeatedly observed. Loss of a copy of chromosome 22 is the single most consistent numerical change seen in mesotheliomas, and monosomy 4 and monosomy 14 are also common. These recurrent losses frequently occur in combination in a given tumor. Loss and/or inactivation of ►tumor suppressor genes residing in recurrent sites of chromosomal deletion are thought to contribute to the development of mesothelioma. ►Loss of heterozygosity (LOH) analysis has demonstrated high frequencies of allelic loss from 1p22, 3p21, 4q, 6q, 9p21, 13q13–14 and 15q11–15 (Fig. 1).

Tumor Suppressor Genes

Most mesothelioma cell lines exhibit ►homozygous deletion of the 9p21 chromosome region. ►*CDKN2A*, which encodes the alternative tumor suppressor gene products p16INK4a and p14ARF, appears to be the critically affected locus in this region. Genes encoding p15INK4b (CDKN2B) and methylthioadenosine phosphorylase (MTAP) are also frequently co-deleted with CDKN2A/ARF in these tumors, although whether CDKN2B and MTAP play a significant role in mesothelioma pathogenesis is uncertain at this time. The p16 ►INK4 protein binds to the cyclin dependent kinase CDK4 to inhibit the catalytic activity of the CDK4/cyclin D enzymes. Therefore, loss/inactivation of p16INK4a leads to cell cycle deregulation through the loss of a key inhibitor of G1/S progression. More than 80% of mesothelioma cell lines have homozygous deletions of one or more p16INK4a exons, and most of the remainder have greatly down-regulated expression of p16INK4a due to ►promoter hypermethylation. Immunohistochemistry studies suggest that loss of p16INK4a expression is a universal finding in mesothelioma specimens, and fluorescence in situ hybridization analysis has revealed absence or reduced copy numbers of the p16INK4a gene in most mesothelioma specimens. Collectively, these data suggest that loss of at least one copy of p16INK4a occurs in most of these tumors, with the remaining allele silenced by promoter hypermethylation. In a given tumor, all or a subset of cells may contain homozygous loss of p16INK4a, with these cells presumably having a proliferative advantage when placed into long-term culture. Importantly, alteration of p16INK4a appears to play a critical role in mesothelial cell tumorigenesis, since re-expression of p16INK4a in mesothelioma cells has been shown to result in cell-cycle arrest and programmed cell death, as well as inhibition of tumor formation or diminished tumor size.

Homozygous deletion of p16INK4a also leads, in most cases, to inactivation of p14ARF, because these two genes share exons 2 and 3, although their reading frames differ. The product of the p14ARF tumor suppressor gene is required for activation of p53 in response to the action of oncogenic proteins such as ►RAS. Unlike p14ARF, mutation of the p53 gene, ►TP53, is uncommon in mesothelioma and has been observed in a subset of tumors that retain the p14ARF locus. Since the product of the p16INK4a gene induces a G1 cell-cycle arrest by inhibiting the phosphorylation of ►pRb, homozygous loss of p14ARF and p16INK4a would collectively affect both the p53- and pRb-dependent cell regulatory pathways, respectively. In vitro studies have shown that adenovirus-mediated transfer of p14ARF in mesothelioma cell lines induces G1-phase arrest and apoptosis. Together, the available evidence suggests that alteration of either product of the CDKN2A locus, i.e., p14ARF or p16INK4a, contributes to the pathogenesis of mesothelioma. In a recent study, homozygous deletion of p16INK4a /CDKN2A was



Mesothelioma. Figure 1 Mesothelioma pathogenesis. Arrowheads indicate a stimulatory effect. Crossed bars indicate an inhibitory effect. The presence of asbestos or erionite leads to the release of TNF-α by mesothelial cells and macrophages. TNF-alpha causes NFκB activity that in turns protects mesothelial cells from the toxic effects of asbestos. This mechanism prevents asbestos-induced mesothelial cell death. Mesothelial cells that have developed genetic damage because of exposure to mineral fibers can now divide and occasionally progress to become a mesothelioma. In cells that survived asbestos exposure, asbestos induces autophosphorylation of the epidermal growth factor receptor (EGF-R), which activates the ERK kinases and leads to AP-1 induction and cell division. If the mesothelial cell is infected with SV40, large T antigen (Tag)-mediated activation and inactivation of the indicated oncogenic or tumor suppressor proteins, respectively, cause cell mitosis and genetic alterations. SV40 small t antigen (tag) inhibits phosphatase 2A (PP2A), which normally dephosphorylates and inactivates cellular kinases. This increases the stimulatory effect of asbestos on AP-1. Also, tag-induced telomerase activity promotes continuous cell growth. In addition, AKT, a critical regulator of cell survival, is also activated. Most cells exposed to SV40 and asbestos die due to apoptosis or cell lysis because of the effects of these carcinogens and because of the DNA damage they accumulate (X symbols in the nuclei). Occasionally, a cell that has accumulated numerous chromosomal changes and other genetic alterations escapes cell death to form a malignancy. Individuals exposed to both asbestos and SV40 may be at higher risk of mesothelioma when compared to individuals exposed to only one of these carcinogens.

shown to be a significant independent adverse prognostic factor in mesothelioma. Overexpression of aurora kinases was also found to be a significant independent adverse prognostic factor.

Although the ►neurofibromatosis 2 tumor suppressor gene, NF2, predisposes affected individuals primarily to tumors of neuroectodermal origin, somatic mutations of NF2 have occasionally been identified in seemingly unrelated malignancies. NF2 somatic mutations predicting either interstitial in-frame deletions or truncation of the NF2 gene product (►merlin) have been reported in 40–55% of mesothelioma cell lines. In many cases, it was possible to confirm the mutation in matched primary tumor DNA. Western blot analyses revealed complete absence of merlin expression in cell lines that exhibited alterations of the NF2 gene, suggesting that truncated forms of the protein are unstable. LOH analyses documented allelic losses of the NF2 locus in more than 70% of mesothelioma cases. All cases exhibiting mutation and/or aberrant expression of NF2 showed allelic losses, implying that inactivation of NF2 in mesothelioma occurs via a "two-hit" mechanism. One mechanism by which merlin acts as a tumor suppressor is by inhibiting the activity of p21-activated kinase (Pak), a downstream target of Rho GTPases Rac and Cdc42. Merlin has been found to

exert an antiproliferative effect, in part, via repression of Pak-induced cyclin D1 expression. Moreover, Pak is known to regulate motility in mammalian cells, which raised the intriguing possibility that merlin loss-of-function, due to biallelic inactivation of NF2, may contribute to invasiveness and/or metastasis in mesothelioma. Re-expression of merlin in NF2-deficient mesothelioma cells markedly inhibited cell motility, spreading and invasiveness. Expression of merlin attenuated the phosphorylation of ►focal adgesion Kinase, a key component of cellular pathways affecting migration and invasion, at a critical phosphorylation site and disrupted the interaction of FAK with oncogenic binding partners. Altogether, these findings suggest that merlin inactivation is a critical step in mesothelioma pathogenesis and is related, at least in part, with up regulation of FAK activity. Recently, merlin has also been shown to suppress cellular proliferation by inhibiting the activation of RAS. Merlin was found to counteract the ►ERM (ezrin, radixin, and moesin)-dependent activation of RAS, which correlated with the formation of a complex comprising RAS, ERM proteins, Grb2, SOS, and filamentous actin. Thus, part of the tumor suppressor function of merlin appears to be its interference with Ras- and Rac-dependent signal transfer.

Recent work has implicated the same set of tumor suppressor genes described above in mouse models of mesothelioma. Asbestos-exposed Nf2 heterozygous (+/−) ►knockout mice exhibited markedly accelerated mesothelioma formation compared with asbestos-treated wild-type littermates, and loss of the wild-type Nf2 allele, leading to biallelic inactivation, was observed in all of the asbestos-induced mesotheliomas from Nf2 knockout mice. As in the human disease counterpart, mesotheliomas from Nf2 knockout mice showed frequent homologous deletions of the *Cdkn2a* (*p16Ink4a/p19Arf*) locus and adjacent *Cdkn2b* (*p15Ink4b*) tumor suppressor gene, as well as reciprocal inactivation of the p53 gene, Tp53, in a subset of tumors that retain Arf. As in the human disease, mesotheliomas from Nf2 knockout mice also showed frequent activation of Akt kinase. Thus, this mouse model of environmental carcinogenesis faithfully recapitulated many of the molecular features of human mesothelioma and thus has significant implications for preclinical testing of novel therapeutic drugs. The involvement of similar somatic genetic and cell signaling perturbations in human MM and asbestos-exposed Nf2 knockout mice suggests that a specific set of molecular events cooperate in mesothelioma pathogenesis.

Diagnosis

Chest pain and accumulation of fluid in the pleura or abdomen are often the first symptoms. Radiological tests and/or cytology often reveal that the patient has a tumor and may raise the suspicion of mesothelioma, but the final diagnosis relies on thoracoscopy or laparoscopy and histological evaluation of the tumor biopsy. Because of their undifferentiated state, mesothelial cells can evolve along either an epithelial type or a fibroblastic type of differentiation. Thus, morphologically mesotheliomas are distinguished as epithelial and sarcomatous, the latter also known as fibrous or spindle cell mesothelioma. Sufficient sampling, however, will often reveal both components, thus the terminology of biphasic or "mixed type" mesothelioma. Epithelial mesotheliomas, especially when well differentiated have median survivals of 2 years or more; fibrous mesotheliomas have a median survival of 6 months from diagnosis and are resistant to therapy. Patients with biphasic mesotheliomas have a median survival slightly more favorable than patients with fibrous mesothelioma. Histologically, epithelial mesotheliomas must be differentiated from carcinomas of the lung and breast, biphasic mesotheliomas from synovial sarcoma and carcinosarcoma, and sarcomatous mesotheliomas, from other types of sarcomas. Electron microscopy (EM) reveals long branching microvilli in epithelial mesotheliomas and is very useful to distinguish these tumors from carcinomas. Immunohistochemistry also helps to distinguish mesotheliomas from carcinomas. All epithelial mesotheliomas stain diffusively and strongly positive for calretinin and ►WT1 (nuclear staining is specific, membranous staining is not), for keratin 7, Cam5.2, CK5/6 and pankeratin AE1/AE3 (membranous staining). All of these markers can also be found in various other tumors, including carcinomas, therefore the diagnosis of mesothelioma requires that the epithelial markers are negative. Mesotheliomas are negative for CEA, LeuM1 (CD15), BerEp4 (up to 5% of mesothelioma may show focal positivity with this marker), Moc31, TTF-1 and B72.3. Carcinomas are positive for some of these epithelial markers and are usually negative for calretinin and WT1. Sarcomatous mesotheliomas stain positive for ►cytokeratin, which distinguish them from other sarcomatous tumors of the pleura, and may also stain positive for WT1 and calretinin. All mesotheliomas are malignant. However, histologically malignant mesotheliomas have occasionally been associated with long survivals of years or even decades. Whether the latter should be called mesotheliomas is debatable. There are also some unrelated tumors called "benign mesotheliomas," which are histologically different from mesotheliomas and are clinically benign. It is unfortunate that the term mesothelioma is often used to identify these lesions, because it generates confusion and patient anxiety. Multicystic mesothelioma, also called multilocular peritoneal inclusion cyst, is a totally benign mesothelial lesion characteristically formed by multiple cysts arranged in grape-like clusters.

Adenomatoid mesotheliomas are benign mesothelial lesions of the genital system. Mesothelioma of the atrioventricular node is neither a mesothelioma nor a tumor. This lesion represents congenital heterotopia of the endodermal sinus in the atrioventricular node. Well-differentiated papillary mesothelioma is found more often in the abdominal cavity of young women. Histologically, it is formed by multiple papillary structures covered by cytologically benign mesothelial cells. The lesion is benign but there are cases in which several years after diagnosis the patient developed a true mesothelioma.

Clinical Approaches

To date, no therapy has been definitively shown to significantly influence the natural course of this tumor. Standard therapy with Alimta and ►cisplatin is associated with a prolonged survival of about three months. Patients with early stage disease are good candidates for surgical resection. Surgery should be performed by surgeons experienced with this type of procedure to reduce the risk of operative mortality, which in experienced hands is about 2%. Either pleurocotomy or extrapleural pleurectomy has the potential to cure very early disease. However, mesotheliomas are usually diagnosed at an advanced stage when curative resection is not possible. Chemotherapy has been disappointing to date, although new drugs (►Onconase for example) are presently being tested alone or in combination with conventional chemotherapeutic agents. The discovery of two serological markers, ►mesothelin and ►osteopontin, that are elevated in patients with mesothelioma has raised the possibility of screening individuals at high-risk of mesothelioma (e.g., asbestos workers) for early detection, which might be associated with a prolonged survival and possibly a cure. Prospective clinical trials are ongoing in Cappadocia Turkey, where there is a mesothelioma epidemic associated with ►erionite exposure and genetic predisposition, to validate these ►serum biomarkers. Moreover, clinical trials are planned to test among high-risk mesothelioma cohorts, the possible benefit of chemoprevention using Onconase, an RNAse inhibitor that has had beneficial effects in some mesothelioma patients in the absence of significant adverse side effects.

MET

Kyle Furge, George F. Vande Woude
Van Andel Research Institute, Grand Rapids, MI, USA

Definition

Met is a member of the ►receptor tyrosine kinase family. Like other members of this protein family, Met possesses a highly glycosylated extracellular ligand binding region, a hydrophobic membrane spanning region, an intracellular region that contains a tyrosine kinase domain, and a C-terminal multisubstrate binding site that mediates interactions with several signal transduction pathways upon receptor activation. Activation of receptor tyrosine kinases results from binding a protein growth factor. The growth factor that activates Met is hepatocyte growth factor/scatter factor, referred to as HGF/SF, as it was identified independently as both a growth factor for hepatocytes (HGF) and as a fibroblast-derived cell motility factor, scatter factor (SF). It was later discovered that HGF and SF were identical proteins and HGF/SF-Met signaling can induce different biological affects depending on the cell context. Since then, HGF/SF-Met signaling has been implicated in a variety of cellular responses including proliferation, motility, ►invasion, chemotaxis, and ►morphogenic differentiation. Through these actions, Met regulates a diverse series of biological processes ranging from lumen formation to neuronal development to ►cancer cell invasion and ►metastasis.

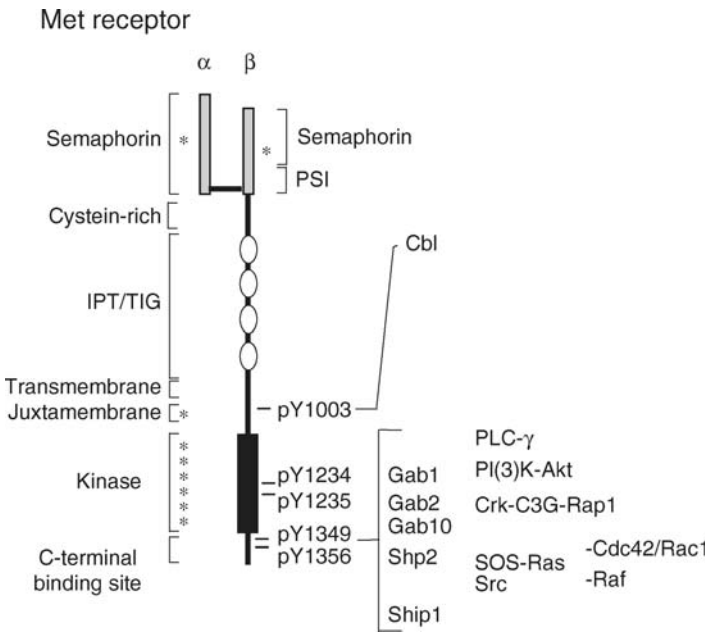
Characteristics

Met was identified in the early 1980s as an ►oncogene. A chromosome rearrangement resulted in the fusion of the N-terminal protein-protein dimerization motif of ►*tpr* (translocated promoter region) to the C-terminal tyrosine kinase domain of ►*met*. The resulting chimeric protein, Tpr-Met, has high constitutive tyrosine kinase activity and can potently transform

cells *in vitro*. Isolation of the ►*tpr-met* cDNA led to the identification of the full length Met receptor.

Human *met* spans over 120 kb of genomic sequence located on chromosome 7q31. The gene consists of 21 exons that when spliced together produce a primary mRNA transcript that encodes the complete receptor. Several *met* splice variants have been identified, but the physiologic role of these variants is not well understood. Mature, full-length, human Met is produced by proteolytic cleavage of a single 1408 amino acid, partially glycosylated precursor protein into an N-terminal α-chain, which is entirely extracellular, and a larger C-terminal β-chain (Fig. 1). The β-chain consists of an extracellular portion, a membrane spanning segment and an intracellular region that contains the tyrosine kinase domain and the C-terminal binding site. Similar to other receptor tyrosine kinases, such as the insulin receptor, the α and β-chains of Met are joined via a disulfide linkage and further glycosylated during transport to the cell surface. While at the cell surface, Met clusters together and may interact with cell ►adhesion molecules, such as ►cadherin, to help regulate cell-cell interactions.

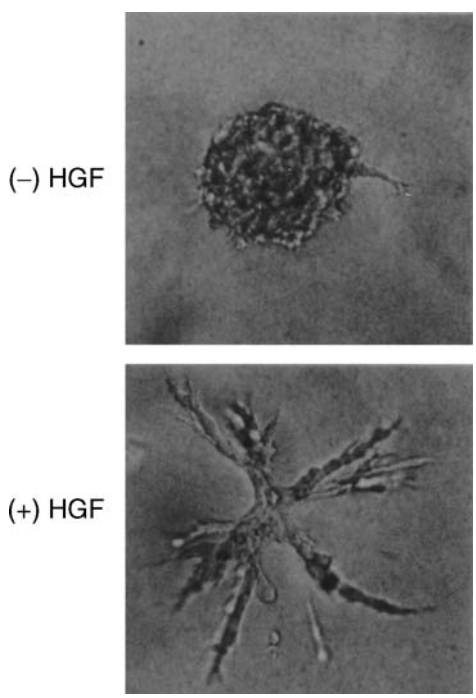
Met is normally expressed in the epithelial cells of several embryonic and adult tissues (kidney, liver, lung, skin, stomach and placenta). In contrast, HGF/SF expression is usually restricted to the surrounding mesenchyme (fibroblast stroma and other mesenchymal cells). Several aspects of organogenesis, such as tissue growth and morphogenic differentiation, are regulated by interactions between the organ epithelia and the surrounding mesenchyme. Endocrine mediated signaling between HGF/SF and Met is believed play an important role in regulating normal epithelial-mesenchyme interactions. If HGF/SF-Met signaling is inhibited by gene disruption in mice, the mouse embryos die in early gestation with several defects in liver and placental organogenesis. Furthermore, while not directly observed in the mouse mutants (partly due to the early embryonic lethality and partly due to compensation by other factors), HGF/SF-Met signaling has been implicated in regulating ►epithelial-mesenchymal transitions and other epithelial-mesenchyme interactions such as mammary gland duct formation, lung tubule formation and kidney development in organ culture models. In addition, several epithelial cell types undergo significant morphogenic



MET. Figure 1 The Met receptor tyrosine kinase stimulates multiple signal transduction pathways. The Met receptor is a membrane spanning α/β heterodimeric protein that binds the HGF/SF growth factor. The extracellular region of Met contains a ►SEMA domain (grey boxes), a ►PSI domain, and four tandem ►IPT/TIG domains (white ovals). The intracellular region of Met contains a tyrosine kinase domain (black box). Phosphorylation of tyrosine residues (-pY) within the kinase domain, following growth factor binding and receptor dimerization, activates the tyrosine kinase domain. Phosphorylation of the tyrosine near the membrane spanning region serves to inhibit the kinase activity of this receptor, though Cbl binding and subsequent receptor degradation. Phosphorylation of tyrosine residues in the C-terminal end of Met activates a multisubstrate binding site that mediates interactions with several adapter and signal transduction proteins to stimulate growth, motility, and morphogenic differentiation. Asterisks (*) indicate where missense mutations have been identified in various human tumors.

differentiation to form branched tubule structures complete with interior lumens when grown in a three-dimensional matrix and stimulated with HGF/SF (Fig. 2). While other growth factors such as ►epidermal growth factor receptor ligands (EGF) may induce proliferation and/or movement, HGF/SF is somewhat unique in its ability to induce all of the cellular responses required for ►branching morphogenesis.

However, HGF/SF-Met signaling is not exclusively involved in regulating epithelial morphogenesis. Met is also expressed in skeletal muscle and in the developing nervous system, and HGF/SF-Met signaling is required for the ►migration of myogenic precursors in limb bud formation and has been implicated in neuronal development. HGF-Met signaling also stimulates the proliferation of hepatocytes, renal epithelial cells and vascular endothelial cells, and increases the motility of both epithelial and vascular endothelial cells and may play a significant role in wound repair and tissue regeneration. The ability of HGF/SF to induce increased growth, motility and capillary-like tubule formation in vascular endothelial cells in vitro and to promote blood vessel formation in vivo suggests that Met may stimulate ►angiogenic processes as well.



MET. Figure 2 Met induced branching morphogenesis of cells grown in a three-dimensional matrix. Several epithelial cell lines (cell line C127 is shown) that express Met undergo significant changes in cellular morphology and three-dimensional organization following stimulation with HGF/SF.

Cellular and Molecular Features

Normal Met activation by HGF/SF is believed to occur through receptor dimerization and induction of ►transphosphorylation of tyrosine residues, which are critical for growth factor mediated signal transduction (Fig. 1). Much work has been done to determine which of the phosphorylated tyrosine residues in the intracellular region of Met (there are 16 of them) are important for stimulating cellular responses. Phosphorylation of two tyrosines located within the activation loop of the tyrosine kinase domain (amino acid positions 1234 and 1235 in human Met) greatly enhances the intrinsic kinase activity of the receptor and are critical for potent receptor activation. Phosphorylation of two closely spaced tyrosines at the C-terminal of Met (amino acid position 1349 and 1356 in human Met) generates a multisubstrate docking site that several adaptor proteins, including Gab1, Grb2, Shp2, and Shc, can bind. In turn, these adaptors recruit numerous signal transduction proteins including phosphotidylinositol-3-OH kinase (►PI3K), phospholipase C-γ (PLC-γ), the ►GTPases Ras, Rac1/Cdc42, ►Rap1, and others signaling molecules. Several assays that monitor HGF/SF-Met meditated cell proliferation, ►cell scattering and branching morphogenesis have been instrumental in identifying the signaling pathways that are responsive to Met activation. However, detailed analysis of which protein pathway mediates each of these cellular responses is complicated by prevalent pathway and ►receptor cross-talk [1, 2]. Generally, activation of the Ras and ►B-Raf signaling pathway via the Grb2/SOS complex is important for both cell proliferation and motility. Activation of PI3K is important for cell survival and prevention of ►apoptosis while activation of the Rac1/Cdc42 pathways and disassembly of ►E-cadherin/catenin complexes at the cell surface promotes loss of intercellular adhesion and gain of cell motility. Induction of branching morphogenesis likely requires all of these factors and additional factors downstream of Gab1, as overexpression of Gab1 can stimulate both cell scattering and branching morphogenesis in the absence of HGF/SF.

As several of the proteins activated by Met have also been implicated in tumor generation and progression, down-regulation of the activated Met signal is important to prevent hyperactivation of these protein pathways and subsequent cellular transformation. One important means of down-regulating growth factor receptors is degradation of the active receptors. ►Endocytosis can clear activated growth factor receptors either transiently, if they are recycled back to the cell surface, or permanently if they are sorted to the lysosome and degraded. Alternatively, activated growth factor receptors can undergo ►ubiquitination and subsequent degradation by the proteosome. For Met, ubiquitination is mediated in part by phosphorylation of a serine residue located

in the receptor juxtamembrane region (serine 1003 in human Met). Phosphorylation of this serine allows the binding of the Cbl E3 ubiquitin ligase. Binding of Cbl results in ubiquitination and degradation of the receptor.

Clinical Relevance

While Met plays several important roles in normal growth and development, abnormal Met signaling likely contributes to generation and progression of human tumors. As previously mentioned, Met was originally isolated as the constitutively activated oncoprotein Tpr-Met. However, Met missense mutations have been implicated in the cause of hereditary and sporadic human papillary ►renal carcinoma (HPRC). The missense mutations are located in the tyrosine kinase domain of Met and produce a constitutively active receptor that promotes tumor formation and/or progression (Fig. 1). Other missense mutation, in the kinase and other domains, have also been identified in ►gastric, hepatocellular, and other cancers. In the absence of an activation mutation, abnormal expression of Met and HGF/SF has now been identified in most solid tumors. A comprehensive table describing the different Met expression and sequence abnormalities in a wide spectrum of human cancers has been collected and can be found at http://www.vai.org/met/.

During tumorigenesis, Met can become constitutively activated by co-expression of HGF/SF in the same cell, forming an autocrine stimulatory loop. Numerous tumor types, including several different carcinomas (►lung, breast and others), sarcomas (osteosarcoma, ►Kaposi sarcoma, and others) and ►brain tumors (►glioblastoma multiforme), express Met and/or HGF/SF. Moreover, in model systems Met-HGF/SF-expressing cells are not only invasive *in vitro*, but also rapidly ►metastasize when injected into mice. Part of the mechanism behind the invasive phenotype of HGF/SF-Met expressing cells is upregulation of the urokinase proteolysis network. Induction of the proteolysis network following Met activation can degrade the surrounding extracellular basement membrane and facilitate invasion and metastasis.

Overexpression of Met is also observed in several gastric carcinoma cell lines as well as carcinomas of the lung, pancreas, thyroid, ►colon and stomach and is thought to participate in cell transformation and tumorigenicity. As HGF/SF has been found in tumor stroma and normal human serum it is possible that activation of Met in some of these cells may result from paracrine or endocrine stimulation. The paracrine model may be responsible for some ►breast cancers. Identification of HGF/SF and Met in breast cancer tumors is a strong negative prognostic indicator of reoccurrence and survival. The effects of HGF/SF in tumor progression may in part result from an increase in tumor ►angiogenesis. Invasive breast cancers that contain high levels of HGF/SF or brain tumors that are engineered to overexpress HGF/SF have increased microvessel density and increased levels of other vascular markers. Other effects, such as sustained proliferation and/or misregulated differentiation, may also contribute significantly to HGF/SF-Met mediated tumor growth/progression. As such, treatments that inhibit HGF/SF-Met signaling may be therapeutic in preventing the onset and progression of many cancer types and may also play significant roles in preventing cell metastasis and angiogenesis in these cancers.

MET, ^{11}C-Methionine

Definition

Amino acid (methionine) labeled with the positron emitter ^{11}C enabling detection of tumor manifestation sites (especially brain tumors) due to increased transport of amino acids.

►Positron Emission Tomography

Metaanalysis

Definition

A statistical technique where all data from all available studies of something are combined, regardless of data quality. The results of several case-control studies, or cohort studies or both, are combined to generate a summary measure of the odds ratio. The individual odds ratios are combined, but are weighted by some function of the variance of each odds ratio. The technique is used by researchers to get a maximum of statistical information without worrying about distortion in the results.

Metabolic Activation

Definition
Bioconversion of unreactive procarcinogens to reactive electrophiles through the action of Phase I and Phase II drug metabolizing enzymes.

►Carcinogen Macromolecular Adducts
►Tobacco Carcinogenesis

Metabolic Capability

Definition
An individual's ability to activate or detoxify absorbed chemicals.

►Biomonitoring

Metabolic Cooperation

Definition
Is the correction of a defect in a cell by the transport of the correct molecules from neighbor cells.

►Gap Junctions

Metabolic Detoxification

Definition
The process by which a carcinogen is converted to a form that is excreted without reacting with DNA.

►Detoxification
►Tobacco Carcinogenesis

Metabolic Polymorphisms

Definition
Are ►polymorphisms of genes encoding enzymes involved in the metabolism of carcinogens or anticarcinogens. These are predisposing gene variations with relatively low penetrance that may result in a moderate increase in the risk of specific cancers. The scientific interest in such genes (e.g. sequence alterations in genes encoding ►cytochrome p450, null-polymorphisms for genes encoding ►glutathione S-transferase, or phenotypic alterations of the activities of N-acetyltransferases) is based on the possibility of identifying population subgroups that are at elevated risk of developing environmentally induced cancer.

Metabolic Polymorphisms and Cancer Susceptibility

Wolf C. Roland
Biomedical Research Centre, University of Dundee, Dundee, UK

Definition
The genetic basis for inter-individual differences in cancer susceptibility.

Characteristics
History
The term ►pharmacogenetics (synonym ►pharmacogenomics) has been used for approximately the last 40 years to describe genetic or inherited factors that determine individuality in response to drugs and other therapeutic agents. In studies starting in the mid-1950s, it became apparent that some individuals were hypersensitive to certain drug treatments. This sensitivity was also observed within other family members and was subsequently shown to be an inherited trait. Early epidemiological studies were focused on the drugs used in the treatment of malaria and tuberculosis. Inter-individual variation in the ability to metabolize these drugs was subsequently attributed to inherited differences in the enzymes glucose 6-phosphate dehydrogenase, which generated sensitivity to the anti-malarial drug primaquine, and in the N-acetyl transferases, which generated sensitivity to antitubercular drugs such as isoniazid. The term pharmacogenetics was first coined by Vogel in the late-1950s. In the 1960s and 1970s there was increased interest in this research area and many genetic variants in a range of genes involved in determining drug response were identified.

Important Genetic Factors

In order to elicit a therapeutic response, a drug first needs to enter the circulation, i.e. to cross the gastrointestinal (GI) tract. We now know that the entry of many drugs into the body is regulated by a multi-gene family of drug transporters (sugar ABC transporters) that have the capacity to pump drugs in and out of cells. In addition, the GI tract also expresses enzymes (Sugar ABC transporters) that can metabolize and inactivate drugs. Variability in the level of expression or activity of these drug metabolizing enzymes is therefore an important determinant of circulating drug concentrations. Once a drug enters the body it is transported to the liver, which is the main organ involved in drug metabolism. Nearly all therapeutic agents are subject to hepatic metabolism before they are eliminated from the body. The rate of metabolism will determine the biological half-life of the drug. Hepatic drug metabolism is carried out by many multi-gene families of proteins. Of key importance are the ►cytochrome P450-dependent monooxygenases that convert lipophilic drugs into more water-soluble products predominantly through hydroxylation reactions. Many anti-cancer drugs are substrates for one or more of the P450 monooxygenases (Table 1). The products of these P450-catalyzed reactions are further conjugated to co-factors such as glucuronic acid or sulfate, further increasing their water solubility and facilitating elimination in the bile or via the kidneys in the urine. The rate of uptake of drugs into liver cells and their rate of metabolism is therefore of central importance in determining therapeutic outcome. Finally, the capacity of a drug to exert its therapeutic effect is determined by its concentration at the target cell and the level of expression and activity of specific receptors and enzymes with which it interacts (Fig. 1).

Pharmacogenetic variability resulting in altered drug response can involve any or all of these pathways, and allelic forms (►alleles) of many drug metabolizing enzymes, drug transporters and drug receptors are now known to exist within the population. In addition to individual genetic variability, for certain types of therapy genetic variability of the target cell will also be a key determinant of therapeutic efficacy. This is particularly the case in cancer chemotherapy where the genetics of the tumor cell is often a major additional determinant of the effectiveness of drug therapy. This is also of central importance in the chemotherapy of infectious agents and in the use of antibiotics, antiviral agents, etc. In these cases, drug resistance is well characterized and has been ascribed to altered patterns of gene expression in the target organism many of the factors that determine drug response in these organisms are the same as those that determine circulating drug levels in man, i.e. drug transporters and drug metabolizing enzymes.

Relevance of Pharmacogenetics

The importance of pharmacogenetics is well illustrated by studies of genetic variability in the cytochrome P450 system, in particular in cytochrome P450 CYP2D6. In the 1970s, clinical trials identified a group of people who were hypersensitive to certain types of drug including sparteine, an anti-hypertensive agent which is prescribed for the treatment of arrhythmia and

Metabolic Polymorphisms and Cancer Susceptibility. Table 1 Anticancer P450 drugs

Metabolic Polymorphisms and Cancer Susceptibility. Figure 1 Factors which can limit the therapeutic effectiveness of drugs.

debrisoquine. It was subsequently shown that this variability in response was inherited and that between 5 and 10% of the white population, "poor metabolizers," do not express a functional form of CYP2D6. In later studies, the molecular basis of this polymorphism was elucidated and shown to be due to gene-inactivating changes in CYP2D6 DNA. This subsequently allowed the development of DNA-based tests to identify individuals with this metabolic defect. Cytochrome P450 CYP2D6 is responsible for the metabolism of up to 25% of therapeutic drugs, including a large number of the drugs used in the treatment of psychiatric illness (Table 2). This polymorphism has now been attributed to aberrant metabolism, and disposition of many of the drugs has been associated with adverse drug reactions induced by many of these agents.

In addition to gene inactivating alleles of CYP2D6, certain individuals contain multiple copies of this gene, which generates an "ultra-rapid metabolizer" phenotype. These individuals metabolize and eliminate drugs at a much faster rate than the rest of the population and as a result the desired therapeutic effect is not achieved. Therefore, pharmacogenetic variability can result in adverse drug reactions, exacerbated drug toxicity or lack of therapeutic effect.

Metabolic Polymorphisms and Cancer Susceptibility. Table 2 CYP2D6 drugs used in the treatment of psychiatric, neurological and cardiovascular disease

Psychiatric disease	Amitriptyline, clomipramine, clozapine, desipramine, fluvoxamine, fluoxetine, haloperidol, imipramine, levomepromazine, nortriptyline, olanzapine, paroxetine, perphenazine, thioridazine, tranylcypromine, zuclopenthixol
Cardiovascular disease	Alprenolol, amiodorine, flecainide, indoramine, mexiletine, nimodipine, oxprenolol, propranolol, timolol

Ethnic Differences

The genes and proteins that determine therapeutic outcome following drug treatment evolved to protect us against the effects of toxic environmental chemicals. Part of the genetic variability in response to these agents may be explained by different populations needing a different spectrum of enzymes to cope with their particular environment and diet. This is exemplified by the large variability in the distribution of pharmacogenetic polymorphisms between different ethnic groups. For example, there is an allele of CYP2D6 that is present in 40% of the Chinese population but is not found in the white population. This allele generates a slower metabolizer phenotype and explains why a high percentage of the Chinese population cannot tolerate doses of drugs prescribed routinely in Europe and the Western world.

Future

The current aim of research in pharmacogenetics is to exploit the information from the Human Genome Project to identify novel variant forms of genes, to establish their functional significance and to apply these usefully in the clinical environment. The ability to identify rapidly and test for variant sequences of genes will allow pharmacogenetic testing to be generally applied in medical practice so that optimal drug doses can be used. This is particularly the case in the treatment

of diseases such as cancer where inappropriate drug dosing is often life threatening and the success or failure of treatment may depend on the genetics of the tumor cell. It is anticipated that with the identification of pharmacologically important genetic variations within the population, rapid tests will be available to hospitals that will allow clinicians to prescribe drugs at optimal dose regimens or to decide whether specific drug therapies will be effective for individual patients.

Metabolism

Definition

Metabolism comprises the chemical reactions that occur in the cell; individuals can be:

- Extensive metabolizer: an individual with the ability to metabolize drugs at a rate that falls within the normal population distribution.
- Poor metabolizer: an individual with a genetically determined deficiency in their ability to metabolize certain drugs.
- Ultra-rapid metabolizer: an individual with increased expression of a particular gene. Drugs which are substrates for these genes are metabolized very rapidly, often requiring increased doses to achieve any therapeutic benefit.

Metaplasia

Definition

Is a reversible change in which a given differentiated epithelial or mesenchymal cell type is replaced by another differentiated cell type. However, persistent metaplastic lesions sometimes evolve to malignancy, and represent preneoplastic lesions. Thought to be an adaptive response to chronic irritation, achieved by a reprogramming of stem cells. Some dysplasias and cancers arise in metaplasias, hence the metaplasia – dysplasia – carcinoma sequence.

►Preneoplastic lesions
►Stem Cell Plasticity

Metastasis

Ruth J. Muschel
Radiation Oncology and Biology, University of Oxford, Oxford, UK

Synonyms

Tumor spread; Secondary tumor

Definition

Metastasis is the growth of a tumor at a site not physically connected to the primary tumor.

Characteristics

The presence of metastasis is a key feature in determining the prognosis and the treatment strategy for any cancer patient. The probability that a patient will have a metastasis varies widely depending upon the type of cancer. Squamous cell carcinoma of the skin rarely metastasizes, but squamous cell carcinoma of the lung frequently does. An important part of the clinical workup for every patient who is diagnosed with cancer is an evaluation for metastasis. The presence and extent of metastases are a critical component of clinical Staging systems that clinicians use to choose appropriate therapy and to judge prognosis.

Metastases follow different routes that can be broadly classified into three. One is metastasis to the regional lymph nodes or lymphatic metastasis. This involves colonization of draining lymph nodes. The second is travel via open cavities such as the pleural cavity or abdominal cavity (peritoneal metastases). The third is travel though the blood stream or hematogenous metastasis.

Metastasis also has organ specificity. Different types of cancer have characteristic tendencies to metastasize to particular sites. For example adenocarcinoma of the proximal colon tends to metastasize to the regional lymph nodes within the colon and distantly to the liver. In contrast prostatic adenocarcinoma tends to metastasize to its regional lymph nodes and to the bone. Other cancer types are more promiscuous – for example breast cancer spreading frequently to the regional lymph nodes, lung, liver, brain, bone, ovaries and adrenals. Or carcinomas of the lung metastasizing, to the lung liver, brain, bone, skin and adrenals. While metastases are often identified at the time of initial diagnosis, they can also become manifest many years after therapy. This feature of tumor dormancy is particularly notable in breast cancer where metastases can emerge after 10 or 20 years. In many cancer types this long dormancy is less likely.

Mechanisms

Cancer is now recognized to be a disease not only consisting of the tumor, but involving the whole organism. Metastasis depends upon properties of the host as well as alterations in the tumor cells. The notion that either the host or the tumor might play a role was first expressed as the soil and seed hypothesis. This frequently cited expression posits that metastasis might be due to alterations in the tumor cell or alternatively to adaptations of the host that now allow the tumor cell to migrate and colonize a distant site. Many years of research now reveal that both mechanisms operate. The study of the molecular changes underlying metastasis is only in its beginnings so that much of the information lacks certainly and detail.

In keeping with the seed hypothesis however are findings showing that the patterns of gene expression in metastatic tumor cells differ from those in non-metastatic cells. The expression of these genes may help explain organ specificity and may potentially be targets for therapeutic intervention. One question that has been addressed in recent years is to ask whether the gene expression profile of a tumor might predict whether that tumor was likely to have formed metastases. If so the genes involved might also be identified from such a screen. In fact in many studies such gene profiles could be identified, but in general the actual genes identified were not the same in different studies. These profiles are now being refined and additional components such as hypoxia and wound healing profiles are being integrated into the original findings. In some cases the genes found were those made by the host stromal response to the tumor rather than by the tumor itself. Furthermore in comparing metastatic to non-metastatic tumors in experimental models, the acquisition of new gene expression patterns were clearly seen. Thus the actual situation is more complicated than the original hypothesis that the tumor might express all of the genes needed for metastasis very early in its development. It seems most likely that some of the necessary genes are present early on, but that others are acquired during progression. Finally some of the identified gene products appear to have been synthesized by host responses. Thus host responses may have several roles some of which impede tumor growth, but others that stimulate metastasis.

Invasion is a necessary precursor to metastasis. For the tumor cell reach a distant lymph node or other organ or cavity, it must first separate from the primary tumor mass itself, either as a single cell or as a clump. *In vivo* imaging in mice has revealed such tumor cell migration through tissue adjacent to the tumor itself. Tumor cells in the blood or lymph then can disseminate. In some systems host cells such as macrophages, fibroblasts and the coagulation system are required for efficient invasion and metastasis, findings in keeping with the soil concept of tumor metastasis.

The microenvironment of a tumor also appears to play a role in metastatic potential. For example hypoxic tumors are more likely to metastasize than tumors with more normal oxygen levels. The infiltrating cells in a tumor may also affect its metastatic potential including fibroblasts, macrophages, and NK cells. For metastasis to the lymph nodes there is some debate about the importance of new host lymphatic channels within the tumor. Recent data raise the exciting hypothesis that the new channels are generated in the lymph nodes themselves.

The contribution by host cells is perhaps most well understood in the formation of bone metastasis in which

tumor cells that are successful in establishing themselves in bone synthesize factors such as parathyroid hormone related protein that activate osteoblasts to produce factors such as RANKL that stimulate osteoclasts that release tumor growth factors setting up a complex positive feedback loop. The elements of this loop then form targets for bone metastasis specific therapy.

Thus potential targets for therapy are being identified, many of which will be organ specific. Less clear are the factors that cause tumors to become metastatic in the first place. While genetic mutations clearly drive tumor progression and malignancy, which changes affect metastasis are less clear. Both tumor cell factors and external factors appear to lay a role.

Metastasis Signaling

Kent Hunter
Laboratory of Population Genetics, CCR/NCI/NIH, Bethesda, MD, USA

Definition

Molecular pathways that cancer cells use to break away from a primary tumor, penetrate into lymphatic and blood vessels, circulate through the bloodstream, and develop into in a distant cell colony (►metastasis) in normal tissues elsewhere in the body.

Characteristics

Metastatic tumor cells interact with a variety of cell and tissue types in their journey that leads them from being a neoplastic cell within a primary tumor to developing into a clinically detectable secondary carcinoma. These cells are therefore required to modulate a multiplicity of signal transduction pathways in order to respond to the ►microenvironment to successfully colonize a distant site. Many metastasis-associated genes, both those that promote and those that inhibit the process of tumor progression, have been found to be components of important signal transduction pathways involved in controlling normal cellular responses.

The Process of Metastasis

Metastasis is the process by which cancer cells escape from a primary tumor and establish discontinuous secondary lesions elsewhere within an organism. It is an extremely complex process that likely involves interactions with many tissues and cell types. To successfully form a metastatic lesion, primary tumor cells must complete a series of sequential steps. First, the cells in the primary tumor must activate pathways that enhance cellular ►motility to enable them to escape from the primary tumor mass. The metastatic cells must be able to invade through the ►extracellular matrix that surrounds the primary tumor. In addition, they must escape from their tissue of origin into vasculature or lymphatic compartments, or in some cases penetrate neighboring body cavities (e.g. peritoneum, pleura). During and after infiltration into these structures, tumor cells must be able to survive hematogenous sheer forces and exist in an anchorage-independent manner and avoid ►anoikis, the apoptotic program that is activated when epithelial cells become detached from the underlying tissue architecture. Once the cells have successfully transited throughout the body, they must arrest in a secondary site, either by receptor-mediated adhesion to specific vascular endothelial cells or by mechanical trapping of the large cancer cells in narrow capillary beds. After the cells have taken up residence in the secondary site they must adapt to the novel microenvironment and avoid local immunological responses, and must develop the ability to proliferate into a clinically relevant secondary tumor. Failure to successfully navigate any of these steps results in failure to complete the metastatic cascade.

The TGF-β Pathway and Other Well Established Metastasis Signaling Networks

One of the most extensively characterized signaling pathways demonstrated to be involved in metastasis is that involving transforming growth factor-β (►TGF-β). TGF-β, rather remarkably, appears to play apparently opposing roles in tumor progression, and its effect upon tumor cells appears to be related to the phase of tumorigenesis. In early stage lesions, it represses tumor growth by inducing cell-cycle arrest and programmed cell death (►apoptosis). However, in the latter stages of tumorigenesis it actually enhances tumor cell invasiveness and metastatic dissemination. An important process induced by TGF-β with regards to tumor cell invasiveness and metastatic capacity is ►epithelial-mesenchymal transition (EMT). EMT involves the progressive lose of epithelial molecular characteristics

by tumor cells of epithelial origin, and the development of more mesenchymal molecular expression patterns. These changes ultimately lead to tumor cells developing more invasive characteristics including loss of the necessity for cell-cell contacts and enhanced motility.

The origins of the effects that TGF-β has upon tumor progression and EMT are currently subject to much debate. However, characterization of the complex signaling networks induced upon TGF-β activation has greatly improved our understanding of the role that this molecule plays in the process of metastasis. It is becoming clear that dysregulation of components of the TGF-β signaling pathway, and the functional relationships between this pathway and other signaling networks, are crucial in regards to tumor progression. TGF-β signaling in the latter stages of tumor progression involves TGF-β binding to its receptors TGF-βRI and TGF-βRII, followed by subsequent activation of a class of transcriptional co-regulators known as ►SMAD, which in turn activate transcription and influence cell behavior. Furthermore, the EMT effects induced by late-stage TGF-β signaling appears, at least in part, to be a result of interaction between TGF-β receptors with the regulator of epithelial ►cell polarity and ►cell junction assembly, Par6, a member of the ►Par gene family. Specifically, it seems that TGF-β-induced EMT is a result of phosphorylated Par6 causing the ►ubiquitination of the small ►GTPase RhoA by E3 ligase SMURF1, and the subsequent proteosomal degradation of RhoA, which results in loss of tight junctions and stress fibers. Other proffered mechanisms for the role of TGF-β in tumor progression include the observation that TGF-β appears to regulate other metastasis-associated genes including those encoding PTHrP, CTGF and IL-11, all of which are factors shown to induce bone metastasis by inducing osteoclast differentiation and subsequent ►osteolysis. Additionally, TGF-β induces angiogenesis by up-regulating angiogenic factors including ►vascular endothelial growth factor-A (VEGF-A) and ►angiopoietin-1.

Another relatively well described metastasis signaling pathway is that involving ►hepatocyte growth factor (HGF) and its associated tumor cell receptor, the ►receptor tyrosine kinase (RTK) ►Met, a pathway that has been shown to be a mediator of tumor invasiveness. The critical molecule in this respect appears to be the product of the *Met* gene, which is frequently up-regulated in a wide variety of cancers through germline and somatic mutation. Activation of Met induces cell scattering and invasive growth, and in addition to being activated by its "classical" ligand HGF, it is also appears to selectively interact with a number of other molecules. For example, Met can interact with and phosphorylate the cell adhesion molecule $\alpha_6\beta_4$ integrin, which creates docking sites for additional adaptor molecules and signaling effectors. This in turn can enhance the invasiveness and ability of tumor cells to metastasize induced by HGF in a manner that is independent of the integrin's adhesion activity. In addition, Met also cooperates with the ►hyaluronic acid receptor ►CD44 to enhance pro-metastatic signaling.

Signaling Pathways Involved in Cytoskeletal Remodeling

The cytoskeleton and its associated signaling molecules have also been demonstrated to be important components in the process of metastasis. The cytoskeleton is responsible for the underlying architecture of the cell, and dynamic restructuring of the cytoskeletal elements is one of a number of cellular mechanisms that must be manipulated by a neoplastic cell residing within a primary tumor to enable it to become capable of not only surviving but replicating within a distant secondary organ to become a clinically relevant metastatic lesion. For example, ►cytoskeletal remodeling is essential for cell motility, a process that is integral to metastasis. Tumor cell motility is facilitated through a number of cellular mechanisms, but typically involves the formation of cytoskeletal actin projections on the mobile edge of the cell known as ►lamellipodia and ►invadopodia. Also, morphological reshaping of a tumor cell during its travels is an integral aspect of the metastasis, and this again necessitates remodeling of the cytoskeleton.

Due to the apparent importance of these functions in tumor dissemination, it is not surprising that a number of metastasis-associated genes are involved in cytoskeleton biology. A significant number of signaling pathways are induced by interaction with adjacent cells and contact with the extracellular matrix during tumor cell migration. These signals are transmitted through the plasma membrane by a variety of integral membrane proteins, including adhesion factors such as the ►integrin family, the hyaluronic acid receptor CD44, cadherins and growth factor receptors. Signals resulting from these interactions are passed through the interior of the cell through linker molecules, such as ►ezrin and ►merlin, the products of the *Vil2* and *Nf2* genes, respectively. Examination of the known cellular processes that involve ezrin reveals that it appears to be an integral component of signaling networks whose constituents include a variety of previously identified metastasis-associated molecules. Therefore, unlike many other previously identified metastasis-associated molecules, dysregulation of ezrin functionality might well be a common point of origin for many of the challenges that a proto-metastatic cell must overcome in order to progress towards completion of the metastatic cascade. Ezrin directly interacts with the cytoplasmic tail of CD44, a highly alternatively spliced molecule implicated in metastasis. CD44 is thought to have a role in cell migration in invasive tumors and is known to induce a number of intracellular signaling pathways. Increased expression of CD44 correlates with increased

invasiveness in ►osteosarcoma. In addition, ezrin associates with Met, and since both of these molecules have been implicated in modulation of cell motility, ezrin might play an important role in mediating invasion. Stimulation of the CD44 receptor also results in both up-regulation and activation of c-Met. Recent evidence has also demonstrated that these proteins cooperate in signaling through the ►MEK/ERK pathway through the ezrin/radixin/moesin (ERM)-binding domain of CD44. ►ERM proteins link adhesion molecules to filamentous actin and participate in membrane and cytoskeletal remodeling during cell migration. Ezrin is likely to play an important role in signals integration during the development of the invasive phenotype.

Ezrin functions as a conduit and linker connecting metastasis-associated cell surface proteins to other molecules in the interior of the cell. ERM activity is regulated by a combination of phosphorylation and phospholipid binding, which in turn are thought to be mediated by the small GTPase Rho. ERM proteins bind to RhoGDI, a negative regulator of Rho activity, and induce the dissociation of RhoGDI and inactive Rho, which permits Rho to become active by exchanging its bound GDP for GTP. Over-expression of ezrin might therefore result in amplification of metastasis-associated signaling originating from plasma membrane molecules through the Rho-associated signal transduction pathways by sequestering negative regulatory molecules. The importance of activation of the Rho signal transduction pathway in metastasis has been proven in at least two tumor types. Over-expression of RhoC activity enhances the metastatic capacity of ►melanoma cells while dominant negative mutants suppress metastases. Dominant negative expression of RhoA reduces the metastatic capacity of highly metastatic cells. In addition, loss of the Rho regulatory gene RhoGDI2 has been implicated in metastatic progression in ►bladder cancer.

Additional evidence of the importance of signaling through cytoskeletal-based pathways comes from recent studies on ►germline susceptibility to metastasis. Mouse genetics and human epidemiological studies have identified the small GTPase molecule ►SIPA1 as an important metastasis molecule. SIPA1 has been shown to negatively regulate ►Rap1, which has been suggested to act at the crossroads between cadherin and integrin signaling. Rap1 is involved in a variety of integrin-related biological processes, including ►immunological synapse formation, ►macrophage ►phagocystosis, ►chemokine-induced adhesion and trans-migration of leukocytes, lymphocyte and dendritic cell homing to peripheral organs, ►platelet adhesion and aggregation as well as adhesion of cell lines to extracellular matrix components. These studies suggest that Rap1 plays an important role in the transmission of signals from the interior of the cell to the integrin signaling machinery. The role of Rap1 in the internalization of signals through the integrin-dependent signaling pathway is still unclear at this time.

Adhesion Molecules and Metastasis Signaling

►E-cadherin is an important adhesion molecule that is known to negatively regulate CD44 and suppress CD44-mediated invasion and branching morphogenesis. Loss of E-cadherin or deregulation of its function by disruption of its downstream signaling is thought to promote metastatic dissemination. Recent studies have demonstrated that disruption of ezrin result in suppression of branching morphogenesis and vasculogenic mimicry, suggesting that imbalance of signals from CD44 and E-cadherin due to ezrin over-expression might substitute for E-cadherin loss.

In addition to E-cadherin associated cell-cell interactions, interactions between tumor cells and the extracellular matrix (ECM), which are usually mediated by integrins, are also thought to be important in metastatic progression. The role of integrins in metastasis is more complex, with some integrin complexes promoting dissemination and others having potentially inhibitory roles. It has been postulated, however, that integrins are mediators in anchorage-independent cell survival and that disruption of integrin signaling may significantly contribute to tumor cell survival in the circulation and in the unfamiliar microenvironment that disseminated tumor cells will encounter at secondary sites. Consistent with this, studies have demonstrated that suppression of ezrin expression correlates with decreased survival of osteosarcoma cells. The origins of this differential survival was then investigated by determining the relative importance of the ►Akt and ►MAP kinase signaling pathways in this process since these have previously been implicated in ezrin-mediated inhibition of anoikis and in the early steps of metastases, respectively. Intriguingly, survival was partially rescued by over-expression of activated p44/42 MAP kinase, but not Akt, suggesting that ezrin-mediated cell survival either bypasses Akt or operates through an alternative anti-apoptotic pathway. Importantly, apoptosis has been demonstrated to be an important mediator of metastatic inefficiency.

Rap1 also plays an important role in cadherin signaling and function, including intercellular contacts mediated by adherens junctions. Loss of Rap1 function results in loss of adherens junctions and may play an important role in the disruption of normal epithelial contacts that accompany tumor cell migration and invasion. The importance of these cell-cell contacts in the metastatic process is further highlighted by the fact that re-expression of the ►metastasis suppressor ►Brms1 results in restoration of adherens junction formation in tumors and a decrease in metastatic

capacity, while leaving tumorigenicity intact. The mechanism by which Rap1 functions in adhesion is likely complex. Rap1 primarily exerts its effects in ►endosomal compartments and has been implicated in vesicular trafficking. As a result, it may function in the intracellular recycling machinery and/or plasma membrane targeting of recycled or newly generated cadherins or other adhesion molecules to sites of cell-cell or cell-matrix attachment.

