In the cancer context 3D co-cultures are generally considered growth of cancer cells together with one or more normal cell types which are known to be associated with the cancer in vivo, in an attempt allow development of a more realistic ECM and to add another level of complexity to cell-cell and cell-ECM interactions. Cancer cells have been co-cultured as spheroids together with fibroblasts, macrophages and endothelial cells but have not been as well characterized or used as extensively as cancer cell only spheroids. Co-cultures of human tumor and stromal cells such as fibroblasts or endothelial cells are also possible as MCL, ►Multilayered Post-Confluent Cultures (MPCC) or through the use of microcarrier beads even if these co-cultures will not establish as spheroids.

Histocultures

►Histocultures (Ex vivo Culture or Excipient Culture) are *ca* 1 mm^3 fragments from tumors which are maintained on a collagen matrix for up to 2 weeks. They have the three dimensional multicellular structure and cellular heterogeneity of the original tumor and microenvironmental gradients such as hypoxia. Their advantage is that they contain human stromal cells and ECM in the appropriate proportion and geometrical

arrangement, and retain the true tissue composition and architecture when harvested from patient tumors. They are also thought to contain more cancer cell heterogeneity, such as polyclonal cancer cells, than the above 3D models which are initiated in tissue culture. Histocultures have been used mainly in experimental chemotherapy to investigate the relationship between the extravascular space, cell density and drug penetration and effect. Taxane distribution studies showed that re-arrangement of stromal tissues and interstitial space induced by apoptosis has a marked effect of drug penetration. Hence the delivery of protein-bound drugs may be enhanced, in a schedule dependent manner, by pretreating to induce apoptosis and reduce cell density. Histocultures have also been used in an attempt to individualize chemotherapy for patients in the histoculture response assay.

Organotypic Cultures

In ►organotypic cultures cells are grown in an extracellular matrix which provides the appropriate mechanical as well as chemical microenvironment. They often contain stromal cells as well as cancer cells and may represent the tumor microenvironment better than spheroids due to more typical and extensive ECM. Cells are seeded into medium containing collagen, ►matrigel or synthetic matrix in approximately the concentration found in vivo. The mixture solidifies and is incubated in culture inserts fed by growth medium from above, or from below through a porous membrane of pore size *ca* 8 μm. Stromal cells may be added to the culture or medium to provide additional complexity or diffusible signals. The mechanical properties of the culture may be accurately regulated by mixing matrigel and collagen type I in particular proportions to produce tissue of appropriate stiffness.

These conditions promote growth of a more heterogeneous and differentiated tumor cell population since the ECM and stromal cells are also of human origin. Typical patterns of tumor invasion have been seen in organotypic skin cultures when melanoma cells of different invasive phenotypes were added and in low and high (E-cadherin negative) grade squamous cell carcinomas. Normal mammary tissue will differentiate into acinar structures whereas mammary tumors retain their characteristic non-acinar appearance, and drug induced differentiation typical of that seen in tumors has been observed in ovarian cancer organotypic cultures but not in monolayer culture. Organotypic models of carcinogenesis are under development. At present these cultures are more difficult to use than spheroids for drug studies and this has lead to the use of collagen implanted spheroids as a compromise. Organotypic cultures do not contain elements such as functional vascular or lymphatic systems but cell interactions such as between vascular or lymphatic endothelium and cancer cells have been investigated, mainly in the context of tumor cell migration.

Organ Cultures and Tissue Engineering

Although histocultures may be considered the tumor equivalent of ►organ cultures (often also termed organotypic cultures) the term could also refer to functional 3D cultures which are grown in bioreactors. ►Tissue engineering refers to this process of growing tissues from the start in devices that provide the correct coupling of mechanical (stress, tension), functional (e.g. fluid flow) and chemical (through the cells and ECM components) signals necessary for cells to grow, differentiate and organize into a tissue or organ structure. This is usually achieved by porous artificial scaffolds, hollow fiber matrices or culture inserts modified to allow a constant pressure gradient to provide flow of culture medium. The technology has arisen for the dual purposes of producing human transplantable tissue and organ replacements and developing in vitro models for scientific study and therapeutic testing.

Most success has been obtained with skin, mammary and liver cultures but their use in cancer research is growing. Bioartificial liver tissue has been extensively investigated with the development of cocultures of hepatocytes, stromal cells and endothelium. Using a supporting extracellular matrix such as gelatin or collagen improves cell viability and channel formation induced by the application of a pressure gradient and medium flow, results in architecture similar to hepatic sinusoids which develop similar genotype and metabolism to that in vivo. Models of cancer liver metastasis have been grown in these liver cultures which also have the potential for toxicological drug testing.

Conclusions and Future Directions

Three dimensional culture studies have become a valuable adjunct to investigations in cancer biology and therapy, since these models are of intermediate complexity between tumor cells and xenografts. The use of established systems such as spheroids and histocultures and newly developed systems such as multicellular layers and organotypic cultures is likely to increase further due to recognition that signals from the cell microenvironment are important determinants of phenotype in a quantitative and dynamic fashion. Several experts consider these studies should be mandatory in the development of new cancer therapeutics. The use of multiple realistic in vitro models may also reduce the time and expense involved in preclinical testing. Advances in tissue engineering have brought increased interest in complex 3D tissue culture models for studying the tumor microenvironment. The National Cancer Institute is encouraging these investigations through its “Understanding and defining the role of the

tumor microenvironment" program, key elements of which are training in organotypic culture and promoting better understanding of signaling networks in the stroma and of the complex composition of the tumor ECM (http://plan2006.cancer.gov/biology.shtml).

Three-Stage Phenomenon

Definition

Vasculogenic mimicry (VM) channels, mosaic blood vessels and endothelium-dependent blood vessels participate in tumor blood supply. A three-stage phenomenon exists among them; that is all three patterns transit in tumor progression. During the early stages of transplanted melanoma, all three patterns are observed in tumor tissues, especially VM. As the tumor grows, more mosaic blood vessels and endothelium-dependent blood vessels are seen, and at the end endothelium-dependent blood vessels become the main blood supply pattern.

Thrombospondin

Xuefeng Zhang
Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, MA, USA

Definition

Thrombospondins (►TSPs, ►THBSs) are a family of multidomain, calcium-binding extracellular glycoproteins which are synthesized, secreted, and incorporated into the extracellular matrix of a variety of normal and transformed cells of both mesenchymal and epithelial origin.

Characteristics

Classification

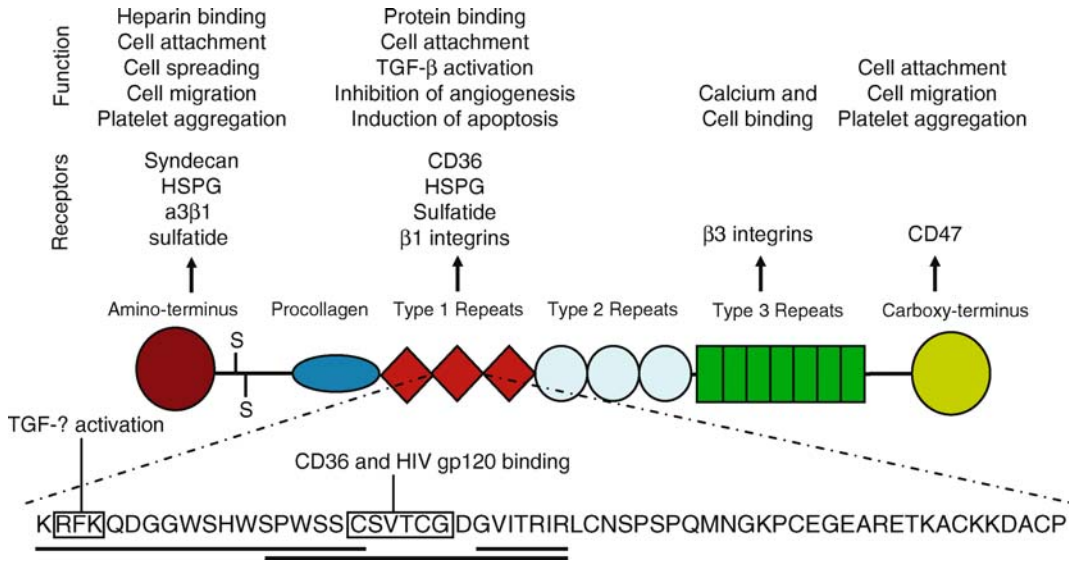
Five distinct forms of thrombospondin have been identified, TSP-1, -2, -3, -4, and -5 (cartilage oligomeric matrix protein, COMP). The TSPs fall into two subgroups, termed A and B, according to their oligomerization status and molecular architecture. Subgroup A includes TSP-1 and TSP-2, which form homotrimers. Subgroup B includes TSP-3, TSP-4 and TSP-5/COMP, which form homopentamers. All five members contain the type 2 repeats, the type 3 repeats and a highly conserved C-terminal domain. The type 2 repeats are similar to the epidermal growth factor repeats, the type 3 repeats comprise a contiguous set of calcium binding sites and the C-terminal domain is involved in cell binding. TSP-1 and -2 also contain three copies of the type 1 repeat (►TSR).

The prototypic member of the family is TSP-1, which has functions in platelet aggregation, inflammatory response and the regulation of ►angiogenesis during wound repair and tumor growth. The structure and functions of TSP-1 are summarized in Fig. 1. The amino sequence of TSR is shown, and the positions of peptides that inhibit angiogenesis are underlined] Many of these properties are shared by TSP-2. TSP-5/COMP (cartilage oligomeric matrix protein) regulates chondrocyte attachment, differentiation and cartilage ►extracellular matrix assembly. TSP-5/COMP has been found highly expressed within the tumor cells of hepatocellular carcinoma, but the pathophysiologic significance is not clear. Little is known about the biology of TSP-3 and TSP-4.

However, the clinical usage of TSP-1 is limited because TSP-1 is a large complicated molecule with numerous receptors and multiple biological functions. However, The anti-angiogenic domain of TSP-1, 3TSR, the three TSP-1 type I repeats, provides a promising alternative for clinical administration.

Previously, recombinant forms of human TSRs have been purified in our lab using a eukaryotic expression system, and showed strong anti-angiogenesis and anti-tumor efficacy in human melanoma and lung cancer xenografts. To date, the effect of TSP-1 and 3TSR on pancreatic cancer progression has not been reported.

Inhibition of angiogenesis by TSP-1 involves the inhibition of endothelial cell ►migration and induction of ►apoptosis. TSP-1 inhibits migration and induces apoptosis in microvessel endothelial cells and consequently inhibits angiogenesis. Besides its anti-angiogenesis efficacy, TSP-1 activates latent



Thrombospondin. Figure 1 Structure and functional domains of TSP-1. TSP-1 is the first naturally occurring anti-angiogenic factor described and a potent tumor inhibitor. The anti-angiogenesis and anti-tumor efficacy of TSP-1 has been well established in animal models.

►TGFβ by interacting with latency-associated peptide, and suppresses tumor cells that respond to TGFβ inhibition

TSP-1 and TSP-2 as inhibitors of tumor angiogenesis.

TSP-1 is the first naturally occurring angiogenic inhibitor to be discovered, and has been shown to play a critical role in inhibiting tumor angiogenesis, resulting in the inhibition of tumor growth and experimental ►metastasis. The suppression of angiogenesis by TSP-1 and -2 involves multiple mechanisms including direct interaction with vascular ►endothelial cell growth factor (VEGF), inhibition of ►matrix metalloproteinase 9 (MMP9) activation, inhibition of endothelial cell migration and induction of endothelial cell apoptosis.

Tumor angiogenesis is regulated by a dynamic balance between angiogenic stimulators and angiogenic inhibitors. The acquisition of an angiogenic phenotype by tumor cells involves the up-regulation of pro-angiogenic factors and the down regulation of endogenous inhibitors. Down-regulation of TSP-1 in tumor cells is a frequent step toward the acquisition of an angiogenic phenotype. In many tumors, down-regulation of TSP-1 accompanies activation of ►oncogenes or inactivation of ►tumor suppressor genes. ►Ras, ►Myc, ►Id1, ►src and ►Jun normally repress TSP-1 expression, and the increased activity of these genes shifts the balance in favor of angiogenesis. Similarly, tumor suppressor genes like ►p53, ►PTEN and ►Smad4 act to increase TSP-1 expression. Loss of their function again leads to a shift in the balance to favor the pro-angiogenic factors. Many gene alterations that lead to decreased TSP-1 expression also lead to increased expression of vascular endothelial growth factor (VEGF). For example, mutations in ras or p53 affect both sides of the angiogenic balance to facilitate the acquisition of a pro-angiogenic phenotype by tumors. In addition, tumor ►hypoxia may also inhibit TSP-1 and induce VEGF expression and thus promote the switch to an angiogenic phenotype.

During tumor progression, the host stromal response increases the level of TSPs. Stromal fibroblasts, endothelial cells and immune cells contribute significant levels of TSP-1 and -2 to the tumor microenvironment, especially at the tumor/stroma border, where TSPs serve as a matrix barrier to halt tumor angiogenesis and prevent tumor cell invasion and expansion. In some cases, tumor growth may be held in check by host TSP-1 and -2. However, genetic changes in tumor cells may eventually enable them to overcome the host defense and induce angiogenesis via further over-expressing angiogenic stimulators.

The roles of TSP-1 and -2 on the progression of spontaneous tumors have been demonstrated in TSP ►knockout mice. In the absence of TSP-1, more rapid tumor progression is observed in ►p53-deficient mice, in APC Min/+ (multiple intestinal neoplasia) mice and in mice that over-express the neu/erbB2 oncogene in mammary tissue. The survival of p53-null and p53-heterozygous mice is reduced in the absence of TSP-1. Genotyping of the tumors in the p53-heterozygotes reveals a higher level of loss-of-heterozygosity in the absence of TSP-1. These data suggest that loss of TSP-1

expression in tumor cells increases their genetic instability and hastens their progress toward life threatening malignancy. Tumor progression of skin cancers is also accelerated in TSP-2-null mice.

The importance of down-regulation of TSPs for tumor progression is further established by the fact that exogenous TSP-1 or -2 inhibits tumor growth. Multiple approaches are designed to systemically or locally increase the levels of TSP-1 or -2, including viral vector mediated or cell-based ►gene therapy, low dose chemotherapeutics and systemic delivery of recombinant proteins or synthetic peptides that include TSR sequences. The TSR domain has been identified as the antiangiogenic domain of thrombospondin, and provides a promising agent for cancer treatment. In general, TSP-based treatment slows tumor growth by inhibiting angiogenesis. Histological analysis revealed a significant decrease in tumor vessel number, vessel size, and ►tumor vessel density. Since the block of ►angiogenesis results in a decrease in tumor blood supply, tumors treated with TSP-1 show increased ►necrosis. The data presented to date indicate that TSP-based reagents are well tolerated and have very little toxicity. A TSR ►mimetic synthetic peptide derived from the GVITRIR sequence, designated ABT-510, is in phase II clinical trials for treatment of cancer. It is clear that therapeutic strategies that are designed to further increase TSP-1 and -2 levels hold great promise for the treatment of cancer. However, the efficacy of these reagents may not be sufficient to be used in single agent therapy, and they may have to be combined with other treatment modalities.

TSP-1 has been shown as an important mediator for some chemotherapeutic agents. A systemic increase in TSP-1 levels reportedly mediates the antiangiogenic and anti-tumor effect of antiangiogenic or metronomic chemotherapy, the frequent administration of low doses of chemotherapeutic drugs. The anti-tumor and anti-angiogenic efficacy of metronomic dosing with cyclophosphamide is associated with increased plasma levels of TSP-1, and is absent in TSP-1-null mice. ►Docetaxel has been reported to up-regulate TSP-1 expression levels in transformed cells. Decreased TSP-1 expression is also associated with tumor cell resistance to taxane-induced apoptosis, and treatment with TSP-1 or TSP-1 mimetic peptide sensitizes tumor cells to taxane cytotoxicity via the interaction of TSP-1 C-terminus and the CD47 receptor.

Mechanism

TSP-1 and -2 act at the interface between the cell surface and extracellular matrix to provide contextual cues that regulate matrix structure and cellular phenotype during tissue remodeling that is associated with inflammation, wound healing and neoplasia. They regulate matrix structure by directly binding to fibrilar components like collagens and fibronectin and by modulating extracellular proteases like ►MMPs and plasmin. The inhibition of angiogenesis by TSP-1 and -2 involves multiple mechanisms including direct interaction with VEGF, antagonizing VEGF-mediated survival signaling, inhibition of MMP9, inhibition of endothelial cell migration, and induction of endothelial cell apoptosis. Since the level of active MMP9 correlates with the amount of VEGF binding to VEGF receptor 2, TSP-1 inhibits VEGF mobilization and signaling by inhibiting active MMP9. In addition, TSP-1 can affect the synthesis of matrix proteins through its ability to activate ►transforming growth factor β1 (TGF-β1) via binding the latency-associated peptide (LAP) of TGF-β1. TSP-1 may also inhibit angiogenesis by decreasing the level of circulating endothelial cell progenitors.

TSP-1 exerts its antiangiogenic effects of on vascular endothelial cells via inhibiting endothelial cell migration and inducing endothelial cell apoptosis. The direct effects on endothelial cell function are reportedly mediated by the interaction of TSR with CD36. Studies with various knockout mice indicate that CD36, the ►Src family kinase, fyn, and c-Jun N-terminal kniase-1 are required for the induction of endothelial cell apoptosis by TSP-1. The CSVTCG sequence in TSR is reportedly the binding site for CD36, however, two other TSR derived peptides, WSHWSPW and GVITRIR, have also been shown to have antiangiogenic function (as shown in Fig. 1). Structural studies indicate that the TSRs fold so that the WSHWSPW and GVITRIR sequences contribute side chains to a single positively charged groove in the surface of TSR that represents the CD36 binding site. Interestingly, TSP-1 or peptides containing TSR sequences can also induce apoptosis of endothelial cells expressing little or no CD36, indicating CD36-independent mechanisms for the induction of endothelial cell apoptosis. The TSRs bind to β1 ►integrins and this interaction can inhibit endothelial cell migration. The interaction between TSRs and the complex of CD36 and β1 integrins results in decreased phosphorylation of VEGF receptor 2. These data suggest that the TSRs may engage a multi-protein complex to inhibit endothelial cell function. In the absence of CD36, β1 integrins may be sufficient to mediate the effects of TSP-1.

Caspase-3, ►Fas ligand and p38MAPK are also involved in the induction of apoptosis by TSP-1. TSP-1 up-regulates Fas ligand expression on endothelial cells, and thus promotes Fas/Fas ligand-mediated apoptosis in endothelial cells. In addition, increased expression of CD47 has also been reported to correlate with increased endothelial cell apoptosis. A peptide that contains the CD47 binding sequence of the C-terminal domain of TSP-1 has been reported to increase endothelial cell

apoptosis and inhibit angiogenesis. In addition to inducing apoptosis, TSP-1 down-regulates survival pathways. TSP-1 inhibits angiogenesis by decreasing expression of ►Bcl-2 and increasing expression of Bax.

Whereas the majority of data indicate that TSP-1 is a potent inhibitor of angiogenesis within the tumor microenvironment, TSP-1 is able to support angiogenesis in some experimental contexts. The pro-angiogenic effect seems to result from the ability of TSP-1 to stimulate recruitment and migration of smooth muscle and inflammatory cells that release pro-angiogenic factors. These divergent responses are probably due, at least in part, to differences in the repertoire of membrane receptors that are expressed by different cell types.

Synonyms

TP; Platelet-derived endothelial cell growth factor; PD-ECGF

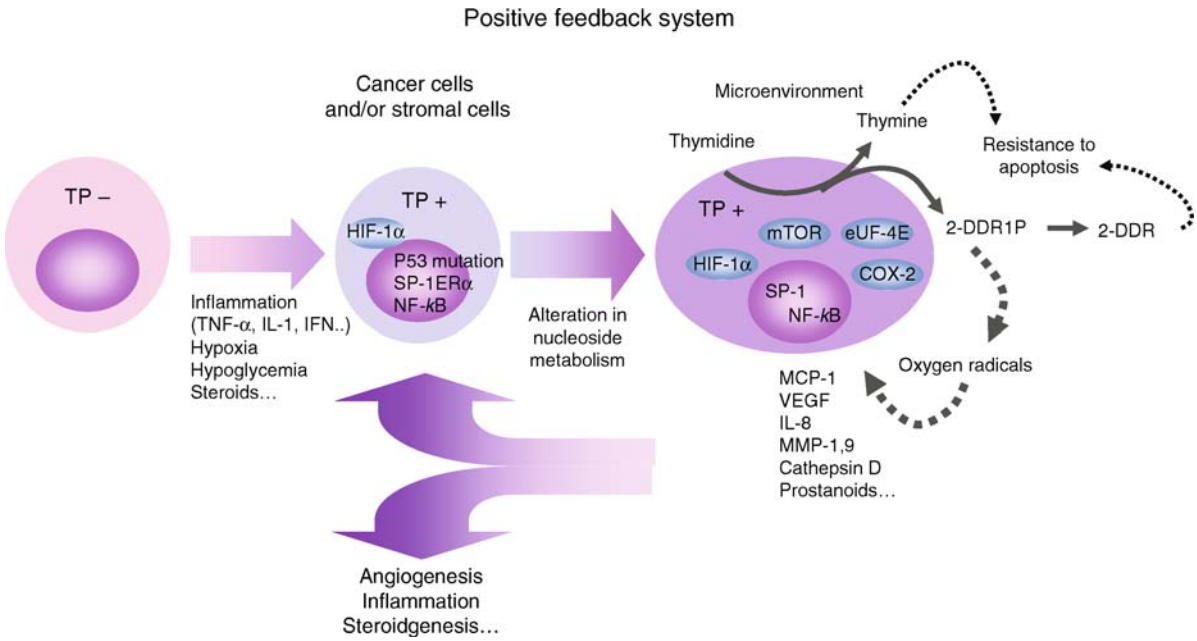
Definition

TP is a nucleoside metabolism enzyme involved in the maintenance of healthy mitochondria and balanced nucleoside triphosphate pool for DNA replication and repair. TP provides multiple cellular biological functions such as stimulation of angiogenesis and antiapoptosis.

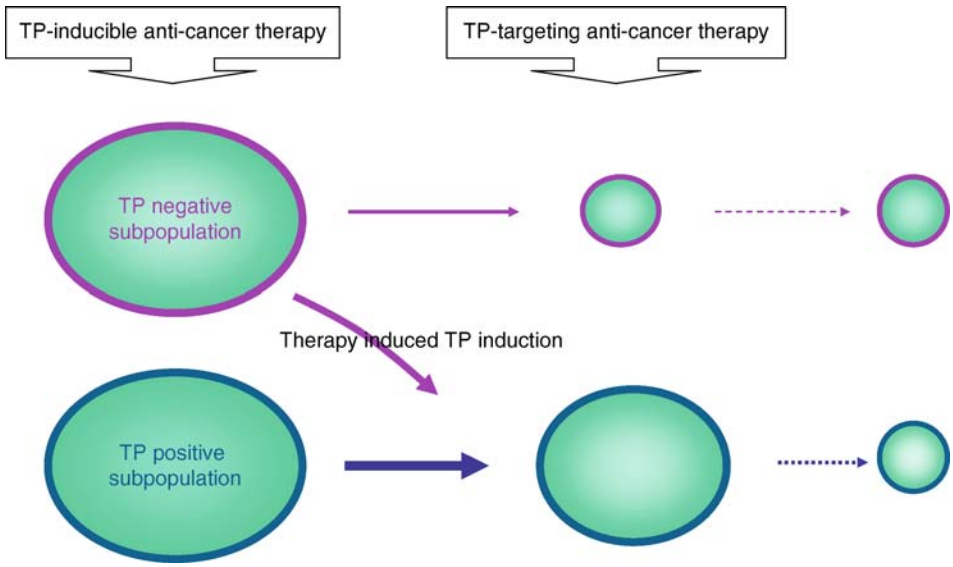
Characteristics

TP was purified in the mid-1970s from both *Escherichia coli* and *Salmonella* as a nucleoside metabolism enzyme; it is a homodimer of 45 kDa subunits. In the middle of the 1980s, a molecule exhibited angiogenic activity was extracted from human platelets and named PD-ECGF. Subsequently, it was discovered that 2-deoxy-D-ribose (2-DDR), a thymidine metabolite, stimulates chemotaxis of the endothelium and angiogenesis, then it was clarified that PD-ECGF had TP activity and these two molecules were the same. Somatic mitochondrial DNA point mutations with TP deficiencies result in mitochondrial neurogastrointestinal encephalomyopathy, with symptoms of gastrointestinal dysmotility, peripheral neuropathy, myopathy, and leukoencephalopathy, indicated that TP plays a role in maintaining mitochondria healthy. TP is induced by chemical and physiological stress such as inflammation and hypoxia. Although the transcriptional control of TP is still unclear, it is known that several cytokines such as tumor necrosis factor ►(TNF)-α, ►interleukin (IL)

►-1, and interferon ►(IFN)-δ are capable of upregulating TP expression in various types of cells including malignant cells. TP is often upregulated in human cancer tissues. Not only tumor cells but also stromal cells such as macrophages and fibroblastic cells possess TP expression. Tumors with overexpression of TP exhibit more angiogenic property as compared with those without TP expression. As to the angiogenic activity of TP, it is reported that TP and 2-DDR stimulated the formation of focal adhesions and tyrosine 397 phosphorylation of focal adhesion kinase (►FAK) and cell surface integrin-$\alpha_5\beta_1$ in human umbilical vein endothelial cells. TP-induced endothelial cell migration was inhibited by antibodies to either integrin-$\alpha_5\beta_1$ or -$\alpha_v\beta_3$, whereas ►vascular endothelial growth factor (VEGF)-induced endothelial cell migration was only blocked by the $\alpha_v\beta_3$ antibody, suggesting that TP and 2-DDR have different roles from VEGF in endothelial cell migration. In addition, a recent report showed that 2-DDR-induced endothelial cell migration and aortic ring formation were blocked completely by rapamycin, indicating that p70/S6 kinase activation is involved in 2-DDR-related endothelial stimulation. In various types of tumors including breast cancer, TP tends to coexpress with other angiogenic factors or cytokines and chemokines such as VEGF, TNF-α, interleukin (IL)-1, and ►macrophage chemoattractant protein (MCP)-1. It is hypothesized that a positive feedback mechanism may exist in tumor microenvironment promoting angiogenesis and chronic inflammation as shown in Fig. 1. In sense, TP-positive cancer stroma correlates with unfavorable prognosis, whereas TP-negative cancer stroma predicts favorable prognosis. In cancer tissues, TP is induced not only by cancer progression but also by anticancer treatments. Various types of anticancer agents such as taxanes, cyclophosphamide (CPA), and oxaliplatin (*l*-OHP) and irradiation are triggers of TP expression. An indirect pathway thorough the induction of inflammatory cytokines may be involved in the induction machinery, however, a direct pathway may also be possible because several chemotherapeutic drugs are known to activate transcriptional factors including ►Sp-1 directly. Therapy-induced TP upregulations are considered to be a prosurvival mechanism of the cells. It is evident that transfection of TP into cancer cells like KB cells renders the cells resistant to apoptosis caused by hypoxia. 2-DDR prevented hypoxia-induced apoptosis and 2-deoxy-*L*-ribose (2-DLR) abrogated the effects. TP also confers resistance to apoptosis induced by chemotherapy such as cisplatin. Therefore, TP functions as angiogenic and antiapoptotic enzyme. TP has been characterized as a therapeutic target in cancer therapy, because 5-FU and its derivatives are, more or less, TP-targeting treatments. In animal experiments using TP-transfected and TP-induced tumor xenografts, 5-FU, 5′-deoxy-5-fluorouridine (5′-DFUR) and capecitabine inhibited tumor growth potently compared with the control. Particularly, treatment with 5′-DFUR or capecitabine is more specific because their conversion to the active compound depends upon TP. Predictive factor research into the role of TP expression in cancer tissues for the clinical efficacy of 5-FU derivatives or 5-FU-containing treatments showed that these treatments were much more effective for TP-positive tumors than for



Thymidine Phosphorylase. Figure 1 A positive feedback system for thymidine phosphorylase upregulation.



Thymidine Phosphorylase. Figure 2 Many chemotherapeutic agents act as an inducer of TP. The addition pf TP-targeting therapy such as 5-FU and its derivatives to TP-inducible therapy would enhance the effect of the TP-inducible therapy by blocking protumor activity of TP-overexpressing cells. In sense, recent clinical trials confirmed that the combination of TP-inducible therapy and TP-targeting therapy achieved additive or synergistic effects on the antitumor effects and/or survival in various types of cancers like breast cancer and colorectal cancer.

TP-negative tumors. Since TP is upregulated by chemotherapy, a unique hypothesis has been raised that TP-targeting chemotherapy might enhance the activity of TP-inducible chemotherapy when it is combined (Fig. 2). Animal experiments data have shown that these combinations of TP-inducible chemotherapy such as taxanes and TP-targeting chemotherapy such as capecitabine often achieve additive or synergistic antitumor effects in various types of human cancer xenografts. Recent clinical trials confirmed that combination treatments between TP-inducible chemotherapy and capecitabine treatment provide favorable combination effects for response rates and time to progression and survival for metastatic cancer patients. For instance, a multicenter, randomized phase III study in metastatic breast cancer patients showed survival advantages by adding capecitabine to standard treatments. Other clinical trials for which the regimen contained TP-inducible chemotherapy, such as paclitaxel, *l*-OHP, *cis*-platinum, CPT-11, CPA, mitomycin C, and irradiation have been examined in the metastatic setting. Furthermore, a variety of combination treatments based upon these concepts are currently being tested for primary diseases as well. As to the possibility for TP inhibition, several agents have been tested preclinically. For example, 2-DLR, a stereoisomer of DDR, inhibited DDR's anti-apoptotic effects and suppressed the growth and metastasis of KB cells overexpressing TP transplanted into nude mice. Oral administration of DLR significantly reduced the number of metastatic nodules in the liver and suppressed angiogenesis and enhanced apoptosis in KB/TP metastatic nodules, which confirmed the importance of TP inhibition and indicated a new direction to control TP-induced protumor functions. In addition to the chemotherapy–chemotherapy combination, the combination of TP-targeting therapy and anti-VEGF therapy has been tested in clinical trials extensively. This strategy looks reasonable because TP and VEGF often coexpress in human tumor tissues. Simultaneous blockade of two different angiogenic pathways would provide some combination effects on tumor growth. The clinical trial results look promising to enhance the antitumor effect and to prolong survival.

Thymidine phosphorylase (TP) is upregulated by various stimuli such as inflammation, hypoxia, hypoglycemia, and steroids. Chemotherapeutic agents and irradiation are also capable of inducing TP. TP upregulation causes the subsequent induction of thymidine metabolites such as 2-DDR-1-phosphate and 2-DDR those are mediators to produce oxygen radicals and to stimulate endothelial chemotaxis, respectively. It is reasonably hypothesized that these reactions may continue chronically in a positive feedback system of the microenvironment.

Thymocytes

Definition

Are lymphoid cells found in the thymus. These consist mainly of developing ►T cells, although a few thymocytes have achieved functional maturity.

Thymoma

Cesar A. Moran
Department of Pathology, M D Anderson Cancer Center, Houston, TX, USA

Definition

An epithelial neoplasm derived from the thymic epithelium.

Characteristics

Thymomas are among the most common epithelial tumors of the thymic gland. The tumor may occur at any age, but it is very unusual for this neoplasm to occur in the pediatric age group. The tumor is most likely to occur in adult individuals of over 40 years of age. The most common anatomic site is in the anterior mediastinum. However, in rare instances, thymomas may also arise in the lung, pleura, and neck. Clinically, patients with thymomas may be completely asymptomatic, and their tumors may become apparent during a routine physical examination. Radiological studies will disclose the presence of an anterior mediastinal mass. On the other hand, thymomas may be associated with other medical conditions such as Myasthenia Gravis. In some series, myasthenia gravis has been associated with thymomas as high as 30–60% of the cases. Although myasthenia gravis is often associated with thymomas, a long and wide spectrum of medical conditions has also been associated with this neoplasm, including neuromuscular, hematologic, immune deficiency, collagen vascular, dermatologic, metabolic, and endocrine processes.

Diagnosis

The two most important parameters in the evaluation of thymomas are whether the tumor is encapsulated or invasive. If the tumor is invasive, pathological staging of the tumor needs to be determined by analyzing the extent of the invasion and/or whether the tumor is limited to the mediastinal region or involves structures such as the pleura, pericardium, lung or other extrathoracic areas. Although, from the histopathological point of view, the diagnosis of thymoma may not represent a challenge, there is very limited information that can be provided in a small biopsy. The same can be said for fine needle aspirate cytology in which one cannot determine the invasion or encapsulation of the tumor. Thus, final diagnosis is best provided after complete surgical resection of the tumor. Histologically, the tumor may not pose a problem in diagnosis, and the vast majority of neoplasms will show similar histopathological features, namely the presence of epithelial cells in a background of lymphocytes, which recapitulates to some extent the normal cellular composition of the thymic gland. The presence of lymphocytes in thymomas may vary, and, in some cases, there is a predominance of lymphocytes, while in other cases the lymphocytes are more inconspicuous. Thick fibrous bands composed of fibroconnective tissue separating the cellular proliferation are usually present giving the appearance of a nodular type of growth pattern. However, the essential component that must be evaluated with more detail is the tissue that is surrounding the tumor. In the great majority of tumors, there is a thick fibroconnective boundary, which is denominated “capsule.” If the tumor is confined within the boundaries of that capsule, then the tumor is diagnosed as encapsulated; in cases in which there is a breach of the capsule by the cellular proliferation, then the tumor is diagnosed as invasive. Although as stated above, the majority of tumors will display the characteristic histology, there is a group of tumors that may show unusual characteristics such as the presence of plasma cells, muscle cells, among others. In this setting, it is very important to be entirely familiar with these neoplasms in order to avoid an equivocal diagnosis. In terms of cytologic atypia and mitotic figures, thymomas do not display marked cellular atypia or increased mitotic activity. In some cases, areas of cystic degeneration, hemorrhage, or necrosis may be present, but it is still the cellular characteristics of the tumor and the presence of capsular integrity that are more significant in predicting outcome.

Thymoma. Table 1 Histological schemes proposed for the classification of thymomas

WHO	Traditional	Muller–Hermelink	Suster and Moran
Type A	Spindle cell	Medullary	Thymoma
Type AB	—	Mixed	Thymoma
Type B1	—	Predominantly cortical	Thymoma
Type B2	Lymphocyte rich	Cortical	Thymoma
Type B2	Lymphoepithelial	Cortical	Thymoma
Type B3	Epithelial rich	Well-differentiated carcinoma	Atypical thymoma

Classification

Over the years thymomas have been the subject of numerous classification systems, which have the goal of predicting their pathologic behavior. Unfortunately, none of the current schemes appears to provide an unequivocal proof regarding the behavior that these neoplasms may follow. Essentially, there is still no cytologic feature that will determine which tumors are more likely to behave aggressively. The most important parameter in the evaluation of the tumors remains the capsular integrity. It has been demonstrated that tumors that are invasive from the outset are more likely to follow an aggressive course, while those tumors that are encapsulated, are more likely to follow an indolent course. Thus, most of the classification schemes that have been presented derived from the need to provide clues as to the clinical course of the tumor. The most common schemes on the classification of thymomas are presented in Table 1.

Treatment and Prognosis

In cases of thymomas, surgical resection is the treatment of choice. However, if the determination is that the tumor is invasive or that the tumor is not completely resected, adjuvant radiation or chemotherapy may be indicated. In cases in which the tumor is large and involves important adjacent thoracic structures, the use of chemotherapy may be necessary prior to surgical resection. The prognosis of patients with thymomas depends largely on the determination of the tumor being invasive or encapsulated. Three main features should be considered in predicting prognosis in patients with thymomas: encapsulation, invasiveness, and resectability of the tumor at the time of diagnosis.

Thyroid Carcinogenesis

Hartmut M. Rabes
Institute of Pathology, University of Munich, Munich, Germany

Definition

Malignant transformation of thyroid follicle-lining epithelial cells and progression to a clinically manifest thyroid carcinoma. Thyrocytes, embryologically derived from the primitive pharynx, produce thyroid hormones and are thus involved in the regulation of metabolic pathways. Malignant transformation of these cells gives rise to various types of differentiated and undifferentiated thyroid carcinomas. In contrast, medullary carcinomas (5–15% of all thyroid carcinomas) originate from calcitonin-producing neural crest-derived C cells and form a separate entity.

Characteristics

The main groups of non-medullary epithelial thyroid carcinomas include

- Follicular carcinoma (<20% of all thyroid carcinomas), composed of closely packed follicles lined by cuboidal or columnar cells with dark-staining round nuclei and eosinophilic cytoplasm. Capsular and/or vascular invasion, missing in follicular adenoma, is crucial for diagnosis of follicular carcinoma. The tumor spreads via the blood stream, with metastasis preferentially to bone and lung, occasionally to brain and liver.
- Papillary carcinoma (>60% of all thyroid carcinomas), cytologically characterized by typical changes of nuclei with ground glass appearance, overlapping pattern, irregular shape with clefts, grooves and pseudo-inclusions. The main histological variants include
  - Typical papillary variant, classical pattern, showing arborized papillae with fibrovascular core, often containing calcified psammoma bodies
  - Follicular variant with irregularly shaped colloid-containing follicles, composed of cells typical for papillary carcinoma
  - Solid variant exhibiting closely packed cell clusters with the characteristic cytology of papillary carcinoma, separate by a thin fibrovascular stroma
  - Diffuse sclerozing variant containing large areas of fibrosis with small foci of cells typical of papillary carcinoma.

Multicentricity is common to papillary carcinoma. Lymphatic spread and metastasis formation in regional lymph nodes is frequent in all variants of papillary carcinoma.

- Undifferentiated anaplastic carcinoma (5–10%), composed of pleomorphic polygonal, round or spindle cells with mitotic figures, shows rapid growth and invasion and early metastasis to regional lymph nodes and to lungs. This type is more common in older individuals.

General Features

Thyroid carcinomas are the most common endocrine malignant tumors with a variable annual incidence in different parts of the world ranging from 5–100 per million, with females two to four times more often affected than males. The incidence of spontaneous tumors increases with age. Tumors are detected and diagnosed by palpation, ultrasound, thyroid scans and fine needle aspiration biopsy.

- Therapy involves surgery (total or near-total thyroidectomy, often combined with lymph node dissection) and, when distant metastasis of iodine-concentrating carcinomas has to be assumed, radioiodine ablation of disseminated metastatic cells. Metastases that do not take up radioiodine may be treated by surgery, external radiation or chemotherapy.
- Prognosis: Young patients have a more favorable prognosis than older persons, irrespective of the tumor type. Widely invasive follicular or undifferentiated anaplastic carcinomas have an adverse prognosis, particularly in males at older age. Anaplastic carcinomas are most aggressive with a mortality of more than 90%. In contrast, the mortality of patients suffering from papillary carcinomas is low; more than 90% have a 10-year survival. Papillary microcarcinomas may remain clinically undetected and are often found only at autopsy.
- Cases of familial thyroid carcinomas (about 3% of all thyroid carcinomas) indicate that hereditary genetic factors might play a role in thyroid carcinogenesis. However, linkage analyses did not reveal typical susceptibility genes. Instead, genetic heterogeneity in familial nonmedullary thyroid carcinomas is most probable.
- Environmental factors contribute to thyroid carcinogenesis. Iodine deficiency is a risk factor: In iodine deficient regions, particularly in mountain areas, an excess of follicular carcinomas is observed in

goiterous thyroid glands. High TSH production, because of the negative feedback regulation by a decreased thyroid hormone level due to iodine deprivation, may act as a continuous mitotic stimulus for thyrocytes and thus as a cofactor for thyroid carcinogenesis. Iodine supplementation in such areas reduces the risk of follicular carcinoma. However, high thyroid tumor incidence has been observed also in areas of high iodine (Hawaii, Iceland) where nutritional factors might interfere with iodine uptake and/or metabolism. It has been hypothesized that papillary carcinomas may be more frequent in iodine-rich areas. Upward trends of this tumor type, however, are observed in most affluent countries. The reasons are unknown.

Role of Ionizing Radiation

Ionizing radiation is an accepted risk factor for thyroid carcinogenesis. The thyroid gland is one of the most radiation sensitive organs of the body. External therapeutic radiation that had been administered in former years to head, neck or mediastinal regions of children suffering from tinea capitis, enlarged tonsils, adenoids or thymus, hemangioma or Hodgkin disease resulted, after a 10–30 years latency period, in an increased incidence of thyroid carcinomas. It was concluded from large epidemiological studies that the risk for thyroid carcinoma is significantly increased in children before an age of 15 years even after a thyroid dose as low as 0.1 Gy, with a linear dose/risk relation except for very high doses at which the cytocidal effect may be more pronounced than the transforming action. A mean excess relative risk of 7.7 per Gy thyroid dose has been calculated for children. A comparable risk has not been observed for adults after external radiation or after 131I treatment because of benign thyroid diseases or for diagnostic purpose.

Knowledge about correlations between radiation exposure and thyroid carcinogenesis has greatly been increased by studies on survivors of the atomic bomb explosions in Japan, or after the testing of nuclear weapons at Bikini with contamination of the Marshall Island, and, above all, by studies after the Chernobyl reactor accident. After the Chernobyl nuclear power plant explosion in April 1986, about 2 × 1018 Bq of radioiodine isotopes, besides other radioisotopes, were released to the environment. Children who lived in the most severely contaminated regions of Belarus, the Oblast Gomel in particular, received thyroid doses in the range of 0.15–4.7 Gy, in exceptional cases even 10 Gy and more. Thyroid doses in adults were lower by a factor of 3–5. After a latency period of about 4 years, thyroid cancer incidence increased steeply in exposed children, up to a factor of nearly 200 in the regions of largest radioactive fallout. Congruence of areas of radioiodine contamination and of elevated thyroid cancer incidence argues for radioiodine as an etiological factor.

Genetic Aberrations

Molecular studies on structural genetic aberrations did not disclose a characteristic tumor-specific pattern in sporadic thyroid carcinomas: Mutations of codons 12, 13 or 61 of H-, K- or N-►RAS are found in 20–30% of follicular adenomas and carcinomas. Obviously, a constitutive activation of the ras/raf signal transduction cascade as a consequence of these RAS mutations is an important molecular change at an early stage of follicular carcinogenesis. Connections to iodine deficiency or radiation exposure are not apparent. The prevalence of RAS mutations is lower in papillary carcinomas.

Mutations at codon 201 or 227 of the Gsa subunit of the ►GSP gene or ►TSH receptor mutations have been observed in hyperfunctioning thyroid adenomas. These mutations are almost completely missing in follicular or papillary carcinomas. Obviously, the ►TSH receptor-adenylate cyclase-protein kinase A pathway is not primarily affected in epithelial thyroid carcinomas. The prevalence of mutations of the tumor suppressor gene p53 (exons 5–8) is high in anaplastic thyroid carcinomas, but rarely found in other thyroid tumors. p53 mutational inactivation appears closely related to progression from a differentiated to an undifferentiated anaplastic, highly aggressive thyroid carcinoma.

►Loss of heterozygosity on a variety of chromosomes has been reported to be a common feature of follicular neoplasms, particularly carcinomas, suggesting loss of tumor suppressor genes during thyroid carcinogenesis. It is less frequently found in papillary carcinomas.

RET Gene Changes

Rearrangements of the ►receptor tyrosine kinase gene ►RET have been detected in about 17% of sporadic papillary thyroid carcinomas of adults, with very high geographic variation. In addition, another receptor tyrosine kinase gene, NTRK1, is rearranged in rare cases of this tumor type. In contrast to sporadic thyroid carcinomas, radiation-induced tumors of the thyroid show a more homogeneous pattern of molecular aberrations, as evident from analyses of post-Chernobyl papillary thyroid carcinomas: In more than 60%, rearrangements of the proto-oncogene RET were found. Oncogenic RET rearrangements are characterized by loss of the 5′ part of RET including exon 11 and replacement by part of a RET-fused gene. In the rearranged fusion gene, the RET tyrosine kinase domain remains intact at the 3′ end, while the RET transmembrane and extracellular domains, located upstream of the tyrosine kinase domain and essential for the stringent normal regulation of RET activity by

ligand-receptor complex interactions, are missing. They are replaced by 5′ regulatory subunits of the RET-fused genes. This leads to an unphysiological activation of the RET tyrosine kinase in thyrocytes which, under normal conditions, are devoid of this activity.

The preferential RET fusion partners in radiation-induced thyroid carcinomas are

- H4, a gene of yet unknown function, giving rise to H4/RET fusions (PTC1)
- ELE1, a transcriptional activator of the androgen receptor (ELE1/RET fusions, PTC3)

Both types of rearrangement are formed by a balanced reciprocal intrachromosomal paracentric inversion of RET at 10q11.2, ELE1 also at 10q11.2, or H4 at 10q21. Less frequently, RET rearrangements involve interchromosomal translocations, as found with the

- RIα gene, coding for the catalytic domain of cAMP-dependent protein kinase A, at 17q23, leading to RIα/RET fusions (PTC2)

or in the newly detected types of RET rearrangement with the fused genes located on chromosomes other than 10:

- GOLGA5, coding for golgin-84 located in the membrane of Golgi vesicles (GOLGA5/RET fusions, PTC5)
- HTIF1, a transcriptional activator of several nuclear receptors (HTIF1/RET fusions, PTC6)
- RFG7, a homologue of HTIF1 (RFG7/RET fusions, PTC7)
- RFG8 of a yet unknown function (RFG8/RET fusions, PTC8) on 18q21–22
- ELKS with unknown function, on 12p13.3 (ELKS/RET fusion)

It is common to all RET-fused genes detected so far that they are ubiquitously expressed and contain coiled-coil structures. Thus a unique type of fusion protein is formed in thyrocytes combining two characteristic peculiarities: the potential for dimerization and the tyrosine kinase domain. Dimerization of this fusion protein may lead to constitutive, RET-ligand-(GDNF)-independent activation of the RET tyrosine kinase, autophosphorylation and activation of signal transduction pathways not normally active in thyrocytes. The processes involved in the aberrant signal transduction which will finally end up in clonal expansion of the transformed cell(s) are not yet understood. However, the dominant thyroid tumor-inducing effect of the fusion genes has convincingly been demonstrated in H4/RET or ELE1/RET transgenic mice.

The balanced reciprocal translocation does not only cause dysregulation of RET tyrosine kinase by the RET-fused gene, but leads also to a reciprocal transcript with RET at the 5′ end and the RET-fused gene at the 3′ part of the fusion protein. The ensuing disturbance of the physiological function of the RET-fused genes may influence the mode of tumor development. For example, ELE1/RET rearrangements induce preferentially solid variants of papillary thyroid carcinomas, in contrast to H4/RET rearrangements that are related to classical papillary or follicular variants.

The relevance of RET rearrangement as a characteristic radiation effect in human thyroid tissue has recently been experimentally corroborated; radiation leads to the formation of H4/RET rearrangements in normal human thyroid tissue transplanted to ►SCID mice. Epidemiological studies revealed that patients who had undergone radiotherapy earlier in life disclosed more often RET rearrangements in papillary thyroid carcinomas than patients without radiation exposure. On the other side, epidemiological data are yet insufficient to conclude that the presence of RET rearrangement proves radiation as a causative factor in an individual papillary thyroid carcinoma.

Thyroid Follicle

Definition

A spherical structure filled with colloid, providing storage for the thyroid-hormone precursor ►thyroglobulin, and lined with a single layer of epithelial cells, the thyrocytes, displaying round nuclei with homogeneous chromatin.

►Follicular Thyroid Tumors

Thyroid Hormone Receptor Activator Molecule 1

►Amplified in Breast Cancer 1

Thyroid Hormone Receptors

Definition

THR; Molecules that receive a thyroid hormone and permits it to dock on the nuclear membrane of a cell. Belong to a family of nuclear receptors that function as hormone-activated ►transcription factors and act by modulating the expression of genes. THRs bind DNA in the absence of hormone, usually suppressing the transcription of genes. Hormone binding involves a conformational change in the receptor that lets it to activate transcription.

There are two THR genes THR alpha and THR beta.

Thyroid Lobectomy

Definition

Surgical removal of one half of the thyroid gland.

►Hurthle Cell Adenoma and Carcinoma

Thyroid Receptor Interacting Protein 6

Definition

TRIP6; Is a member of the ►zyxin family of proteins. Synonym ZRP1.

►Lipoma Preferred Partner

Thyroidectomy

Definition

Surgical removal of all the thyroid gland.

►Hurthle Cell Adenoma and Carcinoma
►Thyroid Carcinogenesis

Tiam1

Rainer Engers
Institute of Pathology, University Hospital Düsseldorf, Düsseldorf, Germany

Synonyms

T-lymphoma invasion and metastasis

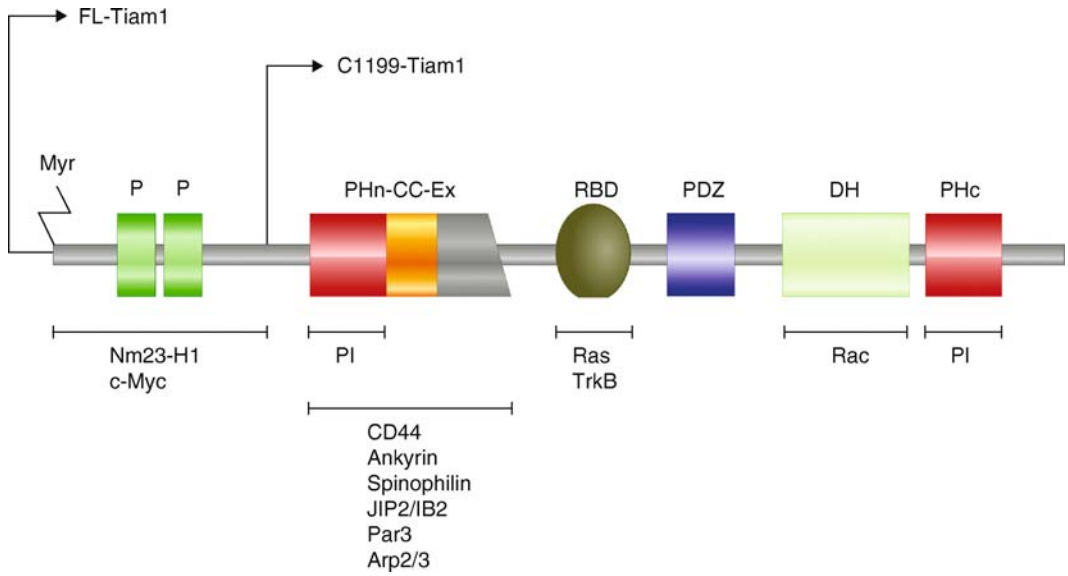
Definition

Tiam1 (T-lymphoma invasion and metastasis) has been identified as a specific activator of the Rho-like GTPase Rac (►Rho family proteins, ►GTPase) and is implicated in the regulation of different cell biological functions, including cell polarity, ►adhesion, ►migration, ►invasion, ►metastasis, and ►carcinogenesis. Tiam1 is a ubiquitously expressed protein of 1,591 amino acids and a predicted molecular mass of 177 kD. The human gene maps to chromosome 21.q22.1. Tiam2 or STEF is a Tiam1-related protein that has been identified in mammals but its expression is mostly restricted to neuronal cells. Still life (SIF) is the *Drosophila* homologue of Tiam1.

Characteristics

Tiam1 is an ubiquitously expressed protein with highest expression levels in brain, testis, and epidermis. It consists of 1,591 amino acids and harbors several distinct domains (Fig. 1). It is myristoylated at its N-terminus, contains two N-terminal PEST domains, an N-terminal pleckstrin homology domain (named PHn), a coiled-coil region with adjacent sequence (named CC-Ex), a Ras-binding domain (RBD), a PSD-95/DlgA/ZO-1 domain (PDZ) and a catalytic Dbl homology (DH)–PH (named PHc) combination. While the PHn–CC-Ex domain of Tiam1 is crucial for membrane localization of the protein, the DH–PHc combination is characteristic for all members of the Dbl-like family of guanine nucleotide exchange factors (GEFs). Accordingly, Tiam1 has been shown to exhibit specific GEF activity toward the Rho-like GTPase Rac in vivo, as reflected by the induction of Rac-mediated membrane ruffling (Fig. 2).

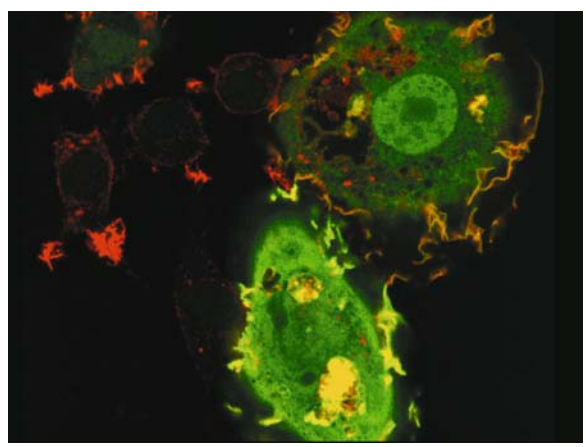
Although the function of Tiam1 as a specific activator of Rac is well-established, the specific regulation of its own activity is far from being fully understood. As was shown for other Dbl-like Rho-GEFs, Tiam1 is activated and translocated to the plasma membrane by N-terminal truncation (as in C1199-Tiam1), but the exact mechanism, underlying the N-terminal autoinhibitory effect of Tiam1 is not yet clear. In addition, Tiam1 may be activated and translocated to the plasma membrane upon stimulation of cells with lysophosphatidic acid (LPA) and ►platelet-derived growth factor (PDGF), and these effects



Tiam1. Figure 1 Domain structures of full-length (FL) Tiam1 and the active (C1199) form of the Tiam1 protein. Myr, myristoylation site; P, PEST sequence; PHn, N-terminal Pleckstrin homology domain; CC, coiled coil region; Ex, extended structure; RBD, Ras-binding domain; PDZ, PSD-95/DlgA/ZO-1 domain; DH, Dbl homology domain; PHc, C-terminal Pleckstrin homology domain. Proteins that have been reported to bind to Tiam1 are indicated below the structure. PI, phospho-inositides.

seem to be mediated by Ca^{2+}/calmodulin kinase II (CaMK-II)-induced threonine phosphorylation of Tiam1. Membrane translocation of Tiam1 is crucial for its capacity to activate Rac-mediated membrane ruffling and activation of c-Jun N-terminal kinase (►JNK subfamily and cancer). Phosphatidyl inositol (PI)3-kinase activity (►PI3K signaling) has often been implicated in the control of Tiam1-driven Rac activation, probably through its effect on membrane translocation of Tiam1. However, a PI3-kinase-independent Tiam1-Rac signaling pathway, stimulated by direct interaction of activated ►Ras with the RBD of Tiam1, has been identified as well. The role of Tiam1 in Ras-induced signaling seems to be complex. On the one hand Tiam1 is activated by active Ras and is required for Ras-induced tumorigenicity. On the other hand Tiam1 reverts Ras-induced ►epithelial-mesenchymal transition and this effect appears to be independent of the RBD of Tiam1. Thus, Tiam1 either potentiates Ras signaling through direct binding or counteracts Ras-induced effects via an independent signaling pathway.

Aside from activated Ras, a number of different cytoplasmic and membrane-associated proteins as well as distinct lipid components of cell membranes, called phospho-inositides, have been reported to bind directly to Tiam1. Of these, the hyaluronic acid receptor isoform ►$CD44_{v3}$ and its cytoskeletal binding partner ankyrin



Tiam1. Figure 2 Characteristic effects of activated Tiam1 (C1199-Tiam1) on cell morphology as determined by ►confocal laser scanning microscopy. BA-HAN-1C ►rhabdomyosarcoma cells of the rat were transiently transfected with C1199-Tiam1 cDNA. C1199-Tiam1 is shown as green fluorescence, F-actin as red fluorescence, and colocalization of both proteins is indicated by yellow fluorescence. While wild type cells (exclusively expressing a red fluorescence) are small and exhibit a round or spindle-shaped phenotype, C1199-Tiam1 transfected cells are much bigger and exhibit a pancake-like morphology as well as characteristic Rac-mediated membrane ruffles (yellow fluorescence).

provide a link between the extracellular matrix and Tiam1. The Par polarity protein Par3 as well as activated ►Rap1 couple Tiam1 to the Par polarity complex and hence to the formation of ►tight junctions and the establishment and maintenance of cell polarity. The Arp2/3 complex links Tiam1 to sites of actin polymerization such as epithelial cell–cell contacts and membrane ruffles. In addition, upon ligand binding the plasma membrane tyrosine kinase receptor TrkB binds and tyrosine-phosphorylates Tiam1, leading to Rac activation and changes in cellular morphology. Other Tiam1 binding partners such as the scaffold proteins JIP/islet brain (JIP/IB2) and spinophilin seem to determine the downstream specificity of Tiam1-induced Rac signaling. Spinophilin enhances Tiam1-induced, Rac-mediated p70 S6 kinase activity in a synergistic manner and at the expense of Tiam1-induced, Rac-mediated activation of p21-activated kinase. In contrast, JIP2/IB2 couples Tiam1-induced Rac signaling to p38 ►mitogen-activated protein kinase activity. Whereas $CD44_{v3}$, ankyrin, Par3, and the Arp2/3 complex bind to the PHn–CC-Ex domain of Tiam1, the metastasis suppressor ►Nm23-H1 and the oncogene c-Myc are suspected to bind to the N-terminus (Fig. 1). However, the biological relevance of the interaction of Nm23-H1 and c-Myc, respectively, with Tiam1 is not yet clear.

Biologically, Tiam1 is involved in the regulation of several cellular functions, including cell polarity, adhesion, migration, invasion, and metastasis. These effects, however, seem to be at least in part cell-type- and cell-substrate-specific. Originally, Tiam1 has been identified as a gene that confers an invasive and metastatic phenotype to otherwise noninvasive murine T-lymphoma cells. In contrast, Tiam1 inhibits migration and invasion of epithelial cells by promoting ►E-cadherin-mediated cell–cell adhesion and by shifting the balance between distinct invasion-promoting ►matrix metalloproteinases (MMP-2 and -9) and invasion-inhibiting ►tissue inhibitors of metalloproteinases (TIMP-1 and -2) toward the TIMPs. However, in other studies, Tiam1 promotes migration and invasion of epithelial cells, as shown for T47D, colon epithelial and Madin Darby canine kidney (MDCK) cells. These seemingly opposing effects of Tiam1 on migration and invasion of epithelial cells were reconciled at least in part by the observations that the effects of Tiam1 and Rac depend on the cell-substrate used, the fact as to whether or not the formation of E-cadherin-mediated cell–cell adhesions is prevented, the relative levels of activity of Rac and Rho, and the cell type studied. For instance, activation of Rac by Tiam1 promoted migration of MDCK cells on a collagen substrate but inhibited migration on a ►fibronectin or laminin (►Laminin signaling) substrate. Moreover, it has been shown that although Rac is required for the formation of E-cadherin-dependent cell–cell adhesions, activation of Rac may also lead to the disruption of these adhesions in a time- and concentration-dependent manner. Finally, Tiam1-induced cell–cell adhesion as well as the inhibitory effect of Tiam1 on cell ►motility was found to require Rac-mediated downregulation of Rho activity, as C1199-Tiam1 downregulated Rho activity and restoration of Rho activity in C1199-Tiam1-transfected cells resulted in a loss of cell–cell adhesion and stimulated cell motility. Nevertheless the maintenance of C1199-Tiam1-induced epithelial-like phenotype in fibroblasts requires at least a basal Rho activity. The mechanism by which Tiam1/Rac antagonizes Rho involves Rac-mediated production of reactive oxygen species that inhibit the low-molecular-weight protein tyrosine phosphatase, resulting in phosphorylation and activation of p190Rho-GAP, a negative regulator of Rho activity.

Aside from these functions in adhesion, migration and invasion, Tiam1 has also been implicated in the development of tumors. For instance, Tiam1 and its effector Rac were shown to be essential for Ras-induced transformation of fibroblasts in vitro. This is underscored by the fact that Tiam1 knock-out mice were proven to be resistant to Ras-induced skin tumors, due to increased ►apoptosis in the basal layer of the epidermis. From this one might speculate that the role of Tiam1 in tumorigenicity is restricted to its function as a mediator of oncogenic Ras signaling. This, however, is not the case, as Tiam1 was also shown to be a Wnt-responsive gene, which is required for the development of intestinal tumors, induced by aberrant ►Wnt signaling. Another mechanism through which Tiam1 may contribute to tumorigenicity is the occurrence of activating Tiam1 mutations. For example, a distinct Tiam1 mutation, located in the PHn domain, has been found in human renal cell carcinomas (►Renal carcinoma) and was shown to be sufficient to transform NIH3T3 fibroblasts in vitro. Recent studies also suggest a role for Tiam1 and Rac in the development and progression of ►prostate cancer, although the underlying mechanisms remain to be determined.