Perspectives and Summary

Metastasis signaling pathways are diverse in their origins and extremely complex in their natures and their intricacies, which reflect the highly multifaceted character of metastasis. The fact remains that approximately 90% of cancer deaths are a direct consequence of metastatic dissemination of cancer cells, and most currently available therapies are still directed towards treating the primary tumor. One of the key elements that could lead to major improvements in the currently unacceptably high levels of cancer-related morbidity and mortality will therefore be to discern how and why a neoplastic cell within an isolated primary lesion is able to disseminate to a distant organ and grow into a clinically-relevant secondary tumor.

At the core of this problem are the mechanisms by which tumor cells, the stroma both at the primary and secondary site, and the immunological system interact to produce the observed pathophysiological phenomena. The manner in which each of these cell/tissue types behave and interact with each other is ultimately a consequence of the intra- and inter-cellular signaling pathways that are induced through these interactions. If researchers are able to more fully appreciate these processes then in is likely that ►anti-metastatic therapies might arise as a consequence, and examples of this knowledge can be applied to the development of clinically-relevant treatments is are being seen with increasing frequency. For instance, initial animal-based studies using soluble Met ►decoy receptors or a soluble version of TGF-βRII have proven encouraging and it is hopeful that these may be developed further to become clinically-applicable treatments. However, the fact remains that to better address the problem of metastasis, we will be required to develop a more comprehensive understanding of all biological aspects of this complex process.

Metastasis Suppressor Gene

Danny R. Welch, Alexandra C. Silveira, Douglas R. Hurst, Kedar S. Vaidya
Department of Pathology and Comprehensive Cancer Center, University of Alabama at Birmingham, Birmingham, AL, USA

Definition

A metastasis suppressor gene blocks metastasis without blocking tumorigenicity. The suppressing activity could be the result of alterations at any of the steps in the multi-step metastatic cascade.

Characteristics

Although the definition of a metastasis suppressor gene would at first appear straightforward, it is important to emphasize the distinctions between tumorigenesis, tumor progression, invasion and metastasis. This section will briefly highlight the key aspects of those differences, but readers are encouraged to refer to individual entries for a more complete understanding of the terms.

Tumorigenesis refers to the ability of cells to proliferate continuously in the absence of persistent stimulation by triggering carcinogenic agent(s). Tumor progression is the evolution of already tumorigenic cells (populations) towards increasing malignancy. Invasion is the migration of tumor cells away from the primary tumor mass. This process can involve the breakdown of physical barriers (e.g., basement membranes) by secretion of proteinases (i.e., protein-degrading enzymes). Metastasis is the process by which a tumor cell(s) spreads to other sites in the body and establishes a secondary tumor colony. The process is complex and involves many steps (i.e., the metastatic cascade).

The genetics of metastasis can be conceptualized as consisting of two components; positive and negative regulators. The positive regulators (i.e., metastasis promoting genes) drive metastasis formation. These genes, when expressed, enhance the ability of cells to complete one or more steps in the metastatic cascade. An example is the MMPs (matrix metalloproteinases) that are involved in enzymatic breakdown of basement membrane matrices. It is important to note that most metastasis

promoting genes are neither necessary (because of redundancy) nor sufficient (because of the multiple steps in the metastatic cascade) to confer metastatic competency upon cells. Two genes, ►RAS and ►MEK1, however, do confer both tumorigenic and metastatic potential upon NIH3T3 cells, which are murine cells established in culture and are often used for analyzing growth parameters of tumor cells.

In contrast, metastasis suppressor genes inhibit metastasis. Since metastasis requires cells to complete every step in the metastatic cascade, these genes can block any step(s) in the process. The first metastasis suppressor gene was discovered in 1989. Since that time several candidate genes have been identified. To date, more than 20 have been shown to suppress metastasis in vivo – ►BRMS1, cadherin-11, caspase-8, CD44, claudin-1, claudin-4, CRSP3, connective tissue growth factor (CTGF), gelsolin, ►E-cadherin, N-cadherin, KAI1 (►KAI1/CD82 metastasis suppressor), ►KiSS1, RECK, RhoGDI2, Src-suppressed C kinase substrate (SSeCKs), JNKK1/MKK4, MKK6, MKK7, ►NME1/Nm23-H1, RKIP, Drg-1 and TXNIP.

The role of metastasis suppressors is context dependent: the ability to suppress varies by cancer type and mode of action. They vary in the step(s) of the metastatic cascade inhibited. Each metastasis suppressor regulates by manipulating specific biochemical functions. Several affect signaling cascades that are involved in cell survival, growth, and motility. JNKK1/MMK4, MKK6, and MKK7 are involved in stress-activated signaling pathways while both Nm23 and RKIP inhibit the mitogenic ERK pathway. RhoGD12, SSeCKs, and gelsolin regulate cell motility through the Rho/Rac signaling pathway. Others modulate cell-cell or cell-matrix interactions. Claudins-1 and -4 are structural components of tight junctions. Cadherins E, N and -11 mediate cell-cell adhesion and may play a role in inhibiting cell migration. Proteins that modulate cell-matrix are important in regulating the interaction of cells with the surrounding tissue. The secreted protein CTGF and the tetraspanin KAI1 are both involved in integrin signaling. RECK negatively regulates some MMPs that are responsible for remodeling stroma while CD44 binds hyaluronic acid, a key component of extracellular matrix.

There is cross-talk among many of the intra- and inter-cellular signaling pathways. BRMS1 is involved in restoring gap junctional communication between cells, down-regulating the PI3K-Akt survival pathway, and remodeling chromatin to regulate transcription. Caspase-8 is a proapoptotic enzyme that links integrin function to apoptosis by effecting intergrin-mediated cell death. The role of some metastasis suppressors have yet to be defined in terms of function but are rather defined in terms of regulation. Drg-1 is known to be regulated by PTEN, an inhibitor of the Akt-cell survival pathway. CRSP3, TXNIP, and KISS1 form a metastasis suppressor pathway where CRSP3 regulates TXNIP which in turn regulates expression of KISS1, a secreted neuropeptide.

Metastasis suppressor genes and metastasis promoting genes are analogous to tumor suppressor genes and oncogenes, but there are important distinctions. Tumor suppressor genes dominantly inhibit tumor formation when wild-type expression is restored in neoplastic cells. By definition then, metastasis would also be suppressed (since the cells are non-tumorigenic). Metastasis suppressor genes, on the other hand, block only the ability to form metastases. Restoring expression of a metastasis-suppressor yields cells that are still tumorigenic, but are no longer metastatic.

How are Metastasis Suppressor Genes Identified?

Two general approaches have been used to identify metastasis-controlling genes. The first involves comparison of gene expression in poorly or nonmetastatic cells with matched metastasis-competent cells. The specific techniques employed are differential display and subtractive hybridization. The second takes advantage of clinical observations that identified nonrandom chromosomal changes that occur during tumor progression. This information localized the gene(s) from which cloning could commence. Based upon karyotypic patterns observed in human cancers, additional metastasis suppressor genes to those listed above are hypothesized to exist. However, the identities of the specific genes have yet to be determined.

Clinical Relevance

The existence of genes and gene products that block metastasis implies that the metastasis could be theoretically controlled by agents that regulate these genes or mimic their behavior. Differential expression also implies that measurements of metastasis suppressor expression might predict prognosis. In general, expression of metastasis suppressors predicts good prognosis, increased survival and decreased likelihood of developing metastasis. There are exceptions however. The therapeutic potential of metastasis suppressors has not yet been realized.

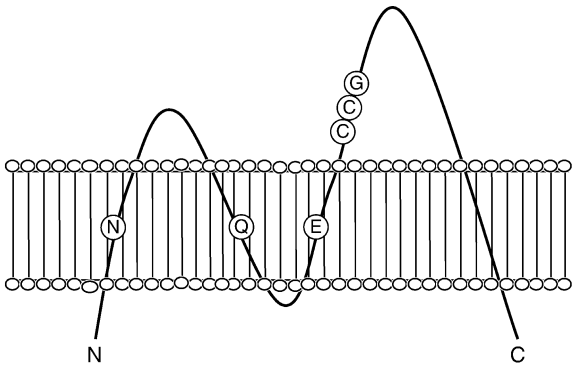
Synonyms

Tetraspanin; Transmembrane 4 superfamily protein; KAI1; CD82; 4F9; C33; IA4; R2

Definition

KAI1/CD82 is an ubiquitously expressed type III transmembrane protein or tetraspanin that functions as a ►metastasis suppressor for a variety of solid malignant tumors, an inhibitor of cell movement, and a costimulator in immune cells.



Metastasis Suppressor KAI1/CD82. Figure 1
Schematic presentation of KAI1/CD82. KAI1/CD82 protein contains a N- and a C-cytopasmic domain, two extracellular domains, one cytoplasmic intercellular loop, and four transmembrane domains. As depicted, the highly conserved CCG motif is located in the large extracellular domain, and three highly conserved polar residues are embedded in the transmembrane regions.

Characteristics

KAI1/CD82 glycoprotein contains 267 amino acid residues and belongs to tetraspanin superfamily. As a member of the tetraspanin family, it has a 11-residue cytoplasmic tail at the N-terminus and a 12-residue tail at the C-terminus region consisting of 11 and 12 amino acids, respectively, and a 4-residue intercellular loop between the second and third transmembrane domains (Fig. 1). The tails and loop forms the intracellular face of KAI1/CD82. It also contains two extracellular loop, known as large extracellular loop (LEL) and small extracellular loop (SEL), and four transmembrane domains (Fig. 1). Based on the sequence homology, the LEL is divided into two regions: variable and constant. The variable region usually mediates the heterogenous protein–protein interaction, while the constant region is predicted to be responsible for the dimerization of tetraspanins. The variable region of LEL of KAI/CD82 contains six cysteine residues that form three pair disulphide bond crucial for the correct folding of the protein. This variable region also contains three N-glycosylation sites, and the glycosylation was reported to be important for KAI1/CD82's ►motility-inhibitory activity. The constant region of KAI1/CD82 LEL likely contains the structural elements needed for the function of KAI1/CD82, since lack of this region KAI1/CD82 can no longer suppress cell ►migration. Little is known about the function of SEL of KAI1/CD82. Evidence from the studies of other members of tetraspanin superfamily suggests that the SEL may be important for the optimal folding of LEL. KAI1/CD82 contains four highly conserved transmembrane domains. The transmembrane domains are needed for the proper posttranslational maturation and the cell surface targeting of KAI1/CD82. For example, it was reported that a truncated KAI1/CD82 which lacks transmembrane domain 1 cannot reach to the cell surface and remains in endoplasmic reticulum. In addition, studies on other tetraspanins suggest that the transmembrane domains are needed for the intramolecular hydrophobic interactions and are likely to be important for the intermolecular associations between tetraspanins in the tetraspanin web or tetraspanin-enriched microdomain. In addition, KAI/CD82 contains three polar residues in its transmembrane domains. The exact biochemical role of these polar residues remains unknown. There are multiple cysteine residues located at or near the intracellular portions of KAI1/CD82. These intracellular cysteine residues are constitutively palmitoylated, and the palmitoylation of KAI1/CD82 are needed for the motility- and invasiveness-inhibitory activity of KAI1/CD82. The YRSV sequence at the C-terminal tail of KAI1/CD82 falls into the category of tyrosine-based endocytosis and sorting motif. The functional relevance of this motif remains to be determined though KAI1/CD82 is found to be internalized and trafficking between different endosomal and lysosomal compartments.

KAI1/CD82 is a component of tetraspanin web or tetraspanin-enriched microdomain, in which tetraspanins associate with other transmembrane proteins such as integrins and immunoglobulin superfamily proteins and intracellular signaling proteins such as kinases and G-proteins. Recent studies also demonstrated that KAI1/CD82 interplays with lipid rafts or ganglioside/cholesterol-enriched membrane microdomains, probably

through the gangliosides enriched in lipid rafts or caveolae.

KAI1/CD82 was initially identified as a metastasis suppressor of prostate ►cancer based on the fact that it only suppresses the formation of metastatic lesion but not the growth of primary tumors. Later studies indicated that KAI1/CD82 actually suppresses the ►progression of a variety of solid tumors. In normal tissues, KAI1/CD82 is ubiquitously expressed, while in invasive or metastatic cancer lesions, KAI1/CD82 expression is constantly reduced or lost. In prostate, gastric, colon, cervix, breast, skin, bladder, lung, pancreas, liver, and thyroid cancers, an inverse correlation between KAI1/CD82 expression and the invasive and metastatic potentials of cancer has been frequently observed. In cancer patients, the presence of KAI1/CD82 expression predicts a better prognosis, whereas the diminution or loss of KAI1/CD82 expression is constantly found in the clinically advanced cancers. Consistent with these observations, Reintroduction of KAI1/CD82 into cancer cells inhibits cell migration and ►cancer invasion in vitro and suppresses ►cancer metastasis in animal model. In addition to the suppression of ►cancer progression, it has been reported that the overexpression of KAI1/CD82 in cancer cells causes ►apoptosis.

Mechanism

The exact mechanism responsible for KAI1/CD82 as a tumor metastasis suppressor is unknown. Several lines of evidence support the notion that KAI1/CD82 may suppress cancer metastasis by primarily inhibiting cancer cell migration and ►invasion. There are several hypotheses regarding the mechanism by which KAI1/CD82 inhibits cell movement. Firstly, KAI1/CD82 may inhibit cell movement by regulating the functions of its associated proteins. The associated proteins of KAI1/CD82 include tetraspanins, integrins, immunoglobulin superfamily proteins, growth factor receptor, intracellular signaling proteins, etc. KAI1/CD82 negatively regulates integrin-dependent cell signaling and cell extracellular matrix ►adhesion. For example, KAI1/CD82 overexpression has been demonstrated to diminish the cell adhesion primarily mediated by laminin-binding integrins. KAI1/CD82 also downregulates the activity of Src family kinases and the formation of $p130^{CAS}$–Crk complex, both are important for cell motility. By associating with epidermal growth factor receptor (EGFR), KAI1/CD82 desensitizes the EGF signaling possibly by accelerating the endocytosis of EGFR and recompartmentalizing the plasma membrane EGFR. KAI1/CD82 expression also reduced the activation of c-Met. Second possible mechanism for suppression of cell movement by KAI1/CD82 is that it directly initiates signal to inhibit cell motility. This hypothesis is based on the observation that the engagement of KAI1/CD82 with its antibody triggers intracellular signaling in immune cells.

In contrast to the notion that KAI1/CD82 suppresses metastasis by directly inhibiting cell motility, a recent discovery opens a completely different avenue to understand KAI1/CD82's metastasis-suppression mechanism. In that study, the extracellular domains of KAI1/CD82 were found to directly bind to ►Duffy antigen receptor for chemokines (DARC), a cell surface protein expressed on the vascular endothelium. The receptor–counter receptor engagement leads to the inhibition of tumor cell proliferation and the induction of cellular ►senescence. In DARC knockout mice or in the absence of DARC, the metastasis suppression activity of KAI1/CD82 was compromised, whereas in DARC wild type and heterozygous littermate mice or in the presence of DARC, KAI1/CD82 inhibits the pulmonary metastasis of the implanted tumor. The proposed mechanism was that, when tumor cells enter into blood vessel after dislodge from primary tumors, only the cells that expressed KAI1/CD82 interact with DARC expressed on the surface of endothelium. This KAI1/CD82–DARC interaction transmits a senescence signal to the tumor cells, resulting in growth arrest and subsequently the suppression of metastasis. The cells that do not express KAI1/CD82 will escape and enter the circulation and subsequently establish metastasis.

Definition

The term metastatic colonization refers to the final biological events required for cancer cells to form a clinically relevant ►metastasis at a ►secondary cancer site(s). It is a distinct process in which disseminated cells survive and subsequently proliferate to form overt metastases within this site.

Characteristics

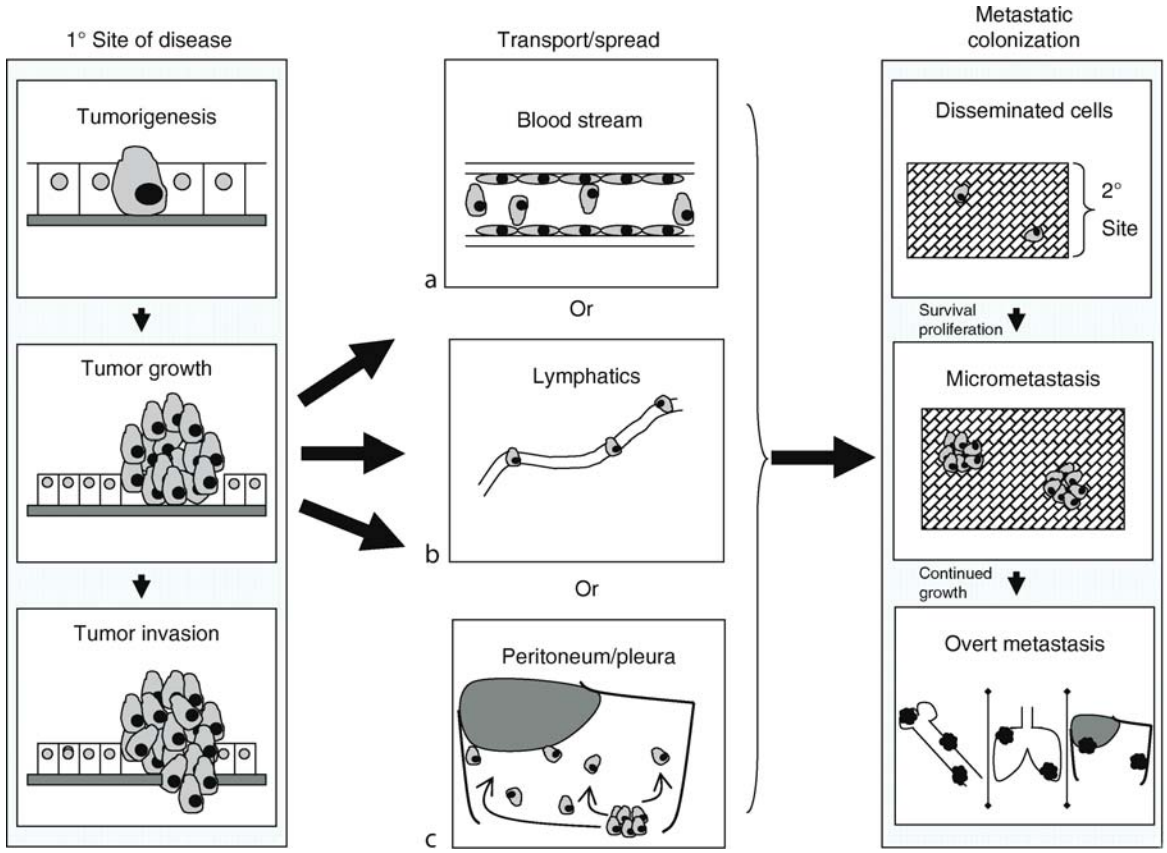
In order to successfully form overt metastases in a secondary organ/site, cancer cells must successfully complete all the steps of the metastatic process, as summarized in Fig. 1. A cancer cells must first survive, grow, and eventually break free from its ►primary cancer site. Figure 1 shows a single layer of cells upon a ►basement membrane (thick grey line), with a single tumorigenic cell. During progressive growth, tumor cells can acquire malignant properties which enable them to invade through the basement membrane and escape the primary site. Cells must then move to a discontinuous secondary site, often via blood vessels or lymphatics in order to travel to other places within the body. After surviving this process, cancer cells arriving at favorable secondary sites can survive and grow into overt metastases. In some instances, such as in the lining of the abdominal cavity and the chest cavity (peritoneum and pleura, respectively), cancer cells can be shed into those spaces and spread to other sites within those spaces without blood vessel or lymphatic transport (Fig. 1).

Once cancer cells disseminate to and lodge within an end organ, they must survive and proliferate within their new environment, often referred to as ►microenvironment. Historically, earlier events in the metastatic process, such as invasion, were considered the more critical steps in cancer metastases, setting the timing and efficiency of metastasis formation. However, work over the last decade has identified metastatic colonization as a biological phenomenon that plays a key role in the regulation and clinical progression of metastatic disease. Cancer cells can be detected in secondary sites as single disseminated cells or as small clusters of cancer cells, termed ►micrometastases, throughout the course of clinical disease. However, in many instances, these cells either remain functionally dormant (►Dormancy) at their secondary sites or are unable to survive and complete the process of metastatic colonization to become clinically apparent metastases.

Metastatic colonization therefore often begins well before symptom presentation or radiographic evidence (by CT scan, MRI, bone scan, etc.) of metastasis is apparent. A clear clinical example of this latency is seen in prostate cancer. Many men with surgically removed prostate cancer are found to have an elevated ►prostate specific antigen (PSA) levels, which is a protein only made by prostate tissue that can be monitored by a blood test, sometimes years after their surgery, despite having no symptoms or evidence of metastatic disease. In most of these instances, the elevated PSA is a marker of microscopic prostate cancer metastases colonizing the bone that have yet to present as clinically significant metastatic disease.

Distinct molecular, cellular, and biological mechanisms regulating metastatic colonization are only now being examined experimentally. There is mounting evidence that interactions between the colonizing cancer cells and their new microenvironment play a key role in regulating the process of metastatic colonization. In the 1880s the physician Stephen Paget, used the analogy of a seed growing in favorable soil, to propose a role for interactions between dispersed cancer cells (the seeds) within the microenvironment of the target organ (the soil) to explain why cells from certain types of cancers have a predilection for particular secondary organ; for example, why prostate cancer cells often metastasize to bone. Molecular insights into the process of metastatic colonization are being elaborated by studies of ►metastasis suppressor proteins. These proteins can specifically inhibit cancer metastasis, while having no effect on primary tumor formation or growth. Functional studies of several of these regulatory proteins, including Map Kinase Kinase 4 (MKK4), demonstrate that they can regulate and inhibit cancer metastasis by directly targeting the process of metastatic colonization.

Metastatic colonization is clearly a clinically relevant phenomenon. In the United States alone, there are projected to be ~1.4 million new cancer diagnoses, and 559,000 cancer deaths in 2007. Cancer is second to heart disease in overall mortality in the U.S. and, in fact, is the primary cause of death in persons under 85 years of age. The majority of patients who die from cancer succumb to metastatic disease. In addition to mortality,



Metastatic Colonization. Figure 1 Simplified schematic of the metastatic process. Metastatic disease begins with the formation of a primary tumor and its subsequent growth and invasion into the surrounding environment. In this example a single cell in becomes cancerous and subsequently replicates and is not subject to normal growth control mechanisms. To successfully metastasize, a cancer cell (or group of cells) must disassociate from the primary tumor, then travel to a discontinuous site via: (a) blood supply, (b) regional lymphatics, or, (c) through the peritoneal/pleural space (in cases such as intraperitoneal/pleural metastasis). In the final process of metastatic disease, termed *metastatic colonization*, the cancer enters its secondary site, where it must survive and proliferate to eventually form overt metastatic disease (such as in the bone, lung, and peritoneum).

cancer metastasis, and metastatic colonization specifically, is a major cause of cancer related morbidity, including pain, fatigue, shortness of breath, etc. Frequently, as is the case in prostate cancer, metastatic colonization is suspected often well before the detection of overt metastatic disease. Keeping disseminated cancer cells dormant or quiescent as long as possible is a key goal of cancer control strategies. As the biology of metastatic colonization becomes clearer, it will likely become a major target for cancer therapeutics.

Metastatic Tumors

Definition

Tumors that arise in one organ and spread to other organs, adjacent or distant.

►Cardiac Tumors
►Metastasis

Methazolastone

►Temozolomide

Methemoglobinemia

Definition

Is a blood disorder in which the body cannot recycle hemoglobin after it is damaged. It is a disorder characterized by the presence of a higher than normal level of methemoglobin in the blood. Hemoglobin is the oxygen-carrying molecule found in red blood cells. Methemoglobin is a form of hemoglobin that does not bind oxygen.

►Polycythemia

Methotrexate

Definition

Is a structural analog of folic acid and, thus, also referred to as an antimetabolite. It strongly inhibits dihydrofolate reductase resulting in inhibition of synthesis of thymine nucleotides and subsequently of DNA synthesis. Methotrexate is used as an anticancer drug. ►Amplification of the gene encoding dihydrofolate reductase results in drug ►resistance.

►Membrane Transporters

Methoxyestradiol

Hyunsuk Shim
Department of Hematology/Oncology, Winship Cancer Institute, Emory University, Atlanta, GA, USA

Synonyms

2-Methoxyestradiol; 2ME2; 2ME; Panzem

Definition

2-Methoxyestradiol (2ME2) is a naturally occurring substance that is produced when the hormone ►estradiol is processed (metabolized) in the body. 2ME2 prevents both tumor growth (►antiproliferative) and the formation of new blood vessels that tumors require to grow (►antiangiogenic). Although 2ME2 is derived from estradiol, it binds poorly to ►estrogen receptors. On the contrary, it binds directly to a protein called tubulin, which is involved in cell division. This binding not only interferes with cell division (cell growth), but also inhibits hypoxia inducible factor-1 (HIF-1), an important factor for tumor cell survival. Additionally, 2ME2 has been reported to preferentially kill tumor cells, sparing normal cells, by causing ►reactive oxygen species (ROS) accumulation in cancer cells.

2ME2 under the trademark Panzem® (EntreMed Inc., Rockville, MD) is currently in Phase I/II clinical studies to investigate its safety and efficacy and evaluate its drug-like properties in patients with advanced cancers.

Characteristics

Mechanisms

2-Methoxyestradiol (2ME2) is a naturally occurring estradiol metabolite that has a low binding affinity for estrogen receptors (ER) α and β, consistent with its low estrogenic activity. In addition, the antiproliferative and ►proapoptotic effects of 2ME2 have been shown to be independent of ERs, since cell lines devoid of ER were sensitive to 2ME2 and ER antagonists did not attenuate 2ME2's inhibitory effects. The biological activity of 2ME2 was first reported by Seegers et al who found it to cause ►mitotic accumulation and the formation of abnormal mitotic spindles in cells, regardless of ER status. These effects were confirmed by others in diverse cancer cell types and in ►endothelial cells.

The antiangiogenic activity of 2ME2 was reported over a decade ago. 2ME2 inhibits the ►proliferation, ►migration and ►invasion of endothelial cells *in vitro* and has antiangiogenic effects in several *in vivo* models. Unlike most antiangiogenic agents, 2ME2 targets both proliferating endothelial cells and tumor cells, leading ultimately to the initiation of ►apoptosis. 2ME2 also has indirect antiangiogenesis effects mediated through inhibition of ►HIF-1 expression in tumor and endothelial cells. HIF-1 is a proangiogenic transcription factor that interacts with ►hypoxia response elements (HREs) to stimulate transcription of multiple proangiogenic genes including, most notably, ►vascular endothelial growth factor (VEGF). In addition, HIF-1-targeted genes also include genes involved in cell proliferation, survival, invasion and drug resistance. Due to its role in several key events of cancer progression, HIF-1 is an attractive molecular target for cancer therapy. 2ME2 inhibits the expression of HIF-1 in cancer cells lines. The effects of 2ME2 are dose-dependent and occur in cells exposed to

both normoxic and hypoxic conditions. The 2ME2-mediated decrease in cellular HIF-1 levels leads to inhibition of its nuclear translocation, inhibition of VEGF transcription and a decrease in VEGF secretion. The activity of 2ME2 on HIF-1 is expected to inhibit the transcription of over 60 genes that have been identified as HIF-1 target genes. 2ME2 does not inhibit HIF-1 transcription or protein stability but rather appears to act by inhibition at the level of translation. The effects of 2ME2 on HIF-1 are not limited to cancer cells: under hypoxic conditions, 2ME2 also downregulates HIF-1 protein levels in ►human umbilical vein endothelial cells (HUVEC). Thus, 2ME2 not only directly inhibits endothelial and tumor cell proliferation leading to ►apoptosis; it also inhibits HIF-1-mediated HREs that are directly tied to ►angiogenesis, proliferation, survival and ►metastasis. Important studies link the ability of 2ME2 to inhibit HIF-1 with its ►microtubule-depolymerizing effects. The effects of 2ME2 on microtubule disruption and inhibition of HIF-1 are not unique. Other microtubule-disrupting drugs, such as ►paclitaxel and ►vincristine, also cause similar effects and these data are consistent with the reported antiangiogenic effects of microtubule disruption, either stabilization or depolymerization. Cell lines with mutations in the paclitaxel-binding site remained sensitive to 2ME2, demonstrating that the two agents do not bind to the same site on tubulin. Rather, 2ME2 binds directly to the ►colchicine binding site of the ►tubulin protein, thereby ►inhibiting polymerization. This disruption not only interferes with the ►mitotic spindle apparatus, but also inhibits HIF-1 translation and its nuclear translocation.

The inhibitory effects of 2ME2 on both cancer cells and endothelial cells involve the activation of apoptotic cascades. In multiple cancer cell lines and in endothelial cells, 2ME2 increases the expression of death receptor 5 (DR5), a member of the tumor necrosis factor (►TNF) death receptor family. Activation of the extracellular domain of DR5 by its ligand, TNF-related apoptosis inducing ligand (►TRAIL), initiates signals through the death adapter protein ►FADD in the intracellular death domain to activate ►caspase-8, an effector caspase. The effects of 2ME2 on DR5 upregulation were confirmed *in vivo* in an ►orthotopic ►xenograft model using therapeutic doses of 2ME2. The expression of dominant-negative FADD significantly inhibited 2ME2-induced apoptosis, suggesting that this apoptotic pathway plays an important role in 2ME2-mediated apoptosis. In addition to the DR5 pathway of apoptosis, 2ME2 has been reported to mediate apoptosis through activation of the c-Jun NH_2-terminal kinase (►JNK). In myeloma cells, 2ME2 causes JNK phosphorylation and translocation to mitochondria, where it initiates a decrease in mitochondrial membrane potential and the release of two key apoptotic modulators, ►cytochrome c and second mitochondria-derived activator of caspase (Smac). The ability of 2ME2 to activate JNK is not limited to myeloma cells. Breast, prostate, hepatic and colorectal cancer cell lines respond to 2ME2 by rapid JNK activation. In 2ME2-sensitive ►pancreatic cancer cell lines, 2ME2 causes cytochrome c release and Bax translocation from cytosol to mitochondria. Thus, in diverse cell types, 2ME2-mediated cytotoxicity involves activation of the mitochondrial apoptotic pathway. Furthermore, the effects of 2ME2 have been shown to be independent of ►p53 status because 2ME2 was equally effective against cell lines with wild-type or mutant p53.

2ME2 was also shown to preferentially kill tumor cells, while sparing normal cells, by causing the accumulation of ►reactive oxygen species (ROS) in cancer cells. Inhibition of the mitochondrial electron transport chain by arsenic trioxide, an antineoplastic medicine, enhanced ROS generation and increased its anticancer effect when combined with 2ME2.

Clinical Aspects

EntreMed, Inc. (Rockville, MD) has formulated 2ME2 as an orally-administered liquid suspension (Panzem® NCD) using NanoCrystal® Colloidal Dispersion (NCD) technology to enhance the bioavailability of 2ME2 in patients. NCD is a proprietary technology of Elan Drug Delivery (Elan) that is currently used in multiple marketed pharmaceuticals. The NCD technology produces nanometer-sized particles, which are up to 500 times smaller than particles manufactured by conventional milling techniques. While ►Phase I and II clinical trials in 171 patients with a prior capsule formulation showed evidence of biological activity, the newer formulation increased bioavailability 5–10-fold to levels at which optimum antitumor activity was observed in preclinical studies.

Studies with ►xenograft and metastatic cancer animal models indicate that 2ME2 targets both the tumor and the tumor vasculature in sarcomas and melanomas. In an orthotopic breast tumor model, 2ME2 caused microtubule depolymerization and the formation of aberrant mitotic spindles in both tumor cells and endothelial cells. Using non-invasive imaging and histological evaluation in a preclinical orthotopic glioma tumor model, 2ME2 treatment resulted in a dose-dependent reduction in tumor size. Tumor burden in the brain was significantly reduced following 2ME2 treatment, as determined by magnetic resonance imaging (MRI). Further histological examination of the 2ME2-treated tumors demonstrated a dose-dependent decrease in acetylated tubulin, a marker of microtubule disruption, consistent with 2ME2 causing tumor inhibition through interfering with microtubules. In this preclinical study, 2ME2 also led to a significant improvement in tissue oxygenation, which may result in improved responsiveness to therapy, and a decrease in HIF-1.

This drug is potentially well suited to ►glioma treatment because of the abundance of neovasculature, and the positive association between high expression of HIF-1 and tumor grade in glioma. The ability of 2ME2 to initiate microtubule changes *in vivo* at therapeutic concentrations suggests that these effects may play critical roles in its antiangiogenic and antitumor activities. Additionally, preclinical models show that 2ME2 has potential therapeutic applications in inflammatory diseases such as rheumatoid arthritis.

Panzem® is currently in Phase I/II clinical studies to investigate its safety, efficacy and ►pharmacokinetics. The results from two Phase Ib studies of Panzem® NCD in patients with advanced cancer conducted at the University of Wisconsin Comprehensive Cancer Center and the Indiana University Cancer Center identified a maximum tolerated dose at one site with fatigue as the dose limiting toxicity and determined a recommended Phase II dose. Since January 2006, the Company has commenced five additional clinical studies with Panzem® NCD. These include: (i) a Phase II clinical trial in ►glioblastoma multiforme (GBM) patients at the Duke University Medical Center Brain Tumor Center; (ii) a Phase Ib study of Panzem® NCD in combination with paclitaxel (Taxol®) in patients with metastatic breast cancer, also being conducted at the Duke University Medical Center; (iii) a Phase II multi-site study in combination with Avastin® in metastatic carcinoid tumor patients; (iv) a multi-center Phase II study in patients with hormone refractory ►prostate cancer; and (v) a multi-center Phase II study in patients with recurrent or resistant epithelial ►ovarian cancer. Additional Phase II studies under consideration include breast cancer, renal cell cancers, and ►multiple myeloma.

Methylation

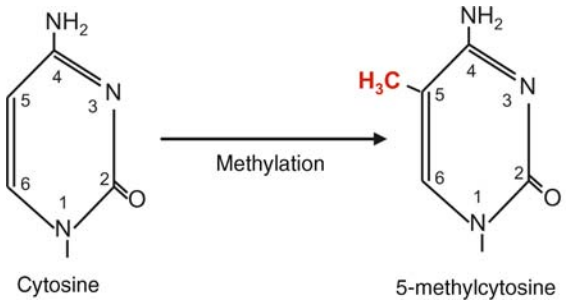
Christoph Plass
German Cancer Research Center (DKFZ), Heidelberg, Germany

Definition

An epigenetic modification of DNA is the addition of a methyl (CH3) group to position 5 of a cytosine residue. The majority of methylation events in humans occur on cytosines that are located next to a guanine (5′-CpG-3′ dinucleotides).

Characteristics

DNA methylation results from the addition of a methyl (CH3) group to position 5 of a cytosine (Fig. 1). The addition of a methyl group by DNA methyltransferases is an ►epigenetic modification to DNA that is maintained after cell division and does not change the DNA sequence. 5′-CpG-3′ dinucleotides are not uniformly distributed in the human genome. ►CpG islands are short stretches of DNA, usually located in promoter regions of genes, with an unusually high GC content and a significantly higher frequency of 5′-CpG-3′ dinucleotides compared to the rest of the genome. It is well accepted that DNA methylation is involved in gene regulation. Inhibition of transcription factor binding by methylation of the target sequence was the first mechanism identified. This mechanism is limited to a subset of transcription factors that contain



Methylation. Figure 1 Cytosine and 5-methylcytosine.

5′-CpG-3′ dinucleotides in their recognition sequence. A second mechanism is the binding of methyl-CpG-binding protein complexes on proteins (MeCP1 and MeCP2) to methylated DNA. Transcription can then be repressed by either the inhibition of transcription factor binding or the recruitment of histone deacetylases (HDACs). HDACs mediate the deacetylation of lysine residues in the N-terminal tails of histones and thus cause an increase in compaction of the chromatin that makes the DNA less accessible for the transcriptional machinery.

The establishment of normal DNA methylation patterns is a tightly regulated process of significant importance in many developmentally regulated pathways.

- Early embryonic development in mice is characterized by a genome wide demethylation in the early cell divisions (8-cell stage) to the blastocyst stage. The methylation pattern is re-established during implantation by a wave of de novo methylation.
- ►X-chromosome inactivation is a developmentally regulated process in which DNA methylation plays an active role. In females most genes on one of the X-chromosomes are silenced. This mechanism assures the same expression levels in male and female cells. Dense methylation of only the inactive X-chromosome is correlated with transcriptional silencing of the genes located on this X-chromosome.
- While most genes are expressed from both the maternal and the paternal alleles, a small number of imprinted genes are expressed in a parent-of-origin dependent manner.

The underlying regulatory mechanisms of genomic ►imprinting are unclear but allele-specific methylation in CpG islands associated with imprinted genes seems to be involved. Since methylation patterns are established in selected sequences of the genome, a sequence specificity for DNA methyltransferases has been postulated. A first indication how this could be achieved came from a recent report describing a protein complex of DNMT1 with ►RB, ►E2F1 and HDAC1. This complex has the ability to target specifically those genes involved in growth regulation that contain E2F1 binding sites.

Cellular and Molecular Aspects

Several steps are required for the establishment of DNA methylation patterns. The methylation of an unmethylated sequence requires an enzyme with de novo methylase activity. This enzyme recognizes a potential target sequence and methylates both DNA strands. During replication of the genome a new DNA strand is synthesized that is unmethylated creating a hemimethylated state. A different enzyme that can detect and methylate the hemimethylated DNA is required for the maintenance of the methylation pattern (DNA maintenance methyltransferase). Since certain developmental processes require the erasure of the methylation pattern, an enzyme with demethylating activity was postulated. However, several rounds of DNA replication without maintaining the original methylation pattern could also accomplish demethylation. Recently, two methyltransferases, Dnmt3a and Dnmt3b, were shown to have de novo methyltransferase activity *in vivo*. The DNA maintenance methyltransferase, Dnmt1, was identified several years ago and fulfills the expected criteria. This enzyme targets hemimethylated DNA, is ubiquitously expressed in somatic tissue and interacts with the replication machinery at the replication fork. Furthermore, recent data suggests that DNMT1 can establish a repressive transcription complex that includes HDAC2, DMAP1 and the transcriptional co-repressor TSG101.

Aberrant DNA Methylation in Cancer

Hypomethylation

Both extensive aberrant hypo- and hypermethylation have been described for several human cancers. Global hypomethylation in human cancers was one of the earliest changes described to be associated with tumor progression. For example, some reports describe the activation of the ►MYC oncogene in correlation with decreased methylation of CpG dinucleotides in the third exon of the gene. The underlying mechanisms however are unclear. In addition, there is convincing evidence that links hypomethylation with chromosomal breakage. Patients with ►ICF syndrome are characterized by instability of the pericentromeric heterochromatin and decondensation in chromosomes 1, 9 and 16, resulting in multibranched chromosomes. The chromosomes involved show hypomethylation of satellite DNA, and recently several groups reported mutations in the de novo methyltransferase DNMT3B in ICF patients, consistent with the idea of a defect in the methylation pathway.

Hypermethylation

Silencing of tumor suppressor genes either by mutations of both alleles, homozygous deletion or deletion of one allele (LOH) combined with mutation of the remaining allele, are well-documented mechanisms. More recently, homozygous DNA hypermethylation of promoter sequences has been identified as an additional

mechanism of inactivation of tumor suppressor genes. The development of a methylation sensitive ►PCR (MSP; PCR) allowed the rapid identification of methylated promoter sequences in various tumor samples. The list of genes that become hypermethylated in human cancers is growing rapidly and includes genes involved in growth/development, repair and apoptosis. Hypermethylation of CpG islands located in promoter region of genes is correlated with the transcriptional silencing of the adjacent genes. Using ►restriction landmark genome scanning (RLGS) for genome wide assessment of methylation patterns in CpG islands it was shown that up to 10% of the total 29,000 CpG islands in a tumor genome could be methylated. The methylation patterns are not random, suggesting a selective pressure for either the methylation of certain susceptible CpG islands or the selection of cells with a certain methylation pattern and a growth promoting transcriptional profile. In addition, by comparing different tumor types it was shown that some targets of methylation are shared between tumor types and others are specific for one tumor type.

Methylation-Controlled J Protein

Janet C. Lindsey, Steven C. Clifford
Northern Institute for Cancer Research, Newcastle University, Newcastle upon Tyne, UK

Synonyms

MCJ; DnaJ (Hsp40) homolog subfamily C member 15; *DNAJC15*; *DNAJD1*; *HSD18*; *MCJ*

Definition

MCJ is a member of the DNAJ family of co-chaperone proteins, whose expression is controlled by methylation of its associated CpG island. Reduced *MCJ* expression increases resistance to several commonly used cancer therapeutics by inducing expression of the ABCB1 drug-transport pump.

Characteristics

The *MCJ* gene maps at 13q14.1 and codes for a protein of 150 amino acids and 16–17 kDa. *MCJ* contains a highly conserved 70 amino acid DNAJ domain (or J-domain) located at the C terminus. J-domain proteins interact with the ►heat shock protein 70 (Hsp70) family of ►chaperone proteins, and act as ►co-chaperones recruiting Hsp70 members to specific substrate proteins. MCJ has been shown to be a type II transmembrane protein localized in the Golgi network, with a cytoplasmic N terminus and a C terminus lying within the Golgi lumen.

The expression of *MCJ* is ►epigenetically (►Epigenetics) regulated by ►methylation of a ►CpG island located in the 5′ transcribed region of the gene. Methylation is present in some normal cell types in a tissue-specific manner and changes in methylation patterns occur during cancer development. In ovarian tissue *MCJ* is methylated and not expressed in normal ovarian cells of epithelial origin, but is unmethylated and expressed in cells of lymphocyte or fibroblast origin. *MCJ* is methylated in approximately 93% of primary ►ovarian tumors (derived from the ovarian surface epithelium) but only approximately 17% show levels of methylation comparable to the normal tissue of origin, suggesting that 83% of tumors have become hypomethylated (►Hypomethylation). In contrast, *MCJ* is unmethylated in normal kidney and brain tissues, but becomes ►hypermethylated in a proportion of ►Wilms tumors (90%) and several different malignant brain tumor types, ►medulloblastomas (7%), supratentorial PNETs (30%) and ependymomas (10%). In addition, 13q14 is a common region of genetic loss in a wide range of human cancers. The disruption of *MCJ* expression in tumorigenesis, suggests it may play a role in tumor development, however the mechanisms underlying this role are not understood at present; studies have failed to demonstrate a difference in the rate of proliferation of *MCJ* ± cells in culture. To date, the major significance of *MCJ* in cancer appears to lie in its role in resistance to chemotherapy.

Initial studies from *MCJ*-►transfected ovarian cancer cell lines implicated loss of *MCJ* expression in chemotherapeutic resistance to a diversity of agents commonly used in cancer chemotherapy including ►paclitaxel, ►topotecan and ►cisplatin. Complementary studies showed that silencing of MCJ expression by ►RNA interference in a drug sensitive breast cancer cell line conferred resistance to doxorubicin and paclitaxel.

Furthermore, high levels of *MCJ* methylation in ovarian cancer patients are associated with both a poor

response to chemotherapy (cisplatin/carboplatin ± a taxoid) and poor overall survival.

Recently insights into the functional mechanism whereby loss of *MCJ* expression confers drug resistance have been made. MCJ associates with c-Jun, a component of the transcription factor complex ►AP-1, leading to its degradation. In the absence of MCJ, levels of c-Jun rise resulting in increased AP-1 mediated transcription of ABCB1 (►P-Glycoprotein), one of a family of drug exporters characterized by an ATP-binding cassette motif. ABCB1 is a large transmembrane protein which functions as an ATP-dependent pump resulting in the efflux of a variety of drugs from the cell, preventing their intracellular accumulation and cytotoxic effects. The development of simultaneous resistance to multiple structurally unrelated drugs is a major problem in cancer chemotherapy. Over expression of *ABCB1* has been associated with drug resistance in tumors. Previously it was known that this up-regulation could occur in cell lines models by amplification of its DNA locus. The discovery that it can also be upregulated by loss of *MCJ* expression has important therapeutic implications as *MCJ* silencing by DNA ►hypermethylation is a feature of certain tumor types and is reversible by DNA methyltransferase inhibitors or demethylating agents. This means that tumors proven to be resistant to chemotherapy as a result of *MCJ* methylation could potentially be re-sensitized by pharmacological re-activation of *MCJ* prior to chemotherapy.

MIC-1

Asne R. Bauskin, David A. Brown, Samuel N. Breit
Centre for Immunology, St. Vincents Hospital and Department of Medicine, University of New South Wales, Sydney, NSW, Australia

Synonyms

PTGF-β; PLAB; GDF15; PDF; NAG-1; PL74

Definition

Macrophage inhibitory cytokine (MIC-1) is a divergent member of the ►human TGF-β superfamily (Transforming growth factor β), that was originally cloned on the basis of increased expression with macrophage activation, but has subsequently been found to be strongly linked to cancer.

Characteristics

The MIC-1 gene, localized on chromosome 19p12-13.1, consists of two exons separated by an intronic sequence of about 1,800 bp. Exon I is 309 bp in length and contains 71 bp of 5′ untranslated sequence. Exon II is 891 bp in length with a 3′ untranslated region of 244 bp. A ►single nucleotide polymorphism in the MIC-1 coding region, results in the change of a histadine (H) to an aspartic acid (D) residue at position 6 of the mature MIC-1 protein (Fig. 1). While other polymorphisms have been documented, this polymorphism significantly impacts on predisposition to cancer and patient survival.

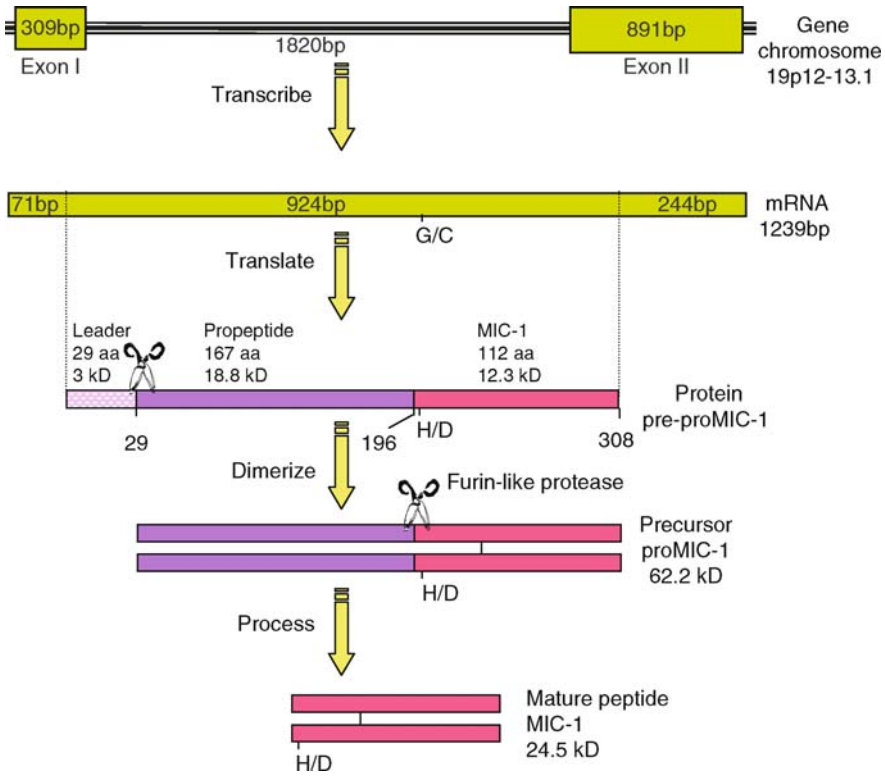
The transcribed MIC-1 mRNA is 1,239 bp, with a coding sequence of 924 bp. MIC-1 is synthesized as a 62 kD intracellular protein, which then undergoes disulphide linked dimerization. This dimeric precursor is cleaved by a furin-like protease (►Furin), separating the propeptide domain from the mature MIC-1 peptide, which is secreted as a 24.5 kD disulphide-linked dimeric protein (Fig. 1).

The receptor for MIC-1 is unknown and its signaling pathways are as yet to be delineated. However, as a TGF-β superfamily cytokine, it probably utilizes elements of the conserved TGF-β superfamily receptors and Smad signaling pathway (►Smad proteins in TGF-β signaling). There is suggestion that MIC-1 also induces activation of Akt (►Akt signal transduction pathway in oncogenesis) and ►ERK pathways.

Regulation of MIC-1 Gene Expression

Under normal physiological conditions, the placenta is the only tissue that expresses large amounts of MIC-1. Low levels of MIC-1 mRNA is found in a wide variety of epithelial cells, but little protein has been detected. However, MIC-1 mRNA and protein is usually dramatically increased in injury, inflammation and cancer in all cells and tissues.

Anti-tumorigenic Stimuli Induce MIC-1 Gene Expression. MIC-1 is one of the major secreted proteins induced by the p53 transcription factor (►p53 Protein, biological and clinical aspects), and may mediate some of the p53 tumor suppressor activity. Indeed, several studies show MIC-1 induction being associated with cell cycle arrest and ►apoptosis. However, other transcription factors such as ►Egr-1 (Early growth response-1) and NFkB are also likely to play a role in inducing MIC-1 expression. A variety of anti-tumorigenic agents, that activate p53 and/or Egr-1 related pathways can induce MIC-1 expression in cancer cell lines. These include many cytotoxic drugs, non-steroidal anti-inflammatory drugs (►Non steroidal anti-inflammatory drugs) as well as dietary compounds such as cruciferous vegetable indole-3-carbinol and green tea catechins (Fig. 2).



MIC-1. Figure 1 Genomic organization, mRNA and protein synthesis and post-translational processing of MIC-1.

M

In normal epithelial cells, there is little or no detectable expression of MIC-1. However, neoplastic transformation causes a major increase in MIC-1 expression, and this is further increased by the tumor response to a variety of anti-tumorigenic stimuli, such as gamma irradiation, cytotoxic drugs, NSAIDs etc. In early stage cancer this could lead to tumor cell apoptosis, inhibition of blood vessel formation and tumor cell cycle arrest. However, in later stage cancers, MIC-1 may help tumor spread and high serum levels of MIC-1 may lead to other systemic effects such as cancer associated anorexia and weight loss. The level of active MIC-1 in the tumor microenvironment is further regulated by creation of stromal stores of unprocessed proMIC-1, which is often secreted in varying degrees from different tumors. Only unprocessed proMIC-1 binds ►extracellular matrix (ECM) via the propeptide, whilst processed mature MIC-1 is freely soluble in the tumor stroma and can move into the blood vessel. Therefore, both intra and extracellular processing will determine levels of available active MIC-1, (Fig. 2). Indeed Stromal MIC-1 storage varies in ►prostate cancer patients and those having low stromal stores are more susceptible to relapse following removal of the affected prostate gland.

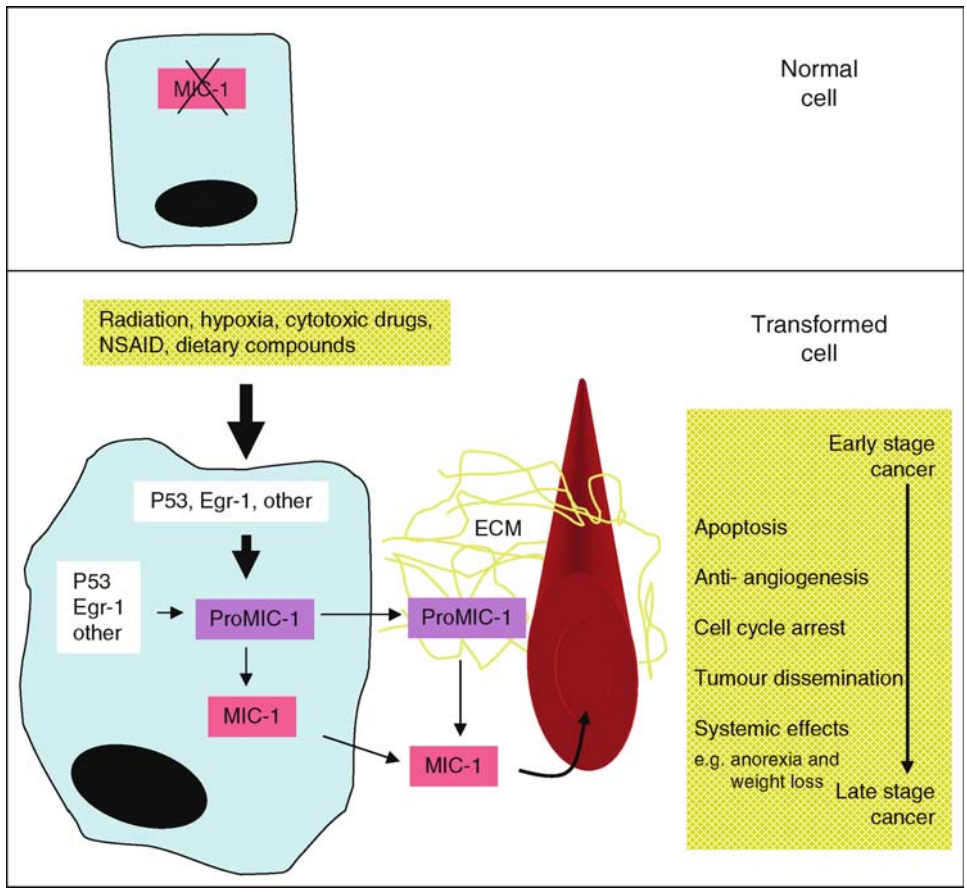
MIC-1 serum levels in advanced prostate cancer patients show a direct relationship between MIC-1 abundance and cancer associated weight loss. Furthermore normal mice given systemic MIC-1 and transgenic mice overexpressing MIC-1, both showed markedly reduced body weight due to decreased food intake. These studies define MIC-1 as a new central regulator of appetite and a potential target for the treatment of cancer associated weight loss.

Serum MIC-1 Measurement as a Clinical Tool

Increased tumor tissue expression of MIC-1 is often associated with serum levels outside the normal range of about 200–1,200 pg/ml. Serum MIC-1 levels in several cohorts of patients have revealed potential clinical utility in the diagnosis and/or monitoring of prostate, breast, pancreatic and colon cancers.

Colon Cancer. MIC-1 serum levels are increased in colonic polyps. Levels increase further with ►colon cancer development in proportion to its stage and extent. MIC-1 serum level at presentation is an independent predictor of metastasis and overall survival. Furthermore, the MIC-1 D allele is associated with significantly better survival in colon cancer.

Pancreatic Cancer. Pancreatic cancer (►Pancreas cancer, clinical oncology, basic and clinical parameters) is often diagnosed late and there is poor survival. Tumor markers have largely been unhelpful. However, measuring serum levels of MIC-1 in



MIC-1. Figure 2 Model for the proposed effects of MIC-1 on tumor biology.

combination with the known tumor marker (►Biomarkers), CA19-9, significantly improved the diagnosis of pancreatic cancer providing a sensitivity of 70% and specificity of 85%. Patients with pancreatic ductal adenocarcinoma had significantly higher levels of serum MIC-1 than those with chronic pancreatitis or healthy controls, while patients with early disease had the highest serum MIC-1 levels. This could help in monitoring patients at higher risk of pancreatic cancer development.

Prostate Cancer. In prostate cancer (►Prostate cancer, clinical oncology), when serum MIC-1 levels are combined with total and free ►PSA (Prostate specific antigen PSA) measurement, diagnosis is significantly improved and is potentially useful for the monitoring of disease progression. Furthermore, the presence of the MIC-1 H allele leads to an increased risk of developing prostate cancer. In established prostate cancer, serum MIC-1 level increases with the development of bone metastasis and measurement early in disease is potentially predictive of future metastatic disease. Additionally, the level of MIC-1 protein expression in prostate tumors is the single best predictor of disease progression in early stage tumors with a Gleason score less than 7 (►Gleason grading).

Role of MIC-1 in Tumor Biology

Whilst a lot is known about MIC-1 expression in cancer, there is less known of its effect on tumor growth and spread. Most studies suggest an anti-tumorigenic role: Firstly, reports suggest MIC-1 induces apoptosis of tumor cells via both p53 dependent and independent mechanisms. Secondly, several in vivo studies using colon and glioblastoma cell lines genetically engineered to express very high levels of MIC-1, inhibited tumor growth when transplanted into ►immunodeficient nude mice (Mouse models). Thirdly, MIC-1 is thought to inhibit blood vessel formation (►Angiogenesis), a process essential to feeding the growing tumor. Finally, transgenic mice that overexpress human MIC-1 in all cells, are resistant to the development of intestinal tumors.

However, one study suggests MIC-1 can promote tumorigenesis. High MIC-1 expression levels in a gastric tumor cell line have been to shown to correlate

with a higher invasive potential. Such contradictory effects can be due to a variety of factors including the nature of the tumor and its environment (Fig. 2).

A lot still needs to be discovered on the precise role of MIC-1 in cancer development. However, there is very strong data to support the measurement of MIC-1 levels in tumor tissue and blood as a means to detect and monitor cancer.

Synonyms

Major histocompatibility complex (MHC) class I-related chain molecules

Definition

MICA and MICB are human inducible MHC class I-related molecules expressed by stressed and malignant cells and serve as ligands for the NKG2D receptor (►NKG2D receptor and cancer) on natural killer (►Natural killer cells) (NK) and T cells thereby stimulating innate and adaptive immune responses.

Characteristics

Human MIC molecules are encoded within the MHC on the short arm of chromosome 6. The *MIC* gene family comprises six genes (*MICA* to *MICF*) of which only *MICA* and *MICB* are functional, whereas *MICC* to *MICF* constitute pseudogenes. *MICA* and *MICB* are tandem genes located between the *HLA-B* gene and the BAT1 locus at the transition from the class I to the class III region. The MICA locus is highly polymorphic with more than 50 alleles known to date. MICA*08 is by far the most frequent allele encoding for a MICA protein with a truncated cytoplasmic domain due to a frameshift mutation. MICA and MICB molecules are type I transmembrane glycoproteins of ~70 and ~58 kDa, respectively, consisting of three extracellular domains (α1, α2, α3), a hydrophobic membrane-spanning domain, and a cytoplasmic domain. The α1 and α2 domains form an MHC class I-like fold followed by an immunoglobulin-like α3 domain much alike an MHC class I heavy chain. However, at difference to classical MHC class I molecules, MIC molecules neither present antigenic peptides nor associate with β2-microglobulin and are not ubiquitously or constitutively expressed. Rather, expression of MIC molecules is inducible by various forms of cellular stress (►Stress response), including oxidative and genotoxic stress which is associated with malignant transformation. Accordingly, MICA and MICB are broadly expressed by malignant cell lines, epithelial tumors and leukemias. In healthy tissue, MICA has solely been detected on epithelial cells of the gastrointestinal tract which has been attributed to stimulation by the intestinal flora.

MICA and MICB are engaged by the activating NKG2D (natural killer group 2 member D) receptor expressed by almost all cytotoxic lymphocytes including NK cells, CD8 T cells, and γδ T cells. The C-type lectin-like, homodimeric NKG2D interacts with the MHC class I-like α1α2 superdomain of MIC molecules in a manner reminiscent of the interaction of αβ T-cell receptors with MHC class I molecules. NKG2D is associated with the adaptor DAP10 that transduces activating signals upon NKG2D engagement leading to stimulation of NK and T cell effector functions. Besides MIC molecules, there is a second family of NKG2D ligands (NKG2DL) in humans, the UL16-binding proteins (ULBP). ULBP are encoded by a gene cluster on the long arm of chromosome 6 comprising six functional members (ULBP1–4, RAET1G, RAET1L). The MHC class I-like α1α2 superdomain of the ULBP is only distantly related to MIC molecules (amino acid sequence identity (~25%)). A hallmark of ULBP is the lack of an immunoglobulin-like α3 domain and the GPI-anchorage of some family members (ULBP1–3) Altogether, there are eight human NKG2DL known to date, including both MIC and ULBP molecules, raising questions about the selective force behind this redundancy. There is emerging evidence that NKG2DL differ in their affinity for NKG2D or in their expression pattern, and are differentially targeted

by viral immunoevasins. For example, there are reports that MICA allelic variants vary broadly in their binding to NKG2D, that MIC molecules are primarily expressed by epithelial tumors whereas ULBP preferentially are expressed on hematopoietic cells, and that MICA and MICB are differentially targeted by immunoevasins (UL16, UL142) of human cytomegalovirus (HCMV).

Expression of MIC molecules is upregulated by cells infected with viruses (e.g., HCMV or adenovirus) or in the course of a ►DNA damage response. The latter has been linked to the frequent expression of MIC molecules on tumor cells. In fact, NKG2DL expression was upregulated during tumorigenesis (►Carcinogenesis) in mice and led to the rejection of tumor cells by stimulating NK and CD8 T cells. Further, NKG2D was shown to protect the host from spontaneous tumors in chemically induced mouse tumor models. These findings led to the hypothesis that the NKG2D/NKG2DL system acts as a novel immunosurveillance mechanism aiding the elimination of transformed, infected or other potentially harmful cells. A strong expression of NKG2DL can render tumor cells susceptible to NK cell cytotoxicity, even in the presence of MHC class I, and thus NKG2D-mediated tumor immunosurveillance may counteract the development of neoplasms already at an early stage. In this context it is noteworthy that patients with the rare autosomal-recessive Chediak-Higashi syndrome characterized by abnormal cytotoxic function of NK cells have a 200-fold higher risk of developing cancer than other individuals supporting the important role of NK cells in antitumor immunity.

During carcinogenesis, however, antitumor immunity also results in selection of cancer cells capable of evading the immune response (►Escape mechanism). Escape from NKG2D-mediated tumor immunosurveillance can be achieved either by silencing NKG2D or abrogation/reduction of NKG2DL expression. Proteolytic shedding of MIC molecules from tumor cells has been shown to impair the NKG2D-mediated immune response in both ways by locally reducing MIC expression levels on the tumor cells and by systemically downregulating NKG2D receptors on NK cells and CD8 T cells through soluble MIC (sMIC) molecules. Similarly, TGFβ which is frequently produced by tumors has been reported to downregulate both MICA and NKG2D surface expression.

Clinical Aspects of MIC Expression by Tumors

Enhanced expression of MIC molecules has been observed in many epithelial tumors as well as in hematological neoplasias. Several studies have shown a beneficial role of MIC expression on tumor cells such as in colorectal cancer or ►multiple myeloma for patient survival. In tumors with low MIC molecule expression or pronounced MICA shedding, novel agents such as ►imatinib mesylate and histone deacetylation (►Histone deacetylases) (►HDAC) inhibitors were found to induce the expression of MIC molecules and subsequently to enhance the tumoricidal activity of natural killer cells. It remains to be shown to what extent stimulation of the NKG2D/NKG2DL-system contributes to the recent clinical success of these agents in antitumor therapy.

Clinical Aspects of Soluble MIC Molecules in Blood

The process of shedding MIC molecules from tumor cell surfaces during ►progression of cancer disease opens the possibility to measure concentrations of sMIC molecules in blood for diagnostic and prognostic purposes. If benign diseases potentially interfering with diagnosis can be excluded by clinical and laboratory means, MIC levels in peripheral blood may represent valuable indicators of tumor development. Recently, sandwich enzyme linked immunosorbent assays (ELISAs) were developed with specific antibodies against MICA and MICB which allow the quantification of such sMIC molecules in serum, plasma, and other body fluids. Several studies have addressed these clinical questions, particularly the potential of MIC molecules for diagnostic, staging, and prognostic purposes.

Soluble MIC in Diagnosis of Cancer Disease

Most studies found higher sMIC levels in individuals with cancer diseases, particularly in those with advanced stages of cancer as compared to healthy controls. However, the potential impact of most studies on the clinical practice was limited due to the small patient numbers investigated. The currently most comprehensive studies analyzed sMICA and sMICB levels in sera of more than 500 individuals with cancer disease (including colorectal (►Colon cancer) and various other gastrointestinal cancers (►Gastrointestinal tumors), ►lung cancer, ►breast cancer, ►ovarian cancer and other gynecologic cancers, renal and ►prostate cancer), with benign diseases and in healthy individuals. Levels of sMICA and sMICB in sera of healthy donors were generally fairly low. In contrast, pretherapeutic serum levels in various malignancies were significantly higher. However, various benign diseases tended to have elevated serum levels of sMIC molecules limiting the diagnostic capacity for cancer disease. Particularly infectious diseases as well as hepatic and renal diseases potently affecting the marker metabolism were associated with increased levels of MIC molecules.

Nevertheless sMICA levels significantly distinguished between benign and malignant diseases in general, but also in subgroups of lung and gynecological cancers. In contrast, soluble MICB molecules failed to discriminate effectively between cancers and the relevant organ-specific benign diseases. This failure was also due to

the considerable number of individuals with "MICB-negative" cancer disease. In about 70% of cancer patients, there were no sMICB levels detectable while only about 20% of cancer patients were "MICA-negative." These data correspond with immunohistochemical analyses which revealed a significant number of tumors lacking MIC molecule expression. Further, there was only a weak correlation found between sMICA and sMICB levels suggesting differences in expression, shedding, or metabolism of MICA versus MICB. No substantial addition in clinical sensitivity was observed by the combined use of both biomarkers (►Serum biomarkers).

Soluble MIC in Staging of Cancer Disease

After diagnosis, pretherapeutic staging (►Tumor staging) of cancer disease is essential for therapy stratification and estimation of prognosis. Interestingly, elevated levels of both sMICA and sMICB significantly correlated with the extent of disease reflected by UICC classification: While there was no association between sMICA and sMICB levels and tumor size, cell differentiation (►Tumor grading), or lymph node involvement, both markers showed a clear correlation with the presence of distant metastasis. Detailed subgroup analysis confirmed the correlation of both markers with the presence of distant metastasis for various cancer entities, particularly for gastrointestinal tumors. In contrast, high levels of sMICA and sMICB were already observed in early stages of lung cancer, and there was no association with tumor stage. Because sMICA and sMICB levels were particularly elevated in patients with distant metastases, the presence of sMICA and sMICB in serum appears to be an indicator for systemic manifestation of malignancy.

Soluble MIC in Cancer Prognosis and Monitoring of Cancer Disease

As sMICA and sMICB correlate with cancer stage and as staging systems are developed to enable an efficient stratification of patients for alternative therapy options and to estimate prognosis, it can be expected that sMICA and sMICB will provide prognostic information in various tumor entities. A first study revealed a correlation between sMICA serum levels and disease progression in 23 patients with prostate cancer. In addition, a further study on 97 patients with multiple myeloma showed a clear correlation between elevated levels of sMICA and poor overall and progression-free survival in univariate and multivariate analyses.

Analysis of sMICA and sMICB in sera enables longitudinal measurements, e.g., for the estimation of therapy response of cancer disease and for the early detection of cancer recurrence. This may turn out to be valuable in advanced cancers with elevated sMICA levels and in therapies affecting the NKG2DL expression such as treatments with imatinib mesylate and HDAC inhibitors.

Altogether, levels of sMICA and sMICB are elevated in sera of cancer patients when compared to healthy controls. However, due to elevations of sMIC levels in patients with certain benign diseases and due to the considerable number of MIC-negative cancer patients, both markers seem not to be suitable for cancer diagnosis. Because MIC levels are particularly elevated in advanced cancer stages, they may add information in cancer staging and estimation of prognosis. Future studies may address the prognostic relevance of soluble MIC molecules as well as their value in longitudinal observations for the estimation of systemic therapy response and the early detection of cancer recurrence.

Definition

cDNA microarray technology is one of several developing functional genomics approaches to comparatively analyze genome-wide patterns of mRNA expression. Parallel gene expression profiling of cancer genomes with cDNA microarrays has revolutionized may aspects of cancer research. Gene expression "fingerprinting" has been used for tumor classification, prediction of therapeutic response and resistance, and for elucidating genetic pathways associated with particular cancer phenotypes.

Characteristics

cDNA microarray technology entails the development and standardization of various hardware, analytical software, statistical methodology, biological resources and biochemical methodologies. The diagram in the Fig. 1 demonstrates the various stages of cDNA microarray analysis.

cDNA Microarray Construction

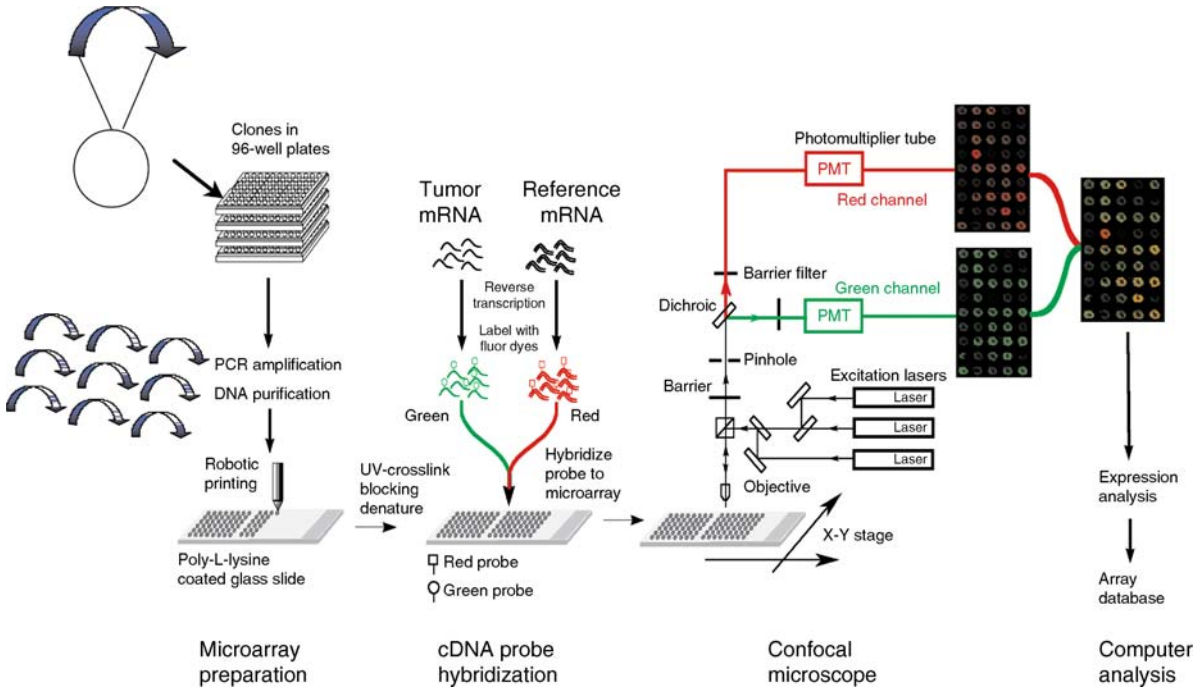
Construction of very high density cDNA microarrays of specific and distinct DNA hybridization "targets," each one representing a single gene, are spotted in an arrayed format on a poly-L-lysine coated glass microscope slide. The printing process involves the sequential transfer of individual purified PCR amplified fragments (200 bp to 2 kb) from a 96 well microtiter tray to an exact predefined location on glass slides. The "arrayer" encompasses a robotic arm that moves (x,y,z axis) the "quill pen probes" into position to either pick up or to spot down DNA (SDS solution), a manifold to hold the slides, a wash station to rinse the "quill pens" when a different DNA is to be picked up, a place to house the microtiter plates, an air flow cabinet to keep everything in and a computer which orchestrates the operation of the components. Multiple glass slides, each containing thousands of spots of DNA, can be synthesized and used in subsequent experiments.

Hybridization with Labeled cDNA

For each experiment, complex "probes" are made that consist of a pool of fluorescently labeled cDNAs. This step begins with the extraction and preparation of mRNAs from two populations of cells. Then each of the two mRNA is reverse transcribed separately with the incorporation of different fluorescently tagged nucleotides, producing two populations of differentially labeled cDNA probes. Typically Cy3 and Cy5 dyes (which emit light at distinct wavelengths after laser excitation) are used to differentially label cDNA pools from different sources. The two complex labeled probes are combined and then simultaneously hybridized to the cDNA targets on the microarray.

Scanning the cDNA Microarray Using a "Reader"

To quantitatively measure the fluorescence of the hybridized probes, the cDNA microarray is scanned by a "reader." This device is a computer controlled inverted scanning fluorescent confocal microscope which detects the emitted fluorescence of the dyes after excitation with a double laser illumination system (a 532 nm, 100 mw NdYag laser is used for Cy3 and a 633 nm, 35 mw HeNe laser for Cy5). Digital images of



Microarray (cDNA) Technology. Figure 1 Schema of microarray technology [adapted from Duggan et al. (1999) Nat Genet (1 Suppl):10–14].

fluorescence intensity data is generated by the "readers" confocal laser scanning microscope.

Image Analysis and Generation of cDNA Microarray Data

Analysis of the image data generated by the "reader" is done with a software for array target segmentation, target detection, background intensity extraction, target intensity extraction, ratio calculation and ratio normalization. Typically, cDNA microarray data is transferred to a relational database so they are available for analysis by query based data mining.

Analysis of Large Scale cDNA Microarray Data

Management and analysis of the large volume of data that results from multiple cDNA microarray experiments represents a formidable challenge. Fortunately, new and effective bioinformatic methods have been developed to effectively analyze large scale expression data in ways conducive to extracting biologically relevant conclusions. Bioinformatic approaches using statistical tools can compare gene expression profiles from multiple experiments. One bioinformatic approach involves clustering, whereby the genes with similar expression profiles across multiple experiments are statistically clustered together. In some cases, the samples can also be clustered based on how similar the global gene expression patterns are. There are a wide variety of statistical methods to cluster microarray data. The most commonly used is unsupervised, hierarchical clustering that, unlike supervised clustering, is not based on fitting the data to a model. Plotting of hierarchical gene clustering results is aided by color representations of the relative gene expression ratios and branching dendograms. Other visualization methods, such as multi-dimensional scaling (MDS), have been developed to visually illustrate (by distance in a three-dimensional graph) the degree of correlation amongst multiple samples based on global scale gene expression profiles. In other words, MDS can cluster samples together in 3-D space based on the similarity of their gene expression profiles. More detailed information on cDNA microarray technology and related links is available in http://www.nhgri.nih.gov/DIR/LCG/15K/HTML/.

Application

DNA microarrays facilitate highly parallel analysis of gene expression. Analysis of cDNA microarray data using statistical clustering has revealed groups of genes that have very similar gene expression profiles associated with a phenotype or a response to a physiological condition. Also, genes sometimes cluster together tightly across a large number of conditions revealing co-regulated genes. Furthermore, investigation of genes that cluster together often reveals that they have related structures and functions. As a consequence, clues about the function and regulation of unknown genes can be hypothesized based on other genes that cluster with it. An added advantage is that cellular phenotypes such

as migration of cancer cells can be correlated with specific clusters and gene expression fingerprints.

Clinical Relevance

Gene clusters from cDNA microarray data analysis have been used as cancer bio-markers for diagnosis, progression and prognosis. For example, the use of global gene expression profiles has successfully identified a gene cluster that distinguishes various classifications of malignancies. This type of classification by gene expression fingerprinting is useful in identifying sub-types of hematological malignancies that were histopathologically not distinguishable but had different clinical outcomes. These profiles can also identify genes that are associated with therapy response and resistance. For example, a gene expression program was identified in prostate cancer that is associated with androgen ablation therapy and resistance to hormonal therapy. As a consequence, such genes can be used to predict individual responses to therapy. Furthermore, identification of genes that mediate therapy response also permit rational drug design to target these genes and gene products.

cDNA microarray analysis of a small set of cancers can identify hundreds of gene expression alterations. Conventional molecular pathology techniques are relatively slow, thus, creating a "bottle-neck effect" in the validation and translation of such alterations to a large population of clinical specimens. To alleviate this problem, tissue microarray technology has been developed for parallel high-throughput molecular pathology (immunohistochemistry, mRNA in situ, and fluorescence in situ hybridization) on hundreds of clinical tissue sections on a single glass microscope slide. The prevalence of candidate gene expression alterations can therefore be assayed in hundreds to thousands of clinical samples in a single experiment. These two types of microarray technology are highly complementary, allowing for rapid identification and translation of genes associated with cancer.

Definition

►Microcell-mediated chromosome transfer (MMCT) is a method of transfer of intact or truncated chromosomes from a donor cell to a recipient cell through microcell fusion and hybrid cell selection. A ►microcell hybrid stably maintains the additional genetic material as functioning units within the cells. This technique is primarily used for transfer of a single donor chromosome (monochromosome transfer) of interest into a recipient cell.

Characteristics

A method of mammalian gene transfer, termed microcell-mediated chromosome transfer (MMCT), allows the stable introduction of exogenous chromosomal material from a donor cell into a recipient cell. MMCT is generally used to transfer a portion of the genetic information (generally one chromosome) from one cell to another. This procedure is used for genetics, gene mapping, and gene expression/regulation studies in mammalian cells. One or more intact or truncated chromosomes from the donor cell can be transferred into the recipient cell. Transferred genes are under the control of their endogenous regulatory elements, ensuring their physiological expression in the recipient cell line.

In ►cancer studies, the transferred donor chromosome is generally a normal human chromosome. Complete libraries of mouse microcell hybrid cell lines containing each individual normal human chromosome, tagged with a dominant selectable antibiotic resistance gene, originating from a diploid fibroblast cell, have been generated. These cell line resources have been invaluable for gene function and mapping studies. Panels of selected donor chromosome cell lines, containing random truncations induced by irradiation to narrow down genomic regions containing tumor suppressive activity, have also been established for MMCT studies. The recipient cells are often human cancer cell lines or murine cell lines.

Using MMCT approaches, functional complementation of genetic defects present in the original recipient cancer cell line by the introduction of a normal exogenous chromosome, provides evidence for the existence of a ►tumor suppressor gene having a role in the cancer cell line studied. This approach has been used in specific tumor cell lines to detect candidate tumor suppressor genes on individual chromosomes and to aid in their identification and mapping to critical regions associated with tumorigenesis. This allowed both validation of the tumor suppressive [►tumor suppression] function of known tumor suppressor genes, such as *RB* [►retinoblastoma] and *WT1* [►Wilms Tumor], for example, and identification of yet other previously unidentified candidate tumor suppressor genes. A summary of some of these MMCT tumor suppressive studies of human cancers is shown in Table 1. Using MMCT approaches, researchers were able to localize tumor suppressor genes to specific chromosomes to provide direct functional evidence for their role in tumor suppression and to demonstrate that restoring a normal copy of a single tumor suppressor gene in a cancer cell line reversed its tumorigenic potential, despite multiple defects on several chromosomes contributing to a malignancy. MMCT approaches are also useful for identifying genes responsible for growth suppression, ►senescence, and ►metastasis.

The MMCT procedure consists of the following key steps, as illustrated schematically in Fig. 1. Exponentially growing donor cells containing the stable exogenous donor human chromosome of interest, which is tagged with a selectable marker such *neo* for G418 selection, are subjected to prolonged ►colcemid (mitotic inhibitor) treatment. Micronuclei (►Micronucleus) are formed, when the nuclear envelope reforms around one or more of the chromosomes. Micronuclei are then ►enucleated by treatment with ►cytochalasin B and centrifugation. Microcells are then formed. They are filtered through membranes to eliminate

[2]Universitäts-Krankenhaus Eppendorf, Hamburg, Germany

Definition

Micrometastases were originally defined by pathologists as small occult metastases (<0.2 cm in greatest dimension). With the recent development of more sensitive diagnostic tools, such as immunocytochemistry and polymerase chain reaction (PCR), the term has been used more liberally in the literature. It now includes isolated disseminated tumor cells (DTC) present in the peripheral blood or in a secondary organ (in particular bone marrow) or in a lymph node, classified as "tumor-free" by conventional histopathological analysis. Considering the different biology of true micrometastases and isolated DTC, both types of findings should be distinguished.

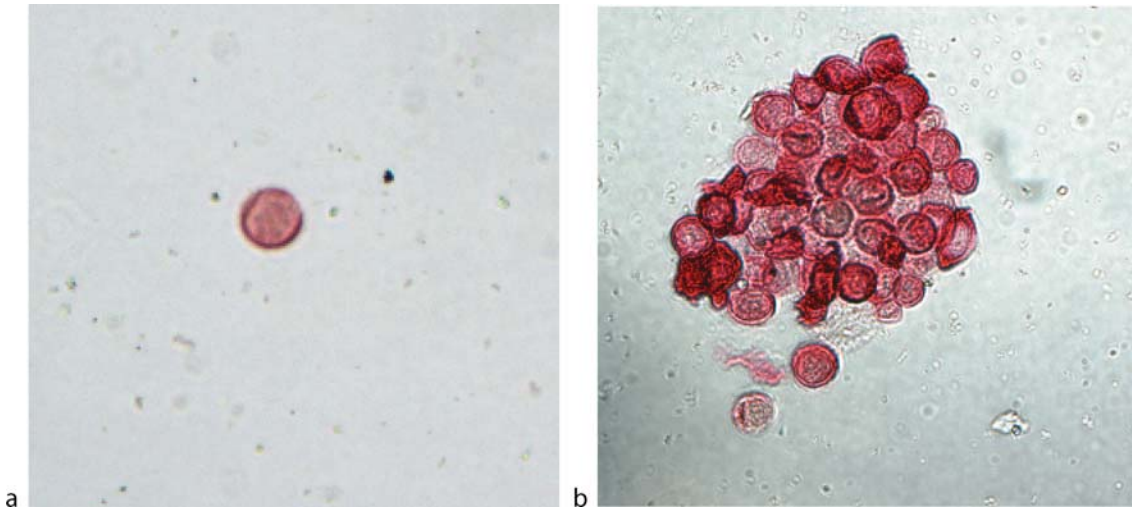
Characteristics

Detection Techniques

During the past decade sensitive techniques have been developed that allow now the detection of DTC in the blood and bone marrow (BM) at the single cell level. DTC must be separated from billions of erythrocytes and millions of leucocytes present in the blood and bone marrow sample. For this enrichment of DTC over several logarithmic units several methods have been successfully used, including density gradient separation, antibody-charged magnetic particles, filtration, and tetrameric antibody complexes. These technical advances provide an excellent opportunity to detect and analyze DTC in clinical studies in order to (i) provide helpful information for the management of patients with ►cancer and (ii) unravel the biology of the metastatic cascade in solid tumors. Solid tumors account for the majority of cancers in the European Union and USA, and the majority of solid tumors are derived from epithelial tissue. The present review will therefore focus on DTC detection in patients with solid epithelial tumors.

Immunocytochemistry

Cytokeratins (CK), as integral components of the cytoskeleton of epithelial cells, are stably expressed characteristics of epithelial tumor cells that can be clearly identified in individual carcinoma cells by means of specific monoclonal antibodies (Fig. 1). Mucin-like tumor-associated cell membrane proteins are less well suited for analysis on account of their expression on hematopoietic cells. Immunohistochemical examinations of BM biopsies have shown that CK-positive tumor cells are mostly situated in interstitial tissue outside the sinusoidal vessels, which indicates that extravasation, one of the last processes in the metastasis cascade, has been successfully completed. Although ectopic or illegitimate mRNA expression of cytokeratins in mesenchymal cells cannot be ruled out, numerous negative findings in patients without identifiable malignant processes show that ectopic expression of CK proteins in BM is very rarely identifiable by immunocytochemistry. The time-consuming microscopic screening of large amounts of



Micrometastasis. Figure 1 Isolated disseminated carcinoma cells (a) and tumor cell cluster (b) on a bone marrow cytospin stained with anti-cytokeratin antibody A45-B/B3.

cytological samples has been facilitated through automated analysis of stained preparations using sophisticated image analysis systems.

Molecular Techniques

Besides immunocytochemistry molecular detection procedures have been increasingly used to identify DTC. The major limiting factor for detection of single DTC by RT-PCR is illegitimate low-level transcription of tumor-associated or epithelial-specific genes in normal cells. Quantitative real-time RT-PCR may increase discrimination between mRNA expression of normal cells and tumor cells, thereby increasing the specificity of the RT-PCR approach. However, in view of the heterogeneity of tumor cells it might be difficult to define one cut-point that is able to discriminate between normal and tumor cells in a wide range of clinical samples.

More recently, a molecular characterization of single DTC has become possible. Using immunocytochemistry or immunofluorescence in combination with FISH or CGH, several groups have reported chromosomal aberrations of DTC in blood and bone marrow indicating the malignant origin of these DTC and their genetic heterogeneity.

EPISPOT Assay

This recent technique is an adaptation of the enzyme-linked immunospot assay. EPISPOT enumerates only viable epithelial tumor cells and can detect secretion of specific proteins at an individual cell level, allowing the direct determination of protein-secreting cell (SC) frequencies. Immunospots are the protein fingerprint left only by the viable SC. Cell culture is needed for a sufficient amount of secreted marker proteins to accumulate to form immunospots; dying tumor cells do not secrete adequate amounts of protein and thus are not detected. MUC-1, ►cathepsin D, and CK19 were studied as relevant released proteins to detect tumor cells in blood and BM from patients with ►breast cancer. In prostate cancer patients, PSA-SCs ►(prostate specific antigen, PSA) were enumerated in blood and have been considered as DTC.

Cellular and Molecular Biology

Immunocytochemical double staining methods have been developed for more precise characterization of DTC. In view of the malignant potential of CK-positive cells, a number of tumor-associated characteristics have been identified. This includes the frequent overexpression of the erbB2 ►HER-2/neu oncogene and deficient expression of MHC class I molecules, which as restrictive elements help T lymphocyte-mediated tumor cell recognition. The malignant nature of CK-positive cells in the BM has been further confirmed through genomic analysis. Extensive cell culture experiments have shown that cells disseminating into BM have a time-limited proliferative potential at the time of primary diagnosis of the tumor. It may therefore be assumed that at the primary stage these cells do not proliferate autonomously, but are in a latent state known as ►"dormancy". This assumption is also corroborated by double staining studies, demonstrating that the fraction of DTC in BM with proliferation marker expression (Ki-67, p120) is small. The low-proliferative activity of DTC is also consistent with the putative stem-like phenotype of DTC ►cancer stem-like cells in BM of early breast cancer patients.

Most DTC have a ►CD44^{+} CD24$^{-/low}$ phenotype, previously shown to represent a minor population in primary breast cancer with a high self-renewal and tumorigenic potential. Moreover, using the EPISPOT assay we showed that a subpopulation of DTC in BM had the CK19^{+}/MUC1^{-} phenotype, previously also suggested as breast stem cell marker ►(stem cell markers). The putative stem cell nature of DTC could explain the relative resistance of these cells to chemotherapy and points to the development of therapeutic strategies that are independent of the proliferative state of cancer cells (e.g., immunotherapy). Nevertheless, it is still debated whether DTC in BM might indeed have cancer stem cell properties.

Some of the DTC circulating in the blood are apoptotic. However, using the EPISPOT assay we could clearly demonstrate the presence of viable DTC circulating in the blood. Tumor cells also express CXCR4 ►(CXCR4 chemokine receptor) at their cell membrane, and it has been shown that metastatic cells may use this chemokine-mediated mechanism to home at specific distant sites (i.e., lung, liver, and bone in breast cancer). After homing, DTC need to secrete relevant growth factors to form a solid ►metastasis, and we could demonstrate that a subset of DTC in the blood of prostate cancer patients secretes FGF-2, a known stem cell growth factor (Fig. 2).

Micrometastasis. Figure 2 Dual fluorescent EPISPOT assay. Fingerprints of single disseminated breast cancer cells from bone marrow. MUC1^{Alexa555}-immunospot (top), CK19^{Alexa488}-immunospot (middle), and MUC1/CK19^{yellow}-immunospot (bottom).

Clinical Relevance

Bone Marrow

Several studies on patients with different types of epithelial tumors have confirmed that BM is a common homing organ for DTC and the presence of these cells is a prognostic factor indicating an unfavorable clinical outcome. The largest data base exists now for breast cancer; analysis of 4,703 patients with primary disease (i.e., no signs of overt metastases) clearly demonstrated an independent prognostic value of immunocytochemical DTC testing. As a result of an international collaboration, the critical variables of the immunocytochemical cytokeratin BM assays have been recently defined, which allows now a reproducible and more precise determination of the DTC count. More recently, encouraging data have also been derived from the use of real time quantitative RT-PCR assays on smaller cohorts of breast cancer patients using CK19 mRNA as DTC-marker. These data need to be sustained in a multi-center setting and standardization of the methods is urgently needed.

The observed correlation to the total metastatic relapse rate is of particular interest in colon carcinoma where clinically manifested skeletal metastases are rare. The presence of DTC in BM is therefore more likely to be an indicator of early systemic tumor cell dissemination, whereas the growth in BM or other organs is being determined by the milieu in question. BM might be an important reservoir that allows DTC to home for an extended period of time and/or recirculate into other organs where they find better growth conditions. In this context it is interesting that the repeat identification of DTC in BM over years postsurgery has shown to be a risk factor for metastatic relapse in breast and gastric cancer.

Peripheral Blood

Peripheral blood is an ideal source for the detection of DTC ►circulating tumor cells because of an easy sampling procedure. It would be therefore excellent for a "real time" monitoring of ►minimal residual disease in cancer patients, in particular during and after adjuvant systemic therapy. However, the prognostic significance of DTC in blood is at present much less clear than for DTC in BM. For tumor cells, blood is only a temporary compartment, and it is not known how many cells survive the blood passage and are capable to home in a secondary organ and form detectable metastases.

Thus far, some promising studies could show that the presence of DTC in blood is correlated with stage and course of the disease in patients with metastatic breast cancer. Furthermore, a significant correlation between the detection of DTC in blood and in BM of patients with primary breast cancer has been shown

with a higher sensitivity of the BM test. Thus far, the prognostic role of DTC detection in blood in primary breast cancer is still unclear and it seems possible that the information derived from BM and blood screening could be complementary and not redundant.

Lymph Nodes

Tumor cell dissemination via the lymphatic vessels to the regional lymph nodes is the second main route of tumor cell dissemination in cancer patients, and the presence of lymph node metastases is a very important prognosticator. The clinical importance of DTC in lymph nodes has been shown by several groups in a variety of solid tumor types, including breast, prostate, lung, and esophageal cancer. However, DTC analyses of all of the resected nodes a cumbersome and time-consuming procedure and has therefore not gained access to clinical pathology.

An important advance in the evaluation of regional lymph nodes has been therefore the development of a more limited dissection, the sentinel lymph node dissection. This is based on the identification, with dyes or radioactivity, of the specific lymph node that drains the tumor and the removal of this lymph node for analysis. This approach has been extensively evaluated in patients with melanoma and breast cancer. Detection of DTC in well selected sentinel lymph nodes may become an important alternative to an extensive lymph node dissection and histopathological search for metastases, which eventually might reduce the significant morbidity associated with tumor staging in cancer patients (e.g., lymph edema in breast cancer patients after axillary node dissection).

Micronucleus Assay

Cholpon S. Djuzenova
Klinik für Strahlentherapie der Universität Würzburg, Würzburg, Germany

Definition

Measurement of ►micronucleus (MN) frequency in peripheral blood lymphocytes is extensively used in molecular epidemiology and cytogenetics to evaluate the presence and the extent of chromosomal damage in human populations exposed to genotoxic agents or bearing a susceptible genetic profile. MN is a small, extranuclear chromatin-containing structure in the cell cytoplasm surrounded by a membrane without any detectable link to the main nucleus.

Characteristics

Micronuclei (MNi) are expressed in dividing cells and they can occur spontaneously or as a result of chemical or radiation treatment. Additional parameters that can influence MN frequencies are inherited or acquired genetic polymorphisms in genes responsible for the metabolic activation of ►clastogens (agents causing chromosomal breaks), for the fidelity of DNA repair/misrepair, DNA replication and/or chromosome segregation. Concerning the induction mechanism two types of MNi exist:

1. MNi that contain chromosome fragments mostly without a ►centromere so called acentric fragments. They may result from direct DNA double-strand breakage, from conversion of DNA single-strand breakage into DNA double-strand breaks after cell replication, or from inhibition of DNA synthesis. Misrepair of two chromosome breaks may lead to an asymmetrical chromosome rearrangement producing a dicentric chromosome and an acentric fragment. Commonly, the centromeres of the dicentric chromosomes are pulled to the opposite poles of the anaphasic cell

resulting in the formation of a nucleoplasmic bridge between the daughter nuclei and an acentric fragment that lags behind to form a MN.

2. MNi that contain whole chromosomes which were unable to migrate with the rest of the chromosomes to the spindle poles during cell division. These are primarily formed from the defects in the chromosome segregation machinery such as deficiencies in the genes controlling cell cycle, failure of the mitotic spindle, ►kinetochore, or other parts of the mitotic or meiotic apparatus, or by mechanical disruption.

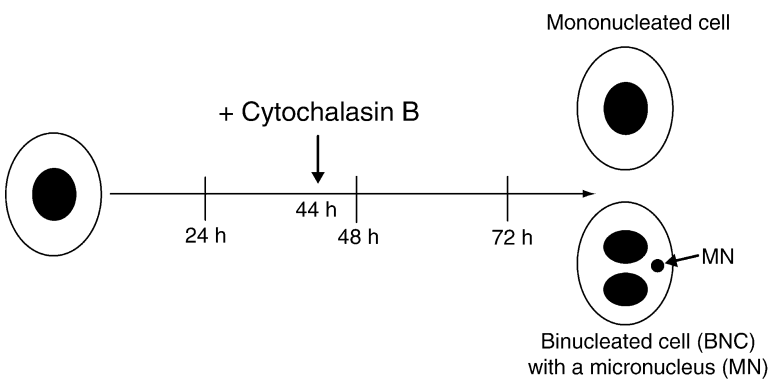
MNi can be detected using different nonspecific (Giemsa, May–Grunwald–Giemsa) or DNA-specific (4′,6-diamidino-2-phenylindole, Feulgen, acridine orange, Hoechst) stains. The frequency of MN can be quantified microscopically or by a flow cytometry. MNi are morphologically similar to the cell nucleus and have the following main features:

- The diameter of MN in human lymphocytes usually varies between 1/16th and 1/3rd of the mean diameter of the main nucleus.
- MNi are not connected to the main nucleus.
- MNi exhibit the same intensity as the main nuclei.

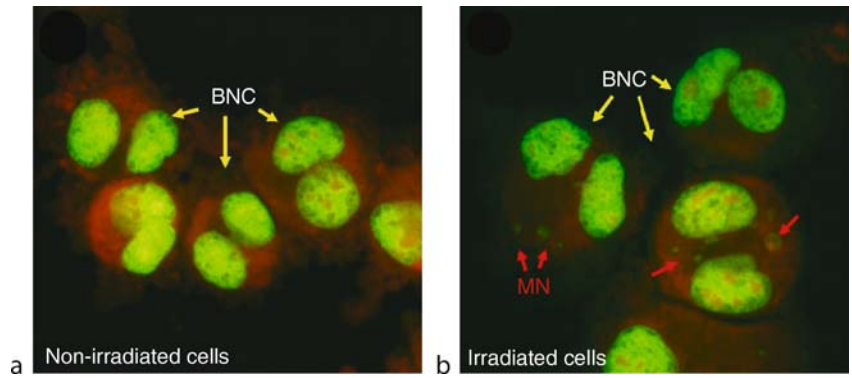
The postmitotic fates of MN are not clearly understood and include: (i) elimination of the micronucleated cells as a consequence of ►apoptosis; (ii) reincorporation into the main nucleus; (iii) retention within the cell's cytoplasm as an extranuclear entity; and/or (iv) exclusion from the cells.

MNi can only be expressed in dividing eukaryotic cells. In order to distinguish between those cells which did not divide and those cells which completed one nuclear division during in vitro culture, Fenech and Morley [1] provided an efficient approach, a ►cytokinesis-block MN (CBMN) assay using ►cytochalasin B as an inhibitor of cell division. Cytochalasin B is a cell-permeable mycotoxin that inhibits ►actin polymerization which is required for the formation of the microfilament ring and the constriction of the cytoplasm between the daughter nuclei during cellular division. Cells treated with cytochalasin B are easily recognized due to their binucleated appearance (Figs. 1 and 2), also termed as binucleated cells (BNCs). The use of cytochalasin B enables the accumulation of almost all dividing cells at the binucleate stage in growing cell population. In a classical CBMN test (Fig. 1), human lymphocytes are cultured in the presence of phytohaemagglutinin to stimulate mitosis. After 24 h of stimulation, the cells are treated with a genotoxic agent (chemicals or ionizing/ultraviolet radiation). At 44 h of culture, cytochalasin B is added and 24 h later the cells are harvested onto microscopic slides, fixed, stained, and analyzed. MNi are scored only in BNCs, which allows reliable comparison of the extent of chromosome damage between cell populations differing in their division kinetics. Although the method was initially developed for cultured human lymphocytes now it has been adapted to various cell types, such as primary fibroblasts, solid tumor and bone marrow cells, and exfoliated epithelial cells.

The advantages of the CBMN assay are simplicity, sensitivity, reliable identification of cells that have completed only one nuclear division, as well as the detection of other endpoints such as dicentric bridges and mitotic indices. Moreover, the combination of the CBMN test with the chromosome- and centromeric/telomeric-specific hybridization techniques allowed the identification of the mechanisms responsible for the induction of MNi. These mechanisms are the



Micronucleus Assay. Figure 1 Schematic diagram showing a cytokinesis-block micronucleus (CBMN) assay established by Fenech and Morley for an in vitro analysis of cells for the presence of micronucleus/micronuclei (MN/MNi). Cytochalasin B, an inhibitor of actin polymerization is added 44 h after initiation of the cell culture in order to prevent cell division thus allowing to discriminate easily between mononucleated cells that did not divide and binucleated cells (BNCs) that completed one nuclear division during cultivation in vitro. [Reprinted from [2] Mateuca et al (2006) Chromosomal changes: induction, detection methods and applicability in human biomonitoring. Biochimie 88:1515–1531, with permission from Elsevier].



Micronucleus Assay. Figure 2 Radiation-induced MNi in cultured human tumor cells. Nonirradiated (a) and irradiated in vitro (b) human melanoma cells were treated with cytochalasin B. Twenty hours later cells were fixed and stained with acridine orange, nuclear material appears green, cytoplasm in red-brown. Red arrows show MNi, yellow arrows show binuclear cells (BNC). Magnification: 1000×.

chromosome breakage leading to MNi with acentric fragments and the failure of the mitotic spindle resulting in MNi containing whole chromosomes. For these reasons the CBMN test has also become an important and useful tool to discriminate ►clastogenic (causing chromosomal breaks) and ►aneugenic (causing loss or gain of whole chromosomes) agents leading to structural and numerical chromosomal aberrations, respectively.

Clinical Aspects

Measurement of MN frequency in peripheral blood lymphocytes is extensively used in molecular epidemiology and cytogenetics to evaluate the presence and the extent of chromosomal damage in human populations exposed to genotoxic agents or bearing a susceptible genetic profile.

In populations not exposed to occupational or environmental toxins, the major contributors to differences in MN frequencies have been shown to be age and gender. Several studies have reported that MN frequencies increase with age in adults, and women have higher MN frequencies than men.

The counts of mononucleated cells containing MN provide an indication of the background level of chromosome/genome mutations accumulated in vivo, whereas the frequencies of BNCs bearing MN reflect the damage accumulated before cultivation as well as mutations expressed during the first in vitro mitosis.

Elevated frequencies of MNi could also be related to genomic instability, as seen in tumor cells, for example. A link between MN induction and ►cancer development was proposed by several studies and it can be supported by a number of findings. First, an increase in MN frequency is observed in lymphocytes of cancer patients and in patients with cancer prone diseases such as ►Bloom syndrome and ataxia telangiectasia. Additional support can be shown from the positive correlation between the induction of MN and chromosomal aberrations, whose frequency in lymphocytes of healthy subjects, in turn, was supposed to be a predictor of cancer risk. Indeed, the hypothesis of a predictive association between MN induction and cancer risk is supported by the study of El-Zein et al. [3] who found that the CBMN test may serve as a strong predictor of lung cancer risk. Another recent study by Olaharski et al. [4] has shown that MNi can be used as an additional criterion to establish cancer risk in cervical malignant transformation. Peripheral blood lymphocytes from ►breast cancer patients with an adverse early skin reaction to radiotherapy also display increased frequencies of both spontaneous and radiation-induced MN as compared with cells from apparently healthy donors [5], so the CBMN assay might be used as a ►radiation sensitivity test for optimization of radiotherapy schedules.

The mechanism of MN induction and its association with tumorigenesis is currently under study in a number of laboratories. Further important questions include the investigation of the mechanisms of genomic instability and the genetic and environmental factors influencing this instability, particularly in cancer cells.

Microprocessor Complex

Definition

Is a Protein complex consisting of at least two proteins: Drosha and DGCR8. Drosha is an RNaseIII type enzyme that cleaves RNA molecules with double-stranded regions. The function of the complex is to recognise and release the hairpin structure precursor of ►microRNAs from the primary miRNA transcript. The complex is active in the nucleus and generates the pre-miRNA molecules.

►MicroRNA

MicroRNA

Tamas Dalmay
School of Biological Sciences, University of East Anglia, Norwich, UK

Definition

MicroRNAs are short RNA molecules that regulate the expression of protein-coding genes.

Characteristics

The expression of protein-coding genes is regulated at several levels including transcriptional and post-transcriptional mechanisms. A recently discovered layer of regulation involves short RNA molecules called microRNAs (miRNAs). These tiny RNA molecules are only 20–24 nucleotides long but are produced from a longer primary transcript (pri-miRNA). The pri-miRNA is either part of an intron of a mRNA or is derived from intergenic regions. Often miRNA genes are very close to each other forming a cluster and the pri-miRNA covers the whole cluster. The pri-miRNA is processed in the nucleus by the ►microprocessor complex. The resulting precursor miRNA molecules (pre-miRNAs) have a characteristic stem-loop secondary structure where the stem is partially double-stranded. Pre-miRNAs are exported to the cytoplasm where they are further processed by the ►dicer that releases an miRNA duplex from the pre-miRNA. The two RNA strands of the miRNA duplex are separated from each other and one of them is incorporated into a protein complex called ►RISC. This strand is called the mature miRNA because this strand has the ability to recognize mRNAs based on sequence complementarity. The mature miRNA guides ►RISC to mRNAs that contain an miRNA target site and the translation of the targeted mRNA is suppressed.

miRNAs and Cancer

At the time of writing this article more than 450 human miRNAs have been identified but it is expected that many more will be found. Some predictions estimate that there are up to 25,000 miRNA genes in the human genome. The current number of miRNAs can be found in miRBASE that is a comprehensive database of miRNAs and is regularly updated (http://microrna.sanger.ac.uk/). The function of most miRNA is unknown but there is an increasing body of evidence indicating a link between miRNAs and cancer. First, miRNAs are involved in cellular growth, differentiation and ►apoptosis, processes that are disturbed in tumor cells. The second evidence came from analyzing the genomic location of miRNAs. Genes involved in cancer often accumulate genetic mutations in patient tumors. These mutations can be point mutations or larger changes including ►amplifications or deletions. It was shown that about half of the miRNA genes are located at regions that are deleted or amplified in human cancers or at ►fragile sites. The third line of evidence was obtained from ►microarray experiments. MiRNA expression was profiled in a range of human tumors and a change in expression was detected in all investigated tumor types. Moreover, miRNA target sites were predicted in genes involved in other processes that play important roles in cancer (cell adhesion, angiogenesis, proteolysis and cell signaling) and some of these miRNAs were found to be up- or down-regulated in tumor samples. These suggest that miRNAs are likely to regulate many genes involved in several stages of tumor genesis.

miRNAs as Tumor Suppressors and Oncogenes

Not all miRNAs are ►tumor suppressor genes that show a down-regulation in tumor samples. Much of the abnormal miRNA expression in tumor samples is not a cause but a consequence, due to the loss of tissue identity that accompanies tumor genesis. However, at least three miRNAs (the miR-15/16 cluster and the let-7 family) are ►tumor suppressor genes. These miRNAs are in regions that are deleted with high frequency in cancer patients or mutations that can be found in the pri-miRNA in other patients. These miRNAs are

also shown to target anti-apoptotic proteins, such as ►BCL-2, and ►oncogenes, such as the ►RAS family, in in-vitro assays.

Other miRNAs, however, promote tumor formation and can therefore be classified as ►oncogenes. The best studied oncogenic miRNAs are members of the miR-17 cluster. This cluster contains six miRNA genes and is amplified and over-expressed in a range of tumors. It also accelerates ►MYC dependent lymphomagenesis and increases cell proliferation. Several members of the cluster target tumor suppressor genes such as ►PTEN, TGFBR2 and ►E2F1. The expression of another cluster (miR-372/373) makes cells insensitive to a normally functioning ►p53 tumor suppressor gene. Another strong oncogene candidate is miR-155 that is in fact located on a known oncogenic locus called the B-cell integration cluster (BIC) non-coding RNA.

In addition to miRNAs encoded by the human genome, other miRNAs encoded by viruses (such as the ►Epstein-Barr virus, ►Kaposi Sarcoma Associated Herpesvirus, etc.) can contribute to tumor formation. Several tumor suppressor genes are predicted targets of these viral encoded miRNAs but at the moment the exact role of viral encoded miRNAs in cancer is not known.

miRNA Profiling and Cancer Diagnosis

►Microarrays are used to profile expression of genes involved in a variety of processes including cancer. Developments in expression technologies have made possible the high-throughput analysis of miRNAs in clinical samples. These experiments show that miRNA expression profiles correlate very well with the type of cancer and the stage of cancer. In fact, it was suggested that the miRNA profile of a tumor sample is a better diagnostic and prognostic marker of human cancer than the mRNA profile. An miRNA based classifier can establish the correct diagnosis of poorly differentiated samples better than the mRNA based classifier. As the number of miRNAs increases and our understanding of their role in cancer grows, the use of miRNA profile in diagnosis and prognosis will be extremely valuable.