Tight Junction

Makoto Osanai
Department of Pathology, Sapporo Medical University School of Medicine, Sapporo, Japan

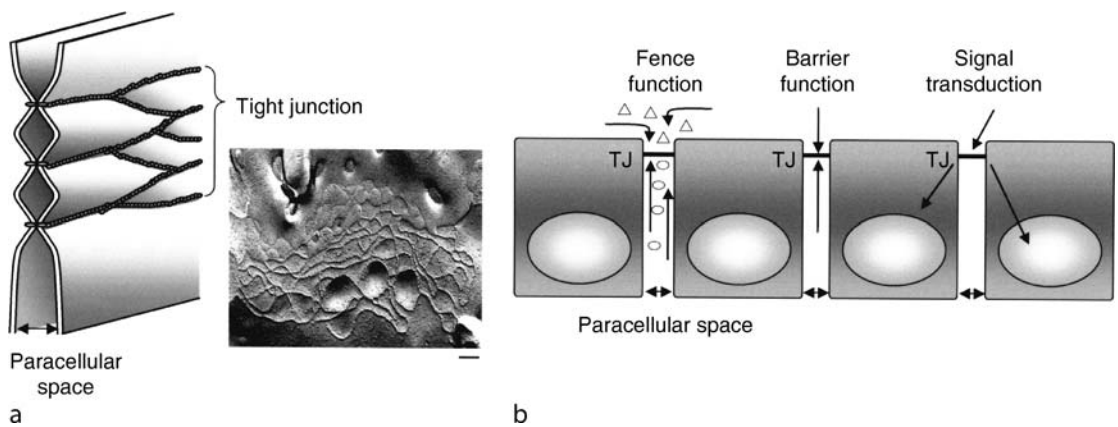
Definition

Tight junctions (TJs) are the apicalmost intercellular structures in epithelial and endothelial cells, playing central roles in the formation of ►cell polarity and functioning as major determinants of paracellular permeability. Cancer cells often exhibit loss of functional TJs, and decreased or impaired TJ formation has been reported for various types of cancer. Disruption of the TJ structure is associated with cancer development, which is causally involved in malignant phenotypes. Endothelial TJs of the host are believed to be the key apparatus to prevent blood-born ►metastasis.

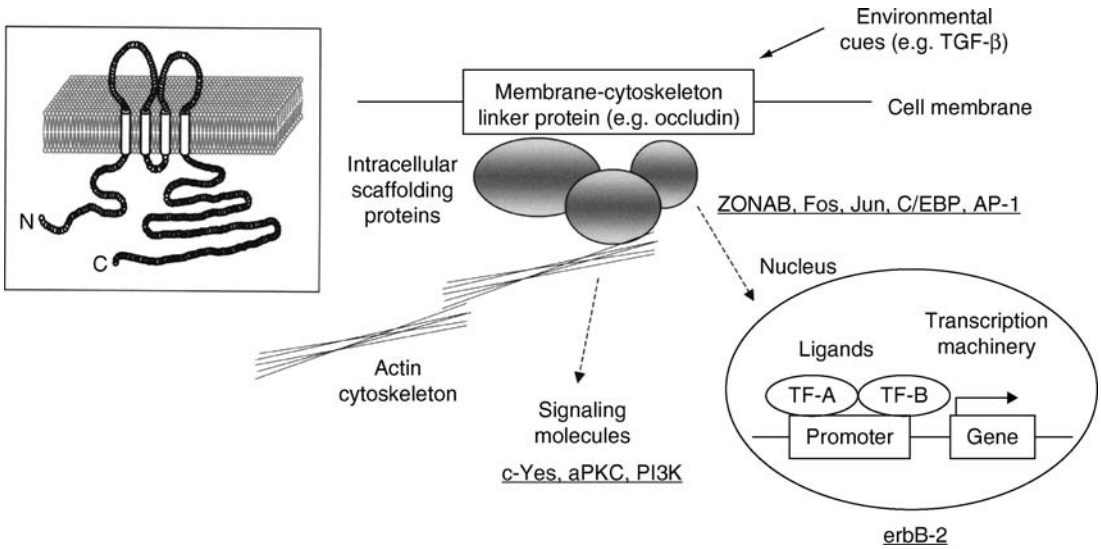
Characteristics

TJs are essential for the tight sealing of cellular sheets, thus functioning as major determinants of paracellular permeability and therefore maintaining tissue homeostasis (Fig. 1). TJs also play a crucial role in the maintenance of cell polarity by forming the fence that prevents lateral diffusion of membrane proteins and lipids, thereby creating a boundary between the apical and the basolateral plasma membrane domains. TJs are involved in the regulation of cellular functions such as proliferation, differentiation, and ►apoptosis, due to the ability of TJ proteins to recruit various types of signaling molecules that have proliferative and differentiative capacities, including ►transcription factors, ►lipid phosphatases, and ►cell cycle regulators. In addition, TJ proteins directly associate with cytoplasmic scaffolding proteins such as zonula occludens (ZO)-1, a submembrane component of TJs, eventually providing a direct linkage to the ►actin cytoskeleton. Another type of apical junctional complex in the epithelial sheet is the ►adherens junction (AJ). The AJ has been extensively studied in cancer, and the expression and/or integrity of several AJ proteins, ►catenins (α, β, and γ), and ►E-cadherin are significantly altered or deregulated in a wide variety of carcinomas. In sharp contrast to the roles of AJ components, the functional impairment of TJ proteins in cancer remains to be clarified.

One of the first identified TJ-associated molecules was occludin, which has been considered to be a requisite integral protein for TJ structure and function (Fig. 2). The long cytoplasmic domain of occludin is rich in serine, threonine, and tyrosine, and accumulating evidence has suggested that occludin is a signaling protein that has functions in receiving or transmitting signals such as atypical protein kinase C (aPKC), Rho proteins, PKC-ξ, c-Yes, and ►phosphoinositide-3-kinase (PI3K). Y-box transcription factor ZO-1-associated nucleic acid binding protein (ZONAB) has been proved to bind the SH-3 domain of ZO-1, and ZONAB and ZO-1 functionally interact in the regulation of erbB-2 promoter activity in cells, indicating that the TJ protein directly participates in the control of gene expression. Another



Tight Junction. Figure 1 Schematic representation of TJ. (a) Left panel: in this structural model of TJ, there are a number of intercrossing TJ strands (depicted as small dots) and three so-called "kissing points" of TJ. Right panel: freeze-fracture replica of a TJ. The TJ consists of an anastomosing network of strands that form irregular interstrand compartments and is comprised of a large number of protein components, including membrane proteins such as occludin and claudins, as well as cytoplasmic scaffolding proteins such as ZO-1. Scale bar, 50 nm. (b) In polarized cells, TJs are positioned at the boundary of the apical and basolateral plasma membrane domains to maintain cell polarity by forming a fence. TJs also seal cells together to generate the primary barrier and prevent diffusion of solutes through the paracellular pathway. In addition, a certain type of TJ protein such as occludin is a signaling molecule that has functions in receiving environmental cues and transmitting signals inside the cells.



Tight Junction. Figure 2 The TJ protein such as occludin is a signal transducer and transmitter for the cell. Inset, schematic presentation of the structure of occludin, with four transmembrane domains and a long cytoplasmic tail. The COOH-terminal region of occludin has many phosphorylated sites, potentially associated with a number of signal transduction pathways. Many of the cytoplasmic TJ components are signaling proteins that have functions in transmitting cellular signals such as c-Yes, aPKC, Rho proteins, PKC-ξ, and ►phosphoinositide-3-kinase (PI3K). Intracellular scaffolding proteins such as ZO-1 and ZO-2 also associate with ZONAB, Fos, Jun, C/EBP, and AP-1, and functionally interact with the regulation of transcription factors (TF-A and TF-B) such as erbB-2 promoter activity in cells, indicating that TJ proteins directly participate in the control of gene expression. In addition, occludin associates with cytoplasmic scaffolding proteins, thereby providing direct linkage to the actin cytoskeleton.

TJ protein, ZO-2, also associates with Fos, Jun, CCAAT/enhancer binding protein (C/EBP), and AP-1 (activator protein-1), suggesting that TJs have a direct functional association with signal transduction pathways. Although transforming growth factor-beta (TGF-β) is known to regulate multiple physiological functions, the second extracellular loop of occludin is a TGF-β receptor, and TGF-β regulates TJ dynamics in vitro via the p38 ►mitogen-activated protein kinase (MAPK) pathway, suggesting that this cytokine plays a crucial role in regulating the opening and closing of the blood–tissue barrier. In addition, occludin regulates TGF-β type I receptor localization for efficient TGF-β-dependent dissolution of TJs during ►epithelial–mesenchymal transitions, which is a cellular transformation crucial for the ►invasion and ►metastasis of many epithelial tumors. Consistent with this, occludin is linked with the apoptotic machinery involving MAPK and Akt signaling pathways. The ►methylator phenotype of occludin provides enhanced tumorigenic, invasive, and metastatic properties of cancer cells via modulation of unique sets of apoptosis-associated genes. It is thus clear that loss of occludin expression favors multiple steps known to be important in tumorigenesis and metastasis, identifying occludin as a likely ►tumor suppressor gene in certain types of cancer.

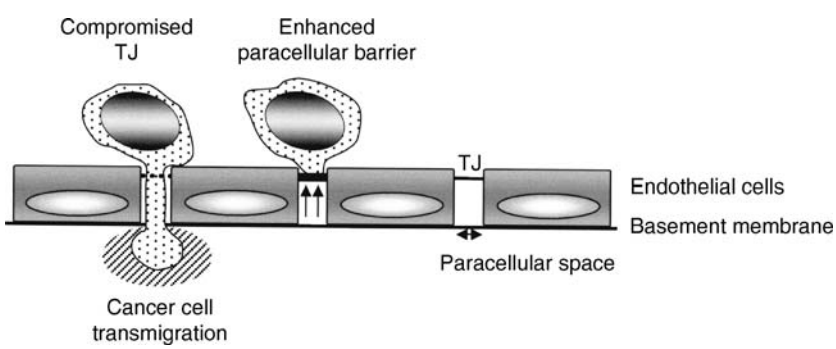
Occludin localizes to the TJ and its overexpression in a number of cell types induces the formation of TJ-like structures, supporting the idea that occludin is a key player in the formation of TJ. However, occludin expression in cells that lack endogenous TJ does not result in generation of typical TJ strands, and occludin-deficient cells and animals have fully developed well-organized TJs structurally. Thus it is now well accepted that the claudin family, which has been shown to contain at least 24 members, is the main constituent of TJs. While many members of the claudin family show a distinct organ-specific distribution pattern within the human body, the role of claudins in cancer has not been clearly defined.

Cancer cells, particularly in those tumors that manifest high metastatic potential, often exhibit loss of functional TJs. In addition, decreased and/or impaired TJ formation has been reported in various types of cancer, and genes having an oncogenic character are known to disrupt TJs. Disruption of the TJ structure is associated with cancer development, which may be causally involved in malignant phenotypes such as local tumor growth, invasion, and metastasis at distant sites. An early study in the field showed that levels of occludin and ZO-1 were often decreased during tumor development and metastasis, and loss of TJ-associated molecules such as occludin was correlated with cancer progression in ►carcinogenesis. Several claudins are regulated by ►oncogenes and tumor-promoting growth factors. In Ras-transformed Madin–Darby canine kidney cells,

claudin-1 was absent from cell–cell contact but was reassembled to the cell membrane after blocking the MAPK pathway, paralleled by TJ formation. Claudin-1 is a possible target of β-catenin/Tcf signaling, which supports a potential role for claudin-1 dysregulation in colorectal carcinogenesis. Transfection of oncogenic *raf-1* into a salivary gland epithelial cell line resulted in downregulation of claudin-1 and loss of TJ function. TGF-β, a potent modulator of invasion and metastasis in cancer cells such as those originating from the pancreas, has been demonstrated to perturb the TJ permeability and assembly of claudin-11 in Sertoli cells. In addition, overexpression of TJ-related proteins such as claudin-1 and -4 in cancer cells induces apoptosis and suppresses the invasive and metastatic potencies of these cells. Histological studies revealed the reduced expression of claudin-1 in breast and colorectal cancers, and down-regulation of claudin-7 in head and neck cancers and metastatic ductal carcinomas of the breast. These reports of decreased TJ protein expression in cancer are consistent with the well-accepted concept that carcinogenesis is accompanied by a disruption of TJs. Phosphorylation of TJ proteins, including claudins, may also affect TJ function in cancer. Typical examples are phosphorylation of claudin-1 by MAPK and PKC, and phosphorylation of claudin-5 by cyclic AMP-dependent protein kinase. Similarly, phosphorylation of claudin-3 and claudin-4 in ovarian cancer has been shown to disrupt TJs.

Aberrant claudin overexpression has been observed in various cancers. Some examples include increased expression of caludin-3 and claudin-4 in pancreatic, uterine, and ovarian cancers, high claudin-4 expression in gastric and pancreatic cancers, and upregulation of claudin-10 in hepatocellular carcinoma and thyroid papillary carcinoma. Besides the overwhelming majority of studies showing the downregulation of claudins in cancer, a number of additional reports have confirmed the paradoxical upregulation of claudins. In addition, certain types of claudins have been shown to modify tumor invasion by the regulation of ►matrix metalloproteinases (MMPs). A number of claudin family members such as claudin-1, -2, -3, and -5 are able to recruit and activate pro-MMP-2 processing mediated by membrane type 1-MMP, which suggests potential involvement in invasion and metastasis in cancer cells. The exact role of claudin overexpression remains to be examined, though the functional importance of these proteins in the development of cancer has been suggested by a number of studies. One finding reported that claudin-4 increased the invasiveness and metastatic potential of pancreatic cancer cells, and claudin-3 and claudin-4, which are highly expressed in ovarian cancer, enhanced ovarian tumorigenesis and metastasis through increased invasion and survival of tumor cells. Future studies will address the detailed molecular mechanisms by which certain types of TJ proteins determine the progressiveness of cancer cells.

Intercellular TJs primarily determine the endothelial barrier, regulating vascular permeability to maintain tightly closed circulating homeostasis. Numerous reports have confirmed the effects of cytokines such as ►vascular endothelial growth factor (VEGF) on endothelial integrity. Although many studies have focused on the strong angiogenic property of VEGF in tumor microenvironments, VEGF is known to have a pathological role in increasing vessel permeability by inducing disruption of TJ dynamics. VEGF overexpression is observed in many tumors, and causally contributes to the extravasation of fluids in the tissue surrounding VEGF-expressing cells (i.e., edema) and in a third space in the body (i.e., ascites and pleural effusion). Vascular endothelial cells also modulate cancer cell extravasation, an important metastatic process of cancer cells, which is believed to be a critical event in a potentially self-limiting step-by-step sequence, including ►migration from the primary lesion, adhesion to the vascular endothelium, extravasation, and growth at a distant site. All-*trans* ►retinoic acid (atRA)



Tight Junction. Figure 3 Enhanced paracellular barrier function prevents cancer cell extravasation. Cancer cells transmigrate through the endothelial monolayer with compromised TJs, which is believed to be an initial step in establishing a metastatic lesion. Therefore, it is feasible that enhancing endothelial integrity by decreasing paracellular permeability of TJs may limit the migration of tumor cells from the vasculature.

has been shown to determine cellular RA bioavailability and is causally an important contributing factor for determining epithelial integrity. In addition, atRA plays an important role in the formation of functional TJs through the involvement of specific RAR/RXR heterodimer-mediated transcription machinery. Based on these observations, it has been demonstrated that enhanced paracellular barrier function in rat lung endothelial cells and mesothelial cells induced by treatment with atRA can significantly suppress the invasion of cancer cells through the epithelial and endothelial monolayer sheet in vitro. It is thus feasible that epithelial and endothelial cells are the defense line of the host against cancer metastasis, controlling cancer cell transmigration by modulating the paracellular permeability of TJs (Fig. 3). This idea is likely to explain the underlying mechanism of endothelial physiology in limiting the migration of tumor cells from vascular structures.

Because of the high specificity of claudin expression patterns in cancer, claudins may represent a useful molecular marker and a prognostic indicator for many different cancers. Importantly, TJ proteins such as occludin and claudins in cancer cells may represent promising targets not only for the tumor detection and diagnosis, but also for therapy that would abrogate the progressiveness of cancer cells. It is clear that the pathology of cancer cells is critical for developing tumors and establishing metastatic lesions; however, epithelial and endothelial TJs will be good candidates for controlling cancer cell transmigration from the compartment defined by intercellular TJs, potentially having promising clinical applications to prevent cancer cell extravasation.

►Stem-like Cancer Cells

Time-of-Flight

Definition

Time-of-flight is a mass analyzer in which ions with a greater velocity and lighter ions flow down to hit the detector first in a field-free region. It is used to measure particle mass-to-charge ratio. An ion of known electrical charge and unknown mass enters a mass spectrometer and is accelerated by an electrical field of known strength. If all ions have the same kinetic energy, the ions with the lower mass will have a higher velocity and reach the detector earlier; whereas the ions with the higher mass will have a lower velocity and hit the detector later.

Definition

A fluorescence based assay technology used in ►high throughput screening to identify potential ►drug candidates against a variety of diseases; particularly cancer.

Characteristics

Identification of drugs for cancer treatment in today's highly technology driven research environment begins with understanding the biology of cancer and those molecules which can modify cancer cells. Early stages of the drug discovery process focus on the identification of potential drug candidates which are then further refined or excluded based on their ability to meet therapeutic efficacy and safety criteria. Thus, early stage discovery can be generally described in three key areas: (i) identification of ►target protein with causality to the disease (ii) identification of ►assays to measure the effect of putative drug candidates against the target protein or ►disease model and (iii) high throughput screening (HTS) of putative drug candidates with assays. Technology is a key driver in each of these activities. Recent advances in fluorescence based technologies have had a significant impact on the identification of potential drug candidates. Time resolved – ►fluorescence resonance energy transfer (TR-FRET) is a frequently applied technology for the identification and characterization of drug candidates.

Anti-cancer drug discovery is a multidisciplinary field combining knowledge of cancer biology, pharmacology, cell biology, medicinal chemistry and biochemistry. Research has benefited from technology advancements which have incorporated automation into data generation and sophisticated software for data analysis and management. HTS combines a biological assay with automation and specialized software, to rapidly screen through large collections (typically >100 K) of ►small molecule libraries to identify a set of compounds which can be developed into drugs. TR-FRET assay technology allows for the generation of a simple automation friendly assay that is amenable to HTS and can be readily adapted to families of target proteins implicated in disease. Members of the family of protein ►kinases have been tied to cancer and TR-FRET is a valuable technology suited to studying kinases.

The processes by which normal healthy cells are transformed into cancer cells are being elucidated. While there are several mechanisms that drive the transitions from normal to cancer cells, a common feature of all cancer cells is the loss of ability of a given cancer cell to control its growth or ►cell cycle. Regulation of cell growth is a complex process where the cell communicates with its external environment and responds with a series of carefully coordinated internal events. This process is termed ►cell signaling. Cell signaling allows a cell to respond to changes in its external environment and exert its own influence in a localized manner. Understanding and compensating for an aberrant mechanism of cell signaling in cancer cells is an underlying quest in drug discovery and development.

Cell signaling within a cell is mediated by various proteins. Typically, cell signaling proteins are either modifiers (►enzymes) of other proteins (►substrates) or subunits of larger complexes that are formed or disbanded for a particular function. For example, kinases are a family of enzymes that modify their substrates by adding a phosphate group to specific amino acid residues. In turn, the phosphorylated protein may now interact with another protein forming a complex such as a ►transcription factor that is able to enter the nucleus and initiate the ►transcription of specific genes. Thus, the activities of several proteins are coordinated together to obtain a change in the cell such as the production of new proteins. In normal cells, cell signaling is carefully regulated. In cancer cells, events in cell signaling such as the activity of kinases are misregulated leading to inappropriate activation of cellular processes, such as cell growth. A central activity in identifying new therapeutics to cancer is the identification of small molecule compounds that inhibit improper kinase mediated cell signaling.

Kinases are a large family of proteins involved in cell regulation and make up ~2% of the human genome; 518 kinases have been identified. Kinases are intracellular proteins and by modifying their substrates through ►phosphorylation they cause changes in protein localization and/or protein complex formation. Most kinases fall into two categories based on their ability to phosphorylate specific amino acid residues on their substrates; typically tyrosine and serine/threonine. Kinases also typically have high homology in their catalytic domains due to the binding of ►ATP and divalent metal ions (Mg^{2+} or Mn^{2+}) to facilitate transfer of γ-phosphate from ATP to substrate. Substrate to kinase specificity is based on cellular localization or the presence of specialized protein domains which facilitate

protein:protein binding interactions. Kinases may be their own substrates; known as ►autophosphorylation. A complex cascade of protein:protein interactions and enzymatic activity is mediated by kinases and their substrates. Phosphorylation of a protein can result in either activation of signaling (►EGFR kinase) or inhibit further signaling from occurring (►src kinase). Misregulation of kinase signaling as in the case of EGFR results in increased cell growth and ►oncogenesis. Thus, specific kinases and the larger protein family have been targeted as a point of intervention for identifying novel anti-cancer drug candidates.

Kinase activity can be inhibited by small molecules which are able to interfere with ATP binding and thus, prevent phosphorylation of substrate. Anti-cancer drug therapies have been identified which take advantage of a small molecules ability to enter cells, locate and block a target kinase. Examples are: ►Dasatinib, ►Erlotinib, ►Gefitinib, ►Imatinib, ►Lapatinib, ►Nilotinib, ►Sorafenib, ►Sunitinib, and ►Vandetanib. Gifitnib (also called Iressa) targets EGFR kinase which is misregulated due to overexpression in some cancers, including incidences of breast cancer. The inappropriate activity of EGFR kinase in cancer cells leads to the activation of the ►Ras cell signaling pathway. The Ras signaling pathway is comprised of a series of distinct kinases which are involved in either further perpetuating or shutting down the pathway. The inappropriate activation of the Ras pathway leads to changes in the cells which result in increased and misregulated cell growth. A mutation in the ATP binding site of the kinase domain of EGFR renders the cells susceptible to the effect of Iressa. The identification of novel small molecules for additional kinases implicated in cell growth misregulation has key implications for cancer therapies.

Since kinases play a key role in cancer and small molecules have been identified as kinase targeted cancer therapies, HTS has emerged as a useful approach for identifying novel anti-cancer small molecule drug candidates. A key component of a kinase based HTS is a biological assay which can be readily adapted to robotics and measure a test molecule's ability to prevent phosphorylation of substrate by the target kinase. Historically, radioactivity based assays were used to measure kinase activity. The cost of radioactive assays is prohibitive for HTS where large numbers of samples are being processed and tested. Radioactive assays have the additional disadvantage of having multiple steps which increases the challenges of automation. Radioactive assays were preferred to conventional fluorescence based measurements which were relatively insensitive due to their limited assay dynamic range. HTS assays generally have a ►homogenous assay format which is automation friendly. Homogenous assays combine the biological event and assay readout (detection) into a single measurement, minimizing the number of steps needed to perform a given measurement. Radioactive assays are often heterogeneous assay formats, where multiple steps are required to separate the desired biological signal from the total signal generated by the radioactive molecule. TR-FRET technology eliminated these hurdles to HTS by providing (i) a non radioactive assay format (ii) reasonable dynamic range of assay and (iii) homogenous assay format for ease of automation.

TR-FRET is based on ►Time Resolved Fluorescence (TRF) and Fluorescence Resonance Energy Transfer (FRET) technologies. Assay sensitivity can be a significant limitation when using conventional ►fluorophores due to the naturally fluorescent properties of many compounds and proteins. In time-resolved detection technology, there is a time delay between the ►excitation of the fluorophore and the ►emission detection of the fluorophore. When TRF detection is coupled with long lasting fluorophores, sensitivity issues can be overcome for biological assays. FRET technology enabled homogenous assay formats using TRF technology by incorporating two distinct fluorophores into the assay. The two fluorophores are defined as a donor molecule and an acceptor molecule. The excitation of the donor fluorophore causes an emission that in turn is able to excite the acceptor fluorophore and cause a specific measurable emission. The ability of the donor fluorophore to excite the acceptor fluorophore is based on the proximity of the two molecules to each other and is the basis of FRET. FRET enables homogenous assay design based on the proximity of two fluorophores which can be used to measure biologically relevant protein to protein binding interactions. Thus, TR-FRET can be applied to measuring the activity of proteins (such as kinases) and adapted for drug discovery with HTS.

TR-FRET assays for drug discovery are designed to use fluorophores specific for TRF and amenable to FRET. TRF uses specific fluorophores from the family of elements known as the ►lanthanides which have a long emission profile and a large ►Stokes shift. The Stokes shift is defined as the difference between the excitation and emission wavelengths. Lanthanides have Stokes shifts of ~300 nm which is three times greater than conventional fluorophores. The large Stokes shift enables detection of emission signal distinct from excitation energy allowing for greater dynamic range in assay measurements. Fluorescence decay of lanthanides is long-lived (microseconds) relative to conventional fluorophores (nanoseconds). This spectral property allows for measurements removing most background fluorescence noise and further improving the assay sensitivity. The lanthanides are coupled to molecules which are able to capture and transfer light to the lanthanide to generate fluorescence upon excitation. Fluorophores modified for TRF are lanthanide

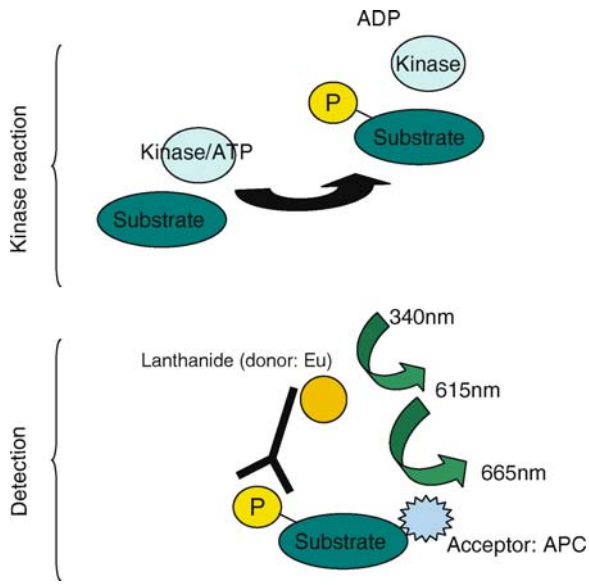
Time-Resolved Fluorescence Resonance Energy Transfer Technology in Drug Discovery. Table 1 Commonly used TR-FRET pairs for drug discovery

Lanthanide[a]	Stokes shift (nm)	Fluorescence Lifetime (μsec)	Excitation (nm)	Emission (nm)	FRET Acceptor	Excitation (nm)	Emission (nm)
Europium (Eu)	300	730	340	615	APC	615	665
Terbium (Tb)	200	1050	340	495	Fluorescein	495	520
Samarium[b] (Sm)	225	50	340	642			

[a]Variations will occur based on specific fluorophore-chelate or fluorophore-cryprate and acceptor molecules.
[b]Samarium has TRF properties and is not routinely used for TR-FRET.

►chelates or lanthanide ►cryptates. TRF fluorophores have been identified which can serve as donors for a FRET pair. A FRET pair for biological measurements is based on the distance between two fluorophores to activate the acceptor fluorophore. Typically, FRET occurs within 70–90 Å which allows for measuring interactions between proteins. TR-FRET pairs must meet the following criteria to be useful for biological measurements as in HTS; (i) emission spectra of each fluorophore must have a non-overlapping region to allow measurement of each molecules' fluorescence (ii) high energy transfer (high ►quantum yield) to enable sufficient signal detection, and (iii) fluorescence emission must fall outside of spectrum of proteins to avoid high background. Several key properties for fluorophores for TRF and the FRET pairs commonly used in kinase assay design are shown in Table 1.

TR-FRET assay format is applied towards kinase assays for the identification of small molecules which are able to inhibit the enzymatic activity of the target kinase. A sample assay design is presented in Fig. 1 which can be generally applied to kinase family members. Advances in fluorescence technology enabling TR-FRET measurements have led to the availability of a variety of assay reagents which can be applied in kinase assays. Many kinases and their specific or a generic artificial substrate are commercially available. Specific antibodies which detect the presence of a phosphorylated substrate in solution can be coupled with a member of the TR-FRET pair. The second member of the TR-FRET pair can be coupled with the substrate protein. An active kinase will phosphorylate the substrate; which is tagged with the acceptor fluorophore of the TR-FRET pair. The phosphorylated substrate becomes bound to the anti-P-antibody which is tagged with donor fluorophore. This binding event can only occur if the kinase is active on the substrate protein. The binding event causes TR-FRET by bringing the donor and acceptor fluorophores into proximity of each other enabling FRET. The TR-FRET signal measured is only generated by the phosphorylated substrate, minimizing background signal from each individual fluorophore. If a small molecule inhibits the kinase activity, FRET does not occur as there is no phosphorylation event to cause the anti-P-Ab to bind to the substrate. Test molecules can have their own fluorescent properties causing artifactual results in TR-FRET. A ratio of emission/excitation wavelengths is routinely used to minimize fluorescence changes within an assay. The general assay design shown in Fig. 1 is frequently used in HTS.



Time-Resolved Fluorescence Resonance Energy Transfer Technology in Drug Discovery. Figure 1

The specific conditions of the assay are customized for each kinase and substrate pair and each donor and acceptor TR-FRET detection pair. A commonly used TR-FRET pair is Eu^{3+} as the donor with ►allophycocyanin (APC) as the acceptor molecule (Fig. 1). Excitation of Eu-chelate or Eu-cryptate at 337 nm causes emission at 613 nm which in turn causes excitation of APC which emits at 665 nm. A ratio of 665 nm/613 nm is typically used to monitor specific assay signal.

TR-FRET technology is not limited to small molecule screening or kinases in drug discovery. Macromolecules (antibody base protein therapies, enzyme replacement therapies) are used treat an array of diseases; most frequently by targeting proteins on the surface of cells. Some examples of the use of TR-FRET technology in drug discovery beyond the kinase family are: (i) ►cytokines in the extracellular environment (ii) key intracellular molecules involved in cell signaling such as ►cAMP and (iii) ►protease family of enzymes where misregulation has serious implications in disease. TR-FRET can be applied as long as an appropriate fluorophore pair can be identified such that the proximity of the two fluorophores leads to a sufficient assay signal. In general, TR-FRET has been applied in large scale to kinases as a protein family due to the range of commercially available reagents and the direct link between kinases and their role in cellular regulation. TR-FRET for anti-cancer drug discovery by HTS has the advantage of a homogenous assay format with sufficient sensitivity to identify putative kinase inhibiting small molecules.

The high throughput nature of TR-FRET kinase assays has made it a useful assay format for characterizing the specificity of kinases. Since there is high homology between kinase domains of different kinases and small molecule drugs interfere with the ATP binding site of the kinase domain, small molecules drugs are known to inhibit kinases beyond the original target kinase. In some cases, this activity can be favorable in cancer treatment. Imatinib targets tyrosine kinase ►BCR/ABL and the tyrosine kinase ►c-kit. Another example is Sorafenib which can inhibit both Raf (serine/threonine kinase) and VEGFR(tyrosine kinase), key players in cell signaling. The selectivity profile of small molecule kinase inhibitors is emerging and could provide key information in determining which small molecules to pursue as a drug. Alternatively, selectivity profile information could determine which small molecules to abandon due to their activity as pan-kinase inhibitors or their ability to inactivate a key kinase necessary for cell viability and thus behave as a toxin.

TR-FRET is a key assay technology for identifying and characterizing anti-cancer small molecule drugs; especially against the protein kinase family which has been implicated in cellular misregulation leading to cancer. TR-FRET combines TRF and FRET technologies to provide a sensitive and high throughput assay format for characterizing the activity of small molecules against kinases. TR-FRET is an approach to rapidly screen large collections of putative drug candidates to identify a subset of molecules able to inhibit kinase activity. Application of TR-FRET extends beyond small molecule and kinase drug discovery. TR-FRET is utilized for characterizing macromolecules and a variety of protein families and signaling events. The central role of kinases in cancer and the ease of kinase assay design with TR-FRET has made TR-FRET technology a key component in today's technology rich anti-cancer drug discovery research.

Synonyms

TIMPs

Definition

The tissue inhibitors of metalloproteinases (TIMPs) are endogenous inhibitors of the ►matrix metalloproteinases (MMPs), proteases that play a central role in the degradation of extracellular matrix components in diseases such as cancer. Four TIMPs (TIMP1–4) which share high sequence homology have been identified. Tumor cells express MMPs that are important for cell ►invasion and metastasis. Because of their implication in tumor progression, TIMPs have been regarded as a potential therapeutic target in the management of cancer.

Characteristics

►Extracellular matrices (ECM) play a central role in the structure and functions of tissues. The ECM consists of a network of fibrous proteins that include collagens, ►laminins, ►fibronectin and proteoglycans that provides a unique structural scaffold for normal tissue function. Alterations in the ECM protein scaffold always develop in pathological conditions such as cancer. In fact, the tumor cells penetrating the subepithelial basement membrane define a malignant tumor. Thus, degradation and remodeling of the ECM are pivotal for tumor growth. These functions are carried out by several enzymatic-cascade systems that control the tumor ►microenvironment and its vascularization. Matrix metalloproteinases, MMPs, are among the major class of enzymes responsible for tumor-associated matrix degradation. This is supported not only by the nature of their association with tumor progression but also by the observations that in animal models MMP inhibitors are effective anti-tumor and anti-metastatic agents. MMPs are a large family of proteases with more than 20 members. Collectively, the MMP family members are capable of degrading essentially all extracellular matrix components. The expression of MMPs by the tumor cells and/or tumor stromal cells determines not only the behavior of malignant cells, but enables them to carry out pivotal functions during the metastatic process such as ►migration and invasion.

It is widely known that the endogenous inhibitors of the MMP family are the tissue inhibitors of metalloproteinases or TIMPs. These proteins regulate the proteolytic activities of the MMPs in the remodeling tissue or tumor microenvironment. TIMPs are a highly conserved, small family of proteins, with sequence homologies present through out evolution including worms, chicken, and *Drosophila*. In contrast to the large number of members in the MMP family, only four *timp* genes are present in the human genome. These genes are located in different chromosomes, *timp-1* on the chromosome X, *timp-2* in chromosome 17, *timp-3* on Chromosome 22, and *timp-4* on chromosome 3. Also, there is an association of the TIMP gene loci with the synapsin gene loci, with the exception of TIMP-2. In both human and mouse, the genes for TIMP-1, 3, and 4 are located in the introns of synapsins I, III and II respectively, but the transcriptional orientation of the two gene families is in opposite direction. TIMPs are small proteins with molecular weight of the core proteins in the range of 21 kDa; TIMP-3 and TIMP-1 are N-glycosylated, while TIMP-2 and TIMP-4 are not. However, they all contain 12 cysteine residues that must correctly pair into six disulfide bonds to give the correct secondary/tertiary structure required for MMP inhibitory activity. The selectivity of TIMPs for inhibiting MMP activity resides in the N-terminal domain. The TIMP family is also unusual in that the N-terminal amino acid is a cysteine residue. X-ray diffraction studies show that it is the amino group of this N-terminal cysteine that actually coordinates with the

Zn atom in the MMP active site, which results in inhibition of the proteolytic activity. Also, TIMP-2 selectively binds to zymogen pro-MMP-2 via the carboxyl terminal domain, and is important for the cell surface activation of pro-MMP-2 by MT-1-MMP. Interestingly, TIMPs -2 and -4 can interact with the catalytic domains in all activated MMPs, but TIMP-1 is a poor inhibitor of MT-1-MMP. TIMP family members have a distinctive pattern of tissue expression. TIMP-2 is unique in that expression of this inhibitor is constitutive in most tissues, whereas TIMP-1, TIMP-3 and TIMP-4 proteins expression is inducible, and TIMP-3 is the only member that is specifically bound to the ECM.

Given that TIMPs regulate MMPs activation, their role in tumor development has been the subject of an intense research. In experimental systems, gene knock-out either in cell lines in vitro or in vivo models reveals that the absence of some TIMPs accelerate tumor growth, as well as tumor-associated ►angiogenesis. In clinical investigations, tumor specimens consistently demonstrate alterations in the balance of MMP/TIMPs. Based on these findings, there has been an interest in these proteins as potential ►biomarkers for prognosis and diagnosis, as well as targets for cancer therapy. In response, synthetic inhibitors of MMPs were developed and tested in clinical trials, but these compounds failed to demonstrate meaningful anti-tumor effects. However, re-examination of TIMP expression in tumor specimens shows no clear pattern when analyzed as an independent variable. For instance, in an increasing number of clinical reports, TIMP-1 has been found to be overexpressed in human tumors and correlated with poor prognosis. These observations lead to the idea that the role of TIMPs in cancer is more complex than one first thought, in that although TIMPs may have MMP inhibition as a main function, these proteins can also regulate steps throughout the malignant process independent of their MMP inhibitory role. Thus, TIMP-1 has been shown as an autocrine growth factor and anti-apoptotic protein even independent of its MMP inhibitory ability. TIMP-3 can directly inhibit tumor growth in vivo by restricting angiogenesis. Recently, TIMP-2 is shown in vitro and in animal models to be an effective anti-tumor and anti-angiogenic factor. These TIMP-2 effects are also direct on cells and independent of its MMP inhibitory activity, mediated by binding to $\alpha_3\beta_1$ integrin.

Despite of their structural similarities, it is clear that TIMPs exhibit a wide spectrum of effects during the process of tumorogenesis. These conflicting TIMP effects in tumor growth are new challenges for the field of MMPs and TIMPs in cancer. Clarifying this will be important for the design of novel anti-cancer therapies. A current approach is being investigated for TIMP-2 and TIMP-3 that involves either over expression of these TIMPs by retroviral-gene transfers into tumor tissues or adenovirus systemic-gene delivery. These are being implemented either as monotherapies or as adjuvants to directly inhibit tumor growth or angiogenesis.

TMPRSS2/ERG Fusions

Jianghua Wang, Yi Cai, Michael Ittmann
Department of Pathology, Baylor College of Medicine, Houston, TX, USA

Definition

TMPRSS2/ERG fusions are fusions of the promoter and 5′ portion of the androgen-regulated *TMPRSS2* gene and coding portions of the *ERG* gene that occur in the majority of prostate cancers.

Characteristics

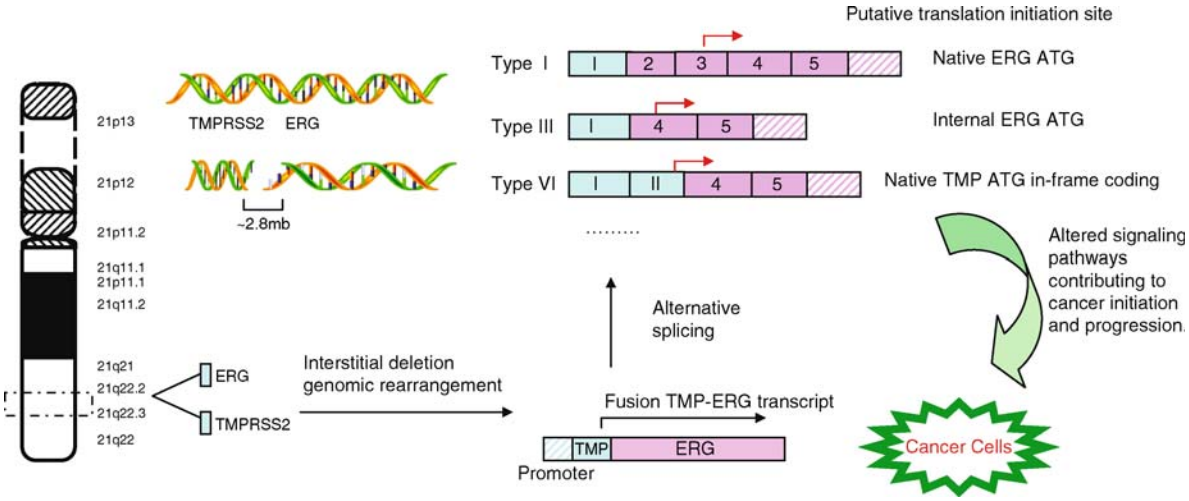
Chromosomal rearrangements resulting in gene fusions with expression of functional proteins are common in leukemias, lymphomas, and sarcomas. The presence of

such ►fusion genes is often linked to specific tumor phenotypes, for example, the ►*BCR–ABL1* fusion encoded by the Philadelphia chromosome in chronic myelogenous leukemia. In contrast, gene fusions with expression of a functional protein have generally been considered to be rare events in common epithelial malignancies such as lung, colon, and breast cancer. This idea has been brought into question by the finding of recurrent fusion of the androgen-regulated *TMPRSS2* gene to the ►ETS transcription factors, particularly the *ERG* gene, in the majority of prostate cancers (►Prostate cancer). Overall, ~50–80% of clinically detected prostate cancers contain *TMPRSS2/ERG* fusion genes, with a much smaller percentage containing fusions with genes for other ETS transcription factors such as *ETV1* and *ETV4*. The existence of a recurrent chromosomal rearrangement in prostate cancer is a paradigm shift in the study of epithelial malignancies and other epithelial tumors may have their own recurrent chromosomal rearrangements that are yet to be identified.

The *TMPRSS2/ERG* gene fusion involves fusion of the promoter region of the *TMPRSS2* gene as well as some 5′ portions of this gene with coding sequence of the *ERG* gene. The *TMPRSS2* gene encodes a transmembrane-bound serine protease that is localized to prostatic epithelium and is overexpressed in neoplastic prostate epithelium. It is well known that normal and neoplastic prostatic epithelium contain the ►androgen receptor and express numerous genes whose expression is regulated by androgens. The *TMPRSS2* promoter contains a 15 bp sequence that is homologous to the consensus androgen response element, which is in accordance with androgen-inducible expression of the gene. Experiments in cells with *TMPRSS2/ERG* fusions indicate that the androgen-responsive promoter elements of *TMPRSS2* mediate the overexpression of ETS family members in prostate cancer. Fusion proteins involving ETS transcription factors are characteristic of ►Ewing sarcoma and occur at lower rates in some leukemias. Based on this finding and the known biology of these transcription factors and fusion proteins, these genes are considered as oncogenes that promote neoplastic progression. Thus, the *TMPRSS2/ERG* gene fusion results in constitutive expression of an oncogenic transcription factor in the neoplastic prostatic epithelium. It is unknown whether decreased *TMPRSS2* expression as a result of loss of one *TMPRSS2* allele due to this rearrangement plays a role in prostate cancer initiation or progression.

The *ERG* gene is located on chromosome 21q22.2 while the *TMPRSS2* gene is ~2.8 Mbp telomeric to *ERG* at 21q22.3. Initial characterization of the mechanism by which the fusion gene arises reveals that about half of the cases there is a large deletion of the genomic DNA between these two genes, while in other cases there appears to be more complex chromosomal translocations. More detailed studies of the mechanism by which the gene fusion arises and the exact regions fused are needed. The fusion gene initiates transcription from the *TMPRSS2* promoter. All reports to date indicate that there is significant heterogeneity in the structure of the mRNA transcripts of the fusion gene, both among different cancers and within a single cancer. Thus some cancers express a single mRNA type, while others express multiple isoforms of the fusion gene. These different isoforms presumably arise via alternative splicing of the initial fusion transcript. In all cases, the fusion mRNA includes the *TMPRSS2* exon 1 and often exon 2 as well. Transcripts with *TMPRSS2* exons 3–5 have also been reported but appear to be uncommon. In some cases, the native ERG translation initiation codon in *ERG* exon 3 is maintained, fused to the untranslated *TMPRSS2* exon 1. The most common transcript contains the TMPRSS2 exon 1 fused to *ERG* exon 4, such that translation would have to arise from an internal ATG codon and give rise to a slightly truncated protein. Of particular interest is an isoform in which *TMPRSS2* exon 2 is fused with *ERG* exon 4. In this case, translation can be initiated from the TMPRSS2 translation initiation codon and results in a true fusion protein containing the first five amino acids of the TMPRSS2 protein fused to a slightly truncated ERG protein. Expression of this isoform is associated with early biochemical recurrence, characterized by detectable serum ►prostate specific antigen (PSA), following radical prostatectomy. Such early recurrence has been shown to be a hallmark of aggressive disease and is associated with cancer progression and death from disease. Thus there is significant heterogeneity in both the structure of *TMPRSS2/ERG* fusion genes and the isoforms of transcripts arising from the fusion gene (Fig. 1).

TMPRSS2/ERG fusion can be detected in high grade prostatic intraepithelial neoplasia, a noninvasive lesion that is generally believed to be the precursor of invasive prostate carcinoma, and thus is the gene fusion may be an early event in prostate cancer initiation. In all series studied to date, 50–80% of clinically detected prostate carcinomas contain the *TMPRSS2/ERG* fusion gene. These findings argue strongly that the fusion gene plays a critical role in prostate carcinogenesis but the exact biological role of the *TMPRSS2/ERG* fusion gene in prostate cancer has not been determined. Analysis of expression microarray databases reveals that ERG expression is associated with increased expression of histone deacetylase 1 (►Histone deacetylases), activation of the ►Wnt signaling pathway and downregulation of apoptotic pathways (►Apoptosis). These observations need to be validated, but indicate that the *TMPRSS2/ERG* fusion gene may have significant biological activities in vivo that promote carcinogenesis. Further studies are needed to characterize the biological



TMPRSS2/ERG Fusions. Figure 1 The TMPRSS2 and ERG genes are located at chromosome 21q22.2–22.3 and undergo interstitial deletions or other genomic rearrangements to yield a fusion gene containing the androgen-regulated TMPRSS2 promoter and 5′ portion of the TMPRSS2 gene fused to coding regions of the ERG gene in 50–80% of clinically detected prostate cancers. The transcript from the fusion gene undergoes alternative splicing to yield various isoforms in prostate cancer cells. The resulting proteins may have a variety of biological activities that promote prostate cancer initiation and progression.

activities of the *TMPRSS2/ERG* fusion gene in human prostate cancer cells.

A number of studies have examined whether the presence of the *TMPRSS2/ERG* fusion gene is associated with more aggressive clinical behavior in prostate cancer. Examination of outcome in patients treated by watchful waiting showed a strong association with death from disease. Retrospective studies have shown an association of the presence of the fusion gene with higher Gleason grade (link Gleason grading), extracapsular penetration, or biochemical recurrence in radical prostatectomy cohorts, although other study did not see these associations. Other factors may also come into play including the isoform(s) of fusion transcript expressed, the total expression level of fusion transcripts and the presence of large interstitial deletions. As described above, certain fusion transcript isoforms are associated with more aggressive disease, possible due to differences in translation initiation efficiency. Increased androgen receptor activity has been associated with prostate cancer initiation and progression and certainly the *TMPRSS2/ERG* fusion gene may be an important androgen receptor target in prostate cancer. Small studies have indicated that when cancers with similar isoforms are compared, that higher transcript expression may be associated with poorer prognosis. Finally, large interstitial deletion of the region between TMPRSS2 and ERG on chromosome 21 may inactivate potential tumor suppressor genes located between these two genes on chromosome 21. Comprehensive studies are needed to understand the impact of the *TMPRSS2/ERG* fusion on prostate cancer progression and clinical outcome.

The presence of a recurrent gene fusion in any malignancy raises the possibility of specific diagnostic tests, such as the use of the Philadelphia chromosome as specific diagnostic test for chronic myelogenous leukemia. A diagnostic test to detect the *TMPRSS2/ERG* fusion transcripts in cancer cells in blood should be specific for prostate cancer and detection of specific isoforms may have prognostic utility to assist in treatment planning. Further studies and development of appropriate technologies are clearly indicated.

TNF-α in HIV Infection

Pascal Clayette
SPI-BIO, Service de Neurovirologie, CEA, CRSSA, EPHE, Fontenay aux Roses Cedex, France

Definition

In the 1950s–1960s, it was reported that several patients with malignant tumors had a spontaneous regression of their tumors after bacterial infections. In the 1970s, a bacterially-induced circulating host factor was associated with this anti-tumor activity and was designated "►tumor necrosis factor" (TNF). Subsequently, TNF was isolated, cloned and found to be the leader of the "TNF superfamily" and a pleiotropic cytokine representing a major mediator of the inflammatory and immune responses. The human TNF gene is located on chromosome 6p23–6q12 between class I HLA region for HLA-B gene and the gene encoding the complement factor c; it contains four exons in a total length of 3.6 kb. Human TNF-α is a non-glycosylated protein of 157 amino acids with a molecular weight of 17 kD. A 233 amino acid precursor (26 kD) is synthesized, expressed at cell surface and cleaved by the 85 kD TNF-α converting enzyme (TACE). This TNF precursor is biologically active and considered as the "membrane TNF" form. The 17 kD peptides interact together and form circulating homotrimers. The level of circulating TNF ranges between 10 and 80 pg/mL in non-pathological conditions. TNF is secreted by various cell populations such as cells of the macrophage lineage (monocytes, macrophages, microglial cells), CD4+ and CD8+ T cells, dendritic cells, neutrophils, adipocytes, keratinocytes, astrocytes, neurons and pancreatic cells.

Two distinct membrane receptors for TNF have been identified and cloned:

- A 55 kD receptor (p55) or TNF-R1, newly designated as CD120a and referred as TNF receptor superfamily member 1A (TNF-RSF1A)
- A 75 kD receptor (p75) or TNF-R2, newly designated as CD120b and referred as TNF receptor superfamily member 1B (TNF-RSF1B)

TNF-R1 and -R2 are glycoproteins of 455 and 461 amino acids, respectively. Soluble forms of TNF-R1 (at least two molecular weights 32 and 48 kD) and -R2 (42 kD) are generated by proteolytic cleavage. Cells such as monocytes/macrophages, endothelial cells express both TNF-R1 and -R2. It was first suggested that TNF-α was bound by TNF-R2 and transferred to TNF-R1, which then is activated; in fact, TNF-R1 may be the main receptor for soluble TNF-α, whereas membrane TNF preferentially interacts with TNF-R2.

Characteristics

Physiopathological Role of TNF-α in HIV Infection

Human immunodeficiency virus (HIV) is a ►retrovirus that infects preferentially T CD4+ lymphocytes and ►macrophages, a major source of TNF-α. As a consequence, close relationships exist between HIV and TNF-α; an implication of TNF-α has been reported in HIV replication, neuroAIDS, ►cachexia and in the development of opportunistic infections and tumors.

Relationships Between HIV Replication and TNF-α

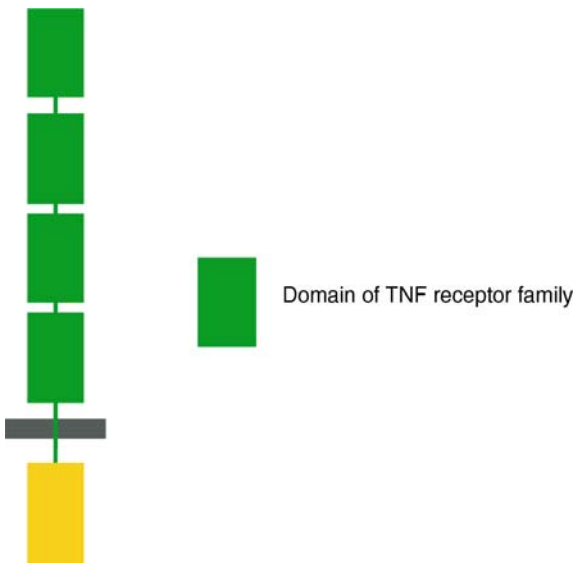
TNF-α is a pro-inflammatory cytokine and thus has been considered as a cytokine that could increase HIV replication. In fact, the effects of TNF-α on HIV replication is dual and opposite:

- Inhibition of HIV entry
- Increase of expression of proviral genome and production of HIV particles

The inhibitory effects on HIV entry is due to the capacity of TNF-α to favor the synthesis of β-chemokines e.g. regulated upon activation, normal T-cell expressed and secreted (RANTES), macrophage inflammatory protein (MIP)-1α and MIP-1β, the natural ligands that compete with HIV particles to bind their receptor, which is also the co-receptor of HIV. The transcription factor ►NFκB participates, in part, to the deleterious effects of TNF-α on HIV production; this transcription factor is activated by TNF-α, and interacts with domains regulating the

expression of HIV (long terminal repeat or LTR), in which two binding sites has been identified (Fig. 1).

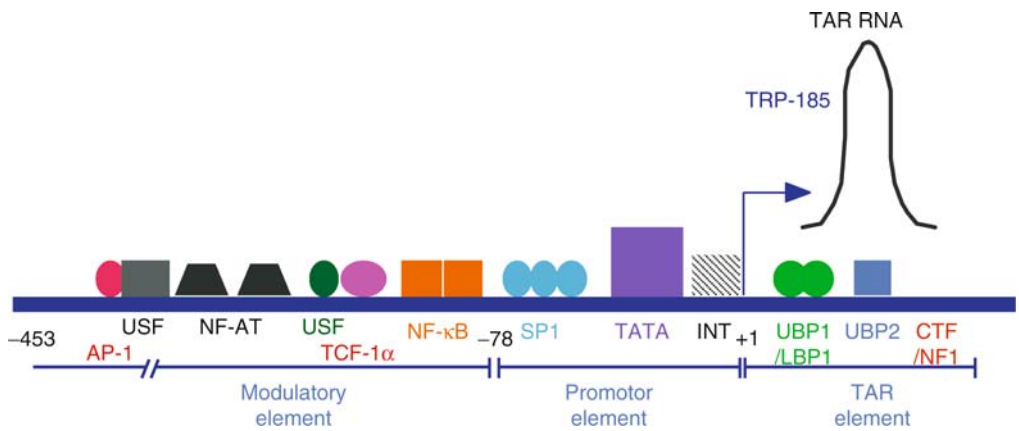
TNF-α is a cytokine that is secreted by cells of the immune system in the area of microbial infections e.g. viral infections. In HIV infection, immune cells are HIV targets, and dysregulations of TNF-α synthesis induced by the HIV infection were explored in macrophages. Several authors demonstrated that the infection of macrophages by HIV is not sufficient to induce the synthesis of TNF-α in the absence of other environmental factors. In contrast, TNF-α synthesis may be increased in the presence of soluble factors or cells; only few contaminating lymphocytes favor, for example, the macrophagic TNF-α synthesis in response of HIV infection.



TNF-α in HIV Infection. Figure 1 Structure of TNF receptor superfamily members. TNF-R1 (p55, CD120a, TNF-RSF1A), TNF-R2 (p75, CD120b, TNF-RSF1Bg).

Role of TNF-α in NeuroAIDS

TNF-α is also a neurotoxic factor that is implicated in the neuronal death in HIV disease. TNF-α can be synthesized in central nervous system (CNS), and the passage of blood brain barrier is not required for its presence in situ. The mechanisms of this neurotoxicity involve the α-amino-3-hydroxy-5-methyl-4-isoxazole propionate (AMPA) receptor and the N-methyl-D-aspartate (NMDA) receptor. TNF-α inhibits the glutamate uptake by astrocytes and favors the synthesis or release of the phospholipid mediator platelet-activating factor (PAF) which enhances excitatory transmission. Moreover, TNF-α also participates in the pathogenesis of neuroAIDS by regulating NFκB activation and HIV replication levels in perivascular macrophages and microglial cells. Indeed, viral factors such as the envelope glycoprotein gp120 and the transactivator protein ►Tat are known to be neurotoxic factors, and Tat can induce TNF-α synthesis. Both TNF receptors are present in the CNS, and on neurons in particular. The role of TNF-R2 in the CNS remains largely unknown. TNF-R1 can promote apoptosis of neurons via the release of silencer of death domains (SODD) permitting the association with intracellular proteins such as TNF receptor-associated death domain (TRADD), FAS-associated death domain (FADD) and caspase-8 (FLICE/CASP8). The activation of acid sphingomyelinase by caspase-8 contributes to the cleavage of sphingomyelin to phosphocholine and ceramide, which activates various enzymes e.g. phosphatases, protein kinases involved in apoptosis (Fig. 2). A new neurodegeneration process has recently emerged; the silencing of survival signal (SOSS). TNF-α, at picogram concentrations, inhibits the survival signaling mediated by insulin-like growth factor 1 (IGF 1) in neurons; TNF-α inhibits tyrosine phosphorylation of insulin receptor substrate 2 (IRS2) and the activation of the survival enzyme, phosphatidylinositol 3′ kinase (►PI3K) and the



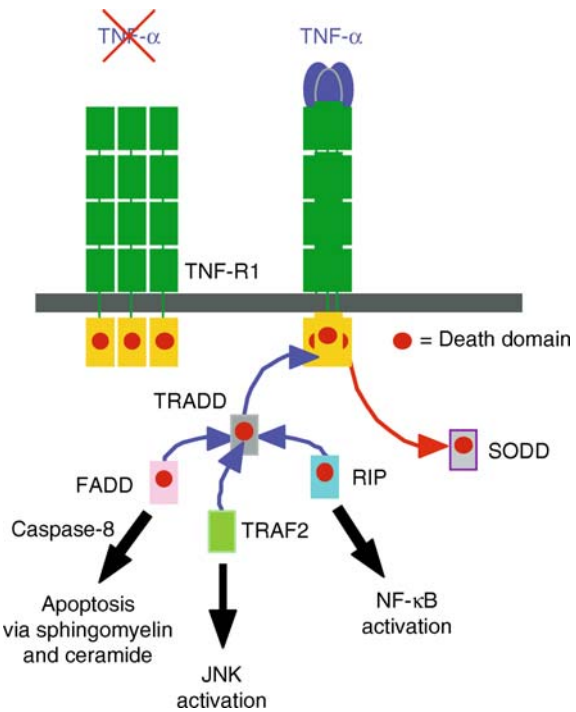
TNF-α in HIV Infection. Figure 2 Different regulatory elements in the HIV LTR domain (LTR: long terminal repeat).

formation of phosphatidylinositol(3,4,5)P3 (►luositoe lipids), known to play a pivotal role in the regulation of cell proliferation and survival.

However, as the effects of TNF-α on HIV replication, the effects of TNF-α in apoptosis may be opposite. TNF-α may be also a neuroprotective factor, for example, in excitotoxic conditions. Members of the family of TNF receptor-associated factors (►TRAF), particularly TRAF2 (Fig. 3), may play a major role in this process; it increases the TNF-α-induced ►JNK and NFκB activation known to favor cell proliferation, and a dominant-negative mutant enhances apoptosis.

Role of TNF-α in Cachexia, Opportunistic Infections and Tumors

TNF-α plays a major role in cachexia in HIV-infected patients but also in the development of opportunistic infections e.g. *Mycobacterium avium*, and tumors e.g. malignant lymphoma and ►Kaposi sarcoma. The immune activation and TNF-α synthesis induced by the Mycobacterium infection amplifies the infection of proximal cells by HIV and their level of viral replication. This viral replication accentuates the TNF-α secretion, and harmful connections between th1e replication of HIV or opportunistic pathogens, and immune activation or inflammation, are created. In Kaposi sarcoma, TNF-α favors the acquisition of the phenotype and functional features of AIDS-related KS spindle cells by endothelial cells. Moreover, TNF-α could be also responsible for deleterious effects of compounds delivered as treatment of opportunistic infections e.g. amphotericin B and cryptococcal meningitis.



TNF-α in HIV Infection. Figure 3 Different signaling pathways mediating biological effects of TNF-α. Tumor necrosis factor-a triggers the release of SODD and the DD domain of TNF-R1, that recruits TRADD via an interaction with the DD domain of this cell factor. Then, TRADD interacts with FADD, TNF-R-associated factor 2 (TRAF2) or kinase receptor-interacting protein (RIP). FADD is involved in the apoptotic signal cascade via caspase-8, TRAF2 in JNK activation, and RIP in NFκB activation.