►Microsatellite Instability
►Mismatch Repair in Genome Stability
►Mutator Phenotype

Microsatellite Instability

Terje Ahlquist, Ragnhild A. Lothe
Department of Cancer Prevention, Rikshospitalet-Radiumhospitalet Medical Centre, Oslo, Norway

Definition

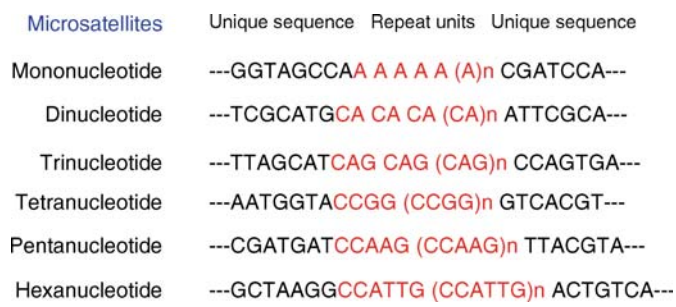
►Microsatellite instability (MSI) is the accumulation of novel microsatellite alleles in genomes (from bacteria to human) due to defect ►mismatch repair.

►Microsatellites are site specific DNA markers with high abundance throughout the genome. They consist of short repetitive motifs of 1–6 nucleotides in length that are tandemly repeated 10–60 times and flanked by unique sequences (Fig. 1).

Characteristics

Multiple different sized alleles at multiple loci in the genome accumulate during tumor development if the mismatch repair system is defect. This phenomenon is referred to as MSI. Tumors revealing such instability are said to have a ►mutator phenotype. Most microsatellites are usually located in noncoding parts of the genome, and mutations in them are selectively neutral. Occasionally the microsatellites are found in expressed regions of a functionally cancer critical gene and mutations may thereby result in a nonfunctional or altered protein with impact on tumorigenesis.

The high abundance and their polymorphic nature make microsatellites to a valuable tool for a variety of applications. Microsatellites were used to identify the chromosomal map position of genes that in a mutated condition predispose to hereditary colorectal nonpolyposis syndrome (HNPCC), also known as ►Lynch



Microsatellite Instability. Figure 1 Microsatellites consist of short nucleotide units tandemly repeated and flanked by unique sequences. The different types of 1–6 base pairs per unit are illustrated. The last unit within each type is in parenthesis followed by a"n" indicating additional units.

syndrome. Several studies of tumors from HNPCC patients revealed the characteristic pattern of novel alleles at simple repetitive sequences. About 90% of ►colorectal carcinomas from HNPCC patients and a subgroup (15%) among sporadic cases exhibit MSI. Other tumor types occurring in the HNPCC syndrome and a subgroup among sporadic cases of the same type also show MSI. This includes ►endometrial cancer, ►ovarian cancer, and ►gastric cancer. Sporadic tumors of types not characteristic to the HNPCC tumor spectrum generally show MSI at lower frequencies and the pattern is characterized by one or only a few new alleles, in contrast to the ladder of alleles often observed in the HNPCC tumor types (Fig. 2).

Sporadic tumors with the MSI phenotype, usually caused by methylation of *MLH1*, typically show promoter hypermethylation of a number of cancer critical genes and are associated with mutations in the *BRAF* gene (v-raf murine sarcoma viral oncogene homologue B1), a protooncogene serine/threonine-protein kinase involved in MAPK signaling pathway.

The HNPCC tumors and the sporadic cases of the same types share clinicopathological characteristics and are different from those with a microsatellite stable phenotype (see later: clinical relevance). In comparison with microsatellite stable colorectal carcinomas the ones which show MSI are more often located in the proximal colon, are characterized by high lymphocyte infiltration, mucinous and undifferentiated growth pattern, exhibit diploid DNA content, and normal genotype/phenotype of the tumor suppressor gene ►*TP53*. Sporadic colorectal cancer patient with tumors that reveal MSI have a prolonged postoperative survival.

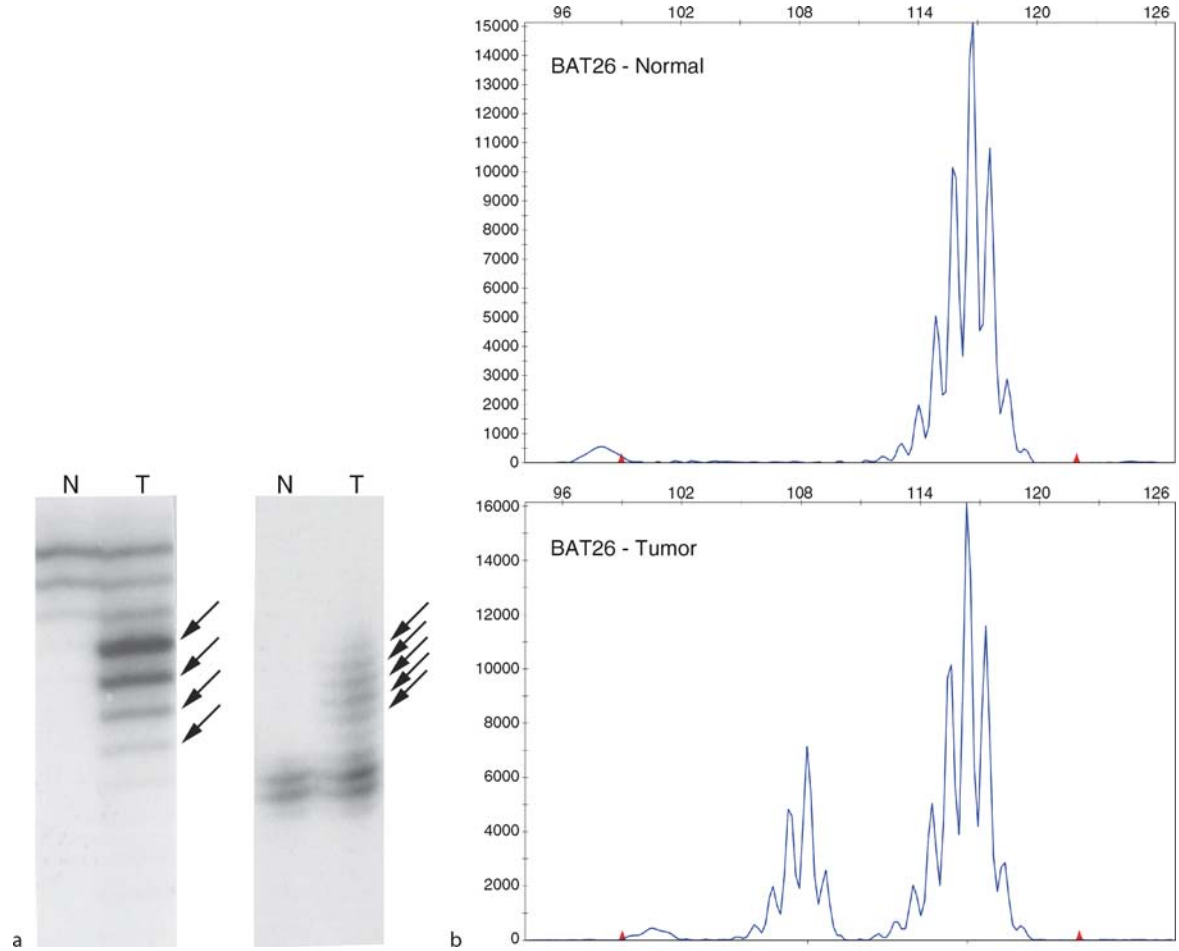
Cellular and Molecular Regulation

The genome-wide MSI pattern seen in human tumors resembles a mutational fingerprint found in the bacteria *Escherichia coli* known to be caused by failure of the mismatch repair system, ►*mutHLS*, in this organism. Several human homologues to the prokaryotic genes have been identified, and germline mutations in some of these components predispose to the HNPCC syndrome. Mutations in ►*MSH2* and ►*MLH1* account for 60% of the identified familial mutations. ►*MSH6* germline mutations are found in HNPCC with increased occurrence of endometrial cancer. Germline mutations are found in ►*PMS1* and ►*PMS2* but occur rarely.

A shared requirement between mismatch repair genes and ►tumor suppressor gene is the need for homozygous inactivation on the cellular level. In addition to the germline mutation in an HNPCC patient a somatic mutation of the second allele are necessary for tumor development. Mutations of both alleles of a mismatch repair gene have been reported in tumor studies as well as mutation of one allele and inactivation of the other by promoter hypermethylation. Among sporadic tumors, MSI is usually caused by promoter hypermethylation of *MLH1*. Biochemical analyses revealed that on the cellular level one mismatch repair gene mutation (heterozygous condition) as opposed to homozygous inactivation do not severely affect mismatch repair function. Comparable interpretation can be drawn from studies with mice.

Mismatched nucleotides arise in the DNA by polymerase misincorporation during replication, by physical damage to existing nucleotides, or by replication slippage in microsatellites with small repetitive units. Replication slippage can occur at repetitive sequences when, following a transient, local dissociation of the nascent and parental DNA strand, reassociation occurs between misaligned repeat units and thereby lengthening or shortening the newly synthesized strand. DNA polymerases are the enzymes that make mistakes especially in DNA with tandemly repeated sequences. Normally these errors are corrected by the mismatch repair system. Due to defects in one or more of these components, insertion of inappropriate bases or the making of loops are stabilized, and the following rounds of replication creates alleles of new sizes.

The genome-wide MSI phenotype does not itself provide tumor cells with a proliferative advantage, let

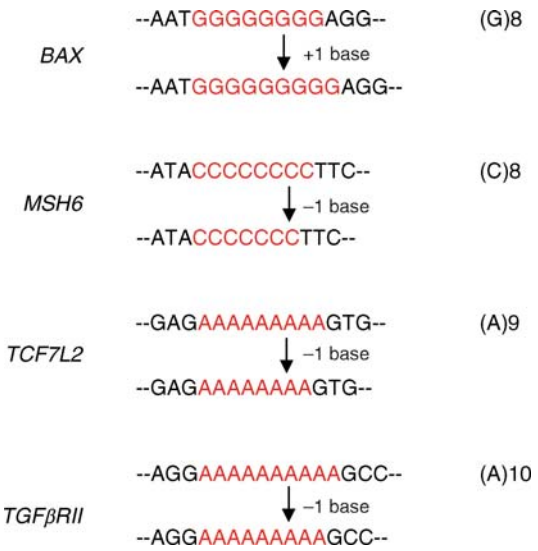


Microsatellite Instability. Figure 2 Microsatellite instability in colon carcinomas. (a) The constitutional alleles are shown in the lanes with normal (N) DNA from the patient, and instability, a ladder of novel alleles, is seen in the patient's tumor DNA (T). The DNA sequences of two microsatellite loci (with dinucleotide repeat sequences) were each amplified by polymerase chain reaction and the fragments were separated by gel electrophoresis. At one locus (to the left) all novel alleles are of smaller size than the normal alleles whereas at the other locus (to the right) the new alleles are all larger (It should be noted that at individual loci one or more novel fragments of smaller, larger, and/or intermediate sizes may be seen in microsatellite unstable tumors). (b) One of the consensus markers for MSI detection, the BAT26, is shown. This marker is monomorphic and provides a typical pattern in the normal sample. The same allele is seen in the corresponding tumor in addition to a smaller sized novel allele with the same pattern. The amplified DNA is here separated by capillary electrophoresis using a DNA sequencer instrument.

alone to transform them malignantly. Nor do mutations in defective mutator genes, known to cause the phenotypic instability, necessarily provide a neoplastic growth advantage. Instead, the genotypic and/or the phenotypic instability increase the likelihood of additional mutations in other mutator genes and in more directly cancer critical genes. Mutations in mononucleotide repeat stretches in coding regions of different genes are characteristic of tumors with MSI. Insertions or deletions in a polymononucleotide sequence may cause frameshift mutations which lead to a shortened protein with no or abnormal function. Known target genes for defect mismatch repair include *TGFβRII*, important in transforming growth factor signal transduction; *BAX*, encoding a protein related to ►apoptosis; ►*PTEN*, an important negative regulator of the ►PI3K – AKT signaling cascade; CASP5, a positive regulator of apoptosis; *E2F4*, a cell cycle regulator and *TCF7L2*, a downstream transcription factor in the ►WNT-signaling pathway (Fig. 3).

Clinical Relevance

Several clinicopathological variables and the family history of HNPCC related cancers decide if further analyses should be performed to identify the disease associated susceptibility gene mutation in a family. First



Microsatellite Instability. Figure 3 Genes revealing frameshift mutations downstream of defect mismatch repair. Examples of genes with mononucleotide repeat sequences within their coding regions prone for replication errors. If a gain (+) or loss (−) of one base(s) is not repaired, this will cause a frameshift mutation leading to a new coding sequence for the protein (each amino acid is read in base-triplets). *BAX*: encodes a protein that accelerates apoptosis, *TCF7L2*: T cell factor, a downstream transcription factor in the WNT signaling pathway, *TGF-β RII*: transforming growth factor *β* receptor II, *MSH6*: encodes a component of the mismatch repair system.

the tumor samples of affected persons should be analyzed for MSI and for altered expression of the mismatch repair proteins, MSH2 and MLH1. These analyses can be performed on serial sections of the archival samples. The criteria for diagnosis of MSI have been standardized and include the analyses of five markers, two mononucleotide repeats (BAT25 and BAT26), and three dinucleotide repeats (D2S123, D5S356, and D17S250). If two (40%) or more markers show instability the tumor is classified as high microsatellite instability (MSI-H) and if only one of the marker display instability, the tumor is classified as low microsatellite instability (MSI-L). Immunohistochemical analyses of the MSH2 and MLH1 proteins add diagnostic information, since loss of expression of either one of them correlates highly with MSI-H and thus specifies which one is most likely to be mutated in the germline. Finally, constitutional DNA from family members should be submitted for germline mutation analyses of the relevant mismatch repair gene(s) to identify the genetic predisposition pattern in the family in question.

Sporadic colorectal cancer patient with tumors that reveal MSI have a prolonged postoperative survival. This was initially shown more than a decade ago, and although many small studies have reported conflicting results the initial observation was recently confirmed in a large meta-analysis study including thousands of samples. However, the use of MSI as a predictive marker of chemotherapy benefit remains debated.

Microtubule binding proteins; Tubulin interacting proteins; Microtubule stabilizing/destabilizing proteins; MAPs

Definition

MAPs are multifunctional proteins that bind to ►tubulins and alter the dynamics of their polymerization and depolymerization.

Characteristics

►Microtubules are hollow cylindrical structures consisting of polymers of αβ-►tubulin heterodimers. They are essential components of the cytoskeleton and play a critical role in many cellular processes including cell division, cell motility, intracellular trafficking, signal transduction and cell shape maintenance. ►Dynamic instability is an important property of microtubules and is indispensable for their function. This property is evident most notably during assembly and disassembly of ►mitotic spindle and segregation of duplicated chromosomes in mitosis. Intracellular dynamic behavior (polymerization/depolymerization) of microtubules is affected by post-translational modifications of tubulins as well as microtubule-stabilizing and microtubule-destabilizing proteins, collectively known as MAPs. Changes in phosphorylation of MAPs are known to influence ►cell cycle–specific dynamics of the microtubule network. MAPs of interest in ►cancer include (i) a family of specialized microtubule associated proteins (MAPs) and Tau, which are found most abundantly in neuronal cells, (ii) oncoprotein ►stathmin/Op18, (iii) ►tumor suppressors ►BRCA1 and pVHL (►Von Hippel-Lindau syndrome) protein and (iv) inhibitor of ►apoptosis protein ►survivin. This diverse group of proteins (ranging in MW 16–300 kDa) is characterized by a common feature, namely, association with microtubules. A microtubule binding domain is present in the N-terminus of MAP1A and MAP1B, while this domain in MAP2 and Tau is present at the C-terminus interspersed with18-amino acid repeats. Stathmin contains a microtubule destabilizing region within its alpha helical region, whereas pVHL contains a microtubule stabilizing domain within its helical domain. A γ-tubulin binding domain and baculoviral inhibitor of apoptosis repeat domain (►BIR domain) mediate the microtubule altering functions of ►BRCA1 and survivin, respectively.

MAPs and Cancer

By virtue of their importance in mitosis and cell division, MAPs are prime targets for anticancer therapy. The discovery of the first microtubule targeting drug, a *Vinca* alkaloid, was made serendipitously even before the term "microtubules" was coined in 1963. Discovery of other natural and synthetic microtubule-targeting compounds and understanding of cellular factors that influence their action was motivated by the observation that certain ►cancers are inherently resistant and others develop resistance to these microtubule targeting drugs. Although MAPs have received attention because of their role in resistance of cancers to microtubule targeting ►chemotherapeutic agents, more recently MAPs have also been implicated in other aspects of cancer including genetic susceptibility to certain cancer syndromes, development and aggressive behavior of a wide variety of cancers.

Cancer Predisposition

►Breast cancer 1 gene (►BRCA1) is a ►tumor suppressor gene implicated in predisposition to early onset of breast and ovarian cancer. ►Germline mutations in BRCA1 account for nearly half of ►hereditary breast cancer cases. A role for BRCA1 in ►microtubule dynamics and ►mitosis is indicated by its centrosomal localization during mitosis. Loss of ►BRCA1 ►ubiquitin ligase activity is thought to cause ►centrosome hypertrophy and subsequent ►aneuploidy typically found in ►breast cancers. A definitive role for BRCA1 in microtubule nucleation is supported by the observation that (i) BRCA1-dependent ►ubiquitination of γ-tubulin inhibits microtubule nucleation, and (ii) a mutant BRCA1 protein that lacks ubiquitin ligase activity, fails to inhibit microtubule nucleation. Another example of involvement of a microtubule binding protein in cancer predisposition is ►Von Hippel-Lindau protein (pVHL). VHL disease is a dominantly inherited cancer syndrome that predisposes people to tumours of the kidney (►renal cell carcinoma), retina and central

nervous system (►hemangioblastoma), the adrenal gland (►phaeochromocytoma) and various lesions affecting the kidney and the pancreas. pVHL is a microtubule-associated protein that can protect microtubules from depolymerization in vivo. Both microtubule binding and stabilization functions of pVHL depend on a region of pVHL that is also a mutational 'hot-spot' in VHL disease. Thus, inherited mutations in genes encoding multifunctional microtubule-binding proteins seem to contribute to a susceptibility to develop some types of cancers.

Cancer Development

The potential role of microtubule binding proteins in tumor development is exemplified by ►stathmin, which was originally identified as an 18 kDa oncoprotein (Op18). Stathmin is a member of a family of microtubule-destabilizing proteins. Stathmin is thought to act as tubulin-sequestering protein and also as a ►catastrophe promoter. High levels of stathmin expression are found in a variety of human malignancies. Increased expression of stathmin has been shown to precede tumor development in the induced rat mammary gland carcinogenesis model, raising the possibility that disruption of microtubule dynamics and abnormal mitosis may be critical events in breast cancer development. In human breast cancers, stathmin/Op18 levels correlate with a high fraction of aneuploid proliferative cells, larger tumor size and poor histopathologic grade. Stathmin has also been implicated in leukemogenesis and prostate tumorigenesis. Mutations in stathmin that affect its phosphorylation may also contribute to tumorigenesis.

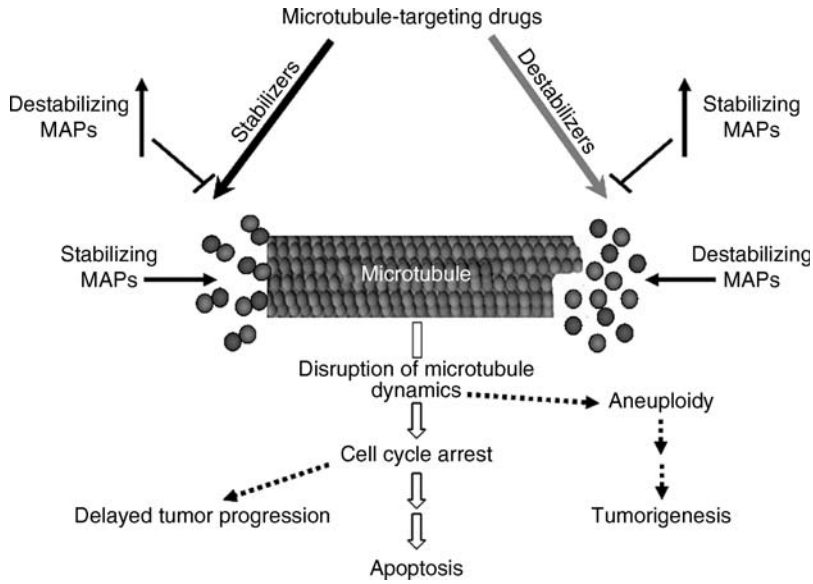
Cancer Diagnosis and Prognosis

The concept that MAPs, specifically neuronal-selective MAPs, could be cancer diagnostic markers originated from the observation that cancers of non-neural origin tend to exhibit neural or neuroendocrine differentiation. Among these MAPs, MAP2 is found most frequently in non-neural cancers. It is expressed primarily in the dendritic extensions of post-mitotic, terminally differentiated neurons. MAP2 plays a critical role in neurite outgrowth and dendrite development and its expression is considered a hallmark of neuronal differentiation. Variable MAP2 immunoreactivity is found in most pulmonary ►neuroendocrine carcinomas and in some non-small cell carcinomas. MAP2 is thought to be a valuable ancillary marker in skin tumors suspicious of neuroendocrine origin. An inducible, high molecular weight isoform of MAP2 is reported to be a diagnostic marker in a subset of oral ►squamous cell carcinomas.

In addition to being useful diagnostic markers, MAPs could also serve as valuable prognostic markers. In a variety of human malignancies, high levels of expression of stathmin is associated with poor prognosis. In contrast, there seems to be an inverse correlation between expression of microtubule stabilizing protein MAP2 and ►melanoma aggressiveness. Accordingly, while a majority of benign melanocytic nevi and primary malignant► melanomas are MAP2-positive, few ►metastatic lesions have MAP2 immunoreactivity. Expression of a neuronal differentiation-specific gene in neural crest-derived abnormal melanocytes is not entirely surprising. However, expression of a microtubule stabilizing protein in cells poised to proliferate rapidly could potentially have significant consequences on tumor growth and ►progression. In support of this notion, it was found that patients diagnosed with $MAP2^{+}$ primary melanomas had significantly better metastatic disease-free survival rates than those with $MAP2^{-}$ disease. Thus, activation of microtubule-stabilizing proteins in primary cancer cells may inhibit their proliferation and correlate with a delay or inhibition of ►metastasis. Conversely, dysregulated expression of microtubule destabilizing proteins may accelerate cell proliferation and tumor progression (Fig. 1).

Cancer Sensitivity/Resistance to Microtubule Targeting Drugs

Several natural and synthetic compounds that disrupt microtubule dynamics, and hence block mitosis, are currently in use as cancer chemotherapeutic agents. Two classes of compounds that are in wide use for chemotherapy of a variety of cancers are: ►Vinca alkaloids originally isolated from periwinkle *Vinca rosea* (►vinblastine, ►vincristine, vindesine and vinorelbine) and ►taxanes (►paclitaxel and ►docetaxel), which are diterpenes produced by the Pacific yew tree of the genus *Taxus*. Although these compounds are quite effective in killing cancer cells in vitro, variable sensitivity of different cancers in vivo and frequent acquisition of drug resistance is a major challenge in the use of these agents for cancer chemotherapy. Investigations to understand cellular factors and mechanisms involved in determining the sensitivity of cancer cells to microtubule-targeting agents have revealed MAPs as important factors in the drug-resistance mechanism. Studies on resistance of breast cancers to taxanes have provided much of our understanding of the role of MAPs in this phenotype. Gene expression analysis has identified Tau, a microtubule stabilizing protein expressed primarily in neurons, as a marker for sensitivity of breast cancer cells to paclitaxel. A low level or loss of Tau expression sensitizes breast cancer cells to the action of paclitaxel, presumably due to increased paclitaxel binding to microtubules when microtubules are assembled in the presence of low concentrations (or absence) of Tau, compared to microtubules that are formed in the presence of physiological (or higher) levels of Tau. Thus, breast cancer patients may be selected for paclitaxel therapy based on low Tau expression, and



Microtubule Associated Proteins. Figure 1 Schematic representation of role of MAPs in microtubule polymerization-depolymerization dynamics. (a) reciprocal relationship of microtubule stabilizing and destabilizing proteins to steady state dynamics as well as influence of MAPs on the effects of microtubule targeting chemotherapeutic agents is shown. Potential consequences of disruption of microtubule dynamics on cancer cells are also shown (*open and dashed arrows*).

inhibition of Tau could be a strategy to make tumors sensitive to paclitaxel. Similarly, overexpression of stathmin decreases polymerization of microtubules and consequently decreases sensitivity to paclitaxel and, to a lesser extent, to vinblastine. In contrast, stathmin content has no significant effect on the sensitivity to chemotherapeutic agents that do not target microtubules. Stathmin can affect the action of microtubule-targeting agents by both altering drug binding to microtubules and growth arrest at ►G_2/M transition of the cell cycle. Similarly, consistent with its role in microtubule nucleation during mitosis, BRCA1 also seems to mediate sensitivity of breast cancer cells to apoptosis induced by microtubule-targeting agents. The exact role of BRCA1 in determining the sensitivity to taxanes, however, is not clear.

In ductal adenocarcinomas and ►pancreas cancer, expression of MAP2 is known to be associated with sensitivity to microtubule-targeting drugs. Increased expression of ubiquitously expressed MAP4 has been observed in ovarian cancer cells and leukemia cells resistant to microtubule-targeting drugs. In ovarian cancer cells, MAP4 phosphorylation and dissociation from microtubules correlated with a decrease in ►Taxol sensitivity. Resistance of ►ovarian carcinoma cells to microtubule-targeting drugs has also been reported to be associated with altered regulatory pathways for stathmin expression and function. Additionally, survivin, a member of the inhibitor of apoptosis protein (IAP) family, also plays a role in the mitotic response in the context of Taxol resistance. Survivin functions at cell division to control microtubule stability and assembly of a normal mitotic spindle. This pathway may facilitate checkpoint evasion and promote resistance to chemotherapy in cancer. In contrast to their parental drug-sensitive counterparts, Taxol-resistant ovarian cancer cells exhibit defective mitotic response to the drug and fail to upregulate survivin levels and survivin phosphorylation.

Thus, a better understanding of factors and mechanisms and their role in conferring resistance to microtubule-targeting agents is essential for rational use of highly effective, often toxic, microtubule-targeting agents for cancer chemotherapy.

Cell motility; Cell locomotion

Definition

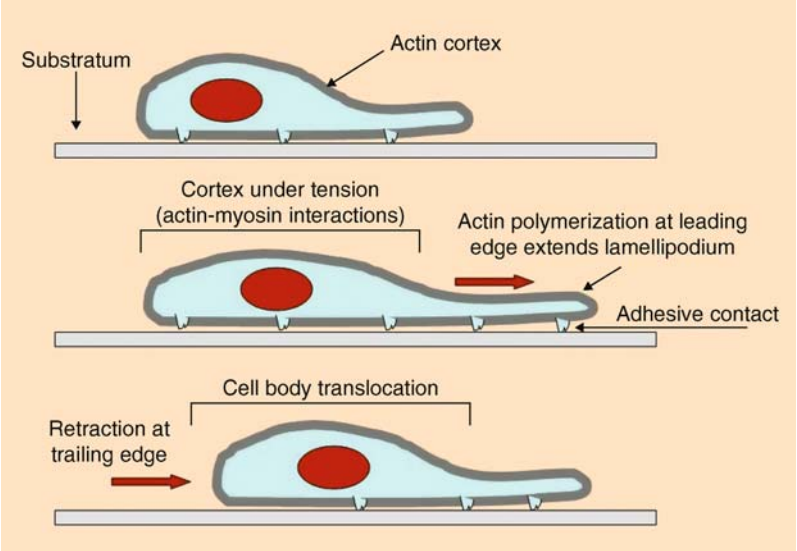
Cell migration can be defined as the movement of cells from one site to another and is a central process in the development and homeostasis of multicellular organisms. The orchestrated movement of cells in a particular direction to a specific location is essential for tissue formation during embryonic development, wound healing and immune responses. Deregulation of cell migration during any of these processes has serious consequences and can contribute to mental retardation, vascular disease, rheumatoid arthritis, tumor formation and metastasis.

Characteristics

Cell migration (the movement of cells from one site to another) is an essential process for normal development and homeostasis that can also contribute to important pathologies such as neoplasia. For example, one of the major mechanisms involved in tumor cell ►invasion is cell migration, a process in which cells demonstrating higher invasive capacity typically show higher migratory ability. Cell migration is a complex and highly coordinated processes which involves changes in the expression of several genes. Cell migration requires an intricate balance between extracellular cues and responsive intracellular signals that lead to dynamic regulation of the interactions between ►actin microfilaments, microtubules, intermediate filaments and associated ►cell adhesion molecules. The driving force for cell movement, however, is normally provided by dynamic reorganization of the actin ►cytoskeleton, directing protrusion at the front of the cell and retraction at the rear. In general, cell migration can be conceptualized as a cyclic process (Fig. 1). For a cell to move, it must establish morphological polarity resulting in leading and trailing edges with directionalized forces. To accomplish this, the initial step requires extension of protrusions in the direction of movement. These protrusions can be large, broad ►lamellipodia or spike-like ►filopodia that are typically formed by active actin polymerization. Frequently, lamellipodia evolve into ruffles either *de novo*, or when the membrane protrusions fail to adhere and are swept backward on the dorsal surface.

Protrusions are then stabilized by adhering to the ►extracellular matrix (ECM) or to adjacent cells via transmembrane receptors which are in turn linked to the actin cytoskeleton. Different forms of ►focal contacts exist that serve as adhesive structures to connect the cell with the ECM. They consist of two main elements: i) A transmembrane component comprised of clusters of ►integrin molecules linked to the ECM; and ii) A submembranous component comprised of a complex of proteins such as vinculin, talin, ►FAK and other proteins. Although, focal contacts react to actin-myosin tension, they also transmit their own tension upon the ECM to which they are linked. Since migrating cells must be able to detach, yet exert traction on the substratum, the velocity of migration is a biphasic function dependent on the strength of cell attachment. Finally, a contractile force, derived by the interaction of actin with myosin II to form a functional actin-myosin motor unit, propels the cell forward and contributes to the release of adhesive contacts in the rear of the cell and cell body translocation.

Considerable research with *in vitro* model systems has led to an increased understanding of cancer cell motility and invasion. The difficulty with many of these systems, however, is their relevance to the *in vivo* situation. Cell movement on a glass surface in a two dimensional plane is clearly different than invasion in a three dimensional environment. To improve our understanding of tumor cell migration, scientists have used *in vivo* imaging by intravital multiphoton technology, three dimensional in vitro models, and histological analyses as techniques to further characterize migration in a more physiological and representative context. The best understood system at present relates to mesenchymal cell motility which is characterized by an elongated morphology with established cell polarity. This polarity is dependent upon proteolysis to degrade the ECM. It is estimated that cancer cells which undergo ►epithelial to mesenchymal transition (EMT), a phenomenon which takes place in ~10% of all solid tumors, use this form of motility. Intravital imaging has



Migration. Figure 1 The Steps of Cell Migration. The migration of cells over substrata is a fundamental and critical function that requires the co-ordination of several cellular processes which operate in a cycle. Cell migration across two-dimensional (2-D) surfaces consists of at least three steps: (i) the protrusion of the leading edge for adhesive cell-substratum interactions is followed by (ii) contraction of the cell body and (iii) detachment of the trailing edge.

demonstrated that some cancer cells move at very high speeds with amoeboid morphology, very similar to the rounded form of migration of leukocytes and *Dictyostelium*. Another form of cell motility is called collective cell motility which involves the movement of whole clusters of sheets of tumor cells. Collective cell motility has been observed in infiltrating ►breast carcinoma and some ►ovarian carcinomas. In several other cancers, including ►gliomas, the type of motility employed has not been clearly defined and will require intravital imaging techniques to help in this assessment in the future.

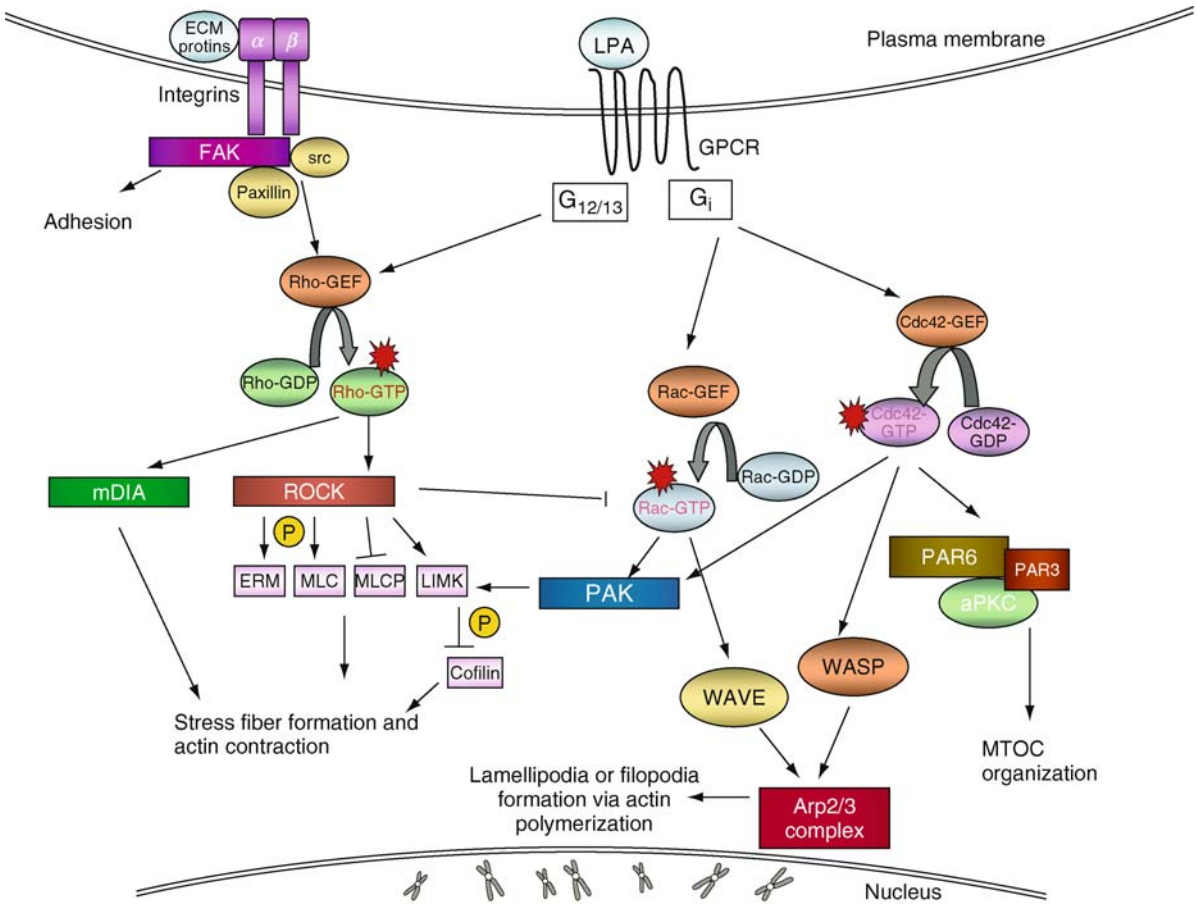
Mechanisms of Cell Migration: Rho-GTPases are Key Players

In the past decade, the analysis of a model cell line, Swiss 3T3 fibroblasts, has led to the identification of three ►signal transduction pathways responsible for controlling actin remodeling leading to directional cell migration. Each of these pathways is controlled by a member of the ►Rho family of small GTPases. Rho-►GTPases are members of the ►Ras superfamily of proteins. They are essentially molecular switches that become activated when they are bound to GTP and inactivated by hydrolysis of GTP to GDP. Rac, Cdc42, and Rho are the best characterized members of this family (Fig. 2).

Rac

Rac is required to regulate actin polymerization and formation of lamellipodia at the leading edge of cells and is thought to be the driving force for cell movement. Formation of small ►adhesions known as focal complexes which help stabilize the lamellipodium to the ECM also depends on Rac. To accomplish this, Rac recruits high affinity integrins to the area where new membrane protrusions are occurring. Members of the WASP/SCAR/WAVE family of scaffold proteins are key regulators of actin polymerization. In their stimulated state, each of these proteins is able to stimulate Arp2/3 complex which can initiate actin polymerization. Rac stimulates lamellipodia extension by activating SCAR/WAVE proteins indirectly and involves the Nck-adaptor complex.

One of the best characterized effectors that transmits the Rac signal is the Ser/Thr kinase, PAK. PAK plays an important role in regulating actin remodeling and cell adhesion during cell migration. The effects of PAK are partially controlled by its subcellular localization and interaction with binding proteins. In quiescent cells, PAK is distributed throughout the cytoplasm; however, when cells are stimulated, PAK is targeted to focal adhesions and membrane ruffles through binding of PIX. PAK has also been shown to phosphorylate and activate LIM kinase (LIMK), which in turn phosphorylates cofilin. Cofilin facilitates subunit dissociation from the pointed end of actin filaments and induces filament severing. It is also essential for promoting filament treadmilling (assembly/disassembly of free filament ends) at the front of migrating cells. PAK can also alter the phosphorylation state of myosin II. However, there are conflicting data on the role of PAK in myosin phosphorylation.



Migration. Figure 2 A schematic overview of Rho-GTPase signaling as it pertains to cell migration. Rho, Rac and Cdc42 are the best characterized members of this family of monomeric GTPases. They exert their action when extracellular stimuli transduce signals to upstream Rho-GTPase activators known as guanine nucleotide exchange factors (GEFs). Activated Rho, Rac or Cdc42 bind to downstream effector kinases which then phosphorylate a plethora of substrates leading to dynamic reorganization of the actin cytoskeleton essential to the efficacy of directed cell migration.

Expression of constitutively activated PAK resulted in decreased phosphorylation of the regulatory light chain of myosin in Hela cells which is in contrast to activated PAK in NIH3T3 cells, where activated PAK promoted MLC phosphorylation.

Cdc42

Cdc42 is the major regulator of cell polarity and plays a crucial role in controlling the direction of migration in eukaryotic organisms ranging from yeast to humans. One way in which Cdc42 influences polarity is by restricting where lamellipodia form. Cdc42 can also affect polarity by localizing the microtubule-organizing center (MTOC) and Golgi apparatus in the front of the nucleus, oriented toward the leading edge. The effects on MTOC position appear to be exerted mainly through a pathway involving the Cdc42 effector protein PAR6 which exists in a complex with PAR3 and an atypical protein kinase C (aPKC). However, the exact molecular mechanism by which PAR6/PAR3/aPKC complex orients the MTOC is still not well defined. PAK, also a downstream target of Cdc42, can itself mediate Cdc42 activation downstream of heterotrimeric G-protein coupled receptors, which are activated by many chemoattractants. These signaling events mediate a positive feedback loop between Cdc42 and PAK.

In response to bradykinin and interleukin 1, Cdc42 also induces parallel actin filament assembly to form filopodia. Filopodia are particularly well designed to serve as sensors and to explore the local environment, although they are not essential for chemotaxis. Cdc42 binds to WASP proteins and in vitro stimulates the Arp2/3 complex to induce dendritic actin polymerization and subsequent filopodia formation. WAVE/WASP proteins may themselves regulate the activity of Rac and Cdc42 by binding to GAPs and GEFs and could therefore generate positive or negative feedback loops to regulate the extent of actin polymerization.

Rho

Rho activity in migrating cells is associated with focal adhesion assembly and stress fiber formation and is responsible for cell body contraction and rear end retraction in response to a variety of extracellular stimuli such as ►lysophosphatidic acid administration or integrin engagement. The inhibition of Rho in cells like fibroblasts decreases adhesion causing a retraction of lamellae and rounding of the cell body. Rho can stimulate the clustering of integrins and thereby increases the strength of adhesion. The clustering is very pronounced and results from tension aggregating dispersed integrins, such that they align through their attachment with the ends of stress fibers in focal adhesions. Contractile actin-myosin filaments are found in all mammalian cells. In cultured fibroblasts, these are readily seen as well organized bundles known as stress fibers that are tethered to the plasma membrane at focal adhesions. The ability of Rho to induce the assembly of actin-myosin filaments and therefore contractility appears to depend on the activation of two distinct targets, Ser/Thr kinase p160ROCK (also known as ROCK, Rho-kinase) and the formin family protein, mDia.

ROCK has many targets but a key one is the myosin binding subunit of myosin light chain phosphatase. Phosphorylation leads to inactivation of the phosphatase which leads to an increase in the levels of myosin light chain (MLC) phosphorylation and cross-linking of myosin II into actin filaments and generation of cell tension. ROCK can also take the place of myosin light chain kinase (MLCK) and directly phosphorylate MLC. In its active state, ROCK, like PAK, can also phosphorylate and activate LIMK, which in turn phosphorylates and inactivates cofilin leading to stabilization of actin filaments within actin:myosin filament bundles. ►Ezrin/radixin/moesin (ERM) family proteins, adducin, and intermediate filaments (IFs) are also substrates of ROCK and the phosphorylation states of these targets are implicated in specific cell functions. mDia is another major player for promoting actin polymerization in eukaryotic cells. Upon binding Rho-GTP, mDia adopts an open conformation and binds to the barbed ends of actin filaments. It has the property of allowing addition of actin monomers to filaments while preventing the binding of capping proteins which would otherwise block elongation. mDia also co-operates with ROCK to assemble properly aligned stress fibers.

Summary

Migration is an extremely important cellular process that is important in both health and disease. For wound healing, nerve regeneration, infection control, and thrombosis, cellular migration plays a pivotal role in returning the host to a repaired and normal basal state. In the context of cancer, tumor cells have subverted the normal molecular pathways controlling migration. It is no small wonder then that the inhibition of tumor cell migration remains an important area of research with great therapeutic potential.

Mimetic Peptide

Definition

Refers to a synthetic drug that has the activity of a native peptide. Peptide sequences, synthesized both

chemically and biologically, are constituents of larger proteins where map to particular domains that are responsible for molecular recognition and biological responses. Inhibition of protein-protein interactions of cancer-related proteins by synthetic peptides has been one of the approaches towards cancer therapies.Peptides have been considered to be ideal drug leads. However, the use of peptides is limited as they are metabolically unstable due to protease cleavage and have poor bioavailability, which is in part due to a low membrane transport characteristics. Synthesis of mimetics follows approaches of rational drug design employing technology platforms of molecular design and structure-activity analysis. Following these approaches, mimetics have been designed that retain biological activities of the native peptide, but due to molecular modifications are metabolically stable, have good membrane transport characteristics and bioavailability, and therefore have drug-like pharmaceutical properties.

►Anti-HER2/Neu Peptide Mimetic.

Min

Definition

Multiple intestinal neoplasia; Refers to the first mouse model used to study the involvement of the Apc gene in ►colon cancer. Apc $^{Min/-}$ mice are heterozygous for an Apc mutation that leads to a truncated protein, they develop numerous intestinal adenomatous polyps therefore providing a good model for human familial adenomatous polyposis (FAP). As the number of polyps varies considerably in different mouse strains haboring mutated Apc, a genetic locus modifying this number has been proposed. Genetic linkage studies located such a modifying locus, Mom1, on mouse chromosome 4. At least two additional such loci appear to exist on other chromosomes. In humans, the existence of these modifier loci could not be confirmed.

Mineral Nutrients

Kevin A. Cockell
Nutrition Research Division, Health Canada, Ottawa, ON, Canada

Synonyms

Dietary essential minerals; Macro- and microminerals; Electrolytes; Trace elements

Definition

Mineral nutrients are inorganic substances that must be ingested and absorbed in adequate amounts to satisfy a wide variety of essential metabolic and/or structural functions in the body. Mineral nutrients are sometimes categorized according to the amount required in the human diet to maintain good nutrition. Macrominerals is a general term encompassing both ►bulk minerals (calcium, phosphorus, magnesium) and ►electrolytes (sodium, potassium, chloride), which are required to be ingested by humans in amounts of hundreds of milligrams to several grams per day. Microminerals or ►trace elements (including iron, zinc, copper, manganese, ►selenium, iodine, chromium, molybdenum) are required in amounts of a few milligrams or less per day. The latter members of this group, which are required only in amounts of micrograms per day, are sometimes referred to as ultratrace elements.

Characteristics

For mineral nutrients, as for other classes of nutrients, nutrition experts have reviewed the available scientific evidence and defined the levels of intake required for nutritional adequacy and the maintenance of good health. Thus we have, for example, the Dietary Reference Intakes in North America and Dietary Reference Values in the United Kingdom. The Dietary Reference Intakes include the Recommended Dietary Allowance (RDA) for nutrients where there is sufficient scientific evidence to allow accurate assessment of the requirement level for nutritional adequacy and the Adequate Intake (AI) for nutrients where there is still uncertainty in the available evidence. In many cases a Tolerable Upper Level of Intake (UL) has also been determined, above which chronic intakes may be expected to yield increased risk of adverse health effects.

Requirements for mineral nutrients in healthy individuals can differ between males and females, at different ages, and in pregnancy and lactation. Genetic variation between individuals can have important influences on individual requirements for mineral nutrients. Mineral nutrient requirements and metabolism can also be altered by chronic diseases such as cancer.

Mineral nutrients are required to meet a wide variety of essential metabolic and structural functions in the body. Mineral nutrients fulfill structural roles in the body on different scales, from whole body to molecular levels. For example, calcium and phosphorus are deposited as hydroxyapatite crystals [$Ca_{10}(PO_4)_6(OH)_2$] in an organic matrix to form bones and teeth which make up the skeleton. Zinc has a structural coordination role through specific amino acids in ►zinc-finger proteins, which interact with DNA in the cell nucleus. Magnesium is required to maintain the optimal orientation of ATP at the active site of kinase enzymes.

The metabolic functions of mineral nutrients are far too numerous to catalogue here, but include such diverse roles as iron complexed in the heme nucleus in hemoglobin and myoglobin for oxygen transport in the blood and muscle tissues, electrolyte flux in nerve transmission, calcium as an intracellular second messenger, phosphorylation and dephosphorylation in control of key enzyme activities through the actions of kinases and dephosphorylases, and the involvement of specific mineral nutrients at the active sites of ►metalloenzymes and metal-associated enzymes. Thus, mineral nutrients are involved in virtually all aspects of normal cellular metabolism. It is not surprising, therefore, that mineral nutrients should also be involved in abnormal cellular metabolism in chronic diseases, including cancer.

Concentrations of mineral nutrients in foods or biological tissues can be measured in a number of ways. As a first step it is often necessary to destroy all of the organic components of the sample, either with high temperature or concentrated acids. The residual minerals can be dissolved in mild acid solution and quantified using technologies such as atomic absorption spectrophotometry or mass spectrometry, to name just two. The total level of a mineral nutrient in a food is often not as revealing, however, as determination of its ►bioavailability, which represents the proportion of the ingested nutrient that can be released from the food matrix by digestion, absorbed across the intestinal wall and utilized by the body to meet the specific functions of that mineral nutrient in the body.

To determine the mineral nutrient status of an individual, in some cases the concentration of the mineral nutrient may be measured in a suitable sample such as whole blood, serum or urine. Blood or serum levels of some mineral nutrients are under close homeostatic control and depart from normal ranges only under extreme medical conditions. Where available, ►functional assays can sometimes provide a clearer picture of adequacy. Iron status, for example, can be measured as hemoglobin concentration (showing adequacy of red blood cells in circulation) or serum ferritin concentration (showing adequacy of body iron stores), among a number of other available indices. Activity of specific metalloenzymes may also be used, such as glutathione peroxidase for selenium or copper, zinc-superoxide dismutase for copper.

Mineral Nutrients and Cancer

The mechanisms of action of mineral nutrients in normal metabolism and in cancer are complex, varied and not yet completely understood. Researching a single component is like picking up a single piece of a complex jigsaw puzzle – you may be able to discover where it fits, but it alone can not provide the whole picture. While a reductionist approach, with the investigation of a single nutrient at a time, has been successful in the discovery and characterization of nutrient-specific deficiency diseases, an integrative approach may be more appropriate to investigation of the complex issues of nutrition, metabolism and a chronic disease having multiple etiological factors, such as cancer. This will continue to be a rich area of research for many years to come.

Epidemiological evidence of inverse relationships between intake of fruits and vegetables or whole grains and cancer incidence has been observed for many types of cancers. While antioxidant vitamins and ►phytochemicals have been implicated as potential active components contributing to this relationship, these foods also can be rich sources of mineral nutrients. Metabolic interactions between mineral nutrients, vitamins and phytochemicals add to the complexity of trying to attribute the benefits associated with these foods to a specific causative agent. The results of several large-scale trials conducted to date to investigate the effects of specific vitamin, phytochemical and/or mineral nutrient supplements on cancer rates have yielded mixed results. Some of these trials may not have used the optimal doses, or were of insufficient duration to allow the discovery of significant effects. It may also be that the interactive effects of several compounds acting together are necessary for the observed effects. Obtaining mineral nutrients through consumption of a well-balanced diet helps to ensure intake of additional dietary components which have beneficial health effects.

With the diversity of different types of cancers at different tissue sites, combined with the complexities of food consumption and combinations, the challenge of evaluating associations discovered in epidemiology studies is formidable. Clear distinction should be made between mineral nutrients used as therapeutic agents (at levels well beyond the defined requirements) and the effects of nutritionally adequate levels in preventing events associated with deficient levels of intake. Dose is also important in reconciling the evidence that excessive amounts of some mineral nutrients can have adverse metabolic effects that may contribute to cancer. Careful distinction should be maintained between epidemiological evidence of an association between a nutrient (or nutritional profile) and a cancer, versus

experimental evidence of plausible mechanisms by which a mineral nutrient may contribute to or aid in prevention of a cancer. Experimental mechanistic investigations should be done to support or refute epidemiological associations. Ultimately, evidence from human intervention trials is required to establish the effectiveness of specific approaches.

There is at present a relative paucity of human clinical intervention trials of efficacy of mineral nutrients in cancer prevention. In many of these studies relatively few doses or even just a single dose have been tested, so that limited dose-response information is provided. Also, the very long time course for development of many tumor types makes it difficult to study interventions. Baseline ►nutritional status may be critically important, as effects might only be observed in individuals with pre-existing deficiency or marginal status of a mineral nutrient.

Mineral nutrients (as with other nutrients) can influence many aspects of cancer, including effects on tissue susceptibility to carcinogens, effects on intestinal microfloral metabolism that can, in turn, influence the activation or inactivation of carcinogens in the intestinal tract, and effects on endogenous activation or inactivation of carcinogens in body tissues. Mineral nutrients may be involved in cellular metabolism in ►DNA repair, as antioxidants, in immune system modulation or in many other ways.

Either deficiencies or excesses of mineral nutrients can lead to disturbances of normal metabolism that can contribute to carcinogenesis, of which a few examples are considered here. Excessive accumulation of iron has been linked to the development of ►hepatocellular carcinoma in individuals afflicted with hereditary hemochromatosis and other iron loading syndromes. This may be related to the potential for ►oxidative stress damage when a transition metal like iron exceeds the capacities of the tissue to properly handle it, but deficiency of iron has also been associated with oxidative ►DNA damage. Adequate tissue levels of iron are also needed for dNTP synthesis as the ribonucleotide reductase enzyme contains iron.

Adequate levels of zinc are required to maintain the structure of zinc finger proteins involved in transcriptional regulation through intercalation with DNA. Deficiency of zinc also leads to loss of activity of zinc-containing DNA repair enzymes such as formamidopyrimidine glycosylase (involved in repair of oxidized guanine), compromising the ability of the cell to repair damage, hence contributing to tumorigenesis.

Several mineral nutrients are found in antioxidant metalloenzymes, including selenium in glutathione peroxidase, copper, zinc and manganese in the different isoforms of superoxide dismutase, and iron in catalase. These enzymes are part of a complex metabolic network controlling cellular redox status. Oxidative stress mechanisms have been implicated in carcinogenesis and also in certain chemotherapeutic strategies.

Inverse relationships have been reported between prediagnostic serum selenium levels and cancers at several sites including ►lung, ►colorectal and ►prostate cancers in men. Supportive evidence of anti-cancer effects of selenium, at levels above those required for maximal expression of known selenoenzymes, have been found in some animal and cell culture models, though the mechanisms of action are not fully known. Selenium is an element with a rich organic chemistry, and further investigation is needed of the effects of specific chemical forms and metabolites.

Low calcium intakes have been weakly associated in several studies with increased risk of colorectal cancer. High intakes (above nutritional requirements) have also been associated with increased risk of prostate cancer in some epidemiological studies indicating that in cancer metabolism, as with normal metabolic functions, there is an optimal range of intakes. One possible mechanism for the effect of calcium in reducing ►colon cancer risk is through binding with free fatty acids and ►bile acids or bile salts in the intestinal lumen, thereby decreasing the influence of these compounds on colonic epithelial cell proliferation.

High consumption of salt-cured or salt-pickled foods has been associated with increased risk of ►gastric cancer, leading to recommendations to minimize consumption of such foods. Excessive ►salt intake (sodium chloride) has been implicated in the development of gastritis leading to carcinogenesis, and may contribute to promoting effects at later stages.

In addition to mineral nutrients having effects on cancer, cancer can have significant effects on mineral nutrient metabolism. Tumor tissues may differ in mineral nutrient content from adjacent normal tissue, suggesting differences in metabolic requirements. Cancer patients can experience a variety of nutritional deficiencies including deficiencies of mineral nutrients, because of altered metabolism, altered dietary intakes, or drug interactions. These may sometimes be overlooked in the course of therapeutic monitoring.

Serum selenium and zinc concentrations have been shown to be significantly lower in patients with digestive tract cancers prior to commencing any therapy, than in control patients, while serum copper concentrations have been shown to be higher. Supplementation with selenium and zinc was found to minimize or prevent further worsening of nutritional status. Serum iron, too, has been shown to be lower in cancer patients in several studies. ►Chemotherapy with ►cisplatin can cause significant alterations in serum levels of mineral nutrients including copper, zinc and magnesium. Adjunctive therapies such as antacids or diuretics can also significantly influence mineral nutrient metabolism. It has

been suggested that at least some alterations in serum mineral nutrient concentrations may reflect the general changes in tissue distribution seen with ►inflammation. Such changes can also complicate status assessment in cancer patients. In all cases it is important to consider the question of whether altered status predisposes to altered metabolism, or results from it.

Restoration of altered mineral nutrient status may benefit patients (as with selenium and zinc, above) either by helping to maintain metabolism in normal tissues or by enhancing metabolic effects of therapy on tumor tissue. However, mineral nutrient supplementation could, in some cases, interfere with therapeutic effects of treatments. Specific situations call for specific understanding of the metabolic interactions involved.

Minimal Residual Disease

Jerald P. Radich
Clinical Research Division, Fred Hutchinson Cancer Research Center, Seattle, WA, USA

Synonyms

MRD; Residual disease

Definition

The presence of disease detected in a patient who by conventional clinical and pathologic measurements is in remission.

Characteristics

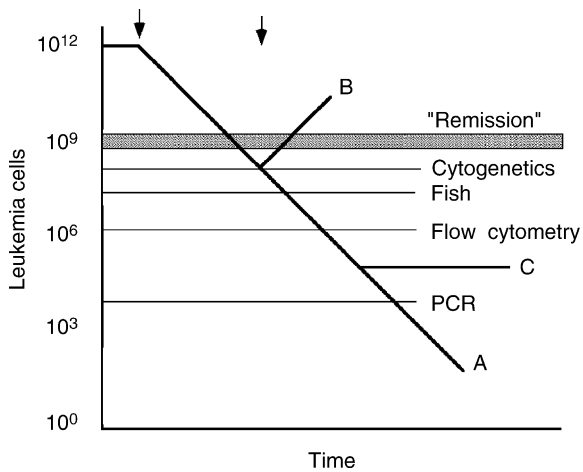
At diagnosis a patient with cancer may have billions of malignant cells. In ►leukemia, these cancer cells circulate in the bloodstream. After chemotherapy many cancer patients achieve "►remission," meaning that their disease cannot be detected by conventional clinical, radiological, and pathological examinations. Nonetheless, the major cause of failure in cancer therapy is the recurrence of disease, usually after the induction of a remission. The problem of defining remission and relapse is illustrated in (Fig. 1). In this essay we will use leukemia, a malignancy of the white blood cells, as a disease example, though the principle of remission, minimal residual disease (MRD) detection, and relapse applies to all malignancies.

At diagnosis leukemia patients may have a disease burden up to 10^{12} leukemia cells (Fig. 1). Thus, even if chemotherapy kills 99.9% of the leukemia population, up to 10^{9} cancer cells may remain despite the microscopic appearance of remission. The study of MRD aims to redefine the concept of remission, and differentiate patients with leukemia destined for relapse from those with a stable or declining leukemia load. Once identified, patients at a high risk of relapse could undergo additional or alternative therapy while the disease burden is several orders of magnitude less than at frank hematological relapse.

Methods of Detecting MRD

The limitation of the conventional definition of remission is apparent, since many leukemia patients who attain remission nevertheless relapse. Other

methods to define residual disease include "classic" metaphase and molecular ►cytogenetics, cell ►cytometry studies, and molecular genetic studies, such as the polymerase chain reaction (►PCR) detection of specific genetic targets. Each method takes advantage of differences in the characteristics of the tumor cell compared to the normal cell, and each has relative advantages, disadvantages, and sensitivity of detecting MRD (Table 1). Cytogenetics can detect approximately one leukemia cell in 10–100 normal cells (denoted as 10^{-1} sensitivity). Limitations of cytogenetics include a small sampling size (since typically only 20–50 cell metaphases can be examined), and the examination of only cells that grow and divide in culture. To increase sensitivity and facilitate genetic screening in non-dividing cells, ►fluorescence *in situ* hybridization (FISH) using chromosome-specific or locus-specific probes has been developed to identify genetic targets in both metaphase chromosomes and interphase nuclei. FISH is most useful in detecting simple losses or gains of chromosomes and ►chromosomal translocations. The sensitivity of FISH is between 10^{-1} and 10^{-2}, and detection of numerical losses or gains of chromosomes is generally more sensitive than for detecting translocations.



Minimal Residual Disease. Figure 1 The detection of MRD. At diagnosis patients may have up to 10^{12} leukemia cells. Treatment (arrows) decreases the load of leukemia below the threshold of microscopic detection ("Remission"). Further treatment further decreases the burden of leukemia. The sensitivity thresholds of other detection methods are shown as horizontal, labeled lines. Studies of MRD attempt to distinguish patients with decreasing disease (1A) versus those with disease in remission, yet bound towards relapse (1B). Lastly, there is a poorly understood phenomenon of "dormancy," whereby patients may have steady, very low disease burdens persisting for years (1C).

Normal cells display a variety of proteins on their outside surfaces, known as cell surface antigens. The expression of cell surface antigens can distinguish malignant from normal cells. Cells labeled with fluorescent antibodies can be detected and quantified by a fluorescence-activated cell sorter (FACS). While truly tumor-specific antigens are rare, studies have shown that malignant cells often express cell surface antigens in subtly different patterns than normal cells. By using combinations of multiple antibodies, flow cytometric assays can use the patterns of aberrant expression to "fingerprint" the malignant clone. The sensitivity of flow cytometry is 10^{-1} to 10^{-3}. The advantage of flow cytometry is that it is rapid, with results within hours of sample collection. However, to fully optimize the sensitivity of detecting the leukemia clone, combinations of several antibodies are needed to define the aberrant antigen expression, requiring considerable technical expertise.

The most sensitive approach to detect MRD involves nucleic acid amplification using the PCR. The power of the technique is the exponential amplification of the target genetic sequence. Each round of the PCR produces an exponential amplification from the initial starting copy number, following the equation N = No (1 + E) C (where N = PCR product, No = initial gene target number, E = efficiency of the PCR reaction, and C = number of PCR cycles). Thus, 30 cycles of amplification will yield over a million-fold amplification of the target. However, the PCR must have a specific genetic lesion as the "fingerprint" of the malignancy in order for PCR-driven reactions to have the desired sensitivity and specificity.

PCR based assays need specific genetic targets that are found in the cancer cells, but not in normal cells.

Minimal Residual Disease. Table 1 Methods to detect minimal residual disease

Technique	Target	Sensitivity
Pathologic examination	Cellular morphology	5%
Cytogenetics	Chromosome structure	1–5%
FISH	Specific genetic marker(s)	0.08–5%
Flow cytometry	Surface antigen expression	0.1–1%
PCR	DNA or RNA sequence	0.0001–0.1%

Chromosomal translocations are the most straightforward leukemia-specific markers for the detection of MRD. The prototypical translocation is the t(9;22) in ►chronic myeloid leukemia (CML), which causes the reciprocal translocation of the ABL gene on chromosome 9 to the BCR gene on chromosome 22. The juxtaposition of BCR-ABL forces the expression of the chimeric BCR-ABL ►mRNA, which can be specifically amplified by reverse transcription (RT)-PCR. Other examples of leukemia-specific translocations include the t(15:17), t(8;21), and inv. (16) found in ~30%, collectively, of ►acute myeloid leukemia (AML) cases, and the t(14;18) rearrangement detected in follicular cell ►non-Hodgkins lymphoma. However, genetic research of leukemia has discovered a rapidly expanding list of disease-specific translocations, and now genetically characterized translocations can be detected and amplified in 40–50% of AML and ►acute lymphoblastic leukemia (ALL).

In lymphoid malignancies, detection strategies take advantage of the rearrangement of the immunoglobulin heavy chain and T-cell receptor genes that occur normally in B and T-cell lymphoid development. During the development of a B-cell, for example, immunoglobulin heavy chain variable, junction, and diversity genes are merged from their germ line configuration to produce a shortened IgH V-D-J rearrangement. Each B cell has a unique IgH V-D-J sequence which determines the unique antibody that it produces. When a B-lineage cell transformed into a malignant clone, all leukemia cells will have the same IgH V-D-J rearrangement. This V-D-J gene rearrangement can serve as the leukemia-specific "fingerprint" of the leukemia. PCR methods can be used to then track the presence or absence of this clonal marker after therapy.

Clinical Relevance

The study of minimal residual disease (MRD) aims to understand the biology and clinical significance of leukemia that persists in patients who are in complete remission by conventional pathological examination. To recap, treatment of cancer during the level of disease burden below the threshold of detection by conventional pathology. This defines conventional "remission" (Fig. 1). Further therapy may drive disease levels further downward (1A). Alternately, the cancer may acquire ►resistance and begin to grow (1B). Lastly, some patients remain with MRD for years without relapse (1C).

The clinical significance of MRD has been most solidly determined in leukemia and lymphomas. The frequency of MRD detection varies with disease, type of treatment, and time in the treatment course. In CML, the detection of BCR-ABL mRNA (arising from the t(9;22) translocation) is associated with a >tenfold increase in relapse after ►hematopoietic stem cell transplant (HSCT). For CML taking tyrosine kinase inhibitors (such as Gleevec), the BCR-ABL level predicts long-term outcome. In AML and ALL, detection of MRD by PCR or flow cytometry is highly associated with subsequent relapse. The same holds for ►chronic lymphocytic leukemia (CLL) and ►multiple myeloma, both B-cell malignancies where MRD can be detected by PCR assays directed at clonal immunoglobulin gene rearrangements.

Not all patients with detectable MRD progress to relapse. The persistence of MRD without subsequent relapse has been referred to as ►dormancy (Fig. 1). Dormancy has been seen in t(8;21) AML following conventional chemotherapy, where most long-term survivors remain PCR-positive. Dormancy has also been seen in CML following HSCT. Furthermore, late relapses in pediatric ALL (who relapse >10 years after the establishment of remission) have the same clonal IgH VDJ gene rearrangement as at diagnosis, suggesting a very long-term dormancy of highly malignant cells. The mechanism of dormancy is unknown. It is likely that the clinical definition of "cure" in cancer does not mean the elimination of *all* cells involved in the leukemia process. The further study of dormancy may clarify what it takes to "cure" leukemia.

Definition

Bisphosphonates are potent inhibitors of bone resorption and are widely used drugs for the treatment of osteoporosis, osteolytic bone metastasis and tumor-associated hypercalcemia. These compounds have high affinity for calcium ions and therefore target bone mineral, where they are internalized by bone-resorbing osteoclasts and inhibit osteoclast function. Minodronate, a nitrogen-containing bisphosphonate, acts intracellularly by inhibiting farnesyl pyrophosphate synthase, thus leading to the inhibition of post-translational prenylation of small molecular weight G proteins, which could also contribute to its anti-resorptive activity on osteoclasts and its anti-tumor effects *in vivo*.

Characteristics

Minodronate is one of the most potent nitrogen-containing bisphosphonates. Farnesyl pyrophosphate synthase is a molecular target of nitrogen-containing bisphosphonates, and inhibition of post-translational ►prenylation of small molecular weight G proteins is likely involved in their anti-tumor effects both *in vitro* and *in vivo*. Further, since nitrogen-containing bisphosphonates accumulate in human vessels as well, it is also probable that they might have pleiotropic effects on vascular cells by blocking the protein prenylation of small G proteins, which serve as lipid attachments for a variety of intracellular signaling molecules.

Effects of Minodronate on Endothelial Cells (ECs)

►Angiogenesis, a process by which new vascular networks are formed from pre-existing capillaries, is required for tumors to grow, invade and metastasize. It is generally considered that a major event in tumor growth and expansion is the '►angiogenic switch'. ►Vascular endothelial growth factor (VEGF), a specific mitogen to endothelial cells, is a crucial factor for tumor angiogenesis. VEGF also acts as a pro-inflammatory cytokine in tumorigenesis. Several lines of evidence implicate VEGF as the key factor involved in tumor growth, expansion and metastasis. Indeed, VEGF expression levels are associated with ►angiogenesis and macrophage infiltration, the extent of which being correlated with the prognosis in various types of tumors. These observations suggest that inhibition of the VEGF signaling in tumor endothelium is a therapeutic target for preventing the development and progression of tumors.

Minodronate inhibits the VEGF-induced increase in DNA synthesis and tube formation in ECs by suppressing NADPH oxidase-mediated reactive oxygen species generation and consequent Ras activation via suppression of Rac-1 geranylgeranylation. In addition, minodronate blocks the VEGF-induced up-regulation of intracellular adhesion molecule-1 (ICAM-1) and ►monocyte chemoattractant protein-1 (MCP-1) in ECs, subsequently suppressing the VEGF-mediated T cell adhesion to ECs. Since small G proteins such as Rac-1 and Ras is involved in the VEGF signaling to ►inflammation as well, minodronate may exert anti-tumor effects *in vivo* by blocking the VEGF-signaling in tumor endothelium.

Reducing sugars, including glucose, fructose and trioses can react non-enzymatically with the amino groups of proteins to form reversible Schiff bases, and then Amadori products. These early glycation products undergo further complex reactions such as rearrangement, dehydration and condensation to become irreversibly cross-linked, heterogeneous fluorescent derivatives termed "►advanced glycation end-products (AGEs)". The formation and accumulation of AGEs in various tissues are known to progress during normal aging, and at an extremely accelerated rate in diabetes mellitus. AGE-their receptor (►RAGE) interaction elicits oxidative stress generation in vascular wall cells, thereby being involved in the pathogenesis of various types of disorders including melanoma growth, expansion and metastasis. Minodronate inhibits the AGE–induced reactive oxygen species generation and ►nuclear factor-κB activation and consequently suppresses ►vascular cell adhesion molecule-1 (VCAM-1) expression in ECs. This also suggests that minodronate may have therapeutic potentials for the treatment of AGE-related tumor growth and expansion. Since prostaglandin F2α (PGF2α) is involved in tumor ►angiogenesis and that minodronate suppresses PGF2α-induced VEGF overexpression in cultured osteoblasts, minodronate may exert anti-tumor effects by suppressing tumor VEGF expression.

Effects of Minodronate on Tumor Cells in vitro

Minodronate induces S-phase cell cycle arrest and ►apoptosis in myeloma cells by inhibiting protein geranylgeranylation and subsequently decreasing the levels of phosphorylated extracellular signal-regulated kinase 1/2 (ERK1/2), which could act as a survival

signal in myeloma cells. Minodronate also induces apoptosis of other types of tumor cells; it decreases bcl-2 expression and induces bax expression as well as ►caspase-3 activation, promoting apoptotic cell death of prostate cancer cells. In addition, minodronate inhibits proliferation of cultured murine osteosarcoma cells with induction of apoptosis. Moreover, minodronate decreases DNA synthesis and increase apoptotic cell death in cultured human melanoma cells via suppression of Ras farnesylation.

Effects of Minodronate on Tumor Cells in vivo

Minodronate inhibits ►melanoma growth and improves survival in nude mice by two independent mechanisms; one is by suppressing the tumor-associated ►angiogenesis and macrophage infiltration via inhibition of the VEGF signaling in ECs, and the other is by inducing directly apoptotic cell death of ►melanoma. These anti-tumor effects of minodronate observed *in vivo* could partly be ascribed to its suppressive properties on protein prenylation in melanoma cells themselves and tumor-associated endothelium (Fig. 1).

Minodronate is reported to exert anti-tumor effects in other animal models. It inhibits prostate cancer cell invasion into the bone matrix of an intratibial tumor injection murine model by suppressing CXC-R-4 expression in the lesions. Minodronate also suppresses osteoclast-mediated bone invasion by oral squamous cell carcinoma in mice by inhibiting cytokine expressions (tumor necrosis factor, interleukin-6, etc.). In addition, minodronate is reported to augment the anti-cancer effects of interferon on renal cell carcinoma in mice by further reducing serum levels of VEGF. Furthermore, in vivo-combination therapy with docetaxel and minodronate is found to significantly to reduce the tumor incidence compared with the control and also growth of intraossal transitional cell carcinoma of urinary tract in athymic nude mice compared with the control. Therapy with minodronate significantly enhances the inhibition of proliferation by docetaxel in osteoclasts of bone tumors compared with single therapy with docetaxel. These observations suggest that combination therapy with minodronate and docetaxel or minodronate plus interferon may also be beneficial for the treatment of tumors.

In conclusion, recent *in vitro*- and *in vivo*-data with minodronate support the concept that minodronate is a novel potential therapeutic agent for preventing the development and progression of various types of tumors. Further clinical investigation is needed to evaluate the efficacy of this new pharmacological approach as an anti-tumor therapy.

Mismatch Repair in Genetic Instability

Margherita Bignami
Istituto Superiore di Sanita', Rome, Italy

Definition

Mismatch repair acts after replication to correct mismatches which have escaped proofreading by the replication apparatus. Thus mismatch repair corrects DNA bases in non-Watson–Crick pairings or small distortions generated by incorrect strand alignment in repetitive DNA sequences. Structural abnormalities such as these can also be generated during recombination between DNA molecules which are not perfectly homologous (►Repair of DNA).

Characteristics

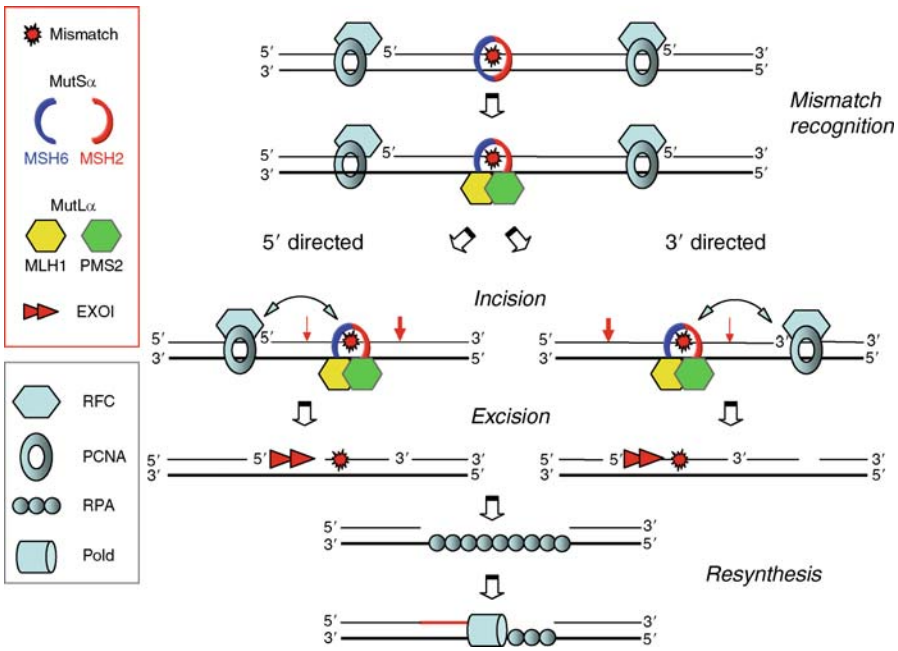
The first step in human mismatch repair is the binding of DNA mispairs by either the MutSα or the MutSβ heterodimer. These comprise of the MSH2/MSH6 and hMSH2/MSH3 proteins, respectively. Biochemical evidence obtained with purified complexes indicates that MutSα selectively recognizes single base mispairs and one base loop, whereas MutSβ prefers loops of 2–10 unpaired bases. Both bind to the two base loops that are the most common abnormalities in repetitive DNA sequences (Fig. 1). MutSα most likely forms a sliding clamp, which encircles DNA in the vicinity of the mismatch. The next step usually involves formation of a ternary complex with the MutLα heterodimer which is composed of the MLH1 and PMS2 proteins. Two minor heteroduplexes of undefined function with PMS1 (MutLβ or MLH3) MutLγ together account for <10% of cellular MLH1. Removal of the mismatch requires an exonuclease targeted to the newly synthesized strand presumably by the presence of nicks. These strand interruptions can be on either side of the mispair requiring mismatch removal in either 5′→3′ or 3′→>5′ mode. EXO1 is an ATP- and mismatch-dependent 5′→3′ exonuclease that paradoxically appears to be sufficient to direct correction in both directions. In the presence of MutSα, EXO1-mediated excision is highly processive and results in removal of >1,000 nucleotides. MutSα, the replication processivity factors PCNA and RFC activate a latent endonuclease of MutLα which yields new 5′ termini for EXO1 entry to permit 3′→5′ correction. PCNA, in its role as a processivity factor for DNA polymerase δ, is also involved together with the single stranded binding protein, replication protein A (RPA) in the subsequent repair synthesis step. It is not known which of the several DNA ligases catalyzes the ligation of the newly synthesized DNA stretch to complete repair.

Biological Consequences

Loss of mismatch repair leads to the accumulation of replication errors particularly in repetitive sequences such as ►microsatellites (long stretches of mono- and dinucleotide repeats scattered throughout the genome). During replication, template and daughter DNA strands in microsatellites are particularly prone to transient dissociation followed by realignment with the repeat units out of phase. This generates extrahelical loops that if uncorrected produce frameshift mutations. Thus loss of mismatch repair results in profound ►microsatellite instability (MSI) and accumulation of frameshifts in mono- or dinucleotide repeats. Thus inactivation of this pathway in human cell lines and in knock-out mice is associated with large increases in spontaneous mutation rates at functional genes (even by two or three order of magnitude) (►Mutator phenotype). Molecular analysis of spontaneous mutations occurring in mismatch repair-defective cells shows that both frameshifts and base substitutions are strongly increased in the absence of a functional mismatch repair.

It is acknowledged that mismatch repair proteins process some altered or damaged DNA bases and loss of mismatch repair can modify sensitivity to some therapeutic DNA-damaging agents. Mismatch repair deficiency is invariably associated with high level of resistance (tolerant phenotype) to methylating agents (►Alkylating agents), to the base analog 6-thioguanine and, to a minor extent, to ►cisplatin. Although the route of killing is not completely understood, it is clear that it involves mismatch repair processing of lesion-containing DNA mismatches. Thus hMutSα can indeed bind duplex oligonucleotides containing single O^6-methylguanine, 6-methylthioguanine, or 1,2 GpG cisplatin adducts. Following recognition, aberrant processing by the MutLα complex ("futile cycles" of repair attempts) might transform these lesions into strand interruptions, which at the next round of replication leads to the formation of lethal lesions, probably double strand breaks.

Mismatch repair is also required for triggering a G2 arrest, occurring in the second cycle after treatment, via the ATR/CHK1-dependent pathway. The late timing in



Mismatch Repair in Genetic Instability. Figure 1 The mismatch bound by MutSα recruits MutLα. The ternary complex forms a sliding clamp which can move in both 5′ or 3′ direction. MutSα, PCNA, and RFC activate a latent MutLα endonuclease, in a mismatch- and ATP-dependent manner. This activity provides incisions that give a 5′ terminus that serves as entry sites for the MutSα-activated EXOI, which removes the mismatch via its 5′→3′ exonucleolytic activity. These strand interruptions can be on either side of the mispair and EXOI is able to direct corrections in both directions. The single strand gap is stabilized by RPA. Once the mismatch is removed and the EXOI activity is inhibited by MutLα and RPA, the gap is filled by polymerase δ.

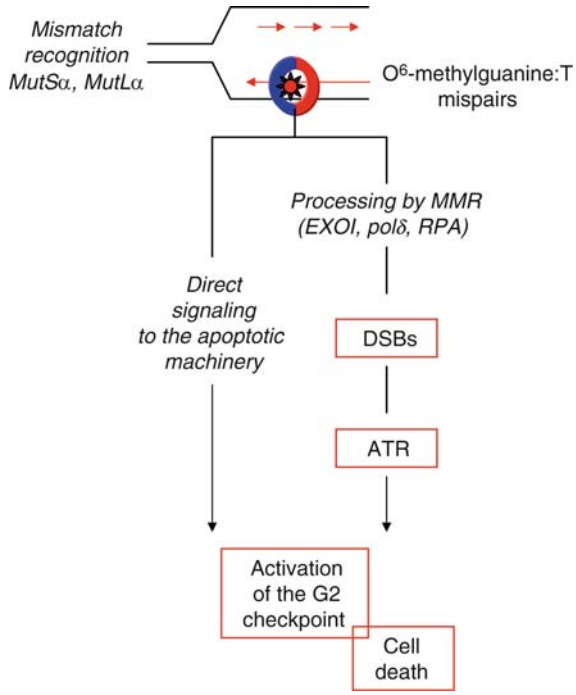
checkpoint activation suggests that the signal might be abnormal DNA structures produced by mismatch repair processing of lesion-containing mismatches. As an alternative to the "futile cycles" hypothesis, it has been proposed that mismatch repair proteins might signal directly to the apoptotic machinery (Fig. 2).

Finally mismatch repair also contributes to the control of endogenous levels of DNA oxidation – probably by removing incorporated oxidized bases from the nascent DNA strand. Thus, embryo stem cells, mouse embryo fibroblasts, and several organs of mice defective in the *msh2* mismatch repair gene show higher steady-state levels of DNA 8-hydroxyguanine, than wild-type controls. The attenuation of the mutator phenotype of mismatch repair-defective mammalian cells by efficient exclusion of 8-hydroxyguanine at replication implicates oxidized bases in the genetic instability, including ►MSI, associated with loss of mismatch repair.

Clinical Relevance

Mutations in genes encoding mismatch repair proteins underlie the predisposition to colorectal tumors in the familial syndrome ►hereditary nonpolyposis colon cancer (HNPCC) (►Lynch syndrome). The inherited germline mutation in at least one of four mismatch repair genes (*hMSH2*, *hMLH1*, *hMSH6*, *hPMS2*) and the subsequent functional inactivation of the second allele predisposes to colon cancer at an early age. It is proposed that the mutator phenotype, following loss of mismatch repair, facilitate the occurrence of mutations in genes controlling proliferation and/or apoptosis thus leading to an increased cancer risk. The majority of the mutations in the HNPCC families occur in the *hMSH2* and *hMLH1* genes. A peculiar characteristic of the *hMLH1* gene is that this gene is often silenced through methylation of its promoter. Some HNPCC families with unusual tumor spectra have mutations in the *hMSH6* gene.

At variance with the classical "tumor suppressor" pathway that usually display gross genome instability (large chromosomal changes and aneuploidy), mismatch repair defective tumors are usually pseudo-diploid. It has been proposed that the multiple genetic changes needed for malignancy can be obtained in two alternative and mutually exclusive ways: in a minority of cases instability at gene level because of mismatch repair deficiency and gross chromosomal changes in the majority of cases. Indeed, colorectal cancer occurring in HNPCC patients show a specific pattern of genetic changes compared with sporadic tumors with chromosomal instability. Runs of



Mismatch Repair in Genetic Instability. Figure 2 Treatment with methylating drugs introduce O^6-methylguanine into DNA. Error-prone bypass of the methylated base will generate O^6-methylguanine:T mispairs, which are recognized by MutSα. Processing by MutSα/MutLα complexes might remain incomplete and result in "futile cycles" of attempted repair leading to strand interruptions, probably DSBs, which become lethal. Lethal lesions trigger a G2 arrest mediated by the ATR/CHK1-dependent pathway. Alternatively, mismatch repair might signal DNA damage directly to the apoptotic machinery.

mononucleotide repeats in coding regions of genes become a preferential target of mutagenic events as a consequence of mismatch repair loss. For example, tumors with ►MSI preferentially accumulate frameshift mutations in genes involved in the control of proliferation and death. Examples of frameshifts that are likely to confer direct or indirect proliferative advantages and which are particularly prevalent in mismatch repair defective tumors include transforming growth factor β receptor (*TGFβRII*), insulin-like growth factor type II (*IGF-II*), *β*2-microglobulin, *Bax*, and *caspase 5* as well as the mismatch repair genes *hMSH6* and *hMSH3*.

►MSI is also quite common in some apparently sporadic tumors suggesting that loss of mismatch repair can be a relatively common event in human cancer. In particular 15% of sporadic colorectal tumors and, to a varying degree, tumors of several other organs (gastrointestinal tract, bladder, endometrium, and ovary) display the mutator phenotype characteristic of mismatch repair defects.

Missense Mutation

Definition

A type of mutation where a base pair change results in a different amino acid being present in the mature protein, for example a lysine to a tyrosine at codon 12 of a given protein.

Mitochondria

Definition

►Mitochondrium

Mitochondria Apoptogenic Factors

Definition

These factors are normally located within the mitochondrial inter-membrane space and are released in response to ►apoptosis stimulation. The release is usually mediated by the pro-death ►Bcl-2 family proteins, Bax or Bak, but could be mediated by other mechanisms. The apoptogenic factors include cytochrome c, which binds to Apaf-1 and activates casapase-9; Smac and HtrA2, which bind to ►XIAP to release its inhibition on caspase-9 or caspase-3; and AIF and Endonuclease G, which move to the nucleus to cause DNA fragmentation.

►Bid
►Mitochondrium

Mitochondria Apoptosis Pathway

Definition

Synonym: intrinsic death pathway; bridges multiple death signals to the mitochondria. It is mediated by the ►Bcl-2 family proteins. The BH3-only pro-death members are sentinels to different death stimuli. For example, Bid is activated by proteases and Bad is activated by growth factor deprivation. While ►PUMA and Noxa are activated by DNA damages, Bim can be activated by cytokine deprivation, UV and calcium flux. The activated BH3-only members are translocated to the mitochondria, where they either directly activate the multi-domain pro-death molecule, Bax or Bak, or indirectly by binding to the anti-death Bcl-2 family members. Activated Bax or Bak mediates the release of mitochondria apoptogenic factors, which in turn activates caspases or inactivates the pro-survival IAP family proteins.

Definition

Mitochondria are double membrane bound organelles, 1–2 μm in length and 0.5–1 μm in diameter and provide energy to the cell. Human cells contain two types of DNA; nuclear DNA (nDNA) and ►mitochondrial DNA (mtDNA). Before the term "mitochondria" was used, these oval subcellular granules, similar in size and shape to bacteria, were called "bioblasts" and were considered the basic unit of cellular activity.

Characteristics

Mitochondria now are considered as centers of energy metabolism and produce up to 80% of the energy needs of a cell. The inner membrane forms a series of folds called cristae and harbors enzymes involved in ►oxidative phosphorylation. Oxidative phosphorylation enzymes are located in the inner membrane and depending on the metabolic activity of a cell, the size of the inner membrane increases or decreases.

Human cells contain two types of DNA; nuclear DNA (nDNA) and mitochondrial DNA (mtDNA). Before the term "mitochondria" was used, these oval subcellular granules, similar in size and shape to bacteria, were called "bioblasts" and were considered the basic unit of cellular activity. Mitochondria now are considered as centers of energy metabolism and produce up to 80% of the energy needs of a cell. The inner membrane forms a series of folds called cristae and harbors enzymes involved in oxidative phosphorylation. Oxidative phosphorylation enzymes are located in the inner membrane and depending on the metabolic activity of a cell, the size of the inner membrane increases or decreases.

A typical mammalian cell contains about 1,000–10,000 copies of mitochondrial DNA. The mitochondrial genome is 16.5 kb which is closed circular double helical molecule encoding 2 rRNAs, 22 tRNAs, and 13 polypeptides and does not contain introns and ►histones. mtDNA represents about 1% of the cellular DNA. mtDNA is double stranded except for the D-loop which is triple stranded (contains extra 7S DNA). Promoter of mtDNA is located in the D-loop, which is the only non-coding region of mtDNA. The D-loop contains cis elements involved in mtDNA replication and transcription. All 13 peptides of mitochondria are located in a mitochondrial respiratory chain complex.

Mitochondria are an important biological source and target of ►reactive oxygen species (►ROS), free radicals and sensitive to environmental mutagens. Normal assembly and operation of the respiratory chain requires an intact and functional mitochondrial genome. Depending on the energy demand of a cell, the number of mitochondria per cell varies. Under physiologic conditions, as many as 2% of electrons leak from the mitochondrial electron transport chain and reduce oxygen into superoxide anion, triggering the formation of free radicals that indescribably damage biological molecules. Damage due to ROS and radiation is severe for mtDNA and unlike nDNA, mtDNA have a limited repair capability. The accumulation of mutations in mtDNA is about tenfold greater than in the nDNA. A continuing cycle of worsening mitochondrial dysfunction with increasing ROS production might be expected from such damage to mtDNA. Mutations in mtDNA can vary widely among tissues in an individual and mutation load may change over time. Tissues are differentially sensitive to levels of mtDNA mutations.

Genetic and/or metabolic alterations in mitochondria may lead to different diseases. The mitochondrial genome has drawn increasing attention in ►cancer research due to its unique genetics, such as maternal

inheritance, and lack of ►recombination as well as functional importance in oxidative phosphorylation. mtDNA is a critical target for cellular reactive oxygen species and the level of oxidative damage is more severe and persistent in mtDNA than in nDNA. MITOMAP (www.MITOMAP.org) is a comprehensive database of human mtDNA variation and its relation with human diseases.

In humans, 99.99% of mtDNA is inherited from the mother because sperm mtDNA is actively degraded. Sperm carries its mitochondria around a portion of its tail and has only about 100 mitochondria compared to 100,000 in the oocyte. As the cells develop, more and more of the mtDNA from males is diluted out and less than 0.01% of the mtDNA is paternal. Thus, mutations of mtDNA can be passed from mother to child. Its implication is in cloning of mammals using somatic cells. For example, when the sheep "Dolly" was cloned, the nDNA was from the donor cells, but the mtDNA was from the host cells.

Abnormality in mtDNA may lead to different diseases such as optic neuropathy (degeneration of the optic nerve accompanied by increasing blindness), myopathy, exercise intolerance, diabetes, deafness, MELAS, Pearson's syndrome, ataxia, and cancer. As an example, cancer and mtDNA has been described in details.

mtDNA has been used in ►epidemiology. ►Admixture populations have been identified based on mtDNA characteristics. To understand the utility of mtDNA in cancer epidemiology, one approach is to evaluate in patients with cancer and matching controls for somatic mutations in mitochondria. Another approach is to look for disease-associated haplotypes. The inheritance pattern of mitochondria in patients with cancer has been studied by haplotype analysis. Polymerase chain reaction (PCR) of key polymorphic sites in the mitochondrial genome was performed in samples from cancer patients and controls to determine presence of an association between mitochondrial genotype and cancer. Such analysis has been accomplished in a few studies of ►prostate and renal cancer. For example, haplogroup U, one of the nine major haplotype groups, was associated with an odds ratio of 1.95 in a prostate cancer case control study and with an odds ratio of 2.65 in a renal cancer study. There are very large differences across racial and ethnic groups in the distributions of the major haplotypes. Haplotyping is performed by restriction analysis whereas for mutation analysis whole mitochondrial genome is sequenced.

Microdissected samples have been successfully used to identify mtDNA mutations from clinical samples. Thus, a pure population of cells could be isolated from heterogeneous cells of the surgically isolated samples. To understand the etiology of the disease and to do mitochondrial genotyping, a pure population of cells is needed.

A variety of clinical samples have been utilized for mtDNA mutation detection. For example, nipple aspirate and paraffin embedded specimens for breast cancer, urine for bladder cancer, buccal cells for head and neck cancer, cerebrospinal fluid (CSF) for meduloblastoma, and sputum for ►lung cancer have been used. High-throughput technology has been developed for somatic mutation detection. Since each copy may be independently replicated, mutations can accumulate in various proportions of the genomes. The presence of a mutation in 100% of the genomes is termed ►homoplasmy, while ►heteroplasmy is a mixture of mutated and wild-type sequences for a given locus.

About 50 years ago Nobel-Laureate Otto ►Warburg reported the fundamental difference between normal and cancerous cells to be the ratio of glycolysis to respiration. Now we see a linking impaired mitochondrial function as well as impaired respiration to growth, division and expansion of cancer cells. Recent work has confirmed that this is, indeed, a promising approach in the treatment of cancer.

Cancer cells accumulate defects in the mitochondrial genome, leading to deficient mitochondrial respiration and ATP generation. In some cases, mitochondrial germline mutations have been shown to provide predisposition to cancer development. Mostly, such mutations are acquired during or after oncogenesis. Tumors rely heavily on glycolysis to meet their metabolic demands. Compared to normal cells, cancer cells exhibit metabolic imbalances and enhanced resistance to mitochondrial ►apoptosis.

Mitochondrial mutations have been reported in preneoplastic lesions suggesting that mutations occur early in multi-step tumor progression and hence, may be used as a tool for ►early detection of cancer in clinical samples. Alterations in mitochondrial structure and function might provide clinical information either for early detection of cancer or as unique molecular sites against which chemotherapeutic agents might be targeted.

The field of mitochondria has seen a recent surge of interest among cancer researchers as alterations in mtDNA have been reported in various neoplasms. Population-based studies involving environmental and occupational exposure, infectious agents, personal susceptibility factors, and acquired genetic factors may identify high-risk populations that are likely to develop cancer; additionally, such studies are very informative and significant in designing future community-based health initiatives. mtDNA biomarkers can be used to follow disease prevalence by determining their level in cohort studies with the potential for identifying high-risk populations.

Mitochondrial Membrane Permeabilization in Apoptosis

Catherine Brenner
University of Versailles/SQY, CNRS UMR 8159, Versailles, France

Synonyms

MMP

Definition

During ►apoptosis, many signals can converge to the mitochondrion to trigger the so-called mitochondrial membrane permeabilization (MMP), a rate-limiting step in the execution of the death process. These signals are mainly endogenous proteins, which translocate from an intracellular compartment (e.g. nucleus, cytosol, lysosomes, etc) to the mitochondrial outer membrane (OM). Accumulation of modified lipids (e.g. oxidized cardiolipin, ceramide, etc) and ions (e.g. Ca^{2+}) by the mitochondrion can also influence MMP. Moreover, the intracellular milieu, such as pH, ►reactive oxygen species (ROS), and ATP levels can contribute to define a permissive environment for MMP execution. Once initiated, MMP leads to the release of intermembranespace factors into the cytosol, caspase-dependent proteins, such as cytochrome *c*, Smac/DIABLO, procaspases and caspase-independent proteins such as apoptosis-inducing factor, AIF, and EndoG. The major consequence of these protein movements is the coordination of the final cellular degradation phase of apoptosis. Concomitantly, MMP provokes a mitochondrial failure, which manifests by an arrest of oxidative phosphorylation and ATP synthesis, an increased ROS level, and dissipation of the inner membrane potential ($\Delta\Psi m$). Therefore, MMP constitutes a point of no return of the activation cascade of apoptosis.

Characteristics

Mitochondria are intracellular organelles involved in the cell energy metabolism and also in the control of the intrinsic pathway of apoptosis. They are surrounded by two different membranes that differ in terms of composition, surface, permeability and function. The OM is permeable to solutes of MM ≈ 6kDa due to the presence of channels, such as the voltage-dependent anion channel (VDAC), which belongs to the porin subfamily. However, with an estimated pore diameter about 2.6–3nm, VDAC would not allow the passage of a folded protein like cytochrome *c*. In contrast, the inner membrane (IM) is almost totally impermeable. Specialized membrane proteins, namely the mitochondrial carriers, carry out the transport of ions and solutes across this membrane. Most mitochondrial proteins, which have been implicated in apoptosis, exhibit dual functions, a vital metabolic function and a lethal pro-apoptotic function. This applies to various channels (VDAC, adenine nucleotide translocase (ANT), Bax, t-Bid, Bak), receptors (e.g. TOM22), chaperones (cyclophilin D, CypD), as well as oxido-reductases (AIF).

Mechanisms of MMP

Mechanisms mediating MMP may be multiple depending on the cell type and the death stimuli. They can affect (only) the OM, or both mitochondrial membranes (OM+IM). Among numerous hypothetic models, experimental evidence support models involving members of the conserved ►Bcl-2 family, which can be divided into pro-apoptotic members (Bax, Bak, Bid, Bik, Bnip3, etc) and anti-apoptotic members (Bcl-2, Bcl-X_L, Mcl-1, etc), members of the permeability transition pore

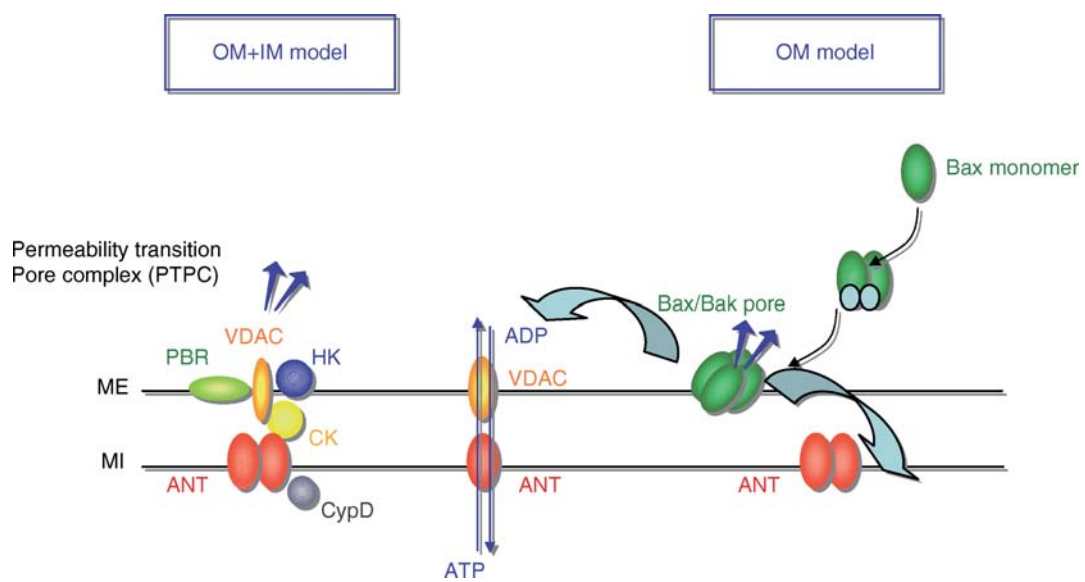
complex (VDAC, ANT, CypD) and lipids. At the onset of MMP, cytosolic and nuclear proteins such as Bax, truncated-Bid (t-Bid), p53, Nurr77, can undergo conformational changes and/or post-translational modifications favoring their translocation to the mitochondrial membranes. Subsequently, protein-protein interaction changes operate and novel homo- or hetero-oligomers form to promote the release of pro-apoptotic factors into the cytosol. In OM models, Bax would oligomerize with Bak and/or VDAC to form megachannels. In OM+IM models, the permeability transition pore would undergo long-lasting openings of high conductance (≈1.5nS) allowing a massive entry of water and solutes (MM<1.5 kDa) that is responsible of matrix swelling and OM ruptures due to the difference of size of both membranes. Thus, in the OM model, intermembrane space proteins are release into the cytosol by passage through large proteic/lipidic channels while in the OM+IM model, intermembrane space proteins are freely released into the cytosol through the OM ruptures. Nevertheless, these two models can be linked in conditions involving in the one hand tBid translocation, and in the other hand, mitochondrial calcium accumulation and ROS increase, as observed in conditions of endoplasmic reticulum stress. Fig. 1 illustrates both models of MMP.

Regulation of MMP

MMP can be regulated positively or negatively by endogenous oncoproteins (e.g. Bcl-2, Bcl-X_L) and tumor suppressors proteins (e.g. Bax, Bak, p53), viral proteins (e.g. Vpr, M11L and vMIA), bacterial proteins (e.g. porB), small molecules (e.g. MT21) and also chemotherapeutic agents (arsenite, lonidamine, nelfinavir, betulinic acid, verteporfin). Pro-apoptotic proteins, which translocate to the OM, can act directly by forming pores or indirectly by modifying proteins. Thus, some kinases and phosphatases can act by modification of constitutive mitochondrial proteins to stabilize or destabilize mitochondrial membranes. In addition, caspases have been shown to cleave NDUFS1, the 75 kDa subunit of respiratory complex I, and in turn to disrupt mitochondrial function and induce apoptosis. In contrast, some proteins (e.g. Bcl-2, gluthathion-S-transferases (GST), superoxide dismutase (SOD)) stabilize the mitochondrial membrane barrier. For instance, a mitochondrial GST can block ANT in its translocase function and thus prevent its lethal pore conversion, in vitro as well as in cellula. Finally, natural ligands (ATP, glucose, creatine) of several metabolic enzymes also favor the metabolic function of proteins rather their apoptotic function.

MMP and Cancer

Apoptosis, as well as senescence, is considered as a barrier against neoplasia. Under pathological conditions, a MMP failure can result in an inhibition of apoptosis and enhanced resistance to chemotherapy. Several non-mutually exclusive mechanisms may account for a defect in the execution or regulation of MMP. These include (i) alterations in gene transcription, (ii) gene mutations resulting in protein inactivation, and (iii) defects of intracellular localization. This may concern structural proteins of PTPC, as well as MMP regulatory proteins, such as Bax/Bcl-2 family members, p53, caspases, and cyclophilin D.



Mitochondrial Membrane Permeabilization in Apoptosis. Figure 1

Thus, a decrease in the ratio Bax/Bcl-2 is frequently observed in human cancers and appears to determine the survival or death of cells following an apoptotic stimulus. Moreover, some shifts in the isoforms expression have been reported for proteins such as ANT in human hormone-dependent cancers.

Therapeutic Implications

The targeting of MMP might be instrumental for the treatment of cancer in the future. Several strategies, inspired by basic research advances, have been designed to neutralize anti-apoptotic targets and to re-activate the death program. These strategies are based on the use of pharmacological agents and/or on selective genetic modulation. Thus, small molecules, peptides, ►antisense, ►siRNA and adeno-associated virus-mediated gene transfer constitute the majority of current preclinical studies and clinical trials in order to fight tumorigenesis. However, the major difficulty in defining clinically efficient molecules arises from the fact that many apoptosis-related proteins harbor vital necessary functions, meaning that their extinction can be deleterious for correct cell function, in particular for immune cell functions.

Mitochondrium

Definition

Plural mitochondria; Is a double membrane-surrounded organelle, in which cellular respiration takes place. The enzymes of the mitochondrial respiratory chain are located in the inner mitochondrial membrane and synthesize most of the cell's energy equivalents (ATP). Each mitochondrium contains a 16569 Bp circular DNA molecule coding for ribosomal and mitochondrial transfer RNA molecules and for several mitochondrial proteins. The inner membrane is folded to cristae comprising the mitochondrial matrix space. Depending on the cell type, mitochondria vary in shape, size, and number but have generally longish/tubular structural characteristics.

►Photodynamic Therapy

Mitogen

Definition

An agent, usually a protein, that triggers the cell to reenter the cell cycle triggering mitosis and can cause cellular transformation.

►Protease Activated Recept Family

Mitogen-Activated Protein Kinase

Definition

MAP Kinase; MAPK; Extracellular-signal regulated protein kinases, N terminal kinases/stress-activated protein kinases, and p38 kinases. The activation of these kinases may occur by translocation to the nucleus, where these kinases phosphorylate target transcription factors.

Mitogen-Inducible Gene 6 in Cancer

Yu-Wen Zhang, George F. Vande Woude
Laboratory of Molecular Oncology, Van Andel Research Institute, Grand Rapids, MI, USA

Synonyms

MIG-6

Definition

Mitogen-inducible gene-6 (*MIG-6*) – also known as gene-33,receptor-associated late transducer (*RALT*), or ErbB receptor feedback inhibitor 1 (*Errfi1*) – is an immediate early response gene whose expression can be rapidly induced by growth factors, serum, and many stress stimuli. The *MIG-6* gene locus is mapped to

human chromosome 1p36.12–33 and in the mouse to the distal region of chromosome 4. Human *MIG-6* encodes a 58-kDa protein consisting of 462 amino acids (461 amino acids for its mouse counterpart).

Characteristics

Mig-6 is expressed in many organs and tissues, with high-level expression in the liver and kidney and moderate levels in the lung and brain. The expression of Mig-6 is robustly regulated at the transcriptional level, and it peaks after serum induction at mid-G1 during cell cycle progression. Many growth factors such as ►EGF, ►FGF, and ►HGF/SF rapidly induce its expression through the activation of the RAS-MEK-►ERK pathway (►MAP kinase).

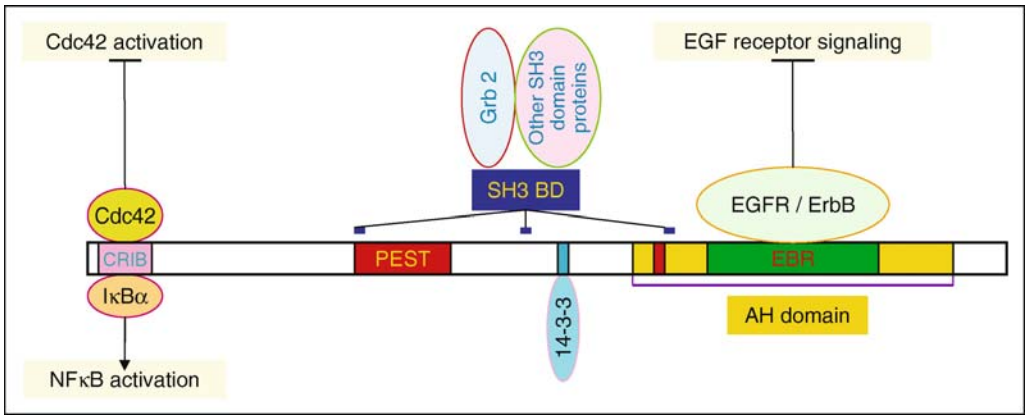
Mig-6 is a nonkinase scaffolding ►adaptor protein localized in the cytoplasm. It contains several well-known protein-protein interaction motifs/domains that allow it to interact with other signaling molecules in regulating ►signal transduction (Fig. 1). Mig-6 can interact with the small GTPase ►Cdc42 through its N-terminal Cdc42/Rac-interaction and binding (CRIB) domain. The Src-homology-3 (SH3) (►SH2/SH3 domains) binding motifs in Mig-6 mediate its interaction with ►Grb2, a bridging molecule between receptor tyrosine kinase (RTK) and the downstream RAS-MAPK pathway. It also contains a 14–3–3 binding motif for interacting with the ►14–3–3 protein. In addition, the AH domain in its C-terminal region shares a striking homology with the activated Cdc42-associated kinase-1 (Ack-1). Both Mig-6 and Ack-1 can physically interact with ►EGFR, and the region required for EGFR interaction is within the AH domain. In addition, Mig-6 contains two ►PEST sequences, and it is a labile protein subjected to ubiquitinylation and proteasome degradation.

In vitro functional analyses and characterization of *Mig-6* knockout mice reveal that Mig-6 may play a crucial role in regulating signal transduction, homeostasis, and stress response, and may act as a tumor suppressor in cancer development.

Signaling Regulation

Mig-6 integrates signal transduction by interacting with other signaling molecules to fine tune signaling output. Most notably, Mig-6 functions as a ►negative feedback regulator of EGF receptor signaling through a mechanism that involves direct interactions with members of the EGF receptor ErbB family (►epidermal growth factor receptor ligands). The up-regulation of Mig-6 by EGF results in down-modulation of the EGFR tyrosine phosphorylation and inhibits the EGF-induced activation of the downstream ERK, ►JNK, and Akt pathways. This inhibition might also involve direct interactions between Mig-6 and other factors like Grb2 or other SH3-domain-containing proteins. In addition, Mig-6 has also been shown to be capable of either activating or inactivating JNK (►JNK subfamily and cancer) in different cell types.

Mig-6 functions as a negative feedback regulator of HGF/SF-►Met signaling as well, although unlike with EGFR, no physical interaction between Mig-6 and Met has been observed. Mig-6 can inhibit HGF/SF-induced Cdc42 activation and cell ►migration in a CRIB-domain-dependent manner, likely through its ability to interact with active GTP-bound Cdc42. The importance of the CRIB domain in signaling regulation also stems from the fact that full-length Mig-6, but not its CRIB domain-deleted version, can sequester



Mitogen-Inducible Gene 6 in Cancer. Figure 1 The functional domains/motifs present in the Mig-6 protein. The CRIB domain is required for the binding of Cdc42 and IκBα. Mig-6 contains three proline-rich SH3-domain binding motifs (SH3 BD) that are capable of Grb2 or other SH3 domain protein binding. The 14–3–3 binding motif is present in the middle region. The ErbB binding region (EBR) resides in the Ack1 homology (AH) domain. Two PEST sequences (shown in red boxes) are also present.

the inhibitor of κBα (IκBα), thereby activating the nuclear factor κB (NFκB). It is possible that other domains/motifs (such as SH3-domain binding motif) of Mig-6 also play a role in regulating HGF/SF-Met pathway, as overexpression of Mig-6 can inhibit both HGF/SF-induced cell proliferation and cell migration.