Clinical Relevance of Molecules Inhibiting TNF-α Synthesis

In order to reduce the TNF-α -dependent HIV replication and the chronic inflammation that is associated with HIV infection, several inhibitors of TNF synthesis and TNF-receptor antagonists were evaluated in vitro or in vivo as therapeutical agent (e.g. RP-55778, pentoxifylline, chimeric humanized monoclonal antibody cA2). These molecules decreased in vitro TNF-α synthesis and HIV-1 replication. In vivo, pentoxifylline and cA2 were tested but no beneficial effects were observed on HIV viral load; only TNF-α synthesis was decreased. These data confirm that an inhibitor of TNF synthesis could not be used as pharmacological agent in monotherapy of HIV disease.

Systemic ►inflammation is decreased by highly active antiretroviral therapy (HAART); therefore, TNF-α and TNF-R2 may constitute reliable predictive markers of efficiency of HAART, or its failure. In tissues, particularly in CNS, HAART is less efficient to decrease HIV replication and chronic inflammation. As a consequence, anti-TNF-α molecules could be theoretically a good pharmacological strategy as adjuvant therapy. Nevertheless, caution is also required because it is important to preserve antimicrobial effects promoted by TNF-α against a variety of infectious agents, and particularly HIV.

TNF-Related Apoptosis Inducing Ligand

Amrik J. Singh, Roya Khosravi-Far
Department of Pathology, Harvard Medical School, Beth Israel Deaconess Medical Center, Boston, MA, USA

Synonyms

APO2 ligand; APO2L; TRAIL

Definition

TRAIL is primarily a membrane-bound cytokine that is one of several members of the ►tumor necrosis factor (TNF) gene superfamily. Members of this family induce apoptosis through engagement of cell surface ►death receptors (DRs).

Characteristics

Introduction

►Apoptosis, or programmed cell death, is a genetically conserved physiological event. Apoptosis plays a major role in the elimination of injured or unwanted cells in many physiological and pathological conditions such as normal development, defense against viral infection, dysregulated immune disease and uncontrolled cell growth. Thus, deregulated apoptosis might be related to serious human pathologies including neoplasia, degenerative disorders, and autoimmune diseases. Induction of apoptosis is an important mechanism for ►chemotherapeutic agents or ►radiation to kill cancer cells. Many endogenous cytokines also kill target cells via induction of apoptosis. Among these cytokines, several members of the TNF family have been extensively characterized: TNF-α, Fas ligand (FasL/APO1L/CD95L) and TRAIL.

TRAIL has a unique selectivity for triggering apoptosis in cancer cells, but not normal cells. In agreement with these observations, TRAIL knockout mice were more susceptible to experimental and spontaneous tumorigenesis and ►metastasis. Thus, TRAIL has been considered an important cellular factor both in natural defense mechanisms and as a potential therapeutic agent to treat human cancers.

TRAIL and Its Cell Surface Receptors

TRAIL was first identified in the mid 1990s by a homology search of an expressed sequence tag database with a highly conserved sequence motif characteristic for the TNF family members. The open reading frame for human TRAIL encodes a protein of 281 amino acids long. TRAIL is primarily expressed as a type II transmembrane protein in which the carboxyl terminus of the receptor-binding domain protrudes extracellularly. Similar to TNF-α and FasL, TRAIL can also be cleaved from the cell membrane by ►metalloproteases to yield a soluble and biologically active form. Structural studies have demonstrated that biologically active TRAIL protein forms a homotrimer. A critical cysteine residue that coordinates with a divalent zinc ion stabilizes this homotrimeric structure.

TRAIL has been shown to bind five different cell surface ►TRAIL receptor molecules: TRAIL-R1 (DR4), TRAIL-R2 (DR5/TRICK2/KILLER), TRAIL-R3 (DcR1/TRID/LIT), TRAIL-R4 (DcR2/TRUNDD), and osteoprotegrin (OPG). These receptor molecules, members of the TNF receptor (TNF-R) family, are type I transmembrane polypeptides. TRAIL-R1 and -R2 containing a cytoplasmic ►death domain (DD) that is essential for death signaling are able to transmit apoptosis-inducing activity of TRAIL across the cell membrane. By contrast, the other three receptors lack a functional death domain. Thus, they may act as ►decoy receptors, probably by competing with DR4 or DR5 for TRAIL. Unlike other TRAIL receptors, OPG is a soluble protein, originally identified to regulate osteoclastogenesis. Although OPG has been shown to interact with TRAIL, it has a much weaker affinity for TRAIL than other TRAIL receptors; therefore, it is unclear whether or not OPG can efficiently act as a decoy receptor for TRAIL under physiological conditions. Expression of TRAIL receptors closely parallels that of TRAIL, suggesting that most tissues and cell types are putative targets for TRAIL.

Organization of TRAIL-Induced Apoptotic Signaling

Biologically active trimeric TRAIL protein activates TRAIL receptors via inducing their oligomerization. Similar to other TNF family members, stimulation of the death domain-containing TRAIL receptors DR4 or DR5 recruits the cellular adaptor protein Fas-associated death domain (FADD/MORT1) through interaction of the death domains on each molecule. FADD, interacting with activated DR4 or DR5, then recruits initiator ►caspases (cysteinyl aspartases) such as procaspase-8 and/or procaspase-10, to form a ►death-induced signaling complex (DISC). Procaspase-8 or procaspase-10 molecules undergo autoproteolytic activation induced by proximity of these procaspases leading to the formation of active ►caspase-8 or caspase-10. Although procaspase-10 has been identified as a DISC component, the involvement of caspase-10 in initial death signaling activated by stimulated TRAIL receptors is controversial.

Once activated, caspase-8 initiates proapoptotic-signaling cascades leading to the cleavage of cellular factors. Active caspase-8 transmits its proapoptotic activity to executioner caspases, such as caspase-3 and caspase-7, through two main pathways. One proapoptotic signal pathway, termed the extrinsic or

mitochondria-independent pathway, directly activates executioner caspases. The other, termed the intrinsic or mitochondria-dependent pathway, involves mitochondrial events that activate the executioner caspases. The mitochondria-dependent pathway can be initiated, in part, by Bid (BH3 interacting death domain agonist), a ►Bcl-2 (B-cell lymphoma/leukemia-2) family member or through the uncontrolled production of ►reactive oxygen species (ROS). In the case of the former, caspase-8-cleaved Bid (tBid, truncated Bid) translocates to the mitochondria and induces cytochrome *c* release into the cytoplasm. The cytoplasmic cytochrome *c* binds to ►Apaf-1 (apoptotic protease activating factor-1) and participates in activation of another initiator caspase, caspase-9. This complex is referred to as the ►apoptosome. The activated caspase-9 is then able to activate executioner caspases. Thus, activation of executioner caspases represents the point at which the mitochondria-dependent and -independent proapoptotic signaling pathways, having diverged at caspase-8, meet again.

In most cell types, despite the existence of a mitochondria-independent TRAIL-induced apoptotic signal pathway, the engagement of the mitochondria-dependent pathway is required, as well, for efficient apoptosis. Mitochondrial events also include the release of SMAC (second mitochondria-derived activator of caspases)/DIABLO, apoptosis-inducing factor (AIF) and endonuclease G from the mitochondria. The release of SMAC/DIABLO from the mitochondria appears to be induced by t-Bid and occurs simultaneously with the release of other mitochondrial factors including cytochrome *c*.

Once activated, executioner caspases liberate a DNase termed CAD (caspase-activated DNase) by cleaving an inhibitor of CAD (ICAD/DFF-45). CAD activation leads to DNA fragmentation, a hallmark of apoptosis. Activation of executioner caspases also leads to the cleavage of numerous cytosolic, cytoskeletal and nuclear proteins.

Mechanisms to Attenuate TRAIL-Induced Apoptosis

Regulation of TRAIL-induced apoptosis occurs at multiple points and involves an intricate network of molecules and signals. The expression levels and subcellular localization of the factors in the TRAIL-induced ►apoptosis signaling cascade influence TRAIL signal strength and cellular susceptibility to TRAIL-induced apoptosis. Anti-apoptotic molecules and diverse extracellular cell survival signals influence TRAIL susceptibility of cells by attenuating cellular factors involved in TRAIL signaling.

Expression and mutations of the death domain-containing TRAIL receptors DR4 and DR5 can influence TRAIL susceptibility. ►DNA damaging agents, such as chemotherapeutic agents and ionizing radiation, have been shown to upregulate DR5 expression. These agents, however, also upregulate the TRAIL decoy receptors DcR1 and DcR2 that, consequently, may abrogate the augmented susceptibility due to upregulated DR4 and DR5. Since numerous DNA damaging agents have been shown to sensitize cells to TRAIL, whether or not TRAIL sensitization by such agents requires upregulation of DR5 is unclear.

Early studies suggested that expression levels of DcR1 and DcR2 might be associated with selective induction of apoptosis in tumor cells because the levels of these decoy receptors were higher in normal cells than in tumor cells. Subsequent studies, however, did not show a solid correlation between the expression levels of the decoy receptors and TRAIL susceptibility. This suggests that physiological levels of the decoy receptors might not be sufficient to inhibit TRAIL-induced apoptosis. Nevertheless, these decoy receptors may contribute to TRAIL resistance under certain physiological or pathological conditions, which may regulate the expression levels and subcellular localization of these decoy receptors.

In addition to receptor molecules, many cytosolic factors also modulate TRAIL-induced apoptosis. Caspase-8 plays a critical role in TRAIL death signaling. Accordingly, caspase-8-deficient Jurkat T cells were shown to be resistant to TRAIL-induced apoptosis. In childhood ►neuroblastoma, the gene for caspase-8 was found to be frequently silenced through ►DNA methylation and gene deletion. Furthermore, cell lines derived from these neuroblastoma tissues were resistant to TRAIL-induced apoptosis.

Cellular FLICE ((FADD-like interleukin-1β-converting enzyme)-like inhibitory peptide (c-FLIP)) is structurally related to procaspase-8 but lacks an active site for proteolytic action. This protein inhibits TRAIL-induced apoptosis by competing with procaspase-8 for FADD, preventing formation of a functional DISC. High expression levels of c-FLIP has been observed in many cancer cells that are TRAIL-resistant.

Anti-apoptotic ►Bcl-2 family members such as Bcl-2 and Bcl-X_L have been shown to inhibit apoptosis mediated by various death receptors. Overexpression of these proteins prevents the release of mitochondrial factors by interacting with proapoptotic Bax (Bcl-2-associated X protein) and Bad (Bcl-xL/Bcl-2-associated death promoter) and attenuating their apoptotic function. Overexpression of Bcl-2 and/or Bcl-X_L protects various TRAIL-sensitive cells from TRAIL-induced apoptosis. Bcl-2 and Bcl-X_L are also upregulated by many extracellular cell survival stimuli, including growth factors and ►hypoxia.

The deficiency of Bax results in a significant reduction of apoptosis induced by TRAIL. Treatment of Bax-deficient cells with TRAIL induces the formation of a functional DISC, caspase-8 activation and Bid

cleavage. Mitochondrial events, however, involving the release of mitochondrial factors, such as cytochrome *c* and SMAC/DIABLO, were impaired in Bax-deficient cells. The impaired mitochondrial events prevent post-mitochondrial proapoptotic signaling, including caspase-9 activation. Recently, a line of evidence showed that Bax requires Bak (Bcl-2 antagonist killer 1), another Bcl-2 family member, to act as a gateway for the tBid-induced release of mitochondrial factors. Cells lacking both Bak and Bax, but not cells lacking only one of these proapoptotic components, are completely resistant to tBid-induced cytochrome *c* release and apoptosis. Whether or not Bax-deficient cells express Bak remains to be determined.

Inhibitor of apoptosis protein (IAP) family members, including c-IAP1, c-IAP2, X chromosome-linked IAP (XIAP) and ►survivin, are potent inhibitors of endogenous caspases, which results in blockade of TRAIL-induced apoptosis. Specifically, IAPs exert their inhibitory activity by interacting with caspase-9, -3, and -7, but not caspase-8. SMAC/DIABLO interacts with IAP family members, antagonizing their inhibitory activity and releasing the bound IAPs from caspases. Caspases free of IAPs are more susceptible to proteolytic cleavage and activation. The protein levels of IAPs are regulated by diverse signals and mechanisms, including autoregulation by intrinsic ►ubiquitin protein ligase activity. This intrinsic E3 ligase activity has also been shown to regulate the levels of other proteins such as caspase-3 and SMAC/DIABLO. Downregulation or inactivation of IAPs induces spontaneous TRAIL-induced apoptosis.

Numerous growth factors and cytokines attenuate TRAIL-induced apoptosis. These survival signals regulate many factors involved in proapoptotic and anti-apoptotic signaling. ►Receptor tyrosine kinase (RTK)-mediated activation of the ►phosphatidylinositol-3 kinase (PI-3K)/protein kinase B (PKB/Akt) signaling axis leads to the direct phosphorylation of numerous downstream targets including proapoptotic factors Bad and caspase-9 as well as class O ►Forkhead box-binding family transcription factors (FOXOs). Phosphorylation of Bad and caspase-9 attenuates their proapoptotic activity, ablating the propagation of downstream proapoptotic signaling cascades. Phosphorylation of FOXOs prevents their translocation to the nucleus and results in the transcriptional blockade of genes implicated in promoting apoptosis and cell cycle arrest. A human ►prostate cancer cell line with constitutive activation of Akt is almost completely resistant to TRAIL, indicating that Akt plays a critical role in tumorigenesis and apoptosis.

Augmentation of TRAIL-Induced Apoptosis

Although TRAIL is a potent apoptosis inducer, some cells are resistant to TRAIL. Resistance to conventional therapies such as chemotherapy or radiation poses a major problem in cancer treatment. Subtoxic levels of chemotherapeutic agents facilitate TRAIL-induced apoptosis *in vitro* and *in vitro*, suggesting that this combination of therapy may be superior to TRAIL alone.

Actinomycin D (Act D) sensitizes many TRAIL-resistant cells to TRAIL-induced apoptosis. The combination TRAIL and Act D effectively killed TRAIL-resistant prostate cancer cell lines. In these cells, Act D downregulated XIAP. Act D also promoted TRAIL-induced apoptosis in TRAIL-resistant ►pancreatic cancer cells by decreasing the expression of c-FLIP. Etoposide increased expression of DR4 and DR5 and significantly promoted TRAIL-induced apoptosis in mammary epithelial cells. CPT-11 (Irinotecan/Camptosar®) and taxol were also observed to enhance TRAIL-induced apoptosis in cells from ►colon, ►breast, ►liver, and ►ovarian cancers. Adriamycin treatment also resulted in synergistic cytotoxicity and apoptosis for multiple myeloma that are resistant to TRAIL alone. Although the potential of a TRAIL combination therapy with chemotherapeutic agents is evident, in many cases the molecular basis of the synergistic action of chemotherapeutic agents for TRAIL is poorly understood.

Clinical Potential for TRAIL Therapy

TRAIL is a potent inducer of apoptosis in a wide variety of tumor cell lines *in vitro* and cancer xenograft animal models *in vivo*. Additionally, TRAIL did not show any detectable toxic side effects in safety tests using animals such as mice and chimpanzees.

From a clinical point of view, one of the most important issues in drug development is safety. Numerous studies have demonstrated stringent selectivity of TRAIL to tumor cells but not to normal or non-transformed cells. Recent reports, however, challenge this established apoptotic selectivity of TRAIL to tumors, demonstrating effective induction of apoptosis in cultured normal hepatocytes and neurons. These observations suggest the potential for damage to normal tissues and organs in clinical trials. Reevaluation of these results, however, reveals that the toxicity observed in cultured normal human hepatocytes is associated with the preparation method of the recombinant TRAIL protein. The non-histidine-tagged form of TRAIL versus the histidine-tagged variant is believed to be safer and more appropriate in clinical trials. Recently, an agonistic ►TRAIL receptor antibody specifically targeting DR5 was also shown to be a safe and effective cancer therapy similar to non-histidine-tagged TRAIL.

Perspectives

In the past, most TRAIL research has focused on its proapoptotic activity. Thus, the normal physiological functions of TRAIL remain poorly understood. Recent studies using TRAIL knockout mice and an animal model for the chronic blockade of TRAIL function have

shed light on the role of TRAIL in normal physiology and have demonstrated a key role for TRAIL in immune surveillance of tumor and infected cells. A better understanding of the physiological role of TRAIL will no doubt broaden the possible therapeutic applications of this molecule.

Still, little is known about TRAIL-triggered death signaling. In particular, the modulation of TRAIL death signaling, under the settings of a continuous challenge with extracellular cell survival stimuli, is poorly understood. Many of these stimuli have been shown to attenuate apoptosis. Identification of signaling pathways and cellular factors involved in cell survival will suggest mechanisms whereby potential targets can be specifically blocked, thus enhancing TRAIL activity in therapeutic applications.

Additionally, understanding the mechanisms by which chemotherapeutic agents act and sensitize cells to TRAIL-induced apoptosis will provide various new combination therapies for TRAIL. Although numerous chemotherapeutic agents have been shown to augment TRAIL-induced apoptosis *in vitro* and *in vivo*, toxicity tests of the combinations in cultured normal human cells have not been intensively investigated. Such tests would reduce the concerns raised in clinical trials and provide better combination therapies that have higher efficacy and less toxicity than individual therapies.

TRAIL has great potential to be further developed as a promising new drug for cancers and autoimmune diseases. Even though there is concern for toxic side effects, there remains great interest to determine whether clinical trials will produce similar results for human cancers as in animal models.

Tobacco

Definition

It is the common name of *Nicotiana* species, particularly of *Nicotiana tabacum*. It can be consumed in many forms although the most common is wrapped in the form of cigarettes. It is consumed worldwide and causes many types of cancers and other diseases due to mainly its content of different carcinogens. The nicotine is the substance causing addiction.

Tobacco Carcinogenesis

Stephen S. Hecht
The Cancer Center, University of Minnesota, Minneapolis, MN, USA

Definition

Refers to cancer induction by tobacco products and their constituents in laboratory animals and humans.

Characteristics

Tobacco Products and Human Cancer

Worldwide tobacco use continues to be immense and pervasive. According to estimates by the World Health Organization, there are about 1.3 billion smokers in the world and millions of smokeless tobacco users. Cigarette smoking causes well over one million cancer deaths annually worldwide, and accounts for 26% of all cancer mortality in developed countries. In addition to lung cancer, cigarette smoking causes the following types of cancer: oral cavity, pharynx, larynx, esophagus, pancreas, bladder, nasal cavity, stomach, liver, kidney, ureter, cervix, and myeloid leukemia. ►Secondhand tobacco smoke causes lung cancer in non-smokers, although the risk is less than in smokers. Smokeless tobacco products, such as moist snuff used orally, are accepted causes of oral cavity cancer and are implicated as causes of pancreatic cancer.

Tumor Induction in Laboratory Animals

Experimental studies demonstrate that cigarette smoke as well as its condensate cause cancer in laboratory animals. Inhalation studies have conclusively produced

cancer in the respiratory tracts of hamsters, rats, and mice. Cigarette smoke condensate has been extensively tested on mouse skin, where it consistently induces benign and malignant skin tumors. Smokeless tobacco has been shown to induce oral cavity cancer in rats.

Chemistry of Tobacco Smoke

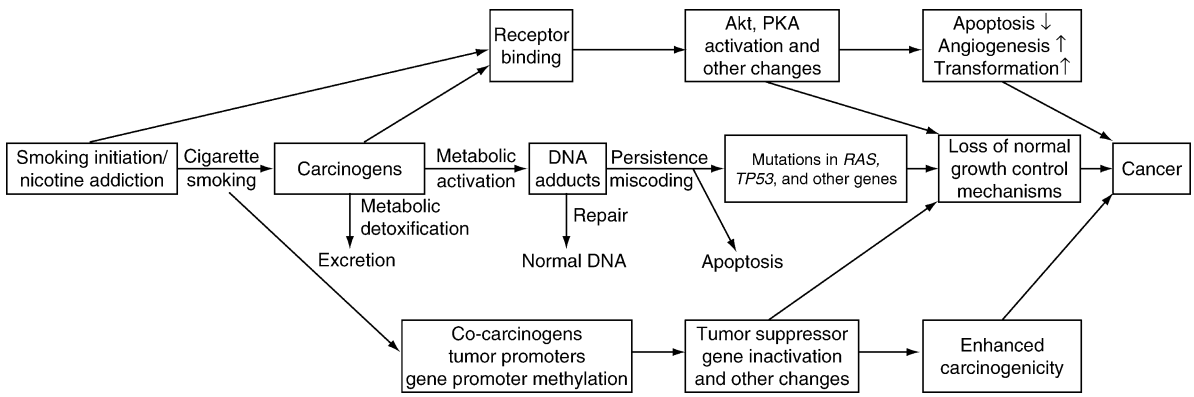
When cigarette tobacco is burned, mainstream and sidestream smoke are generated. Mainstream smoke is the material drawn from the mouth end of a cigarette during puffing. Sidestream smoke is the material released into the air from the burning tip of the cigarette plus the material which diffuses through the paper. Secondhand tobacco smoke is a composite of sidestream smoke and exhaled smoke. Mainstream smoke is an aerosol containing about 1×10^{10} particles per milliliter. About 95% of the smoke is made of gases, mainly nitrogen, oxygen, and carbon dioxide. The particulate phase of mainstream smoke contains more than 4,000 compounds. Many components are present in higher concentrations in sidestream than in mainstream smoke, but a person's exposure to sidestream smoke is far less than to mainstream smoke because of dilution with room air.

There are over 60 ►carcinogens in cigarette smoke that have been evaluated by the International Agency for Research on Cancer, and for which there is sufficient evidence for carcinogenicity in laboratory animals or humans, and 15 are rated as carcinogenic to humans. Carcinogens in cigarette smoke include ►polycyclic aromatic hydrocarbons (PAH) and their nitrogen containing analogues, ►*N*-nitrosamines, ►aromatic amines, heterocyclic aromatic amines, aldehydes, low molecular weight organic compounds such as benzene and 1,3-butadiene, and inorganic compounds. In addition, cigarette smoke contains tumor promoters, co-carcinogens, and toxicants such as acrolein and nitrogen oxides. The most important compounds with respect to human lung cancer appear to be the PAH, typified by benzo[*a*]pyrene (BaP), and the tobacco-specific *N*-nitrosamine ►4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), both considered as human carcinogens. Other compounds that may play a role as causes of lung cancer include 1,3-butadiene, benzene, aldehydes, and metals. Whereas PAH occur in all products of incomplete combustion, ►tobacco-specific *N*-nitrosamines are found only in tobacco products because they are derived from ►nicotine and related compounds. Tobacco-specific *N*-nitrosamines are the most prevalent strong carcinogens in unburned tobacco and are believed to play a significant role in the induction of oral cavity cancer by these products.

Mechanisms of Tumor Induction

Fig. 1 presents a conceptual framework for understanding mechanisms of tobacco carcinogenesis. While this scheme focuses on smokers, similar considerations apply to smokeless tobacco users. The central track of Fig. 1, involving exposure to carcinogens, the formation of covalent bonds between the carcinogens and DNA (►DNA adduct formation), and the resulting permanent mutations in critical genes of somatic cells is the major established pathway of cancer causation by cigarette smoke. While nicotine, the main known addictive agent in cigarette smoke, is not carcinogenic, each puff of each cigarette contains a mixture of carcinogens. Extensive data using specific ►biomarkers, including carcinogen metabolites in urine, DNA adducts, and protein adducts, demonstrate the uptake of these carcinogens by smokers and confirm the expected higher levels of their metabolites in urine of smokers than non-smokers.

Most cigarette smoke carcinogens require a ►metabolic activation process, generally catalyzed by ►cytochrome P450 enzymes (P450s), to convert them to forms that can covalently bind to DNA, forming DNA adducts. P450s 1A1 and 1B1, which are inducible by cigarette smoke via interactions with the aryl hydrocarbon receptor, are particularly important in the metabolic



Tobacco Carcinogenesis. Figure 1 Conceptual framework for understanding tobacco carcinogenesis.

activation of PAH. The inducibility of these P450s may be a critical aspect of cancer susceptibility in smokers. P450s 1A2, 2A13, 2E1, and 3A4 are also important in the activation of cigarette smoke carcinogens. Competing with the activation process is ►metabolic detoxification, which results in excretion of carcinogen metabolites in generally harmless forms, and is catalyzed by a variety of enzymes including ►glutathione-*S*-transferases and UDP-glucuronosyl transferases. The balance between ►carcinogen metabolic activation and detoxification varies among individuals and is likely to affect cancer susceptibility with those having higher activation and lower detoxification capacity being at highest risk. This is supported by considerable evidence from molecular epidemiologic studies of polymorphisms, or variants, in these enzymes.

The metabolic activation of carcinogens results in the formation of DNA adducts which are absolutely central to the carcinogenic process. Starting in the mid 1980s, extensive studies have demonstrated the presence of DNA adducts in human tissues. There is massive evidence, particularly from studies which use relatively non-specific adduct measurement methods, that adduct levels in the lung and other tissues are higher in smokers than in non-smokers, and some epidemiologic data link higher adduct levels with a higher probability of cancer development.

Cellular DNA repair systems remove DNA adducts and return the structure of DNA to normal. These systems include direct base repair by alkyltransferases, excision of DNA damage by base and ►nucleotide excision repair, mismatch repair, and double strand repair. If these repair enzymes are overwhelmed by DNA damage or for other reasons cannot efficiently perform their function, then adducts may persist, leading to higher probability of cancer development. There are polymorphisms in some DNA repair enzymes and the resulting deficient DNA repair can lead to a higher probability of cancer development, according to some molecular epidemiologic studies.

Persistent DNA adducts can cause miscoding during replication when DNA polymerase enzymes process them incorrectly. There is considerable specificity in the relationship between specific DNA adducts caused by cigarette smoke carcinogens and the types of mutations which they cause. G to T and G to A mutations are often found. Mutations have been frequently observed in the *KRAS* ►oncogene in lung cancer and in the *TP53* ►tumor suppressor gene in a variety of cigarette smoke-induced cancers. The cancer causing role of mutations in these genes has been firmly established in animal studies. The *KRAS* and ►*TP53* mutations observed in lung cancer in smokers reflect DNA damage by cigarette smoke carcinogens. In addition, numerous cytogenetic changes have been observed in lung cancer, and chromosome damage throughout the aerodigestive tract is strongly linked with cigarette smoke exposure. ►Apoptosis can remove cells with DNA damage, and serves as a protective counterbalance to these mutational events. The balance between mechanisms leading to apoptosis and those suppressing apoptosis will have a major impact on tumor growth.

While the central track of Fig. 1, proceeding through genetic damage, is clearly established as a major pathway by which cigarette smoke carcinogens cause cancer, epigenetic pathways also contribute, as indicated in the top and bottom tracks of Fig. 1. Nicotine and tobacco-specific nitrosamines have been shown to bind to nicotinic and other cellular receptors leading to activation of Akt (also known as protein kinase B), protein kinase A, and other changes, resulting in decreased apoptosis, increased ►angiogenesis, and increased transformation. Furthermore, the occurrence of co-carcinogens and tumor promoters in cigarette smoke is well-established. These compounds, while not carcinogenic themselves, clearly enhance the carcinogenicity of cigarette smoke carcinogens. This occurs through mechanisms which to date are poorly defined. Another important epigenetic pathway is enzymatic ►methylation of promoter regions of genes, which can result in gene silencing. If this occurs in tumor suppressor genes, the result can be unregulated proliferation.

The chronic exposure of smokers and smokeless tobacco users to the DNA damaging intermediates formed from tobacco carcinogens is consistent with our present understanding of cancer induction as a process which requires multiple genetic changes. Thus, it is completely plausible that the continual barrage of DNA damage produced by tobacco carcinogens causes the multiple genetic changes that are associated with cancer, and lead to a series of well established ►signal transduction mechanisms resulting in uncontrolled cell growth. While each dose of carcinogen from a tobacco product is small, the cumulative damage produced in years of usage is substantial.

Tobacco-Related Cancers

Alberto Ruano-Ravina, Mónica Pérez-Ríos, Juan Miguel Barros-Dios
Área de Medicina Preventiva y Salud Pública, Facultad de Medicina y Odontología, Universidad de Santiago de Compostela, C/San Francisco, s/n CP 15782

Definition

Refers to all those cancers where ►tobacco has an etiologic role either in active or in passive form. Due to the risk for health associated with tobacco consumption and also to its widespread use, tobacco-related cancers have been sometimes studied as a whole.

Characteristics

Tobacco as a Carcinogen

In 2000, 1.47 million deaths from cancer were attributable to smoking, accounting for 32% of all smoking attributable deaths. Tobacco is estimated to cause about 1 of each 5 cancer deaths worldwide, with a higher ►attributable fraction of 29% in high-income countries and 18% in low and middle-income regions. Although the most known tobacco product is cigaret, there are other types of tobacco products, such as pipes, cigars, bidis, or betel quids, among others. The last two ones are especially frequent in India. Scientific evidence has shown that all tobacco forms cause cancer.

Tobacco smoking was declared a human carcinogen in 1986 by the International Agency for Research on Cancer (IARC). Tobacco contains more than 4,000 different chemical substances and about more than 60 have been classified as human carcinogens or probable or possible carcinogens. These substances can be classified mainly in ►polycyclic aromatic hydrocarbons (PAHs) and ►tobacco-specific nitrosamines. The most characteristic substance of the first group is benzo[a]pyrene and of the second is 4-(methylnitrosamino)-1-(3-pyrydil)-1-(butanone), also known as NNK. ►Nicotine, which accounts for 0.5–4% by weight of tobacco leaves, is readily absorbed after tobacco use and is responsible for the addiction. Around the world, there are ~1.1 billions of smokers and a quite high percentage of them will develop a tobacco-related cancer.

When inhaled, tobacco smoke goes through the mouth, pharynx, larynx, main bronchus and then diffuses on the lungs, where its components entry in the circulatory system and are distributed into the body. These components are eliminated mainly on the urine. As can be deducted, all the organism of a smoker is exposed to the harm caused by tobacco, although not all the organs have the same susceptibility for developing a cancer caused by it.

Although it is not exactly known how the tobacco causes cancer on different anatomic locations, one of the most important mechanisms of action is the following: carcinogenic substances contained in tobacco smoke are activated in different cells into more reactive ones. These activated substances can bind to the DNA forming the so-called ►DNA adducts. These DNA-adducts have a covalent union among the activated carcinogenic substance (usually a PAH) and the double-strand of the DNA. If the adduct is not repaired by the replication machinery, it can cause a mutation when the cell replicates that can ultimately lead to cancer. It has also been observed a specific mutation in the ►*p53* gene due to tobacco exposure, especially in ►lung cancer. This mutation appears on the second position on codon 249 and is a guanine to thymine transversion.

Cancers Related with Tobacco

In general, the risk of developing a tobacco-related cancer depends mainly on the duration on smoking and on the number of cigarettes per day. Cumulative exposure increases with time, so the probability of developing a cancer increases with age. The risk of cancer diminishes from the time since quitting and, for some cancers, it can be the same of a never-smoker's risk after some years of abstinence. This is an important message to keep in mind, it is never too late to abandon the tobacco habit and the human health will be benefited with this decision at any age.

Lung Cancer. This is the best known cancer related to tobacco consumption and is the one which causes more deaths. About the 80% of lung cancer deaths are attributed to tobacco in males and the 48% in women worldwide. When comparing a smoker with a nonsmoker, the former has 20-fold more possibilities of developing lung cancer. In the appearance of the disease, the number of cigarettes per day along with smoking duration determines the risk, although the last factor is more important than the first. Some discrepancies exist on the time since quitting for the risk of lung cancer of a former smoker to be the same to the risk of a never smoker. There also exist interactions between tobacco smoking and other risk factors of lung cancer including occupation or radon exposure in the risk of developing the disease.

Oral Cavity and Pharyngeal Cancers. Tobacco is a risk factor for both cancers. Men smokers pose a risk tenfold higher versus never smokers while the average risk in women is fivefold higher. There is also an interaction with alcohol consumption.

Laryngeal Cancer. Tobacco causes laryngeal cancer, there is a strong dose–response relationship between tobacco and the risk of developing this cancer and also an interaction with alcohol intake.

Esophageal Cancer. Tobacco is a risk factor for this cancer; the average risk is about seven to eight times higher than the risk of lifetime nonsmokers. The risk of esophageal cancer due to tobacco increases with heavy alcohol consumption.

Pancreatic Cancer. Tobacco increases the risk of having a pancreatic cancer. For heavy smokers, the risk of this cancer is about three to five times higher than for never-smokers.

Bladder and Kidney Cancers. Smoking increases the risk of bladder, kidney, and renal pelvis cancers. An interesting finding was that the urine of smokers is more mutagenic than the urine of never smokers.

Cervical Cancer. Smoking women have a risk of cervical cancer two to three times higher than never smoking women. Although it is not clear if there is an interaction with human papillomavirus (HPV), it seems to exist a higher risk for smokers that are HPV positive.

Stomach Cancer. Tobacco causes stomach cancer. The risks of smokers versus nonsmokers are around 1.5–2 times higher. Although not confirmed, there seems to be an interaction with Helicobacter Pylori. This infection is harder to be eradicated in smokers compared with nonsmokers.

Acute Myeloid Leukemia. There exists a risk of acute myeloid leukemia for smokers versus nonsmokers and that is 1.5–2 times higher in smokers.

Evidence for Other Cancers

Some cancers have not been related to tobacco. Although the studies performed on them cannot allow us to conclude a causal relationship, we should not disregard a possible association, since there are methodological aspects in the design of such studies that make difficult to assess a possible relationship. In any case, it is true that these cancers would not pose the association (in terms of relative risk) of those cancers with a demonstrated causal association nowadays. For ovarian cancer and endometrial cancer, tobacco does not seem to pose a risk for the former but seems to reduce the risk of the latter. For colorectal cancer, although the published literature seems to indicate a higher risk for smokers, this is not conclusive. For liver cancer, although it seems to be a positive association among smoking and liver cancer, the studies are inconclusive due to the lack of adjustment for other risk factors of this cancer. For prostate, brain, and breast cancers, it seems that tobacco is not associated with the incidence of these cancers.

Passive Smoking

We refer to ►passive smoking exposure when we breath (or are exposed to, i.e., the case of the fetus) tobacco products produced by others. This is also called involuntary smoking. Passive smokers inhale the mixture of the mainstream smoke exhaled by the smoker and also the sidestream smoke produced by the smoldering cigarette. This complex mixture has essentially the same composition that the one to which smokers are exposed and the main difference with smokers is that this mixture is usually diluted on the air, although its concentration depends on many factors. It is called ETS (Environmental tobacco smoke) or more recently ►secondhand smoke. In 1992, the US Environmental Protection Agency (EPA) declared the ETS as a human carcinogen.

In 2006, the US Surgeon General has published an extensive report on the health consequences of involuntary smoking (see references for more information). It states that there is no risk-free level of exposure to secondhand smoke. Some of the results affecting cancer incidence related with this exposure are the following: ETS causes lung cancer, with exposed lifetime nonsmokers having a 20–30% more risk than nonexposed. The evidence is suggestive but not sufficient for nasal sinus cancer. Respecting prenatal and postnatal exposure to ETS the literature suggests that there could be some relationship with ►childhood leukemias, ►lymphomas, and ►brain tumors. These last relationships have to be demonstrated in more rigorous studies.

Conclusions

Tobacco use is nowadays one of the most, if not the most, hazardous agents for human health and also in the cancer appearance. This modifiable exposure causes many different types of cancer (along with cardiovascular and respiratory diseases among others) such as lung, oral cavity, pharynx, larynx, esophagus, bladder, kidney, pancreas, cervix, stomach, and acute myeloid leukemia. The best way for prevention is not to smoke and a clear message has to be given to current smokers that their risk of cancer diminishes immediately from the moment they decide to abandon the habit. A great effort has to be made in order to avoid tobacco use in the new generations. Passive smoking also entails a risk for health, for both adults and for infants. In adults, it causes lung cancer and in infants it could cause childhood cancer (to be further studied), along with other diseases and alterations different than cancer. Exposure to ETS should also be avoided at any concentration in every place.

Tobacco-Related Lung Cancer

Definition

Cancer that develops in the lungs those who smoke and/or use of smokeless tobacco for long-term period.

►Toxicological Carcinogenesis

Tobacco-Specific *N*-Nitrosamines

Definition

A group of carcinogens structurally related to nicotine which occur only in tobacco products.

►Tobacco Carcinogenesis

Tolbutamide

Definition

Is a potassium channel blocker; may be used in the management of type II diabetes if diet alone is not effective. Tolbutamide stimulates the secretion of insulin by the pancreas. Since the pancreas must synthesize insulin in order for this drug to work, it is not effective in the management of type I diabetes, where the beta-cells of islets of Langerhans are unable to produce insulin, for instance as the result of cell degeneration.

Tolbutamide Intravenous Test

Definition

A test to detect insulin-producing tumors (insulinoma). After a 1-g intravenous dose of tolbutamide, plasma insulin and glucose are measured at intervals up to 3 h; higher insulin responses and lower glucose values characterize patients with such tumors.

Tolerance

Definition

State in which the immune system shows a lack of reactivity toward certain antigens, notably those that are expressed by normal cells and tissues.

Tolfenamic Acid

Definition

A ►non-steroid anti-inflammatory drug (NSAID) that also induces Sp protein degradation.

Toll-Like Receptors

Kasper Hoebe
Cincinnati Children's Hospital Research Foundation, Divsion of Molecular Immunology Cincinnati, OH, USA

Definition

Toll-like receptors (TLRs) represent a family of proteins that are involved in the innate sensing of conserved microbial components. They are composed of an extracellular domain containing leucine-rich repeats and a cytoplasmic Toll/Interleukin-1 receptor/Resistance (TIR) domain that is responsible for mediating downstream signaling cascades and subsequent inflammatory response, ultimately leading to the eradication of infectious agents.

Characteristics

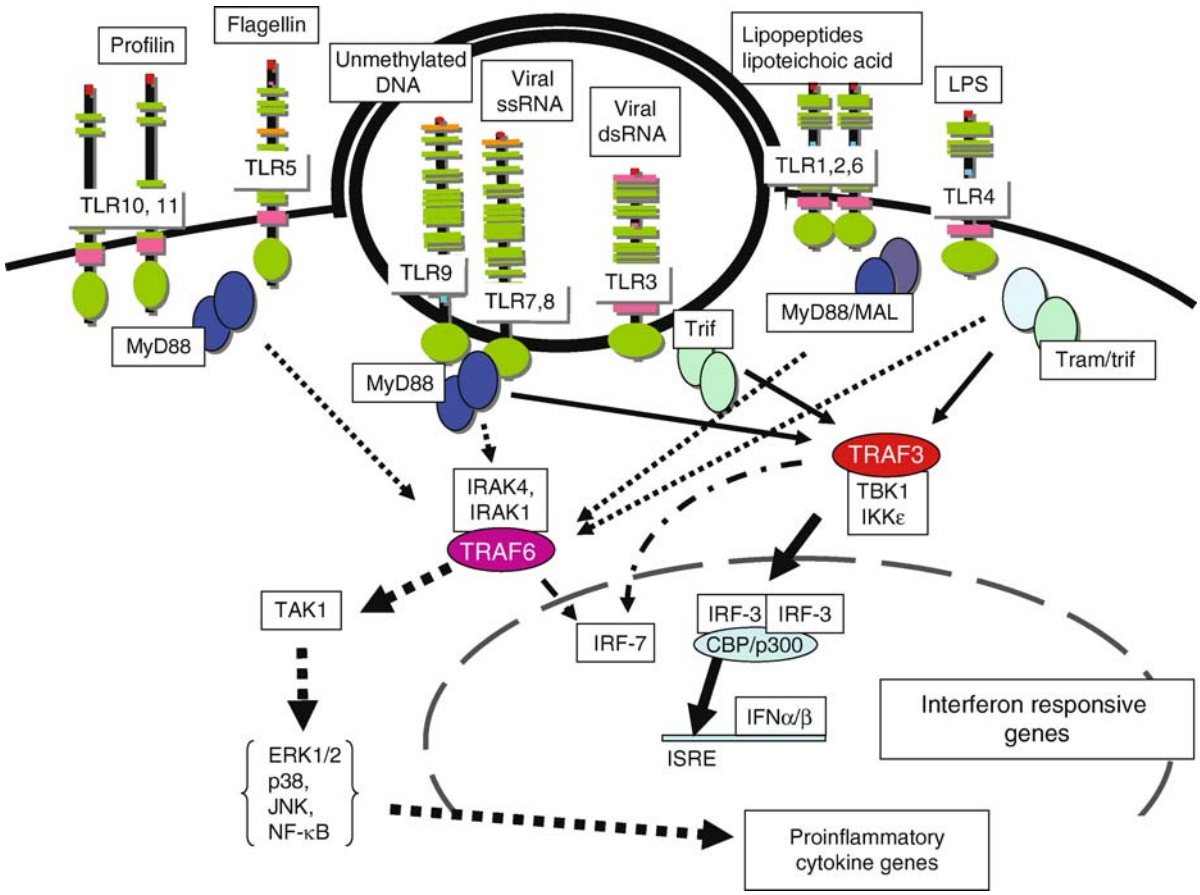
Toll-like receptors were originally described as proteins with homology to the protein Toll, which was first identified in *Drosophila melanogaster*. In flies, Toll served a regulatory function in the embryonic dorsoventral polarity, and was later shown to be an essential component of the *Drosophila* ►innate immune system. Based on the fact that Toll serves an immune function in *Drosophila*, it was proposed that TLRs might "activate ►adaptive immunity" in mammals, but the precise function of TLRs was revealed by forward genetics.

It was long recognized that the inflammatory responses induced by pathogens could be mimicked by specific molecules of microbial origin initially referred to as "endotoxin" and later shown to be lipopolysaccharide (LPS). It was then shown that LPS was capable of augmenting the adaptive immune response to a protein antigen, and in 1975, it became clear that the immuno-►adjuvant effect of LPS depended upon the integrity of a single locus known as *Lps*. It was not until 1998, that positional cloning revealed TLR4 as the membrane spanning component of the LPS receptor and this discovery accelerated our understanding of how the innate recognition of microbes occurs. Further genomic analysis revealed additional TLRs and to date a total of ten human TLRs (1–10) and 12 mouse TLRs (1–9; 11–13) have been described. Each of these recognizes a limited repertoire of broadly conserved molecules of microbial origin. For example, unmethylated DNA (common to prokaryotic genomes and DNA viruses) is recognized by TLR9; gram-positive bacterial lipopeptides are recognized by TLR2, acting in conjunction with TLRs 1 and 6, whereas TLR7 and TLR8 recognize single stranded viral RNAs or guanosine related analogues such as loxoribine and imidazoquinoline. All TLRs have a common cytoplasmic TIR motif that is believed to bind to intracellular adaptor molecules containing TIR motifs as well. Besides TLRs, the TIR motif is shared by the IL-1 receptor and IL-1 receptor-related family of signaling adaptor molecules. To date a total of five TIR domain-containing intracellular proteins have been identified that include MyD88, Mal (also known Tirap), Trif (also known as TICAM-1), Tram (also known as TICAM-2) and Sarm. Although most TLRs activate a common signaling pathway involving the adaptor molecule MyD88, other adaptor molecules involving Tram and/or Trif are able to activate a MyD88-independent pathway specifically downstream of TLR3 and/or TLR4. To date, many of the kinases involved in the TLR signaling pathways have been described and include for instance IRAK-1, IRAK-4 and Transforming Growth factor-β-activated kinase-1 (TAK1) (Fig. 1). Although TLRs are primarily expressed on cells of the innate immune system, including monocytes macrophages and dendritic cells, their expression is not limited to these cells and can also be found in lymphoid or non-hematopoietic cells. Whereas most TLRs are expressed on the surface of the cells, TLRs that recognize nucleotide structures (TLRs 3/7/8/9) are expressed in intracellular compartments such as endosomes and/or endosplasmic reticulum.

TLRs and Cancer Treatment

Although TLRs have limited involvement in the recognition, development or initiation of tumor growth, their immunostimulatory function has been utilized in cancer treatment in a variety of ways. Particularly, TLR7/8 agonists such as ►imiquimod, have long been used as topical immunomodulators, indicated for the treatment of external genital and perianal warts. This drug has also been approved for the treatment of superficial basal cell carcinoma and actinic keratoses, and also has activity against cutaneous metastases of malignant melanoma and vascular tumors. Many of the therapeutic effects of TLR activation can be attributed to the production of proinflammatory cytokines including tumor necrosis factor-alpha (►TNFα), type I ►interferons and interleukin 12. These cytokines have diverse functions that range from direct anti-tumor or pro-apoptotic effects (e.g. TNF), priming of natural killer (NK) cells (e.g. type I IFN) and the maturation of DCs leading to cytolytic T cell activation (e.g. type I IFN and IL-12).

Although many cells of the immune system are involved in tumor surveillance and tumor recognition, the induction of anti-tumor immune responses capable to suppress or eradicate tumors is generally poor. $CD8^+$ cytolytic T cells are the main cells involved in tumor eradication. As the antigens on tumor cells originate from self, most $CD8^+$ T cells have low avidity or are tolerant to these antigens and require a potent



Toll-Like Receptors. Figure 1 Toll-like receptors are key proteins in the innate recognition of microbial components. Upon recognition, TLRs initiate a signaling cascade that involves the TIR domain containing adaptor molecules MyD88, MAL/TIRAP, Trif and/or Tram, ultimately leading to NFκB activation resulting in proinflammatory cytokine production and/or translocation of IRF3/7 leading to type I interferon production (see text for further explanation).

stimulatory environment to become activated and acquire and execute their effector functions. Tumors create a suppressive environment by secretion of anti-inflammatory molecules, prevention of antigen expression and recruiting and inducing regulatory T cells on the site of tumor growth.

The design of experimental therapies is currently geared to implement TLR agonists to act on the above mentioned ►immunosuppressive pathways, thereby enhancing the induction of tumor specific cytolytic T cells. Specifically, vaccines based on the administration of dendritic cells containing tumor antigens or the administration of irradiated autologous or allogeneic tumor cells, have shown improved efficacy when coadministered with TLR-agonists. In both settings, the addition of TLR-agonists is thought to target DC function, leading to proinflammatory cytokine production and the subsequent upregulation of costimulatory molecules. In the event tumor cells were used as a vaccine therapy, only cell associated but not soluble TLR-agonists were shown to improve the adaptive immune response, suggesting targeting of TLRs with antigen in the same DC is crucial for efficacy. In addition, consistent TLR activation also leads to a reversal of T regulatory cell-mediated immune suppression and as such break tolerance towards self antigens. Together, these effects lead to an enhanced tumor-specific $CD8^+$ and $CD4^+$ T cell response ultimately leading to a regression and/or eradication of tumor growth.

Synonyms

Lingual cancer

Definition

Tongue cancers are malignant neoplasms of the tongue affecting oral tongue in the oral cavity or tongue base in the oropharynx.

Characteristics

Epidemiology

The world age standardized incidence is about 1.6 per 100,000 persons. The age standardized incidences of tongue cancer increase with age from about 0.1 per 100,000 persons in age group 15–19 years to about 7.5 per 100,000 persons in age group 65–75 years. The male to female ratio is about 1.5. The common predisposing factors of tongue carcinoma are smoking and drinking. Betel leaf chewing is the main reason for high incidences of tongue carcinoma in a few Asian countries including India and Taiwan.

Pathology and Genetic Aberration

The commonest cancer affecting the tongue is squamous cell carcinoma (►oral cancer) arising from the mucosal epithelial cells. Other pathology including minor salivary gland malignancies and sarcomas are rare. The development of cancer is believed to be a multi-step process with accumulation of many genetic abnormalities. A common genetic abnormality in tongue carcinoma is p53 (►p53 protein, biological and clinical aspects) mutation and its overexpression. The aberrantly underexpressed and overexpressed genes of tongue carcinoma are summarized in Table 1. These aberrantly expressed genes are involved in the control of cell cycle (►cell cycle target for cancer therapy), cell proliferation, ►apoptosis, cell ►adhesion, cell ►motility, and ►angiogenesis.

Clinical Features

The stepwise development of tongue cancer sometimes appears clinically in its premalignant stage as leukoplakia (white discoloration) or erythroplakia (red discoloration). These lesions histologically have various degrees of dysplasia. With further accumulation of genetic abnormalities involved in cancer development, these dysplastic epithelial cells become cancer cells which can invade and metastasize. The risk of malignant change of these dysplastic lesions is in the range of 5–20%. Carcinoma of tongue appears as nonhealing painful ulceration mostly at the lateral border of oral tongue. A typical ulcerative carcinoma of the lateral border of oral tongue with surrounding leukoplakia is shown in Fig. 1.

Subclinical Nodal Metastasis

Tongue carcinoma has high propensity of nodal metastasis even in its early stage. The nodal recurrence rate is 30–50% in untreated clinically N0 neck of T1-2 carcinomas. The commonest site of nodal metastasis is ipsilateral level II, and 95% metastatic nodes are found in the ipsilateral levels I, II, and III. Contralateral nodal metastasis and contralateral nodal recurrence are found only in less than 5% patients.

Most subclinical nodal metastases contain only tiny focal micrometastasis of less than 2 mm diameter within the lymph nodes or on the capsular lymphatic vessels. It has been reported that these cancer cells occupied a median of only 6% of nodal cross-sectional area of a lymph node and only 1% nodes in the neck contained micrometastasis. The small size of the micrometastasis amidst the large number of normal nodes in the neck would cause tremendous difficulty in the clinical detection. Although preoperative radiologic screening including CT, MRI, PET, or ultrasound scans are useful screening methods, they are not sensitive in the detection of most micrometastasis inside the small nonpalpable nodes. The risk of nodal recurrence of observed N0 neck remains high after these radiologic imaging screening.

TNM Staging and Prognostic Factors

The current TNM staging system for carcinoma of oral tongue is shown in Appendix 1. The largest tumor diameter has been used for many years in staging T1-3 oral tongue carcinoma. The largest diameter of oral tongue carcinoma is however either the tumor length or width. Tumor thickness is almost never the largest diameter of oral tongue carcinoma and therefore has no contribution to the current staging system.

It has been shown by many studies that tumor thickness, but not the largest dimension, is a significant independent prognostic factor in predicting subclinical nodal metastasis, local recurrence, and survival of oral

Tongue Cancer. Table 1 Aberrantly expressed genes of tongue carcinoma

Underexpressed genes	Overexpressed genes
►E-cadherin (83–85%)	Akt (►AKT signal transduction pathway in oncogenesis) (46%)
α-Catenin (94%)	AMFR (42%)
β-Catenin (89%)	►bcl-2 (9–26%)
γ-Catenin (83%)	Cerb-B2 (17–50%)
►Maspin (49%)	C-myc (75%)
P14 (21%)	c-Met (42%)
P15 (47%)	cyclin B1 (37%)
P16 (54–74%)	►cycin D1 (53–68%)
►P21 (40–73%)	EGFR (►epidermal growth factor receptor ligands) (32–34%)
P27 (72%)	EpCam (63%)
►PTEN (29%)	Ets-1 (►ETS transcription factor)(42%)
RARβ (►retinoid receptor crosstalk in cancer) (78%)	►Furin (76%)
	MMP-2 (►matrix metalloproteinases) (49–53%)
	MMP-9 (►matrix metalloproteinases) (78%)
	MT1-MMP (►matrix metalloproteinases) (35%)
	►Osteopontin
	$p34^{cdc2}$ (66%)
	p53 (►p53 protein, biological and clinical aspects) (27–62%)
	PCNA (32%)

	TIMP-2 (►matrix metalloproteinases) (43%)
	VEGF-A (►vascular endothelial growth factor) (67%)
	VEGF-C (►vascular endothelial growth factor) (49–100%)
	VEGFR-1 (►vascular endothelial growth factor) (89%)
	VEGFR-3 (►vascular endothelial growth factor) (74%)

tongue carcinoma. The thicker the tumor, the higher would be the risk of local recurrence, subclinical nodal metastasis and treatment failure. It is however still unresolved yet on the best cutoff thickness value for staging purpose. The proposed cutoff thickness values for prognosis or staging by various studies vary between 3 and 9 mm. The other important prognostic factor is histologic feature of perineural spread which is a significant risk factor of local recurrence after surgical treatment.

Pretreatment Assessment

Preoperative endoscopy and biopsy should be done to confirm the diagnosis and evaluate the extent of local tumor infiltration. Small neck nodes less than 1 cm along the jugular chain may not be palpable with fingers. Ultrasonography of the neck and ultrasound guided fine needle aspiration for cytology should be done to screen for presence of small nodal metastasis that may not be palpable.

Tumor thickness is an important factor for prognosis evaluation and treatment planning. Preoperative assessment of tumor thickness cannot be done with palpation. Intraoral ultrasonography using 7.5 MHz probe can be used to document the tumor thickness. MRI can also be used to assess the tumor thickness for preoperative evaluation of prognosis. Both T1 and T2 weighted MRI images can show the tumor thickness satisfactorily. MRI images in three-dimensional planes can also help the surgeon in the planning of surgical resection.

Tongue Cancer. Figure 1 Ulcerative carcinoma over the lateral border of tongue with surrounding leukoplakia.

Treatment Options

The treatment of oral tongue carcinoma remains controversial. Brachytherapy alone or surgery alone are each commonly used as primary treatment for early carcinomas by radiation oncologists and surgeons. The curative results of brachytherapy and surgery are similar for early stage carcinoma with over 90% local control. Either surgery or brachytherapy alone are not effective for stage III and IV carcinomas, combined surgery and postoperative chemoradiotherapy are recommended for advanced stage carcinomas.

Other less commonly practiced alternative treatment options include laser surgery or photodynamic therapy for early stage carcinomas. Concurrent intra-arterial regional chemoperfusion of high dose of cisplatin and radiotherapy may be considered as alternative treatment option for advanced T4 stage carcinoma.

Controversy of Elective Neck Dissection Versus Observation of N0 Neck

Since there is high risk of nodal recurrence of observed N0 neck of early tongue carcinoma, elective neck dissection is commonly practiced in many cancer centers worldwide. In retrospective studies of elective selective neck dissection versus observation of N0 neck, the regional recurrence rates could be reduced from 30–50% of observation to 10–15% after for elective selective I,II,III neck dissection. The regional recurrence related mortality rates could be reduced from 20–25% for observation to 4–10% for elective selective I,II,III neck dissection group. From the results of retrospective studies, elective neck dissection can reduce both initial regional recurrence rate and regional recurrence related mortality, and the reduction of node-related mortality contributes to long-term survival benefit.

Appendix I TNM stage of oral tongue carcinoma, AJCC/UICC 2002

Primary tumor (T)	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma *in situ*
T1	Tumor ≤2 cm in greatest dimension
T2	Tumor >2 cm but ≤ 4 cm in greatest dimension
T3	Tumor >4 cm in greatest dimension
T4	Tumor invades adjacent structures (e.g., through cortical bone, into deep extrinsic muscle of tongue, maxillary sinus, skin; superficial erosion of bone/tooth socket by gingival primary is not sufficient to classify as T4)
Regional lymph nodes (N)	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in single ipsilateral node, ≤3 cm in greatest dimension
N2a	Metastasis in single ipsilateral node, >3 cm but ≤6 cm
N2b	Metastasis in multiple ipsilateral nodes, all ≤6 cm
N2c	Metastasis in bilateral or contralateral nodes, all ≤6 cm
N3	Metastasis in lymph node >6 cm in greatest dimension
Distant metastasis (M)	
Mx	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
Stage	
0	Tis N0 M0
I	T1 N0 M0
II	T2 N0 M0
III	T3 N0 M0, T1-2 N1 M0, T3 N1 M0
IV	T4 N0-1 M0, anyT N2-3 M0, anyT anyN M1

There is however no prospective randomized study comparing the long-term benefit of elective neck dissection compared with observation in the treatment of N0 neck of early stage I and stage II oral tongue carcinoma. There is risk of mortality and morbidity of elective neck dissection. Both elective neck dissection and observation have their proponents in different cancer centers. Instead of performing elective neck dissection for all patients with early tongue carcinoma, patients should be informed of the possible choice of both treatment options of either observation or elective neck dissection of N0 neck. Observation is particularly suitable for patients with thin carcinomas of less than 3–4 mm. The risk of nodal recurrence of patients with thin tumors of 3–4 mm is in the range of

10–15%. Patients choosing observation treatment of N0 neck should be advised to have regular follow-up after primary treatment for early detection of nodal recurrence. Early nodal recurrence can be salvaged with modified or radical neck dissection successfully. Of those patients who cannot be closely followed up, elective neck dissection is a more suitable treatment of choice.

Outcome of Treatment

Local or regional lymph node recurrences account for over 90% of recurrences. Majority of local recurrences cannot be salvaged. Over 90% nodal recurrences of closely observed neck can be successfully salvaged with neck dissection. Of those patients with elective selective neck dissection of cN0 neck, the nodal recurrence rate of pN0 neck is less than 5% and is 30–40% for pN+ neck. Radiotherapy of pN+ neck is therefore advised. The overall 5-year disease free survival rates are in order of 90–100% for stage I, 60–80% for stage II, 30–50% for stage III and less than 20% for stage IV.

Tonsils and Adenoids

Definition

Prominent oval masses of lymphoid tissues on either side of the throat.

Topoisomerase II

Definition

Is a nuclear isomerase enzyme that alters the topology of DNA. This enzyme transiently cleaves double-stranded DNA, processes an unbroken double-strand DNA and then reanneals the broken strand. It is a major target for antineoplastic agents, such as anthracycline antibiotics, and ►etoposide.

►Adriamycin
►Topoisomerases

Topoisomerase II-DNA Cleavage Complexes

Definition

Transient intermediates in the catalytic cycle of DNA ►topoisomerase II.

►Replication Factories and Foci
►Topoisomerases

Topoisomerase III

Definition

Topoisomerase III is an enzyme that changes the degree of supercoiling of DNA by cutting one strand of DNA and passing an intact strand through the break.

►Topoisomerases
►Poly(ADP-Ribosyl)ation

Topoisomerases

Definition

Enzymes that produce a reversible covalent complex with DNA through which another DNA strand or duplex is passed. Passage of strands or duplexes changes DNA topology introducing or removing supercoils. Type I and III topoisomerases pass single

strands and change DNA supercoiling in units of one. Type II topoisomerases pass duplex DNA and change DNA supercoiling in units of two. ►Topoisomerase II nuclear enzymes induce transient breaks in both strands of the DNA helix simultaneously. The clinically used DNA topoisomerase II inhibitor ►etoposide is known to induce DNA double strand breaks.

►Celastrol
►Decatenation G2 Checkpoint
►Genistein

TOR

Definition

The phosphatidylinositol (PI) kinase homologue TOR ("target of ►rapamycin") is the cellular target of the complex of FK506 binding protein (FKBP) with the immunosuppressant rapamycin. TOR is part of the general mitotic signaling pathway involving a tyrosine kinase, a phosphatidylinositol 3-kinase (PI3K), Akt/PKB kinase, p70S6 kinase (p70S6k) and 4E-BP1 (PHAS-I). TOR is conserved from yeast to mammals and is also known as FRAP, RAFT, RAPT ►mTOR refers to mamalian TOR.

►Autophagy

Torisel

Definition

An inherited condition characterized by benign tissue masses that form on the skin, hair follicles, and gums during infancy, and in the breasts following puberty, and are associated with a higher risk for developing cancers.

►Temsirolimus

Torsade de Pointes

Definition

A peculiar ventricular tachyarrythmia, with characteristic ECG (lengthened QT interval), that can be self limiting or degenerate into ventricular fibrillation and result in death. Drugs that prolong action potential duration (as a result of a reduction in repolarizing current), induce early after depolarizations, which can generate ectopic beats and increase the spatial dispersion of repolarization, which in turn increases the possibility for reentry, have the potential to cause this tachyarrythmia.

►Lead Optimization

Totipotent

Definition

Able to give rise to all cell types. In mammals, only the fertilized egg and early cleavage stage blastomeres are truly totipotent. Cells of the inner cell mass and ►embryonal stem (ES) cells are unable to differentiate into cells of the trophectoderm lineage.

►Adult Stem Cells

Totipotent Stem Cells

Definition

Are produced from the fusion of an egg and sperm cell. Cells produced by the first few divisions of the fertilized egg are also ►totipotent. These cells can differentiate into embryonic and extraembryonic cell types.

►Adult Stem Cells

Toxic Epidermal Necrolysis

Definition

A life-threatening, exfoliative mucocutaneous disease in which much of the skin becomes intensely red, blisters, and peels off in the manner of a second-degree burn. It is thought to be an idiosyncratic reaction to a drug or other chemical agent.

►Rituximab

Toxicity

Definition

Refers to unwanted biological activity.

►ADMET Screen

Toxicity Testing

►Preclinical Testing

Toxicokinetics

Definition

Refers to study of the fate of administered drug and metabolites in the animals used in toxicity studies. The term usually refers to those studies of drug disposition that form part of toxicity study rather than specialist studies of adsorption, distribution, metabolism and excretion conducted as separate studies.

►Preclinical Testing

Toxicological Carcinogenesis

Takuji Tanaka
Deaprtment of Oncologic Pathology, Kanazawa Medical University, Kanazawa, Japan

Synonyms

Chemical carcinogenesis; Experimental carcinogenesis

Definition

In the broadest possible sense, ►carcinogenesis is a process of generation of benign and malignant neoplasm. Agents such as viruses, radiation, and chemicals are able to induce ►cancer in humans and experimental animals. However, the importance of chemicals as a cause of cancer has long been recognized in basic and clinical studies, and is emphasized by the epidemic of ►tobacco-related lung cancer in the twentieth century. Carcinogenesis may be considered as a form of toxicity in which cells achieve a different steady state from the normal and do not respond normally to homeostatic mechanisms. Carcinogenesis induced by chemicals is called "toxicological (chemical) carcinogenesis." Basic and clinical research in the field of toxicological carcinogenesis has led to many major advances, ranging from the fields of epidemiology and international human studies to laboratory research on mechanisms involved in the complex processes that are associated with the initiation and development of malignant disease (cancer).

Many chemical carcinogens have been identified, and their effects documented in experiments in which animals exposed to the agents at the maximum tolerated dose develop neoplasm. Toxicological carcinogenesis and ►human cancer epidemiology studies have clearly identified specific chemicals that can act as human carcinogens in both occupational and environmental settings. The main groups of relevance to human disease include ►polycyclic aromatic hydrocarbons, aromatic amines, nitrosamines, ►alkylating agents, and heterocyclic amines. Cancer resulting from exposure to chemicals in the environment has taken on new importance. Knowledge about the mechanisms and natural history of cancer development from toxicological carcinogenesis as well as epidemiology of human cancer is critical in the control and prevention of human neoplastic disease.

Characteristics

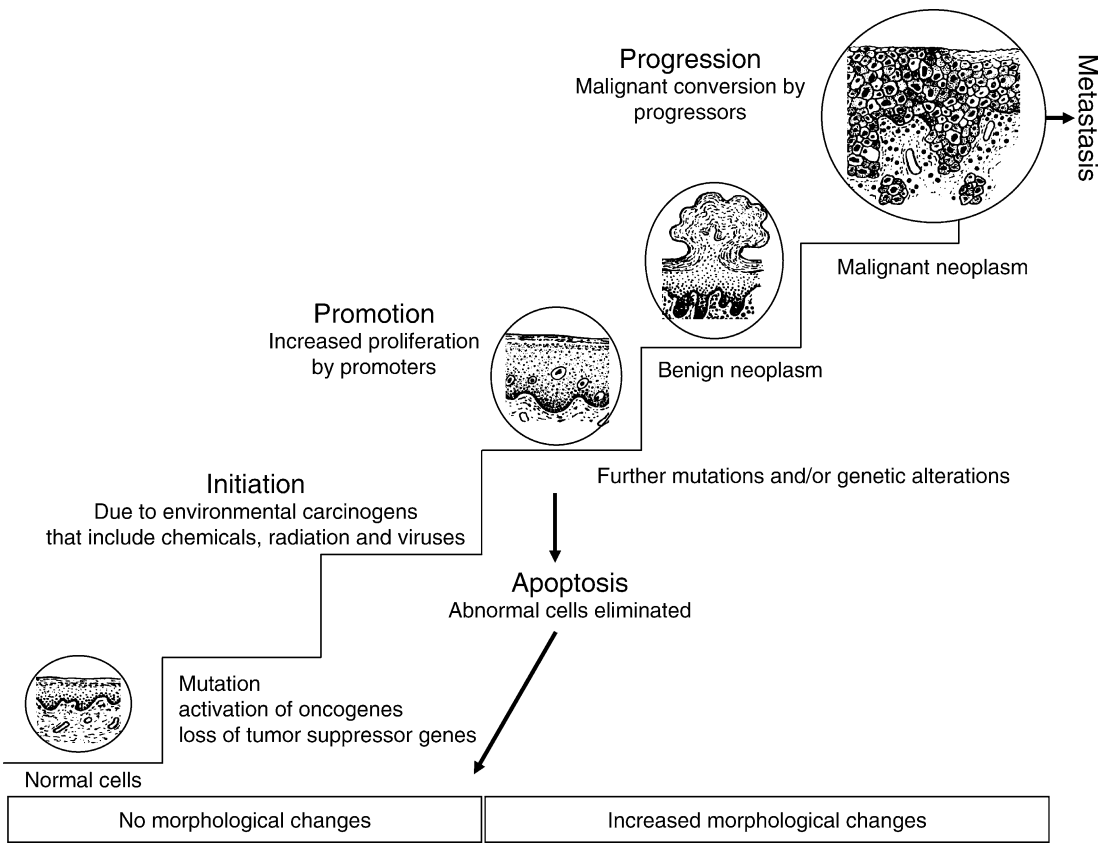
Mutagens are agents that can permanently alter the genetic constitution of a cell. The most widely used screening test, the Ames test, uses the appearance of mutants in a culture of bacteria of the *Salmonella* species. Approximately 90% of known carcinogens are mutagenic in this system. Moreover, most, but not all, mutagens are carcinogenic. This close correlation between carcinogenicity and mutagenicity presumably occurs because both reflect ►DNA damage. The *in vitro* mutagenicity assay is a valuable tool in screening for the carcinogenic potential of chemicals. Cultured human cells are also being increasingly used for assays of mutagenicity.

Chemical carcinogens may cause development of neoplasm either directly or indirectly. They can be grouped into two main classes according to the mechanism by which they stimulate development of neoplasm: (i) ►Genotoxic carcinogen causes direct damage to DNA by forming chemical:►DNA adducts. The abnormal areas of DNA are prone to damage in replication and some adducts are resistant to normal ►DNA repair mechanisms. (ii) ►Non-genotoxic carcinogen is a carcinogen for which there is no evidence of direct interaction with cellular DNA. This type of carcinogen can be divided into two subgroups. ►Mitogenic carcinogen binds to receptors on or in cells and stimulates cell division without causing

direct DNA damage. In experimental skin carcinogenesis such agents have been shown to bind to and activate ►protein kinase C, causing sustained epidermal hyperplasia. ►Cytotoxic carcinogen produces tissue damage and leads to hyperplasia with cycles of tissue regeneration and damage. In some cases it is believed that cytokines generated in response to tissue damage act as mitogenic factors. Chemical carcinogens can be further divided into two groups: (i) ►Direct-acting carcinogen: the agent is capable of directly causing neoplasia. (ii) ►Procarcinogen: the agent requires conversion to an active carcinogen. This conversion takes place through normal metabolic pathways. In procarcinogens the ►cytochrome P450 (CYP) monooxygenase system plays an important role in conversion in many instances. ►Detoxification reactions also occur, the accumulation of carcinogen being determined by a balance between: (i) dose of procarcinogen; rate of detoxification and elimination; and (ii) rate of conversion to the active form.

Three stages have been defined in toxicological carcinogenesis (Fig. 1). Studies of toxicological carcinogenesis among experimental animals have shed light on the individual stages in the progression of normal cells to cancer. From these studies, one can define three stages (►multistep development) of toxicological carcinogenesis:

1. *Initiation* is the first stage and likely represents mutations in a single cell. The nature of the initial changes in cells is still uncertain. In experimental toxicological carcinogenesis in skin, the Harvey ►*ras* gene has been identified as being frequently mutated. This gene is involved in epidermal proliferation and when it becomes abnormal epidermal cells are less responsive to signals that normally cause terminal differentiation. Only relatively few genes have been identified as being mutated in other animal models of toxicological carcinogenesis.
2. *Promotion* follows initiation and is characterized by clonal expansion of the initiated cell. Induction of cell proliferation takes place at this stage. The altered cells do not exhibit autonomous growth, but remain dependent on the continued presence of the promoting stimulus, including an exogenous chemical or physical agent or an endogenous mechanism, such as hormonal stimulation. In this phase of carcinogenesis a promoting agent brings about increased cell proliferation. Promotion is initially reversible if the promoting agent is withdrawn.



Toxicological Carcinogenesis. Figure 1 Toxicological carcinogenesis as a multi-step process.

3. *Progression* is the third stage, in which growth becomes autonomous and is independent of the carcinogen or promoter. At this stage, additional genomic changes presumably endow cells with a relative growth advantage that, in turn, results in their further clonal expansion. Cancer is the end result of the entire sequence and is established when the cells acquire the capacity to invade and metastasize. If there is persistent cell proliferation, initiated cells acquire secondary genetic abnormalities in oncogenes, which first lead to dysregulation and eventually to autonomous cell growth. The ultimate end-point of progression is development of an invasive neoplasm.

The various tests that have been applied to identifying agents with carcinogenic potential may be classified into several general areas on the basis of the time involved in the assay: short, medium, and long. These include short-term tests for mutagenicity (e.g., the Ames test), gene mutation assays *in vivo* (e.g., The LacZ mouse, the LacI mouse, the LacI rat), assay for chromosomal alterations (e.g., ►micronucleus assay, sister chromatid exchange), measurement of primary DNA damage *in vitro* and *in vivo*, and chronic bioassays for carcinogenicity (e.g., chronic 2-year bioassay, medium-term bioassays-Ito model, multi-stage models of neoplastic development, transgenic and knockout mice as models of carcinogenesis).

History

It is widely recognized that exposure to chemicals in the workplace and the environment can contribute to human cancer risk. This was first indicated in 1775 by Dr. Pott, who attributed scrotal skin cancers to prolonged exposure to soot in London chimney sweeps. In 1914, Dr. Boveri first hypothesized that cancer was a genetic disease, prior to the discovery of the genetic material. In 1915, Dr. Yamagiwa and co-workers successfully induced skin cancer in rabbits by painting their ears continuously with benzene solutions of tar. In the 1930s Dr. Kenneway and co-workers demonstrated that pure chemicals isolated from coal tar could also produce tumors in animals. In the 1950s there were parallel discoveries of the structure of the DNA double helix and its establishment as the hereditary material and mutagenic potential of ionizing radiation and certain chemical carcinogens in humans and experimental systems, and extensive investigations into the relationship between chemically induced mutations and human cancer. The 1980s saw the elucidation of the first oncogenes that appeared to be responsible for the initiation of cancer as first predicted by Dr. Boveri. This era also saw the development of the Ames *Salmonella* bacterial mutagenesis assay (the Ames test) and similar genetic toxicology assays. These developments firmly established the basic paradigm for the field of toxicological carcinogenesis: chemicals capable of induction of mutations are presumed to be carcinogens. It was predicted that any chemical or physical agent that can covalently damage DNA could also cause mutations through its DNA-damaging mechanism, and hence can be a carcinogen. The data that followed in the 1990s appeared to strongly support this central assumption, as numerous chemicals that were initially tested for DNA damage or mutations were also carcinogens in experimental animals. Since then, our understanding of the molecular basis of cancer has improved substantially. In addition, investigations into the molecular basis of toxicological carcinogenesis, as well as more extensive human cancer epidemiology studies using modem molecular tools, have greatly expanded our knowledge in this area.

TP53

Pierre Hainaut
International Agency for Research on Cancer (IARC), Lyon, France

Synonyms

p53

Definition

The TP53 ►tumor suppressor gene is located on chromosome 17p13.1 and encodes an ubiquitous phosphoprotein of molecular mass 51–53,000, essentially expressed in the nucleus. This gene is frequently inactivated by somatic mutation or by loss of alleles in many common human cancers. More than 25,000 such mutations have been described so far. Inherited, heterozygous mutations have been identified in about 400 families with ►Li-Fraumeni Syndrome and Li-Fraumeni-like syndromes (LFS and LFL), characterized by the early occurrence of cancers at multiple organ sites. TP53 belongs to a ►p53 family that also includes TP73 (1p36) and P63 (3p28). In contrast with TP53, these two genes have a restricted, tissue specific and developmental expression pattern and are not frequently mutated in cancer.

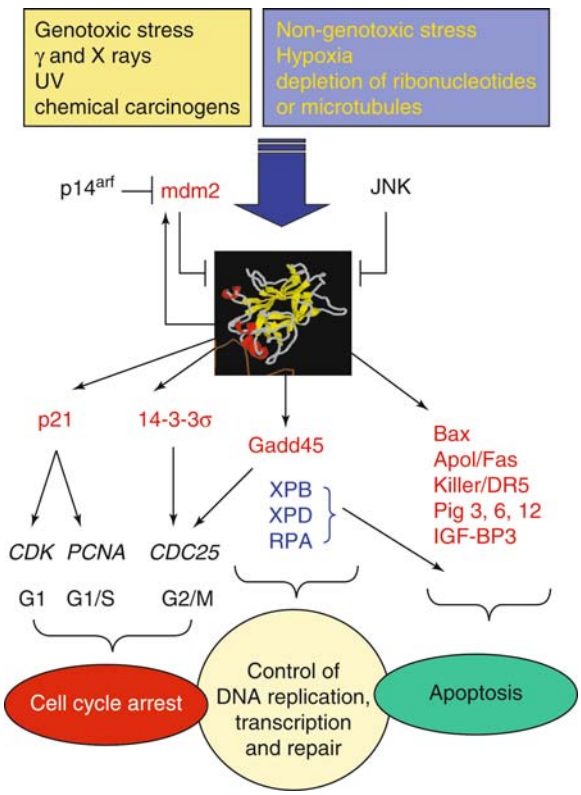
The p53 protein is a latent ►transcription factor that is activated in response to multiple forms of physical and chemical stress to exert diverse, complementary effects in the regulation of cell proliferation, genetic integrity and survival. These effects include:

- Induction of ►apoptosis,
- Control of cell ►division through regulation of ►cell-cycle progression in G1 and G2, ►centrosome duplication and mitosis, and
- Modulation of DNA replication and ►repair of DNA.

The main function of the p53 protein is to act as an "emergency brake" to prevent the proliferation of cells with damaged genetic material, caused by exposure to genotoxic agents (Fig. 1). In a broader context, the protein acts as an integrator of multiple exogenous and intracellular signals to regulate cell proliferation during replicative ►senescence, differentiation and development. Inactivation of TP53 in mice resulted in accelerated development of multiple tumors, while a fraction of p53-deficient embryos displayed a lethal defect in neural tubule closure, resulting in exencephaly.

Characteristics

The TP53 gene spans 20 kb and contains 11 exons, the first one being non-coding. The coding sequence contains five regions showing a high degree of conservation in vertebrates, located in 2, 5, 6, 7 and 8. An ►orthologue has recently been described in

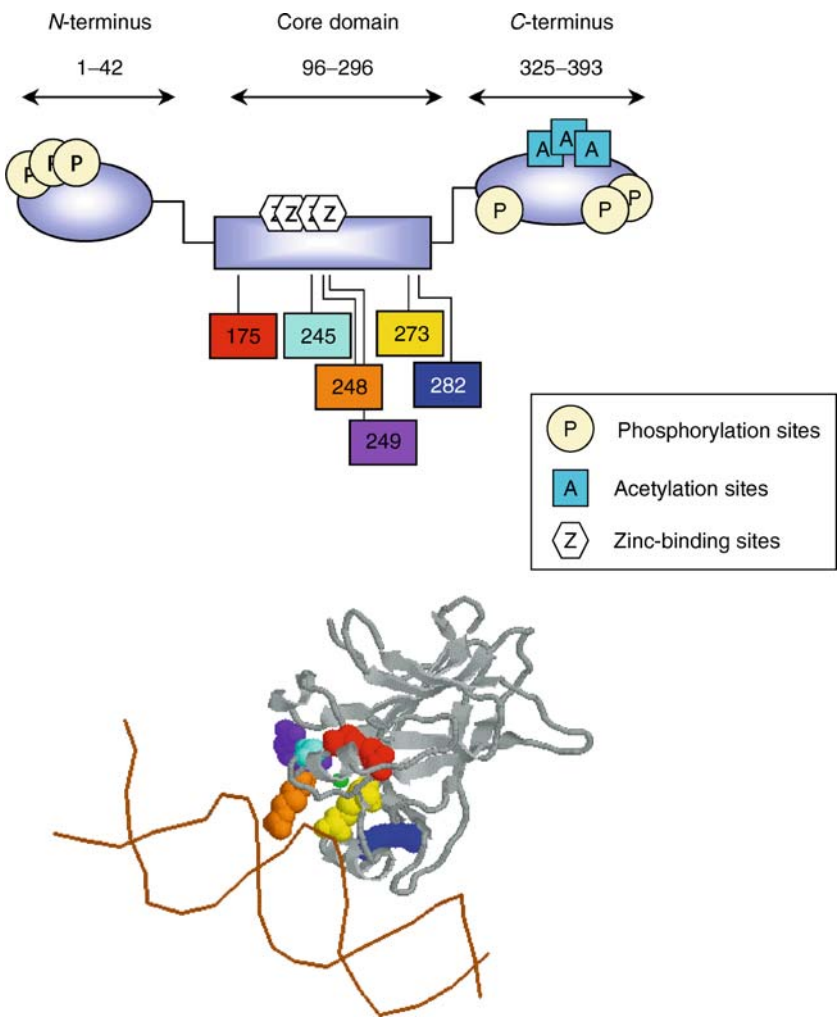


TP53. Figure 1 The p53 pathway. The p53 protein is induced in response to various forms of stress and mediates a set of coordianted, anti-proliferative responses including cell-cycle arrest, control of replication, transcription, repair and apoptosis. Blue: factors that bind to p53 and that are regulated by protein interactions. Red: factors that are regulated by p53 at the transcriptional level.

Drosophila. Several ►gene polymorphisms are identified in the human population, with ►allele frequencies that vary with ethnic origin. However, there is only limited evidence to prove that these polymorphisms play a role in tumor susceptibility.

The TP53 gene does not contain a conventional TATA box, but is under the control of several ubiquitous transcription factors, including ►NFkB, Sp1 and Jun. It is expressed in the form of one major transcript of 2.8 kb and several isoforms generated by alternative splicing or use of an alternative promoter, intron 4.

The protein contains 393 residues and is organized in a hydrophobic, central core (residues 110–296, encoded by exons 5 to 8), flanked by an acidic N-terminus and a basic C-terminus (Fig. 2 *top*). The N-terminus contains two complementary transcriptional activation domains, with a major one at residues 1–42 and a minor one at residues 55–75, specifically involved in the regulation of several pro-apoptotic genes. The central core is made of a scaffold of two β-sheets supporting a set of flexible loops and helices stabilized by the binding of an atom of zinc. These loops and helices make direct contact with DNA sequences containing inverted repeats of the motif RRRC(A/T). The C-terminus contains the main nuclear localization signals and oligomerization domains (residues 325–366). The active form of the protein is a tetramer (in fact, a pair of dimers). The extreme C-terminus has multiple regulatory functions and exerts a negative control on sequence-specific DNA binding activities. Both N- and C-terminal regions contain



TP53. Figure 2 Diagram of the p53 protein structure. *c*: linear structure, showing the three main structural domains. Codon numbers of the main mutation hotspots are shown as coloured boxes. Sites of post-translational modifications are shown as "P" (phosphorylations), "A" (acetylations) and "Z" (zinc binding sites). *bottom*: 3-D structure of the central core of p53 in complex with target DNA. Hotspot residues are shown in the same color code as above.

multiple post-translational modification sites, while only a few have been identified so far in the central core (see Table 1).

Upstream of p53: Signaling of DNA Damage

The p53 protein is constitutively expressed in most cells and tissues as a latent factor. Due to its rapid turnover (5–20 min), the protein does not accumulate unless it is stabilized in response to a variety of intracellular and extra cellular stimuli. Signals that activate p53 include diverse types of ►DNA damage (strand breaks, bulky adducts, oxidation of bases), blockage of RNA elongation, ►hypoxia, depletion of ►microtubules, ribonucleotides or growth factors, modulation of cell ►adhesion and alteration of polyamine metabolism. Most of the current knowledge of p53 protein activation is derived from studies using DNA strand breaks as inducing signals.

The main regulator of p53 protein activity is ►mdm-2, a protein which binds p53 in the N-terminus (residues 17–29); it conceals its transcription activation domain, redirects p53 from the nucleus to the cyclasm and acts as a ►ubiquitin ligase to target p53 for degradation by the ►proteasome. The MDM-2 gene is a transcriptional target of p53, thus defining a regulatory feedback loop in which p53 controls its own stability. The p53/mdm-2 complex is regulated by Arf (Alternative Reading Frame), a 14 kD protein encoded by the p16/CDKN2A gene.

The kinetics, extent and consequences of p53 activation vary according to the nature and intensity of the inducing signals. In response to ionizing radiation, activation of the p53 protein is thought to proceed through several consecutive steps, with first phosphorylation of p53 in the N-terminus by kinases involved in the sensing of DNA damage such as Atm

TP53. Table 1 Factors involved in the activation and post-translational modification of p53

Factor	Biochemical function/activated by p53	Interaction with p53
PARP	ADP-ribose polymerase/DNA strand breaks, nucleotide depletion	ADP-ribose polymers bind to p53
HMG-1	High mobility group 1/?	Binding to N-terminus or to DNA-binding domain
E6AP	E6 accessory protein/ubiquitin-mediated degradation	Binding to p53
Hif-1	Hypoxia-inducible factor/Hypoxia	Binding to p53
14-3-3 s	Cell-cycle regulator/ionizing radiations	Binding, C-terminus (Ser-376)
p300/CBP	Histone acetyl-transferases/co-activators of transcription	Binding, N-terminus acetylation, C-terminus
c-abl	Tyrosine kinase/irradiation, DNA-strand breaks	Binding, proline-rich region
mdm-2	oncogene/negative control of p53	Binding, residues 13–29
NO	Nitric oxide/oxidative stress, inflammation, irradiation	Oxidation of cysteines in DNA-binding domain
Cdc2/Cdk2-Cyclin A/B	Cell-cycle dependent kinases	Phosphorylation of Ser-315; forms complexes with p53
cdk7-cyclin H	Component of TFIIH	Phosphorylation of Ser-33
CKII	Kinase/UV	Phosphorylation of Ser-389; forms complexes with p53
MAPK	Mitogen-activated protein kinase/UV?	Phosphorylation, Thr-73 and 83 (mouse p53)
ATM	Kinase/ionizing radiations	Phosphorylation, Ser-15
DNA-PK	Kinase/UV	Phosphorylation, Ser-15 and Ser-37
Chk-2	Cell-cycle-dependent kinase	Phosphorylation, Ser-20
JNK/p38	Stress-activated kinases/UV	Phosphorylation, Ser-34, mouse p53
PKC	Protein kinase C	Phosphorylation, Ser-378
CKI	Kinase/?	Phosphorylation, several N-terminal serines (including Ser-6 and Ser-9)
p19arf	Cell-cycle inhibitor, alternative product of CDKN2A	Prevents p53-mdm2 interactions
Ref-1	Redox-repair enzyme/oxidative stress, hypoxia	Reduction of cysteine in DNA-binding region binding to C-terminus

(the product of the ►ataxia telangiectasia mutated gene) and Chk-2 (a cell-cycle regulatory kinase). These phosphorylations contribute to the dissociation of the p53/mdm-2 complex and stabilize the protein. Second, p53 binds co-activators with acetyl-transferase activity such as ►p300/CBP co-activators and pCAF. These factors acetylate p53 in the C-terminus. These processes, as well as other coordinated post-translational modifications of the C-terminus, induce conformational changes that turn the protein into an active form with a high affinity for specific DNA binding sites. The third step involves redox regulation of sensitive cysteines within the DNA-binding domain of the protein. This three-step mechanism may account for p53 induction in response to most forms of DNA damage.

Downstream of p53: Cell-Cycle Control, Apoptosis and DNA Repair

Once activated, p53 exerts its effects through two major mechanisms: transcriptional control (activation or repression of specific genes) and complex formation with other proteins. Important downstream effectors of p53 (Table 2) include regulators of ►cell-cycle ►checkpoints (in G1/S, G2 and during mitosis), factors involved in the signaling of apoptosis, and components of the transcription, replication and repair machineries. At the cellular level, activation of p53 most frequently results in either cell cycle arrest (mostly in G1 and/or G2/M) or apoptosis. How a given cell "chooses" between cell cycle arrest and apoptosis in response to specific stimuli may depend upon many factors, such as the nature and intensity of the stress, as well as the cell type. In many tissues, p53 plays a role in drug-induced apoptosis and is thus an important effector in the response of cancer cells to chemo- or radio-therapy. In addition, loss of p53 function results in deficient cell cycle arrest, inefficient ►mitotic spindle checkpoint, aberrant centrosome duplication, premature re-entry into S phase, ►genomic instability and ►aneuploidy.

TP53. Table 2 Some important downstream effectors of p53 functions

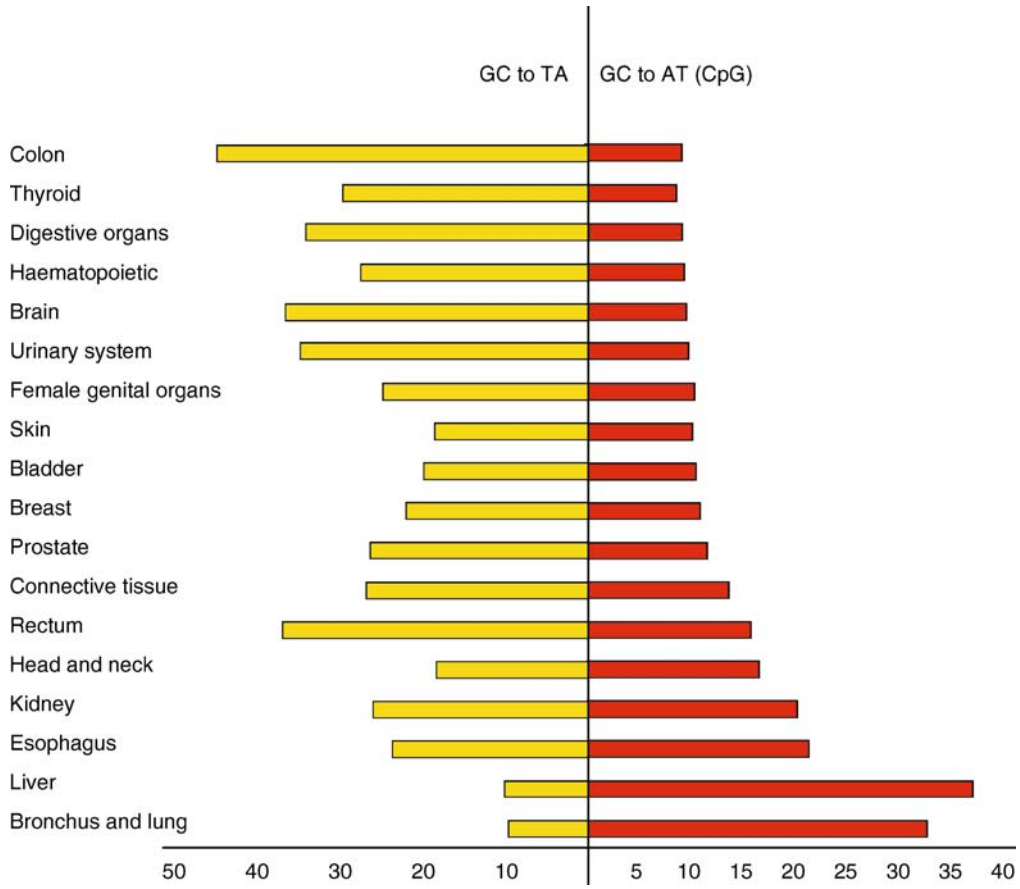
Factor	Activity	Mode of regulation	Function
Apo-1/Fas/CD95	Death signaling receptor	Transcriptional activation?	Apoptosis
Bax-1	Dominant-negative inhibitor of bcl2	Transcriptional activation	Apoptosis
Bcl-2	Repressor of apoptosis	Transcriptional repression	Apoptosis
IGF-BP3	Inhibitor of IGF-I	Transcriptional activation	Apoptosis
Killer/DR5	Death signaling receptor	Transcriptional activation	Apoptosis
P85	Regulatory subunit of PI3 kinase	Transcriptional activation	Apoptosis
Pig-12	Glutathione transferase homologue	Transcriptional activation	Apoptosis
Pig-3	Quinone oxidase homologue	Transcriptional activation	Apoptosis
Pig-6	Proline oxidase homologue	Transcriptional activation	Apoptosis
IGF-I	Growth factor	Transcriptional repression	Apoptosis?
IL-6	Survival factor	Transcriptional repression	Apoptosis?
thrombospondin-1	Inhibitor of angiogenesis	Transcriptional activation	Apoptosis?
Gadd45	Binding to PCNA	Transcriptional activation	Cell-cycle arrest ?
BTG2	Inhibitor of proliferation	Transcriptional activation	Cell-cycle arrest, G1
p21waf-1	Inhibitor of CDK2–4 and 6	Transcriptional activation	cell-cycle arrest, G1 and G2/M
cyclin A	Cell-cycle regulation, S phase	Transcriptional repression	Cell-cycle arrest, G1/S
cyclin G	Cell-cycle regulation	Transcriptional activation	cell-cycle arrest?
GPx	Glutathione peroxidase	Transcriptional repression	Control of oxidative stress
NOS2/iNOS	Inducible Nitric Oxide synthase	Transcriptional repression	Control of oxidative stress
COX2	Inducible cyclooxygenase	Transcriptional repression	Control of oxidative stress?
Pig-1	Galectin-7	Transcriptional activation	Differentiation?
PCNA	Auxiliary subunit of polymerase δ	Transcriptional activation	DNA repair/replication
RPA	Replication protein A	Inhibition by protein binding	DNA repair/replication
ERCC2/ERCC3	Helicases, TFIIH complex	Activation by protein binding	DNA repair/transcription
P53RR2	Ribonucleotide reductase homolog	Transcriptional activation	DNA repair?
TBP	TATA box-binding protein	Inhibition by protein binding	Inhibition of transcription
Mdm-2	Oncogene	Transcriptional activation	Repression of p53
MDR-1	Multi-drug resistance	Transcriptional repression	Resistance to chemotherapy

Clinical Relevance

The TP53 gene is often inactivated by ►missense mutations, in contrast with many other tumor suppressors such as ►APC, ►RB1, ►BRCA1 or p16/►CDKN2A that are inactivated by gene deletion or truncation. The mutations described to date mostly occur in the region of the gene encoding the DNA binding domain. Most of these mutations impair DNA binding by disrupting the structure of the domain or crucial contact points between the protein and target DNA. About 30% of missense mutations affect six "hotspot" codons (175, 245, 248, 249, 273 and 282) (Fig. 2 *bottom*). The other mutations are scattered over 300 different codons. Mutations are very common in the invasive stages of many epithelial tumors. A database of all published mutations is available at the International Agency for Research on Cancer (►IARC TP53 database, http://www-p53.iarc.fr/).

In many cancers, the patterns of mutations show variations, revealing clues about the mechanisms responsible for the formation of the mutations. Specific carcinogen-induced mutations have been identified in ►hepatocellular carcinoma (mutations induced by ►aflatoxins in sub-Saharan Africa and in south-east Asia), in skin tumors (double transitions at adjacent cytosines, a typical signature of mutagenesis by UV in squamous and in basal cell carcinomas) and in lung cancers (G to T transversions associated with exposure to tobacco smoke; ►tobacco carcinogenesis; (Fig. 3).

The usefulness of TP53 mutation detection in molecular pathology is still a matter of debate. As mutation often results in the accumulation of the protein, ►immunohistochemistry (IHC) has often been used as a criterion to detect TP53 abnormalities. However, positive IHC does not always correlate with mutation as several common missense mutants, as well as most



TP53. Figure 3 Prevalence of two common mutation types: G to T transversions and C to T transitions at dipyrimidine (CpG) repeats in tumors of various organs. Tumors with high prevalence of G to T transversions often have a low prevalence of transitions and vice-versa. G to T transitions are a common molecular signature of many environmental carcinogens, such as tobacco smoke components (lung and esophageal cancers) or dietary mycotoxins (liver cancer).

frameshift and nonsense mutants, do not result in protein accumulation. Several well-established methods have been described for the detection of mutations in the TP53 gene, including SSCP (Single Stranded Conformation Polymorphism) analysis, TTGE (Temporal Temperature Gradient Electrophoresis), yeast-based functional assays and, recently, micro-array hybridization assays.

TP53 gene mutations are good markers for the clonality of tumor lesions. In many tissues, mutation correlates with bad prognosis and poor response to therapy, but TP53 mutation has been shown to behave as an independent marker of prognosis only in rare cases such as breast and head and neck cancers. Recent evidence suggests that the nature and position of the mutation may help to predict poor response to treatment. Detection of circulating anti-p53 antibodies as well as of free plasmatic DNA containing mutant TP53 may be of interest in the early detection of cancer lesions.

TP53 is the target of several experimental therapeutic approaches. Gene transfer of wild type TP53 into cancer cells has been tested in several human tumors. However, the effects reported to date are limited and, at best, transient. Another approach is based on the use of cytolytic viruses selectively replicating in TP53-deficient cells (►ONYX vectors). Several pre-clinical studies have investigated the use of small lipophilic coumpounds or peptides to activate TP53 function or to restore the activity of mutant proteins.

Definition

A potent antitumor tetrahydroisoquinoline alkaloid in clinical development originally derived from a marine tunicate and now obtained by a synthetic process developed by PharmaMar starting from microbially produced cyanosafracin B.

Characteristics

Crude aqueous ethanol extracts of the ascidian, or sea squirt, *Ecteinascidia turbinata* were shown to have powerful immunomodulating and antiproliferative properties as early as 1969 but the active principles were not identified until the early nineties. The first six alkaloids that were characterized received the names ecteinascidins 729, 743 trabectedin, (Fig. 1), 745, 759A, 759B, and 770, in accordance with the molecular masses ascribed to these compounds. They revealed a unique chemical structure consisting of a novel pentacyclic skeleton composed of two fused tetrahydroisoquinoline rings (subunits A and B) linked to a 10-member lactone bridge through a benzylic sulfide linkage and attached through a spiro ring to an additional ring system (subunit C) made up of either tetrahydroisoquinoline (as in trabectedin) or tetrahydro β-carboline (as in ET-736). The first two subunits bear a clear structural resemblance to microbially derived safracins and saframycins, and also to sponge-derived renieramycins, all of them less potent anticancer agents than ecteinascidins. On the other hand, a reactive α-carbinolamine or hemiaminal (N-C-OH) group is also present in naphthyridinomycins, quinocarcins, and pyrrolo[1,4]benzodiazepine antibiotics such as ►anthramycin, sibiromycin and tomaymycin. By analogy to these related antibiotics, the potent biological activity of trabectedin and other ecteinascidins was rapidly associated with their ability to form covalent adducts to DNA following *in situ* dehydration of the carbinolamine group to an iminium intermediate that is covalently attached to the amino group of guanine in the minor groove.

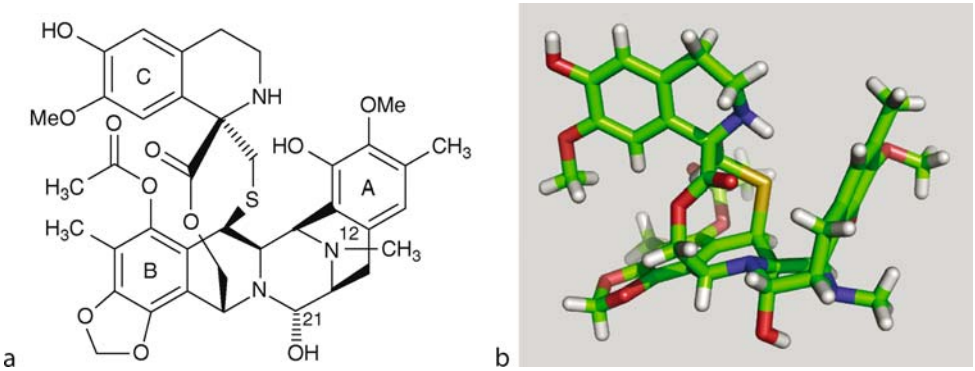
Ecteinascidia turbinata was first harvested from the wild and then successfully grown by the Spanish pharmaceutical company, PharmaMar, in aquaculture facilities in Spain (near Formentera island, in the Mediterranean sea). Subsequently, several synthetic schemes were developed to produce the multigram quantities required for clinical studies worldwide and overcome the limitation of the very low yield (0.0001%) of trabectedin in its natural source.

The first enantioselective total synthesis of trabectedin was achieved in 1996 but industrial manufacturing was made possible through a synthetic route involving the conversion of cyanosafracin B, readily available by fermentation of the bacterium *Pseudomonas fluorescens*, to trabectedin in a very short and straightforward way developed by PharmaMar.

Structural and Biophysical Characterization of Trabectedin-DNA Adducts

Direct evidence that trabectedin alkylates duplex DNA at the exocyclic amino group of guanines was provided by a variety of experiments including gel electrophoresis, DNA footprinting, nuclear magnetic resonance (NMR) spectroscopy, and band shift assays, as well as molecular modeling studies. As a result of this work, it was found that trabectedin was protonated on N12 at physiological pH and a role for hydrogen bonding in sequence recognition and orientation in the DNA minor groove was demonstrated, with TGG, CGG, AGC, GGC, and AGA being established as the preferred DNA triplets for stable adduct formation, and much higher rates of reversibility being measured for site-directed AGT- versus AGC-containing adducts.

The proposed mechanism for activation takes advantage of the increased strength of the hydrogen bond between the proton on N12 and the hydroxyl group on C21 as the trabectedin molecule approaches the minor groove and is desolvated. This proton, which is essential for both sequence recognition and adduct



Trabectedin. Figure 1 Chemical formula and three-dimensional stick representation of the X-ray crystal structure of trabectedin.

stabilization, would then catalyze the dehydration of the carbinolamine yielding the reactive iminium intermediate that undergoes nucleophilic attack at C21 by the exocyclic amino group of the guanine. Since a similar mechanism operates in the activation of pyrrolo[1,4] benzodiazepine antibiotics, it appears that Nature ensures the reactivity of these carbinolamine-containing molecules by the inclusion of an internal catalytic proton adjacent to the leaving hydroxyl group.

As a consequence of trabectedin bonding, the double helical structure is only minimally perturbed except for widening of the minor groove and a net smooth bending towards the major groove due to the introduction of positive roll. This latter feature was novel among minor groove DNA monoalkylating agents as covalent modification of N3 of adenine in AT-rich regions by (+)-CC-1065 and related compounds is accompanied by bending of the DNA into the minor rather than the major groove. Furthermore, if multiple binding sites for trabectedin are properly phased in a relatively short stretch of DNA, the imposed cumulative curvature could bring closer together specified fragments not contiguous in primary sequence, and the drug could be serving a surrogate protein function. On the contrary, binding of three trabectedin molecules in a head-to-tail fashion to three adjacent optimal binding sites would result in no net DNA curvature because the localized bends, brought about by the increase in roll at the sites of covalent attachment, would cancel out over virtually one turn of the helix. In fact, the DNA structure in one such complex (containing the sequence TGGCGGCGG) was shown to be intermediate between the canonical A and B forms of DNA, thereby strongly resembling the conformation that DNA adopts when bound to the consecutive C_2H_2 zinc fingers that are present in transcription factors (►Transcription factor) such as EGR-1 and Sp-1 (which bind to the major groove of GC-rich regulatory sequences in many gene promoters) or that observed in the hybrid double helix of template DNA paired to nascent RNA in the active site of ►RNA polymerase II (RNAPII) elongation complex.

The close contacts and the hydrogen-bonding interaction network that are established between trabectedin and DNA on both sides of the covalent adduct involve both DNA strands and therefore give rise to a significant increment in the stability of the resulting drug-DNA complexes. As a consequence, notable increases in the temperature of thermal denaturation of duplex DNA and substantial blockade of the helicase activities of both simian virus (SV40) large tumor antigen (T-antigen) and bacterial UvrABC and RecBCD enzymes have been reported for DNA oligonucleotides containing trabectedin adducts. This hampering or prevention of strand separation is also expected to result in stalled replication and transcription forks, as observed for a variety of conventional interstrand crosslinkers (e.g. nitrogen mustards, mitomycin or cisplatin). An added advantage in the case of trabectedin would be the minimal distortions inflicted on the normal DNA structure that could help evade some of the recognition and repair mechanisms used for the processing of crosslinks produced in the major groove by these other agents.

Biological Activity

In vitro cytotoxicity studies with trabectedin and other ecteinascidins established subnanomolar potencies against L1210 and P388 mouse leukemia cells, as well as human A549 lung cancer, HT29 colon cancer, MEL-28 melanoma cells and human tumors explanted from patients. Tumor-specific responses and concentration-dependent relationships were observed when a soft agar cloning assay was used to determine the effects of a continuous exposure of trabectedin at different concentrations. These experiments clearly indicated that the duration of exposure to trabectedin was an important factor in human tumors thereby pointing to preferential administration schedules in clinical trials.

In vivo activity was then evaluated in several mouse tumor models and a variety of human tumors xenografted into nude mice, including melanoma, non-small-cell lung carcinoma and ovarian cancer. Long-lasting, complete or partial regressions were observed in both chemo-sensitive and marginally cisplatin-resistant xenografts at the maximum tolerated dose (MTD) but no activity was seen in highly chemo-resistant tumors such as MNB-PTX-1, MEXF 514 and LXFA 629. Importantly, the absence or incomplete cross-resistance with cisplatin and the comparable efficacy against the ovarian carcinoma xenografts justified the clinical assessment of trabectedin in ovarian cancer.

The activity parameters for trabectedin in the panel of 60 human tumor cell lines of the National Cancer Institute (NCI) Anticancer Drug Screen revealed a rather unique profile that encouraged further development as an anticancer agent. The COMPARE algorithm (►COMPARE analysis) established a very high correlation coefficient (0.96) with ►chromomycin A_3, an aureolic acid derivative shown to give rise to a pattern of distinct bands in human metaphase chromosomes, thus suggesting similarities in their apoptotic mechanisms. Despite the fact that these two compounds display very different modes of binding to DNA (i.e. covalent versus noncovalent, carbinolamine activation versus ion-mediated dimerization, etc.), both share a strong binding affinity for some common DNA sites, such as the self-complementary hexanucleotide TGGCCA, to which two trabectedin molecules can bind in a tail-to-tail fashion, each covalently bonded to a different strand. Furthermore, these two natural products are known to exert at least part of their cytotoxicity by interfering with DNA replication and transcription. Thus, at physiologically relevant concentrations (1–100 nM), trabectedin has been

shown to effectively inhibit intracellular DNA synthesis by decreasing replication origin activity and by inducing unusual replication intermediates that may be blocked in fork progression. In addition, trabectedin is able to abrogate the transcriptional activation of a number of genes, including those encoding the multidrug resistance P-glycoprotein (*MDR1*), heat shock protein 70 (*hsp70*), the cell cycle inhibitor p21 ^{Cip1} (*p21*), and collagen α1(I) (*COL1A1*). Nevertheless, global gene expression profiling of trabectedin-treated cancer cells has revealed rather complex patterns of both up- and down-regulation. The reported effects on *MDR1* and additional in vitro data showing enhancement by trabectedin of the cytotoxicity exerted by other chemotherapeutic agents that are substrates for P-gp/MDR1 suggest that combination treatment may be valuable in the clinic.

The extremely low concentrations of trabectedin that are necessary to cause cell cycle arrest and cell death are suggestive of a *trans*-acting mechanism that probably operates through one or more cellular DNA damage response pathways or checkpoints. In this respect, it is notable that cell sensitivity to trabectedin appears to be somehow dependent on a proficient transcription-coupled ►nucleotide excision repair (TC-NER) machinery, and more specifically on the presence of selected components that are implicated in ►xeroderma pigmentosum and Cockayne syndromes. Thus, the initial observation that hamster cells deficient in XPB, ERCC1 or CSB, as well as human XPA and XPC cells, had reduced sensitivity to trabectedin was followed by the report that a human colon carcinoma cell line selected for increased (~20-fold) resistance to trabectedin (following continuous exposure to increasing concentrations of this drug for 1 year) had a truncated and inactive form of the XPG structure-specific endonuclease. Furthermore, drug sensitivity was restored in all cases upon complementation with the respective wild-type protein.

These intriguing effects were recapitulated and expanded using yeast as a simpler eukaryotic model system. It was seen that trabectedin activates the G_2-M and S phase DNA damage checkpoints, in good agreement with the G_2/M block and S phase delay reported in human cells. Likewise, cells deficient in the *XPG* orthologue (*rad13* in *Schizosaccharomyces pombe*) were shown to be much more resistant to trabectedin and underwent much less DNA damage than the corresponding isogenic wild-type strains. However, it became clear that it was not the missing endonuclease activity of this protein that conferred resistance to trabectedin but the lack of part of its DNA-binding domain in the COOH-terminal region. Furthermore, on the basis of a homology model suggesting that the rad13:DNA:trabectedin ternary complex could be stabilized through the direct interaction of subunit C of the drug with a highly conserved arginine residue, an *S. pombe* strain carrying an Arg961→Ala point mutation in rad13 was generated. This mutant displayed normal endonuclease and NER activity but was found to be strongly resistant to the drug.

Haploid yeast mutants with deletions in the *RAD52* epistasis group of genes encoding proteins responsible for ►homologous recombination (HR) and hence most ►double-strand break (DSB) repair in eukaryotic cells (e.g. rad51, rad22 (the fission yeast counterpart of mammalian rad52), and rad54) were found to be extraordinarily sensitive to trabectedin. This result reinforced other indications that the drug is giving rise (directly or indirectly) to DSBs that need to be repaired by homologous recombination, and the fact that the absence of *rad13* partially rescued *rad51Δ* cells supports the view that a rad13-containing complex is somehow involved in the induction or irreparability of lethal DSBs.

These results may have important implications for the optimal use of trabectedin in cancer therapy because patients harboring tumor cells with proficient NER and deficient HR systems would be expected to respond best to the treatment.

Clinical Studies

Trabectedin was selected for clinical development in preference to other related ecteinascidins because of its outstanding potency and greater relative abundance in the tunicate. Among the criteria that were taken into account for bringing it into clinical trials in early 1996 both in Europe and in the United States, we can summarize the following: (i) a novel chemical entity harboring a potential new mode of action, (ii) evidence for a positive therapeutic index, (iii) lack of complete cross-resistance with conventional chemotherapeutic agents, and (iv) feasibility of supply for clinical development. Toxicity to trabectedin so far has been shown to follow a transient-reversible pattern and to be predictable, dose-related, and mostly limited to bone marrow and liver.

Following a favorable opinion adopted by the Committee for Orphan Medicinal Products (COMP) of the European Agency for the Evaluation of Medicinal Products (EMEA), trabectedin was granted by the European Commission orphan medicinal product designation for the treatment of ►soft tissue sarcoma (STS) in April 2001 and for ►ovarian carcinoma (OC) in October 2003. The United States Food and Drug Administration (FDA) awarded Orphan Drug Designation to trabectedin in the indication of STS in October 2004, and in OC in April 2005.

Trabectedin is currently in phase III clinical trials worldwide for ovarian cancer. Extended phase II trials and comparative studies have produced evidence of long lasting responses and tumor control in advanced pretreated sarcomas, breast carcinoma, ovarian carcinoma

and prostate cancer. In July 2007, Yondelis received a positive opinion from the EMEA for the treatment of metastatic or advanced soft tissue sarcoma after failure to anthracyclines and ifosfamide.

TRAIL Receptor Antibodies

Claus Belka
Department of Radiation Oncology, University Tübingen, Tübingen, Germany

Synonyms

DR4 antibodies; DR5 antibodies; Lexatumumab; Mapatumumab; TRA-8

Definition

►TRAIL induces ►apoptosis preferentially in malignant tissues. Therefore TRAIL is considered to be a potential antineoplastic drug. Agonistic TRAIL receptor antibodies have been developed as alternative pharmacological tool for apoptosis induction via the TRAIL receptors.

Characteristics

After having identified TRAIL as a member of the family of cell death inducing ligands, it became obvious that TRAIL has a strong propensity for transformed or malignant tissues. Therefore TRAIL is considered to be a candidate anticancer drug. TRAIL exerts its apoptosis inducing activity via the two respective agonistic TRAIL receptors DR4 and DR5. TRAIL itself is able to induce cell death in a wide array of cancer cells in vitro or when grown in xenograft settings. The efficacy of TRAIL is increased whenever the ligand is combined with conventional cytostatic agents or ionizing radiation. Depending on the production process, there was concern that TRAIL, like ►CD95-L, could exert considerable hepatotoxicity. Recently released data from phase I trials suggest that TRAIL can be safely administered in patients up to serum concentrations consistent with those demonstrating efficacy in tumor xenograft models.

In parallel to the development of TRAIL as anticancer drug, agonistic antibodies directed against both death inducing TRAIL receptors were developed. Up to now relevant data on three agonistic TRAIL antibodies are available. The signaling pathways triggered by agonistic antibodies have not been reported to differ from the cascades triggered by TRAIL. Treatment of susceptible cells with agonistic antibodies results in the activation of ►caspase-8, caspase-9, and cleavage of ►PARP. As shown for TRAIL, agonistic TRAIL antibodies also induce cleavage of the anti-apoptotic MCL-1 protein. How far key regulatory molecules including ►FADD, ►c-FLIP, and caspase-10 are involved in the regulation of cell death induction via agonistic TRAIL antibodies has not been tested in detail. However, the fact that there is a cross resistance between TRAIL and the agonistic antibodies in such a way that cells being resistant towards TRAIL cannot be killed by either antibody indicates that the signaling pathways are identical or at least highly similar.

The agonistic TRA-8 antibody directed against DR5 has been developed by Sankyo together with researchers from the University of Alabama (Birmingham, USA) and was the first agonistic antibody being described. TRA-8 was generated by immunizing BALB/c mice with a fusion protein containing the extracellular domain of DR5 and the Fc proportion of human IgG1. The antibody does not cross react with murine DR5. The K_d values for TRAIL or TRA-8 binding to DR5 were estimated at 59 and 3 nM, respectively. The high specificity of TRA-8 for DR5 was documented by competition assays showing that TRA-8 efficiently competed with TRAIL for binding to DR5 but not for binding to DR4. In addition, these results indicate that TRA-8 potentially recognizes an epitope within the TRAIL-binding site on DR5. In general, TRA-8 induces apoptosis in tumor cell systems in vitro as well as in murine xenograft model systems (Jurkat and 1321N1 astrocytoma cells). In contrast to the TRAIL preparation used for comparison, the TRA-8 antibody did not induce any signs of hepatopathy in mice.

In subsequent studies, the increased efficacy of multimodal approaches combining either TRA-8 with radiation, chemotherapy or other response modifiers was documented. In this regard it is important to notice that the efficacy of the tested combinations in term of growth delay was shown in ►xenograft models for ►cervical cancer, ►breast cancer and ►pancreal cancer. The overexpression of Bax using an adenoviral vector system increased the efficacy of TRA-8 in a wide array of glioma cells suggesting that bax is involved in the efficacy of the combined treatment. The increased cell death induction translated into an increased growth delay. Besides the TRA-8 antibody, Sankyo also develops an agonistic DR4 antibody 2E12. However, considerably less data are available regarding the pharmacology and efficacy of this antibody.

The second group of antibodies was developed by Cambridge Antibody Technology in conjunction with Human Genome Sciences (Rockville, USA). HGS-ETR1 (Mapatumumab) is directed against DR4 and HGS-ETR2 (Lexatumumab) is directed against DR5. HGSI also develops a third agonistic TRAIL antibody (HGS-TR2, targeting DR5) that was initially developed by Kirin Brewery Ltd. Up to now only data on Mapatumumab and Lexatumumab are available. Mapatumumab is a fully humanized monoclonal antibody and was isolated from 102 different anti-TRAIL receptor mAbs that were generated by phage display technology. The antibody has a high affinity for the DR4 receptor and exerts antitumor activity (EC50 values of ~3.4 nM) in diverse preclinical tumors models including breast, gastrointestinal, lymphoma, ovarian carcinoma, and uterine cancers. Mapatumumab was shown to specifically recognize the TRAIL-R1 protein without any relevant interactions with the TRAIL decoy receptors. The efficacy of mapatumumab is increased by combinations with various cytostatic drugs including carboplatin, cisplatin, camptothecin, topotecan, paclitaxel as well as radiation. Xenograft models for breast, colorectal, nonsmall cell lung cancer as well as uterine cancer revealed a high activity of either the drug alone or in combination with other cytotoxic treatment approaches including radiation.

Like mapatumumab, lexatumumab is a fully humanized IgG1g antibody. The antibody was also generated using a phage display and screening with 383 short chain fragments for DR5 binding properties. In contrast to mapatumumab, no data on specificity, selectivity, and affinity of the antibody are publicly available. Similar to TRA-8, lexatumumab exert pronounced apoptotic reactions in a wide array of malignant cell systems when used alone. Importantly the drug has proven efficacy on tumor growth in xenograft systems from renal cell carcinoma, nonsmall cell lung cancer, breast cancer, and glioma. As already shown for TRA-8, the combination of lexatumumab with various chemotherapeutic agents (camptothecin, cisplatin, carboplatin, paclitaxel, doxorubicin, bortezomib) or radiation increased the efficacy in cell lines and xenografts. The underlying mechanisms of sensitization are still not completely understood. However, it seems likely that the presence of the proapoptotic Bax molecule as well as the upregulation of the respective receptor participate in the increased efficacy of the combined approach.

Clinical Aspects

Mapatumumab (anti-DR5)

Data from several early clinical trials are available and allow a cautious judgment regarding pharmacological and toxicological aspects of mapatumumab. An open label phase Ia/b trial was conducted in 39 patients with various advanced solid tumors.

During the first phase, dose escalation of mapatumumab was performed (0.01, 0.03, 0.1, 0.3, 1.0, or 3.0 mg/kg). The second phase of the trial involved administration of mapatumumab (10 mg/kg) once every 28 days or once every 14 days. The i.v. administration of mapatumumab produced dose-proportional pharmacokinetics up to a dose of 1.0 mg/kg, with a half-life of 15 days for 1.0 mg/kg. The pharmacokinetic data indicate that distribution and clearance follow a two-compartment model, with first order elimination from the central compartment. The best clinical responses reported so far are stable diseases in a proportion of the heavily pretreated patients. No data from ongoing trials combining chemotherapy with TRAIL are available at present.

In addition to various phase I trials, mapatumumab was tested in a multicenter phase II trial in patients with relapsed or refractory non-Hodgkin lymphoma. Patients (n = 40) received either (3 or 10 mg/kg mapatumumab once every 21 days). Partial responses were observed in three patients, and on one patient with relapsed follicular mixed-cell lymphoma demonstrated a more pronounced regression. Two other phase II trials with mapatumumab are ongoing. One trial was conducted in patients with relapsed or refractory colorectal cancer. No data on safety, tolerability, pharmacokinetics, tumor response, time to response, duration of response, and progression-free survival from this trial are available.

The second phase II trial including patients with solids tumor was performed in 32 patients with nonsmall cell lung cancer (median of three previous treatment cycles). These patients received 10 mg/kg mapatumumab every 21 days until disease progression. Mapatumumab was well tolerated with not treatment discontinuations due to drug-related toxicity. In 29% of these patients a stable disease (median duration of 2.3 months) was observed. The most common mapatumumab related adverse events were nausea, fatigue, hypotension, myalgia, pyrexia, peripheral sensory neuropathy, diarrhea, constipation or abdominal pain, rash, hypertension, and thrombocytopenia. A clear maximum-tolerated dose had not been achieved. No antibodies to mapatumumab had been observed. The phase II trial in NSCLC patients revealed that mapatumumab administration was generally safe and well tolerated. In 97% of these patients at least one adverse event reported, however, only 44% of the patients experienced an adverse effect that was considered to be drug related. Again, no immunogenic responses were observed.

Lexatumumab (anti-DR5)

Data from several phase I trials using lexatumumab are available. Results from a US dose escalation trial (0.1, 0.3, 1.0, 3.0, and 10 mg/kg i.v. lexatumumab every 2 weeks) revealed that dose responses were linear up to the 10mg/kg level with a mean half-life of 11 day at the 10-mg/kg dose level. The analysis of a similar trial performed in the UK (37 patients with advanced cancer of different organs sites treated with doses of 0.1, 0.3, 1.0, 3.0, 10, or 20 mg/kg every 3 weeks) revealed linearity over the whole dose range and a distribution model consistent with a two compartment model with first-order elimination from the central compartment (reported pharmacological values: mean parameters for the 1- and 10-mg/kg groups were: C_{max} = 24.0 and 195.9 μg/ml; AUC = 190.8 and 2379 μg.days/ml; half-life = 12.0 and 15.3 days; plasma clearance = 5.7 and 4.8 ml/kg/day; V1 = 44.1 and 50.8 ml/kg and VdSS = 83.7 and 87.1 ml/kg).

Clinical results from both trials have been reported with no major toxicity. Of 31 patients entered in the US trial, 10 experienced disease stabilization and 20 had disease progression. Of 37 patients entered in the UK trail, 11 experienced disease stabilization and 26 had disease progression. Data from the studies indicate that lexatumumab was well tolerated at doses up to 10 mg/kg. The most frequently reported toxicities were: fatigue, nausea, anorexia, constipation, diarrhea, tachycardia, and vomiting. The DLT for Lexatumumab was

defined as 10 mg/kg. No data from phase II trials are available at present.

TRA-8 (CS1008)

Up to now no results from clinical trials have been reported with the humanized version of TRA-8 (CS1008).

Perspectives

TRAIL receptor based treatment strategies are currently entering clinical trials. The feared liver toxicity of TRAIL and agonistic compounds has not been documented in any of clinical trials currently available. No judgment on the definitive clinical anticancer activity of agonistic TRAIL receptor antibodies can be made although the phase I and phase II data revealed some clinical activity.

TRAM-1

►Amplified in Breast Cancer 1

Trans-Golgi Network

Definition

Is part of the Golgi apparatus, which is an ►organelle found in ►eukaryotic cells. The primary function of the Golgi apparatus is to process and package ►macromolecules synthesized by the cell, primarily ►proteins and ►lipids. Trans-Golgi network is the last station of the Golgi apparatus and it directs proteins in the secretory pathways to the appropriate cellular destination.

Transabdominal Metastasis/ Dissemination

►Transcoelomic Metastasis

Trans Activating Protein

Definition

Is a protein that alters gene expression at sites other than those adjacent to where it is being encoded.

►Transcription Factor

Transactivation

Definition

Is the stimulation of gene expression by diffusible mediators, for example proteins that are usually encoded on distant regions of the genome.

►Transcription Factor

Transactivation Domain

Definition

TADs are most frequently found in ►transcription factors. These protein modules interact with the basic ►transcription machinery and functions to actively mediate transcription of downstream target genes.

Transarterial

Definition

Through the artery.

Transarterial Chemoembolization

Definition

An interventional procedure mostly used to treat cancer. Physicians first use a needle to puncture into the artery. Then a thin catheter is threaded into the tumor through

the blood vessel under continuous radiological imaging guidance. Anti-tumoral chemotherapeutic agents and small ►embolization particles are injected into the tumor to induce tumor cell death.

Transcoelomic Metastasis

David S. P. Tan, Stanley B. Kaye
Section of Medicine, Institute of Cancer Research, The Royal Marsden Hospital, London, United Kingdom

Synonyms

Peritoneal metastasis/dissemination; Transabdominal metastasis/dissemination

Definition

Dissemination or spread of malignant tumor throughout the peritoneal (abdominal and pelvic) cavity.

Characteristics

Transcoelomic (meaning "across the peritoneal cavity") ►metastasis refers to the dissemination of malignant tumors throughout the surfaces and organs of the abdominal and pelvic cavity covered by ►peritoneum. Transcoelomic metastasis can occur as a result of ►invasion into the peritoneal cavity by: (i) a primary cancer arising from within the abdominal/pelvic cavity e.g. ►ovarian cancer; (ii) as a manifestation of systemic metastasis following haematogenous or ►lymphatic invasion by a primary cancer e.g. advanced ►breast cancer; or (iii) following intraperitoneal seeding during surgical manipulation e.g. during surgical resection of a colorectal tumor.