The role of Mig-6 in regulating the signaling of other RTKs (such as FGFR or PDGFR) remains to be determined, even though its expression can also be induced by FGF or PDGF.

Clinical Relevance

The *MIG-6* gene resides at the human chromosome 1p36, a locus that is one of the most commonly deleted regions in many human cancers. Loss of heterozygosity (LOH) on 1p36 is frequently observed in human lung cancer, implying that putative tumor suppressor gene(s) in this locus might be responsible for lung carcinogenesis. This is supported by the fact that LOH on the distal region of mouse chromosome 4, the homologous region of human chromosome 1p36, is strongly associated with mouse lung carcinogenesis. The emergence of *MIG-6* as a tumor suppressor gene arises from data in both mouse and human cancers. In mice, targeted disruption of the *Mig-6* gene leads to the development of bronchi/bronchiole epithelial ►hyperplasia, adenoma, or adenocarcinoma in the lung, as well as the gallbladder, bile duct, gastrointestinal (GI) track, and skin cancers. Sequence analyses of the *MIG-6* gene in human non-small-cell lung cancer (NSCLC) cell lines and primary lung cancers have led to the identification of several mutations: a missense mutation at codon Asp109 to Asn in the NCI-H226 squamous cell carcinoma cell line, a nonsense mutation at codon Glu83 causing premature truncation in the NCI-H322 adenocarcinoma cell line, and a heterozygous germline mutation at codon Ala373 to Val in a primary squamous cell carcinoma patient. Mutation of *MIG-6* in the lung seems to be a rare event, as only one mutation was identified among 41 primary lung cancer samples screened. However, given that LOH on 1p36 is associated with smoking, squamous cell carcinoma, and late-stage lung cancer patients, there is a strong possibility that certain lung cancers may have a higher incidence of mutations in *MIG-6*.

LOH on 1p36 is also frequently observed in breast cancer. However, only a single nucleotide polymorphism (SNP) at codon Asp109 in *MIG-6* has been identified in breast carcinomas. Notably, this SNP is identical to the mutation identified in the NCI-H226 lung cancer cell line, and it has also been identified in several normal control populations. Although the importance of this SNP is not clear, it is possible that it might lead to predisposition to breast or other cancers. Other SNPs in the *MIG-6* gene have also been identified in lung cancer patients.

Even though genetic alteration in the *MIG-6* coding region seems to be a rare event, loss/reduction of MIG-6 expression has been observed in human breast, skin, pancreatic, and ovarian cancers. Breast cancer patients with decreased MIG-6 expression have poor prognosis. Moreover, MIG-6 expression in NCI-H226 human lung cancer cells, as well as in BT474 and SKBr-3 breast cancer cells, displays either no or low response to the activation of the MAPK pathway by either HGF/SF or EGF. The mechanism underlying MIG-6 deregulation is unclear, although loss/reduction of tumor suppressor gene expression is usually caused either by genetic changes such as mutation or deletion in its promoter regulatory region or by epigenetic modification associated with promoter hypermethylation (►epigenetic gene silencing).

MIG-6 is a negative feedback inhibitor of EGFR and the Met pathway, and the consequence of losing Mig-6 function can be a prolonged or inappropriate activation of these RTKs that may lead to a malignant phenotype. As revealed in *Mig-6*-deficient mice, losing Mig-6 function causes hyperproliferation of cells in several tissues including skin, gallbladder, and joints. Mig-6 deficiency causes prolonged activation of the EGFR-MAPK pathway in skin keratinocytes and results in skin hyperplasia. This hyperplasia can be reversed to normal appearance through the inhibition of the EGFR activity either using the EGFR inhibitor Gefitinib (Iressa) or by replacement of wild-type EGFR with a hypomorphic allele. The carcinogens 7,12-dimethylbenz[*a*]anthracene (DMBA) or 12-*O*-tetradecanoylphorbol-13 acetate (TPA) increase the incidence of skin melanomas and papilomas in *Mig-6*-deficient mice, which can be prevented by Gefitinib treatment. These data suggest that prolonged activation of the EGFR pathway is responsible for skin carcinogenesis in *Mig-6*-deficient mice. The loss of MIG-6 expression in ErbB2-amplified human breast carcinoma cells increases resistance of the cells to ►Herceptin, the antibody directed against the ErbB2 receptor. *In vitro*, overexpression of Mig-6 can inhibit EGFR- or ErbB2-mediated cell transformation, as well as cell cycle progression induced by EGF.

Further study will be required to determine if and how other functional domains/motifs in Mig-6 besides the EBR (Fig. 1) play a role in regulating the RTK signaling and in the tumorigenesis caused by Mig-6 deficiency.

Mitogenic Carcinogen

Definition

A carcinogen that induces mitosis and cell proliferation.

►Toxicological Carcinogenesis

Mitomycin C

David Jamieson
School of Clinical and Laboratory Sciences, Newcastle University, Newcastle upon Tyne, UK

Synonyms

MMC6-Amino-1,1a,2,8,8a,8b-hexahydro-8-(hydroxymethyl)-8a-methoxy-5-methyl-azirino[2′, 3′ :3, 4] pyrrolo[1, 2-a]indole-4,7-dione carbamate (ester)

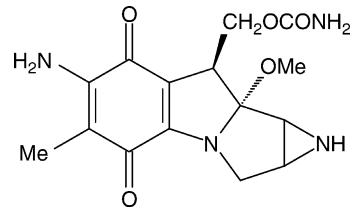
Definition

MMC is a naturally synthesized antibiotic ►alkylating agent used in ►cancer chemotherapy. Once metabolically activated, it functions as a cytotoxic drug by covalently binding DNA on both strands of the double helix, thus preventing them from separating when necessary for transcription prior to gene expression or replication prior to cell division. The binding of MMC to DNA is not amenable to repair and the affected cell subsequently dies.

Characteristics

Form

MMC was first isolated from *Streptomyces caespitosus* in 1958 and has subsequently been isolated from a number of other *Streptomyces sp*. Synthesis of MMC is coded for by a number of genes in a distinct locus of the microbial chromosome that also contains genes which confer resistance.



Mitomycin C. Figure 1 Chemical structure of mitomycin C.

The mitomycins are unique molecules being the only naturally synthesized compounds known to contain an ►aziridine ring. MMC (Fig. 1) has ►quinone, aziridine, carbamate and oxymethyl groups surrounding a mitosene (pyrrolo[1, 2-a]indole) nucleus. It is soluble in both aqueous and organic solvents. While MMC is readily soluble in water it is also unstable and is therefore shipped and stored as lyophilized powder. It is a light purple powder and immediately prior to use is dissolved in water.

Bioreductive Activation

MMC is relatively unreactive and therefore non-toxic when compared to metabolites formed following the two-electron reduction of the quinone group to the ►hydroquinone. It is considered as the prototype ►bioreductive drug, a term that is generally defined in two ways;

- That it is preferentially activated in ►hypoxic cells
- That it needs reductive activation via enzymatic catalysis

Reductive activation of MMC occurs following the two-electron reduction of the quinone to the hydroquinone, either as sequential one-electron or simultaneous two-electron reductions. Following reduction, a spontaneous rearrangement occurs resulting initially in the expulsion of oxymethyl group and opening of the aziridine ring to yield an electrophilic carbon capable of alkylating DNA. A subsequent expulsion of the carbamate group yields a 2nd reactive carbon and the MMC metabolite is capable of forming the highly toxic interstrand DNA crosslink.

In a hypoxic intracellular environment, both one-electron and obligate two-electron quinone reductase enzymes can catalyse the reduction of MMC to the hydroquinone. In contrast, in an oxygen rich environment, while the two-electron reductase activities still generate the hydroquinone which is a prerequisite for DNA alkylation, the semiquinone product of one-electron reduction is unstable in the presence of molecular oxygen and prone to oxidation back to MMC with superoxide free radical generation. Therefore four general situations can be envisaged dependent on the presence/absence of oxygen or of two electron-reductase activities. In a hypoxic environment alkylating MMC

metabolites will be generated in the presence of either or both one-electron and two-electron reducing enzymes. Alkylating MMC metabolites will also be generated in an aerobic environment in the presence of a two-electron reducing enzyme. In contrast in an aerobic intracellular environment, in the absence of two-electron reducing activity, DNA alkylation is less likely to occur and the less-damaging free radical generation is more likely.

The dependence of MMC cytotoxic activity on two-electron reduction suggested that MMC therapy could be specifically directed towards tumors that express relatively high levels of two-electron reducing enzymes or, in the absence of appropriate enzyme activities, hypoxic areas of tumors. The selective targeting of hypoxic tissues provides the rationale behind the use of MMC together with ►radiotherapy in the treatment of solid tumors. Radiotherapy preferentially targets tissues with a high oxygen content and combined with the use of MMC all regions of a tumor are attacked by one of the two treatments.

Enzymatic Bioreductive Activation of MMC

Many enzymes have been shown to reduce MMC, these include both one- and two-electron reductases, and the most widely studied are described below.

NQO1

►NAD(P)H:quinone oxidoreductase *1* (DTD, DT-diaphorase, NQO1, EC1.6.99.2) activity was first identified in 1958 on the basis that it catalyzed the oxidation of NADH and NADPH at the same rate. The human NQO1 gene has been sequenced and mapped to chromosome 16q22, comprising 6 exons and 5 introns the NQO1 gene is around 20 kb long, with the initial methionine codon at the 3′ end of exon 1 and the stop codon occurring ~300bp into the 6th codon. NQO1 is a 274 amino acid protein that exists as a homodimer and has 1 flavin adenine dinucleotide (FAD) prosthetic group per subunit non-covalently bonded to loop residues in the N-terminal domain. Both the NAD(P)H nicotinamide group and the substrate bind non covalently to the enzyme proximal to the flavin ring of the FAD. A C to T polymorphism at position 609 of the NQO1 gene results in a proline to serine substitution in the protein primary structure and loss of enzyme activity without a loss of cDNA expression. The 609C-T polymorphism results in negligible if any NQO1 activity in homozygous individuals and cell lines. Small amounts of NQO1 protein have been detected in homozygous mutant cell lines, but none in samples from mutant homozygote individuals as assayed by immunodetection methods. The protein half life of the mutant allele product is 1.2 h compared to 18 h for the wild type protein. ►Ubiquitin mediated proteosomal degradation has been implicated in the rapid breakdown of the mutant form. The 609TT genotype occurs at a frequency of between 5 and 30%, depending on the population being studied.

In contrast to the other reductase enzymes described, NQO1 activity has been observed to be higher in tumors matched to tissues that normally express low NQO1 levels (►breast cancer, ►colon cancer, ►liver cancer and ►lung cancer).

Despite some skepticism, MMC has been shown to be a substrate for NQO1 catalyzed reduction at physiological pH, although maximal reaction rates are seen at more acidic pH. It has been demonstrated that the decrease in NQO1 catalyzed reduction of MMC with increasing pH is due to the irreversible inhibition of NQO1 by MMC in a concentration- and time-dependent manner. Preincubation of purified NQO1 with MMC at pH 7.8 for 1 h results in total loss of NQO1 activity as assayed by the reduction of 2,6-dichlorophenol-indophenol. Cross-linking of NQO1 protein by MMC has been observed, and NQO1 activity is not restored following gel filtration to separate MMC and NQO1. In contrast, NQO1 activity is not lost following incubation with MMC at pH 5.8. Nevertheless, some NQO1 activity at physiological pH occurs and DNA:MMC adducts and crosslinks following NQO1 reduction have been observed. Controversy still exists concerning the putative role of NQO1 in the bioreductive activation of MMC in the clinical setting. However a large volume of research has been undertaken, resulting in a clarification of the role of NQO1.

NQO1 and Mitomycin C In vitro

Several studies have demonstrated NQO1 activation of MMC to a cytotoxic species in aerobic environments *in vitro*. These include heterogenic and isogenic cell line models comparing MMC toxicity in high NQO1 expressing cell lines with cell lines with no NQO1 activity, correlation of MMC toxicity with NQO1 activity over a cell line panel, comparing NQO1 activity in cell lines conditioned to be MMC resistant with parental cell lines, and increases in MMC sensitivity following induction or inhibition of NQO1 activity.

NQO1 and Mitomycin C in Anaerobic Conditions

The picture is somewhat different when sensitivity to MMC under hypoxic conditions is investigated. For example, the NQO1 inhibitor dicumarol potentiates MMC-induced cytotoxicity in hypoxic conditions. An indication that reductases other than NQO1 are more effective at reducing MMC to a cytotoxic species under hypoxic conditions came from studying a CHO cell line resistant to MMC under aerobic conditions. While it expressed significantly less NQO1 than the parental cell line, it was no more resistant to MMC under hypoxic conditions. While NQO1 may be important for

the efficacy of MMC under aerobic conditions, it is not a requirement for hypoxic toxicity.

However, evidence that NQO1 activates MMC under hypoxic conditions was provided by CHO cells transformed to overexpress NQO1. MMC was equally toxic to the transformed cells under hypoxic and aerobic conditions. In both conditions MMC toxicity was potentiated when compared to the parental cell line. However other reports have suggested that high NQO1 activity under hypoxic conditions will decrease MMC-induced cytotoxicity by out competing one electron reductase enzymes, believed to be more efficient at reducing MMC to cytotoxic species.

NQO1 and Mitomycin C In vivo

The role of NQO1 ►bioreductive activation of MMC *in vivo* is less clear than that seen *in vitro*. Four human tumors expressing a range of NQO1 activities implanted in nude mice showed an inverse correlation between tumor growth and NQO1 activity following treatment with MMC. NQO1-transformed BE cells respond no differently to MMC compared to the parental cell line when implanted as xenografts in nude mice. In contrast, xenografts of NSCLC cell lines with high NQO1 activity were more sensitive to MMC than ►SCLC cell lines with low NQO1 activity.

Clinical evidence that NQO1 activity potentiates MMC sensitivity *in vivo* was seen in a recent clinical study. The NQO1 genotype of patients with disseminated peritoneal cancer was assessed prior to surgical removal of cancer tissue followed by intraperitoneal administration of mitomycin C. Patients with the wild type NQO1 genotype whose disease was of colonic origin survived significantly longer than those who were heterozygotes or homozygous for the 609C-T mutation (18.2 vs. 11.5 months median survival). Significantly longer survival times were also seen in patients with the wild type genotype following complete removal of all visible tumor when compared to those who were heterozygotes or homozygous for the 609C-T mutation (43.6 vs. 23.0 months median survival). Other clinical studies have failed to identify a relationship between NQO1 expression or genotype and response to MMC.

Xanthine Oxidase/Dehydrogenase

Xanthine dehydrogenase (XDH) and ►xanthine oxidase (XO) both catalyse the conversion of xanthine to uric acid. Both enzymes can use NAD+ as an electron acceptor, but XO can also use O_2. Both enzymes are the product of the same gene with XO being a proteolytically cleaved or oxidized modification of XDH.

The reductive activation of MMC by purified XO has been described and MMC metabolites formed following this activation identified under anaerobic, but not aerobic conditions. Under aerobic conditions the generation of reactive oxygen species was identified. In contrast, XDH is capable of directly reducing MMC to its hydroquinone and, as such, can form alkylating metabolites under aerobic conditions. Neither XO or XDH are present at elevated levels in tumor cells compared to healthy tissue and it is not envisaged that either enzyme confer specificity for MMC against tumors.

NADPH-Cytochrome C P450 Reductase

As with XO, ►cytochrome P450 reductase (cytochrome C reductase) reductively activates MMC to the semiquinone in anaerobic conditions, and generates free radicals under aerobic conditions. ►CHO cells transfected with human P450 reductase show slightly greater sensitivity to MMC under oxic and much greater sensitivity under hypoxic conditions than the parental cell line. MMC sensitivity does not correlate with P450 reductase activity in the NCI 60 cell line panel under aerobic conditions. Cytochrome p450 reductase activity may contribute to the toxicity of MMC in hypoxic regions of tumors.

Other Reductases

Additional reductase enzymes have been shown to reduce MMC and include NADH:Cytochrome b5 reductase, neuronal nitric oxide synthase, and NADPH-ferredoxin reductase. All these enzymes appear to reduce MMC to the semiquinone and as such are believed to be more effective under hypoxic conditions. Two-electron activities implicated as activators of MMC include ►NRH:Quinone oxidoreductase 2 and GRP58.

Analogues of MMC

Attempts have been made to enhance the anti tumor activity of MMC by the synthesis of compounds that do not require enzymatic reduction or are improved substrates for NQO1. Compounds investigated that did not require enzymatic activation showed pulmonary toxicity in phase 1 clinical trials. One compound synthesized as an improve NQO1 substrate, EO9, was more toxic to high NQO1 expressing cells than low NQO1 expressing cells in preclinical models. However phase II trials revealed that IV EO9 was ineffective as an antitumor agent with rapid elimination from the plasma and dose-limiting renal toxicities. Intravesical administration of EO9 may be effective against superficial ►bladder cancer following ►transurethral resection.

Pharmacokinetics

Following dissolution, MMC is administered either systemically by intravenous injection, or locally by ►intravesicular instillation in the bladder or intraperitonealy in the peritoneal cavity.

Following systemic administration MMC is eliminated with a half-life of approximately 1 h and only between 1 and 20% of the unchanged drug is recovered

in the urine. The remainder is subject to both activating and deactivating metabolism, carried out predominantly in the liver but also in the spleen, kidney, heart and brain as well as tumor tissue.

Clinical Use of MMC

MMC is active against numerous solid tumors including those off the breast, ►non-small cell lung carcinoma, head & neck and anus. However, concerns about MMC toxicity mean that use of the drug is largely restricted to treatment of low grade superficial bladder cancer. Treatment of superficial bladder cancer is by the intravesical administration of 40 mg/ml in 100ml saline following transurethral resection of the tumor.

Side Effects of MMC

Systemic administration is associated with a severe dose-limiting hematological toxicity. This effect is cumulative resulting in treatment regimens of MMC involving iv administration every 6–8 weeks. MMC can also cause severe ►extravasation reactions at the site of intravenous administration. Other reported toxicities associated with MMC include nausea, vomiting and ►anorexia as well as pulmonary and cardiac toxicity.

Mitosis

Definition

Is a process of cell division, which results in the production of two identical daughter cells from a single parent cell.

Mitosis Promoting Factor

Definition

MPF; A cyclin-dependent kinase complex composed of cyclin B1 and CDK1 that is required for progression of G2 cells into ►mitosis. The activity and intracellular location of mitosis-promoting factor are regulated by kinases and phosphatases that respectively phosphorylate and dephosphorylate the subunits.

►Decatenation G2 Checkpoint

Mitotane

Definition

[1,1-dichloro-2-(*o*-chlorophenyl)-2-(*p*-chlorophenyl) ethane, or *o*,*p*′DDD], an insecticide derivative that produces adrenocortical necrosis, has been used extensively in adults with adrenocortinal tumors (ACT), but its cytotoxic effect on adrenocortical cells produces focal degeneration of the zona fasciculata and in particular the zona reticularis; the zona glomerulosa is relatively unaffected. Moreover, mitotane impairs adrenal steroidogenesis and has a direct inhibitory effect on steroidogenic enzymes.

Mitotic Accumulation & Inhibition of Microtubule Polymerization

Definition

►Mitosis is a cell division process by which the mother cell generates two identical daughter cells. Microtubules are one of the components of the cytoskeleton, which serve as structural components and are involved in mitosis. They are polymers of α- and β-►tubulin dimers. The dynamic polymerization and depolymerization of the tubulin dimers are critical for mitotic process. There are chemical or biological agents that interfere with this dynamic process and result in the accumulation of cells in mitosis.

►Methoxyestradiol

Mitotic Arrest-Deficient Protein 1

Ya-Hui Chi, Kuan-Teh Jeang
National Institute of Allergy and Infectious Disease, NIH, Bethesda, MD, USA

Synonyms

TXBP181; Tax binding protein-181; MAD1L1; homo sapiens mitotic arrest deficient-like 1 protein; MAD1

Definition

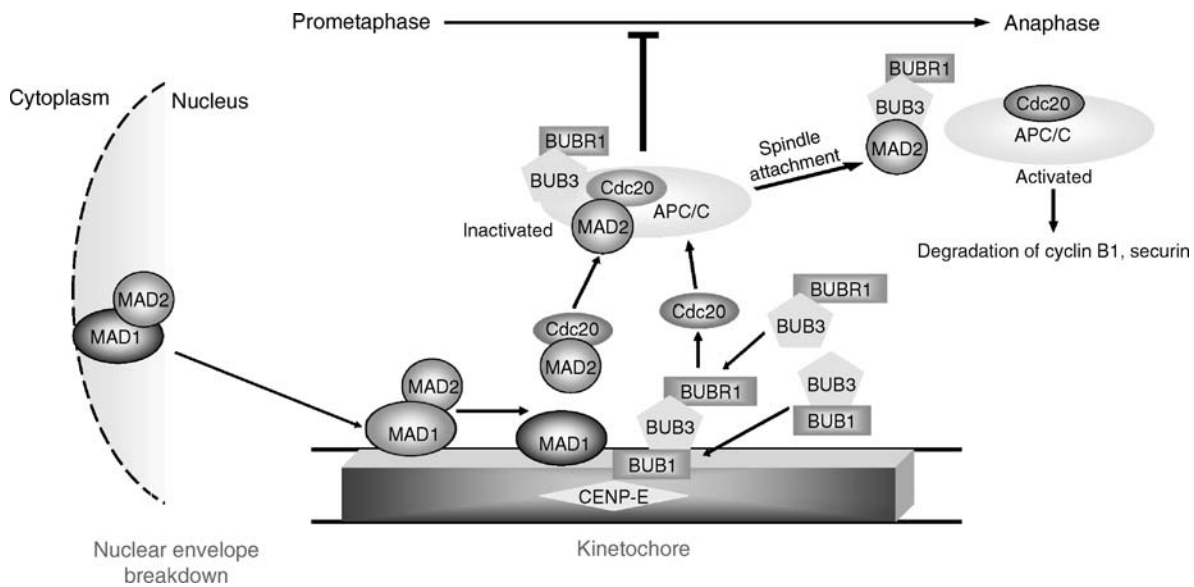
Human *mad1* gene is located on chromosome 7p22. MAD1 is a protein constituent of the mitotic ►spindle assembly checkpoint (SAC). Human MAD1 was first identified as a cellular factor targeted by ►Tax, an oncoprotein encoded by the ►human T-cell leukemia virus type 1 (HTLV-1). Cellular insufficiency of MAD1 induces gain or loss of whole chromosomes (i.e. ►aneuploidy) during mitosis. In mice, haploinsufficiency of MAD1 provokes increased tumor incidence.

Characteristics

In mitosis, duplicated chromosomes are intended to be distributed equally to two daughter nuclei. Loss of fidelity in this process can cause aneuploidy. Eukaryotic cells have evolved a checkpoint (SAC) to monitor fidelity of chromosome segregation. The SAC is a complex composed of many proteins, several located at kinetochore, which include the mitotic-arrest deficient (MAD) proteins (MAD1, ►MAD2 and MAD3), the budding uninhibited by benzimidazole (BUB) proteins (►BUB1, BUB2 and BUB3), the monopolar spindle 1 protein (►MPS1), the ►ROD-ZW10-Zwilch complex, and the microtubule motor centromere protein E (►CENP-E). Aberrant expression of SAC proteins is seen in many ►cancers, suggesting a link between SAC function and neoplasia. MAD1 is a cellular target for the HTLV-1 Tax oncoprotein. Overexpression of either Tax or a dominant-negative MAD1 results in multinucleated cells, a phenotype that is also found in some cancer cells. For ATL development, an attractive model suggests that Tax targets MAD1 abrogating SAC, creating aneuploidy which provides an initial impetus for cellular transformation (Fig. 1).

Mechanisms

In interphase cells, MAD1 binds MAD2 as a heterodimer at the nuclear pore complex (NPC). As the cell enters prophase and the NPC dissolves, MAD1 is thought to ferry MAD2 to kinetochores, and MAD1 + MAD2 compose a part of the SAC. During chromosomal partitioning, each face of replicated kinetochores is tethered by microtubules to opposing spindle poles, placing the duplicated chromatids under equal bilateral tension. If microtubule attachment is missing or improper, mis-segregation of chromatids could result. The current view suggests that a mitotic kinetochore which is not bilaterally attached by microtubules triggers MAD2 to dissociate from MAD1 to shuttle onto ►CDC20-anaphase promoting complex/ cyclosome (►APC/C). MAD2-CDC20 binding halts APC/C's proteolytic activity, prohibiting degradation of cyclin



Mitotic Arrest-Deficient Protein 1. Figure 1 A schematic representation of the role of MAD1 in spindle assembly checkpoint during the prometaphase to anaphase period of mitosis.

B1, ►securin and other factors, thus arresting the cell's progression from metaphase to anaphase. This arrest is alleviated by the proper bipolar (re-)attachment of microtubules to the kinetochore. In this paradigm, MAD1 is needed for the kinetochore localization of MAD2 and for converting kinetochore-bound MAD2 to a CDC20-receptive form. Thus, a MAD1-mediated SAC-enforced mitotic arrest offers an opportunity for aberrancies to be corrected before progression is allowed.

Although human and rodent MAD1 share 81–84% identify, they differ in the stringency of their respective SAC. Rodent cells are less responsive to spindle toxins induced mitotic arrest. It has been found that ectopic expression of human MAD1 in mouse and hamster cells corrected a relaxed rodent SAC to a more stringent human phenotype. This finding suggests that MAD1 is a species-specific determinant which influences the stringency of cellular response to microtubule depolymerization and spindle damage.

Clinical Aspects

Although the direct link between SAC and carcinogenesis in human remains to be established, up to 40% of human lung cancer cells have been found to carry mitotic checkpoint defects, including MAD1. In a study that examined for MAD1 alterations by RT-PCR-SSCP and nucleotide sequencing from a total of 44 cell lines (►hematopoietic, ►prostate, ►osteosarcoma, ►breast, ►glioblastoma and ►lung) and 133 fresh cancer cells (hematopoietic, prostate, breast and glioblastoma), eight missense, nonsense and frameshift mutations were found, along with a number of nucleotide polymorphisms. All the alterations found in these cell lines were heterozygous. Frequency of mutations was relatively high in ►prostate cancer (2/7 cell lines and 2/33 tumor specimens).

In mice, homozygous deletion of MAD1 causes embryonic lethality, suggesting an essential role for MAD1 in mouse development. Heterozygous knock out of MAD1 in mice weakens the SAC, and over an 18 months course, created a twofold constitutive increase in tumor incidence in $Mad1^{+/-}$ mice compared to wild type siblings. Tumors in $Mad1^{+/-}$ mice developed in a wide range of tissues, including ►lung adenocarcinoma, ►hepatocellular carcinoma, ►rhabdomyosarcoma, osteosarcoma, hemangiosarcoma, and uterine sarcoma. Moreover, $Mad1^{+/-}$ mice treated with spindle toxin, vincristine, showed a heightened propensity for developing ►lung tumors (42%), similar to the tumor tissue type observed in $Mad2^{+/-}$ mice (25%). It is intriguing that mouse lung tissue seems to be relatively more sensitive to deregulation in the MAD components of the SAC. Future studies are needed to establish correlations between lung tissue development and MAD-SAC functions.

Mitotic Catastrophe

Igor B. Roninson
Department of Molecular Genetics, University of Illinois at Chicago, Chicago, IL, USA

Synonyms

Mitotic cell death

Definition

Mitotic catastrophe is a process of cell death induced by radiation, chemotherapeutic drugs or hyperthermia. Mitotic catastrophe results from aberrant mitosis, which is followed either by cell death through apoptosis or necrosis or by partial or complete fragmentation of interphase nuclei with eventual cell death or seneseence. Mitotic catastrophe is identifiable from ►apoptosis by morphologic criteria.

Characteristics

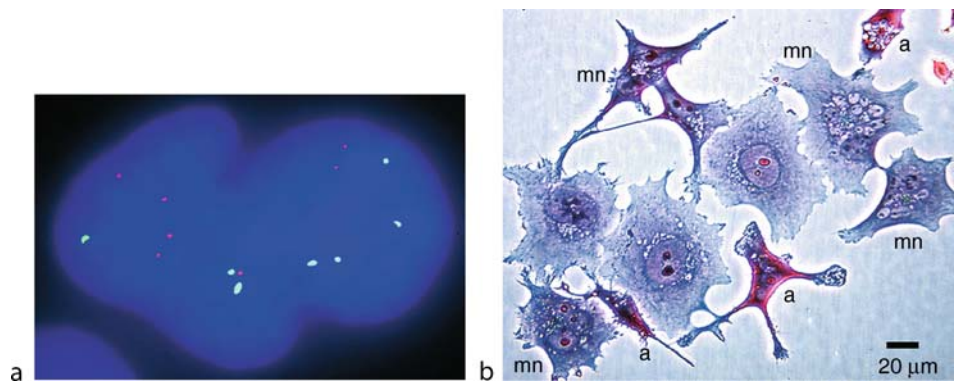
Interphase cells that suffer lethal damage from radiation or cytotoxic drugs may die before reaching mitosis. This rapid cell death usually occurs through the process of apoptosis. Alternatively, damaged cells may proceed into aberrant mitosis, which does not produce proper chromosome segregation and cell division, but results either in cell death or in the formation of large nonviable cells with two or more micronuclei that are completely or partially separated from each other. In the case of partial separation, the cell displays a large

lobulated nucleus. The micronuclei arise through the formation of multiple nuclear envelopes around chromosome clusters at the end of abnormal mitosis. Chromosomes are randomly distributed among the micronuclei of a multilobulated nucleus of a drug-treated tumor cell (Fig. 1a). The described process is called mitotic cell death or mitotic catastrophe.

Micronucleated (mn) cells, indicative of mitotic catastrophe, can be easily distinguished by their morphology from apoptotic (a) cells (Fig. 1b). While apoptotic cells may have fragmented nuclei, they are characterized by shrunken cytoplasm and condensed chromatin, whereas micronucleated cells are large and contain uncondensed chromosomes micronucleated. Cells that undergo mitotic catastrophe do not usually show DNA ladder formation or DNA breaks that are detectable by ►TUNEL staining in apoptotic cells. Mitotic catastrophe and premitotic apoptosis often arise in the same population of cells treated with a cytotoxic agent. Furthermore, the onset of mitotic catastrophe may be followed in the same cells by the activation of the apoptotic program. For this reason, mitotic catastrophe has been sometimes described as an early stage of apoptosis. However, the importance of mitotic catastrophe as an independent determinant of radiation- or drug-induced cell death has been demonstrated by the suppression of apoptosis by ectopic overexpression of apoptosis-inhibiting proteins, such as Bcl-2 or ►P-glycoprotein (the latter inhibits apoptosis through a presently unknown mechanism that is distinct from its function as a multidrug transporter). In the presence of these inhibitors, the number of apoptotic cells induced by drugs or radiation is greatly diminished, but the number of cells undergoing mitotic catastrophe (as well as terminal growth arrest in the form of ►accelerated senescence) is correspondingly increased. As a result, inhibition of apoptosis was found in several studies to have little or no effect on the survival and regrowth of treated cells. In other words, cells that have initiated the process of mitotic catastrophe may be dying through apoptosis but not because of it. This functional distinction underscores the importance of mitotic catastrophe in cellular response to anticancer agents.

Cellular and Molecular Aspects

Some insights into the mechanism of mitotic catastrophe come from the studies where this response was induced in mammalian cells or in fission yeast by genetic manipulations. In particular, mitotic catastrophe was observed in cells that were forced into mitosis through untimely activation of the mitosis-initiating complex, comprised of Cyclin B and Cdc2 kinase. This complex is regulated by a number of proteins that control the G2/M checkpoint (►G2/M transition) of the cell-cycle. Ectopic coexpression of cyclin B1 and Cdc2, cyclin A and Cdc2, and cyclin B1 and Cdc25C (an enzyme that dephosphorylates and activates Cdc2) was shown to induce premature mitosis and subsequent mitotic catastrophe in mammalian cells. The extent of mitotic catastrophe has been further increased through the use of a Cdc2 mutant, which is resistant to inhibitory phosphorylation. Mitotic catastrophe was also shown to result from mutations or inactivation of other genes that act in mitosis, such as RCC1 involved in chromosome condensation, the nuclear-mitotic apparatus (NuMA) protein and the centrosome-associated protein ►survivin. Survivin is best known as an inhibitor of apoptosis, and the loss or displacement of survivin during abnormal mitosis may potentially account for the link between mitotic catastrophe and apoptosis.



Mitotic Catastrophe. Figure 1 Morphology and chromosome distribution in micronucleated cells arising after mitotic catastrophe. (a) Random distribution of chromosomes among the micronuclei of a partially fragmented nucleus of human HT1080 fibrosarcoma cells treated with 20 nMol doxorubicin for 3 days. Fluorescence in situ hybridization was carried out with probes specific for chromosomes 18 (*green*) and 21 (*red*); nuclei were stained with DAPI [reproduced with permission from Chang et al (1999) Cancer Res 59:3761–3767]. (b) Micronucleated (mn) and apoptotic (a) cells in a population of HCT116 colon carcinoma cells treated with 50 nMol doxorubicin for 4 days [reproduced with permission from Chang et al (1999) Oncogene 18:4808–4818].

Induction of mitotic catastrophe by heat or ionizing radiation has been associated with increased cellular levels of cyclin B1 and Cdc2 kinase activity, suggesting that cellular damage may induce premature mitosis. The entry of damaged cells into mitosis is delayed by growth arrest at the G2/M checkpoint. Agents that abrogate this checkpoint, such as caffeine, okadaic acid or staurosporine, were shown to promote mitotic death in irradiated or drug-treated cells. Mitotic catastrophe is also enhanced by genetic inactivation of G2/M checkpoint control genes, such as the cyclin-dependent kinase inhibitor ►p21 (Waf1/Cip1/Sdi1) or 14–3–3-σ, a protein that maintains cytoplasmic sequestration of cyclin B1 and Cdc2. Damage-induced p21 induction is mediated largely (but not exclusively) by p53 protein, and p53 was found in several studies to be a negative regulator of mitotic catastrophe (in contrast to the usually positive effect of p53 on apoptosis). While the key role of the G2/M checkpoint in preventing mitotic catastrophe is well documented, the events resulting in the aberrant mitosis of damaged cells remain to be elucidated.

Clinical Relevance

Mitotic catastrophe has been characterized as the main pathway of cell death induced by ionizing radiation and is recognized as a prominent response to different anticancer drugs, such as doxorubicin, etoposide, taxol, cisplatin or bleomycin. This response has been documented in many cell lines derived from different tumor types, including apoptosis-resistant lines. As a general trend, mitotic catastrophe is more frequently induced by lower doses and apoptosis by higher doses of cytotoxins. Mitotic abnormalities and micronucleation have been observed both in vitro and in vivo; in fact, micronuclei formation has long been used as a common indicator of genotoxic damage.

The importance of mitotic catastrophe as a major response of tumor cells to chemotherapy and radiation has been obscured over the past decade by the emphasis on apoptotic cell death and the view that mitotic catastrophe is merely an early stage of apoptosis. However, the interest in this topic has been recently revived by the demonstration of the importance of the G2/M checkpoint as a determinant of cytotoxicity of anticancer agents and by the demonstration that the inhibition of apoptosis increases the fraction of cells that die by mitotic catastrophe. Mitotic catastrophe is potentiated by p53 deficiency and a weakened G2/M checkpoint. These are distinguishing characteristics of many tumors, suggesting that tumor cells may be more susceptible to mitotic catastrophe than normal cells. The elucidation of the molecular determinants of mitotic catastrophe may help to exploit this preferential mode of tumor cell death in a therapeutic setting.

Mixed Lineage Leukemia Protein

Definition

MLL protein; is a nuclear protein that binds DNA through its three AT-hooks. It is required for the regulation of HOX gene expression during development and hematopoiesis. The MLL gene is located at human chromosome region 11q23 and is a common target for chromosomal translocations in human acute lymphoid and myeloid leukemias. Interacts with the promoters of HOXA7-10 to promote transcription. Chromosome translocations involving the MLL gene are found in 4% of adult acute myeloid leukemia and involve up to 40 different fusion partner genes.

Modifier Loci

Tommaso A. Dragani
Fondazione IRCCS Istituto Nazionale Tumori, Milan, Italy

Synonyms

Genetic polymorphisms; Genetic predisposition; Quantitative trait loci; Susceptibility loci

Definition

Cancer modifier loci are genetic loci characterized by allele-specific effects on cancer development, e.g., stimulation or inhibition of tumor development and/or tumor size/progression. Cancer modifier loci may comprise a "null" allele, with no effects on tumor phenotypes, and a "susceptibility" or "resistance" allele, which affect tumor phenotype in a dominant, codominant, or recessive way.

Characteristics

Evidence for the existence of cancer modifier loci came first from studies in rodent models. Indeed, several studies showed that susceptibility to spontaneous and induced tumorigenesis are under genetic control. Crosses between cancer-susceptible and -resistant strains may result in F1 hybrids either susceptible or resistant to tumor formation, depending on which of the two alleles (susceptibility/resistance) is dominant in the cross.

In humans, evidence for the existence of cancer modifier loci derives from epidemiological studies reporting segregation of disease severity in families with cancer that cannot be explained by the type of germ-line mutations. Moreover, several epidemiological studies report an increased risk of the same type of cancer in first-degree relatives of cancer patients, i.e., a family risk ratio >1.0, consistent with a ►polygenic model of inherited predisposition to cancer. Such a model predicts that genetic susceptibility to tumorigenesis may be conferred by multiple genes with small effects and a powerful approach to identify the genetic loci involved may lie in linkage/association analyses of the entire genome in large samples.

Rodent Models

In mice, genome-wide analyses require only a few hundred genetic markers due to the genetic homogeneity of inbred strains, the limited number of genetic recombinations in crosses, and the consequent tight linkage of genetic markers over wide chromosomal regions.

The availability of a large number of genetic markers easy to genotype (►microsatellites) allowed the first genome-wide linkage studies in mouse models and lead to the mapping of hepatocellular cancer susceptibility loci (Hcs), the pulmonary adenoma susceptibility 1 locus (Pas1), the Mom1 locus as a modifier of the germ-line Apc gene mutation (►APC gene in familial adenomatous polyposis), which induces intestinal tumorigenesis, and loci affecting plasmacytomagenesis (►plasmacytomas). The hepatocellular cancer model provided the first formal demonstration of the polygenic nature of inherited cancer predisposition in mice. Since then, cancer modifier loci affecting almost all types of tumors have been mapped in the mouse. Loci affecting different types of rat carcinogenesis have also been mapped; among them, loci affecting susceptibility to hepatocarcinogenesis have been chracterized in more details and showed to control multiplicity and size of neoplastic lesions. Therefore, in liver, as well as in other models, cancer modifier loci may affect either single or multiple stages of carcinogenesis.

Humans

In humans, some authors proposed a polygenic model of inherited predisposition to cancer, whereas others propose models based on rare dominant alleles or additive gene effects, or on common alleles of low penetrance. Although all these models agree in part with epidemiological evidence, no combination of genetic polymorphisms that convincingly defines an additive or polygenic inheritance of predisposition to sporadic cancer has yet been described in humans. Despite many reports indicating a higher or lower risk of cancer associated with metabolic polymorphisms, several meta-analyses showed that the relative risks associated with most of the metabolic polymorphisms are low. The exceptions include arylamine *N*-acetyltransferase 2 (NAT2) polymorphism [►arylamine *N*-acetyltransferases (NAT)] and bladder cancer risk, where mechanistic and epidemiological evidence is strong.

The discovery of millions of single-nucleotide polymorphisms (SNPs) in human and in the genome of other mammalian species now make feasible large scale

genome-wide association studies, also thanks to the recent introduction of ►SNP array systems that enable screening of thousands of SNPs. Because of the genetic heterogeneity of the human population, complete analysis of the human genome by association studies might require a huge number of genetic markers and large sample collections. However, the presence of haplotype blocks in the human genome suggests that even a less dense marker coverage might be sufficient for a whole-genome analysis. Although the characterization of these haplotype blocks awaits completion, population-based association studies are complicated by complex ►linkage disequilibrium (LD) patterns, possible population admixture in the selection of cases or controls, differences in environmental factors, and other factors.

However, as these studies test hundred thousands polymorphisms in cases and controls, the need for robust replication in one, or preferably, several independent studies is paramount to distinguish the true positive results from the large number of expected false positives. Genome-wide association studies and family-based linkage studies mapped several modifier loci affecting different types of tumors, including breast, colon, lung, or prostate cancer.

Mechanisms

Few studies to date have addressed the site of action of cancer modifier genes, i.e., whether cancer modifier genes act directly within the tumor cells or instead in a cell-autonomous way, to determine the host response to the tumor. This issue likely bears on the mechanism of action of cancer modifier genes and on the targeting of these gene products. Experiments using chimeric mice generated by aggregation of embryos derived from genetically susceptible and resistant strains indicate that at least for hepatocarcinogenesis, intestinal tumorigenesis, and plasmacytomagenesis, most of the tumors in these mice derive from the susceptible strain. Thus, the cancer modifier loci in these models appear to act in the target cells, with no apparent systemic effects.

In humans, most inherited major germ-line defects appear to confer predisposition to one major tumor type, with several others exhibiting a minor increased incidence in families. For example, carriers of the BRCA1 mutations (►BRCA1/BRCA2 germ-line mutations and breast cancer risk) are at high risk of breast and ovarian cancer, and may have an increased risk of colon, pancreas, and stomach cancers. BRCA2 mutation carriers show a high risk of breast cancer and an increased risk of pancreatic cancer. Compared with the general population, carriers of the mutations causing hereditary-nonpolyposis-colorectal-cancer (HNPCC) syndrome (►Lynch syndrome) show, in addition to colorectal cancer, an increased incidence of endometrial, ovarian, gastric, biliary tract, and kidney cancers. On the other hand, ►Li–Fraumeni syndrome is characterized by a wide spectrum of neoplasms in children and young adults. Thus, both specificity and pleiotropy, i.e., single-gene allelism that influences two or more types of tumorigenesis, in genetic susceptibility to cancer in humans have been described.

Perspectives

Genetic loci affecting risk of several types of tumors have been identified in mouse models but the relationships with the risk of corresponding human cancer have not yet been established. The major locus affecting inherited susceptibility to lung cancer in mouse (Pas1) seems either lacking its human counterpart or playing a much weaker effect on lung cancer phenotype, whereas a human homology has been found for the rat Mcs5a locus affecting breast cancer risk. The difficulties in the identification of human homologs of mouse cancer modifier genes is obvious considering that some mouse alleles may not be carried in humans and that the human population is much more genetically complex than the relatively few mouse inbred strains used so far for mapping cancer modifier loci.

Overall, it seems highly unlikely that the enormous genetic variability underlying susceptibility and resistance to tumorigenesis in mice evolved only in rodents and not in all mammals, including humans. In fact, quantitative trait loci affecting several noncancer phenotypes have been mapped in cattle, pigs, and in humans, and it seems reasonable to expect that cancer modifier QTLs are present in humans. Even in cases where the human homologous gene does not display allelism and cancer modifier effects, identification of cancer modifier genes in any given species would provide a step toward understanding the biochemical mechanisms of inherited resistance/susceptibility to cancer. Eventually, it may become possible to devise new chemoprevention and therapeutic strategies for cancer based on the biochemical effects of such genes.

Also, new diagnostic markers might be devised to identify groups of individuals at higher risk of sporadic cancer as compared with the general population. This is now possible for members of families with ►monogenic cancer syndromes, which represent a minority of cancer cases. Identification of individuals at high risk of cancer raises the possibility of chemoprevention. For example, FAP carriers (APC gene in familial adenomatous polyposis) benefit from long-term use of nonsteroidal ►anti-inflammatory drugs.

In conclusion, the identification of cancer modifier genes may allow understanding of the genetic mechanisms responsible for the variability in the individual risk to develop a cancer and it may also provide new opportunities for diagnosis and cure.

Modular Recombinant Transporters

►Modular Transporters

Modular Transporters

Alexander S. Sobolev
Department of Molecular Genetics of Intracellular Transport, Institute of Gene Biology,
Russian Academy of Sciences, Moscow, Russia

Synonyms

Modular recombinant transporters; Multi-domain transporters

Definition

Modular transporters are engineered ►polypeptides consisting of several interchangeable parts, or ►modules designed for delivery of anti-cancer drugs to the target cancer cell and its specific subcellular compartment.

Modular transporters can also be considered as nanomedical drug vehicles (►nanotechnology), which recognize the cancer cells of choice, and once in those cells, are transported to the most sensitive compartment of the cell (e.g. nucleus).

In order to reach the desired compartment of the cancer cell, the modular transporters are first passively delivered to the surface of the cell in the blood stream. Once within the cell, depending upon the nature of the ►polypeptide modules, they are transported to a particular ►subcellular compartment utilizing the cell's intrinsic transport machinery.

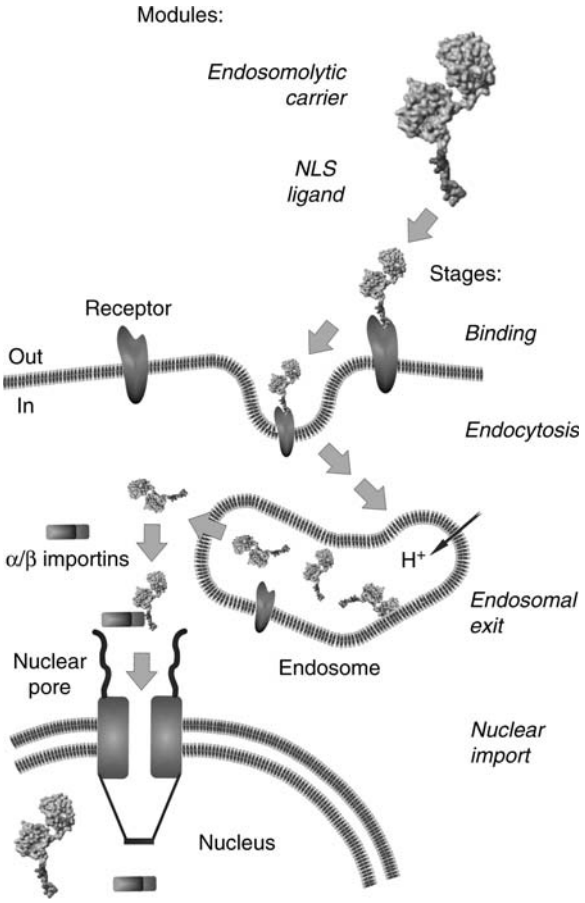
Characteristics

Objectives

To minimize side effects, many anti-tumor agents need to be delivered (►drug delivery) not only to the target cancer cell but also into a specific subcellular compartment, usually into the most sensitive/vulnerable site of the cancer cell. Examples of such anti-tumor agents are: (i) foreign DNA for cancer gene therapy, (ii) ►photosensitizers for ►photodynamic therapy or (iii) ►radionuclides emitting ►alpha-particles for endoradiotherapy (►radioimmunotherapy). All of the above should be delivered into the nuclei where they can perform their specific function. On the other hand, (iv) toxins, most of which are active in the cytosol, require a different modular transport strategy to retain in the cytoplasm.

Principles

This goal can be achieved with the use of modular transporters with preset properties, which would ensure recognition of the desired target cell and subsequent directed transport to the subcellular compartment of choice. The necessity of different modules is determined by the following considerations. First, cell type specificity together with internalization into the target cell can be achieved if the engineered transporter possesses a ►ligand module, which has high binding affinity to the ►receptor overexpressed on the target cancer cell but not on non-cancer cells. This highly specific ►ligand-receptor binding will ensure recognition of the target cell as well as a subsequent receptor-mediated ►endocytosis. The internalized transporter will then be delivered to endocytotic vesicles, or endosomes, localized in the cytoplasm (►endosomal compartments). Second, because the internalized transporter moves along the endocytotic pathway, it is necessary to provide the transporter with an endosomolytic module enabling the transporter's escape from the endosome. Third, a specific subcellular delivery can be achieved if the transporter has a specific localization amino-acid sequence, e.g. a nuclear localization sequence to target the cell nucleus. Finally, the modules as well as the anti-tumor agent should be integrated into one moiety; this goal can be achieved by inclusion of the fourth module, a carrier module. Therefore, modular transporters for nuclear drug delivery should include the following parts: (i) an internalizable ligand module providing for target cell recognition and subsequent receptor-mediated endocytosis; (ii) an endosomolytic module ensuring escape of the transporter from endosomes; (iii) a module containing a nuclear localization sequence (a sequence of amino acids that is recognized by ►importins needed for the active translocation into the nucleus); and (iv) a carrier module for attachment of an anti-tumor agent (Fig. 1).



Modular Transporters. Figure 1 Scheme of a modular transporter, and stages of its transportation within the target cell. NLS, nuclear localization sequence. *Arrows* indicate successive steps of the transporter binding to over-expressed internalizable receptors on the target cancer cell, internalization, endosomal localization within an acidifying milieu, escape from endosomes, binding to importins, and transport through the nuclear pores into the cell nucleus. (From Rosenkranz et al (2003) Recombinant modular transporters for cell-specific nuclear delivery of locally acting drugs enhance photosensitizer activity. FASEB J 17:1121–1123, with permission.)

Features

Fundamental to the success of this strategy is that the modules are functional within the transporter, i.e. they retain their activities within the chimeric molecule. Depending on the type of target cancer cells, the ligand module can be replaced; the module with subcellular localization signal can be replaced or omitted (e.g. omission of the nuclear localizing signal will leave the transporter in the cytoplasm of the target cell).

Several types of modular transporters have been created that can deliver photosensitizers into the nuclei of ►melanoma cells; photosensitizers and radionuclides into the nuclei of glioma and epidermoid carcinoma cells and toxins into the cytoplasm of ►acute myeloid leukemia cells. In all these cases, cell specificity was achieved by inclusion of a specific ligand module into the transporter that bound to a corresponding internalizable receptor overexpressed on the surface of the target cancer cell: melanocortin-1 receptor, epidermal growth factor receptor (►epidermal growth factor receptor inhibitors), (►tyrosine kinase receptors), and interleukin-3 receptor (►cytokine receptor as target for immunotherapy and immunotoxin therapy), respectively. Anti-tumor agents carried by these modular transporters acquired a significantly higher efficacy aside from cell specificity. In cases when they are delivered into the most sensitive sites of the target cancer cells, the agents become 10–3,000 times more effective.

►Biomarkers

Molecular Chaperones

Marissa V. Powers, Paul Workman
Cancer Research UK Centre for Cancer Therapeutics, The Institute of Cancer Research, Sutton, Surrey, UK

Definition

Proteins that transiently interact with nascent polypeptide substrates to protect them from misfolding and aggregation. They also have an important role in helping to achieve the native conformation of the newly synthesized protein without forming part of the final folded product. The molecular chaperone ►HSP90 is responsible for the stability and activity of a range of oncogenic client proteins and is a target for cancer drugs.

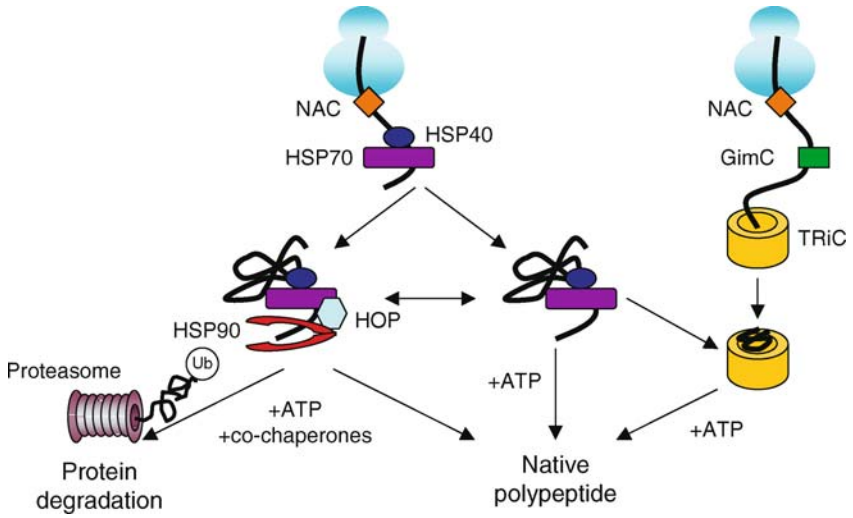
Characteristics

Proteins are mediators of a vast array of biological processes and their activity is dependent on obtaining their correct three-dimensional conformation. It has been widely accepted from *in vitro* folding experiments that the formation of the native state is a spontaneous process which is dictated by the amino acid sequence of the protein. However, protein folding *in vivo* is complicated by the crowded cellular environment which naturally favors protein mis-folding and aggregation. Under certain conditions aggregation may lead to the production of amyloid fibrillar aggregates that are associated with pathological conditions including Alzheimer's or Huntington's disease. To prevent this, nascent or partially folded proteins interact with various chaperone proteins which encourage the formation of the correct three-dimensional structure. Generally, chaperones interact with non-native proteins by recognizing hydrophobic residues and regions of the polypeptide backbone which are not normally exposed to solvent when the correct conformation is achieved. Chaperones may promote *de novo* protein folding by binding directly to the non-nascent protein to shield regions which may be involved in intermolecular aggregation and intramolecular mis-folding.