The incidence of transcoelomic metastasis is higher with tumors that arise from the peritoneal cavity e.g. ovarian (up to 70% of patients at presentation) and colorectal (up to 28% of patients at presentation). In contrast, extraperitoneal cancers e.g. breast and lung, are associated with a much lower overall incidence of transcoelomic metastasis, although certain histological subtypes e.g. infiltrating lobular breast cancers, have demonstrated a greater predilection for metastases to the gastrointestinal tract, gynecological organs and peritoneum/►retroperitoneum. This suggests that whilst the location of the primary tumor may be a key determinant in the development of transcoelomic metastasis, the tumor phenotype is also an important factor. Hence it appears that a combination of anatomical and tumor-specific factors is involved in the transcoelomic metastatic process.

Transcoelomic metastases contribute considerably to the morbidity associated with carcinomatosis because they have the capacity to affect multiple vital organs within the abdomen. Common examples include bowel obstruction caused by lesions along the gastrointestinal tract, and renal failure caused by obstruction of the ureters. In addition, transcoelomic metastases are frequently associated with the formation of malignant ►ascites, resulting in raised intra-abdominal pressure with consequent abdominal distension and discomfort. This results in early satiety, leading to dietary deficiency, impaired circulation of blood and ►lymphatic vessels, and respiratory compromise secondary to diaphragmatic splinting. Hence, there are potentially significant therapeutic advantages to be gained in understanding the process of transcoelomic metastasis.

Mechanisms of Transcoelomic Metastasis

Models of Metastasis

Two models have been hypothesized for the genetic origins of tumor metastases. The first model, often referred to as the seed-and-soil hypothesis, is that tumors are genetically heterogeneous and metastases arise from clones with a genetically acquired metastatic phenotype, which determines the final site of metastasis. The alternative hypothesis, the stochastic model, is that metastatic cells do not represent a genetically selected clone distinct from the primary tumor, but arise as a stochastic event from tumor cell clones genetically identical to the primary tumor. Recent studies exploring this question using *in vivo* models have suggested a combination of both models of metastasis. Regardless of metastatic model, there are certain observed characteristics that appear to be important for transcoelomic metastastic progression, in which complex cellular adaptations need to occur after cell detachment from the primary tumor mass to ensure survival within the peritoneal cavity.

Cell Detachment

Anchorage-independent growth and the ability to resist ►anoikis is a vital step for the initiation of metastasis. This process appears to involve the increased expression of ►survivin and X-linked inhibitor of ►apoptosis (XIAP), members of the inhibitor of apoptosis protein (IAP) family, which suppress apoptosis by inhibition of ►caspases. Other mediators of anoikis resistance include the family of ►extracellular matrix (ECM) to ►cell-adhesion molecules known as ►integrins. Alterations in levels of integrin-mediated ECM-ligand binding have been found in many different tumor types and can result in decreased cell-adhesion, changes in cell morphology and increased ►migration *in vitro*, and

activation of ECM degrading enzymes including ►matrix-metalloproteinases (MMP).

Peritoneal Fluid and Anatomy

The peritoneal cavity is normally empty except for a thin film of fluid that keeps surfaces moist. Peritoneal fluid arises primarily from plasma transudate and ovarian exudate. Other sources of peritoneal fluid include fallopian tubal fluid, retrograde menstruation and macrophage secretions. The volume of peritoneal fluid is usually 5–20 ml, and varies widely depending on physiological or pathological conditions. Peritoneal fluid contains a variety of free-floating cells, including ►macrophages, ►natural killer (NK) cells, lymphocytes, eosinophils, mesothelial (peritoneal surface epithelial) cells and ►mast cells, which are all involved in immunological surveillance. Intraperitoneal fluid flow is directed by gravity to its most dependent sites and then drawn via the paracolic gutters to the diaphragm by the generation of negative intra abdominal pressure in the upper abdomen during respiration. There is preferential flow along the right paracolic gutter, liver capsule, and diaphragm. Therefore, a natural flow of peritoneal fluid exists within the abdominal cavity, providing a route for the transcoelomic dissemination of detached tumor cells.

As the epithelial surfaces of the female genital tract (i.e. ovaries, fallopian tubes and endometrium) share a common embryological lineage with the peritoneal epithelium, it has been suggested that transcoelomic metastasis from gynecological malignancies, such as fallopian tube and ovarian tumors, are not true metastases but a result of malignant transformation at multiple foci throughout the peritoneum, i.e. peritoneal ►metaplasia. If the metaplasia hypothesis is correct, then one might expect metastatic lesions to be randomly distributed throughout the peritoneum. Alternatively, if the theory of dissemination via peritoneal/ascitic fluid is true, then one might expect that detached tumor cells would, by virtue of gravity, be more frequently implanted in the floor of the pelvis, e.g. the pouch of Douglas (the space between the rectum and back wall of the uterus), followed by the organs in the paracolic gutters, and finally on the diaphragm, i.e. along the normal route of peritoneal fluid circulation. Studies have shown that a high incidence of metastatic implants for all cancers, including ovarian malignancies, within the peritoneal cavity is found on organs where peritoneal fluid resorption occurs (►omentum and omental appendages). In addition, the colon, greater omentum and pouch of Douglas are most often affected, with a reduced incidence of implants seen on the small bowel and its mesentery, which is free to move by peristalsis, compared to the ileocaecal area (the junction between the ileum and cecum), which is fixed to the retroperitoneum. Hence, location and topography with regard to the flow of peritoneal/ ascitic fluid appear to be key determinants in the process of transcoelomic dissemination for all cancers. As such, in the case of gynecological cancers, peritoneal metaplasia alone appears unable to fully account for the peritoneal distribution of carcinomatosis.

Ascites: A Metastatic Milieu

The development of transcoelomic metastasis is often associated with the formation of excess peritoneal fluid known as malignant ascites. It is hypothesized that, in addition to hypoalbuminaemia (low plasma albumin levels) secondary to dietary deficiency, at least three other pathological events can cause ascites: (i) reduced lymphatic drainage from the peritoneal cavity caused by the obstruction of lymphatic vessels by tumor cells; (ii) increased vascular permeability of the peritoneal cavity; and (iii) tumor neo-►angiogenesis. While lymphatic obstruction is a well-recognized cause of ascites, the fact that massive amounts of fluid can accumulate in patients despite relatively little tumor burden suggests the involvement of other non-obstructive factors. These include ►vascular endothelial growth factor (VEGF), a glycoprotein which induces angiogenesis and increased vascular permeability in response to hypoxia. Other immune modulators, vascular permeability factors, and MMPs secreted by both tumor cells and mesothelial cells also contribute significantly to ascites formation and stimulate tumor growth, invasion and angiogenesis.

Immune Evasion

Many immune cells, such as macrophages, are present in peritoneal fluid, and accumulate in so-called "milky spots" within the omentum. These omental macrophages have been found to be cytotoxic against tumor cells *ex vivo*. Consequently, omental macrophages might play an important role in killing tumor cells, thereby preventing development of transcoelomic metastasis and local peritoneal recurrences. Paradoxically, however, *in vivo* studies have shown that cancer cells seeded intraperitoneally specifically infiltrate the milky spots in the early stage of peritoneal metastasis. These studies suggest that omental milky spots are insufficient to prevent tumor progression, and that intraperitoneal metastasis requires tumor cells to possess or acquire mechanisms for evasion of immunological surveillance.

Tumor-infiltrating and malignant ascites-derived lymphocytes, in particular gamma–delta T cells, from patients with metastatic ovarian and colorectal cancer, have also been shown to possess antitumor activity. Hence, it appears that metastatic tumor cells have also developed strategies to evade T cell-mediated cytotoxicity. Fas ligand (FasL) is a transmembrane protein belonging to the tumor necrosis factor superfamily

that can trigger apoptotic cell death following binding to its receptor, Fas. Expression of FasL has been observed in renal, ovarian, colorectal, and head and neck tumors and may be responsible for the immune privilege of tumor cells by inducing apoptosis of antitumor immune effector cells within the tumor microenvironment – the "Fas counterattack". Studies have also shown that tumor progression and metastasis is associated with increased expression of FasL. Other examples of immune evasion include the recruitment of regulatory T (Treg CD4+CD25+) cells to suppress tumor-specific T cell immunity; the presence of high concentrations of soluble forms of the complement pathway inhibitors C1 inhibitor, factor H and FHL-I on isolated metastatic ovarian cancer cells in ascitic fluid; and the phenomenon of spheroid formation observed in ►breast, colorectal and ovarian cancer where tumor cells clump together by upregulating cell-adhesion molecules, thus resulting in increased complement resistance due to insufficient penetration of antibodies and complement into the spheroids.

Tumor Implantation

Although topography appears to be a key determinant in the final site of metastatic implantation within the peritoneum, the actual mechanisms behind tumor implantation remain unclear. However, there is evidence to suggest the involvement of a dynamic regulation of the tumor cell's adhesiveness, and its interaction with the underlying peritoneal mesothelium.

Potential mechanisms for the attachment of tumor cells to the peritoneal mesothelium include binding to ECM proteins like collagen type I and IV, laminin, and fibronectin via tumor cell surface integrins, and to hyaluronan expressed on the surface of human peritoneal mesothelial cells via the ►CD44 tumor cell surface protein, of which there are 10 alternative exon splice variants (v1–v10). Upregulation of certain CD44 variants have been associated with distant metastasis in breast, colorectal and ovarian cancer. Recently, tumor antigen/marker CA125, a glycoprotein overexpressed on the cell surface and secreted by ovarian tumor cells in the majority of ovarian cancer patients, has been shown to bind to mesothelin, a glycosylphosphatidylinositol-linked cell surface molecule expressed by mesothelial cells. Upregulation of the cell adhesion molecule ►E-cadherin may also mediate adhesion of circulating tumor cells to metastatic sites. Adhesion onto the peritoneal surface may be followed by haptotatic migration in which coordinated anti- and pro-migratory signals mediated by ECM proteoglycans confers directionality to tumor cell motility, effectively laying the tracks until a "stop" signal is encountered. Once attached to the peritoneal surface, metastatic cells proliferate and invade into the subjacent epithelium. The MMP family of proteinases and the urokinase-type ►plasminogen activator (uPA) system appear to be major contributors to this process. Human peritoneal epithelial cells and their associated immune and stromal cells, have been shown to release regulatory ►chemokines and cytokines, such as IL-1, ►IL-6 and IL-8, in response to serosal inflammation and injury induced by tumor implantation, which in turn facilitate tumor angiogenesis and ascites formation (via increased secretion of VEGF), and enhanced tumor migration, attachment, proliferation and invasion.

Finally, just as extraperitoneal tumors can metastasize to the peritoneum, intraperitoneal tumors can also metastasize extraperitoneally. Apart from the rich intraperitoneal network of blood and lymphatic vessels which can be invaded by tumors, peritoneal fluid is also continually being returned to the systemic circulation via the subdiaphragmatic lymphatic network and thoracic duct into the left subclavian vein, thus providing a direct "metastatic expressway" for peritoneal metastases to gain access into the lymphatic and circulatory system.

Clinical Aspects

Patients with transcoelomic metastasis often present with signs and symptoms of abdominal pain, abdominal distension secondary to an enlarging tumor or ascites, constipation or diarrhea, shortness of breath, fatigue, loss of appetite, and weight loss. A careful clinical history followed by thorough clinical examination is required to ascertain the likely source of the primary tumor. Investigations should include routine blood tests, including relevant tumor markers, followed by radiological investigations including ultrasound and computer tomographic (CT) scans of the chest, abdomen and pelvis to confirm the likely source of tumor and disease ►stage. In all cases, particularly those in which there is no obvious source of primary tumor (i.e. carcinoma of unknown primary origin), a biopsy of an accessible lesion should be obtained for histopathological and immunohistochemical confirmation and diagnosis.

In the past, clinical situations involving transcoelomic metastasis were treated mainly with ►palliative intent. Increasingly, studies have shown that an aggressive approach to peritoneal surface malignancy involving ►peritoneal debulking (cytoreductive) procedures, combined with optimal perioperative or postoperative systemic or intraperitoneal ►chemotherapy in carefully selected patients can result in long term survival. Clinical assessment parameters that need to be considered include the patient's ►performance status, preoperative abdominal and pelvic CT scans to define the extent and operability of disease, including the presence of extraperitoneal metastases, and tumor histopathology. Key prognostic indicators following surgery include the completeness of ►peritoneal debulking

surgery, the presence of intraperitoneal lymph node and visceral metastases, and tumor type. Of the various scoring systems used to assess the extent of peritoneal carcinomatosis, the most frequently quoted is the peritoneal cancer index (based on the intraoperatively observed distribution and size of intraperitoneal metastasis) and the completeness of cytoreduction score (based on the amount of residual disease following peritoneal debulking surgery), which have been found to correlate well with prognosis in ►colorectal, ►gastric and ►ovarian cancer. A meta-analysis of studies comparing combined peritoneal debulking surgery and perioperative intraperitoneal chemotherapy with systemic chemotherapy alone for the treatment of peritoneal carcinomatosis from ►colorectal carcinoma, has demonstrated improved survival in the combination therapy group. In patients with ovarian cancer and peritoneal metastasis, 2-year survival following radical resection of all macroscopic tumors is 80%, in contrast to less than 22% for the patients with residual lesions larger than 2 cm. Early aggressive treatment of minimal peritoneal surface dissemination appears to confer the most benefit.

In patients with inoperable tumors at presentation, primary systemic or intraperitoneal chemotherapy is recommended, following which reassessment for surgical intervention may be possible if a good treatment response is observed. Palliative measures in the management of malignant ascites include repeated paracentesis (drainage of ascites), which provides relief in up to 90% of patients, and permanent percutaneous drains. The creation of a peritoneovenous shunt (which allows ascitic fluid to drain from the peritoneal cavity into the superior vena cava) prevents the need for repeated paracentesis. Promising experimental approaches in the treatment of transcoelomic metastasis include the use of intraoperative hyperthermic intraperitoneal chemotherapy, anti-►angiogenic agents such as the MMP inhibitors and the VEGF antagonists, as well as ►immunotherapy approaches including antibody targeted T cell therapy and combinations of intraperitoneal immunotherapy and thermochemotherapy.

Transcript

Definition

Fragment of RNA synthesized from a given DNA template.

Transcription

Definition

Messanger RNA (mRNA); The process by which the genetic code is transferred from DNA to messenger RNA, so that it can be subsequently translated into a protein sequence. Is the first step in gene expression. It involves the faithful synthesis of RNA from the genetic information stored in DNA. It is carried out in the nucleus by DNA-dependent RNA polymerases. A transcriptional activator is a DNA-binding protein that stimulates transcription by interacting with DNA sequence motifs present in the regulatory sequences of the controlled gene. A transcriptional repressor inhibits transcription.

►Orphan Nuclear Receptors and Cancer

Transcription-Coupled Repair

Definition

Is a DNA repair mechanism that operates in tandem with transcription. It directly repairs damaged base on the DNA strand by directly removing or repairing the damaged DNA base. Is the rapid repair of DNA damage in the transcribed strand of expressing genes.

►Homologous Recombination Repair
►DNA-Damage Tolerance

Transcription Factor

Definition

A protein that regulates gene ►transcription by binding to regulatory regions of DNA and/or to other

transcription factors. The presence of these specific DNA sequences confers upon a specific gene the ability to respond in a specific cellular context, to particular stimuli, or at a defined developmental stage. The most fundamental property of all transcription factors is their ability to influence the transcriptional activity of specific genes by acting in either a positive or negative manner. In the context of cancer, there is often a dysregulation in the balance between transcriptional activation and transcriptional repression that alters the expression of critical cancer-promoting or cancer-suppressing genes. Transcription factors are generally divided into two groups: (i) basal transcription factors (BTFs) and (ii) gene-specific transcription factors (GSTFs). The types of GSTFs are named based on the characteristic motifs involved in DNA binding and protein dimerization.

Transcription Factory

Definition

Discrete nuclear compartment where ►transcription takes place.

Transcriptional Complex

Definition

A complex of proteins that directly or indirectly, affects the initiation of ►transcription.

Transcriptional Coregulators

Definition

These are proteins that interact with transcription factors and regulate transcription. They can either be activators of transcription (enhance) or repressors of transcription (inhibit) and may act to modify chromatin structure.

►Orphan Nuclear Receptors and Cancer

Transcriptional Memory

Definition

Mechanism to ensure that specific genes are expressed at specific times so that the genetic information is transmitted to daughter cells to maintain the differentiated cell type.

Transcriptional Regulation

Definition

Regulation of gene expression by ►transcription factors.

Transcriptional Silencing

Definition

Repression of gene ►transcription in a localized region via structural changes in chromatin.

►Histone Deacetylases
►Methylation

Transcriptome

Definition

The full complement of activated genes, mRNAs, or transcripts in a particular tissue at a particular time.

Transdifferentiation

Definition

Transformation of a non-stem cell into a different cell type or the production of cells from a differentiated stem

cell that are not related to its already established differentiation path.

►Adult Stem Cells
►Stem Cell Plasticity

Transduction

Definition

Transfer of genetic material into a cell by means of a virus

Section of Molecular Genetics and Microbiology and Institute for Cellular and Molecular Biology, The University of Texas at Austin, Austin, TX, USA

Synonyms

Oncogene transduction; Retroviral transduction

Definition

►Retroviruses are RNA-containing viruses that replicate through a DNA intermediate (►provirus) using the enzyme ►reverse transcriptase. During retroviral replication, which requires integration into the host chromosomal DNA for efficient transcription of viral RNA, some retroviruses have acquired specific cellular ►oncogenes, usually with multiple modifications, and often with the loss of trans-acting viral functions. Inclusion of one or more oncogenes in the viral genome then imparts transforming activity on the recombinant virus independent of the site of integration in the cellular genome.

Characteristics

Identification of Cellular Oncogenes

In 1911, Peyton Rous described the isolation of a virus that caused fibrosarcomas in chickens. The Rous sarcoma virus (RSV) subsequently was shown to transform chicken embryos and the surrounding membranes and formed small tumors on the chorioallantoic membrane in proportion to the number of virus particles. Further quantitative assays were developed when RSV and other ►retroviruses were shown to transform or induce morphological and growth behavior changes in cultured cells that mimicked tumor formation in the animal. The ability of RSV to transform cells in culture led to the conclusion that the virus encoded a gene responsible for such changes. Isolation of transformation-defective variants of RSV allowed comparisons with wild-type RSV and the discovery of the viral oncogene, v-*src*. Experiments from the laboratories of Harold Varmus and Michael Bishop revealed that the v-*src* gene is highly related to a specific cellular gene or proto-oncogene, c-*src*, which encodes a protein tyrosine kinase. Unlike the v-*src* gene in RSV, the cellular homologue contained introns, which could be alternatively spliced in various cell types to give different mRNAs. Further characterization showed that the product of the v-*src* gene, v-Src, had substitutions within several functional domains that prevented the normal regulation of the kinase activity during the process of ►signal transduction.

Shortly after the discovery of v-*src*, other transforming viruses were isolated and characterized. Some of these viruses were recovered by treatment of normal cells with halogenated pyrimidines to induce ►endogenous retrovirus expression, by co-culture of primary cells with chemically transformed cells that express non-transforming ►retroviruses, whereas others were isolated by in vivo passage of non-transforming ►retroviruses. In each case, the transforming virus appears to be the result of recombination between a non-transforming ►retrovirus and one or more cellular genes. The ability of ►retroviruses to acquire cellular sequences in their genome and transmit these genes to other cells is known as retroviral ►transduction or, in the case of proto-oncogenes, oncogene ►transduction. Examples of transforming viruses and the acquired proto-oncogenes are listed in Table 1. Deregulation can occur at many steps of ►signal transduction, leading to oncogenesis.

Nevertheless, recombination events leading to the generation of a transforming ►retrovirus appear to be rare in nature. Most of the resulting viruses are defective for replication because the acquisition of cellular proto-oncogenes is accompanied by the deletion of viral structural genes, which are necessary to produce viral particles. Such defective transforming viruses are not transmissible unless they successfully co-infect a cell with a related ►retrovirus that provides the missing gene products in *trans*. Thus, most transforming viruses are more interesting as research tools for the identification and functional characterization of oncogenes and the process of ►transduction than as a major cause of disease in animals and humans.

Transduction of Oncogenes. Table 1 Oncogenes transduced by retroviruses

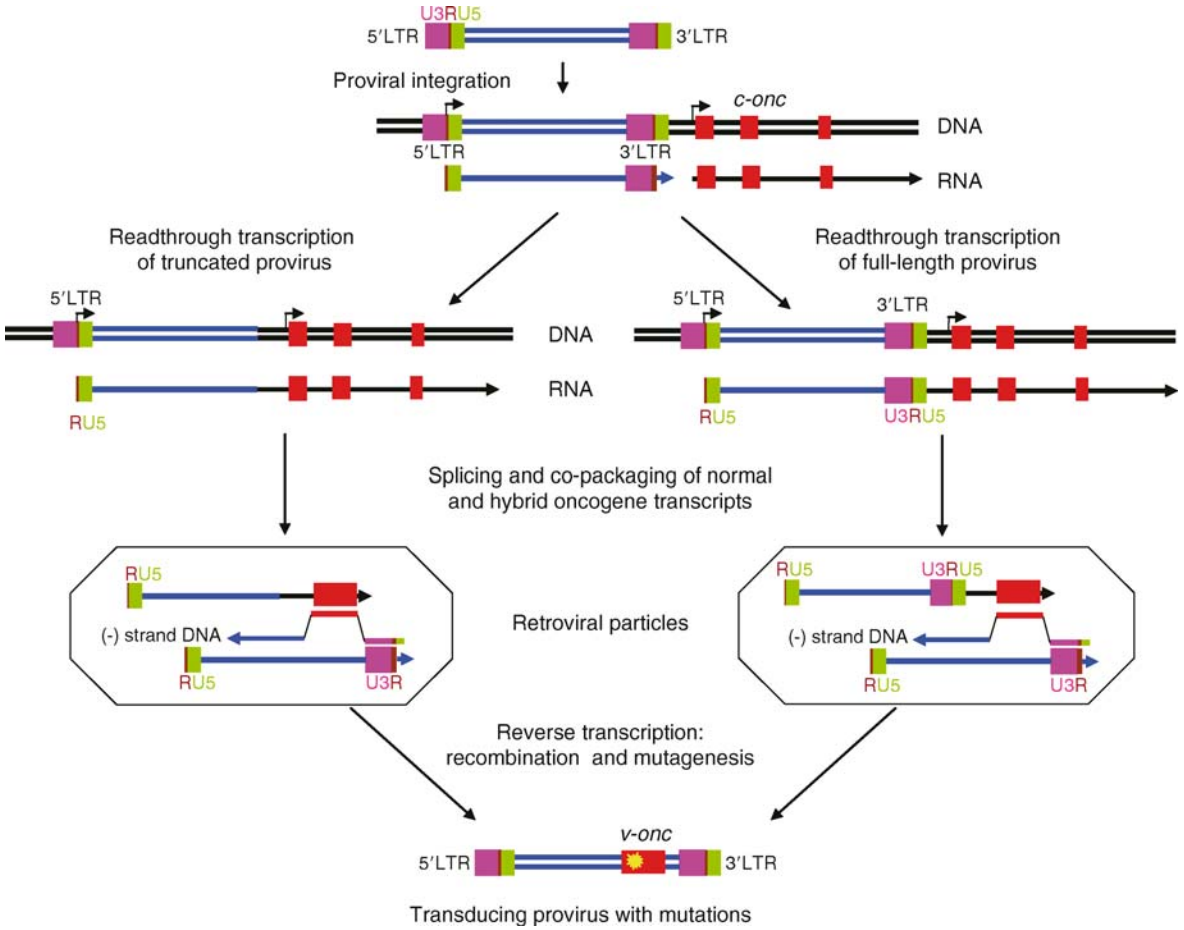
[a] *fes* and *fps* are the same oncogene derived from feline and avian genomes, respectively.
[b] *mil* and *raf* are the same oncogene derived from avian and murine genomes, respectively.

Mechanism of Oncogene Transduction

The majority of transforming ►retroviruses are defective for viral replication. Since these viruses are isolated after acquisition of transforming activity, the exact steps required to form these ►retroviruses is unknown, nor is it clear whether every transforming virus has been generated by the same mechanism. However, a general model has emerged for the formation of such viruses (Fig. 1).

First, a non-transforming ►retrovirus integrates upstream of a cellular gene, an event known to occur at a reasonable frequency. Many ►retroviruses integrate preferentially within coding sequences or near sites of active transcription. Non-transforming ►retroviruses often cause tumors by insertion in or near proto-oncogenes, resulting in the activation of transcription or production of abnormal transcripts. These transcripts arise due to enhancer activation of the cellular promoter or activity of the viral promoter on the cellular gene. If the proviral integration results in cellular transformation, cells containing the integration site will be selected for growth. However, some ►retroviruses integrate upstream or downstream and in the opposite orientation relative to the proto-oncogene, and it is believed that the generation of transforming ►retroviruses requires proviral integration upstream and in the same orientation as the oncogene. Such events can result in cancer



Transduction of Oncogenes. Figure 1 Mechanism of retroviral oncogene transduction. (See text for details.)

induction without ►transduction of oncogenes. Thus, many proviral insertion events may lead to cancer, but not formation of transforming ►retroviruses.

Second, transcription initiating in the 5′ LTR generates a transcript that would read through the normal polyadenylation sequences in the 3′ LTR. Recent evidence suggests that increases in retroviral transcriptional readthrough also result in transductive recombination. Potentially, this readthrough transcript could be packaged into virions, although it is generally believed that transcripts longer than 150% of the genome would be accommodated poorly in the virus capsid. Alternatively, a rare deletion of cellular DNA or aberrant splicing could provide a truncated provirus or mutant transcripts that may encompass a much greater portion of the cellular transcripts.

Third, hybrid oncogene transcripts may be packaged along with normal viral transcripts into virions. Retroviruses have a diploid genome that includes cis-acting sequences (usually near the 5′ end of the viral genome) necessary for packaging into the viral capsid (designated the psi sequence). Thus, hybrid transcripts including the psi sequence would be preferentially packaged with normal retroviral sequences to give an RNA heterodimer instead of the normal RNA homodimer. However, normal cellular RNAs can be packaged into retroviral particles at low frequency, and co-packaging would allow copying by reverse transcriptase, which is not template-specific.

Fourth, the hybrid oncogene transcript and the wild-type transcript both will be used as templates for reverse transcriptase, which also is incorporated into viral particles. In some cases, incorporation of the proto-oncogene and expression at high levels from the retroviral promoter appears to be transforming. Nevertheless, most transduced oncogenes have multiple genetic alterations. Reverse transcriptase has several properties that favor the types of genomic changes observed in transforming retroviruses. These properties include template switching, deletion formation, and the introduction of point mutations. If the resulting recombinants retain all of the cis-acting sequences needed for replication, the transforming virus will be capable of propagation in the presence of replication-competent retroviruses. Supporting the importance of readthrough transcripts for this process, transforming retroviral

genomes have been observed that carry poly(A) stretches typical of mRNAs at the junction between the host and 3′ viral sequences. Furthermore, the incorporated oncogenes lack introns.

Lessons from Retroviral Transduction of Oncogenes

Cancer is believed to be a multistep process, where several genetic events contribute to the generation of tumor cells. Some avian retroviruses are known to have transduced two oncogenes, including avian erythroblastosis virus-ES4 and -R (AEV-ES4 and AEV-R) (*erb*B and *erb*A), Mill-Hill-2 (MH2) avian myelocytoma virus (*mil* (aka *raf*) and *myc*), and avian myeloblastosis virus (AMV-E26) (*ets* and *myb*). Some viruses may have transduced more than one cellular proto-oncogene to improve their transforming capacity, a process that may be similar to the acquisition of multiple genetic changes in cancer cells during tumor progression. For example, evidence suggests that *erbA* expression is necessary for the full transforming activity of the *erbB* oncogene in AEV. Also, the MH2 ►retrovirus requires expression of both *mil/raf* and *myc* to transform neuroretinal cells from 7-day-old chicken embryos, an event that *myc*-expressing retroviruses cannot induce. However, AMV-E26 contains two oncogenes, but only one of them has been shown to be necessary for full transforming ability. Deletion of the *ets* oncogene does not diminish the transforming ability of AMV-E26 relative to wild type virus when injected in newborn chickens. Furthermore, many of the transduced oncogenes contain deletions or point mutations that reveal regulatory regions of the encoded gene products, leading to a greater understanding of their normal functions in cellular growth control.

Retroviruses, including simple retroviruses that lack regulatory genes as well as lentiviruses, have become common vectors for therapeutic gene delivery. These viruses have been used to deliver genes for treatment of a variety of illnesses, including cancers and genetic disorders. Lentiviral vectors offer the advantage of being able to infect and replicate in non-dividing cell types. However, simple retroviruses may be advantageous for preferential infection of dividing tumor cells and delivery of the therapeutic gene relative to adjacent normal cells. In both cases, viral structural genes in the vector are replaced with a therapeutic gene of interest. Expression of the transduced genes can be controlled by non-viral promoters, internal ribosome entry sites or splicing. Although these vectors have shown promise as therapeutic agents, the safety of such vectors has been the overriding concern, i.e., preventing the formation of replication competent viruses and avoiding the ill effects of integration. Limitations to replication and the avoidance of multiple insertions within target cells should minimize insertional activation of oncogenes. A recent improvement to the retroviral vector system was removal of the 3′ U3 region, thus creating a self-inactivating (SIN) virus after reverse transcription. Another possible safety concern associated with ►gene therapy is the generation of new transforming viruses, especially in human patients. These events should be extremely rare because of several precautions included during the construction of these vectors, including removal of U3 sequences as well as viral structural genes, thus confining these retroviruses to a single round of replication. Furthermore, the absence of homologous endogenous lentiviruses in humans should reduce recombination events that lead to generation of transforming retroviruses.

In the early part of this century, a major milestone in human gene therapy was achieved. To date, more than 20 children with X-linked severe combined immune deficiency (SCID) or adenosine deaminase (ADA) deficiency SCID have been successfully treated using a Moloney murine leukemia virus-based vector to allow normal expression of the defective gene. Unfortunately, in three of the patients, this vector inserted in close proximity to the *LMO2* proto-oncogene, leading to dysregulation of *LMO2* expression and development of leukemia. Many gene therapy clinical trials are being performed, and current efforts have focused on further improvements to vector safety. Such improvements include prevention of transcriptional readthrough or inclusion of insulator elements to block the formation of hybrid viral-cellular transcripts that may lead to oncogene ►transduction.

Transfection

Definition

Introduction of DNA into live cells is referred to as:

- Transformation when the cells are bacterial or yeast cells;

- Transfection when the cells are eukaryotic and DNA is offered to the cells as a complex
- Transduction when the cells are eukaryotic and the vector is a non-self-replicating virus
- Infection when the cells are eukaryotic and the vector is a self-replicating virus

Transformation

Definition

Malignant transformation is the collection of events that leads to loss of normal cellular function and acquisition of tumorigenic properties. Transformation of eukaryotic cells describes the failure to observe the normal constraints of growth. It refers to their conversion to a state of unrestrained growth in culture, resembling or identical with the tumorigenic condition. Transformed cells become independent of growth factors usually needed for cell growth. In vitro cell transformation tests are used as a model for predicting in vivo ►carcinogenesis. Hallmarks of transformation in experimental settings include ►anchorage independent growth, cell proliferation without exogenous growth factors, loss of ►contact inhibition and tumor formation in ►xenograft assays.

Transforming Growth Factor Beta

Jorma Keski-Oja
Departments of Pathology and of Virology, Haartman Institute, University of Helsinki, Helsinki, Finland

Definition

Transforming growth factors were identified on the basis of their ability to induce soft agar growth and morphological changes in nonmalignant cells. The original observation was of an activity, which was named sarcoma growth factor. Soon afterward the term transforming growth factor, ►TGF, was adopted. Sarcoma growth factor was subsequently found to be composed of an epidermal growth factor like protein, which was named transforming growth factor alpha, ►TGF-α, and of ►TGF-β. TGF-α is a member of the epidermal growth factor family, and is unrelated to TGF-β.

Characteristics

TGF-βs are multifunctional polypeptide growth factors involved in the regulation of cellular growth and differentiation and immune functions. The number of known members of this family is rapidly increasing and stands at more than 40 different growth modulating proteins. Besides TGFβs, these include bone morphogenetic proteins (BMPs), growth and differentiation factors, inhibins and activins. TGF-βs are in many senses unique among growth factors in their potent and widespread actions. Three different mammalian gene products, TGF-βs 1–3, have been molecularly cloned. Almost all types of cells in the body make some form of TGF-β, and nearly all cells have cell surface receptors for it. One of their major effects is inhibition of cell proliferation, a property needed in developmental processes, for instance. TGF-βs have important roles in the control of the pericellular proteolytic balance and in the regulation of the production and structure of the components of the connective tissues and extracellular matrices. TGF-β stimulates the transcription and synthesis of various components of the extracellular matrix like collagens, ►fibronectin, vitronectin, tenascin and proteoglycans. TGF-βs are potent chemotactic factors for many cell types like fibroblasts, eosinophils and various inflammatory cells at very low concentrations. They also suppress matrix degradation by decreasing the expression of proteinases (►Serine proteases (type II) spanning the plasma membrane), such as plasminogen activators (►Plasminogen activating system), numerous metalloproteinases, and by inducing proteinase inhibitors, such as plasminogen activator inhibitor-1 and ►tissue inhibitors of metalloproteinases (TIMPs). In addition, TGF-βs regulate cellular functions by modulating the expression of matrix receptors, the

integrins. For these reasons the activities of TGF-βs must be tightly regulated.

TGF-β Receptors and Signaling Mechanisms

Members of the TGF-β superfamily have diverse functions in cell-cell signaling. TGF-βs play different roles in tissue homeostasis and at various stages of development. The mechanisms of regulation of TGF-β activity are multifaceted and complex. Three different TGF-β isoforms and the types, affinity, and signaling functions of its receptors also add complexity to the regulation of their effects. The effects of TGF-βs and the other family members are mediated from the cell membrane to nucleus through distinct combinations of type I and type II serine/threonine kinase receptors, ►TβRI and ►TβRII and downstream effectors, the ►Smad proteins. The TGF-β receptors form a signaling receptor network with activin like kinase (ALK) receptors. The receptor-regulated Smads become phosphorylated by activated type I receptors, and they form heteromeric complexes with a common partner, Smad4, which gets translocated into the nucleus for gene transcription control. In addition to the signal transducing Smads, inhibitory Smads also play a role in the outcome of the signaling. They down-regulate the activation of receptor-regulated Smads. In contrast to the still growing TGF-β growth factor superfamily, relatively few type I and type II receptors or Smads have been identified. The signaling specificities between different TGF-β superfamily members vary, and a certain family member can elicit a broad spectrum of biological responses.

Latency TGF-β

TGF-βs are produced by the majority of cells in latent complexes unable to associate with TGF-β signaling receptors. Some primary cells and established cell lines secrete active TGF-β. TGF-βs are secreted from cells as latent dimeric complexes containing the mature C-terminal TGF-β and its N-terminal pro-domain, ►LAP, the TGF-β ►latency-associated peptide. The two polypeptide chains of pro-TGF-β associate to form a disulfide bonded dimer. TGF-β is cleaved from its propeptide by furin-like endoproteinase during secretion at RRXR sequence. The LAP propeptide dimer remains associated with the TGF-β dimer by non-covalent interactions. This complex is referred to as small latent TGF-β. TGF-βs are secreted in most cultured cell lines as large latent complexes, consisting of small latent TGF-β covalently bound to one of the three ►latent TGF-β binding proteins (►LTBPs -1, -3 or -4) covalently linked to LAP (Fig. 1). Interestingly, LTBP-2 is unable to form complexes with any of the small latent TGF-βs, suggesting some other functions for this widely expressed molecule. The true LTBPs have a central role in the processing and secretion of TGF-βs, but they evidently have other, for example, structural roles like fibrillins. The expression and secretion of LTBPs and TGF-βs is, in general, coordinately regulated.

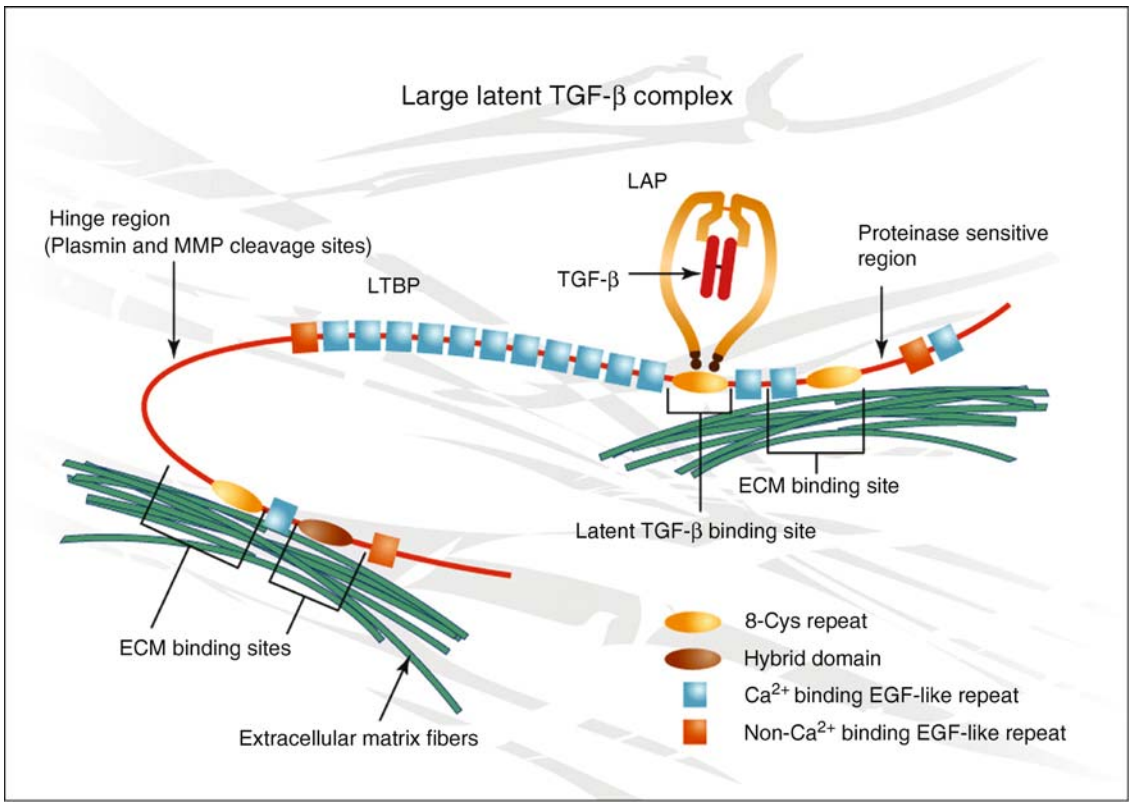
Matrix Association and Release of TGF-β

LTBPs have a central role in the targeting of TGF-β to extracellular matrix structures. LTBPs are produced in excess to TGF-β, and since TGF-β secretion is very inefficient in the absence of LTBP, most secreted cellular TGF-β is in the large latent complexes (Fig. 1). Release of active TGF-β from matrix associated latent complexes appears to require two steps, the release of the large latent complex from ECM by proteolytic truncation, and subsequent activation, which can be achieved by different mechanisms like the integrins. Since TGF-β regulates the cellular production of ECM components as well as the proteolytic balance, the matrix association and activation of TGF-β complexes form a finely tuned control network for the maintenance of the organization of extracellular structures. Cancer cells produce frequently aberrant amounts of both the matrix components and TGF-β. Malignant cells do also frequently fail to deposit TGF-β complexes to the extracellular matrix, probably due to their perturbed deposition of fibronectin-collagen matrix, as well as altered LTBP production.

Latent complexes of TGF-β in the ECM may provide tissues with a readily available storage form of this growth factor. The release and activation of stored growth factors by proteases or migrating cells can generate rapid and highly localized signals like in wound healing or during radiotherapy. Cell movement causes traction of the latent matrix-associated complexes and induces activation. Rapid activation of extracellular signaling mechanisms could be important in the healing of tissues after damage, in the control of cells of the immune system during acute infections and in the initial stages of angiogenesis. It is unclear how soluble growth factors could form gradients in highly cellular tissues. Matrix bound growth factors might generate this kind of an immobilized activity gradient.

LTBPs: Expression and Functions

Relatively few functions have been identified for LTBPs thus far. Structurally they resemble fibrillins, which are components of the extracellular microfibrils. LTBPs have a typical structure consisting of four eight cysteine (8-Cys) repeats and several EGF-like repeats. The association of latent TGF-β with the matrix is mediated by LTBPs (Fig. 1). Not only the N-terminal domains, but also a region of the C-terminus of LTBP are important in this association. The N-terminus contains transglutaminase substrate motifs, and transglutaminase is required for the covalent ECM association. In addition, TGF-β2 and -β3 become associated with LTBPs. It is thus likely



Transforming Growth Factor Beta. Figure 1 Large latent TGF-β complex. The small latent complex contains the C-terminal mature TGF-β and its N-terminal pro-domain, LAP (TGF-β latency-associated peptide). This complex forms a disulphide-bonded complex with the third 8-Cys repeat of LTBP. LTBP associates with the ECM mainly via the 8-Cys domains and some adjoining regions.

that LTBPs mediate and target the binding of all three TGF-β isoforms to various extracellular matrices.

The TGF-β1 binding region in LTBPs is located close to their C-terminus in the third 8-Cys repeat. The association between LTBP-1 and the propeptide part, LAP, is mediated by disulfide bonding. The respective 8-Cys repeats of LTBPs-3 and -4 also bind small latent TGF-βs. Of the numerous known 8-Cys repeats of the LTBPs and fibrillins only three have been found to have the capacity to associate in a covalent manner with the small latent TGF-βs.

Activation of Soluble and Extracellular Matrix Forms of Latent TGF-β

TGF-β can be activated *in vitro* by multiple mechanisms, including proteolysis, enzymatic deglycosylation and extremes of pH. Activation of latent TGF-β involves proteolytic disruption of the non-covalent interaction between the propeptide LAP and TGF-β, which releases biologically active TGF-β capable of binding to its signaling receptors. LAP may also undergo conformational changes in such a manner that TGF-β is released or exposed to its receptors. The existence of different TGF-β isoforms and latent complexes, as well as the number of different LTBPs, suggests that there are variable mechanisms for the activation of TGF-βs.

The electrostatic interaction between LAP and TGF-β can be dissociated *in vitro* by extremes of pH, chaotropic agents, and heat treatment. From the physiological point of view, the acidic environment in the bone (osteoclasts) or during wound healing could induce this kind of ►TGF-β activation.

In vivo analyses of tumor-bearing mice indicated that irradiation (02372) causes rapid activation of TGF-β in the tumors. This effect appears to result from the activation of existing, most probably of matrix-bound latent TGF-β. Irradiation produces reactive oxygen species leading to redox-mediated activation of latent TGF-β complexes. Redox-mediated TGF-β activation may be involved in chronic tissue processes, where oxidative stress is implicated, such as carcinogenesis.

TGF-β can be activated by deglycosylation of LAP. Mechanisms involving proteolysis are, however, more diverse and more likely to operate *in vivo*. Various proteases can degrade LAP and release active TGF-β. Protease inhibitors prevent the activation of TGF-β in cell culture. Cell-cell contacts, targeting of TGF-β, as

well as transglutaminase activity appear to be important in the generation of active TGF-β in vivo.

The processing of pericellular matrix-associated LTBPs and activation of TGF-β are constant events in the ►apoptosis or ►anoikis of endothelial and epithelial cells, pinpointing the importance of pericellular latent complexes as a physiological source of TGF-β.

Thrombospondin-1 (TSP-1), a platelet α-granule and ECM protein, plays a role in the activation of latent TGF-β complexes via a mechanism that does not involve cell surfaces or proteases. Using purified plasma TSP-1 or the recombinant protein it was found that it is able to activate both small and large latent TGF-β complexes. The activation mechanism is not fully understood, but seems to involve the N-terminal end of LAP and the type I repeats of TSP-1, possibly by inducing a change in the conformation of LAP and thus releasing the active TGF-β. TSP-1 interacts with LAP as a part of a biologically active complex, and this may prevent the re-association of the inactive complex of LAP with TGF-β. The expression of TSP is induced during wound healing. TGF-β may thus get focally activated at sites of injury by enhanced TSP synthesis. Accordingly, TSP deficient mice display many phenotypic features, similar to those detected in TGF-β1 deficient mice. The abnormalities in some tissues of the TSP null animals were even reverted by TSP-derived TGF-β activating peptides, further emphasizing the role for TSP in TGF-β activation.

The LAP part of TGF-β contains an RGD-motif, which is recognized by integrins (►Integrin signaling and cancer) $\alpha_v\beta_1$ and $\alpha_v\beta_6$. Integrin $\alpha_v\beta_6$ is also able to activate TGF-β. This activation model is particularly interesting, because $\alpha_v\beta_6$ integrin is expressed solely on epithelial cells, which are very sensitive to TGF-β mediated growth inhibition, and also because the overlap of the phenotypes of TGF-β1 and integrin β_6 chain deficient mice. β_6 integrin deficient mice show increased inflammation and decreased fibrosis, processes that are regulated by TGF-β.

Hormonal effectors (►Tamoxifen) can also affect TGF-β activation. Originally it was found that antiestrogens could induce the production and secretion of active TGF-β in cultured breast cancer cells. Activation of TGF-β has subsequently been observed in a number of cell culture models using estrogens and antiestrogens, retinoids and vitamin D derivatives. Steroid hormone superfamily members are efficient regulators of the expression of TGF-β isoforms, and TGF-βs are likely to act as local mediators of the diverse actions of steroids. Estrogens and antiestrogens regulate TGF-β1 formation in different cells and tissues like in mammary carcinoma cells and in fetal fibroblasts. TGF-β functions, for instance, as an autocrine negative growth regulator in breast carcinoma cells.

TGF-Beta and LTBP Knockout Mice

The importance of the three different TGF-βs is elucidated in the gene knockout studies. Knockout of TGF-β1 results in multifocal inflammatory disease leading to the death of the animal. TGF-β2 knockout is embryonally lethal. The mice develop severe cardiac, lung and craniofacial defects. Inner ear and eye are also affected. TGF-β3 null mice develop cleft palate.

Accordingly, null-mice unable to produce LTBPs develop serious physiological defects. LTBP-3 knockout mice develop multiple defects such as growth retardation, emphysema, bone malformations and abnormalities of thymys and spleen. Their lifespan is, however, normal and they are able to reproduce. Hypomorphic LTBP-4−/− mice develop early emphysema and colorectal tumors, indicative of missing growth inhibitor. The short and long splice forms have different functions. LTBP-1L null mice exhibit a cardiac phenotype, which reveals a crucial role for Ltbp1L and matrix as extracellular regulators of Tgf-beta activity in heart organogenesis.

Perspective

Growth factors of the TGF-β family are important autocrine and paracrine regulators of cell proliferation and differentiation. The regulation levels of their activities include the expression of TGF-β receptors, availability of TGF-βs, their activities and modulation of the cellular response. Most cells secrete TGF-β in a large latent complex, which associates with the extracellular matrix and is unable to bind to the TGF-β signaling receptors. LTBPs have a central role in TGF-β secretion, extracellular matrix deposition and activation. In addition, LTBPs have structural and other functions not directly related to TGF-β signaling. Structural diversity in LTBP proteins is tremendous, and the possible functions of the different forms include, amongst others, the modulation of cell adhesion and the functions of integrins.

Focal activation of latent TGF-β in the matrix by physicochemical means offers a rapid way to induce TGF-β signaling. In addition to plasmin-mediated TGF-β activation novel mechanisms have been found including other proteases, reactive oxygen species, thrombospondin and integrin mediated activation.

The modulation of pericellular proteolytic activity by TGF-β supports a general cascade of events, where proteinases and latent matrix-bound growth factors are components of extracellular signal transduction machinery. This directs tissue construction and remodeling, and probably also regulates the activity of infiltrating immune cells. Disturbances in these control systems could participate in the pathogenesis of a variety of disease states like atherosclerosis, cancer, various fibrotic diseases and chronic inflammation.

Transforming Retroviruses

Definition

A class of ►retroviruses that is capable to transform host cells. Two classes of transforming retroviruses can be distinguished:

1. Acute transforming retroviruses are characterized by the presence of an oncogene in their genome that has been acquired during host cell passage by retroviral transduction. Elimination of this retroviral oncogene (v-*onc*) by deletion or mutations within the oncogene that affect its function (e.g. a temperature-sensitive mutation), results in the loss of the transforming activity of the virus. This demonstrates that the presence of v-*onc* in the retroviral genome is necessary and sufficient to induce host cell transformation. Examples for this sub-class are the Rous Sarcoma Virus (v-*src*), Abelson leukemia virus (v-*abl*) and Mill Hill 2 virus (v-*myc*; v-*mil*/*raf*-1).
2. Slow transforming retroviruses lack a v-*onc* gene, but often trigger tumorigenesis by inserting their proviral genome into genomic regions that control the expression of proto-oncogenes (insertion mutagenesis). For example, avian B cell lymphomas often contain proviral sequences derived from the Avian leukosis virus in the promotor region of the c-*myc* proto-oncogene. As the retroviral control elements represent strong promotors, the transcription of the c-*myc* gene is largely driven by the provirus and uncoupled from its tight control by the cellular signaling network. This results in Myc overexpression and malignant transformation.

Transgene

Definition

A foreign gene introduced into a cell by viral or non-viral gene transfer techniques.

Transgenic

Definition

Transgenic animals or plants are created by introducing new DNA sequences into the germ line via addition to the egg. The use of transgenic mice carrying an alien gene in every cell is a widely used experimental system in biomedical science. They are generated by microinjection of DNA (transgene) into fertilized eggs, which are then implanted into pseudopregnant foster mothers. The offspring often carries the transgene in all cells, including germ cells. Thus, the transgene will be transmitted according to Mendelian genetics. Transgenic mice represent a tool to study gene effects in the context of the whole organism.

►Mouse Models

Transgenic Animal

Definition

An animal to which new DNA has been inserted into its genome.

►Mouse Models

Transgenic Mice

Transglutaminase-2

KAPIL MEHTA
The University of Texas MD Anderson Cancer Center, Houston, TX, USA

Synonyms

Tissue-transglutaminase; tTGase; Transglutaminase type-2; TG2; Cytosolic transglutaminase; TGc; Endothelial transglutaminase; Liver transglutaminase and G_h

Definition

Tissue transglutaminase (►TG2; EC 2.3.2.13) is a ubiquitous and most diverse member of the transglutaminase family of enzymes. TG2 catalyzes calcium-dependent post-translational modification of proteins by inserting highly stable ►isopeptide bonds between polypeptide chains or by conjugating ►polyamines to proteins. In addition, TG2 exhibits ►GTPase activity and can serve as a ►signal-transduction G protein. Less studied functions of TG2 include its protein disulfide isomerase and ►protein kinase activities.

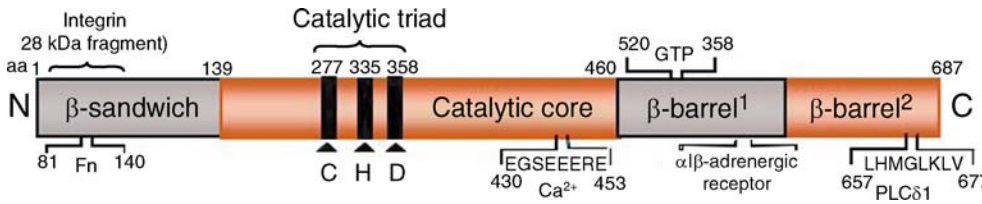
Characteristics

TG2 is a multifunctional protein whose expression in some cell types (e.g., endothelial and smooth muscle cells) is constitutively high. In other cell types, TG2s expression is up-regulated via discrete signaling pathways, such as those induced by certain stress factors, inflammatory stimuli, differentiation agents, and growth factors. Although predominantly a cytosolic protein, TG2 can translocate to the nucleus by "piggy-back riding" other proteins, such as ►importin-alpha-3, or translocate to membranes in association with ►integrins. TG2 can also be secreted outside the cell (by an as-yet unknown mechanism), where it can crosslink extracellular matrix (ECM) proteins and promote ►adhesion of several cell types. An important feature of TG2 is its high binding affinity for ►fibronectin; in cancers, membrane-associated TG2 can promote a stable interaction between cell surface integrins and fibronectin and promote cell growth and survival (Fig. 1).

TG2 and Apoptosis

A role for TG2 in apoptosis was initially suggested by Dr. Laszlo Fesus and his coworkers in 1987 based on the observation that lead-induced hypertrophy of the liver in rats was associated with cellular expression of increased TG2. Since then, many reports have supported the role of TG2 in apoptosis. In general, the expression of TG2 is markedly increased in cells undergoing apoptosis. Forcibly increasing the expression of TG2 in several cell types results in apoptosis or makes them susceptible to death-inducing stimuli. Conversely, reducing TG2 levels by antisense RNA renders the cells more resistant to apoptosis. It is believed that TG2 promotes apoptosis by crosslinking intracellular proteins, preventing their leakage from cells and induction of an inflammatory response. These observations suggest that cells generally do not tolerate the increased expression of TG2 and that TG2 overexpression leads to apoptotic death.

However, some recent reports have provided paradoxical evidence and suggest that TG2 expression and apoptosis do not always go hand in hand. For example, $TG2^{-/-}$ knockout mice (mice lacking all TG2 expression) did not show any genetic alterations that are suggestive of perturbed apoptosis. The possibility that some other proteins compensate for the loss of TG2 in these mice cannot be ruled out. Furthermore, various other studies have provided data suggesting that increased expression of TG2 can prolong cell survival by preventing apoptosis.



Transglutaminase-2. Figure 1 Schematic representation of various functional domains of the TG2 protein. In addition to catalyzing calcium-dependent protein crosslinking function, TG2 can catalyze calcium-independent GTPase, ATPase, protein kinase, and protein disulfide isomerase activities. TG2 can modulate the functions of other proteins by directly interacting or associating with them; examples include ►phospholipase-δ_1, members of the β-integrin family, focal adhesion kinase, fibronectin, osteonectin, ►RhoA, multilineage kinases, and ►retinoblastoma protein. Through these activities, TG2 plays a role in biological processes such as ►apoptosis, wound healing, and cataract formation. Recent work suggests that TG2 can also serve as a signaling molecule and promote cell growth, drug resistance, and metastatic functions in tumor cells.

TG2 in Drug Resistance and Metastasis

Evidence is accumulating that cancer cells that are resistant to chemotherapeutic drugs or that are isolated from metastatic sites express elevated levels of TG2. Also, there is evidence that drug-resistant and metastatic cancer cells share some common pathways. For example, cells from advanced-stage cancers accumulate a large number of genetic alterations that can render them resistant to apoptosis. Resistance to apoptosis can enable cancer cells not only to grow and survive in the stressful environment of distant tissues (i.e., to metastasize) but also to withstand the toxic effects of drugs. Moreover, cell lines selected *in vitro* for resistance against chemotherapeutic drugs are more metastatic *in vivo*, while cancer cells isolated from metastatic sites, in general, exhibit higher resistance to chemotherapeutic drugs. Based on these observations we hypothesized that aberrant expression of TG2 in drug-resistant and metastatic cancer cells may deregulate some intrinsic apoptotic pathways in order to protect cells from apoptosis. Indeed, down-regulation of endogenous TG2 by antisense RNA, TG2-specific ribozyme, or small interfering RNA (►siRNA) could reverse drug resistance in ►lung cancer and ►breast cancer cells. Similarly, inhibition of TG2 by siRNA in breast cancer and malignant ►melanoma cells augmented their response to chemotherapeutic drugs and reduced their invasiveness in laboratory experiments. In pancreatic cancer cells, inhibition of TG2 by siRNA resulted in massive accumulation of lysophagosomes and onset of ►autophagy (type II apoptosis). These properties suggest that TG2 expression in cancer cells contributes to the development of drug resistance and ►metastasis.

Studies to elucidate the mechanisms involved in the development of TG2-mediated drug resistance in cancer cells revealed that TG2 expression augments cell survival signaling by promoting a stable interaction between cell surface integrins and the ECM proteins. Depending on the cell type, 20–30% of total TG2 can exist in complex with β-integrins (e.g., β1 β4 and β5). The association of TG2 with integrins occurs primarily at their extracellular domains and promotes their interaction with ECM ligands such as fibronectin, collagen, and vitronectin. Down-regulation of TG2 in glioblastoma cells resulted in decreased assembly of fibronectin in the ECM and cell death. Importantly, treatment of mice that had orthotopic glioblastomas with the TG2 inhibitor ►KCC009 sensitized the tumors to chemotherapy, induced apoptosis of cancer cells, and prolonged survival of the animals. Further, the interaction between TG2 and integrins is independent of the crosslinking activity of TG2 and results in increased cell adhesion, ►migration, and activation of downstream survival signaling pathways such as ►focal adhesion kinase (FAK). Interestingly, TG2 can also interact directly with focal adhesion kinase and result in its autophosphorylation (pY397) and consequent activation of the downstream ►PI3K and ►Akt signaling.

Activation of the ►nuclear factor-κB (NF-κB), which plays an important role in regulating cell growth, apoptosis, and metastasis, has also been associated with increased TG2 expression in cancer cells. Tumor cells that overexpressed TG2 exhibited increased levels of constitutively active NF-κB. Activation of TG2 led to activation of NF-κB, and conversely, inhibition of TG2 activity inhibited the activation of NF-κB. Similarly, ectopic expression of TG2 caused activation of NF-κB, and inhibition of TG2 expression by siRNA abolished the NF-κB activation and rendered drug-resistant breast cancer cells sensitive to doxorubicin-induced cytotoxicity. Notably, immunohistochemical analysis of pancreatic ductal adenocarcinoma tumor samples further supported a strong correlation between TG2 expression and NF-κB activation. These observations suggest that TG2 induces constitutive activation of NF-κB in tumor cells via a novel pathway. Therefore, TG2 may be an attractive target for inhibiting constitutive NF-κB activation and rendering cancer cells sensitive to anticancer therapies.

Clinical Relevance

Drug resistance and metastasis are major impediments to the successful treatment of cancer. More than 90% of cancer-related deaths can be attributed to the failure of chemotherapy. On the basis of published results that drug-resistant and metastatic tumors and tumor cell lines express high levels of TG2, that TG2 expression promotes cell survival and invasion and that down-regulation of TG2 results in increased sensitivity of cancer cells to chemotherapeutic drugs and to undergo programmed cell death (apoptosis or autophagy), TG2 may offer an attractive target for treating drug-resistant and metastatic tumors.

Synonyms

Urothelial tumor; Transitional cell carcinoma of bladder; Transitional cell carcinoma of renal pelvis; Transitional cell carcinoma of ureter; Urothelial Carcinoma, Clinical Oncology

Definition

Transitional Cell Carcinoma (TCC) arises in the urothelium that covers the lining of the renal calyx, renal pelvis, ureter, bladder and part of the urethra. Although the WHO/ISUP consensus conference has determined that the term *urothelial cancer* is preferable to the term *transitional cell cancer*, the latter remains in widespread use. "Urothelial cancer" may also be confusing because cancers of other histologic types, such as squamous cancers and adenocarcinomas, also arise in the urothelium.

Characteristics

Epidemiology

It was estimated that in 2007, 67,160 new cases of bladder cancer would be diagnosed and 13,750 patients

would die of invasive bladder cancer in the United States. ►Bladder cancer is nearly three times more common in men than in women and more than 90% of bladder cancers are TCCs. The median ages at diagnosis for TCC are 69 years in males and 71 years in females.

Upper urinary tract urothelial tumors involving the renal pelvis or ureter are relatively uncommon, accounting for about 5–7% of all renal tumors and about 5% of all urothelial tumors.

Etiology

One of the genetic changes that must occur for malignant transformation is the induction of oncogene. Oncogenes associated with TCC include those of the ►RAS gene family, including P21 RAS oncogene, and up to 50% of TCCs have been claimed to have RAS mutations. Another important molecular mechanism in the process of carcinogenesis is the inactivation of tumor suppressor genes. These include that of ►P53, the most frequently altered gene in human cancers, the retinoblastoma (RB) gene (►Retinoblastoma Protein, Biological and Clinical Functions), and genes on chromosome 9. Overexpression of normal genes including those for EGF receptor (ERBB1) and ERBB2 (►Epidermal Growth Factor Receptor Ligands) occur in most TCCs.

Cigarette smokers have a fourfold higher incidence of TCC than do people who have never smoked (►tobacco-related cancers). Ex-smokers have a reduced incidence of TCC, but the reduction of this risk down to baseline takes nearly 20 years. ►Nitrosamines, 2-naphthylamine and 4-aminobiphenyl are suggested as being responsible for TCC in cigarette smoke. Women treated with radiation for carcinoma of the uterine cervix or ovary, have a two- to fourfold increased risk of developing bladder cancer. Patients treated with ►cyclophosphamide have up to a ninefold increased risk of developing bladder cancer.

Signs and Symptoms

Microscopic or gross ►hematuria is the most common presenting symptom. Patients with gross hematuria have reported rates of bladder cancer of 13–35%. With microscopic hematuria, the rates decreased to 0.5–10.5%. So, if a patient has unexplained hematuria, either microscopic or gross, cystoscopic examination is usually warranted, especially in individuals older than age 60 or younger people with a smoking history.

The second most common presentation is the constellation of lower urinary tract irritative symptoms such as urinary frequency, urgency, and dysuria. These irritative symptoms usually occur with hematuria. In fact, the risk of TCC may be doubled in patients with irritative voiding symptoms that coexist with hematuria.

Evaluations

In all patients with signs and symptoms suggestive of bladder cancer, ►excretory urography (IVU) is indicated. It is useful in examining the upper urinary tracts for associated urothelial tumors. Large bladder tumors may appear as filling defects in the bladder, but small ones may not be detected. More recently, computed tomography (CT) has replaced IVU in the evaluation of hematuria. After imaging studies, all patients suspected of having bladder cancer should have cystoscopy. Retrograde ►pyelography should be done if the upper tracts are not visualized on IVU or CT.

CT can help to assess the extent of the primary tumor and provides information about the presence of pelvic and para-aortic lymphadenopathy and visceral metastases. But CT fails to detect nodal metastases in up to 40–70% of patients who have them. MRI is not much more helpful than CT. Pelvic lymphadenectomy, which can be done with cystectomy, is the most accurate means of determining regional node involvement. The primary regions of lymphatic drainage of the bladder are the perivesical, hypogastric, obturator, external iliac and presacral nodes. As some patients with limited nodal metastases can be benefited by lymphadenectomy, bilateral node dissection should be done. The usually recommended metastatic evaluation for invasive bladder cancer includes a chest radiograph, abdominal-pelvic CT, bone scan and liver function tests.

A flexible cystoscope is often used for the initial diagnosis and follow-up of patients with bladder tumors. It has much less discomfort than a rigid cystoscope. Bugbee electrode devices can be inserted through a flexible cystoscope to allow destruction of small, non-invasive papillary tumors.

Ta	Papillary, epithelium confined
Tis	Flat carcinoma in situ
T1	Lamina propria invasion
T2a	Superficial muscularis propria invasion
T2b	Deep muscularis propria invasion
T3a	Microscopic extension into perivesical fat
T3b	Macroscopic extension into perivesical fat
T4a	Cancer invading pelvic viscera
T4b	Extension to pelvic sidewalls, abdominal walls, or bony pelvis
N0	No histologic pelvic node metastasis
N1	Single positive node ≤2 cm in diameter, below common iliacs
N2	Single positive node 2–5 cm in greatest diameter or multiple positive nodes
N3	Positive nodes >5 cm in diameter
M0	No distant metastases

Malignant urothelial cells have large nuclei with irregular, coarsely textured chromatin and can be observed on microscopic examination of the urinary sediment. This microscopic cytology is more sensitive in patients with high grade tumors or ►carcinoma in situ (CIS). The specificity and positive predictive value of cytology are quite high.

Staging (1997 AJCC-UICC, TNM Staging)

As tumor stage forms the foundation for determining therapy, accurate staging is critical. The first treatment decision based on tumor stage is the presence or absence of muscle invasion. Because metastases are very rare with a superficial (non-muscle-invasive) tumor, treatment strategy can be grouped into superficial (Ta, T1 and Tis), muscle-invasive, and metastatic tumors. About 70% of bladder tumors are superficial at presentation. Of these, 70% present as stage Ta, 20% as T1, and 10% as CIS.

Treatment of Superficial Bladder Cancer

Local resection of a bladder tumor usually enables complete removal of the tumor and provides diagnostic information about the depth and the grade of the tumor. For this, first the bulk of the tumor and then the deep portion with some underlying bladder muscle should be resected. To detect dysplasia or CIS elsewhere in the bladder, selected site mucosal biopsies from areas adjacent to the tumor, bladder dome, trigone and prostatic urethra have been recommended. If 5-aminolevulinic acid (ALA) is administered into the bladder in conjunction with fluorescent cystoscopy, lesions invisible with normal cystoscopy can be detected.

The most important issue in tumor biology of superficial tumors is recurrence and progression to higher stages. Low-grade Ta tumors recur at a rate of 50–70% and progress in about 5%. High-grade T1 lesions recur in 80% and progress in 50% of patients. The most important risk factor for progression in superficial bladder tumors is grade, not stage. Prognosis also correlates with the presence of CIS, tumor size, multiplicity, lymphovascular invasion and the configuration of the tumor (papillary vs. sessile). Of patients with CIS, 40–83% will develop muscle invasion if untreated.

For T1 tumors, the depth of lamina propria invasion determined by the muscularis mucosa invasion or the extent of invasion below the urothelial surface has been known to be correlated with prognosis. CT and MRI appear to be inaccurate in determining the microscopic muscle infiltration and the minimal extravesical spread, which can also be aggravated by post-tumor recurrence (TUR) changes.

To prevent recurrence and progression of bladder tumors, intravesical immunotherapy using BCG (►Bacillus Calmette-Guerin) has been used. Treatments are generally begun 2–4 weeks after TUR and a 6-week course is usually administered. With BCG, tumor recurrence was reduced by 20–65% and progression was reduced by 23–27%. Intravesical chemotherapy using ►Mitomycin C, ►Doxorubicin, ►Thiotepa, ►Epirubicin and ►Gemcitabine also has been administered.

Treatment of Invasive Bladder Cancer

The standard surgical approaches to muscle-invasive bladder cancer are radical cystoprostatectomy in the male patient and anterior exenteration in the female patient, with bilateral pelvic lymphadenectomy. Anterior exenteration in the female requires removal of the uterus, fallopian tubes, ovaries, bladder, urethra, and a segment of the anterior vaginal wall. A nerve-sparing modification has been proposed in the male patient and results in improved postoperative return of erectile function.

The more prevalent the orthotopic reconstruction becomes, the stricter indications for urethrectomy have been applied. The most significant factor for the anterior urethral recurrence and local/distant failure in the male patient has been identified as prostatic urethral involvement. The estimated 5-year probability of urethral recurrence is 5% without any prostate involvement and 12–18% with prostate involvement. CIS of the bladder neck and trigone was also significantly associated with prostatic urethral involvement. In the female patient, overt cancer at the bladder neck and urethra, diffuse CIS, or positive margin at surgery should be treated by en bloc urethrectomy as a part of the radical cystectomy.

The mortality rate for radical cystectomy is 1–2% and the overall complication rate is about 25%. After urinary tract diversion, bowel obstruction rate is 4–10%. Stricture of anastomosis between ureter and bowel are found in less than 3%. Depending on the type of neobladder, metabolic disorders, vitamin deficiency, and urinary tract infection can occur.

As for the ►neoadjuvant chemotherapy, recent results suggested improvement in overall survival of 5–6% among patients with locally advanced disease (stage T3 to T4a). Some reports suggest that for patients with locally advanced disease and lymph node involvement, ►adjuvant chemotherapy may also provide a survival advantage. Due to the small numbers of patients, these results are as yet insufficient for the routine use of adjuvant therapy.

Treatment of Metastatic Bladder Cancer

These patients are routinely treated with systemic chemotherapy. The most commonly used agents are ►methotrexate, ►vinblastine, ►doxorubicin, and ►cisplatin (MVAC). MVAC chemotherapy produces a complete response in about 20% of patients, although long-term disease-free survival is rare. The combination of cisplatin and a newer agent, ►gemcitabine (GC) has

produced similar survival outcomes with less toxicity compared with MVAC. ►Paclitaxel and ►docetaxel have also been used in clinical trials and demonstrate response rates of 25–83%.

Translation

Definition

Process by which proteins are synthesized from messenger RNA templates. It has three stages: initiation, elongation and termination.

Translation Initiation Complex

Definition

Protein complex that promotes the proper association of ribosomes with messenger RNA and is necessary for the initiation of ►translation.

Translesion DNA Polymerases

W. Glenn McGregor
James Graham Brown Cancer Center, University of Louisville School of Medicine, Louisville, KY, USA

Definition

Translesion DNA synthesis (TLS) is a highly conserved mechanism for the completion of replication of

T

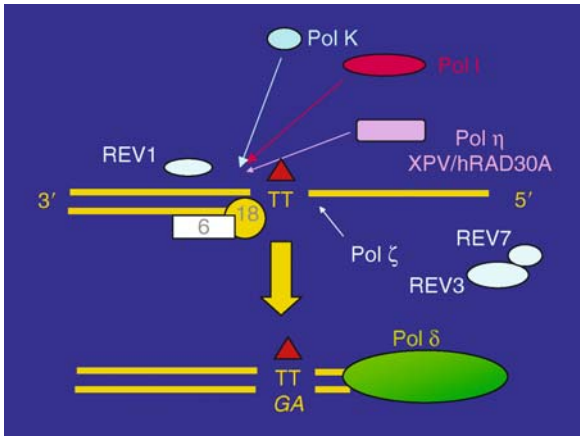
damaged genomes. Analogous pathways exist in bacteria, and homologs with remarkable similarity exist in all eukaryotic cells, including post-mitotic organisms such as *D. melanogaster*. Recent advances in elucidating the molecular mechanisms of carcinogen-induced mutagenesis indicate that replication of DNA templates that contain replication-blocking adducts is accomplished with error-prone DNA polymerases. These polymerases have relaxed base-pairing requirements, and can insert bases across from adducted templates, but with potentially mutagenic consequences.

Characteristics

Most mutations induced by genotoxic carcinogens occur when a DNA template that contains residual (unrepaired) damage is replicated during S-phase of the cell cycle. Presumably, the replication complex is blocked by bulky adducts in the DNA such as those induced by ultraviolet light (UV) or a variety of chemical carcinogens (►Adducts to DNA).

As diagrammed in Fig. 1, recent advances indicate that error-prone translesion synthesis (TLS) is responsible for the majority of base substitutions induced in the DNA. TLS is defined as the incorporation of a nucleotide across from DNA damage followed by extension of the potentially mispaired primer-template. This process is undertaken by at least five accessory DNA polymerases, several of which have been purified and studied in vitro (►DNA damage responses). The properties of these polymerases have been extensively reviewed. Based on structural homology, these polymerases fit into one of two families: the Y-family (REV1, pol η, ι, and κ), or the B-family (pol ζ). The cellular roles of this universe of polymerases are not known. In particular, the extent to which each of these polymerases participates in TLS most likely depends on the structure of a particular adduct and on the sequence context. As shown in Fig. 1, it has been suggested that pol η, ι, and/or κ inserts a base directly across from a lesion, and that pol ζ extends the mispair to form a template-primer that can be extended by pol δ. Although REV1 is a DNA polymerase, its role in mutagenesis is thought to be structural rather than catalytic.

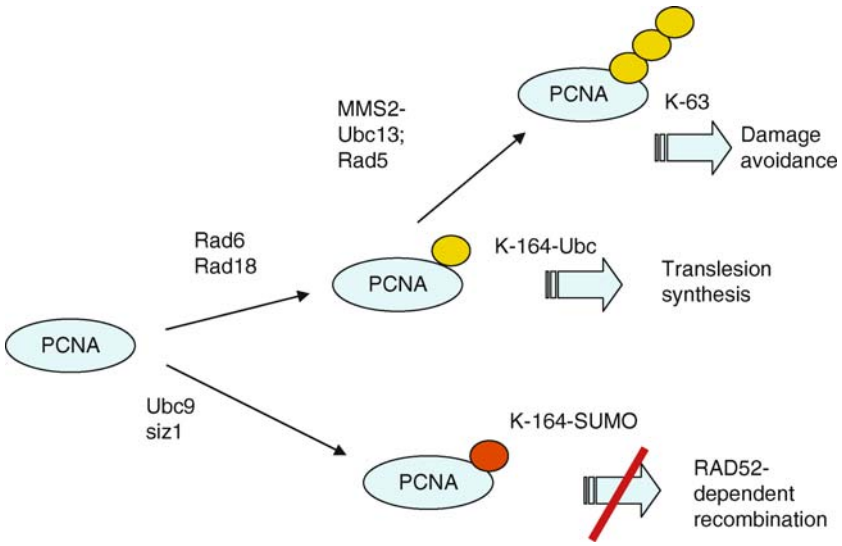
The unrestrained activity of error-prone polymerases would lead to widespread mutagenesis and genomic instability, so there are signaling mechanisms that tightly control polymerase switching events. Although not fully understood, the mechanisms used by cells to accomplish polymerase switching events at blocked primer temini have been studied most intensively in the budding yeast, *Saccharomyces cerevisiae*. In this organism, replication-blocking lesions in the template strand can be bypassed by proteins in the Rad6-dependent DNA damage tolerance pathway. This process



Translesion DNA Polymerases. Figure 1 Model for translesion replication. The replicative polymerase complex stalls at sites of helical distortion induced by DNA damage, such as UV-induced photoproducts. The presumed ubiquitin ligase RAD18 targets a ubiquitin conjugating enzyme, RAD6, to the site of damage. There are two closely related homologs of RAD6 in higher eukaryotic cells, termed RAD6A and RAD6B. One of the targets of ubiquitination appears to be PCNA, which signals accessory polymerases in ways that are not fully understood, although at least one TLS polymerase, pol η, has a higher affinity for monoubiquitinated PCNA. Current thinking is that one of the Y-family polymerases (pol η, pol ι, or pol κ) may insert a base directly across from the lesion, but pol ζ is required to extend the resulting primer such that the pol ***δ*** can continue processive DNA replication. REV1 is required for mutagenesis, but this role is probably separate from its dCMP transferase activity. Recent data indicate that REV1 may tether pol ζ to the other accessory polymerases.

prevents the collapse of stalled replication forks, and replication of the damaged template is completed by TLS with potentially mutagenic consequences, or by damage avoidance mechanisms mediated by recombination that are largely error-free.

As diagrammed in Fig. 2, the ubiquitin conjugating enzyme encoded by *Rad6* and the presumed ubiquitin ligase encoded by *Rad18* are central to this process, since mutants cannot bypass replication-blocking lesions in the template and are sensitive to many DNA damaging agents. Insights into the biochemical function of this complex were gained when the Rad18/Rad6 complex was found to be responsible for the monoubiquitination of PCNA at K164. PCNA modified in this fashion is thought to signal translesion synthesis and further ubiquitination is thought to signal damage avoidance (Fig. 2). Although the molecular details of the signaling pathways downstream of monoubiquitination are unknown, at least one TLS polymerase, pol η, has



Translesion DNA Polymerases. Figure 2 Regulation of lesion bypass in the budding yeast *Saccharomyces cerevisiae* is thought to be signaled by modification of PCNA at lysine 164 (K-164). The presence of a stalled DNA replication fork recruits Rad18, which is a presumed ubiquitin ligase, and Rad6, a ubiquitin conjugase, to the site of the replication-blocking lesion. Monoubiquination at K-164 leads to recruitment of TLS polymerases with potentially mutagenic consequences. Polyubiquitination at lysine 63 (K-63) of ubiquitin by MMS2-Ubc13 leads to damage avoidance. A proposed mechanism for damage avoidance is uncoupling of the replication fork, such that the undamaged strand is replicated for some distance beyond the blocked replication complex. The nascent strand, which has the same sequence as the damaged strand, then acts as a template for replication. The damage is thereby avoided in an error-free manner. A competing reaction is sumoylation at K164 by the SUMO (small ubiquitin modifier)-specific ligase Siz1 and conjugase Ubc9. This reaction is thought to suppress Rad52-dependent recombination and damage-induced genomic instability.

been shown to have enhanced affinity for monoubiquitinated PCNA.

The strategies used by yeast cells to complete the replication of damaged genomes appear to have been conserved in higher eukaryotes, but with additional layers of complexity. For example, higher eukaryotic cells have at least two Y-family polymerases that are not found in yeast and one of these (pol κ) appears to be independent of RAD18. Human RAD18 was cloned and the protein was purified. It is a 56 kDa protein that shares 26% identity and 59% similarity with its yeast counterpart. The protein interacts with the two RAD6 homologs found in higher eukaryotes (RAD6A and RAD6B) with equal affinity and is ubiquitously expressed in all human tissues. Among the conserved regions are a RING finger motif found in the N-terminus that is required for the interaction with RAD6A/B, and a zinc finger that is presumably required for interaction with DNA.

In principle, the accessory DNA polymerases and associated proteins described herein represent potential targets for antimutagenesis strategies. However, deficiency of individual polymerases may result in enhanced carcinogenesis. The most well-studied example of this is the human syndrome xeroderma pigmentosum variant, which is a skin cancer-prone condition that results from an inherited deficiency of DNA polymerase η. This enzyme is posited to be specialized for the error-free bypass of cyclobutane dimers between adjacent thymidine bases. In its absence, recent data indicate that polymerase iota assumes its function and is error-prone when doing so. Unexpectedly, however, when both polymerases are deficient in mouse models, UV-induced skin cancer is accelerated despite reduced UV-induced mutant frequencies in the double knockout. These data support a role for polymerase iota as a tumor suppressor separate from its role in TLS.

Translesion Synthesis

Definition

Error-prone DNA-repair process that involves a switch to low fidelity DNA-dependent polymerases to bypass an unhooked interstrand crosslink. Since both DNA strands are damaged at the site of such lesion, the antisense strand cannot serve as a template for repair.

►Translesion DNA Polymerases

Translin

Definition

TSN; A Protein encoded by the TSN gene is reported to recognize single-stranded DNA ends of staggered breaks that may occur at recombination hotspots. A role in recombination repair has been suggested, but has still to be confirmed.

►ALU Elements

Translocase

Definition

Is an enzyme that translocates lipids between the two leaflets of the lipid bilayer.

►P-glycoprotein

Translocation

Definition

- Translocation of chromosomes is the illegitimate recombination between nonhomologous chromosomes, a rearrangement in which part of a chromosome is detached by breakage and then becomes attached to another chromosome. The translocation may or may not be reciprocal; in reciprocal balanced translocations, genetic material is exchanged without loss between nonhomologous chromosomes; in unbalanced translocations chromosomal material, often the translocated material from one of the nonhomologous chromosomes is deleted.
- Translocation of proteins is the regulated movement of proteins or other molecules from one cellular compartment or organelle to another.

Translocation ETS Leukemia Gene

►ETV6

Translocation Non-homologous

Definition

Non-homologous translocation; rearrangement of chromosomes that results in the fusion of two chromosomal segments that are not normally attached to one another, often resulting in a microscopically visible alteration of karyotype; unbalanced translocations often involve deletion of genetic material.

Translocation Reciprocal

Definition

Reciprocal translocation; exchange of chromosomal segments between two chromosomes from different chromosome pairs, resulting in the conservation of all participating chromosomal segments; no phenotypic change will occur when the translocation is balanced, which means at the same position of the two homologous chromosomes.

Translocation t(14;18)

Definition

Chromosomal translocation commonly associated with non-Hodgkin B-cell lymphomas. This chromosomal

translocation event places the ►Bcl-2 gene into juxtaposition with powerful enhancer elements associated with the IgH locus, causing a transcriptional deregulation of the Bcl-2 gene and resulting in elevated levels of Bcl-2 mRNA and Bcl-2 protein production.

Transmembrane

Definition

Referring to the domain of a protein that is threaded through a membrane and therefore exists in the hydrophobic environment of a lipid bilayer.

Transmembrane 4 Superfamily Protein

►Metastasis Suppressor KAI1/CD82

Transmembrane Domain

Definition

The portion of a protein that spans the lipid bilayer of the cell membrane.

►Prostate-Specific Membrane Antigen (PSMA)

Transmembrane Protein Type I

Definition

A transmembrane protein that exposes its carboxyl terminus into the cytosol.

►Endoplasmic Reticulum Stress

Transmembrane Protein Type II

Definition

A transmembrane protein that exposes its amino terminus into the cytosol.

►Endoplasmic Reticulum Stress

Transmembrane Signaling

Definition

The plasma membrane of mammalian cells provides a protective barrier and many extracellular agonists are unable to enter the cell. Instead, they recognize and activate specific receptors at the cell surface that in turn stimulate activity of proteins (e.g., lipid-hydrolyzing enzymes) present inside the cell and in this way transmit the signal across the membrane, i.e., from extracellular to intracellular environment.

Transmigration Assay

Definition

Is an *in vitro* assay where cells are placed on one side of a chamber containing a porous membrane (usually coated with an artificial ►extracellular matrix), a hormonal stimulus is applied, and the rate at which cells migrate across the membrane is determined. It measures cell invasiveness, or the ability of metastatic cells to escape from a tumor.

Transphosphorylation

Definition

When two receptor tyrosine kinases are brought into close proximity to each other, the tyrosine kinase domain of one of the receptors phosphorylates the kinase domain on the other receptor. Likewise, the

freshly phosphorylated kinase domain is now more active and can phosphorylate and activate the kinase domain on the remaining receptor.

Transplacental Carcinogen

Definition

A substance that is able to cross the placenta, inducing cancer in the offspring.

►Diethylstilbestrol

Transporter Nomenclature

Definition

Refers to the names used to describe the various biological transporters and pumps used to move a drug through the body.

►ADMET Screen

Transporters

Definition

Are biological protein pumps which move a chemical from one place in the body to another.

►ADMET Screen
►ABC Drug-Transporter

Transposon

Definition

A mobile DNA element that is capable of moving within the genome, either by copying itself or by cutting itself out of its original site and inserting in a new location.

►Retroviral Insertional Mutagenesis

Transpupillary Thermal Therapy

Definition

Near-infrared frequency laser used to concentrate thermal injury on the site of interest (e.g., tumor) leaving the surrounding tissue generally undisturbed.

►Uveal Melanoma

Transurethral Resection

Definition

TUR; Endoscopic operation to remove tumor tissue from the bladder or the prostate via the urethra.

►Urothelial Carcinoma, Clinical Oncology

Transversion

Definition

A point mutation in which a purine base is mutated to a pyrimidine base or vice-versa. Mutations from purine to purine or pyrimidine to pyrimidine are transitions.

►UV Radiation

Trastuzumab

Definition

Synonym ►Herceptin; is a humanized IgG1κ monoclonal antibody specifically binding to HER-2.

Human epidermal growth factor 2 (►HER2/neu), also known as ErbB-2, is a member of the epidermal growth factor receptor (ErbB) family and is notable for its role in the pathogenesis of ►breast cancer and as a target of treatment. It is a cell membrane receptor tyrosine kinase normally involved in the signal transduction pathways leading to cell growth and differentiation.

HER2 is named because it has similar structure to human epidermal growth factor receptor, or HER1. ErbB2 was named for its similarity to ErbB (avian erythroblastosis oncogene B), the oncogene later found to code for EGFR. Gene cloning showed that *neu*, HER2, and ErbB2 were the same.

Trastuzumab is approved for treatment of HER-2 overexpressing metastatic breast cancer in combination with chemotherapy and as single-agent therapy in those patients with metastasic breast cancer who do not respond to chemotherapy.

►Monoclonal Antibody Therapy
►Drug Design
►Herceptin

βTrCP

Definition

Beta-transducin repeats-containing proteins (βTrCP) serve as the substrate recognition subunits for the SCF complexes. βTrCP interact with substrates phosphorylated within the DSGXX(X)S destruction motifs. SCFβ-TrCP mediate ubiquitination and proteasomal degradation of phosphorylated substrates.

Trefoil Factors

Christian Gespach
INSERM U. 673, Paris, France; Laboratory of Molecular and Clinical Oncology of Solid tumors, Faculté de Médecine, Université Pierre et Marie Curie-Paris 6, Paris, France

Synonyms

Trefoil peptides; SMAD-4/DPC4; TFF

Definition

Trefoil factors (TFF) belong to a family of heat, acid, and protease-resistant regulatory peptides ubiquitously expressed in brain, blood, and peripheral organs. In inflammatory conditions and generation of cancer lesions, they are induced, lost, or modified by gene silencing and somatic mutations. Thus, TFF overexpression or invalidation is either the consequence or the causal origin of human solid tumors and their ►progression to metastatic situations. While the TFF receptors or recognition systems are not still clearly identified, TFF are involved in mucosal and epithelial cell cytoprotection, wound healing, cancer cell survival and ►invasion, ►angiogenesis, through several oncogenic pathways involved in neoplasia. Finally, TFF are now considered as multifaceted factors with beneficial and pejorative functions on inflammatory and cancer diseases, according to their dual and divergent impacts at early and late stages of these pathological states.

Characteristics

TFF Discovery and Expression

Since the discovery and molecular annotation of the trefoil factor pS2 (TFF1) in human breast cancer, much attention has been devoted on TFF1 and its structurally related protease and acid-resistant factors spasmolytic polypeptide (SP-TFF2) and intestinal trefoil factor (ITF-TFF3). These TFF contain either one (TFF1 and -3) or two (TFF2) trefoil domains delimited by three disulphide bridges. TFF are involved in the stabilization of the mucus layers secreted by mucosal epithelial cells. The three human trefoil genes are located in a cluster region of 55 kb on chromosome 21q22.3. A novel two trefoil domains Bm-TFF2 protein activating platelet aggregation has been recently purified from the frog *Bombina maxima* skin secretions. TFF are widely expressed in brain, the urogenital system (breast, kidney, ►prostate), the lymphoid tissue, the respiratory and the digestive tract (esophagus, ►stomach, intestine, exocrine and endocrine ►pancreas, and liver), in conjunctival goblet cells and pterygium. TFF1 and -2 are predominantly detected in the normal stomach whereas TFF3 is found mainly in the small and large intestine. TFF are regulated via genetic, ►epigenetic, and tissue-specific mechanism including amplification of the chromosomal region 21q22 harboring TFF family genes in ►cholangiocarcinoma, promoter methylation, chromatin modification, histone H3 acetylation, and transcription factors downstream signaling pathways involved in cellular ►stress responses, ►inflammation, and cancer. These pathways include gastrin and bFGF growth factors, the ►interleukin 6 family cytokine receptor gp130/►STAT1–3 and ►SHP-2/►ERK cascades, ►ras, the ►hypoxia-induced HIF-1α transcription factor, allergens in lungs, nuclear ►estrogen receptors and ►GATA-6, ►NF-κB,

peroxisome proliferator-activated receptor gamma (PPAR-γ), hepatocyte nuclear factor 3 (HNF3), the homeodomain transcription factor CDX2, and the activator protein ►AP-1 via the negative control of COBRA1, the cofactor of ►BRCA1 (breast cancer-associated protein 1) involved in ►DNA damage repair.

TFF are secreted by the gastrointestinal mucosa in a mucus, inflammation, and ulcer-associated cell lineage (UACL)-dependent manner. Chronic inflammation and ulceration in the gastrointestinal tract is associated with the development of the reparative UACL from mucosal ►stem cells. UACL was originally described as pyloric metaplasia in the ileum, reflux esophagitis associated with Barrett's esophagus, peptic ulcer in the stomach, and chronic cholecystitis. TFF display multifaceted roles in mucosal repair and during cancer progression.

TFF in Mucosal Repair and Protection

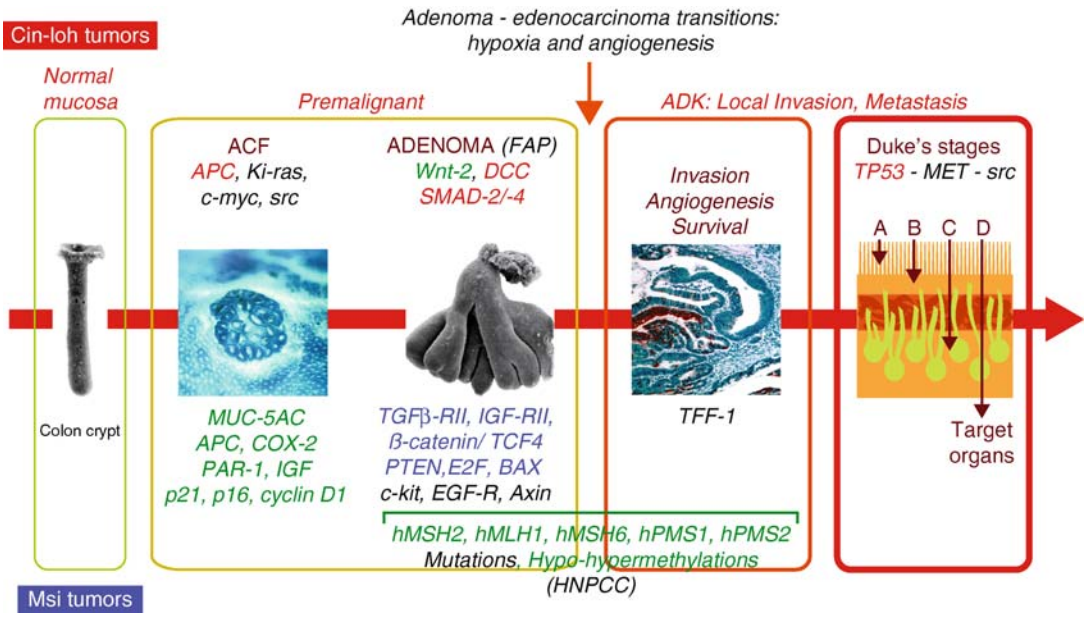
It is now well accepted that TFF are involved in maintenance and repair of the mucosal barrier, wound healing, and cytoprotection during hypoxia and transient inflammatory situations in experimental ulcerative colitis. Local administration of recombinant TFF and ectopic expression of TFF3 in cellular models and transgenic animals supported this general idea of a cytoprotective role for TFF in mucosal repair. Both epithelial and stromal cells contribute to wound healing and mucosal repair. Consistent with a signaling role of TFF in mucosal protection, the tetraspanin family member Vangl1 is involved in the migratory response to TFF3 through Ser/Thr phosphorylation in intestinal epithelial cells. In addition TFF3 improved intestinal crypt stem cells survival following combined radiation and ►chemotherapy in both wild-type and TFF3$^{-/-}$ knockout transgenic mice.

TFF in Chronic Inflammation and Cancer Progression

Although some studies argue for a therapeutic potential of TFF in mucosal injury and wound healing, recent advances in the field support their adverse effects during chronic inflammation and cancer progression. Persistent inflammatory situations initiate several genetic, molecular, and cellular dysfunctions associated with tumor promotion and cancer progression. Notably, self-induction and cross-talk between TFF at their regulatory sequences have been described as a molecular signature of chronic inflammatory situations and neoplasia.

For example, TFF1 exerts divergent functions in the digestive mucosa. In the stomach, gastric TFF1-deficient mice develop antropyloric adenomas and carcinomas, suggesting that *TFF1* is a candidate gastric-specific ►tumor suppressor gene to protect the mucosa against repetitive injury from digestive secretions, ulceration, and chronic inflammation induced by acid, proteases, and pathogens, such as ►*Helicobacter pylori*. Somatic mutations and loss of heterozygosity (LOH) of the *TFF1* gene is observed in human gastric cancers, in association with TFF3 overexpression. In coherence with these observations, ►cyclooxygenase (COX)-2 was strongly induced in pyloric adenomas induced by genetic ablation of the *TFF1* gene in mice. Similarly, COX-derived products are reported to exert beneficial roles in mucosal protection and wound healing, but deleterious functions during chronic inflammation and neoplasia. Conversely, in the normal human colon TFF1 is absent but is induced at high levels in Crohn disease, colitis, and colorectal cancers. It is therefore likely that TFF1 is a cancer progression factor in the human colon, according to its aberrant expression and transforming functions at the adenoma and carcinoma transitions (Fig. 1). Thus, TFF exert opposing functions, one counteracting transient inflammatory situations and the other linked to pejorative functions, in cooperation with other dominant genetic and molecular alterations during the neoplastic progression in the human colon. These include the cancer predisposition pathways controlled by ►Wnt/►APC/β-catenin, ►TGF-β/►SMAD-4, ras, ►src, and deleted in colon cancer (DCC). Validation of this model can be explored in transgenic animals harboring selectively these oncogenic alterations, in cooperation with forced expression of TFF1 in intestinal stem cells, through intestinal promoters that are functional in this cellular compartment, such as the villin promoter (pVIL) and the carcinoembryonic antigen (p►CEA) regulatory regions.

The emergence of colorectal adenocarcinomas (ADK) is a complex multistep process linked to genomic and ►chromosomal instability (CIN) and LOH, ►microsatellite instability (MSI), DNA ►aneuploidy, and generalized deregulation of gene expression and signal transduction pathways. The first mechanism, which accounts for 80% of sporadic cases, is connected with CIN and LOH targeting the tumor suppressors *APC* (5q), ►*TP53* (17p), *DCC* (18q), and TGFβ pathway signaling elements *SMAD-2* and *SMAD-4* (►*SMAD-4*/*DPC4*) at 18q. Sporadic MSI tumors are frequently mucinous, predominantly localized in the right colon, and generally diploid. In MSI patients, alterations in TGFβ-RII, IGF receptors IGF-RII, β-catenin, TCF-4, and E2F transcription factors, as well as loss of the ►*PTEN* tumor suppressor, and the ►apoptosis regulator BAX are frequently reported. Sporadic cancers are also driven by epigenetic mechanisms, hypo and ►hypermethylation of promoter genes encoding cancer markers and/or effectors, such as TFF, MUC-5AC, COX-2, ►protease-activated receptors PAR-1, ►IGF, ►p21/p16/cyclin D1. Dominant activation of protooncogenes by point mutations or constitutive activation by other oncogenic pathways are also frequently observed at early stages (►ACF, polyps: src, ras, ►c-myc) and late stages concomitant with cellular invasion, angiogenesis, and ►metastasis (►c-Kit, ►EGF-R, ►VEGF, the hepatocyte growth factor receptor ►MET, src, and many others).



Trefoil Factors. Figure 1 Genetic and molecular alterations linked to the multistep progression of familial and sporadic human colorectal cancers.

Familial adenomatous polyposis (FAP) is induced by mutations of the *APC* gene, a defect that contributes to CIN and appearance of more than 100 colorectal adenomas. Molecular alterations in other elements of the Wnt pathways are also concerned in sporadic ►colon cancers, including Wnt-2, Axin, β-catenin, and TCF4 transcription factor. Nonpolyposis form of the hereditary colon cancer (HNPCC) is more frequent than FAP, and is caused by germ cell mutations that invalidate the DNA repair systems. DNA ►mismatch repair is deficient in 90% of the HNPCC patients. The mutations concern mostly the hMSH2 and hMLH1 DNA repair enzymes, less frequently hPMS1 and hPMS2.

Such genetic and molecular changes lead to the formation of aberrant crypt foci (ACF), which precede the appearance of ►premalignant adenomas anchored in the colon mucosal wall. The next stage is the evolution of the adenoma toward more aggressive lesions (ADK), and irreversible acquisition of dominant and anarchic functions, chronic inflammation, oxidative ►DNA damage, autocrine and paracrine regulatory loops linked to IGF-R, VEGF-R, EGF-R ligands, induction of thrombin protease-activated receptors PAR-1, trefoil factor pS2 (TFF-1), and the immediate response gene *COX-2*.

Aberrant Expression of TFF as Clinical Markers of the Neoplasia

TFF are involved in the neoplastic progression in human epithelial tumors according to their ability to confer several transforming functions including resistance to apoptosis, induction of cellular scattering, anchorage-independent growth in soft agar, proinvasive and proangiogenic activities in vitro and in vivo. Both TFF1 and TFF3 reduced apoptosis induced by serum privation and loss of cellular adhesion (►Anoikis), a major response linked to cancer cell transformation, survival, and dissemination. Accordingly TFF are connected with several oncogenic and tumor suppressor elements such as ►E-cadherins, EGF-R, the ►RhoA-►ROCK axis, ►PI3-kinase (►PI3K), phospholipase C, COX-2, nitric oxide synthase 2, NF-kB, STAT3, and ►Cdc25. The nuclear phosphatases Cdc25A and B are associated with hypergrowth activity and control of the ►G2/M checkpoint in response to DNA damage and repair.

This is supported by clinical investigations on aberrant expression of TFF in human solid tumors of the prostate (TFF3), premalignant► changes and neuroendocrine differentiation in human prostate cancer (TFF1), human hepatocellular carcinomas (promoter hypomethylation of the *TFF3* gene), hepatolithiasis, and cholangiocarcinomas (TFF1–MUC5AC), primary mucinous carcinomas of the skin (TFF1–TFF3), and ulcerating Barrett esophagus, a precancerous lesion considered as a gastric-type metaplasia. Barrett esophagus is characterized by the specific expression of the gastric-type markers TFF1 and MUC5AC with high levels and strong colocalization in the surface epithelium. In contrast, TFF3, MUC6, and MUC5B were found in the deeper glandular structures. Similarly, gastric metaplasia of the duodenum (GMD) is characterized by replacement of the intestinal epithelium with gastric-type mucus cells, villus

damage and atrophy, and is frequently found in association with inflammation and gastritis induced by *H. p*. GMD expressed TFF1, TFF2, and the colon cancer-associated ►mucin MUC5AC, a marker of ACF now considered as precancerous lesions in the large bowel.

Progressive loss of TFF1 and TFF2 associated with reciprocal induction of TFF3 is likely to be involved in the early stages of gastric ►carcinogenesis. In the normal gastric mucosa, TFF2 is expressed in surface mucus neck cells. Decreased TFF2 expression in chronic atrophic gastritis possibly attributes to the decrease in the number of surface epithelial cells expressing TFF2. Reexpression of TFF2 in gastric epithelial dysplasia implies that TFF2 possibly contributes to the progression of ►gastric carcinoma. Recently, it has been reported that TFF3 induction in gastric tumors correlated with an aggressive phenotype with advanced stages, infiltrative growth pattern and positive lymph nodes. TFF3 is now considered as a marker of poor prognosis in human gastric carcinomas and is associated with aggressive behavior and lethality of colon cancer cells in rats. Ectopic expression of TFF3 promoted the invasive phenotype in Rat-2 fibroblast cells associated with upregulation of β-catenin, MMP-9 matrix ►metalloproteinase, and downregulation of the tumor suppressor gene product ►E-cadherin involved in β-catenin-associated ►adherens junctions. In fact, several reports suggest that TFF participate to morphogenesis and differentiation programs for epithelial cells in breast, gastrointestinal tract, and lungs. Conversely, depletion of TFF3 in the human gastric cancer cell line SNU-1 that expresses TFF3 resulted in decreased ability to form colonies in soft agar and in a marked increase in apoptosis and chemosensitivity to anticancer agents. The situation is probably more complicated since both TFF2 and TFF3 are induced in advanced gastric carcinomas and linked with neoangiogenesis, thus having a negative impact on patient survival, and are independent predictor of disease recurrence. Both TFF1 and TFF2 are strongly expressed in diffuse-type gastric cancers, suggesting that the academic definition of TFF1 as a gastric-specific tumor suppressor gene should be applied in relation with the corresponding status of TFF2/TFF3, and the clinicopathologic context and oncogenic status of human gastric tumors. Several reports indicate that TFF2 is a gastric marker of tumor metastasis frequently upregulated in diffuse gastric cancers in correlation with decreased survival. TFF2-expressing cells are upregulated in the stomach of *Helicobacter*-infected mice and seem to give rise to invasive cancerous lesions. Consequently, both TFF2 and COX-2 are overexpressed in patients with *H.* ►*pylori*-induced chronic fundic gastritis in association with dysplasia. In the established *H.* felis/C57BL/6 mouse model of gastric cancer induced by chronic infection with *Helicobacter* felis, bone marrow-derived mesenchymal progenitor cells, but not hematopoietic stem cells, are recruited to site of gastric mucosa injury and inflammation. This proliferative zone gives rise to spasmolytic expressing metaplasia (SPEM) and differentiation toward an epithelial phenotype, evidenced by positive staining for TFF2 and the epithelial cell cytokeratin KRT1–19 in deep antral and fundic glands. Thus, experimental *Helicobacter* infection can give rise to a new mucosal microenvironment in the infected gastric mucosa following upregulation of the stem cell factor SCF-1 (the ligand of the c-kit tyrosine kinase) and the ►chemokine ►SDF-1 binding the ►G-proteins coupled receptor CXCR4, two key factors involved in the mobilization of bone marrow progenitors and cancer metastasis. It remains to be elucidated whether subpopulations of human gastric cancers may originate from the neoplastic transformation of bone marrow progenitors with gastric mucosal cell gene expression pattern. In addition, SPEM was suppressed by invalidation of the ►TNF-α gene in $Tnf^{-/-}$ K19-C2mE transgenic animals expressing simultaneously COX-1/-2 in gastric mucosa via the cytokeratin 19 gene promoter. Finally, we cannot exclude the possibility that illegitimate and constitutive expression of TFF2 by mesenchymal bone marrow stem cells may also target the gastric progenitor niche for metaplasia and dysplasia. Notably, SPEM is associated with gastric *H.* ►*pylori* infection, aberrant expression of the mucin 6 (*MUC-6*) gene, and progression of human gastric adenocarcinoma. Therefore, the combined loss of the gastric-specific tumor suppressor gene TFF1 with induction of TFF2 and TFF3 provide insights into the complex mechanisms underlying the biological significance and versatility of TFF in gastric cancer progression and neoplasia.

In breast cancer, TFF1 and TFF3 but not TFF2 were identified as informative markers for the detection of ►micrometastases in axillary lymph nodes and blood. Significance analysis of microarrays identified a positive correlation between TFF1 overexpression and breast cancer metastasis to bone in a cohort of 107 patients with primary breast tumors who were all lymph node negative at the time of diagnosis. The involvement of the FGF signaling pathway was also incriminated in preference of tumor cells that relapse to bone. The fact that TFF1 may contribute to tumor relapse to bone is underscored by its abundant presence in breast cancer micrometastases.

In addition, morphogenetic effects have been attributed to TFF2 in human breast cancer cells following the induction of highly complex branched ductular structures typical of migratory, invasive, and survival functions, in a TFF1-dependent manner. TFF3 was also expressed in breast ductal and lobular breast carcinomas in situ, and invasive lobular carcinomas. While TFF1 is a surrogate indicator for the response to antihormonal therapy and favorable outcome in estrogen receptor-α (ERα)-positive and well-differentiated breast cancers, its deregulated expression is now considered to contribute

to the progression of both ER-α-positive and -negative human breast cancers. Of note, plasma levels of TFF were found elevated in patients with advanced prostate cancer.

Conclusions

TFF are now considered as valuable therapeutic tools for the treatment of injured mucosal epithelial cells and protection against mucosal and tissular damages following transient injury and other damages caused by radiation therapy and chemotherapy. Selective loss, induction, and overexpression of TFF observed during inflammatory processes and neoplasia deregulate TFF signaling cross-talks and signals, and compensatory functions linked to TFF. The molecular complexity of TFF is further illustrated by their ability to form covalent disulphide-linked dimers in vitro and in vivo. The possibility that TFF could form heterodimers adds further complexity for their relevance in receptor and signal transduction. Despite increasing interest on TFF in molecular research and clinical applications, TFF are still orphan signaling peptides facing unknown receptors in the classical definition of receptor-mediated signal transduction pathways from the plasma membrane, cytoplasmic and nuclear domains, and vice versa. Recent advances in the field pointed the discovery of new TFF-binding proteins apparently linked to mucosal protection, such as MUC-5AC and the gastrokine-1-like peptide blottin. It is conceivable that TFF are not released via normal secretory pathways in inflammatory situations and neoplasia. The epithelial cell polarity and its normal microenvironment with stromal and vascular cells, immune cells, and extracellular matrix components and their receptors, are lost during cancer progression. In this case, it is tempting to assume that TFF are in the abnormal situation interact with key signal transducers and cancer-associated stromal cell lineages during cancer progression, via illegitimate, pejorative, and persistent mechanisms. In this scenario, TFF were shown to signal through distinct transduction pathways following external addition of the peptides versus ectopic expression. Future attempts and new strategies to identify the stricto sensu TFF receptors and direct transducers are therefore expected in order to exploit the positive facets of TFF for therapeutic purpose and to fight against their deleterious functions in pathological states.

Trefoil peptides

►Trefoil Factors

Treg

Definition

►T Regulatory cells; are a subset of CD4+ T lymphocytes responsible for the regulation of immune responses. Treg have a defined phenotypic profile (CD4+ $CD25^{high}$Foxp3+) and can suppress functions, (e.g. proliferation or cytokine production) of other (responder) cells. Treg are expanded in the periphery and at tumor sites of patients with cancer. In patients with autoimmune disease, Treg are few or, if present, mediate no suppressor functions. Thus, the quantity and quality of Treg control the immune responsiveness in health and disease.

►Autoimmunity and Prognosis in Cancer
►Regulatory T Cells

Tremolite

Definition

Is an amphibole form of ►asbestos with a basic composition of calcium and magnesium silicates. Upon increased iron content, its color changes from C reamy white to dark green. The iron-containing samples are carcinogenic.

TRF1-interacting, ankyrin-related ADP-ribose polymerases

►Tankyrases

TβRI and TβRII

Definition

Type I and type II serine/threonine kinase receptors of ►TGF-β.

►Transforming Growth Factor Beta

Tribbles Homologue 3

Definition

TRB3; Also synonym TRIB3, NIPK and SKIP3. A pseudokinase that has been shown to regulate several targets potentially involved in controlling tumor growth including Akt.

►Cannabinoids
►Akt Signal Transduction Pathways

Trichilemmoma

Definition

Benign tumor of the hair follicle infundibulum. Multiple trichilemmomas are present on the face in ►Cowden Syndrome.

Trichostatin A

Definition

TSA; Is a potent reversible inhibitor of the family of ►histone deacetylases (HDAC). Was originally reported (1976) as a fungistatic antibiotic obtained from a culture broth of Streptomyces platensis. TSA has some uses as an anti-cancer drug.

Trichothiodystrophy

Definition

PIBIDS, this is an acronym for photosensitivity, ichthyosis, brittle hair and nails, intellectual impairment, decreased fertility and short stature. Disease related to ►nucleotide excision repair. Patients with PIBIDS have mutations in the ►xeroderma pigmentosum (XP) genes XP-B or XP-D.

Trident

►Forkhead Box M1

Trifunctional Antibody

Definition

A hybrid bispecific IgG antibody containing 2 Fab segments with specificity for different antigens and Fc portions that may be derived from different species.

Triglyceride

Definition

A glyceride in which the glycerol is esterified with three fatty acids. It is the main constituent of vegetable oil and animal fats.

►Fatty Acid Synthase

4′,5,7-Trihydroxyisoflavone

►Genistein

3,4´,5-Trihydroxystilbene

►Resveratrol

Trinucleotide Repeat

Definition

Any three nucleotide sequence that is repeated. CGG, CAG, and GAA expansions are associated with human genetic disorders.

►Fragile Sites

Triple Negative Breast Cancer

Definition

Breast cancer that lacks expression of estrogen receptor and progestaron receptor and amplification/overexpression of HER2; a feature of many basal-like breast tumors that is often used as a synonym for basal-like breast cancer.

►Basal-like Breast Cancer

Tripterine

►Celastrol

Trisomy

Definition

Presence of three copies of a particular chromosome instead of the normal two.

Trivalent Chromium (Cr^{+3})

Definition

Chromium ion in the highly reduced state, with a valence of +3. This is thermodynamically the most stable state of chromium ion.

►Chromium Carcinogenesis

Trk Family Tyrosine Kinase Receptors

Definition

Includes Trk (synonym TrkA), TrkB, and TrkC; they are responsible for mediating the tropic effects of the ►NGF family of ►neurotrophins. Nerve growth factor (NGF) specifically recognizes Trk, a receptor identified in all major NGF targets, including sympathetic, trigeminal, and dorsal root ganglia as well as in cholinergic neurons of the basal forebrain and the striatum. ►Brain-derived neurotrophic factor (BDNF) and neurotrophin-4 (NT-4) specifically activate the TrkB tyrosine kinase receptor. TrkB transcripts encoding this receptor are found throughout multiple structures of the central and peripheral nervous system. Trk was originally cloned as an oncogene fused with the tropomyosin gene in the extracellular domain. The rearranged Trk oncogene is often observed in non-neuronal neoplasms such as ►colon cancer and ►papillary thyroid carcinoma, while the signals through the receptors encoded by the proto-oncogene Trks regulate growth, differentiation and apoptosis of the tumors with neuronal origin such as ►neuroblastoma and ►medulloblastoma. The intracellular Trk signaling pathway is also different depending on the Trk family receptors, cell types and the grade of transformation Furthermore, developmentally programmed cell death of neuron, which is largely regulated by ►neurotrophin signaling is at least in part controlled by tumor suppressors ►p53 and ►p73. Thus, Trk and its downstream signaling function in both ontogenesis and oncogenesis.

TRK-A

Definition

Member of the Trk Family Tyrosine Kinase Receptors.

►TRK

Troglitazone

Definition
A synthetic that can suppress cancer expression as a ligand for peroxisome proliferator-activated receptor-γ.

►Fucoxanthin

TROP-1

►EpCAM

Trophoblast

Definition
Extra embryonic layer of epithelium that forms around the mammalian blastocyst and attaches the embryo to the uterus wall.

►Cancer-Germline (CG) Antigens

Tropism

Definition
Generally movement of an organism or cell; for viral vectors: Targeting of specific tissues or cell types within an organism. The predilection of a virus or another pathogen to invade, and replicate in, a particular cell type or tissue or organism.

►Oncolytic Virotherapy

Tropomyosin

Definition
Structural protein involved in muscle contraction.

Trousseau Syndrome

Definition
Armand Trousseau initially described the phenomenon that malignancies are sometimes associated with spontaneous thrombotic events. Unexplained thrombotic episodes may occasionally lead to the diagnosis of cancer

►Tumor-Endothelial Cross-talk

Trp73

►p53 Family

Trx

Definition
►Thioredoxin.

Trypsin

Definition
Serine proteinase expressed not only in the pancreas for food digestion but also by uPA (urokinase-type plasminogen activator).

►Proteinase-Activated Receptor

Tryptase

Definition
A protein secreted by mast cells and related blood and tissue cell types, involved in allergic reaction, and used as a marker for mast cell activation.

►Mastocytosis

TSC

Definition
►Tuberous sclerosis complex.

►Tuberous Sclerosis Complex

TSC1

►Hamartin

TSH

Definition
Thyroid-stimulating hormone; Synonym thyrotropin; Is secreted from cells in the anterior pituitary called thyrotrophs, finds its receptors on epithelial cells in the thyroid gland, and stimulates that gland to synthesize and release thyroid hormones.

►Thyroid Carcinogenesis

TSH

Definition
Thyroid-stimulating Hormone.

TSH Receptor

Definition
The receptor for thyroid stimulating hormone (TSH), which is also called thyrotropin. Encoded by a gene on chromosome 14q, TSHR is largest of all known glycoprotein hormone receptors. It is one of the primary antigens in autoimmune thyroid disease. Autoantibodies to TSHR act as TSH agonists in ►Graves disease and as TSH antagonists in ►Hashimoto thyroiditis.

►Thyroid Carcinogenesis

TSP

Definition
Thrombospondin.

TSR

Definition
►Thrombospondin type 1 repeat.

►Thrombospondin

TTF-1

Definition
Thyroid transcription factor 1 is a marker of thyroid and lower respiratory epithelium often used in immunohistochemistry to detect tumors arising from the thyroid or lung.

►Hurthle Cell Adenoma and Carcinoma

tTGase

►Transglutaminase-2

Tuberin

Definition

Heterodimer partner of ►hamartin, forming the ►Tuberous sclerosis complex (TSC). Hamartin is encoded by the TSC1 gene, tuberin by TSC2. These two proteins function within the same pathway(s) regulating ►cell cycle, cell growth, ►adhesion, and ►vesicle trafficking.

Tuberous Sclerosis Complex

Andrew R. Tee, Julian R. Sampson, Jeremy P. Cheadle
Institute of Medical Genetics, Cardiff University, Heath Park, Cardiff, UK

Synonyms

TSC

Definition

►Tuberous sclerosis complex (TSC): An autosomal dominant disorder caused by a mutation in either the *TSC1* or *TSC2* genes and characterized by the development of hamartomatous growths in multiple organ systems.

Characteristics

Clinical Aspects

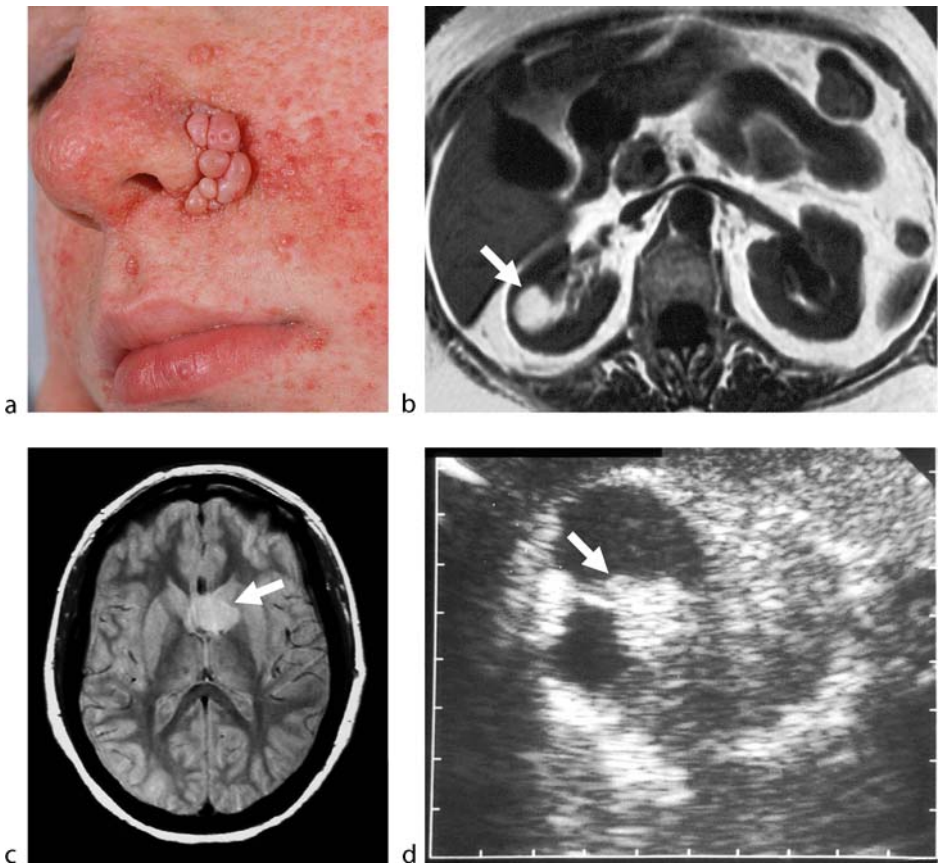
Tuberous sclerosis complex (TSC) is an autosomal dominant disorder that occurs in up to 1 in 6,000 live births, without apparent ethnic clustering. TSC is characterized by the development of unusual tumor like growths, called hamartomas, in a variety of tissues and organs. Subependymal giant cell tumors in the brain occur in about 1 in 10 individuals with TSC, with reported incidence ranging from 6.1 to 18.5%. On serial imaging, these tumors appear to arise from subependymal nodules which are believed to be present in 88–95% of individuals with TSC. Involvement of the brain is associated with some of the most problematic clinical manifestations of TSC, including intellectual handicap, epilepsy, and abnormal behavioral phenotypes, particularly autism and attention deficit disorder with hyperactivity. Other organs commonly and significantly involved in TSC include the skin, kidneys and heart, where associated hamartomatous growths include facial angiofibromas, subungual fibromas, forehead plaques, shagreen patches, renal angiomyolipomas and cysts and cardiac rhabdomyomas (Fig. 1). Renal cell carcinoma (RCC) occurs at an earlier age and is more frequently multifocal in individuals with TSC than in the general population, although it is still uncommon (<5%).

Identification and Characterization of the TSC Genes

Linkage of TSC to chromosome 9q34 was reported in 1987 (locus termed *TSC1*); however, subsequent studies provided strong evidence for locus heterogeneity and led to the identification of a second locus at 16p13.3 (*TSC2*). Among families large enough to permit linkage analysis, approximately half show linkage to 9q34 and half to 16p13, and there is no evidence for a third locus.

Initial definition of the 1.5 Mb *TSC1* candidate region on chromosome 9q34 was achieved by identification of key meiotic recombination events in large *TSC1* families. Two putative recombinants in unaffected individuals then narrowed this region to 900 kb. Large deletions and other rearrangements of the candidate locus were sought in patients with TSC, but no abnormalities were detected. Complete genomic sequencing of the region was initiated and GRAIL2 (Gene Recognition and Assembly Internet Link) and BLAST (Basic Local Alignment Search Tool) were employed to predict putative coding exons and genes. Systematic amplification and mutation screening of exons using TSC patient DNA samples, revealed mobility shifts corresponding to small truncating mutations in the 62nd exon screened. This exon corresponded to a previously identified cDNA clone and various techniques were used to defined the remainder of the open reading frame (ORF). Comparison of cDNA and genomic sequences revealed 23 exons, the first two of which were untranslated. The 8.6 kb full-length transcript was predicted to encode a novel 1,164 amino acid/130 kDa protein termed hamartin.

During 1992–1993 linkage studies identified an ~1.5 Mb region of chromosome 16p as likely to contain the *TSC2* gene. At the same time, a family with both tuberous sclerosis and autosomal dominant polycystic kidney disease was found to segregate a translocation between chromosomes 16p and 22q. The translocation breakpoint on chromosome 16 in this family was shown to disrupt the previously unidentified *PKD1* gene and the *TSC2* gene was predicted to lie telomeric to this breakpoint. The breakpoint was mapped to 150 kb telomeric to 16AC2.5 (the most centromeric flanking marker then identified for *TSC2*). The telomeric limit of the candidate region was greatly reduced by the position of a second breakpoint in a previously reported patient who had a de novo truncation of 16p but no clinical or radiological evidence of TSC. The deletion in this patient effectively excluded ~1.1 Mb of the remaining 1.4 Mb *TSC2* candidate region. A cosmid contig was constructed for



Tuberous Sclerosis Complex. Figure 1 Tuberous sclerosis complex is characterized by the development of hamartomas in a variety of tissues and organs. (a) A facial angiofibroma, (b) an abdominal MRI scan showing a renal angiomyolipoma (arrowed) (c) a cranial MRI scan showing a partly intraventricular subependymal giant cell astrocytoma (arrowed), and, (d) a renal unltrasound scan showing a renal cell carcinoma (within a cyst) (*arrowed*).

the remaining 300 kb candidate region and probes generated from it were used to analyze a panel of TSC patients for rearrangements by pulsed field gel electrophoresis and Southern blotting. Five TSC patients were found to have genomic deletions of between 30 kb and 100 kb, which involved the same 120 kb interval. cDNA clones were isolated corresponding to four genes in the interval, and one was found to be disrupted by all five deletions, making it a strong candidate for *TSC2*. Four smaller intragenic deletions were then identified in TSC patients, including a de novo deletion that was associated with a truncated TSC2 transcript. These findings confirmed the identity of the *TSC2* gene. The 5.5kb *TSC2* transcript was predicted to generate a novel 1,807 amino acid protein product of ~198 kDa termed tuberin.

TSC1 and *TSC2* Act as Tumor Suppressor Genes

Most individuals who have tuberous sclerosis carry a mutant tuberous sclerosis gene in each of their somatic cells. However, it is clear that a huge majority of these cells proliferate, differentiate and function normally, while very occasionally, further localised events result in focal tumorigenesis. In 1971, Knudson proposed that inherited predisposition to tumors might reflect the germ-line mutation of "tumor suppressor genes" and that tumor development might be the result of somatic "second hit" mutations. Investigations of somatic mutations in a variety of tuberous sclerosis hamartomas supports classification of the TSC genes as tumor suppressor genes - several groups have reported evidence for large somatic deletions of the wild-type *TSC1* or *TSC2* allele, manifested as "loss of heterozygosity." The observation of loss of heterozygosity implies clonality of hamartomas, and this has also been confirmed by demonstration of non-random X chromosome inactivation in hamartomas from female patients with tuberous sclerosis.