In addition to promoting productive *de novo* protein folding and preventing non-specific aggregation under normal conditions, molecular chaperones also have an important role in the cellular response to stress. This is because conditions such as elevated temperatures, ionizing radiation, heavy metals and oxidative stress may cause some proteins in their native state to unfold. Many molecular chaperones demonstrate increased expression under such conditions and are referred to as heat shock proteins (HSPs).

In the mammalian cytosol a number of chaperones are involved in native protein folding and the ►stress response (Fig. 1). Chaperone involvement begins as newly synthesized proteins exit the ribosome. This is particularly important because the tendency to aggregate at this stage is increased due to exposure of non-native features and the close proximity of nascent polypeptides of the same type at the polyribosome complex. Nascent polypeptide chains emerge from the peptide exit tunnel of the ribosome and interact with the nascent-chain-associated complex (NAC). It has been hypothesized that the NAC exerts its chaperone function passively by simply binding to and protecting the exposed hydrophobic regions of the newly synthesized polypeptides. This is because it lacks an ►ATPase domain which is characteristic of most molecular chaperones (see below). After release from the ribosome, most small proteins do not require additional chaperones. Longer polypeptide chains may require additional help by association with the HSP70 chaperones which can act in higher eukaryotes both co- and post-translationally. The HSP70 family consists of both constitutively expressed (HSC70) and stress-inducible forms (HSP72) which promote the correct folding of nascent proteins through ATP-dependent cycles of binding and release. HSP70 stably interacts with substrates in its ADP-bound form which is encouraged by its co-chaperone HSP40, a ►J-domain protein which significantly stimulates the ATPase activity of HSP70 to prolong its association with substrate. The substrate binding sites for HSP70 are typically extended hydrophobic stretches of seven residues which statistically occur every 40 residues.

Nascent polypeptides leave the ribosome via the NAC. The majority of small polypeptides require no further assistance to achieve the correct conformation



Molecular Chaperones. Figure 1 Chaperone-mediated protein quality control in the eukaryotic cytosol.

following release from the ribosome. For longer polypeptides the native conformation may be achieved via an interaction with HSP70 and its co-chaperone HSP40. The chaperone function of HSP70 may be extended through its interaction with the HSP90 molecular chaperone via the adaptor protein p60/HOP. According to the compliment of co-chaperones associated with HSP90, its function can be altered from assisting protein folding to promoting protein degradation via the ubiquitin (Ub)-►proteasome pathway. A limited number of proteins have been shown to be reliant on transfer to the GimC/TRiC pathway; these include the abundant proteins actin and tubulin.

In eukaryotes, cytosolic HSP70 can further promote the folding of a particular group of cellular proteins by interacting with the ATP-dependent HSP90 chaperone family. Proteins which are reliant on HSP90 for their correct folding, stability and functional regulation include many ►kinases and other ►signal transduction proteins such as steroid hormone receptors. Substrate transfer from HSP70 to HSP90 is mediated by the adapter protein p60/HOP which binds to the carboxy-terminus of the two chaperones via its ►tetracopeptide repeat (TPR) domains. Similar to HSP70, HSP90 chaperone function is reliant on the orchestrated interaction of a number of co-chaperones which collectively control substrate binding, ATPase activity and substrate release. In addition, co-chaperone interaction may alter HSP90 function from polypeptide folding to protein sorting either into intracellular organelles or to the ubiquitin-proteasome system for degradation. For example, in mammals the HSP70-HSP90 chaperone system can interact with the ubiquitin ligase CHIP (carboxyl-terminus of HSP70 interacting protein) via its TPR domain, promoting the ►ubiquitination of non-native or mis-folded proteins and their degradation by the proteasome. In addition, HSP70 and CHIP can interact with BAG-1 which contains an ubiquitin-like domain that can interact with the proteasome. Therefore, the chaperone function of the HSP70-HSP90 system can be modified by co-chaperone interaction to control protein quality in the cell by mediating a balance between protein folding versus proteasomal degradation.

A restricted group of proteins that are slow-folding and sensitive to aggregation are dependent on the activity of ►chaperonins. These molecular chaperones are a conserved class of large double ring complexes which are exemplified in the eukaryotic cytosol by the Group II chaperonin TRiC (TCP-1 ring complex). As with HSP70 and HSP90, chaperonins mediate folding by undergoing a conformational cycle which is driven by ATP binding and hydrolysis. The most abundant substrates for folding by TRiC are the cytoskeletal proteins actin and tubulin. However, additional proteins which have been shown to co-precipitate with TRiC include von Hippel-Lindau tumor suppressor and ►WD40-repeat 7-blade propeller proteins. Substrate transfer to the TRiC complex has been suggested to be mediated by the cytosolic chaperone Gim1-6 complex (GimC)/prefoldin. This ATP-independent chaperone is made up of six coiled-coil domains each of which contains a hydrophobic extension which is responsible for substrate recognition and interaction with TRiC. GimC/prefoldin interacts with the TRiC substrates actin and tubulin during their translation. It has also been shown to interact with TRiC during the post-translational folding of actin. However, GimC/prefoldin does not contribute to the TRiC-mediated folding of the WD40-repeat proteins.

HSP90 as an Anticancer Drug Target

At first glance molecular chaperones may not appear as obvious candidates for selection as anticancer drug targets because, unlike many oncogenic targets, they are not subject to mutation or amplification. However, the expression of HSP70 and HSP90 is frequently increased in a number of different human ►cancers. In addition, the client proteins which are reliant on HSP90 function for their stability and function includes a wide range of oncoproteins including ERRB2, BCR-ABL, ►C-RAF, mutant B-RAF, AKT/PKB, CDK4, mutant p53, PLK-1, ►HIF-1α, estrogen receptor and ►androgen receptor (for a an up to date compilation see http://www.picard.ch/downloads/Hsp90interactors.pdf). Inhibition of HSP90 function has been shown to cause the depletion of client proteins via the ubiquitin-proteasome pathway, suggesting that modulation of HSP90 function may offer a novel mechanism to simultaneously inhibit multiple oncogenic pathways, all of which may contribute to the hallmark traits of malignancy. These combinatorial effects will be valuable not only in treating cancers which are driven by multiple molecular abnormalities but should also reduce the opportunity for resistance developing.

The increased expression of HSP90 in malignant cells may be a reflection of the stress imposed on cancer cells by the effects of deregulated ►oncogenes and ►tumor suppressor genes. These molecular stresses may be coupled with the micro-environmental stress of solid tumors caused by hypoxia, acidosis and nutrient deprivation. Collectively these factors may lead to greater dependence on HSP90 and other chaperones in cancer versus normal cells, offering the prospect of therapeutic selectivity.

As described above HSP90 (along with many of the other molecular chaperones) are ATPase enzymes. The natural products radicicol and geldanamycin bind to the intrinsic N-terminal ATPase domain of HSP90 to inhibit its function and cause client protein degradation and growth arrest. Since the original discovery of these two natural products there has been an explosion of interest in the development of novel HSP90 inhibitors. Proof-of-concept for the clinical use of HSP90 inhibitors was provided by the completion of several phase I ►clinical trials on the first-in-class HSP90 inhibitor 17-AAG (tanespimycin), an analogue of the natural product geldanamycin. ►Biomarker evidence demonstrated client protein depletion and heat shock protein expression in the tumor tissue and peripheral blood lymphocytes of treated patients at doses which were well tolerated. As a result 17-AAG is now in phase II clinical trial. In addition, a more soluble analogue of 17-AAG, 17-DMAG (alvespimycin) has recently entered phase I clinical trial. Several other inhibitors are in development.

The exciting observations made *in vitro* and *in vivo* with HSP90 inhibitors highlight the possibility of modulating chaperone function which may have benefits not only in the treatment of cancer but also in the management of other protein folding diseases.

Molecular Epidemiology

Definition

Application of biochemical and/or molecular biomarkers within an epidemiological study design to identify events directly or indirectly associated with the pathway between exposure and disease. A long-term goal of molecular epidemiology is attenuation of disease by manipulation of biomarkers early in the disease process.

►Cancer Epidemiology
►Molecular Cancer Epidemiology

Molecular Genetics

Definition

Group of methods applied for the detection of molecular genetic alterations, includes fragment analysis (Genescan), heteroduplex analysis, melting point analysis, nested PCR, PCR, real time PCR, sequence analysis, single stranded conformation analysis (SSCP).

►Leukemia Diagnostics

Molecular Imaging

Definition

Imaging of contrast agents or tracers targeted to a specific cell-surface receptor to noninvasively assess the extent to which a tissue or organ expresses that receptor. The targeted receptor is usually a marker of a disease-related process, such as angiogenesis or inflammation, or a potential target for drug activity. Image-based quantification of the binding of targeted agents yields information about molecular-scale events that would not otherwise be detectable *in vivo* with preclinical or clinical imaging. Molecular imaging can be performed with any imaging technology given a suitable choice of targeted contrast agent or tracer.

►Ultrasound Micro-Imaging

Molecular Memory

Definition

The inheritance of specific pattern of gene expression, which persists in daughter cells from generation to generation.

Molecular Mimicry

Definition

It has been proposed that infectious agents could provoke autoimmunity by molecular mimicry, the induction of antibodies, and T cells that react against the pathogen but also cross-react with self antigens.

Molecular Morphology

►Immunohistochemistry
►Molecular Pathology

Synonyms

Molecular morphology

Definition

Molecular pathology is the study of the molecular genetic causes of abnormal cell and tissue functioning with the goal of improved disease diagnosis and treatment. As a medical discipline, molecular pathology is a specialty training that incorporates the subject matter of genetics, inherited cancers, solid tumors, neoplastic hematopathology, infectious diseases, identity testing, HLA typing, and laboratory management, and impacts both anatomic and ►clinical pathology practice.

Characteristics

Historical and Clinical Background

►Pathology, the study of the origin, nature, and courses of diseases, has its foundation in the studies of Giovanni Battista Morgagni of Padua (1682–1771), (the "father of ►anatomic pathology") and Rudolf Virchow of Berlin (1821–1902), (the "father of cellular pathology"). Dr. Morgagni documented the relationship between diseases and the gross changes observed in autopsy specimens, and Dr. Virchow established the correlation of cellular changes with disease having formulated the cellular theory of life, *omnis cellula e cellula* (all cells come from cells). Modern anatomic pathology retains gross and microscopic tissue examination as the basis of clinical diagnostics via standardized classifications; tumor specimens are described in terms of organ of origin (e.g. breast, colon etc), cell type (e.g. carcinoma, describing cells of epithelial type; adenocarcinoma, referring to a cancer of glandular origin), and in terms of ►tumor staging and ►tumor grade. The "TNM Staging" characterizes solid tumors by the extent to which a tumor (T) has spread locally, the amount of regional lymph node (N) involvement, and whether or not there are metastases (M) to distant organs or lymph nodes. Tumor grade refers to the degree of cellular divergence from the normal condition. These criteria are increasingly supplemented by tests for additional ►biomarkers to improve disease diagnosis. The discoveries of molecular cell biology and the human genome project together with technological advancements resulting in methodologies that are reliable, rapid and cost effective have set the stage for molecular pathology as an essential and routine discipline

M

for improved patient care. Potentially, molecular pathology will yield a comprehensive molecular classification of cancer improving early tumor diagnosis, resolution of equivocal diagnoses including tumors of uncertain grade or unknown organ of origin, tumor chemoresistance/drug therapy investigation, and individualized medicine. Numerous putative markers are reported in the scientific literature; the challenge is to identify those individual or sets of biomarkers that have high ►sensitivity, ►specificity, and predictive value (►Negative predictive value, ►positive predictive value) for vital clinical parameters. The following illustrates by way of current common techniques how molecular pathology can support cancer diagnosis.

Immunohistochemistry

Immunohistochemistry (IHC) allows by microscopic inspection the correlation of protein staining patterns with ►cytology or ►histology and is the most routinely used adjunct technique of anatomic pathology. Aberrant molecular genetic changes frequently result in an altered immunophenotye (nuclear, cytoplasmic, or membrane protein expression staining patterns). Typically, IHC involves application of a primary antibody to the antigen of investigation to tissue sections followed by secondary antibodies labeled to allow chromogenic or fluorescent detection. IHC has been a routine part of pathology practice since the mid-1970s, often to identify cell or tissue origin. For example, the lineage of an undifferentiated tumor or the organ of origin of a metastasis can be identified after IHC with panel of antibodies for cytokeratins as the expression fingerprint of these cytoskeletal markers is not compromised by malignant transformation. IHC is also used to differentiate lymphomas and sarcomas. Panels of markers (e.g. CD5, CD23, CD43, Cyclin D1 and bcl-6) are used to help distinguish different categories of lymphomas such as follicular, mantle cell, marginal zone and chronic lymphocytic leukemias (►Leukemia diagnostics). Similarly, IHC markers including desmin, myogenin, CD99, CD43 and FLI-1 may be used to distinguish ►rhabdomyosarcomas, ►Ewing sarcoma, ►desmoplastic small round cell tumor (DSRCT), ►neuroblastoma, and lymphoblastic lymphoma.

"Genogenic" IHC supports the demonstration of genomic translocations that result in novel chimeric proteins; for example ~90% of Ewing sarcoma cases harbor a t(11;22)(q24;q12) translocation resulting in the EWS-FLI-1 chimeric product; over-expression of the FLI-1 protein can be used to distinguish Ewing's sarcoma from histologically similar tumors. IHC can also be used as a marker of gene mutations that result in protein under- or overexpression; hereditary nonpolyposis colon cancer (HNPCC) is characterized by ►microsatellite instability (MSI) due to mutations in genes such as *hMLH1* and *hMSH2*. These mutations translate as under-expression of MLH1 and MSH2 proteins detected by IHC.

Routinely, IHC markers are employed to assess tumor aggressiveness and the appropriate course of treatment; breast tumor diagnostics requires IHC for ►estrogen receptor (ER), progesterone receptor (PR), and ►HER-2 status. ER and PR positive tumors are generally less aggressive and are more responsive to hormone suppression treatments such as tamoxifen; HER-2 positive tumors tend to be aggressive but are candidates for treatment with ►herceptin.

Defective cell-cycle checkpoint control may be critical for tumor development and there is a variety of potential IHC markers. For example, $p57^{Kip2}$ expression may be associated with poor prognosis, whereas $p21^{WAF1}$ and $p27^{Kip1}$ overexpression may signify a favorable prognosis; $p16^{INK4a}$ is widely used as a surrogate marker of ►human papillomavirus (HPV) infections and pre-invasive cervical lesion grade. High-risk HPV type E7s open-reading frame product inactivates pRb (►Retinoblastoma protein), thereby disrupting pRb negative feedback of $p16^{INK4a}$ with consequent overexpression of the latter and increased staining the more severe the lesion (Fig. 1).

IHC can also be used in the direct demonstration of oncogenic viruses. Detection of ►Epstein-Barr virus (EBV) latent membrane proteins (LMPs) and/or nuclear antigens can be used in the diagnosis of ►nasopharyngeal carcinoma, Burkitt lymphoma and ►Hodgkin lymphoma. Detection of human herpesvirus 8 (HHV-8) may assist in the diagnosis of ►Kaposi sarcoma, and detection of the HPV *L1* capsid protein of infective virions may be a marker of low-grade cervical lesions.

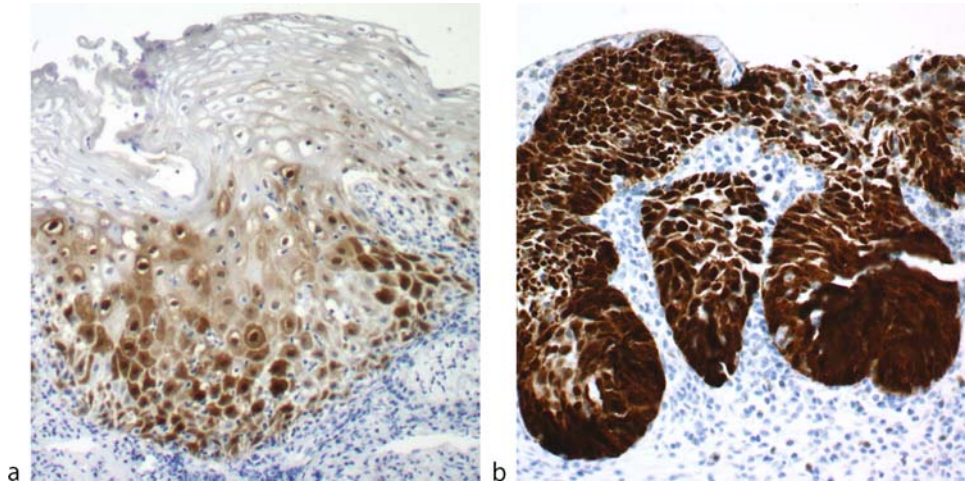
In Situ Hybridization

Fluorescent *in situ* hybridization (FISH) or chromogenic *in situ* hybridization (CISH) allow the demonstration of DNA or RNA in tissue samples by hybridization with labeled nucleic acid probes or synthetic analogs; like IHC, in situ hybridization (ISH) supports the direct correlation of test data with specimen morphology. FISH techniques represent an efficient and easier option than classical metaphase cytogenetic techniques for the detection of chromosomal rearrangements; additionally, ISH supports interphase cytogenetic applications.

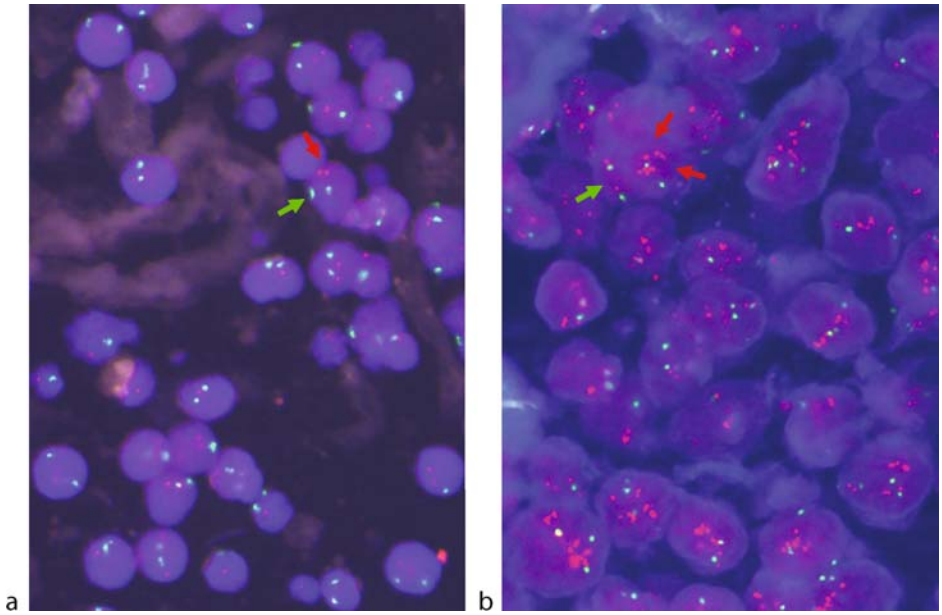
FISH is utilized in the diagnosis of hematological malignancies. For example, chronic myelogenous leukemia (CML) is characterized by the ►*BCR-ABL* reciprocal translocation involving fusion of the *BCR* region of chromosome 22 with the *ABL* region of chromosome 9. The fusion results in a shortened chromosome 22 (the Philadelphia chromosome). Predictable FISH signal patterns can be observed in interphase cells depending on whether the probes span or flank the translocation breakpoint. Other

hematological diagnoses by FISH include ►acute promyelocytic leukemia (APL) (t(15;17)(q22;q12)), and follicular lymphoma (t(14;18)(q32;q21)). Soft tissue tumors such as synovial sarcomas can also be diagnosed by FISH; the t(X;18)(p11;q11) translocation is present in ~90% of these tumors and results in the juxtaposition of the *SYT* gene (18q11) and the *SSX* gene (Xp11).

Among solid tumors, FISH is routinely used to confirm HER-2 amplification indicated after IHC assay. The PathVysion™(Vysis Inc. IL. USA) FISH assay involves dual hybridization with a probe for the centromeric region of chromosome 17 together with a probe to the HER-2 locus at 17q11.2-12; comparison of the ratio of signals is used to score amplification (Fig. 2). The UroVysion™(Vysis Inc. IL. USA) FISH assay is a non-invasive test for ►bladder cancer. The test is applied to urinary cytology specimens and uses a panel of four probes to targets frequently altered in bladder cancer (centromeres 3, 7, and 17, and 9q21 (site of the p16 gene)); if ≥4/25 cells show multiple chromosome gains, or there is loss of both copies 9q21 in ≥12/25 cells, this is taken as predictive of cancer.



Molecular Pathology. Figure 1 Differential nuclear and cytoplasmic $p16^{INK4a}$ staining patterns in low-grade (a) and high-grade (b) cervical lesions.



Molecular Pathology. Figure 2 (a) Non-amplification of HER-2 indicated by a 1:1 ratio of chromosome 17 centromeric signals (green) to HER-2 FISH signals (red). (b) Amplification indicated by abundant HER-2 signals relative to centromere 17 signals.

ISH is the preferred choice for the demonstration of EBV by the detection of EBV encoded RNAs (EBER) in circulating B lymphocytes of patients with suspected lymphoma. ISH supports the detection of low- or high-risk HPV types and HPV signal types may be useful in determining (cervical) lesion grade. "Diffuse" signals are associated with episomal HPV, whereas "punctate" signals may be demonstrative of HPV integrated into the cell genome (Fig. 3). In addition to cervical tissues, HPV ISH is applicable to head and neck, esophageal, and other tumors with a suspected HPV etiology.

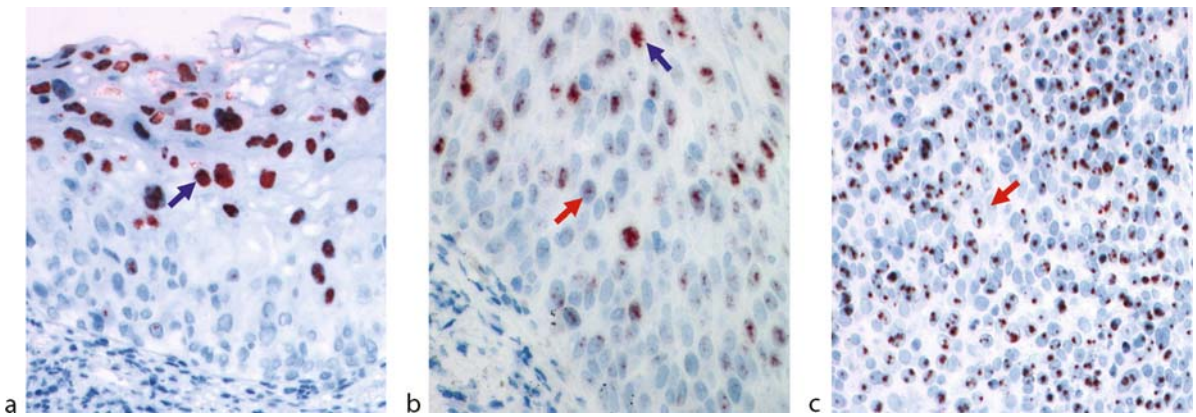
Other ISH applications include investigation of chromosome instability/aneusomy in tumors or cell lines using panels of centromeric probes. Locus specific probes can be used to investigate the association of defined abnormalities with tissue morphology. Centromeric and locus specific probes can also be used to examine intra-tumoral heterogeneity and to investigate the relationship between tumors and putative precursor lesions. Combining ISH with IHC allows observation of the correlation between nucleic acid detection and protein expression patterns. Specialized FISH techniques such as spectral karyotyping (SKY) or multiplex (M) FISH utilize chromosome paints specific for each of the 24 human chromosomes and detectable by fluorescent microscopy and computer imaging. Application of the paints to metaphase spreads from tumors allows the identification of chromosomal rearrangements with a resolution down to ~2–3 Mb.

Polymerase Chain Reaction

Pathology specimens are frequently highly limiting with respect to the amounts of nucleic acids that can be recovered for diagnostic or research applications. The polymerase chain reaction (PCR) utilizes a thermostable DNA polymerase, DNA primers, and deoxyribonucleic acid building blocks to amplify a DNA template; theoretically, after 30 cycles of denaturation, annealing, and extension, the starting template DNA sequences are amplified 1 billion-fold. Consequently, PCR techniques have been at the vanguard of molecular pathology investigations. Using fluorescent-labeled primers, PCR can be adapted for real-time quantitative (Q) PCR to allow an estimation of relative DNA load or mRNA expression. By combining PCR with microdissection of specific tissues or cells off a slide, it is possible to correlate PCR data directly with tissue morphology.

PCR is used diagnostically to screen for gene mutations (by PCR product sequencing or by techniques such as single strand conformation polymorphism (SSCP)). Mutation screening of all 19 *hMLH1* exons, all 16 *hMSH2* exons, or all 10 exons of the *hMSH6* is possible in the diagnosis of HNPCC; or MSI can be investigated directly by PCR for a panel of 5–12 standardized microsatellite loci that includes mono- and dinucleotide repeat sites (►Colon cancer). PCR mutation screening is also applicable in the diagnosis of other familial tumors such as the ►APC gene in familial adenomatous polyposis, which can lead to an autosomal dominant condition resulting in the development of myriad colon polyps some of which may have the potential progress to colon carcinoma. Mutation screening is also performed for ►BRCA1/BRCA2 germline mutations and breast cancer risk.

Numerous candidate genes associated with sporadic tumors have been described; however, uncertainty about the relationship of mutations in these genes to tumor diagnosis and prognosis has stalled translation to routine screening tests. For example, mutations leading to aberrant expression of the ►tumor suppressor



Molecular Pathology. Figure 3 HPV detection by CISH in cervical tissues. Diffuse signals (blue arrows) detected mainly in upper epithelial layers characterize low-grade lesions (a). In high-grade lesions (b) diffuse and punctate signals (red arrows) may be detected throughout the epithelial thickness. Punctate signals alone in an invasive cervical carcinoma (c).

TP53 protein ("guardian of the genome") are estimated to be present in up to 50% of sporadic tumors. Despite the undoubted contribution of *p53* mutations to tumor pathology, *p53* mutation screening is of uncertain clinical utility.

PCR is used in the diagnosis of oncogenic viruses; in particular, several PCR strategies are available for detecting HPV and determining which of more than forty HPV types associated with cervical lesions are present in a patient (cervical smear) sample. In the reverse-line blot assay, labeled PCR product is hybridized to a blot spotted with HPV type specific probes. Patients positive for high-risk HPV types may be at an increased risk for high-grade lesions/cancer. An elevated HPV DNA load as determined by Q-PCR may also correlate with increased tumor risk.

Reverse-transcriptase (RT) PCR converts RNA to DNA for PCR amplification. RT-PCR allows the detection of RNA fusion transcripts and is widely used in soft tissue tumor diagnostics. For example, alveolar rhabdomyosarcoma diagnosis is aided by the detection of mRNA transcripts created after the t(2:13)(q35;q14) reciprocal translocation that juxtaposes part of the *PAX3* gene on chromosome 2 with part of the *FKHR* gene on chromosome 13. The *API2/MALT1* RT-PCR test can be applied to stomach or other gastrointestinal tissues for the diagnosis of ►B-cell tumors of mucosa-associated lymphoid tissue (MALT lymphoma). This condition commonly develops against a background of chronic inflammation caused by ►*Helicobacter pylori* infection. Diagnosis of DSRCT can be aided by RT-PCR for transcripts from the t(11:22)(p13;q12) translocation associated with DSRCT and involving the *EWS* and *WT1* genes. RT-PCR is also used in the diagnosis of Ewing sarcoma, synovial sarcomas, and *BCL-ABL*/CML. Q-RT-PCR is used in the diagnosis of APL to detect transcripts of the fusion of the retinoic acid receptor alpha gene (*RARA*) with the promyelocytic leukemia (*PML*) gene; monitoring the tumor burden may be helpful in predicting disease relapse. The PCR based methods have greater sensitivity than their FISH counterparts for detecting tumor specific rearrangements, nevertheless "false-negative" diagnoses may occur because of variant translocation points not detected by PCR primer sets. RT-PCR also supports the assessment of HPV integration. The amplified papillomavirus oncogenic transcript (APOT) assay confirms integration by the detection of HPV transcripts that are contiguous with human sequence transcripts.

Future Developments

Improved techniques and new findings are a constant in molecular pathology. For example, application of a sophisticated high-throughput PCR mutation screening strategy of more than 13,000 genes in 11 breast and 11 colorectal cancers has shown that individual tumors typically accumulate ~90 mutant genes and that only a subset of these contribute to the neoplastic process; an average of 11 genes per tumor were mutated at significant frequency. Follow-up of such studies in course of time may reveal (sets of) mutations that have high utility as sporadic tumor diagnostic markers. Similarly, ►microarray cDNA technology and the findings of ►proteomics studies are expected to greatly increase and refine knowledge of the molecular basis of cancer, translating into effective clinical tests including improved IHC, ISH, or PCR, or the development of cost effective microarray or proteomic tests for limited sets of biomarkers. Additionally, there remains much to be learned about genome regulation; for example, the significance of ►microRNAs in the control of gene expression and contribution to tumor biology has only recently been recognized, and there is increasing awareness of the importance of ►epigenetics in tumor etiology. Advances in the conceptual frameworks within which cancer is understood will also direct the interpretation of biomarkers. Whilst ►oncogenes and ►tumor suppressor genes remain key concepts, there is a growing appreciation of cancer as a process involving a multi-interaction of cellular systems.

Molecular Shape

Definition

This approximation of lipid structure is a simple but convenient way to explain the volume occupied by lipid molecules. The model explains the three dimensional structure of lipids in a simple manner and the membrane structure as a consequence of the "shape" of the lipid molecules. Thus, a phospholipid with a bulky polar head, such as phosphatidylcholine, has a molecular shape that resembles a cylinder. In contrast, the

molecular shape of phosphatidylethanolamine, with a small polar head, is similar to a truncated cone, while the fatty acids oleic and elaidic acid, are similar to a boomerang and a rod, respectively.

►Membrane-Lipid Therapy

Molecular Therapy

Ingo Kausch, Christian Doehn
Department of Urology, University of Luebeck, Medical School, Luebeck, Germany

Definition

Therapy with compounds which are rationally targeted against certain specific molecular structures.

Characteristics

There is yet no generally accepted definition of the term molecular therapy. A frequent opinion is that molecular therapeutics target diseases on an early molecular level and thus modulate the disease at its roots. This would comprise the classic ►gene therapy as well as other DNA- or RNA-based strategies. However, also other non-molecular therapeutics such as ►chemotherapy interact with nucleic acids. Additionally, nucleic acid based drugs may also interact with proteins. Therefore it seems more useful to define molecular therapy as a strategy which specifically targets certain molecular structures although all therapies that work have a target with some kind of molecular structure. In some cases the target is discovered first while in others the drug is discovered before the target. In contrast to other therapeutic concepts such as chemotherapy or immunotherapy molecular therapy is usually directed against a biologically important process with a measurable target in the clinic. Based on this definition certain compounds which are frequently designated as "targeted therapy" such as monoclonal antibodies or ►small molecule drugs should in addition to DNA- or RNA-based strategies also belong to the class of molecular therapeutics.

Gene Therapy

Classic gene therapy is the direct use of genetic material in the treatment of diseases. The various strategies for inhibiting cancer growth by gene therapy approaches comprise the reversion of the malignant phenotype by correcting abberrant gene expression, induction of genes that inhibit tumor growth, immune gene concepts, cytoreductive or oncolytic approaches.

Additive or corrective gene transfer involves on the one hand the introduction of foreign genes such as suicide genes or antiangiogenesis genes. On the other hand physiological but mutated and malfunctioning genes which are associated with tumor development and progression such as tumor suppressor genes may be restored. Since the cellular uptake of naked longer nucleic acid molecules is inefficient, gene therapy is dependent on effective delivery. The clinically relevant gene transfer techniques can be classified into viral (vector) delivery systems and nonviral delivery sytems. DNA molecules may be packed in viral vectors. Viruses can transfer these molecules into cells and the transgene of interest enters the nucleus and is integrated into the host gene pool, and eventually expressed. Common clinically used viruses are adenoviruses, retroviruses, lentiviruses, adeno-associated viruses, the herpes simplex virus and parvoviruses. The gene transfer by viral vectors in general is characterised by a high effectivity but considerable toxicities such as for instance immune responses. Common non viral delivery systems are polymeric systems and liposomal systems. These systems are characterised by lack of immune response as well as ease of industrial production but also by significantly lower transfection efficiency compared to viral vectors.

Clinically several gene transfer phase I-III studies in different tumours have been performed or are in progress. Earlier trials suffered especially from inefficient expression of the transgene. One modified adenovirus that delivers the p53 gene to cancer cells has been approved by the FDA.

Oncolytic gene therapy viruses are designed to infect and destroy cancer cells by expression of cytotoxic proteins while remaining innocuous to the rest of the body. Several different viruses such as adenoviruses and herpes virus have been used clinically. However, only few trials with oncolytic therapy have been performed. Most advanced (Phase-III) is the approach with an adenovirus that replicates and mediates cell lysis only in cancerous cells with p53 mutation (ONYX-015).

Since cancer cells tend to develop mechanisms to evade immune detection traditional immunotherapy is often characterised by limited effectivity. In order to overcome these problems immune gene therapy concepts have been advocated. One popular strategy are recombinant cancer vaccines. Autologous or allogeneic cancer cells are engineered to be more recognisable to the immune system by the addition of one or more genes. These genes are are mostly cytokine genes or highly antigenic genes. Another approach is the direct delivery of immunostimulatory genes such as cytokines to the tumor. The goal is to unmask the cells from immune evasion and enhance an antitumor response. A third strategy is the direct alteration of the patients

immune system by adding tumor antigens or stimulatory genes to the patients immune cells. Although early clinical trial were quit successful, long lasting immune responses were the exception rather than the rule. Several large phase-III-studies are currently underway.

Nucleic Acid Constructs

The various nucleic acid therapeutics include ►antisense oligonucleotides, ►small interfering RNAs (siRNA), aptamers, ribozymes and DNAzymes. Nucleic acid based drugs have emerged in recent years to yield extremely positive candidates for therapy of various diseases including cancer. In opposite to gene therapy the major goal of nucleic acid drugs is the inhibition and silencing of specific cancer-associated genes such as oncogenes.

The most extensive applications have been performed with antisense oligonucleotides. These are short chemically modified DNA sequences (10-25 nucleotides), designed to modulate the information transfer from gene to protein. Sequence-related hybridisation with the mRNA of a specific protein results via different mechanisms such as RNAseH-dependent mRNA clavage in selective inhibition of gene expression and downregulation of protein expression. Antisense oligonucleotide inhibitors can be designed directly from genomic sequence information by simply making the reversed complement of the desired sequence. However, active compounds are more effectively generated by computer-based approaches. One antiviral antisense drug (fomivirsene) has already been approved by the FDA. Phase-III studies with several antisense constructs in oncological patients are underway or have been finished. Some results have been particularly encouraging although antitumoral effects have to a certain extent been attributed to unspecific immunostimulatory mechanisms. In clinical studies antisense oligonucleotides have mostly been applied without any delivery system. In the majority of the current trials, oligonucleotides are combined with one or more traditional chemotherapeutic agent or another targeted agent.

Ribozymes are RNA molecules which may selectively bind to a target mRNA and form a duplex which results in cleaving of the target mRNA. Two types of ribozymes, the hammerhead and hairpin ribozymes have been extensively studied for therapeutical purpose. In DNAzymes the RNA backbone chemistry is replaced by DNA motifs which confers greater biological stability. DNAzymes have high catalytic activity. Aptamers are small single-stranded or double-stranded nucleic acid segments that directly interact with proteins. In comparison to protein inhibition by antibodies aptamers are highly specific, non immunogeneic and stable. In some cases and as opposed to antisense oligonucleotides, effects can be mediated against extracellular targets, thereby preventing a need for intracellular transportation. The three latter classes of nucleic acid drugs have been evaluated in preclinical oncological studies or have entered early clinical trials.

Small interfering RNAs are short double-stranded RNA segments with a length of typically 21-23 nucleotides. SiRNA are also complementary to a target mRNA sequence. They are upon application incorporated into RNA-induced silencing complexes (RISCs) which bind to the mRNA of interest and stimulate mRNA degradation via different mechanisms such as nuclease activation. These compounds are, compared to other gene silencing instruments, substantially more effective and nonimmunogenic. Initial non oncological phase-I studies have been initiated. A new class of non-coding small RNA molecules are the microRNAs (miRNAs). Many miRNAs are known to be up- or downregulated in a variety of cancers, suggesting a role for miRNAs in tumorigenesis. These compounds are beginning to be used therapeutically.

Nucleic acid drugs offer in comparison to viral vectors or plasmids greater safety since they do note integrate into the genome. Furthermore, delivery is mostly easier since most of these compounds do not have to enter the nucleus for their activity and because of the small size (especially antisense oligonucleotides and siRNA). However, for most medical applications several obstacles related to toxicity, stability, affinity, cellular delivery and specificity remain to be clarified and may be overcome by new chemical modifications.

Small Molecule Drugs

The small molecules of highest interest in cancer therapy are protein tyrosine kinases (PTK). They comprise over 100 ►oncogenes and more than 40 ►tumor-suppressor genes. Overexpression of PTK receptors is correlated with poor prognosis in some malignancies. Tyrosine kinase inhibitors (TKIs) are orally available, synthetic chemicals with a small molecular weight. They reversibly bind to the ATP-binding site on the receptor and prevent its activation as well as signal transduction. Small-molecule agents can translocate through plasma membranes and interact with the cytoplasmic domain of cell-surface receptors and intracellular signalling molecules. TKIs have shown objective tumor responses in chronic myeloid leukemia (CML), gastrointestinal stromal tumors and non-small-cell lung cancer. The TKIs gefitinib and erlotinib are specific for the ►epidermal growth factor receptor (EGFR). In contrast, Imatinib inactivates the kinase activity of the BCR–ABL fusion protein in CML. Sorafenib is a dual kinase inhibitor inhibiting different isoforms of Raf serine kinase as well as various receptor tyrosine kinases such as VEGFR, EGFR and PDGFR. This results in an inhibition of tumor proliferation and angiogenesis. Sunitinib is another multi-targeted tyrosine kinase inhibitor of VEGFR,

PDGFR, KIT and Fms-like tyrosine kinase 3 (FLT3). Both drugs are approved for the treatment of metastatic kidney cancer. Bortezomib, which was first developed as a selective, reversible inhibitor of the chymotryptic protease in the 26S proteasome, has been reported to be effective against hematological malignancies.

Antibody Therapy

In 1975 Köhler and Milstein first described the generation of murine monoclonal antibodies (mAbs). The typical antibody consists of two antigen-binding fragments (Fabs) which are linked via a flexible region to a constant (Fc) region. This structure comprises two pairs of polypeptide chains, each pair containing a heavy and a light chain of different sizes. Antibodies bind to antigens on the surface of cells or pathogens. The first therapeutic antibody for cancer therapy (retuximab) was approved in 1987 for the treatment of non-Hogkin's lymphoma. mAbs are relatively large proteins with a high molecular weight. They are generally administered via an intravenous infusion and often have a half-life of several days.

Disadvantages of mouse antibodies are a short half-life in serum, the inability to trigger human effector function and the induction of human antimouse antibodies (HAMA) which in turn inactivate murine mAbs. Chimeric antibodies such as retuximab combine human constant regions and mouse variable antigen-binding regions to reduce their immunogenicity. However, they can also induce human anti-chimeric antibody response (HACA). Thus, human antibodies seem ideal to overcome the latter problems.

Today about 200 antibodies are in clinical trials for cancer therapy, chronic inflammation, transplantation, infectious and cardiovascular diseases. For cancer therapy more than 10 mAbs are approved by the FDA, predominantly for the treatment of non-Hogkin's lymphoma, breast cancer and colorectal cancer.

Antibody cancer therapy aims to target tumor-associated antigens and/or tumor-specific antigens (e.g. CEA, EGFR, HER2, MUC1, CD20) to alter their signalling. They can function by three principal modes of action: blocking the action of specific molecules such as growth factors or cytokines, targeting specific cells or functioning as signalling molecules. Also, mAb therapy may result in an elimination of tumor cells by immune-effector cells via complement-dependent cytotoxicity (CDC) and antibody-dependent cellular cytotoxicity (ADCC).

Limitations beside immunogenicity of murine mAbs and chimeric mAbs are a potential lack of selectivity and poor penetration into solid tumors. The latter problem is due the size of mAbs and a poor permeability of the tumor surface. Monoclonal antibodies are relative specific therapies associated with low toxicity.

Clinically antibodies are often safe well tolerated with some fever and chills at first infusion. A possible side effect of antibody therapy is the cytokine-release syndrome that is probably mediated through recruitment of the immune effector cells. However, treatment-associated deaths have been described in few patients.

An other limitation is the restriction of targets to those on the surface of host cells. This problem could be solved by the development of functional antibodies within cells, so called intrabodies. Beside the development of unconjugated or naked mAbs, a conjugation with cytotoxic dugs, cytokines, toxins, radionuclides and DNA molecules have been tested in order to optimise delivery and enhance specificity and effectivity.

MOMP

Definition

Mitochondrial outer membrane permeabilization is the event that triggers the mitochondrial apoptotic cascade. MOMP is regulated by proapoptotic members of the BCL-2 family. These proteins induce disruptions in the outer mitochondrial membrane and subsequent release of death-promoting proteins like cytochrome-c.

►APAF-1 Signaling

Monoclonal Antibodies

Definition

Monoclonal antibodies are antibodies that are identical because they are all clones of a single parent cell. Monoclonal antibodies are typically made by fusing a normally short-lived, antibody-producing B cell to a fast-growing cell, such as a cancer cell.

►CD Antigens
►Monoclonal Antibody Therapy

Monoclonal Antibody Therapy

Stephanie Sasse, Andreas Engert
Hematology and Oncology, University Hospital of Cologne, Department of Internal Medicine I, Cologne, Germany

Definition

►Monoclonal antibody therapy is a passive ►immunotherapy consisting of in vitro-generated identical immunoglobulin clones which specifically bind to a defined membrane-bound surface antigen and induce tumor cell-lysis or -►apoptosis via different pathways.

Characteristics

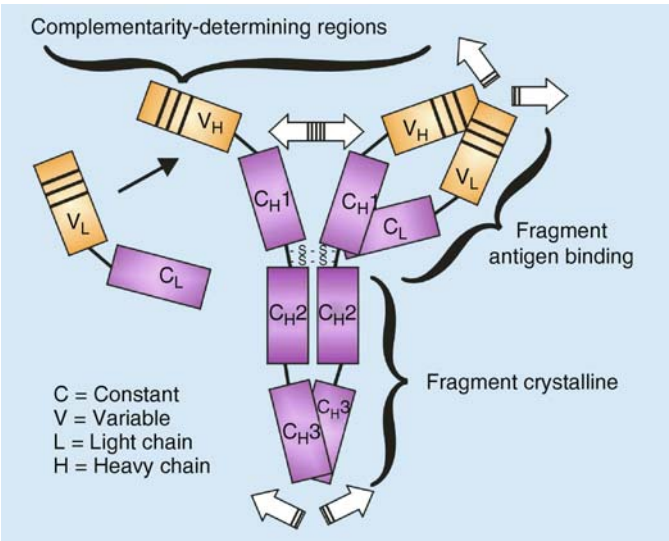
The idea of a monoclonal antibody based cancer therapy was first proposed by Paul Ehrlich at the beginning of the twentieth century. Development of monoclonal antibody therapy required characterization of defined target antigens and the establishment of monoclonal antibody production.

Antibody Structure

For generation of ►monoclonal antibodies (mAbs) the exact knowledge of antibody-structure is indispensable. As shown in Fig. 1 antibodies are Y-shaped glycoproteins composed of two heavy and two light chains connected by disulfide bonds. Heavy and light chains consist of two domains, a constant and a variable domain. Antigen specificity is mediated by ►complementarity-determing regions (CDRs) of the variable domains. In addition to the CDRs, the framework regions of the variable domains and the neighboring constant regions (CH1 and CL) contribute to the conformation required for antigen binding. The effector function of antibodies is defined by the C-terminal structure of the heavy chain; there are five main heavy-chain isotypes, IgM, IgG, IgA, IgD and IgE. The physiologically most abundant immunoglobulin isotype is IgG subtype 1. IgG subtype 1 and IgG subtype 3 are the immunoglobulins with the highest binding affinity to the Fc-receptor expressed on ►macrophages.

Monoclonal Antibody Generation

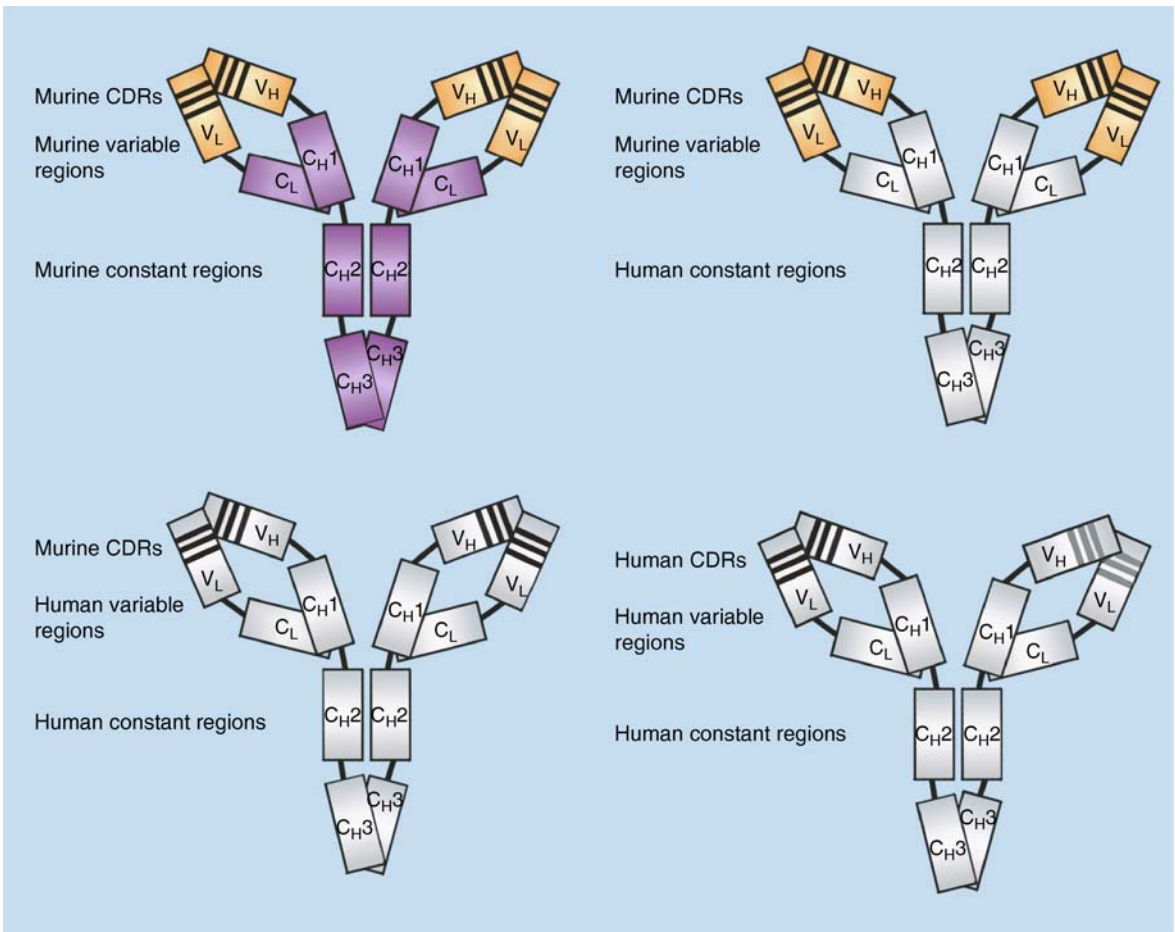
The first monoclonal antibodies were generated after the invention of ►hybridoma technology by Georges Köhler, César Milstein and Niels Jerne in 1975.



Monoclonal Antibody Therapy. Figure 1 Structure of an antibody molecule. Reprinted with permission from "UNI-MED Verlag, Bremen."

The key idea of hybridoma technology was to fuse cells of a non-secreting myeloma cell line with antibody-producing murine B-cells from animals which had been immunized with the antigen of interest. The application of mouse-derived ►hybridomas enabled the production of large amounts of murine monoclonal antibodies. Murine monoclonal antibodies are highly effective diagnostic tools; however, the application as cancer therapeutics is limited by the development of human anti-mouse antibodies. The production of human anti-mouse antibodies results in neutralization of murine antibodies and in shortening of their circulation half-lives; an anaphylactic reaction is a rare, but quite serious complication. Therefore, only two murine monoclonal antibodies have been approved to date, both serving as targeting agents for isotopes (Y90-Ibritumomab; I-131 Tositumomab).

Through advances in genetic engineering in the 1980s and 1990s less immunogenic and more efficient monoclonal antibodies have been designed. Depending on the ratio of human and mouse cDNA sequences chimeric, humanized and human monoclonal antibodies are differentiated; the difference in structure of these genetically engineered monoclonal antibodies is illustrated in Fig. 2. Replacement of murine constant regions by human DNA sequences resulted in the production of chimeric antibodies. Examples of approved chimeric antibodies are the anti-►CD20 antibody ►Rituximab and the anti-►EGF receptor antibody ►Cetuximab. Further improvement of monoclonal antibody engineering led to the generation of ►humanized antibody or completely human antibodies. Humanized monoclonal antibodies are created by insertion of murine complementarity-determing regions into the variable framework regions of a human antibody. Examples of humanized monoclonal antibodies approved for cancer therapy are the anti-HER2 antibody ►Trastuzumab and the anti-►CD52 antibody



Monoclonal Antibody Therapy. Figure 2 The graphs show a fully murine antibody on the upper left, a chimeric antibody consisting of human constant and mouse variable regions on the upper right, a humanized mouse antibody, where the murine CDR are grafted on a human antibody scaffold, on the lower left, and a fully human antibody on the lower right. ►Alemtuzumab. Completely human monoclonal antibodies could be obtained by development of transgenic mice or by use of ►phage display technology. The anti-EGF receptor antibody Panitumumab is the first completely human monoclonal antibody approved for treatment of cancer (Table 1).

Clinically Relevant Anticancer Monoclonal Antibodies

Approved Anticancer Monoclonal Antibodies

Since 1980 over 200 monoclonal antibodies have been evaluated in clinical trials for their efficacy and safety in the treatment of certain cancer entities. To date, 12 of these anticancer monoclonal antibodies have been approved for marketing in at least one country. The currently approved monoclonal antibodies including their target antigens, the antibody-structure and the first approved indication are described in Table 1. So far, one of the approved monoclonal anticancer antibodies has been withdrawn from the market: in a post-approval study it was shown that Edrecolomab, a murine anti-EpCAM antibody, is inferior to standard adjuvant treatment of colorectal cancer.

Unmodified Monoclonal Antibodies

As listed in Table 1 seven unmodified anticancer monoclonal antibodies have been approved to date. Two unmodified monoclonal antibodies which have significantly improved the treatment of certain cancer entities are exemplarily characterized in more detail:

Rituximab is a chimeric monoclonal antibody that binds to ►CD20, a cell surface protein located on mature B-lymphocytes and expressed on most B-cell ►non-Hodgkin lymphoma (NHLs) and on certain subtypes of B-cell differentiated ►acute lymphoblastic leukemia. Rituximab was initially approved as a single-agent therapy for relapsed or refractory low-grade, follicular ►B-cell NHL. The role of Rituximab for treatment of non-Hodgkin lymphoma has evolved

Monoclonal Antibody Therapy. Table 1 Currently approved monoclonal anticancer therapeutics

Generic name	Trade name	Description of antibody structure	Targeted Antigen	First approved indication	Year of first approval
Rituximab	Rituxan	Chimeric, IgG1κ	CD20	Single-agent therapy of relapsed or refractory low-grade or follicular B-cell NHL	1997
Trastuzumab	Herceptin	Humanized, IgG1κ	HER-2	Metastatic breast cancer expressing HER2	1998
Gemtuzumab ozogamicin	Myelotarg	Humanized, IgG4κ anti-CD33 linked to calicheamicin	CD33	Relapsed acute myeloid leukemia	2000
Alemtuzumab	Campath	Humanized, IgG1κ	CD52	Relapsed or refractory CLL	2001
Ibritumomab tiuxetan	Zevalin	Murine, IgG1κ radiolabeled (Y-90)	CD20	Relapsed or refractory low-grade, follicular B-cell NHL (refractory to Rituximab)	2002
I-131 ch-TNT		Chimeric, IgG1κ anti-DNA-associated antigens, radiolabeled (I-131)	DNA-associated antigens	Advanced lung cancer	2003
I-131 Tositumomab	Bexxar	Murine, IgG2aλ, anti-CD20, radiolabeled (I-131)	CD20	Follicular B-cell NHL, relapsed after chemotherapy, refractory to Rituximab	2003
Cetuximab	Erbitux	Chimeric, IgG1κ	Epidermal growth factor receptor (EGFR)	EGFR-positive, irinotecan-refractory metastatic colorectal carcinoma (colon cancer)	2003
Bevacizumab	Avastin	Humanized, IgG1	Vascular endothelial growth factor (VEGF)	Metastatic colorectal cancer	2004
Nimotuzumab	TheraCIM	Humanized, IgG1	EGF-receptor	Advanced head/neck epithelial cancer	2005
Panitumumab	Vectibix	Human, IgG2κ	EGF-receptor	Metastatic colorectal cancer	2006

significantly since its introduction. Current recommendations for application of Rituximab include the initial treatment of follicular and diffuse large B-cell non Hodgkin lymphoma in combination with polychemotherapy. Further clinical trials indicate that Rituximab is also beneficial in the treatment of ►CLL, ►Burkitt lymphoma and of mature and precursor B-ALL in combination with polychemotherapy. In addition to its relevance in anticancer therapy Rituximab is gaining increasing importance in the treatment of B-cell mediated autoimmune diseases such as rheumatoid arthritis. Most patients tolerate Rituximab well; the most common side effects are fever, chills, and nausea.