Lymphangioleiomyomatosis and Pulmonary TSC

Lymphangioleiomyomatosis (LAM) is a disorder seen almost exclusively in females and is characterized by

bronchiolar smooth muscle infiltration and cystic changes in the lung parenchyma. LAM patients often have angiomyolipoma of the kidneys and/or abdominal and hilar lymph nodes. Symptomatic LAM is estimated to occur in ~1 per million of the population without other evidence of TSC, but in up to 5% of females with TSC, implicating a role for the TSC genes in the etiology of LAM. It has recently been shown that somatic mutations of the *TSC2* gene occur in the angiomyolipomas and pulmonary LAM cells of women with sporadic LAM, strongly supporting a direct role of *TSC2* in the pathogenesis of this disease. Interestingly, a mutation in the *TSC2* gene was identified in pulmonary and lymph node LAM cells from a patient with sporadic LAM prior to lung transplantation and the same mutation was subsequently found in the recurrent LAM. These data indicate that histologically benign LAM cells can migrate or metastasize in vivo to the transplanted lung.

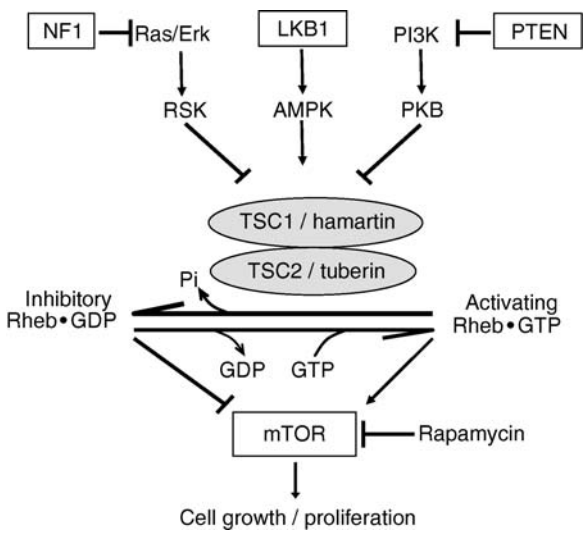
A model in which LAM cells migrate or metastasize to the lung challenges the boundary between benign and malignant diseases. There are other examples of histologically benign diseases in which cells appear to metastasize, including benign metastasizing leiomyoma, and disseminated peritoneal leiomyomatosis. If LAM cells containing *TSC2* gene mutations have the potential to migrate in vivo, it may indicate that the TSC genes have key functional roles related to cellular metastasis.

Role of hamartin and Tuberin in the mTOR Pathway

Genetic screens for growth suppressors in *Drosophila Melanogaster* showed that dTsc1 and dTsc2 play a pivotal role in the conserved insulin-signaling pathway to suppress cellular growth. Hamartin and tuberin function together to repress cell growth signaling through the mammalian target of rapamycin (mTOR). Tuberin possesses a guanine nucleotide triphosphate (GTP)-ase activating protein (GAP) domain which acts on the small G proteins Ras homologue enriched in brain (Rheb) and Rheb like 1 (RhebL1). Mutations in *TSC2* that are associated with tuberous sclerosis often result in the loss of the GAP domain through the deletion of the C-terminus. Furthermore, a clustering of single amino acid mutations within the GAP domain of *TSC2* has also been reported, implying that the GAP domain of tuberin is necessary for normal cell growth control. The normal function of hamartin and tuberin is to suppress the activity of Rheb and RhebL1: when in a complex with hamartin, tuberin reverts Rheb from an active GTP-bound state to an inactive guanine nucleotide diphosphate (GDP)-bound state through loss of the third phosphate on the guanine nucleotide. Active Rheb and RhebL1 have both been shown to associate with mTOR kinase and to specifically promote mTOR-directed phosphorylation of downstream signaling molecules involved in cell growth control that includes eukaryotic initiation factor 4E-Binding Protein 1 (4E-BP1) and ribosomal protein S6 kinase 1 (S6K1). mTOR also coordinates other critical cellular processes that if deregulated, can lead to cancer. These include cell cycle progression, autophagy (breakdown of cellular proteins), and nutrient uptake that feeds the growth of the cell. As a consequence, elevated mTOR signaling contributes to the pathology in numerous other human diseases associated with cancer.

mTOR and other Hamartoma Syndromes

Germline mutations that impair the normal tumor suppressor function of *PTEN* (phosphatase and tensin homolog), *NF1* (neurofibromin 1), and *LKB1* (also known as *STK11* (serine/threonine kinase 11)) can also lead to inherited hamartoma syndromes. Loss of *PTEN* function causes Cowden's disease, Lhermitte-Duclos disease and Bannayan-Zonana syndrome, while functional loss of either *NF1* or *LKB1* causes Neurofibromatosis "-type1" Peutz-Jeghers syndrome, respectively. Tuberin's ability to function as a RhebGAP is regulated by multiple phosphorylation events that involve cell signaling pathways that are regulated by PTEN, LKB1 and NF1 (Fig. 2); therefore lesions associated with each of these hamartomas syndromes show activation of mTOR and enhanced cell growth signals. PKB and RSK kinase, which lie within the PI3K/PTEN and Raf/NF1 signaling pathways, phosphorylate tuberin on overlapping Serine and Threonine sites. PKB inhibits



Tuberous Sclerosis Complex. Figure 2 Converging signaling pathways that regulate hamartin and tuberin. The NF1, LKB1 and PTEN tumor suppressors negatively regulate mTOR via the PI3K/PKB, AMPK and Ras/Erk/RSK signaling pathways. The hamartin/tuberin heterodimer act as a RhebGAP that converts the active Rheb˙GTP it to an inactive GDP-bound state. Rheb˙GTP activates mTOR, which promotes cellular growth.

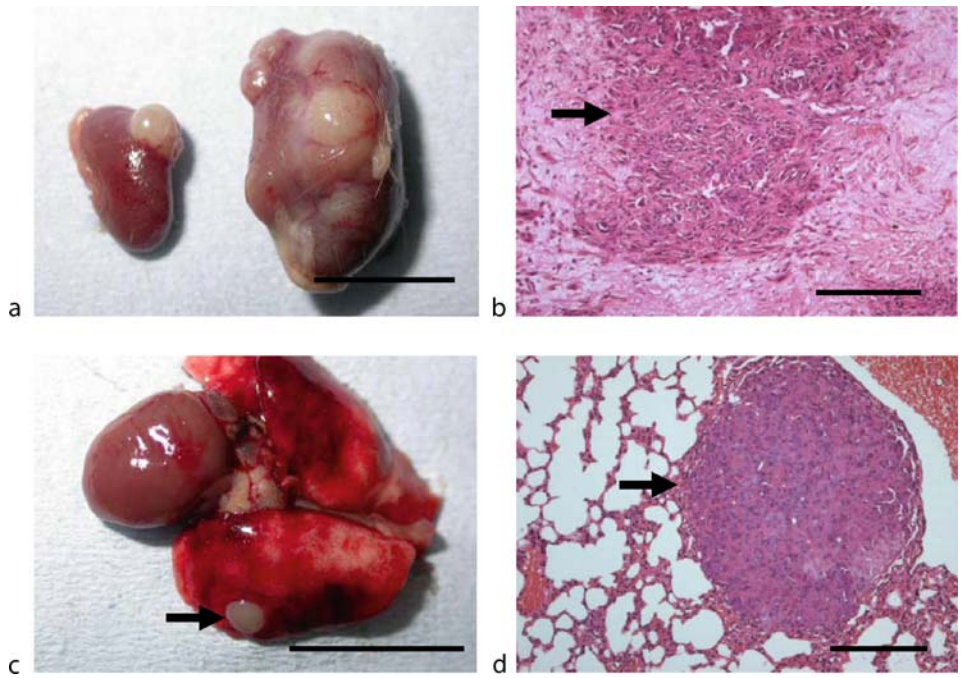
tuberin through the direct phosphorylation of Ser939 and Thr1462 that leads to elevated mTOR activity. Conversely, the LKB1 regulated energy-sensing pathway inhibits cell growth through AMPK-mediated phosphorylation of tuberin, which activates tuberin and represses mTOR. Interestingly, cancer cells deficient in *PTEN* have heightened sensitivity to the anti-proliferative and anti-cancer properties of rapamycin, which potently and specifically inhibits mTOR.

Rodent Models of Tuberous Sclerosis

Genetically engineered mice that carry a single mutant *Tsc1* allele (*Tsc1*$^{+/-}$ mice) develop renal cysts which develop into cystadenomas and RCCs. In one such model, the RCCs had a sarcomatoid morphology consisting of spindle cells with nuclear anaplasia arranged in whorled patterns and occasionally metastasized to the lungs (Fig. 3). Although the occurrence of RCC in humans with TSC is unusual, an association is recognized. The carcinomas are typically discovered at a young age and are thought to evolve from the lining of hyperplastic cysts. The proportion of sarcomatoid features in human TSC-associated renal carcinomas is far greater than in sporadic RCC.

Tsc2$^{+/-}$ mice develop renal lesions by 6 months, which appear to grow progressively throughout the life of the mouse. Histologically, the lesions resemble cystadenomas consisting of a spectrum of lesions including pure cysts, cysts with papillary projections and solid adenomas. Renal carcinoma, characterized by nuclear atypia, massive growth and metastatic disease developed in 5–10% of mice by 18 months, suggesting a very low rate of malignant progression for the cystadenomas (~1 in 1,000), indicating that additional genetic or epigenetic events are required for transformation. Liver hemangiomas, characterized by endothelial and smooth muscle proliferation with large vascular spaces, are seen in about half of *Tsc2*$^{+/-}$ mice by 18 months. Hemangiosarcomas also develop on the tail, paws, or mouth region in about 7% of *Tsc2*$^{+/-}$ mice by 12 months; these lesions do not metastasize but are malignant by cytologic criteria and exhibit bone invasion.

The Eker rat harbors a naturally occurring mutation (insertion of a 6.3 kb intracisternal A particle) in one allele of *Tsc2* and was first described as an autosomal dominant, hereditary model of predisposition to renal adenoma and carcinoma in 1954. Kidney lesions vary in morphology and include pure cysts, cysts with papillary projections and solid adenomas which can be seen as early as 4 months. A small minority of these tumors become malignant, with nuclear atypia and expand to include the entire kidney and metastasize to the lungs, pancreas and liver. Eker rats also develop pituitary



Tuberous Sclerosis Complex. Figure 3 *Tsc1*$^{+/-}$ mice described by Wilson et al. (2005) are predisposed to renal cysts that develop into RCCs that occasionally metastasize to the lungs. (a) Paired kidneys from a Tsc1$^{+/-}$ mouse with RCC ≥5 mm. (b) Microscopic view of a sarcomatoid RCC with elongated sheets of spindle cells. (c) Macroscopic, and (d) microscopic RCC metastases in the lungs. Macroscopic bars are 1 cm and microscopic bars are 200 μm.

adenomas, uterine leiomyomas and leiomyosarcomas, splenic hemangiomas and, at a low frequency, brain hamartomas resembling human TSC subependymal nodules.

Tuberous Sclerosis Complex 1

►Hamartin

Tuberous Sclerosis Syndrome

Definition

A rare congenital disease in which the essential pathology is the appearance of multiple tumors in the brain and in other organs, such as the heart or kidneys. The name tuberous sclerosis comes from the characteristic tuber or root-like growths in the brain, which calcify with age.

►Tuberous Sclerosis Complex

Tubulin

Definition

A tubulin is a globular protein. There are five kinds of tubulins such as α-, β-, γ-, δ-, and ε-tubulins. Microtubules are assembled from dimers of α- and β-tubulins. γ-tubulin is involved in the nucleation and polar orientation of microtubules. δ- and ε-tubulins are localized at centrioles.

►Doublecortin
►Microtubule Associated Proteins

Tubulin Interacting Proteins

►Microtubule Associated Proteins

Tubulogenesis

Definition

Tube forming process, that gives rise to hyperpermeable tumor capillaries.

►Anoxia

Tumor

Definition

A neoplasm, or "new growth," of cells; a group of cells that has proliferated beyond the constraints of the normal tissue from which it was derived, in an unregulated, uncontrolled fashion, leading to an abnormal mass of cells.

►Chemical Carcinogenesis

Tumor Antigens

Definition

Proteins or carbohydrates that can be recognized by lymphocytes. Malignant cells can be specifically recognized by T lymphocytes or antibodies in cancer patients. This specificity is mediated by the somatically rearranged antigen-receptors in T cells and B cells,

i.e. the T cell receptor alpha and beta chains and the immunoglobulin light and heavy chains. The T cell receptor "sees" peptide fragments derived from any cellular protein of tumor cells in the binding-groove of the major histocompatibility complex on the cell surface. In contrast, the B cell receptor/immunoglobulin is able to bind various three-dimensional macromolecular structures with its variable domain. Common tumor antigens include normal proteins expressed by tumor cells in a lineage-restricted fashion (►Lineage differentiation tumor antigens), proteins expressed by malignant cells and cells in the germ line (►Cancer-testis-antigens) as well as individually mutated or viral antigens.

►Melanoma Vaccines
►Sentinel Node

Tumor-Associated Angiogenesis

Definition

The process of use of blood vessels already existent as well as the development of new blood vessels which provide critical nutrients and oxygen to tumors which are undergoing rapid expansion in mass. This process occurs at a time that is simultaneous with tumor promotion, and is first noted as an increase in vascular permeability. Tumor associated angiogenesis is in itself a multi-step process. There are angiogenic growth factors as well as anti-angiogenic growth factors and when the balance favors the positive signals, tumor-associated angiogenesis begins. This tipping over of pro-angiogenic factors to outweigh anti-angiogenic factor production has been termed "the angiogenic switch."

►Skin Carcinogenesis
►Angiogenesis

Tumor-Associated Antigen

Definition

TAA; Synonym Tumor Antigen. Malignant transformation of the cell, caused by viral infection, mutations, gene ►amplification, chromosomal deletion or translocation, can result in the expression of additional proteins in the malignant cell or in alterations of the expression of normal proteins. These changes are possibly immunogenic and can be recognised by the host's immune system. Over the years, several different antigens with tumour-dependent expression profiles were characterised and can be subdivided in different groups:

1. Tumour-specific shared TAA: encoded by genes that are frequently expressed in a wide variety of tumours, but not in normal tissues, except testis and placenta. Examples are MAGE, BAGE, GAGE and NY-ESO families. This group also includes antigens that arise from mutations in normal proteins such as ►p53, ►Ras, ►β-catenin, or from aberrant fusion proteins (e.g. ►bcr-abl).
2. Patient-specific TAA: arise from patient-specific mutations that occur in DNA, generating altered cellular proteins (e.g. the mutated form of the ►*CASP-8* gene,). These antigens are tumour-specific, hence not found in normal cells. Because they are patient-specific, this type of TAA are difficult to identify and to characterise.
3. Viral antigens: expressed in tumours which arise by infection with oncogenic viruses, for example ►human papillomavirus (HPV) E7 protein in ►cervical cancer.
4. Overexpressed TAA: present at low levels in normal cells, but overexpressed in tumour cells. Examples are PRAME, ►PSA and ►Her2/neu.
5. Differentiation TAA: present in tumour cells and their normal counterparts, e.g. Melan-A, gp100 and tyrosinase in melanoma).

►CD Antigens
►Melanoma Antigens

Tumor Associated Carbohydrate Antigens

Definition

TACA; Structure of carbohydrate nature that is produced by, but not unique for, tumor cells and which can evoke an immune response.

►Myofibroblasts.

Tumor-Associated Macrophages

Antonio Sica, Alessandra Mancino, Paola Larghi, Luca Rubino, Graziella Solinas, Paola Allavena, Alberto Mantovani
Department of Immunology, Fondazione Humanitas per la Ricerca, Rozzano, Milan, Italy

Definition

Tumor-associated ►macrophages (TAM) define a subset of myeloid cells that highly infiltrate solid tumors. Accumulating evidence clearly demonstrates, in various mouse and human malignancies, including colon, breast, lung, and prostate cancer, a strict correlation between increased numbers and/or density of TAM and poor prognosis. Based on this, recruitment and activation of TAM are regarded as pivotal steps of tumor progression, and TAM are putative targets for therapeutic intervention.

Characteristics

Experimental and clinical studies have revealed that chronic ►inflammation predisposes to different forms of cancer, including ►colon cancer, ►prostate cancer, and ►liver cancer, and that usage of ►nonsteroidal antiinflammatory drugs can protect against the emergence of various tumors.

In the late 1970s, it was found that a major leukocyte population present in tumors, the so-called TAM, promote tumor growth. Over the years it has become increasingly clear that TAM are active players in the process of tumor progression and invasion. In several experimental tumor models, the activation of an inflammatory response (most frequently mediated by macrophages) is essential for full neoplastic transformation and progression. This evidence strongly supports the idea that cancers originate at sites of chronic inflammation and suggests that the inflammatory circuits activated at the tumor microenvironment may represent suitable targets of novel anticancer therapies.

Macrophages

Macrophages (Mφ) play an indispensable role in the immune system with decisive functions in both ►innate immunity and ►acquired immunity. In innate immunity, resident Mφ provide immediate defense against foreign pathogens and coordinate leukocyte infiltration. Mφ contribute to the balance between antigen availability and clearance through phagocytosis and subsequent degradation of senescent or apoptotic cells, microbes, and possibly neoplastic cells. Their role is essential for triggering, instructing and terminating the adaptive immune response. Mφ collaborate with T and B cells, through both cell-to-cell interactions and fluid phase-mediated mechanisms, based on the release of cytokines, chemokines, enzymes, ►arachidonic acid metabolites, and reactive radicals. Mφ activation can be either proinflammatory or antiinflammatory, thus contributing to tissue cell destruction or to tissue regeneration and wound healing. These polar phenotypes are not expressed simultaneously, but regulated in such a manner that Mφ display a balanced, harmonious pattern of functions.

Mφ are critical effector cells in the acute innate response, for delayed-type hypersensitivity reactions and T cell-mediated immunity. In 1986 Mosmann et al. described two polarized sets of mouse T helper (Th) cells – Th1 and Th2 – with distinct cytokine secretion patterns. Th1 cells secreted interleukin-2 (IL-2), interferon-γ (IFN-γ), and lymphotoxin (LT, TNF-β). Th2 cells secreted IL-4, IL-5, and IL-6 and promoted B cells proliferation and antibodies secretion. Moreover, additional studies clarified that Th1 and Th2 cells may play opposite roles in pathological conditions, including infections and cancers.

Although excluded from the original "type I–type II" paradigm, Mφ role in the balance of polarized immune responses is being increasingly appreciated. Mφ are able to secrete either IL-12 or IL-10, cross-regulatory cytokines crucial for the elicitation of IFN-γ production and development of Th1 cells and IL-4/IL-13 secretion and Th2 cells proliferation correspondingly. The preferential production of IL-12 and IL-10 sets the basis for the M1/M2 Mφ polarization paradigm, elsewhere defined as the elicitation of functionally distinct Mφ populations, in response to the factors that dominate the inflammatory scene. In analogy with the Th1 and Th2 dicotomi, macrophages can be phenotypically polarized by the microenvironment to mount specific M1 or M2 functional programs. Chronic infections can tightly regulate the immune responses, being able to trigger highly polarized-type I or -type II inflammation and immunity. Classical or M1 macrophage activation in response to microbial products or IFN-γ are characterized by: high capacity to present antigen; high expression of proinflammatory cytokines, such as interleukin-12 (IL-12) and tumor-necrosis factor-α (TNF-α), and consequent activation of a polarized-type I response; and high production of toxic intermediates (►nitric oxide (NO), ►reactive oxygen species). Thus, M1 macrophages are generally considered potent effector cells that kill microorganisms and tumor cells and produce copious amounts of proinflammatory cytokines. In contrast, various signals (e.g., IL-4, IL-13, glucorticoids, IL-10, immunoglobulin complexes/TLR ligands) elicit different M2 forms, able to tune inflammatory responses and adaptive Th2

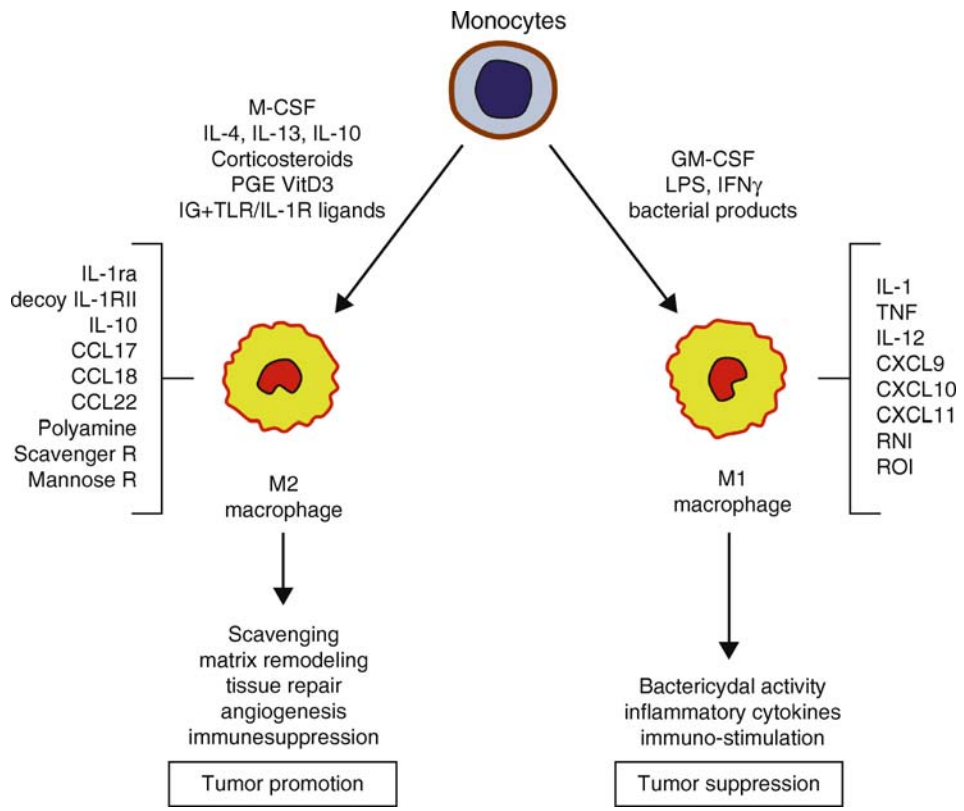
immunity, scavenge debris, promote ►angiogenesis, tissue remodeling and repair. Figure 1 shows selected functions of M1 and M2 polarized macrophages. Microenvironmental signals expressed at the tumor ►microenvironment have the capacity to pilot recruitment, maturation, and differentiation of infiltrating leukocytes and play a central role in the activation of specific transcriptional programs expressed by TAM.

Tumor-Associated Macrophages

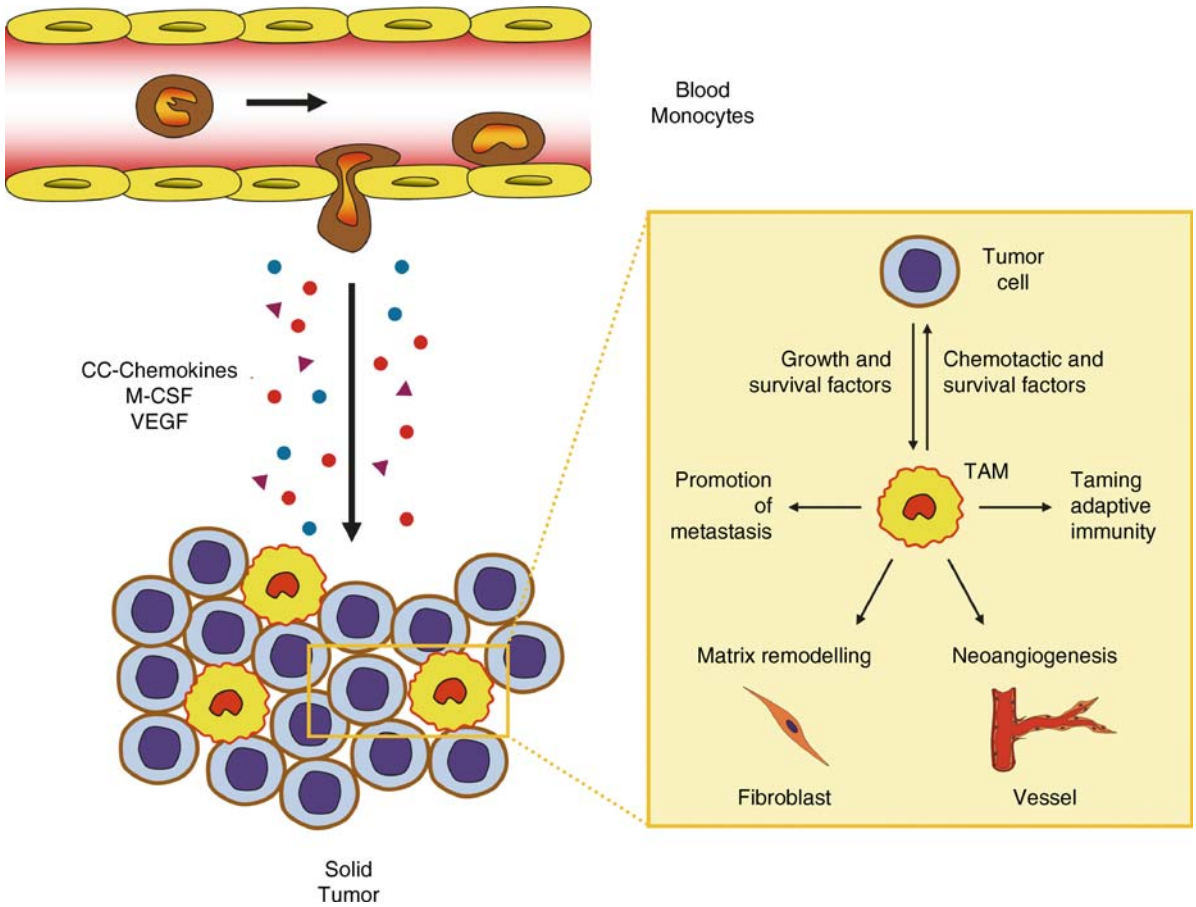
To the extent that they have been investigated, differentiated mature TAM have a phenotype and function similar to type II or M2 macrophages. TAM have been shown to exert a negative effect on antitumor immune responses.

TAM Recruitment

TAM are protumoral cells that are derived from circulating monocytes (Fig. 2) and are recruited to the tumor by a tumor-derived chemotactic factors, originally identified as CC-chemokine ligand 2 (CCL2; also known as MCP-1). Following this observation, other chemokines active on TAM were detected in neoplastic tissues as products of either tumor cells or stromal elements. These molecules have an important role in tumor progression by directly stimulating neoplastic growth, promoting inflammation, and inducing angiogenesis. Evidence supporting a pivotal role for chemokines, in addition to CCL2, in the recruitment of monocytes to neoplastic tissues includes a direct correlation between chemokine production and monocyte infiltration in mouse and human tumors. Molecules other than chemokines can also promote TAM recruitment. In particular, tumor-derived cytokines such as ►vascular-endothelial growth factor (VEGF) and ►macrophage-colony stimulating factor (M-CSF) promote macrophage recruitment, as well as macrophage survival and proliferation, and their expression correlates with tumor growth.



Tumor-Associated Macrophages. Figure 1 Monocytes differentiate into polarized macrophage subsets when exposed to different cytokine milieu. In the presence of GM-CSF, IFN-γ, LPS, and other microbial products, monocytes differentiate into M1 macrophages. In the presence of M-CSF, IL-4, IL-13, IL-10, immunosuppressive agents (Corticosteroids, Vitamin D3, prostaglandins, and immunocomplexes (IG) in combination with IL-1 or TLR ligands), monocytes differentiate into M2 macrophages. M1 and M2 subsets differ in terms of phenotype and functions. M1 cells have high microbicidal activity, immunostimulatory functions, and tumor cytotoxicity. M2 cells have high scavenging ability; promote tissue repair and angiogenesis, immunosuppression and favor tumor progression.



Tumor-Associated Macrophages. Figure 2 Tumor-derived chemotactic factors (CC-chemokines, e.g., CCL2, macrophage-colony stimulating factor (M-CSF) and vascular endothelial growth factor (VEGF)) actively recruit circulating blood monocytes at the tumor site. In the tumor microenvironment monocytes differentiate into tumor-associated macrophages (TAM) that establish a symbiotic relationship with tumor cells. The above tumor-derived factors positively modulate TAM survival. From their own, TAM secrete growth factors that promote tumor cell proliferation and survival; regulate matrix deposition and remodeling, thus favoring metastasis formation, activate neoangiogenesis and promote immunosuppression.

TAM Express Selected M2 Protumoral Functions

The cytokine network expressed at the tumor site plays a central role in the orientation and differentiation of recruited mononuclear phagocytes, thus contributing to direct the local immune system away from antitumor functions. Immunosuppressive cytokines IL-10 and tumor-growth factor-β (TGF-β); are produced by both cancer cells (ovary) and TAM. IL-10 promotes the differentiation of monocytes to mature macrophages and blocks their differentiation to dendritic cells (DC). Thus, a gradient of tumor-derived IL-10 may account for differentiation along the DC versus the macrophage pathway in tumors, resulting in tumor promotion. IL-10 promotes the M2c alternative pathway of macrophage activation and induces TAM to express M2-related functions. Under many aspects, TAM summarize a number of functions expressed by M2 macrophages, involved in tuning inflammatory responses and adaptive immunity, scavenge debris, promote angiogenesis, tissue remodeling and repair. The production of IL-10, TGF-β, and PGE2 by cancer cells and TAM contributes to a general suppression of antitumor activities.

TAM are poor producers of nitric oxide (NO) and, in situ in ►ovarian cancer, only a minority of tumors and, in these, a minority of macrophages localized at the periphery scored positive for ►iNOS. Moreover, in contrast to M1 polarized macrophages, TAM have been shown to be poor producers of ROI, consistent with the hypothesis that these cells represent a skewed M2 population. Moreover, TAM were reported to express low levels of inflammatory cytokines (e.g., IL-12, IL-1β, TNF-α, IL-6). Activation of the transcriptional factor NF-κB is a necessary event promoting transcription of several proinflammatory genes. TAM display defective NF-κB activation in response to M1 polarizing signals lipopolysaccharide (LPS) and TNF-α. Thus, in

terms of cytotoxicity and expression of inflammatory cytokines, TAM resemble the M2 macrophages.

Angiogenesis is an M2-associated function that represents a key event in tumor growth and progression. In several studies in human cancer, TAM accumulation has been associated with angiogenesis and with the production of angiogenic factors such as VEGF and platelet-derived endothelial cell growth factor. Additionally, TAM participate to the proangiogenic process by producing the angiogenic factor thymidine phosphorylase (TP), which promotes endothelial cell migration in vitro and whose levels of expression are associated with tumor neovascularization.

Moreover, TAM accumulate in hypoxic regions of tumors, and ►hypoxia triggers a proangiogenic program in these cells. Therefore, macrophages recruited in situ represent an indirect pathway of amplification of angiogenesis, in concert with angiogenic molecules directly produced by tumor cells. On the antiangiogenic side, in a murine model, GM-CSF released from a primary tumor upregulated TAM-derived metalloelastase and angiostatin production, thus suppressing tumor growth of metastases.

Finally, TAM express molecules that affect tumor cell proliferation, angiogenesis, and dissolution of connective tissues. These include epidermal growth factor (EGF), members of the FGF family, TGF-β, VEGF, chemokines. In lung cancer, TAM may favor tumor progression by contributing to stroma formation and angiogenesis through their release of PDGF, in conjunction with TGF-β1 production by cancer cells. Macrophages can produce enzymes and inhibitors that regulate the digestion of the extracellular matrix, such as ►MMPs, plasmin, ►urokinase-type plasminogen activator (uPA), and the uPA receptor. Direct evidence has been presented that MMP-9 derived from hematopoietic cells of host origin contributes to ►skin carcinogenesis. Chemokines have been shown to induce gene expression of various MMPs and, in particular, MMP-9 production, along with the uPA receptor. Evidence suggests that MMP-9 has complex effects beyond matrix degradation including promotion of the angiogenesis switch and release of growth factors.

Modulation of Adaptive Immunity by TAM

It has long been known that TAM have poor antigen presenting capacity and can actually suppress T cell activation and proliferation. The suppressive mediators produced by TAM include ►prostaglandins, IL-10, TGF-β, and indoleamine dioxygenase (IDO) metabolites. Moreover, TAM are unable to produce IL-12, even upon stimulation by IFN-γ and LPS. With this cytokine profile, which is characteristic of M2 macrophages, TAM are unable to trigger Th1-polarized immune responses, but rather induce ►T regulatory cells (Treg). Treg cells possess a characteristic anergic phenotype and strongly suppress the activity of effector T cells and other inflammatory cells, such as monocytes. Suppression of T cell-mediated antitumor activity by Treg cells is associated with increased tumor growth and hence, decreased survival. For instance, in patients with advanced ovarian cancer, an increase in the number of functionally active Treg cells present in the ascites was predictive of reduced survival.

The complex network of chemokines present at the tumor site can play a role also in the induction of the adaptive immunity. Chemokines also regulate the amplification of polarized T cell responses. Some chemokines may enhance specific host immunity against tumors but on the other hand other chemokines may contribute to escape from the immune system, by recruiting Th2 effectors and Treg cells. Figure. 2 summarizes symbiotic relationship between TAM and cancer cells.

Conclusion

Though the presence of TAM has been long considered as evidence for a host response against the growing tumor, it has become increasingly clear that TAM are active players in the process of tumor progression and invasion. Molecular and biological studies have been supported by a large number of clinical studies that found a significant correlation between the high macrophage content of tumors and poor patient prognosis. TAM share many similarities with prototypic polarized M2 mononuclear phagocyte population, in terms of gene expression and functions. In line with known properties of M2 macrophage populations, several lines of evidence suggest that TAM promote tumor progression and ►metastasis by activating circuits that regulate tumor growth, ►adaptive immunity, stroma formation, and ►angiogenesis. This hypothesis is now receiving new supporting evidence indicating that in vivo functional switching of infiltrating M2 macrophages toward an M1 phenotype provides therapeutic benefit in mice bearing tumor ►xenograft. Identification of mechanisms promoting functional diversion of macrophages toward an M2 direction may disclose new valuable therapeutic targets against tumors.

Definition

►Tumor cell-induced platelet aggregation (TCIPA) is the ability of cancer cells to generate crucial molecules or surface receptor molecules that mediate platelet aggregation and accelerate the survival advantages of tumor cells in the vasculature, which is important for distant ►metastasis of cancer.

Characteristics

Hematogenous metastasis of cancer cells to critical distant organs is one of the major reasons for death in most cancer patients. After ►invasion into blood vessels, circulating cancer cells may interact with various vascular cells such as leukocytes, platelets and endothelial cells that may affect the survival and metastasis of tumor cells. Although normal platelet functions are important to control vascular hemostasis and thrombosis, cancer cells may express many factors which modulate the platelet activities. Clinically, the interactions between circulating cancer cells and platelets are crucial for tumor metastasis in patients with cancers. Cancer cells may induce the morphological changes and aggregation of platelets and subsequently trap the cancer cells in capillaries and enhance the adhesion of cancer cells to capillary endothelial walls. These events facilitate further tumor cell invasion and metastasis into distant organs. During these processes, the activated platelets release various factors (like serine proteases factor VIIa, factor Xa, ►platelet-derived growth factor (PDGF), ►vascular endothelial growth factor (VEGF), fibrinogen and thrombospondin), which increase vascular permeability and promote the growth, survival, motility and the extravazation of metastatic cancer cells to neighboring organs. Expression of PDGF-receptor in breast cancer tissues has been reported to increase the risk of lymph node metastasis. Similarly, the expression of von Willebrand factor (vWF) in tumor tissues and serum may also affect the metastasis of ►osteosarcoma patients. A number of clinical studies further suggest the increased risk of thrombosis in patients with various cancers, indicating the roles of TCIPA and activation of the coagulation system in the progression of cancer.

Mechanisms

Induction of TCIPA may form platelet-cancer cell aggregates to prevent cancer cells from killing by human cellular and humoral immunities, and from the damage by shear force of blood flow. Platelet activation further facilitates ►angiogenesis, tumor cell adhesion to endothelium and subsequent invasion into distant organs. Various cancer cells may produce differential amounts of critical factors such as ►ADP, ►thromboxane A_2 (TXA_2), thrombin, cathepsins, ►matrix metalloproteinases (MMPs), ►membrane type matrix metalloproteinases (MT-MMP), cancer procoagulant, mucin, tissue factors (TF) and ►Aggrus/Podoplanin etc. These molecules may activate various receptors ($P2Y_{12}$ purinergic receptor, thromboxane receptors, ►protease-activated receptors (PARs), integrin receptors etc.) and downstream signaling cascades to initiate platelet aggregation and coagulation disorders.

TF-bearing cancer cells can stimulate platelet aggregation via generation of thrombin and signaling by ►glycoprotein IIb/IIIa and VEGF release. The localized production of thrombin and fibrin may increase endothelial cell motility as well as platelet activation. Tumor cells have the capacity to convert fibrinogen into fibrin *in vitro* and histologically the deposition of fibrin is popularly noted in the connective tissue surrounding tumor cells, an event being critical for tumor angiogenesis and metastasis. Generation of MMPs by tumor cells may activate platelet integrin receptors followed by induction of platelet aggregation. This event can be inhibited by anti-MMP antibodies and phenanthroline, an MMP inhibitor. MMPs generated by tumor cells and platelets are further shown to degrade the basement membrane and facilitate metastasis.

Cancer cells may also activate platelets to release ADP, which binds further to platelet $P2Y_{12}$ receptors, leading to full platelet aggregation. The ADP-mediated platelet aggregation by tumor cells can be attenuated through degradation of ADP by apyrase (APT102). Moreover, the interaction between platelets and tumor cells can be mediated by cell adhesion proteins, e.g. P-selectin in platelets and P-selectin glycoprotein ligand-1/CD162, heparin sulfate proteoglycan and sialyl-Leqis A/X in cancer cells. This is followed by β3 integrin mediated processes with concomitant activation of thrombospondin and fibrinogen.

Using venous blood from cancer patients for testing, current techniques can detect the presence of circulating tumor cells in the blood stream. Interestingly, podoplanin (Aggrus), a mucin-line glycoprotein, has recently been shown to induce platelet aggregation and affect the invasion/metastasis of cancer. The expression of podoplanin in astrocytic tumors has been linked to the malignancy of astrocytic tumors. This is possibly due to early interactions by surface mucins and other selectin ligands of tumor cells with the platelet p-selectin and L-selectin. Heparin as an antithrombotic agent is able to inhibit metastasis further by blocking the tumor cell mucin P-selectin ligands and thus also the platelet-tumor cell interaction.

Clinical Aspects and Therapy

Higher platelet numbers have been found in many kinds of cancers including lung, gastric, colorectal and breast cancers. Clinically, cancer patients also have higher risk for development of vascular thromboembolism. This can be attributed to abnormalities in platelet functions as well as in the thrombotic and haemostatic systems by tumor cell- released factors. Understanding the mechanisms for TCIPA is helpful for the clinical design of therapeutic agents to control tumor metastasis. A number of clinical studies have found higher levels of thromboxane and lower levels of prostacyclin in plasma and tumor tissues from lung, bone and breast. Moreover reports have also observed the over-expression of ►cyclooxygenase-2 (COX-2) and thromboxane synthase in the tumors of colon, breast, prostate, brain and endocrine. Some tumors may generate excessive amounts of TXA2 to enhance tumor growth and metastasis. An elevation of urinary 11-dehydro-►TXB_2 (a major enzymatic metabolite of TXB2) in patients with colorectal cancers has been noted, suggesting the beneficial use of a low dose ►COX-1 inhibitor to reduce platelet activity in some cancer patients. BM-567, a thromboxane synthase inhibitor and TXA2 receptor antagonist, can inhibit the MG-63 osteosarcoma cell-induced platelet aggregation. Administration of SQ29548, the other TXA2 receptor antagonist, also reduces chondrosarcoma tissue TXB2 levels, vascular permeability and tumor size in experimental animals in vivo. Whether TXA2 receptor antagonists can be effectively used clinically to prevent tumor metastasis should be further addressed. ►Non-steroidal anti-inflammatory drugs (NSAIDs) such as aspirin and ibuprofen may reduce the risk of cancer in colon, esophagus, stomach, prostate and lung as well as the metastasis of prostate cancer. Aspirin as a COX-1 inhibitor and antiplatelet agent is also tested for its anti-metastatic effects. In experimental animals, aspirin may reduce the metastasis of injected ►hepatocellular carcinoma cells to lung. However, a multicenter study shows little effect of aspirin in combination with chemotherapy to improve survival of 303 patients with small cell ►lung cancer. More studies on the dosage, duration and timing of aspirin or other therapeutic administrations are needed.

In experimental animals, heparin administration seems effective in the suppression of tumor metastasis, but not primary tumor growth. This can be due to its inhibition of blood coagulation, tumor cell-platelets and ►tumor-endothelial cross talks. Accordingly, clinical administration of aspirin and heparin to humans may suppress platelet aggregation and therefore promote survival in cancer patients. In addition, heparin, warfarin (a vitamin K antagonist) and antiplatelet agents (prostacyclin and dipyridamole) are able to inhibit the metastasis of ►pancreatic cancer cells and ►melanoma cells to the liver and lung. Intriguingly, recent studies have found that low molecular weight heparin (LMWH) successfully prevents the progression of cancer and improves the survival of patients with advanced ►non-small cell lung cancer, colon, pancreatic, breast and pelvic cancers.

Since tumor cells may also express PARs, glycoprotein IIb/IIIa and integrin αvβ3, inhibition of these receptors and activation and signaling by agents such as Hirudin, PPACK, antithrombin III, receptor neutralizing antibodies are potentially useful methods for inhibition of TCIPA and metastasis by some tumor cells. XV454, a glycoprotein IIb/IIIa antagonist, has

recently been shown to suppress the metastasis of Lewis lung carcinoma cells in experimental mouse metastasis models. A combination of LMWH and XV454 is even more effective in reducing cancer-induced thrombosis in vitro. Currently, some new reagents are being tested for their inhibition of TCIPA. Administration of antiplatelet agents (such as antiplatelet antibody, dansylarginine N-(3-ethyl-1,←5-pentanediyl)amide) before inoculation of tumor cells has been shown to effectively reduce tumor metastasis to lung and bone tissue. Integrilin, a platelet-specific integrin inhibitor, was able to effectively suppress TCIPA, but showed only partial inhibitory effects on physiological platelet functions. An elevated expression of aggrus/podoplanin, a new platelet aggregation inducing factor in tumor tissues has been found and promotes pulmonary metastasis in experimental animals. Administration of anti-podoplanin antibody is also shown to inhibit the neuroglioblastoma cell-induced platelet aggregation. More clinical trials by inhibition of TCIPA using antiplatelet and anticlotting agents are now in progress. These results will be helpful in developing effective clinical strategy and regimens for antimetastatic therapy of cancer in the near future.

Tumor–endothelial communication

Definition

Research in the field of tumor–endothelial communication focuses on specific interactions and pathways that allow circulating tumor cells to interact with the endothelium – the inner lining of the vascular wall. These interactions lead to modifications of the endothelium that eventually facilitate both tumor cell adhesion and ►extravasation. These processes are frequently accompanied by microthrombotic events and tumor–endothelial communication relies in many aspects on mechanisms known from the inflammatory response.

Characteristics

Neoplastic growth and survival of tumor cells in the host environment critically depends on effective mechanisms of tumor–host interactions. This dependency of tumor cell survival in the ►microenvironment is not only limited to the early phase of primary tumor growth, where obviously, e.g., nutritive supplies are needed, but persists throughout the entire life span of

tumor presence that is actually characterized by continuous multiple tumor–host interactions.

A characteristic hallmark of malignant tumor cells is their ability to spread via the host vascular system, settling up colonies distant from their place of origin, a process generally referred to as "►metastasis." There is general agreement that in this process of metastasis via the vascular system – which is the most fearsome aspect of cancer as to the survival prognosis – tumor cells that have managed to leave their site of origin need to apply ►escape mechanisms allowing avoidance of the host immunosurveillance and an eventual extravasation from the blood stream. The transmigration of circulating tumor cells into the host tissue is a highly regulated process, which up-to-date has not been completely understood. Circulating tumor cells extravasating to the host-stroma tissue will have to cross the natural barrier between blood and tissue: the endothelium. This interaction is a complex process that requires molecular mechanisms similar to those known from the proinflammatory and prothrombotic response. This encyclopedic entry will display the mechanisms that have coined the expression of tumor–endothelial communication. On the one hand, it summarizes the findings on tumor cell–endothelial interactions facilitating the transmigration of tumor cells; on the other hand, it will highlight the molecular mechanisms that are currently known for describing how tumor cells modify endothelial functions that eventually may lead to tumor-induced thrombotic events. It goes without saying that the current trend of linking thrombotic events to mechanisms of the inflammatory response also holds true for the understanding of tumor–endothelial communication.

There are multiple evidences that neoplastic cells from a variety of tumor entities actively modify the vascular endothelium. Tumor cells are capable of transforming the endothelial physiological quiescent disposition into a ►prothrombotic, proinflammatory, and proadhesive endothelium. One of the oldest documented observations of this phenomenon is generally accepted to date back to works by Trousseau in the late nineteenth century (1865). These studies showed that tumor cells are associated with thrombi of platelets and neutrophils. In addition, there are multiple clinical reports that a thromboembolic event of so far unknown origin might occasionally be the first hint to an ongoing metastatic tumor disease of a patient. So evidently, these observations reflect tumor–host cross-talk.

Adhesion Molecules in Tumor–Endothelial Cross-talk Mediating Extravasation

The extravasation from the flowing blood stream is a highly regulated process that relies on a specific interaction of ligands on the circulating cell and their receptors on the vascular endothelium. Much of the current knowledge in this field derives from the studies on thrombosis and inflammation, where platelets and leukocytes are specifically directed to bind to the activated endothelium and vascular wall. So-called ►selectins are a family of adhesion molecules that are crucial in this process. There are L-, P-, and E-selectins that all recognize carbohydrate structures. While L-selectin is constantly present on leukocytes, P- and E-selectin become upregulated on activated endothelium. Absence of selectins severely delays or even prevents the adhesion of circulating cells. The lectin domain of selectins recognizes sialylated, fucosylated structures displayed mostly on mucin-type glycoproteins containing a terminal tetrasaccharide sLe^x and sLe^a. Next to platelets and neutrophils, selectin-ligands have been shown to be expressed by several tumor entities and thus support tumor–endothelial communication. In different mouse models of metastasis, it could be shown that P- and E-selectin deficiency reduces the amount of extravasation of tumor cells. It was also reported that heparin, apart from its properties as an anticoagulant, interferes with binding-ligands for selectins and thus prevents metastatic tumor spread. The use of heparin for prevention of tumor metastasis has been shown to be beneficial in many human studies and has become an accepted option for the clinical treatment of cancer patients. In continuation of the initial selectin-mediated interaction of tumor cell and endothelium, ►integrins are recognized to play an important role in cell adhesion. Integrins are heterodimeric transmembrane proteins, that consist of noncovalently bound alpha and beta chains. They play a crucial role in cellular processes such as cell adhesion and migration as well as in the control of cell differentiation, proliferation, and survival. Several binding partners for integrins on and below endothelial cells have been characterized so far, such as VCAM-1, ICAM-1, and extracellular matrix proteins such as fibronectin, vitronectin, and ►laminin.There is also well documented expression of integrins on several tumor entities. During the malignant transformation, the expression of integrins has been reported to alter and leads to different binding avidity. Research on ►integrin-mediated tumor extravasation currently focuses on alphavbeta3 integrin and alpha5beta1 integrin, as their inhibition could decrease metastasis in several studies.

In summary, crossing the endothelial barrier, tumor cells rely on mechanisms that resemble those of cell arrest in the inflammatory and thrombotic response.

Tumor–Endothelial Cross-talk Leading to Prothrombotic Endothelial Activation

Apart from modifying the vascular endothelium towards a proadhesive state, tumor–endothelial cross-talk also

activates the prothrombotic activities of the vascular wall. The clinical observation is that of the so-called ►Trousseau's syndrome, where especially visceral cancers lead to venous thrombotic events. In addition, there are several reports showing that progressive cancer is associated with elevated levels of circulating ►von Willebrand Factor (VWF), a plasma surrogate marker for endothelial activation. The pathogenesis of the prothrombotic state in cancer is complex, and probably multifactorial, however, some studies could elucidate molecular mechanisms critically involved in tumor-induced prothrombotic endothelial activation. A well studied protein involved in endothelial activation is ►tissue factor (TF). Several tumor cells can directly release TF or stimulate circulating leukocytes to increase TF-release, e.g., by the generation of prothrombotic TF-rich microparticles. Once released, TF activates coagulation factor VII, which in turn activates factorX, thus activating prothrombin to ►thrombin. On the endothelium, via activation of the thrombin-receptor (Proteinase-activated receptor 1/PAR-1), thrombin leads to an immediate release of VWF and P-selectin promoting thrombosis and inflammation. A similar mechanism has been described for cancer procoagulant (CP). CP is a single chain cysteine protease that has been identified in a variety of tumors. It can directly activate factorX and thus contribute to the generation of thrombin. Recently, another direct mechanism of endothelial cells by metastatic tumor cells could be demonstrated. It was shown for human ►melanoma and ►colon cancer that metastatic tumor cell lines of these cancers are capable of generating and releasing matrixmetalloproteinase-1 (MMP-1). MMP-1 has been demonstrated to directly activate the thrombin-receptor on endothelial cells followed by VWF and IL-8 release. This mechanism does not rely on the presence of coagulation factors and is therefore proof of immediate tumor–endothelial communication.

Conclusion

The prothrombotic reaction of the endothelium upon contact with malignant circulating cells might be understood as a mechanism for prevention of further dissemination of the tumor, making trapped tumor cells more accessible to the host defense system. Indeed, it could be shown that in the absence of surrounding platelets tumor cells were more prone to ►natural killer cells attacks than when protected in platelet-emboli. However, it can also be speculated that tumor cell arrest in a thrombus might facilitate tumor cell extravasation. As antithrombotic treatment and depletion of circulating platelets has been demonstrated to positively influence tumor metastasis, specific strategies of interference with tumor–endothelial cross-talk might eventually prove beneficial for the prevention of tumor cell metastasis.

Tumor-Infiltrating Lymphocytes

Definition

TILs; Recognize unique cancer antigens isolated from human tumors and/or inflammatory infiltrate present around solid tumors. ►Adoptive immunotherapy is based on the *ex vivo* selection of tumor-reactive lymphocytes, and their activation for use in an autologous, tumor-bearing host. TILs are activated and expanded *in vitro* in the presence of cytokines (e.g. IL-2) and the patient's own tumor antigens, and then transferred into the same patient followed by

maintenance treatment with cytokines. TILs are capable of lysing autologous cancer cells in a highly-specific fashion restricted by the major histocompatibility complex (►MHC) class I molecules.

►Immunotherapy

Tumor Infiltrating T Cells

Definition

T cells that are found in the tumor tissue.

►T-Cell Response

Tumor-Initiating Cells

►Stem-like Cancer Cells

Tumor Lysis Syndrome

Definition

TLS; Is a very serious and sometimes life-threatening complication of cancer therapy. It can be defined as a constellation of metabolic abnormalities resulting from spontaneous or treatment-related tumor ►necrosis or fulminant ►apoptosis. The metabolic abnormalities observed in patients with tumor lysis syndrome include hyperkalemia, hyperuricemia, and hyperphosphatemia with secondary hypocalcemia. These can lead to acute renal failure (ARF).

►Rituximab

Tumor Markers

Definition

Tumor markers are broadly divided into three groups, which include the oncofetal protein, cancer-related antigen and hormone. They are detected by the analyses of blood, tissue, or body fluid. Their productions result either from the increased or decreased expression of a normal or cancer gene/protein. Theoretically, tumor markers are useful in diagnosis, predicting treatment response, and prognosis, as well as aiding the follow up of patient. However, the value of different tumor markers varies. Some markers may not be tumor specific, whereas some are important tumor-associated genes/proteins that may become the target of cancer therapy.

►Biomarkers
►Clinical Cancer Biomarkers
►Serum Biomarkers

Tumor Matrix

Definition

Synonym tumor stroma, summarizes cells and connective tissue elements that embed the tumor (fibroblasts, endothelial cells, collagen fibers, proteoglycans, etc).

Tumor Metabolism

Definition

The overall biochemical processes that occur in tumors to provide energy for cellular function and growth. Tumor metabolism can proceed through glycolysis and/or oxidative phosphorylation. Factors that determine the pathway and rate through which tumor metabolism proceeds include oxygen content, glucose availability, and pH of the tumor environment.

►Hyperthermia
►Oxygenation of Tumors

Tumor Microenvironment

Isaac P. Witz
Department of Cell Research and Immunology, Tel Aviv University, Tel Aviv, Israel

Synonyms

Cancer (or tumor) stroma

Definition

The specific conditions existing in the tumor tissue, the nonmalignant cells and the molecules present in proximity to the tumor cells.

Characteristics

It is now widely accepted that "Although abnormalities of cancer genes (►Oncogene; tumor suppressor genes) are essential contributors to cancer, most abnormalities in these genes occur relatively early in the disease process and none of them is known to be associated with the metastatic stage. It is this final stage – the seeding and growth of satellite lesions in other organs – that is ultimately responsible for the great majority of neoplastic deaths." It is the tumor microenvironment that determines and shapes the malignancy phenotype of cancer cells, in other words its metastatic behavior (►Metastasis).

The tumor tissue can be viewed as an ecosystem composed of two compartments being intimately associated with each other. The first compartment constitutes the malignant cells. The second is the tumor microenvironment composed of resident cells such as fibroblasts, endothelial cells (►Tumor-endothelial cross-talk), and other nonmalignant cells; of infiltrating cells such as lymphocytes or macrophages (►Tumor-associated macrophages) and of numerous molecules released by the tumor cells as well as by the non malignant cells. These molecules may be in complex with other molecules, for example, in the extracellular matrix. Other molecules such as growth factors, cytokines, ►chemokines, antibodies, proteases, other types of enzymes, various metabolites, or drugs may be present in soluble form. The microenvironment of many solid tumors may be characterized by hypoxia (►Hypoxia and tumor physiology; ►hypoxia inducible factor-1); low extracellular pH and by low glucose concentration. Cellular products released from necrotic tumor cells are also present.

Although the term tumor microenvironment is used most often with respect to solid tumors, other types of malignancies have also their specific microenvironments. The bone marrow serving as a microenvironment for certain leukemias (►Leukemia diagnostics) and for ►multiple myeloma is a case in point.

Stephen Paget, over 100 years ago, is credited with being the first to postulate the important role played by the microenvironment in metastasis formation. The concept of his "►seed and soil" theory, explaining site specific metastasis in ►breast cancer, has been supported and confirmed. However, numerous studies published in the last three decades demonstrate very clearly that the "soil" functions also, or even primarily, as an active "educational/inductive" venue in which cancer cells are directed, by interacting with microenvironmental factors, into one of several molecular evolution pathways. In other words, by exerting regulatory functions and selective pressures, the tumor microenvironment determines and shapes the malignancy phenotype of cancer cells.

The tumor microenvironment is an interaction arena between microenvironmental components and tumor cells and between different microenvironmental components. This arena is characterized by four major hallmarks: complex regulatory circuits; a yin-yang (double edged sword) interplay; plethora of vicious cycles; abnormality of its "normal," nonmalignant compartment.

Complex Regulatory Circuits. The major function of the tumor microenvironment is a regulatory one. Many genes in the tumor cells and in nontumor cells residing in or infiltrating to the tumor microenvironment are regulated by microenvironmental components.

Several hundred proteins were identified in the microenvironment of breast cancer. An extremely large number of signaling cascades (►Signal transducers and activators of transcription in oncogenesis; signal transduction) would operate in this microenvironment even if only a small portion of these proteins would interact with tumor cells or with nontumor cells. It is safe to predict that a similar number of proteins will be detected in the microenvironment of other types of solid tumors.

These signaling cascades take part in the regulation of genes in tumor and in nontumor cells thereby shaping the phenotype of cancer cells and drive their ►progression.

The regulatory power of the microenvironment can be amplified by the agonistic or antagonistic cross-talk (►Receptor cross-talk) between different signaling cascades. Furthermore, several signaling cascades in cancer cells are aberrant. This may well increase the number of combinatorial signaling pathways, augment their complexity, and decrease the capacity of physiological feedback mechanisms to confront these malignancy-associated processes. Another factor contributing to the complexity of the interactions taking place in the tumor microenvironment is tumor heterogeneity. It is thus to be expected that different tumor variants, expressing different profiles of signaling receptors (►Receptor tyrosine kinases), would respond differentially to microenvironment-derived signals.

The Yin-yang (Double Edged Sword) Interplay in the Tumor Microenvironment. The cross-talk between tumor cells and microenvironmental factors may result in diametrically opposed effects which could either enhance or block tumor formation or progression. There are several examples of such a yin-yang interaction. The activity of transforming growth factor-beta (TGFβ) (►Transforming growth factor) is an example for a microenvironmental molecule manifesting a "love–hate

relationship" with tumor cells. Whereas TGFβ is a potent inhibitor of normal mammary epithelial cells, it enhances tumor cell ►invasion and metastasis of advanced breast cancer cells (►Epithelial tumors). Moreover, cancer cells may secrete TGFβ which augments ►angiogenesis and is capable of suppressing antitumor immune responses of the host. On the other side of the coin, it was recently demonstrated that the progression of pancreatic and of intestinal tumors is enhanced by the inactivation of the TGF signaling cascade.

Another prominent example for yin-yang interplay in the tumor microenvironment is inflammation (►Inflammation in cancer) versus protective tumor immunity. Cells and molecules of the immune system may, under certain circumstances, inhibit tumor growth and under different circumstances promote it.

Vicious Cycles in the Tumor microenvironment. A vicious cycle may be described as an input event that drives and amplifies other events which, in turn, promote tumor progression. Among such activities, the input event may also augment itself (positive feedback). A well studied vicious cycle in the tumor microenvironment is the cross-talk between osteoblasts, osteoclasts and other microenvironmental factors on the one hand and breast, prostate (►Prostate cancer, clinical oncology) and lung (►Lung cancer) tumor cells on the other hand. This cross-talk promotes bone metastasis (►Bone tropism and cancer). Tumor-derived molecules such as cytokines cause either an osteoblastic or an osteolytic response. Such molecules feedback on the tumor and on various cells in the microenvironment causing the release of factors driving tumor progression.

Another example of a vicious cycle in the tumor microenvironment is the cross-talk between chemokines (►Chemoattraction and cancer; chemokine) such as CCL2 and CCL5 secreted from mammary tumors of mice or from breast cancer cells of humans and cytokines such as TNFα secreted from macrophages infiltrating into these tumors. The tumor-derived chemokines attract monocytes to the microenvironment. These monocytes differentiate into macrophages which secrete TNFα. This cytokine up regulates the secretion of CCL2 and CCL5 from the tumor cells. CCL2 and CCL5, in turn, promote the secretion of TNFα from the tumor-associated macrophages. In this vicious cycle, the tumor cells and the macrophages promote each other's ability to express and secrete pro malignancy factors.

Hypoxia (Hypoxia and tumor physiology; hypoxia inducible factor-1) characterizes the microenvironment of solid tumors. Hypoxia-induced changes in the proteome (►Proteomics) may lead to either impairment of tumor growth and spread or, alternatively, to tumor propagation and progression. In the later case, a vicious cycle is created in which tumor cells surviving and propagating under hypoxia will aggravate the state of tumor hypoxia which in turn promotes genomic instability and further progression.

The Nontumor Cells in the Tumor Microenvironment may Express a Different Phenotype than Their Counterparts at Distant Sites. The conditions in the tumor microenvironment, for example, hypoxia, may induce or promote genetic instability and cause mutations and alterations in gene expression profiles of cancer cells (►Genetic disorders associated with cancer predisposition and chromosomal instability). It is not unlikely that such conditions may induce genetic alterations also in nontumor cells present in the microenvironment. The question, if the phenotype and functions of nontumor cells in the tumor microenvironment are similar or different from those of their counterparts in normal microenvironments, is by and large open. Several studies clearly demonstrate that at least some of the nontumor cells in the tumor microenvironment may not represent faithfully the characteristics of their counterparts in other sites of the body. Cancer-associated fibroblasts and endothelial cells are two prominent examples that illustrate the abnormality of tumor-associated nontumor cells.