Trastuzumab is a humanized anti-HER2 monoclonal antibody, which has major impact on the treatment of breast cancer. Human epidermal growth factor receptor 2 (►HER-2) is overexpressed in 25–30% of ►breast cancer patients and is associated with a more aggressive form of malignancy. The addition of Trastuzumab to first-line chemotherapy in patients with ►HER2-overexpressing metastatic breast cancer significantly improved response rate, time to progression and overall survival. The first approved indication for trastuzumab therefore included the treatment of HER2-overexpressing metastatic breast cancer in combination with chemotherapy. In addition, Trastuzumab received approval as single-agent therapy in those patients with metastatic HER2-overexpressing breast cancer who do not respond to chemotherapy. Further clinical trials revealed a significant improvement of adjuvant chemotherapy results through addition of Trastuzumab. Thus, Trastuzumab has also become an important component of ►adjuvant therapy for those patients with HER2-overexpressing breast cancer. The most important adverse reaction of ►Herceptin is cardiac dysfunction; the incidence of cardiac dysfunction is highly dependent on prior ►anthracycline exposure.

The anti-cancer activity of unmodified monoclonal antibodies can be mediated by different mechanisms. An important, but not necessarily the most relevant mechanism is the destruction of targeted cells through activation of cell- and complement-mediated cytotoxicity, also called antibody-dependent cell cytotoxicity (ADCC) and complement-dependent cytotoxicity (CDC). Only for two of the currently approved monoclonal antibodies, Rituximab and Alemtuzumab, ADCC and CDC have been identified as primary mode of action. Other modes of anti-tumor cell action of unmodified monoclonal antibodies include inhibition of growth factor and growth factor receptor interaction, downregulation of growth factor receptors and induction of ►apoptosis by influencing intracellular signaling. Three approved monoclonal antibodies, ►Cetuximab, Nimotuzumab and Panituzumab, are believed to function primarily by blocking epidermal growth factor receptor (►EGF-R inhibitors). One approved unmodified monoclonal antibody, ►Bevacizumab, inhibits tumor ►angiogenesis by binding to the ►vascular endothelial growth factor (VEGF). The in vivo mechanisms of the anti-HER2 antibody Trastuzumab have not been clearly resolved yet; downregulation of HER2-mediated signaling and induction of tumor-cell apoptosis have been proposed as possible modes of action in addition to activation of ADCC. However, functional assays with the anti-CD20 antibody Rituximab have shown that the target specific cytotoxic effect of unmodified monoclonal antibodies might be mediated by several pathways. Rituximab does not only activate cellular and complement mediated cytotoxicity; it additionally induces tumor-cell apoptosis by an increase of the intracellular calcium concentration.

Immunoconjugates

Immunoconjugates are antibodies or antibody fragments linked to cytotoxic substances such as radioisotopes, drugs or toxins. Through coupling with these cytotoxic substances the efficacy of immunotherapy with monoclonal antibodies might be improved.

Radioimmunoconjugates

Rationale of the application of ►radioimmunoconjugates in cancer therapy is a tumor-specific delivery of beta- or gamma-radiation emitting isotopes with minimal involvement of surrounding healthy tissue (synonym ►radioimmunotherapy). Additionally, tumor-resistance to unmodified monoclonal antibodies due to inhomogeneous target antigen expression and due to development of escape mechanisms might be overcome by radioimmunoconjugates.

The most commonly conjugated and clinically best studied radioisotopes are iodine-131 (^{131}I) and yttrium-90 (^{90}Y). Iodine-131 and yttrium-90 differ markedly in their physical properties including half-life, path-length, type of energy emissions, intracellular stability, and the organs targeted by the free radionuclide. ^{131}I emits beta- and gamma-radiation. Beta- and gamma-radiation of ^{131}I can be applied therapeutically; the highly energetic gamma-radiation can be additionally used for calculation of the individually required therapeutic dose of the applied radioimmunoconjugate. On the other hand, application of ^{131}I-conjugated immunoconjugates requires defined security procedures to protect the environment from gamma-radiation. Besides, gamma-radiation might be associated with severe myelotoxicity. The other radioisotope, ^{90}Y solely emits beta-radiation. Advantages of ^{90}Y might be its safety regarding environment exposure, its longer path length and its superior intracellular stability compared to ^{131}I.

The three radioimmunoconjugates currently approved for cancer therapy are the anti-CD20 immunoconjugates ^{131}I Tositumomab and ^{90}Y Ibritumomab

tiuxetan and the ^{131}I tumor necrosis treatment (TNT) antibody. The anti-CD20 immunoconjugates ^{131}I Tositumomab and ^{90}Y Ibritumomab tiuxetan received approvement for treatment of relapsed follicular or transformed B-cell non-Hodgkin Lymphoma. The ^{131}I anti-TNT immunoconjugate is approved for treatment of advanced ►lung cancer.

Toxin Immunoconjugates

Toxin immunoconjugates or ►immunotoxins are protein toxins that specifically target tumor cells via tumor-selective antibodies or antibody-fragments coupled to the toxin. Killing of tumor cells by immunotoxins requires internalization of the immunotoxin and subsequent translocation of the toxin domain to the cytosol. Various plant, bacterial or fungal toxins have been genetically fused or chemically conjugated to tumor-specific ligands. The most common fusion partners are Diphtheria toxin (DT), Pseudomonas exotoxin (PE), ricin and gelonin; these extremely potent catalytic toxins induce ►apoptosis of tumor cells by inhibition of protein synthesis.

More than twenty different immunotoxins have been evaluated concerning efficacy and safety, so far. Some of these immunotoxins including recombinant anti-CD22 Pseudomonas exotoxin have shown promising results in clinical phase I and II trials, but further clinical application has been limited through development of neutralizing antibodies, through immunotoxin-associated toxicities such as "vascular leak syndrome" and through the short half-life of recombinant, especially single chain-based immunotoxins.

Drug Immunoconjugates

Drug immunoconjugates are antibody-targeted cytotoxic drugs. One drug immunoconjugate, ►Gemtuzumab ozogamicin, has been approved for cancer treatment to date. Gemtuzumab ozogamicin is a humanized anti-►CD33 antibody that is linked to the anti-tumor antibiotic calicheamicin. In vitro studies have shown that Gemtuzumab ozogamicin induces apoptosis of ►CD33 expressing leukemic blasts. After binding to CD33, Gemtuzumab ozogamicin is internalized and calicheamicin, which is released inside the lysomomes, causes DNA double-strand breaks and cell death. Gemtuzumab ozogamicin is approved for treatment of relapsed ►acute myeloid leukemia in patients older than 60 years.

Monoclonal Gammopathy of Undetermined Significance

Siegfried Janz
Department of Pathology, University of Iowa, Carver College of Medicine, Iowa, IA, USA

Definition

Monoclonal gammopathy of undetermined significance (MGUS) is defined by a monoclonal immunoglobulin in serum that amounts to 30 g/L or less, the presence of 10% or fewer plasma cells in the bone marrow, the absence of anemia and lytic bone lesions, and the absence of hypercalcemia and renal insufficiency related to the aberrant clonal proliferation of plasma cells. MGUS is the most common disorder among a group of diseases referred to as plasma cell dyscrasia. Because of the high prevalence in elderly patients (~5%), MGUS is a very common finding in the doctor's office. MGUS does not require treatment, but the need for monitoring is life long. This is due to the intrinsic propensity of MGUS cell clones to complete the malignant transformation process and, thus, undergo progression to multiple myeloma (MM). The progression from MGUS to MM, an invariably fatal neoplasm, occurs at a slow but remarkably steady rate of 1% per year.

Characteristics

Epidemiology

A comprehensive population-based study on the prevalence of MGUS in persons 50 years of age or older used serum samples from more than 21,000 residents of Olmsted County, Minnesota (corresponding to 77% of all county residents in this age bracket!) to find MGUS in 694 (3.2%) individuals. The age-adjusted rates were greater in men (4.0%) than in women (2.7%). The prevalence of MGUS was 5.3% among persons 70 years or older and 7.5% among persons 85 years or older. The concentration of M-protein was less than 10 g/L in the majority (64%) of cases. Of 79 patients tested, 21% had monoclonal urinary light

chain. The prevalence of MGUS was 8.6% in black individuals compared with 3.6% in white individuals. This race-related difference was confirmed in an independent study of inpatients from the U.S. Veteran Affairs hospitals, which showed that the age-adjusted prevalence rate for MGUS was 3.0-fold higher in African Americans than in Americans of Caucasian ancestry.

Etiology

The etiology of MGUS is not known. Epidemiological evidence points to age, gender and race as genetic risk factors for MGUS.

Pathogenesis

The pathogenesis of MGUS, including the reason why MGUS is a stable non-malignant disorder in the great majority of affected individuals but undergoes malignant progression in a subset of cases, is poorly understood. Approximately 50% of MGUS cell clones carry chromosomal translocations that rearrange the immunoglobulin heavy-chain gene cluster, *IGH*, at 14q32 with loci on one of five partner chromosomes: *CCND1* (cyclin D1 gene) at 11q13; *FGFR3* and *MMSET* (WHSC1) at 4p16.3; *CCND3* (cyclin D3) at 6p21; *MAF* (c-MAF) at 16q23; and *MAFB* at 20q11. Translocations of this sort are thought to play an important role in the initiation of MGUS and, in some cases, its subsequent progression to MM.

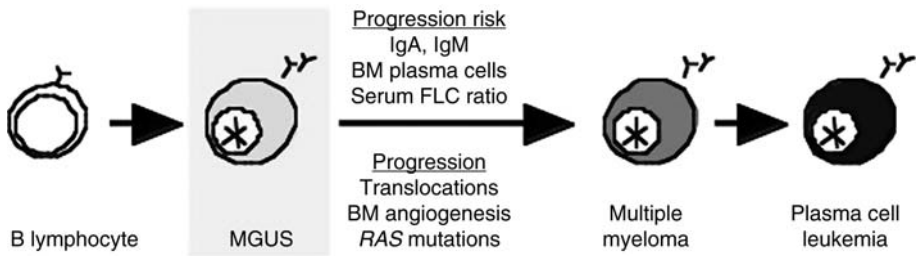
Approximately 40% of the plasma cell clones in MGUS, smoldering MM (SMM) and frank MM are hyperdiploid, suggesting that hyperdiploid MM originates from hyperdiploid MGUS. Likewise, deletions of chromosome 13q, which have an adverse prognostic association in MM, are found in similar frequencies in MGUS and MM, indicating a direct precursor-and-product relationship between the $13q^-$ pre-neoplastic and neoplastic state. Empirical observations of this kind suggest that MGUS occurs as distinct molecular subtypes, which lead, in turn, to different forms of MM.

The mechanism of progression of MGUS to MM appears to be multi-factorial, possibly involving (i) the breakdown of immune surveillance mechanisms that normally limit MGUS to the pre-malignant disease stage, (ii) the acquisition of *RAS*-activating point mutations in certain MGUS cell clones, and (iii) the shift in the balance of pro- and anti-angiogenic factors that results in increased angiogenesis in the bone marrow.

Considering that the most important features that differentiate MM from MGUS are the occurrence of lytic bone lesions, osteopenia, hypercalcemia, and pathological fractures, it is interesting to note that a recent study of 488 patients with MGUS revealed a 2.7-fold increase in axial fractures. The implication is that MGUS is associated with increased focal bone loss, albeit less severe than that seen in myeloma bone disease. This blurs the line between distinct stages of plasma cell neoplasia (MGUS, SMM, MM, plasma cell leukemia) and suggests, instead, that these disorders comprise an overlapping continuum characterized by increasing autonomy, malignancy, and clinical aggressiveness (Fig. 1).

Diagnosis

Serum protein electrophoresis in agarose gels provides a good screening method to detect the presence of a monoclonal immunoglobulin (mIg, M-protein, M-spike, paraprotein). Electrophoretic analysis is usually followed by immunofixation, which confirms the monoclonal immunoglobulin and determines the



Monoclonal Gammopathy of Undetermined Significance. Figure 1 MGUS is caused by a pre-malignant plasma cell clone that resides in the hematopoietic bone marrow and secretes monoclonal immunoglobulin (M-protein, paraprotein). MGUS is derived from a mature post-germinal center B lymphocyte that expresses immunoglobulin on the cell surface (*left*). MGUS clones that secrete IgA or IgM, lead to elevated numbers of plasma cells in the bone marrow, and/or distort the normal ratio of immunoglobulin κ and λ light-chains in the serum (FLC) exhibit increased propensity to undergo progression to multiple myeloma (MM). The molecular mechanism of this progression has been shown to include oncogene-activating *IGH* translocations and *RAS* mutations that occur in the MGUS clone and elevated blood vessel formation (neoangiogenesis) in the bone marrow. MM may be preceded by a less aggressive form of neoplasia, smoldering MM (SMM). MM may evolve into a more aggressive, terminal form of neoplasia, plasma cell leukemia (PLC). MGUS, SMM, MM and PLC thus comprise a continuum of plasma cell dyscrasias with increasing neoplastic potential.

underlying isotype of the Ig heavy-chain (γ1–4, μ, α, ε, δ) and Ig light-chain (κ, λ). The concentration of the M-protein is then measured with a rate nephelometer. This results in an estimate of the size of the plasma cell clone, which is useful for disease monitoring. Nephelometry is also used to measure the serum level of free light-chain (FLC). Deviations from the normal FLC kappa to lambda ratio (0.26–1.65) are a strong indication of monoclonal plasma cell disorder including MGUS. Serum M-protein higher than15 g/L should lead to electrophoresis and immunofixation of a concentrated aliquot from a 24-h urine specimen.

Predictors of Progression from MGUS to MM

At the time of recognition of MGUS, one cannot distinguish a patient whose condition will remain stable from one in whom progression to a plasma cell malignancy, particularly MM, will occur. Parameters not predictive of progression include age and sex; hepatosplenomegaly; levels of hemoglobin, serum creatinine and serum albumin; presence, type and amount of urinary light chain; and reduction of uninvolved immunoglobulins. Parameters that can predict progression include the concentration of serum M-protein; the type of M-protein, with IgA and IgM carrying an increased risk of progression compared to IgG; the abundance of bone marrow plasma cells; and an abnormal serum FLC ratio. Even in individuals at high risk of progression, death from unrelated diseases is greater than death from plasma cell neoplasia.

Distinguishing MGUS, SMM, and MM

Differentiating MGUS from MM can be difficult at initial presentation. It requires a complete blood count and radiographic bone survey as well as serum creatinine and calcium. A bone marrow aspirate and biopsy are indicated if the M-protein is higher than 15 g/L and the MGUS clone expresses IgA or IgM. Abnormal FLC ratio, radiographic bone survey and lab parameters are additional indications. The diagnosis of SMM is considered to be present in patients that do not have anemia, renal insufficiency, hypercalcemia or lytic bone lesions, but exhibit serum M-protein levels higher than 30 g/L and/or bone marrow plasma cell contents exceeding 10%. Elevated numbers of plasma cells undergoing cell division (plasma cell labeling index) and occurrence of plasma cells in the peripheral blood are also indicative of MM versus MGUS/SMM.

MGUS Variants

- IgM MGUS: Occurs in approximately 20% of patients with MGUS and deserves special attention because of IgM-related autoimmune disorders
- Biclonal gammopathies: Characterized by the presence of two different M-proteins; occurs in 2–6% of patients with monoclonal gammopathies including MGUS; rare cases of triclonal gammopathies have also been reported
- Idiopathic Bence Jones proteinuria: Urinary excretion of sometimes large amounts of monoclonal immunoglobulin light chain (Bence Jones protein) in the absence of "end-organ" damage, particularly kidney damage; rare, because Bence Jones proteinuria is usually associated with B cell and plasma cell neoplasms
- IgD MGUS: Almost always indicates MM, amyloidosis, or plasma cell leukemia; nonetheless, 6–8 year follow-ups in rare patients for without evidence of progression to malignancy have been reported

Association of MGUS with Other Diseases

- Lymphoproliferative disorders, such as Waldenström's macroglobulinemia, chronic lymphocytic leukemia/small lymphocytic lymphoma and marginal zone lymphoma; rarely in cases of leukemia, such as acute leukemia, hairy cell leukemia and T cell and chronic myelocytic leukemias
- Other hematological diseases including acquired von Willebrand's disease, pernicious anemia, refractory anemia, polycythemia vera, idiopathic myelofibrosis and Gaucher's disease
- Connective tissue disorders, such as rheumatoid arthritis, lupus erythematosis, scleroderma, polymyositis and ankylosing spondylitis
- Neurological disorders, particularly IgM MGUS neuropathy, in which the M-protein exhibits binding activity to myelin-associated glycoprotein (MAG).
- Motor neuron and other neurological diseases including amyotrophic lateral sclerosis and spinal muscular atrophy
- Rare dermatological diseases, such as *lichen myxedematosus*, *pyoderma gangrenosum*, necrobiotic xanthogranuloma; Schnitzler syndrome (chronic urticaria plus IgM monoclonal gammopathy)
- Liver disease associated with hepatitis C virus (HCV)
- Immunosuppression, frequently after transplantation
- Miscellaneous conditions; e.g., acquired angioedema, systemic capillary leak syndrome and idiopathic focal and segmental glomerulosclerosis

Antibody Activity of Mig and Associated Diseases

M-proteins, particularly IgM, can exhibit immunologic specificity (antibody activity) to certain self antigens and/or foreign antigens, possibly leading to full blown autoimmune disorders, such as chronic cold agglutinin disease, type II mixed cryoglobulinemia, and peripheral neuropathy. The self/foreign antigens implicated in these disorders are I/i red cell antigens/bacterial lipopolysaccharides, IgG Fc/hepatitis C virus, and neural carbohydrates/bacterial lipopolysaccharides, respectively. M-proteins with specificity for actin, von Willebrand's factor, thyroglobulin, insulin,

riboflavin, dextran, antistreptolysin-O, double-stranded DNA, apolipoprotein, thyroxin, lactate dehydrogenase, and several antibiotics have also been detected in rare cases.

Aggregation and Deposition of Mig and Associated Diseases

Independent of their immunologic specificity but dependent upon their concentration and physicochemical properties, M-proteins can become insoluble in the aqueous phase (serum, urine), resulting in homotypic aggregation (precipitation) and formation of a variety of amorphous (crystals) or structured (fibrils) protein deposits in various tissue sites. Diseases associated with protein depositions of this sort include AL amyloidosis, light chain-deposition disease, light chain-cast nephropathy, adult Fanconi syndrome due to crystal storing histiocytosis, and cryoglobulinemia type I.

Management of MGUS

Although patients with MGUS do not require treatment, they do need indefinite follow-up. Serum M-protein electrophoresis should be repeated 6 months after initial presentation and, if stable, annually thereafter. Low-risk MGUS (serum M-protein <15 g/L; IgG subtype; normal FLC ratio) can be followed less frequently. MGUS with increased risk for malignant conversion to MM (M-protein ≥15 g/L; non-IgG subtype; abnormal FLC ratio) should prompt a bone marrow examination and radiographic bone survey. Determination of the plasma cell labeling index, search for circulating plasma cells in the peripheral blood, and cytogenetic studies should also be done in these cases. Patients in the high-risk group should also be encouraged to participate in clinical trials of chemo-preventive agents, such as dehydroepiandrosterone (DHEA), biphosphonates and celecoxib, that may slow or abrogate the MGUS-to-MM progression.

Monocyte

Definition

A large phagocytic white blood cell which, when it enters tissue, develops into a ►macrophage.

►Macrophages

Monogenic

Definition

A mode of inheritance characterized by familial segregation of the phenotype. It is due to the segregation of susceptibility/resistance alleles at one gene.

►Modifier Loci

Monokines

Definition

Powerful biomolecules secreted by ►monocytes and ►macrophages. These soluble molecules help direct and regulate the immune responses.

Monolayer Culture

Definition

Culture of cells in one cell thick sheets, usually in multiwell plates, Petri dishes or culture flasks, on flat surfaces coated with substances to promote cell attachment. Their advantage lies in high-throughput and the ability to grow cells from xenograft and patient tumors. They do not however incorporate the tumor cell microenvironment or tumor physiology.

►Three-Dimensional Tissue Cultures

Monomeric GTPases

Definition

Are a large superfamily of GTP-binding proteins that function in various cellular processes such as growth control (►Ras family members), organization of the cytoskeleton (►Rho family proteins), or intracellular transport between different compartments of the cell (Rab, ARF, Sar1, or Ran family members). Analogous

to the heterotrimeric ►G-proteins, they function as molecular switches by cycling between a GDP- and a GTP-bound state.

►G-Proteins

Mononeuropathy

Definition

Malfunction of a single peripheral nerve.

►Peripheral Neuropathy

Monosomy

Definition

A form of aneuploidy with the presence of only one chromosome (instead of the typical two in humans) from a pair.

►Gastrointestinal Stromal Tumor

Monoubiquitination

Definition

Addition of a single ubiquitin moiety to a protein.

►Ubiquitination

Morpheaform

Definition

Refers to ►basal cell carcinoma (BCC);Is an insidious tumor possessing innocuous surface characteristics that can mask its potential for deep, wide extension. The tumor is waxy, firm, flat-to-slightly raised, either pale white or yellowish, and resembles localized scleroderma, thus the designation morpheaform. Localization of this tumor by inspection or biopsy is impossible. The average subclinical extension beyond clinically delineated borders was 7.2 mm in one study. Treatment consists of wide excision or, preferably, ►Mohs micrographic surgery.

Morphogenesis

Definition

Is the development of body shape and organization during the embryonic development of an organism. It refers to a process in which cells organize into well defined three-dimensional structures that resemble the tissue of origin. For example, scatter factor has been shown to induce kidney epithelial cells (MDCK) to organize into renal tubular-like structures, breast epithelial cells to organize into mammary duct-like structures, lung epithelium to organize into alveolar-like structures, and microvessel endothelial cells to organize into capillary-like tubes. Apparently, scatter factor, acting through the c-Met receptor, activates a cell type-specific program of differentiation.

►Scatter Factor

Morphogenic Differentiation

Definition

The process in which cells convert from a less specialized structure to a more specialized structure. For example, individual cells aggregating to form a fluid filled lumen. Often, this involves significant cell movement, complex interactions to regulate cell proliferation and ►apoptosis, significant remodeling of the cytoskeleton, and differentiation into more specialized cell types.

►MET

Morphological Cell Transformation

Definition

The process by which carcinogenic chemicals, oncogenic viruses, or radiations, change the genotype and phenotype of the cell, such that the cells' morphology or

shape is changed, and the cells grow and pile up on top of one another, leading to the formation of foci.

►Chemically Induced Cell Transformation

Mortality Stage

Definition

Immortalization is the consequence of the inactivation or bypass of two mortality stage mechanisms, M1 and M2. Abrogation of M1 controls can be obtained through the activity of DNA tumor virus genes such as early genes E6 and E7 of human papillomavirus 16 (HPV16). In human fibroblast, retinoblastoma (Rb) and p53 proteins may be key factors regulating the mortality stage 1 mechanism. On the other hand, the inactivation of a second event, M2, was required to achieve immortalization by telomere stabilization due to telomerase activation or ALT.

►Early Genes of Human Papillomaviruses
►Human Papillomaviruses
►Stem Cell Telomeres

Mosaic

Definition

Mosaic tissue is composed of patches of cells from at least two sources, e.g. two sources of normal cells or a source of tumor and a source of normal cells, which, if part of the mouse skin, might result in striped or patchy patterns.

►Stromagenesis

Mosaic Vessels

Definition

Is another microcirculation pattern in tumors and the wall of mosaic blood vessels contains both tumor cells and endothelial cells. It may be a transition between Vasculogenic mimicry (VM) and endothelium-dependent vessels.

►Vasculogenic Mimicry

Mother Against Decapentaplegic, Drosophila, Homolog of 4

►Deleted in Pancreatic Carcinoma Locus 4

Motif

Definition

A distinctive sequence of residues (nucleotides or amino acids).

►Chromosomal Translocations

Motility

Cheng-Long Huang
Department of Second Surgery, Kagawa University, Kagawa, Japan

Synonyms

Cell movement; Chemotaxis; Chemokinesis

Definition

Motility is a cellular function that leads to the translocation of the cell body through a coordinated sequence of distinct biological processes, including membrane protrusion at a leading edge, the formation of cell-substrate adhesion, the development of contractile force in the cell body, and detachment at the tail of the cell.

Characteristics

Cell motility is a critical feature of various physiological and pathological processes, such as development, wound healing, immunity, ►angiogenesis, ►invasion, and ►metastasis. It includes chemokinesis

(non-directional movement) and chemotaxis (directional movement). Cell motility is generally triggered by extracellular stimuli such as gradients of chemotactic factors. In the presence of chemoattractants, extracellular signals are transduced through cell-surface receptors which thus induce various intracellular responses, such as polarization and the reorganization of the actin cytoskeleton.

Cell motility has multiple processes: (i) membrane protrusion at the leading edge (filopodia and lamellipodia) (Fig. 1), (ii) ►adhesion of the protrusion to the substrate (focal complexes followed by focal adhesions), (iii) the development of contractile force (stress fibers and actin-myosin filaments) (Fig. 1), (iv) de-adhesion at the tail of the cell (rear detachment) and contraction causing a tail retraction toward the leading lamella.

Cell motility can be evaluated by various assays in experimental studies using cell lines. A gold colloid method can be used to evaluate chemokinesis. Transwell plates (Boyden Chamber method) can evaluate chemotaxis of cell penetration through the micropore membrane in such experiments; the membrane is uncoated in motility assays, with the membrane coated by matrigel in invasion assays. A wound healing assay evaluates the restoration rate of the monolayer of cultured cells after they are scratched by tips. Fluorescence imaging using green fluorescent protein (GFP) is a useful modality to elucidate the actin remodeling and focal adhesion dynamics in live cells.

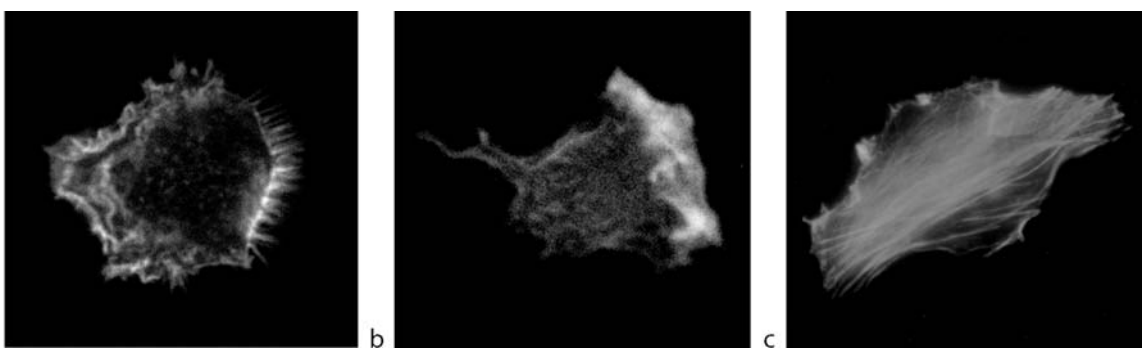
Mechanisms

The reorganization of the actin cytoskeleton and cell-substrate adhesion and de-adhesion are involved in the multiple processes of cell motility. Therefore, many molecules, including signaling molecules (►Signal Transduction), actin binding proteins, and ►cell adhesion molecules, thus play a role in cell motility.

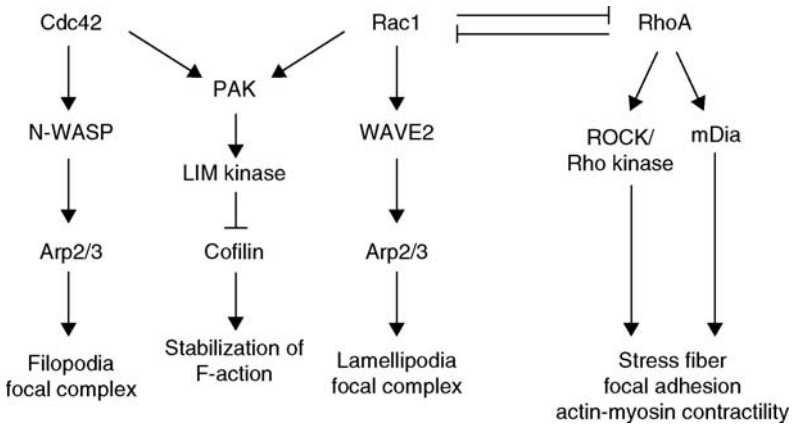
Cell motility is generally triggered by extracellular stimuli, and ►PI3K signaling plays a central role in the amplification of internal signaling asymmetry, thus helping to establish cell polarity and define the leading edge of the cells. PI3K activation in response to chemoattractants leads to the accumulation of phosphatidylinositol 3,4,5 triphosphate (PIP_3) which stimulates the ►Rho family proteins, such as Cdc42 and Rac1, and thereby inducing the formation of a leading edge.

Cell motility requires a cycle of actin polymerization and depolymerization (reorganization of actin filaments). The cytoskeleton of fibrous actin (F-actin) is formed by globular actin (G-actin), through the dynamic reorganization of actin filaments. Regarding the reorganization of actin filaments, important downstream targets of Rho family proteins are actin-related protein (Arp) 2/3 complex and actin depolymerizing factor (ADF)/cofilin (Fig. 2).

The Arp2/3 complex is composed of two Arps (Arp2 and Arp3) which act as templates for new actin filaments, and five additional subunits called ARPC1–5. The principal function of the Arp2/3 complex is to create branch points by nucleating the assembly of actin filaments near the leading edge. The activation of the Arp2/3 complex is governed by the Rho family and the Wiscott-Aldrich syndrome protein (WASP) family. Among the Rho family, Cdc42, Rac1 and RhoA play important roles in the reorganization of the actin networks. Through the activation of members of the Rho family, the WASP family can activate the Arp2/3 complex. Subsequently, the activated Arp2/3 complex can nucleate the assembly of new actin filaments, while also assembling a daughter filament at an angle of 70° to the mother filaments. As a consequence, Arp2/3 is localized at branch points in the cortical filament network, binding the pointed end of a new daughter filament to the mother filament thus leaving the barbed (growing) end available for filament elongation. This Arp2/3 complex activation is thus considered to play a critical role in the rapid formation of the actin networks at the leading edge.



Motility. Figure 1 Actin filaments in a human fibrosarcoma cell line HT1080. (a) filopodia, (b) lamellipodia, (c) stress fibers.



Motility. Figure 2 Signal pathways associated with cell motility.

The WASP family proteins, including the WASP subfamily and the WAVE/Scar subfamily, are physiological activators of the Arp2/3 complex. The WASP family proteins have a common C-terminal VCA domain (Verprolin-homology, cofilin-homology and acidic) which is responsible for the Arp2/3 complex activation. Among the WASP family members, neural-WASP (N-WASP) and WAVE2/Scar2 are widely expressed. N-WASP plays a key role in the formation of filopodia and microspike, composed of straight-bundled actin filaments. Cdc42 controls the extension of filopodia through the activation of N-WASP. In contrast, WAVE2 plays a key role in the formation of lamellipodia (membrane ruffle), branched actin filament networks. Rac1 regulates the formation of lamellipodia through the activation of WAVE2. Unlike Cdc42 and Rac1, RhoA regulates the assembly of stress fibers and actin-myosin filaments. The targets of RhoA include ROCK/Rho kinase and mDia. RhoA regulates myosin-mediated contractility through these downstream effectors. Therefore, during directional cell movement, Cdc42 and Rac1 stimulate formation of protrusions at the leading edge, and RhoA induces a retraction at the tail end of the cells.

ADF/cofilin is also involved in the reorganization of actin filaments. Cofilin increases the rate of depolymerization of the actin filaments by interacting with both G-actin and F-actin. In addition, cofilin can also increase the number of free barbed ends by severing the actin filaments and thereby increasing the rate of actin polymerization. The cofilin's actin binding and severing activities are regulated by its phosphorylation. The stimulation of cofilin's activities requires dephosphorylation of cofilin. In contrast, the inhibition of cofilin's activity requires its phosphorylation by activated LIM-kinase. The activation of LIM-kinase occurs through the stimulation of PI3K-induced activated Cdc42 and activated Rac1, which activate PAK (p21-activated kinase). PAK in turn phosphorylates LIM-kinase thereby activating it.

Regarding cell-substrate adhesion, focal contacts are the main adhesive structures connecting the cell with the extracellular matrix (ECM). Focal contacts have several stages of development such as focal complexes and focal adhesions. Focal complexes are usually formed at the surface of filopodia and lamellipodia. RhoA changes focal complexes into mature focal adhesions. They consist of two components: (i) transmembrane component made by clusters of integrins linked to ECM and (ii) submembranous component made by a complex of specific proteins such as vinculin, talin, and focal adhesion kinase (FAK), which is linked to the ends of actin microfilaments. Integrins are transmembrane receptors that function as heterodimers, thus consisting of distinct α and β subunits which are linked to form binding sites for specific ECM components such as fibronectin and laminin. The integrin-linked focal adhesions not only support cell adhesion to ECM but also transmit extracellular signals to intracellular signal transduction pathways. As a result, the dynamic regulation of focal adhesion assembly and disassembly regulates integrin-dependent cell ►migration.

The actin-myosin contractility in the cell body is directly controlled by modulating the myosin light chain (MLC). The activation of myosin contractility is achieved by the action of MLC kinase and the opposite action of MLC phosphatase. The RhoA-mediated activation of downstream effectors such as ROCK/Rho kinase and mDia promote the polymerization of actin bundles and phosphorylation of MLC. The resulting actin-myosin contractile forces contribute to the formation of stress fibers and mature focal adhesions. Therefore, the RhoA-mediated actin-myosin contractile force promotes the locomotion of the cell body and the trailing edge.

The final stage of the cell motility involves the disruption of ECM-integrin interactions, cell-substrate

detachment, and tail retraction toward the leading lamella. The cell detachment also depends on the coordinated interaction of actin and actin-binding proteins, integrins, signaling molecules and effecter enzymes including proteases, kinases, and phosphatase. However, its mechanisms are still not well understood.

Clinical Aspects

Metastasis is a critical biological behavior of cancer. The metastatic spread of a primary tumor to distant organs involves a series of predicable processes; (i) tumor cell detachment from the primary tumor, (ii) migration and invasion through the basement membranes of blood and lymph vessels, (iii) embolization, arrest and binding to vascular endothelium at secondary organs, and (iv) extravasion, and invasion to the secondary organ. During these processes, cell motility is an essential cellular function. Clinical studies in human cancers have revealed that several molecules associated with cell motility affect tumor metastasis. For example, a reduced expression of integrin α3 is associated with a poor prognosis in lung cancer patients. In addition, tetraspanins, also known as transmembrane 4 superfamily (TM4SF), are glycoproteins which have been shown to form functional complexes with integrins (tetraspan network). Among the members of tetraspanins, motility related protein-1 (MRP-1/CD9) and KAI1/CD82 (►KAI1/CD82 Metastasis Suppressor) suppress cell motility. Clinical studies among human cancers have demonstrated that a reduced expression of MRP-1/CD9 and KAI1/CD82 frequently occurs in human cancers and that such a reduced expression of MRP-1/CD9 and KAI1/CD82 is associated with tumor metastasis and a poor prognosis in cancer patients. As a result, these molecules play an important role as ►metastatic suppressor genes. Therefore, elucidating the regulation of motility in tumor cells would greatly help in the development of new treatment strategies for cancer patients (►Anti-Metastatic Therapies).

M

Definition

Mouse models of human cancer are mice that are used experimentally in a laboratory to understand genetic susceptibility to cancer, unravel the mechanisms of particular cancer pathways, aid in drug development, identify carcinogens, test chemopreventative and therapeutic agents, study the effect of environmental exposures on cancer risk, and understand tumor biology.

Characteristics

History

The use of mice to study cancer began in 1916 when Clarence Cook Little noted that different strains of inbred "fancy" mice had different susceptibilities to transplanted ►sarcomas. In 1928 at Cold Spring Harbor, Edwin Carleton MacDowell discovered that particular inbred strains of mice developed spontaneous leukemia. One year later, Little founded what is now known as the Jackson Laboratory for the purpose of developing pure inbred strains of mice to study biology and in particular, genetics. The breeding of mice to generate models for understanding cancer continues today, as does the Jackson Laboratory, but a wealth of sophisticated tools for manipulating and tracking genes and cancer cells using the mouse have since been developed.

Biological Relevance

Why are mice good models for human cancer? From comparative biology, it is clear that the pathology of many mouse tumors are similar to their human counterparts. Tumors in mice often begin as benign lesions, progress to an invasive stage and then may metastasize as in human cancer. Environmental factors that predispose humans to cancer including ►UV light, radiation, and ►tobacco smoke also induce cancers in mice. The same tumor suppressor genes and ►oncogenes that are important in human tumorigenesis such as ►*TP53*, ►*CMYC (MYC)*, ►*KRAS2* (RAS) and ►*PTEN* are mutated, amplified or activated in mouse tumors. There are some aspects of human tumorigenesis that are not mimicked in the mouse. For example, the size of telomeres is different between mice and humans, and the site of ►metastasis from a primary tumor varies between humans and mice. Nonetheless, mouse models have contributed greatly to the understanding of human cancer and the development of drugs for cancer therapy.

Genetically Engineered Mice

Genetically engineered mice, also known as transgenics and knock-out mice, are the work horse of mouse models. The use of GEM has led researchers to a better understanding of the mechanism of hundreds of cancer-related genes. GEM containing different genetic alterations can also be crossed to each other in order to understand the effects of perturbing both genes.

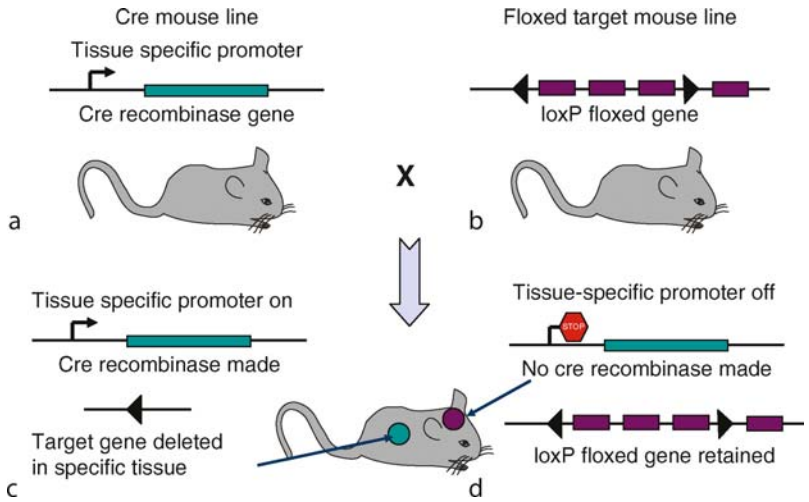
Transgenic Animals

The breakthrough in the use of mouse models to study cancer was the ability to introduce specific genetic alterations into target endogenous genes in mouse embryonic stem cells by homologous recombination. To do this, a transgene consisting of DNA of interest is injected into a newly fertilized mouse egg by pronuclear injection. Embryos carrying the inserted DNA are then implanted into females and the pups that are delivered are chimeric (carry the newly inserted sequence in some tissues but not others). Mice that have the transgene inserted into germline cells (cells that produce eggs or sperm) are bred to other mice. The resulting offspring carry the transgene in every cell of the body. Different types of mutations including null, point mutations, insertions, deletions or inversions can all be introduced into cancer genes in the mouse. Knock-out mice are those that have disruption of a target gene by insertion of a null allele. Knock-in mice are those that carry an insertion of a different form of a working target gene.

Conditional Transgenics

Since total disruption of many genes is lethal during mouse embryonic development, more sophisticated strategies for conditionally knocking-out genes have been developed. One added benefit of these conditional genetic alterations is that they more closely mimic sporadic human cancer since the gene perturbation is limited to a certain cell type or a certain phase in life. A commonly used strategy for creating conditional transgenic mice is the Cre/LoxP site-specific recombination system (Fig. 1). In this strategy, the target gene is flanked by loxP recombinase recognition sites in such a way that normal gene function is not altered in mice lacking Cre recombinase. When Cre recombinase is present, the sequence between the LoxP sites is deleted somatically. Cre expression can be driven by tissue or developmental specific promoters introduced by a second gene construct or by treating of the mice with hormones such as estrogen. Other systems that work in a similar manner include the Flp/FRT recombination system.

Two transgenic mouse lines are created. The first mouse line has the Cre recombinase gene driven by a tissue specific promoter. The second mouse line carries a construct with loxP recombination sites flanking the gene or exons to be deleted. The two lines of mice are crossed. In offspring, Cre recombinase will be expressed only in the specific tissues in which the



Mouse Models. Figure 1 Strategy for creating a tissue-specific knock-out mouse.

promoter driving cre is normally active. In those tissues the target gene will be deleted by recombination driven by Cre recombinase. All other tissues will retain a normal working copy of the target gene.

Inducible Systems

Alternative models for conditional-transgenic mice are inducible systems. These are transgenic systems in which the gene of interest is under the control of a promoter, such as the Tet promoter, and is expressed only in the presence of an antibiotic such as Doxycycline. Some inducible systems are "leaky" in that gene expression can occur in the absence of antibiotic.

Spontaneous Recombination

To more closely mimic the timing of mutations in oncogenes that occur in human tumorigenesis, a "hit and run" method of introducing oncogene mutations was developed. Transgenic mice carrying a non-activated form of an oncogene are created. After spontaneous recombination, the latent allele becomes active, and the cell in which this occurs becomes predisposed to cancer. This method leads to the creation of mice that develop activated mutations in oncogenes in somatic cells at a low frequency similar to the somatic rate of mutations that occur in humans.

Genetic Susceptibility

Inbred Strains

Inbred mice are mice in which sister and brother pairs have been mated together for many generations to produce mice that are genetically homogenous. Different inbred lines show large genetic and phenotypic differences. There are multiple inbred strains of mice used for the identification of cancer susceptibility genes due to large differences in predisposition to cancer. Some strains used for cancer susceptibility gene mapping include *FVB/NJ, C57Bl/6, 129/Sv, Cast/EiJ, Spret/EiJ, A/J, AKR/J, C3H,* and *Balb/C*.

Mapping of Susceptibility Genes

To map susceptibility genes, researchers create mice that have different combinations of genes from susceptible and resistant parents and grandparents. In brief, mice from strains that are susceptible to cancer are crossed to mice from strains that are resistant to cancer. The resulting F1 mice are a 50/50 mix of genes from susceptible and resistant strains of mice. F1 mice are then either crossed to other F1 mice (F2 intercross) or are crossed to one of the parental strains (F1 backcross). The resulting F2 or F1 backcross mice are phenotyped for cancer susceptibility and are genotyped for polymorphisms that exist between the strains of mice. Statistical correlations, called linkage or quantitative trait locus analysis, between phenotypes and genotypes are performed to identify genomic regions housing putative susceptibility or resistance genes. In addition to identification of single genes contributing to cancer susceptibility, mouse models allow the detection of genetic interactions, or specific combinations of genetic variants that determine cancer risk.

Congenics

Congenic lines are used to refine regions of linkage. Congenic mice are mice that carry a little bit of the chromosomal region housing a susceptibility gene and the rest of their DNA is from the resistant strain

of mice. To create congenic mice, susceptible F2 or F1 backcross mice that carry a particular susceptible locus are crossed to mice from the susceptible parental strain. Offspring are genotyped to determine which still carry DNA from the susceptible parent at the general region of interest. These mice are phenotyped to determine which are still susceptible to cancer. Mice carrying smaller pieces of the susceptibility region, due to recombination events in meiosis, and are still cancer prone are crossed back to the resistant parent until the locus is small enough to identify potential candidate genes.

Recombinant Inbred-Lines and Other Types of Inbred Mice

A variety of specialized inbred lines have been used for mapping cancer susceptibility genes. Recombinant inbred-lines are the result of using F2 sister/brother pairs from a mating between two different strains to establish a new set of inbred lines. A variation on classic recombinant inbred lines is recombinant congenic lines in which one parent contributes 1/8 of the genome and the other parent 7/8. Advanced intercross lines are those in which multiple generations of random mating precede interbreeding. Consomic lines are lines in which just one chromosome is replaced by a donor strain.

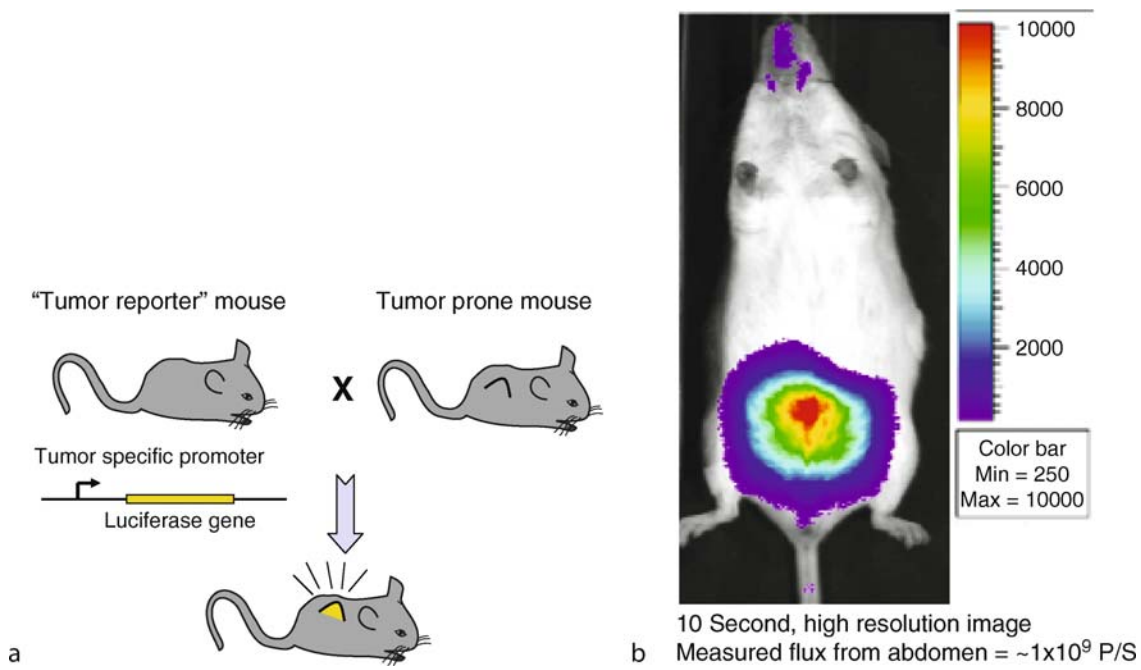
Outbred Strains

Outbred strains of mice are lines of mice which have not been bred to homogeneity. These mice retain a small number of polymorphisms which can contribute to phenotypic differences. The strength of using outbred strains for gene mapping is that the phenotypic differences and small genetic differences can be used to refine regions of linkage.

Therapeutics

Xenografts

A xenograft is the surgical transplantation of tissue from one species to another. Xenograft mouse models have been an integral part of the oncology drug discovery and development process. To make a xenograft for cancer studies, human tumor cell lines or tumor cells are injected into the flanks of nude mice. Since these mice lack a functioning immune response, most tumor cells are able to grow unchecked. Mice with tumors can be treated with potential therapeutic agents and the response of the cells or cell lines to the drugs monitored by assessing the change in tumor size.



Mouse Models. Figure 2 Bioluminescence Imaging of Tumors in Mice. (a) To create mice in which tumors can be studied and followed using bioluminescence, mice that are predisposed to developing tumors are crossed to transgenic mice that have a copy of the luciferase gene under the control of a tumor-specific promoter. The resulting offspring have tumors that can be visualized using detection systems. (Figure complements of Byron Hann). (b) A mouse predisposed to prostate cancer has been crossed to a mouse with the PSA (prostate specific antigen) promoter driving the luciferase gene. The mouse was treated with luciferin and anesthetized. The growth of the tumor can be followed over time. (Figure complements of Bryon Hann and Scott Lyon).

Several weaknesses of using xenographs for the study of human cancer have been identified; these include the inability to study premalignant states, the inability to study stromal interactions, and the lack of an intact immune response in the host animals.

Molecular Imaging

The use of the mouse for therapeutic development is enhanced by the recent ability to image tumors *in vivo*. *In vivo* molecular imaging allows researchers to continually monitor the size, growth and response rate of tumors to chemotherapeutic agents without sacrificing the mouse. Methods for imaging include magnetic resonance imaging (MRI), position emission tomographic imaging (PET) and fluorescence-based imaging with green fluorescent protein (GFP) tagged proteins or bioluminescence. Bioluminescence imaging utilizes mice that both carry a transgene with the firefly gene luciferase under a tumor-specific promoter and are tumor prone due to direct injection of tumor cells, treatment with carcinogens, or genetic causes (Fig. 2a). Following development of a tumor, these mice are injected with luciferin, a substrate for luciferase, and imaged (Fig. 2b). Imaging of the same mouse can be done on a repeated basis.

mRNA

Definition

Messenger RNA, the type of RNA that transports the genetic information coded in DNA residing in the nucleus to the cytoplasm where it is translated into protein.

mRNA Profiling

Definition

Corresponds to specific patterns of gene expression in a particular cell type of an organism, at a particular time, under particular conditions. DNA-based microarrays enable us to analyze the mRNA present in a tissue, and to quantify the levels of expression of tens of thousands of genes simultaneously in a single sample and to compare with the levels in normal control tissue. Changes in gene expression may underlie many biological phenomena, such as the tumoral process. These profiles can help to establish diagnosis and often correlate with different prognoses and different responses to therapy.

Definition

Mammalian target of rapamycin; Is a serine/threonine kinase of ~289 kDa, contains a catalytic kinase domain and a FKBP12-rapamycin binding (FRB) domain near the C-terminus. The C-terminus of mTOR shares strong homology to the catalytic domain of PI3K. mTOR is considered a member of the PIK-related kinase (PIKK) family, which includes MEC1, TEL1, DNA-PK, ATM, and ATR.

MTS1

►CDKN2A

MTT Assay

Definition

(3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) is a standard colorimetric assay for measuring cellular proliferation (e.g., cell growth). MTT is reduced to formazan by the mitochondria of living cells. It is used to determine drug cytotoxicity.

MUC1

Definition

Transmembrane glycoprotein tumor antigen that is overexpressed on cells of different tumors; can be found in large amounts in soluble form in serum and ►ascites fluid. MUC1 represents a target of human antitumor antibody and ►cytotoxic T-lymphocyte responses that are generated in the absence of ►helper T cells.

MUC1–20

Definitions

Mucins1–20.

Mucin

Definition

Large polymers of glycosylated proteins that participate in the physiological activity of the gastrointestinal tract. Often detected in glandular or adenocarcinoma tumor samples.

►Mucoepidermoid Cancer

Mucinous Cystadenocarcinoma

Definition

Type of Pancreas Cancer.

►Appendiceal Epithelial Neoplasms

Mucinous Neoplasms

Definition

Cancerous cells that produce mucus that may progress to develop gross mucinous ascites as part of the ►pseudomyxoma peritonei syndrome.

►Appendiceal Epithelial Neoplasms

Mucins

Eduardo Osinaga
Departamento de Inmunobiología, Facultad de Medicina, Universidad de la República, Montevideo, Uruguay

Definition

Mucins, a family of heavily glycosylated high-molecular-weight proteins built by tandemly arranged repeat domains, establish a selective molecular barrier at the epithelial surface. Alterations in mucin expression or in their ►glycosylation patterns influence cellular growth, differentiation, transformation, adhesion, invasion, and immune surveillance. Cancer-associated mucin antigens can be exploited for the diagnosis and prognosis, as well as for the development of cancer vaccines.

Characteristics