Cancer-associated fibroblasts have genetic changes both at the DNA level as well as at the expression level. For example, fibroblasts in human carcinomas have tumor suppressor gene mutations. DNA microarrays (►Microarray (cDNA) technology) identified over 100 genes differentially expressed by prostate carcinoma (Prostate cancer, clinical oncology)-derived fibroblasts and by systemically derived ones. These alterations may well manifest themselves by altered functions of such tumor-associated cells. Similar findings were also reported for endothelial cells. Cytogenetic abnormalities have been shown to occur in tumor endothelium and such cells may also express proteins that are not expressed by endothelial cells of the corresponding normal tissue.

The fact that nontumor cells in the tumor microenvironment express a different phenotype than that expressed by the corresponding cells residing in other microenvironments might be exploited in cancer therapy modalities, targeting these differentially expressed molecules.

►Pathology

Tumor Progenitors

►Stem-like Cancer Cells

Tumor Progression

Definition

Tumor progression is a process characterized by progressive accumulation of genetic defects in tumor cells and the outgrowth of tumor cell populations possessing more invasive properties, increased ability to spread to other sites and reduced response to therapeutic intervention. It represents genetic and epigenetic changes of tumor cells resulting in higher malignancy of the tumor. ►progression of tumors; multistep development.

Tumor Promoter

Definition

A non-genotoxic substance that induces tumor formation, after tumor initiation by genotoxic carcinogens.

A well-known tumor promoter is phorbol 12-myristate acetate, (►PMA).

►Protein Kinase C Family

Tumor Promotion

Definition

Characterized by a reversible phase of clonal expansion of initiated cells containing mutations/inactivated genes, with a dysregulation of apoptosis of the initiated cells as well as by accumulation of epigenetic changes such as DNA methylation, inflammation characterized by infiltration of activated leukocytes, production of growth factors, cytokines, reactive intermediates including oxygen free radicals and nitrogen radicals which stimulates formation of DNA damage, with inhibition of DNA repair enzymes. These alterations become irreversible and lead to development preneoplastic papillomas, which are benign skin lesions

Tumor-Specific Stroma

Definition

The ►stroma in a malignant tumor, comprising ►extracellular matrix and embedded cells, constitutes up to 90% of tumor mass and has characteristics not found in normal tissues. In tumor stroma, tumor-associated cells such as carcinoma-associated fibroblasts, inflammatory cell and endothelial cells among others are found that secrete soluble growth factors and cytokines as well as extracellular matrix molecules and extracellular matrix degrading enzymes that promote transformation and malignant progression of tumor cells. Cancer appears to be a product of the tumor-host ►microenvironment, where mutual stimulation of tumor and stromal cells induces tumor formation and, extensive tumor ►angiogenesis and ►metastasis.

Tumor Spread

►Metastasis

Tumor Staging

Definition

►Staging of Tumors.

Tumor Stroma

Definition

Tumor ►microenvironment that is largely a product of the host and is induced as the result of tumor cell-host interactions. Stroma consists of non malignant supporting tissues with ►extracellular matrix and includes connective tissue, blood vessels and inflammatory cells. It is essential for the growth of the tumor and its ability to progress and metastasize.

►Stromagenesis

Tumor Suppression

Eric Stanbridge
Department of Microbiology and Molecular Genetics, University of California, Irvine, CA, USA

Definition

Tumor suppression is the consequence of the functional presence and activity of ►tumor suppressor genes

Tumor Suppression. Table 1 Predisposing Germ Line Mutations in Tumor Suppressor Genes

Associated cancer syndrome	Tumor suppressor gene	Human chromosomal location	Gene function	Cancer type
Familial ►retinoblastoma	*RB1*	13q14	Transcriptional regulator of cell cycle	Retinoblastoma, osteosarcoma
►Wilms tumor	*Wt1*	11p13	Transcriptional regulator	Nephroblastoma
►Li-Fraumeni Syndrome	*p53*	17q11	Transcriptional regulator/growth arrest/apoptosis	Sarcomas, breast/brain tumors
►Von Recklinghausen Disease	*NF1*	17q11	Ras-GAP activity	Neurofibromas, sarcomas, gliomas
►Neurofibromatosis type 2	*NF2*	22q12	ERM protein/cytoskeletal regulator	Schwannomas, meningiomas
►Von-Hippel Lindau Disease	*VHL*	3p25	Regulates proteolysis	Hemangiomas, renal, pheochromocytoma
Familial adenomatous polyposis	*APC*	5q21	Binds/regulates β-catenin activity	Colorectal cancer
Familial ►melanoma	*INK4a*	9p21	$p16^{Ink4a}$ cdki for cyclinD/cdk4/6; $p19^{ARF}$ binds mdm2, stabilizes p53	Melanoma, pancreatic
►Gorlin syndrome	*PTC*	9q22.3	Receptor for sonic hedgehog	Basal cell carcinoma, medulloblastoma
Juvenile polyposis	*DPC4*	18q21.1	Transduces TGF-β signals	Pancreatic, colon, hamartomas
►Cowden syndrome BZS, LDD	*PTEN*	10q23	Dual specificity phosphatase	Glioblastoma, prostate, breast
►Tuberous sclerosis complex	*TSC2*	16	Cell-cycle regulator	Renal, brain tumor
Familial prostate carcinoma	*NKX3.1*	8p21	Homeobox protein	Prostate
►Peutz-Jeghers Syndrome	*LKB1*	19p13	Serine/threonine kinase	Hamartomas, colorectal, breast
Familial gastric cancer	*E-Cadherin*	16q22.1	Cell adhesion regulator	Breast, colon, skin, lung carcinoma
►Ataxia telangiectasia	*ATM*	11q23	P13K-like kinase	Leukemias, lymphomas
►HNPCC	*MSH2*	2p22	Mut S homologue, mismatch repair	Colorectal cancer
HNPCC	*MLH1*	3p21	Mut L homologue, mismatch repair	Colorectal cancer
HNPCC	*PMS1*	2q31	Mismatch repair	Colorectal cancer
HNPCC	*PMS2*	7p22	Mismatch repair	Colorectal cancer
HNPCC	*MSH6*	2p16	Mismatch repair	Colorectal cancer
►Bloom Syndrome	*BLM*	15q26.1	DNA helicase	multiple
►Fanconi anemia				
Complementation Gr A	*FAA*	16q24.3	Involved in DNA cross-link repair	Leukemia
Complementation Gr C	*FAC*	9q22.3	Involved in DNA cross-link repair	Leukemia
►Xeroderma pigmentosum (seven complementation groups)	*XPA*	9q34.1	Binds damaged DNA	Skin
	XPB	2q21	helicase; part of TFIIH	
	XPC	3p	?	
	XPD	19q12.3	Helicase; part of TFIIH	
	XPE	?11	Binds damaged DNA	
	XPF	16p13	Structure-specific endonuclease	
	XPG	13q23-33	Structure-specific endonuclease	
►Nijmegen Breakage Syndrome	*NBS1*	8q21	Involved in DNA doublestrand break repair	Lymphomas
►Familial breast cancer	*BRCA1*	17q21	Transcriptional regulator/DNA repair	Breast/ovarian tumors
Familial breast cancer	*BRCA2*	13q12	Transcriptional regulator/DNA repair	Breast/ovarian tumors

(TSGs). TSGs are recessive genes whose protein products appear to directly or indirectly negatively regulate cell proliferation, promote ►apoptosis and maintain in vivo homeostatic growth and differentiation potential.

Characteristics

Three major classes of genes are involved in cancer causation and progression:

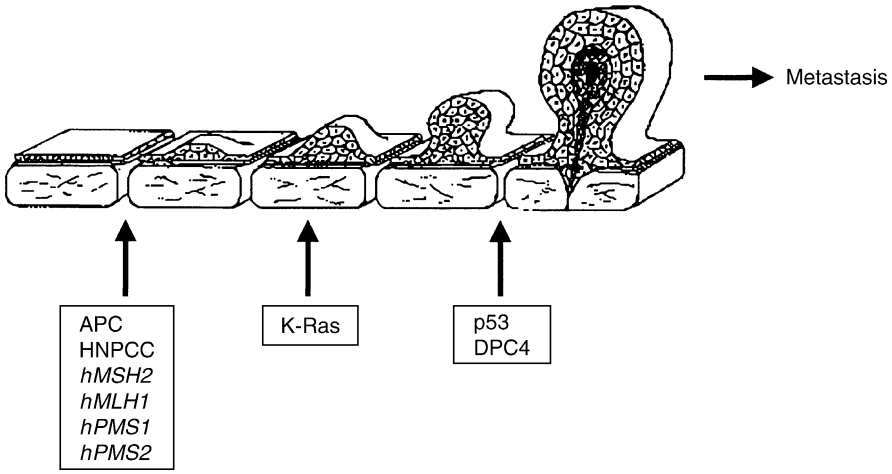
- Dominantly-acting ►oncogenes, whose proteins serve to stimulate cell growth and survival
- Recessive genes involved in ►repair of DNA
- Recessive TSGs

The recessive TSGs and ►DNA repair genes are often included under the rubric of tumor suppressor genes. The importance of TSGs in the genesis of cancer became apparent when individuals predisposed to early onset cancer were found to contain a mutated allele of a certain TSG in their germline. This condition predisposes the individual to earlier onset cancer at a significantly higher probability than individuals who possess a sporadic cancer of the same histologic type. This is best illustrated by the prototypic TSG, ►RB1, that predisposes to childhood ►retinoblastoma. The incidence of sporadic retinoblastoma is ~1:40,000, and is often unilateral, whereas the incidence of heritable retinoblastoma within an affected family is ~40%, and often involves both eyes (bilateral retinoblastoma). The affected proband inherits the mutant allele from one of the parents. Thus, the classic presentation of a heritable recessive TSG is one of dominant autosomal inheritance. In the classic ►two-hit model, the affected individual inherits one mutant RB1 allele and the second allele is eliminated somatically in the retinoblastoma tumor. In the case of sporadic retinoblastoma both alleles are eliminated somatically.

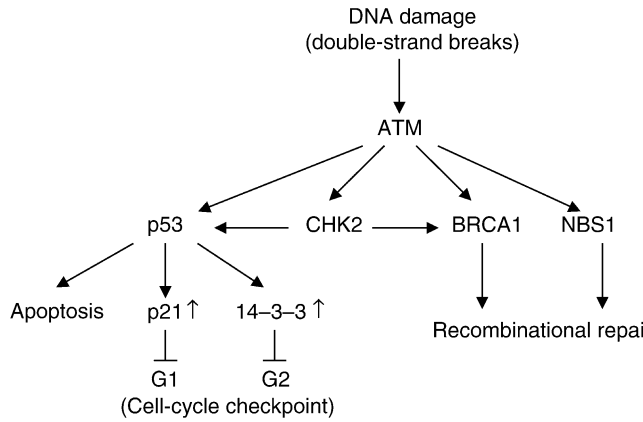
Since the identification of the RB1 TSG, a large number of cancer-predisposing germline mutations in TSGs have been found (Table 1), and they include DNA repair genes. Many, but not all (e.g. ►BRCA1 and ►BRCA2), are commonly found to be mutated in sporadic cancers of the same histologic type as those seen in the relevant familial cancer cases.

Progression to the cancerous condition is a multistep phenomenon. This is best illustrated by the colorectal cancer model (►multistep development; Fig. 1). Tumorigenesis proceeds through a series of cellular alterations, including hyperplasia of the colonic epithelium, benign polyps of increasing size and disordered growth, and ►carcinoma in situ with localized invasion. Distant metastases may occur. Accompanying these cellular alterations are genetic alterations, including activating mutation of the K-ras proto-oncogene and loss-of-function mutations in multiple TSGs. In the case of TSGs, mutations in both alleles must occur for complete loss of function. Loss-of-function of multiple TSGs is a hallmark feature of most, if not all cancers.

TSGs span a broad range of functions (Table 1). These include kinases, phosphatases, cyclin-dependent kinase inhibitors, transcription factors, cell adhesion molecules, proteins involved in specific protein degradation pathways and a variety of DNA repair processes. There is increasing evidence that tumor suppressor proteins and DNA repair proteins interact in functional networks (an example is given in Fig. 2). The ATM kinase phosphorylates and activates the tumor suppressor ►p53 and CDSI/►CHK2 proteins, and the



Tumor Suppression. Figure 1 Multistep progression model for colorectal cancer. Tumorigenesis proceeds through a series of cellular alterations, including hyperplasia, benign polyps of increasing size and disordered growth, and carcinoma in situ with localized invasion. Genetic alterations associated with this progression include inactivation of TSGs, e.g. APC, p53 and DPC4, mutational activation of the K-Ras, oncogene and inactivation of one of the DNA mismatch repair genes.



Tumor Suppression. Figure 2 Networking of tumor suppressor and DNA repair proteins. In response to DNA damage, ATM phosphorylates and activates p53 and the cell cycle kinase CHK2. This kinase also enhances activation of p53 via phosphorylation. Activated p53 upregulates expression of the cyclin dependent kinase inhibitor, p21, and 14–3–3 proteins, resulting in cell-cycle arrest at the G1 and G2 checkpoints, respectively. The activated p53 protein may also induce apoptosis. Transient cell-cycle arrest allows for repair of damaged DNA by preventing the duplication and propagation of damaged DNA. ATM also plays an important role in DNA repair by phosphorylating and activating BRCA1 and NBS1 proteins. See Table 1 for identification of the genes. → = activation; ⊣ = inhibition.

DNA repair proteins, BRCA1 and ►NBS1. These activations lead to cell-cycle checkpoint arrest and repair of DNA damage. Loss-of-function of any one of these factors compromises DNA repair, culminating in genomic instability and increased probability of progression to the cancer phenotype.

Clinical Aspects

Identification of specific germline mutations in TSGs in affected families allows the recognition of those members who are carrying the mutant allele and, therefore, are at a significantly higher risk of getting cancer. Detection of mutant tumor suppressor proteins, e.g. p53, or loss of expression of such proteins may aid in cancer diagnosis and prognosis. Experimental investigations have established that restoration of TSG function in cancer cells that are defective for that function result in suppression of tumor growth or death of the cancer cells. Clinical trials are in progress using ►gene therapy and pharmacologic approaches that aim to apply these procedures to the treatment of human cancers.

Synonyms

Recessive oncogenes

Definition

Tumor suppressor genes are genes whose products normally negatively regulate cell growth or cell behavior (Fig. 1).

Characteristics

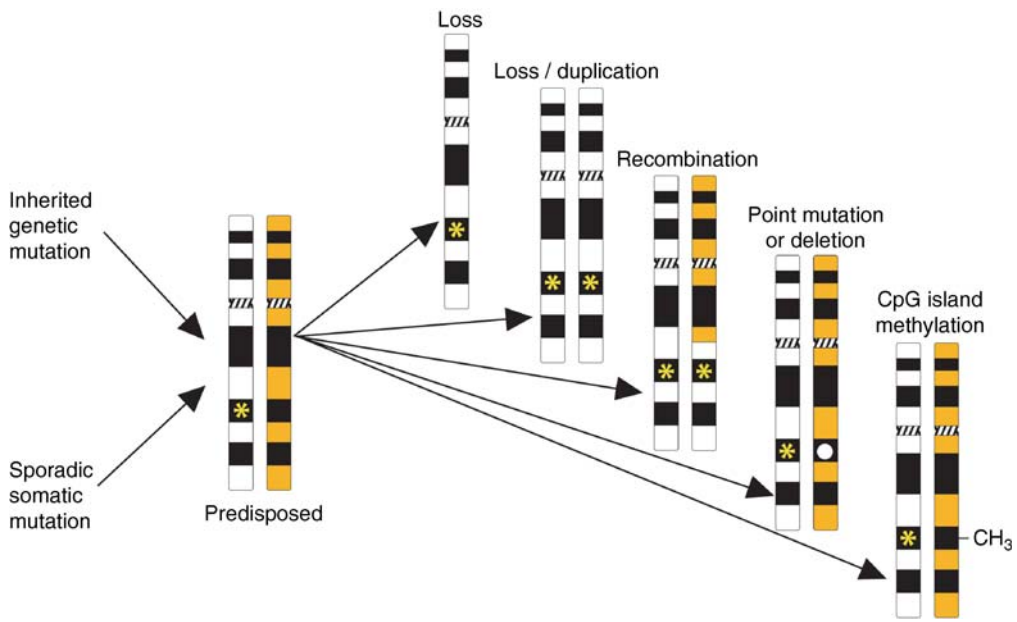
The hallmark of a tumor suppressor gene is that its function is lost during tumor initiation or progression. This typically occurs by one of a set of chromosomal processes called ►loss of heterozygosity but, in some cases, can occur by forming dominant negative forms of the tumor suppressor gene product. Their presence is usually inferred through the cytogenetic or molecular detection of subchromosomal loss. Upon molecular isolation, the genetic inference can be confirmed and dissected by demonstrating a restoration of growth regulation upon ectopic expression of the gene and/or by the formation of tumors or growth abnormalities in animals lacking the functional gene, either naturally occurring mutant strains or those constructed by in vivo homologous recombination "►gene knockout" techniques.

What was the Evidence for Tumor Suppressors?

The primary lines of evidence are genetic: One is that specific kinds of cancer can cluster in families. In most cases, the inheritance pattern is autosomal dominant which means that it is not sex-linked, may be transmitted from either parent and involves the transmission of a gene whose presence is sufficient to cause disease. In addition to familial clustering of the common cancers, two additional clinical observations provide strong epidemiological support for the contention that cancer has a genetic etiology.

- First, some individuals and their families have an ►autosomal dominant transmission of cancer predisposition, not to a single tumor, but to multiple tumors occurring independently at different body sites.
- Second, individuals with a variety of multi-organ developmental defects often also develop specific rare tumors. A statistical argument can thus be made that the combined occurrence of multiple independent tumors or the routine association of developmental defects with tumors which are very rare in the general population is so unlikely as to suggest an etiologic relationship.

The apparent dominant transmission of cancer traits is paradoxical in light of three observations. First, hybrid cells formed from the experimental fusion of highly malignant tumor cells with normal cells are not usually tumorigenic, suggesting that the normal phenotype is dominant in the presence of tumorigenic mutations. Furthermore, the occasional hybrid cell that regains tumorigenicity in these experiments has lost specific chromosomes originally contributed by the normal cell,



Tumor Suppressor Genes. Figure 1 Chromosomal mechanisms for tumor suppressor gene inactivation. Left side, the first mutation (*) can occur in a single somatic cell and result in sporadic disease. Alternatively, it can occur in a germ cell (de novo mutation) or be inherited from an affected parent and result in heritable disease. Right side, the first mutation can become completely inactivated by (from top to bottom) physical deletion or recombination of the wild type chromosome, by a targeted second mutation or deletion of the remaining wild type gene or by methylation of the promoter of the wild type gene leading to loss of expression.

implying that it is not gain of a dominant cancer trait but specific chromosomal loss that is responsible for the tumor phenotype. Second, if a single mutation was sufficient in itself to elicit a tumor, then families segregating for autosomal dominant forms of cancer would be expected to have no normal tissue in the diseased organ. This expectation is in direct contrast to the clinical description of these tumors as focal lesions surrounded by normal, functioning tissue of the same organ. Finally, epidemiological analyses of sporadic and familial forms of several human cancers have indicated that the conversion of a normal cell to a tumor cell requires multiple events.

Retinoblastoma – The First Suppressor

►Retinoblastoma is a relatively rare tumor (1 in 20,000 births) of young children and occurs in both a sporadic and autosomal dominant inherited form. Based entirely on statistical data from epidemiology and clinical observations, several remarkable conclusions were made regarding the nature of events leading to retinoblastoma tumor formation. First, the inherited mutation alone was not sufficient to cause the disease, since there are at least 107 retinoblast cells which are potential targets for retinoblastomas, each carrying the inherited mutation, yet on average, only three independent tumors form per affected individual. This also suggested that at a genetic level, mutations leading to retinoblastoma may be recessive, rather than dominant as suggested by the inheritance pattern. The hereditary tumors were proposed to arise through an initial germline mutation followed by a second mutation in a somatic cell. The rate at which somatic mutations occurred was similar in hereditary and sporadic cases, although sporadic tumors required two somatic mutations, each in the same retinoblast for tumor formation. Entirely consistent with this was the observation that hereditary cases usually occurred at an earlier age, were often bilateral and had multiple tumors, whereas the sporadic cases were invariably unilateral and single tumors. Because of the small possibility that a second somatic mutation may never occur in hereditary cases, ~5% of carriers do not develop any tumor. The nature of the two mutational targets in the genome was unknown at the time of these clinical observations, but cytogenetics and molecular genetics eventually led to the answer as well as to a general approach to other human cancers.

Analysis of the ►chromosome band patterns from hereditary and sporadic retinoblastoma patients revealed a deletion of chromosome 13q14 (chromosome

13, q or long arm, band one-four), suggesting that the gene for retinoblastoma (Rb) resided somewhere within this region. DNA from hereditary tumors was then analyzed with cloned DNA probes (termed "DNA markers") that could distinguish the two copies, or ►alleles, of chromosome 13 within each cell. It was found that, in tumors of affected individuals, the region containing the suspected Rb gene on chromosome 13 was present in a mutant only state. This conversion from a heterozygous state to homozygosity for the mutation was termed loss of heterozygosity (LOH), and constituted the second hit required for tumor formation in hereditary cases. Furthermore, LOH on chromosome 13q14 also occurred in sporadic retinoblastoma. These data lent strong support to the idea that retinoblastoma tumor formation occurs by the unmasking of a recessive genetic defect. The discovery that LOH occurs in other hereditary and most sporadic cancers in humans marked the simultaneous emergence of somatic cell cancer genetics and its coupling to the genetics of hereditary cancer. By identifying the region of chromosome 13q14 with the most consistent LOH in tumor DNA, the gene responsible for retinoblastoma was eventually isolated and its functionality assessed. Most importantly, the gene was shown to be mutationally inactivated in retinoblastoma tumors. When a normal copy of the gene was transferred to tumor cells, their growth and tumorigenic behavior was reduced. Thus, the conjoint application of epidemiology, cytogenetics, molecular genetics and molecular biology allows the identification of a gene with tumor suppressing function.

Are There Other Tumor Suppressors and What Cellular Role do They Normally Play?

Since the first suppressor was isolated, many others have been molecularly identified. As might be expected, these represent genes whose products are involved in many different aspects of cell growth and behavior. These include regulators of the ►cell cycle, growth and transcriptional regulators, ►DNA repair enzymes, differentiation factors, elements of cell ►motility and regulators of cellular signaling. Thus, elucidation of the function and nature of tumor suppressors is not only of importance for understanding cancer etiology but also useful for dissecting normal cellular function.

Clinical Relevance

The intimate involvement of tumor suppressor genes in the etiology of most human cancers places them at the center of cancer research. Such knowledge has been exploited for the first prenatal and premorbid predictions of cancer occurrence, for molecular pathology approaches to tumor subtyping, for ►gene therapy approaches toward gene replacement and as targets for agonist/antagonist development in rational drug design. Just as in research, the continued exploitation of tumor suppressor genes for clinical benefit to cancer patients is likely to assume a central role in modern therapies (Table 1).

TUNEL

Definition

TdT (terminal deoxynucleotidyl transferase)-mediated dUTP nick end labeling (TUNEL), also known as ISEL (in situ end labeling), is a DNA-tailing reaction using TdT. DNA degradation is considered the key biochemical event in ►apoptosis, resulting in cleavage of nuclear DNA into ►nucleosome-sized fragments (approximately 180 base pair unit size). TUNEL can be used to determine apoptosis in individual cells, preferentially labeling apoptotic rather than necrotic cells. The principle is that DNA ends generated during apoptosis are extended by TdT using biotin- or digoxigenin-labeled BrdUrd (bromodeoxyuridine). The incorporated material is detected by fluorescent reagents.

Tunicamycin

Tatsushi Yoshida, Toshiyuki Sakai
Department of Molecular-Targeting Cancer Prevention, Graduate School of Medical Science, Kyoto Prefectural University of Medicine, Kyoto, Japan

Definition

Tunicamycin is an antibiotic identified and isolated from the fermentation broth of *Streptomyces lysosuperificucs*. Since the antibiotic interferes with the formation of viral and cellular surface coats, it was termed "tunicamycin" after the Latin word "tunica" for coats.

Characteristics

Structure and Function

Tunicamycin is a nucleoside antibiotic composed of uracil, a fatty acid and two glycosidically linked sugars. The sugars are *N*-acetylglucosamine and an unusual 11-carbon aminodeoxydialdose, which has been named tunicamine. Tunicamycin is a white crystalline powder which is soluble in alkaline water, pyridine, and hot methanol, slightly soluble in ethanol and *n*-butanol and insoluble in acetone, ethylacetate, chloroform, benzene and acidic water. High performance liquid chromatography (HPLC) of tunicamycin shows that the antibiotic is separated into ten different components that have molecular weights ranging from 802 to 858. These differences in molecular mass are attributable to differences in the acyl chain length of C_{13}–C_{17} (Fig. 1) Tunicamycin inhibits the first step in the lipid-linked saccharide pathway. Tunicamycin specifically inhibits the formation of dolichyl(pyro)-phosphate *N*-acetylglucosamine (dolichyl-PP-GlcNAc) in the step of the transfer of GlcNAc-1-P from UDP-GlcNAc to dolichyl-P. As a result of inhibition in the lipid-linked saccharide pathway, tunicamycin consequently inhibits the *N*-linked oligosaccharide formation of ►glycoproteins in the ►endoplasmic reticulum (ER) (Fig. 2).

Anti-viral Effect of Tunicamycin

Tunicamycin strongly inhibits the multiplication of enveloped RNA and DNA viruses such as Newcastle disease virus, vesicular stomatitis virus, semlici forest virus, fowl plague virus, Sindbis virus, measles virus, influenza virus, Rous sarcoma virus, Rauscher murine sarcoma virus and herpes simplex virus. Hemagglutinin and neuraminidase are glycoprotein components of the viral envelope. Tunicamycin specifically inhibits the biosynthesis of viral envelope glycoproteins. Tunicamycin possesses cytotoxic activity towards transformed mammalian cells infected with virus such as mouse 3T3 cells transformed by ►SV40 virus,

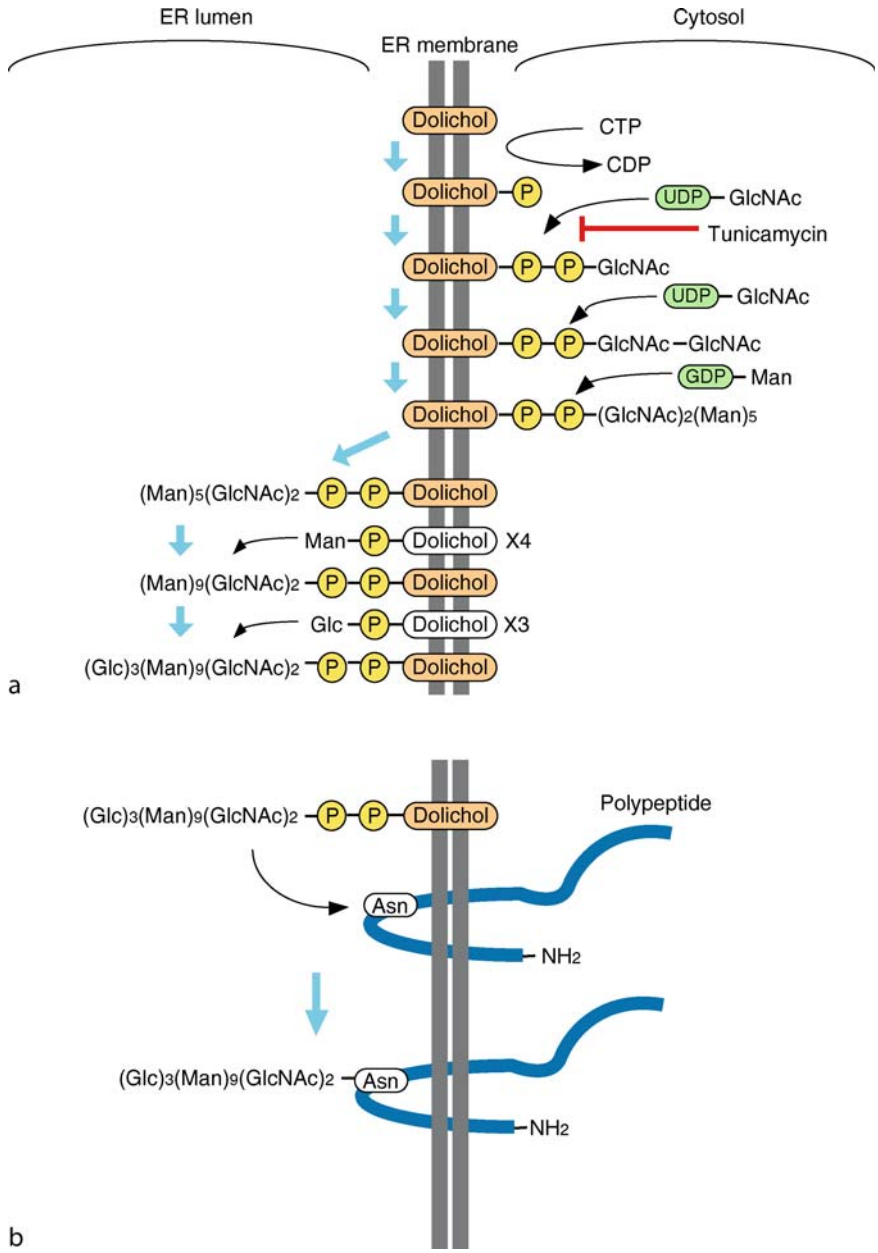
Apoptosis Induction by Tunicamycin

Tunicamycin induces ►apoptosis in various types of human cancer cells containing ►neuroblastoma, ►breast cancer, ►hepatocellular carcinoma and ►cervical cancer. Recent studies have revealed the mechanism of tunicamycin-induced apoptosis. In eukaryotic cells, ER provides an environment for the synthesis and modification of membrane proteins and secreted proteins. These co- and post-translational modifications including N-linked ►glycosylation are involved in subsequent protein folding and assembly. The accumulation of unfolded proteins causes ►endoplasmic reticulum stress, the term given to an imbalance between the cellular demand for ER function and ER capacity. Cells respond to ER stress by activation of the ►unfolded protein response (UPR). The UPR is mediated through three ER transmembrane receptors, activating transcription factor 6 (ATF6), inositol-requiring enzyme 1 (IRE1) and pancreatic ER kinase (PKR)-like ER kinase (PERK). Under unstressed conditions, these sensor proteins are maintained in an inactivated state by an association with ER chaperone protein, glucose-regulated protein (GRP78) (also called Bip). The UPR is a cytoprotective response to reduce the accumulation of unfolded proteins and restore normal ER function; however, prolonged ER stress switches from pro-survival to pro-apoptotic signaling. Inhibition of *N*-linked glycosylation by tunicamycin leads to ER stress. Tunicamycin is a representative ER stressor used to elucidate the mechanism of ER stress and UPR followed by apoptosis. The accumulation of unfolded proteins in ER results in the release of GRP78 from IRE1, PERK and ATF6. PERK phosphorylates the eukaryotic translation initiation fctor-2α (eIF-2α and allows the activating transcription factor 4 (ATF4). ATF4 transactivates C/EBP-homologous protein (CHOP). CHOP is an important factor in the induction of apoptosis by tunicamycin. CHOP-deficient mouse embryonic fibroblasts (MEF) provide partial resistance to apoptosis induced by tunicamycin treatment. MEF are not cells derived from cancer tissues but normal cells. MEF is often used to elucidate the mechanism of tunicamycin-induced apoptosis, since MEF leads to apoptosis by tunicamycin treatment and specific gene deficiency is easily provided in MEF. CHOP is a transcription factor and transactivates various genes. Tribbles-related protein 3 (TRB3) is a CHOP-downstream gene induced by CHOP at the transcriptional level. Knockdown of ATF4 and CHOP expression represses tunicamycin-induced TRB3 upregulation. Furthermore, down-regulation of TRB3 by small interfering RNA (►siRNA) partly blocks the apoptosis induced by tunicamycin treatment in human cervical cancer HeLa cells. Tunicamycin treatment also induces a ►p53-up-regulated modulator of apoptosis (►PUMA) and NOXA in a tumor-suppressor p53 gene-dependent manner. Both PUMA-deficient MEF and NOXA-deficient MEF partially reduce tunicamycin-induced apoptosis. These factors are key molecules of tunicamycin-induced apoptosis.

Tunicamycin Increases Effects of Anti-cancer Agents

Many glycoproteins exist on the plasma membrane of tumor cells, including the efflux pump of anti-cancer



Tunicamycin. Figure 2 Oligosaccharide formation and the action site of tunicamycin. (a) Lipid-linked oligosaccharide formation. Oligosaccharide is assembled onto the carrier lipid dolichol in the ER membrane. Tunicamycin inhibits the formation of dolichyl PP-GlcNAc. (b) N-linked oligosaccharide formation. Synthesized oligosaccharide $(Glc)_3(Man)_9(GlcNAc)_2$ is transferred from the lipid dolichol to the asparagine side chain of a nascent polypeptide on the ER membrane. GlcNAc, *N*-acetylglucosamine; Man, mannose; Glc, glucose.

agents. ►P-glycoprotein is a product of the MDR1 gene and protects cells against a broad spectrum of anticancer agents by functioning as an energy-dependent drug efflux pump. Inhibition of *N*-linked glycosylation of P-glycoprotein results in a reduced multidrug-resistance phenotype of cancer cells. Tunicamycin treatment increases the cytotoxicity of doxorubicin, epirubicin, ►cisplatin and vincristin against NIH-3T3 cells into which an exogenesis MDRs gene had been introduced. The human epidermoid carcinoma KB-8-5-11 cell line contains the amplified MDR1 gene. The sensitivity of this cell line to ►doxorubicin, epirubicin, cisplatin and ►vincristin also increases by treatment with tunicamycin. Tunicamycin does not influence the

uptake of these anti-cancer agents but reduces efflux of the agents in cells with a ►multidrug-resistance phenotype. Human ►colon cancer cells with a strong multidrug-resistant phenotype mediated by high constitutive levels of the expression of P-glycoprotein increase daunorubicin accumulation by incubation with tunicamycin. Tunicamycin exposure reduces P-glycoprotein expression on the surface of the cell membrane. Tunicamycin also decreases the 50% inhibitory concentration (IC_{50}) of cisplatin in human pharyngeal carcinoma KB cells and human maxillary squamous-cell carcinoma IMC-3 cells. Combined administration of tunicamycin with cisplatin injected by s.c. around the tumor inhibits tumor growth in C3H/He mice bearing cisplatin-resistant squamous-cell carcinoma *in vivo*, and increases the *in vivo* apoptosis of tumor cells.

Tunicamycin Enhances Death Ligand TRAIL-Induced Apoptosis

TNF-related apoptosis-inducing ligand (►TRAIL) is a type-II membrane protein belonging to the TNF family, which preferentially induces apoptosis in a variety of tumor cells but not in normal cells *in vitro* and *in vivo*. Since some tumor cell lines are resistant to TRAIL, an agent that can overcome resistance to TRAIL has been sought. Tunicamycin sensitizes ►hormone-refractory ►prostate cancer cells to TRAIL-induced apoptosis. The combination of tunicamycin and TRAIL activates ►caspases under the condition in which a single agent hardly activates caspases. Tunicamycin enhances TRAIL activity through the induction of a TRAIL receptor, TRAIL-R2 (also called death receptor 5 (►DR5)). Tunicamycin up-regulates the transcription of TRAIL-R2 through a transcription factor, CHOP.

Normal Cellular Toxicity of Tunicamycin

The hepatotoxicity of tunicamycin has been reported in guinea pigs given a single dose of 400 μg/kg of tunicamycin. A periportal pattern of hepatocellular damage was observed with the death of many hepatocytes up to 72 h post-injection. Swollen hepatocyte cytoplasm protruded into many hepatic blood vessels and detached portions of hepatocytes producing emboli in pulmonary and cerebral capillaries. The toxic effects of tunicamycin have been examined in rats at gestation day 15. At 16 h post-dosing, all pregnant rats had moderate to extensive vaginal bleeding and 1/4 died. The other rats had free blood in the uterus and large decreases in red cell counts, hemoglobin and packed cell volume. Tunicamycin toxicity has been reported in 6- to 8-week-old mice given a single injection of tunicamycin at a dose of 3 μg/g body weight intraperitoneally (i.p.) After 2 days, characteristic renal lesions were detected in tunicamycin-treated mice. Apoptosis was caused in the renal tubular epithelium. Moreover, tunicamycin treatment inhibited mammalian embryogenesis. Although early cleavage was normal, mammalian embryos did not undergo normal compaction and blastocyst formation. Trophoblast cell adhesion may be disrupted since tunicamycin is cytotoxic to these cells. In later development, tunicamycin inhibits kidney tubule formation when present during the embryonic induction of these structures.

Tunicamycin induces apoptosis in a variety of malignant tumor cells and possesses cytotoxic activity to virus-transformed cells compared with parental normal cells. Moreover, tunicamycin enhances the effects of anti-cancer agents; however, tunicamycin also has cytotoxicity against normal cells and causes crucial damage during *in vivo* administration. The mechanism of tunicamycin-induced apoptosis through ER stress has been revealed, but it has not been completely elucidated yet. If tunicamycin is applied to cancer treatment, its usage should be restricted to local administration, but further studies are needed.

Turban Tumor Syndrome

Definition

►Cylindromatosis.

Turcot Syndrome

Paola Izzo
Dipartimento di Biochimica e Biotechnologie Medicine a Chirurgia, Facoltà di Medicina, Università di Napoli Federico II, Napoli, Italy

Definition

Turcot syndrome (TS) is a rare inherited neoplastic disease characterized by the association of primary malignant neuroepithelial tumors of the central nervous system and colon cancers and/or multiple colorectal adenomas.

Characteristics

Clinical Criteria

The 130 or so Turcot syndrome (TS) cases described to date include various histopathologic types of ►brain tumors, e.g. glioma, ►medulloblastoma and astrocytoma, associated with a broad spectrum of colorectal findings, from a single adenoma to typical adenomatous polyposis. Usually, polyps are fewer in number than in familial adenomatous polyposis (FAP [►APC gene in familial adenomatous polyposis]) but are larger in size, and multiple adenomas or colorectal cancers occur at an early age and undergo an earlier malignant transformation than in FAP or in hereditary non-polyposis colorectal cancer (►HNPCC).

The clinical definition and the mode of inheritance of Turcot syndrome is controversial; some authors propose that TS is an allelic variant of FAP and support an autosomal dominant inheritance, while others postulate that TS is a disease independent of FAP with an autosomal recessive pattern of inheritance.

Genetics

Dominantly inherited cases have been associated with germline mutations in either the tumor suppressor adenomatous polyposis coli gene (APC), usually mutated in FAP, or in the DNA ►mismatch repair (MMR) genes, which are usually mutated in HNPCC.

Few recessive cases have been reported and only in two cases were the causative mutations found to be within the PMS2 gene, a minor MMR gene that is only rarely involved in HNPCC. In the first recessive case described, a germline nonsense mutation (PMS2-134) that was inherited from the healthy mother was found in one allele. The second recessive case was found to be a compound heterozygote for two frameshift germline mutations within the PMS2 gene; a G deletion (1221delG) in exon 11 and a four-base pair deletion (2361delCTTC) in exon 14, both of which were inherited from the patient's unaffected parents. This was the first evidence of recessive dominance of TS because two germline mutations in PMS2 are not individually pathogenic, but become so when occurring together in a compound heterozygote. Since all carriers of only one PMS2 gene mutation are clinically healthy, a lower penetrance of PMS2 gene mutations may be inferred for colorectal tumor development compared with mutations in other MMR genes, e.g. MLH1 and MSH2. Accordingly, there are no reports of HNPCC patients compound heterozygous for MLH1 or MSH2 mutations, which suggests compound heterozygosity is lethal.

PMS2 Gene

The PMS2 gene, localized to chromosome band 7p22, encompasses 16 kb and consists of 15 exons. It encodes a protein involved in the mismatch repair system that physically interacts with the MLH1 protein through the carboxyl terminus. Both PMS2 mutations (1221delG and 2361delCTTC) found in the compound heterozygous TS patient, caused the loss of the MLH1 interaction domain with PMS2, thus indicating that a disruption of the MLH1-PMS2 heterodimer might block the process of the MMR system.

Microsatellite Instability

►Microsatellite instability, an indicator of the defective DNA mismatch repair system, is characteristic of HNPCC colorectal tumors, of a small fraction of sporadic colon and brain cancers, and of colon carcinomas and adenomas in TS patients. It results from germline mutations in each of the MMR genes, i.e. MSH2, MLH1, PMS1 and PMS2, with somatic mutation inactivating the second allele in the tumor tissues or loss of protein expression in the tumor tissues. Brain and colon tumors in TS patients exhibit severe microsatellite instability at several DNA marker loci, at the repeated regions of the TGFβRII and of MSH3 and MSH6 genes as well as somatic mutations within the APC and p53 genes. High frequencies of the microsatellite instability have also been found in normal colon mucosa from TS patients bearing germline PMS2 mutations, in contrast to HNPCC patients in which microsatellite instability is very rare in normal tissues. Therefore, the high DNA hypermutability in normal tissues of TS patients is associated with a severe biochemical defect in the MMR system and it might trigger the early development of multiple cancers in this syndrome.

Clinical Aspects

Patients with hereditary forms of colon cancer and neurologic symptoms require immediate and thorough investigation because of their significantly increased risk of developing central nervous system (CNS) tumors. Patients diagnosed with a CNS tumor with a family history of colon tumors should undergo screening and

surveillance colonoscopy because the CNS lesion may precede colonic symptoms. The elucidation of the gene defects responsible for TS has therefore important implications in the genetic testing of relatives at risk and in the management of young patients with brain tumors and asymptomatic subjects.

Two-Hit Model

Definition

Based on epidemiological and clinical data, it has been inferred that as few as two mutations are sufficient to initiate the development of ►retinoblastoma (Rb). Specifically, it was hypothesized that

- In hereditary Rb one mutation is transmitted via the germline and the second mutation occurs in a somatic cell
- In non-hereditary Rb both mutations arise in somatic cells

In principle this may apply to the inactivation of other tumor suppressor genes.

Tyrosine

Definition

Is one of the 20 amino acids that are used by cells to synthesize proteins. Although it is among nonessential amino acids that can be made in vivo by animals, tyrosine is synthesized by the hydroxylation of an essential amino acid phenylalanine obtained from dietary sources.

Tyrosine Kinase

Definition

Tyrosine Kinase is a kinase enzyme that modifies other proteins by chemically adding phosphate groups from ATP (phosphorylation) to the tyrosine residues in them. Phosphorylation usually results in a functional change of the target protein by changing enzyme activity, cellular location, or association with other proteins. This process is an important mechanism in signal transduction for regulation of enzyme activity.

Tyrosine Kinase Inhibitors

Roy J. Duhé
Department of Pharmacology and Toxicology, University of Mississippi Medical Center, Jackson, MS, USA

Synonyms

Protein-tyrosine kinase inhibitors; PTKIs

Definition

Low molecular weight or macromolecular compounds that selectively inhibit the enzymatic activity of one or more protein-tyrosine kinases and which may therefore be useful in the treatment of diseases associated with unregulated kinase activity.

Characteristics

Tyrosine kinase inhibitors are a relatively new class of anticancer drugs which beautifully illustrate the promises and pitfalls of molecularly-targeted drug design. Since the market approval of the first drug in this class, ►imatinib (Gleevec® Imatinib), there has been a steady growth in market approvals of tyrosine kinase inhibitors. To date, there are seven tyrosine kinase inhibitors approved for cancer therapy. In addition to imatinib (Gleevec®), these include dasatinib (Sprycel™), erlotinib (Tarceva®), gefitinib (Iressa®), lapatinib (Tykerb®), sorafenib (Nexavar®), and sunitinib (Sutent®).

The term "tyrosine kinase inhibitor" is usually reserved for low molecular weight compounds that are capable of directly interacting with the catalytic site of the target enzyme and thereby inhibiting catalysis (►Inhibitors, molecular and chemical). Macromolecular drugs, most notably recombinant monoclonal antibodies such as cetuximab (Erbitux®) and trastuzumab (Herceptin®), have also been targeted against tyrosine kinases. Because recombinant monoclonal antibodies employ a different mechanism of drug action and have different pharmacological properties than low molecular weight kinase inhibitors, they will not be further discussed in this essay.

The molecular targets for these drugs are protein-tyrosine kinases, a class of enzymes originally reported as oncoproteins in 1980. It is now recognized that there are at least ninety distinct tyrosine kinases encoded in the human genome. There are two major families of tyrosine kinases. Receptor tyrosine kinases have an intracellular catalytic domain, a transmembrane domain and an extracellular ligand-binding domain; the ►epidermal growth factor receptor tyrosine kinase is a member of this family. Non-receptor tyrosine kinases lack both the extracellular ligand-binding domain and

the transmembrane domain and are hence cytosolic enzymes often non-covalently associated with other receptor systems; Janus kinases, which are typically associated with a variety of cytokine receptors, are members of this family.

Many tyrosine kinases are essential transducers of mitogenic signals from a variety of intercellular stimuli, such as cytokines or growth factors. The normal forms of these enzymes do not appear to be oncogenic when their expression levels and activity levels are properly regulated. It is only when these regulatory mechanisms break down by the introduction of mutations, chromosomal translocations, or due to epigenetic events, that tyrosine kinase activities result in the loss of cellular homeostasis. This loss of homeostasis can be manifested in diseases ranging from relatively benign conditions such as polycythemia vera to serious diseases such as chronic myelogenous leukemia to highly aggressive cancers such as non-small cell lung carcinoma. In such circumstances, cellular physiology appears to become dependent on these tyrosine kinase pathways, a circumstance referred to as "oncogene addiction" (►Pathway Addiction).

While tyrosine kinase inhibitors can sometimes effectively inhibit normal forms of tyrosine kinases under circumstances of oncogene addition, they appear to yield the greatest therapeutic benefit when the target is a mutated form of the enzyme. This may be because tyrosine kinase inhibitors do not equally affect all conformations or activity states of a given tyrosine kinase, but rather appear to be state-selective inhibitors. To illustrate, here are several examples. Imatinib (Gleevec®) preferentially binds and inhibits a form of the ABL kinase in which the activation loop is in a closed configuration, rather than the open configuration that ensues upon phosphorylation of tyrosines within the loop. Gefitinib (Iressa®) shows greatest therapeutic benefit to patients whose epidermal growth factor receptor (►EGFR, ►EGF Receptor, EGFR, ►Epidermal Growth Factor Receptor) kinase contains mutations within the P-loop region of the catalytic domain, but showed little to no benefit to patients with the normal form of the EGFR kinase.

Such examples raise the issue of using suitable diagnostic biomarkers to identify those patients who are most likely to benefit from tyrosine kinase inhibitor therapy. The fact that patients with chronic myelogenous leukemia (►Chronic Myeloid Leukemia) ►could be readily screened for the ►Philadelphia chromosome greatly facilitated the clinical trials which led to the approval of imatinib (Gleevec®). Precise DNA sequencing now identifies those patients who will not likely respond to imatinib (Gleevec®), but who would likely respond to dasatinib (Sprycel™). And it is now evident that gefitinib (Iressa®) is most effective against mutated EGFR kinases which harbor certain mutations in the P-loop of the catalytic domain.

It should be noted that therapeutically useful tyrosine kinase inhibitors are not specific for a single tyrosine kinase, but rather they are selective against a limited number of tyrosine kinases. Such selectivity has generally provided more clinical advantages than if the drugs were truly specific. In the case of imatinib (Gleevec®), which inhibits BCR/ABL, c-kit (►Kit/►Stem Cell Factor Receptor in Oncogenesis), and platelet-derived growth factor receptor (PDGFR) kinases, this leads to a broader range of indications for the treatment of several different diseases related to these tyrosine kinases. In the case of sunitinib (Sutent® ►Anti-Angiogenic Drugs), which inhibits most isoforms of PDGF receptor kinase and vascular epithelial growth factor (VEGF) receptor kinase, this leads to the simultaneous inhibition of tumor proliferation and tumor angiogenesis and greater therapeutic efficacy by inhibiting multiple targets involved in the progression of cancer.

Tyrosine kinase inhibitors are based on only a few common structural motifs, such as phenylaminopyrimidines, anilinoquinazolines, and indolinones. Most of these drugs bind reversibly to the ATP binding site of the tyrosine kinase catalytic domain. An important feature of these drugs is that they are somewhat water soluble, which improves their oral bioavailability. These drugs are formulated as pills. Thus, unlike drugs such as taxol which must be administered through an intravenous infusion in the clinic, tyrosine kinase inhibitors let cancer patients follow a more normal lifestyle because they can be administered in a home setting, rather than in the clinic. Furthermore, these tyrosine kinase inhibitors have a much better safety profile than classical cytotoxic anticancer drugs, which allows them to be taken on a daily basis.

However, a tyrosine kinase inhibitor is not a "magic bullet." Tyrosine kinase inhibitors are generally cytostatic, rather than cytotoxic, drugs and hence drug resistance often emerges after several years of excellent response to therapy. As is the case with other molecularly-targeted anti-cancer drugs, the medical community must learn the most efficacious way to use these new drugs by matching these drugs with the patients most likely to respond to them and to rationally incorporate them into effective combination drug regimes.

Tyrosine Kinase Receptors

Definition

A vast family of membrane receptors involved in signal transduction of stimuli relevant to proliferation, differentiation and apoptosis. They all contain, in their intracytosolic region, a conserved domain encoding a ►tyrosine kinase activity. Upon ligand engagement receptors undergo autophosphorylation on tyrosine residues. This modification serves the dual purpose of further propagating the signal inside the cell and of activating the process of ►endocytosis, which ultimately leads to signal attenuation. It is controversial whether signaling can also occur in the various intracellular compartments of the endocytic route.

Tyrosine Phosphorylation

Definition

Binding of a phosphate group to the amino acid tyrosine in a protein. Most proteins undergo then conformational changes and are activated. ►Tyrosine kinases catalyze this process and phosphatases again eliminate these phosphate groups.

►Focal Adhesion Kinase (FAK)

Ubiquitin

Definition

Is a small 76 amino acid protein that can be conjugated to other proteins via its C-terminus. The primary function of ►ubiquitination is to target acceptor proteins for degradation by the ►proteasome.

Ubiquitin-directed Protein Degradation

Definition

Plays an important role in regulating a broad spectrum of biological processes, including transcription, signal transduction, cell cycle progression, apoptosis, cell growth and differentiation. Proteins that are targeted for degradation by this mechanism undergo series of ubiquitin-modification steps carried out by the successive activity of E1 (activating), E2 (conjugating), and E3 (ligating) ubiquitin enzymes.

►Ubiquitin Ligase SCF-Skp2
►Ubiquitination

Ubiquitin Ligase

Definition

Synonym E3 ubiquitin ligase; Is a protein which covalently attaches ►ubiquitin to a lysine residue on a target protein. The ubiquitin ligase is typically involved in polyubiquitination: a second ubiquitin is attached to the first, a third is attached to the second, and so forth. Polyubiquitination marks proteins for degradation by the proteasome.

Ubiquitin Ligase SCF-Skp2

Frank Westermann
German Cancer Research Center,
Department of Tumour Genetics, Heidelberg, Germany

Synonyms

S-phase kinase-associated protein 2; Skp2; CDK2/cyclin A-associated protein p45; F-box and leucine-rich repeat protein 1 – Fbxl1; Fbl1

Definition

The SCF-Skp2 ubiquitin ligase belongs to the multi-subunit ►RING-type of E3 ligases involved in ►ubiquitin-directed protein degradation of key cell cycle regulators.

Characteristics

Cell cycle progression is coordinated by the activation of cyclin-dependent kinases (CDKs), the activities of which are controlled by the ubiquitin-directed degradation of key regulators such as ►cyclins and ►CDK inhibitors (CKIs). Two major classes of ►ubiquitin ligases, the SCF (Skp1-Cul1-Fbp) and ►APC/C (anaphase-promoting complex/cyclosome), have a central role in cell-cycle regulation. The SCF complexes are used throughout the ►cell cycle, whereas the APC/C acts primarily during ►mitosis and G1 phase. The SCF complex and the APC/C are structurally similar. Each is constituted of common subunits and a variable substrate-recognition subunit: F-box proteins for the SCF and activators for the APC/C.

Three F-box proteins in the SCF complex – Skp2 (S-phase kinase-associated protein 2), FBW7 (F-box and WD-40 domain protein 7) and β-TRCP (β-transducin repeat-containing protein) – and two activators in the APC/C – CDC20 (cell division cycle 20) and CDH1 (►cadherin 1) – are the most important in cell-cycle regulation. In the SCF ligase, the common subunit Cul1 functions as a molecular scaffold that simultaneously interacts at the amino terminus with the adaptor subunit Skp1 (S-phase-kinase-associated protein-1) and at the carboxyl terminus with a RING-finger protein (Rbx1) and a specific ►ubiquitin-conjugating enzyme (E2). Skp1, in turn, binds to one of many F-box proteins. Each F-box protein appears to be matched with a discrete number of specific substrates through a protein-protein interaction domain. Conventionally, the F-box protein is superscripted after "SCF" to indicate distinct SCF complexes (e.g. SCF^{Skp2}).

Several lines of evidence from both biochemical and genetic studies have shown that the SCF^{Skp2} complex is required for cell cycle progression at multiple stages, including G1/S, S phase progression, and S/G2 transition. As the substrate-recognition subunit in the SCF^{Skp2} complex, Skp2 targets CDK inhibitors such as ►$p27^{Kip1}$, $p21^{Cip1}$, and $p57^{Kip2}$ for degradation. Up to now, it has also been reported that Skp2 targets other key cell cycle regulators such as ►cyclin D1, cyclin E, ►E2F-1, p130, cyclin A, and ►Myc. However, it is $p27^{Kip1}$ that seems to be the primary target of Skp2, given that $Skp2^{-/-}$ ►knockout mice show a marked accumulation of $p27^{Kip1}$, and that prominent cellular phenotypes apparent in $Skp2^{-/-}$ knockout mice, including polyploidy, nuclear enlargement, and ►centrosome amplification, disappear in $Skp2^{-/-}$ $p27^{Kip1}$ double-knockout mice.

Regulation

Cells have different ways to regulate SCF^{Skp2} activity. The Rb tumor suppressor protein has a dual role in controlling the SCF^{Skp2} activity. Skp2 expression is cell cycle regulated, with *Skp2* transcription being activated at the ►G1/S transition by activating E2Fs – *Skp2* is a direct E2F target. In addition, during ►pRb-mediated cell-cycle arrest, pRb associates with Skp2, favors the degradation of Skp2, and promotes the stability of $p27^{Kip1}$. This is at least partly controlled by an interaction of pRb with another ubiquitin ligase, APC/C^{Cdh1}, *via* its activator Cdh1. Beside the degradation of Skp2, APC/C^{Cdh1} also favors the ubiquitin-directed degradation of Cks1, an important cofactor of the SCF^{Skp2} complex. The SCF^{Skp2} complex itself is also subject to post-translational modifications which controls activity of the complex. Skp2 ubiquitylation is inhibited by Cks1. Intriguingly, increased destabilization of Skp2 in response to ►transforming growth factor-β has been linked to loss of expression of Cks1, whose interaction with Skp2 appears to physically protect it from ►ubiquitination. Another post-translational modification that controls the activity of the SCF^{Skp2} complex is ►neddylation on the Cullin subunit. Neddylation describes the linkage of Nedd8 – a small 76-residue protein with sequence similarity to ubiquitin – to a lysine residue on the substrate. Although Nedd8 conjunction is known to dramatically increase ubiquitin transfer by ubiquitin-conjugating enzymes bound to the Rbx1/Cullin complex, the precise mechanism for this stimulation is unknown.

An important step in the process of substrate recognition by the SCF^{Skp2} complex is post-translational modification of the substrate itself. The SCF^{Skp2} complex targets $p27^{Kip1}$ only after phosphorylation on threonine 187 (T187). Active cyclin E/CDK2 complexes are crucial in the phosphorylation process on T187 of cyclin/CDK-bound $p27^{Kip1}$. While free and active cyclin/CDK2 efficiently phosphorylates CDK-bound $p27^{Kip1}$, $p27^{Kip1}$-bound CDK2 is thought to be catalytically inactive. This suggested that degradation by the SCF^{Skp2} complex may require $p27^{Kip1}$-free cyclin E/CDK2 and led to the enigma of how $p27^{Kip1}$ degradation can be initiated in G1 when all CDK2 complexes are bound by $p27^{Kip1}$. $p27^{Kip1}$ phosphorylation on T187 and SCF^{Skp2} dependent $p27^{Kip1}$ degradation at the G1/S transition can be initiated even in the absence of free cyclin/CDK2 complexes. $p27^{Kip1}$ can be phosphorylated on a tyrosine residue at position 88 (Y88) within its CDK-binding domain by tyrosine kinases. Y88-phosphorylated $p27^{Kip1}$ still bind to cyclin/CDK complexes, but the associated kinase retained significant catalytic activity. Furthermore, Y88-phosphorylated $p27^{Kip1}$ is an efficient substrate for phosphorylation on T187 by CDK2 within the trimeric complex (cyclin/CDK2/$p27^{Kip1}$).

Beside its function in ubiquitin-dependent degradation of cell cycle regulators, Skp2 has an unanticipated function as a transcriptional regulator. Skp2 controls mRNA synthesis not only by mechanisms involving ubiquitin-dependent degradation of transcription factors by the proteasome, but also by mechanisms that appear to be independent of the proteasome. Skp2 is a cofactor for transcriptional activation by ►MYC oncoproteins. It has been shown that Skp2 interacts with c-Myc, and thereby mediates its ubiquitylation and degradation. However, Skp2 unexpectedly increases the transcriptional activation activity of Myc, indicating that Skp2 is a transcriptional cofactor. Consistent with this, Myc accumulates, but its transcriptional activity is reduced, in mouse $Skp2^{-/-}$ cells.

Clinical Significance

Skp2 was originally identified as a protein that associates with cyclin A-CDK2 in transformed cells, but not in normal cells. It has become evident that Skp2

expression is negatively correlated with levels of $p27^{Kip1}$ in many cancers, and positively correlated with the grade of malignancy in certain human tumors. It is widely accepted that $p27^{Kip1}$ is a tumor suppressor, not only because of its activity as a CDK inhibitor, but also because of evidence from mouse models and the marked correlation between reduced $p27^{Kip1}$ levels and poor prognosis found in clinical studies of patients with cancer. Indeed, a reduction in the concentration of $p27^{Kip1}$ is common in many types of human malignancies. However, in contrast with other tumor suppressors such as ►p53 or Rb, mutation or deletion of the *$p27^{Kip1}$* gene is an uncommon event in the development of human cancers, indicating that deregulation of $p27^{Kip1}$ expression in human tumors is often due to post-transcriptional mechanisms. Deregulated components of the ►ubiquitination machinery for $p27^{Kip1}$, primarily Skp2, have been described in many cancer types. Overexpression of Skp2 or Cks1 is strongly and independently associated with a loss of tumor differentiation and poor survival. Frequent ►amplification and overexpression of the *Skp2* gene has been observed in lung cancers and in cell lines expressing high-risk ►human papillomavirus. Furthermore, Skp2 has oncogenic potential in transgenic mouse models.

The role of Skp2 in cancer initiation and progression is further supported by findings describing a new tumor suppressor function of pRb. It has been shown that pRb mediates cell cycle arrest also independent of its function to repress E2Fs, but through a mechanism by which pRb directly interacts with Skp2, and inhibits ubiquitylation of $p27^{Kip1}$. Intriguingly, full-penetrance mutations of *Rb* fail to repress both, E2F and Skp2 activities, whereas a naturally occurring partial-penetrance mutant, RbR661W, still inhibits cell cycle progression *via* controlling the SCF^{Skp2} activity despite impaired E2F repression. Together, available evidence strongly supports the notion that Skp2 is a growth promoter and an oncoprotein.

Ubiquitination

Daniel Finley
Department of Cell Biology, Harvard Medical School, Boston, MA, USA

Definition

Is the covalent modification of a protein by conjugation to ►ubiquitin (Fig. 1). Ubiquitin is a small, 76-residue protein found in all eukaryotes. Conjugates are formed through the ligation of the C-terminus of ubiquitin to the ε-amino groups of protein lysine residues. The major, but not sole, function of ubiquitination is to target proteins for degradation by the ►proteasome. A large number of proteins are substrates for this regulatory pathway. Efficient targeting of proteins for degradation usually involves formation of a multiubiquitin chain on the target protein. Such chains are characterized by specific ubiquitin-ubiquitin linkages.

Characteristics

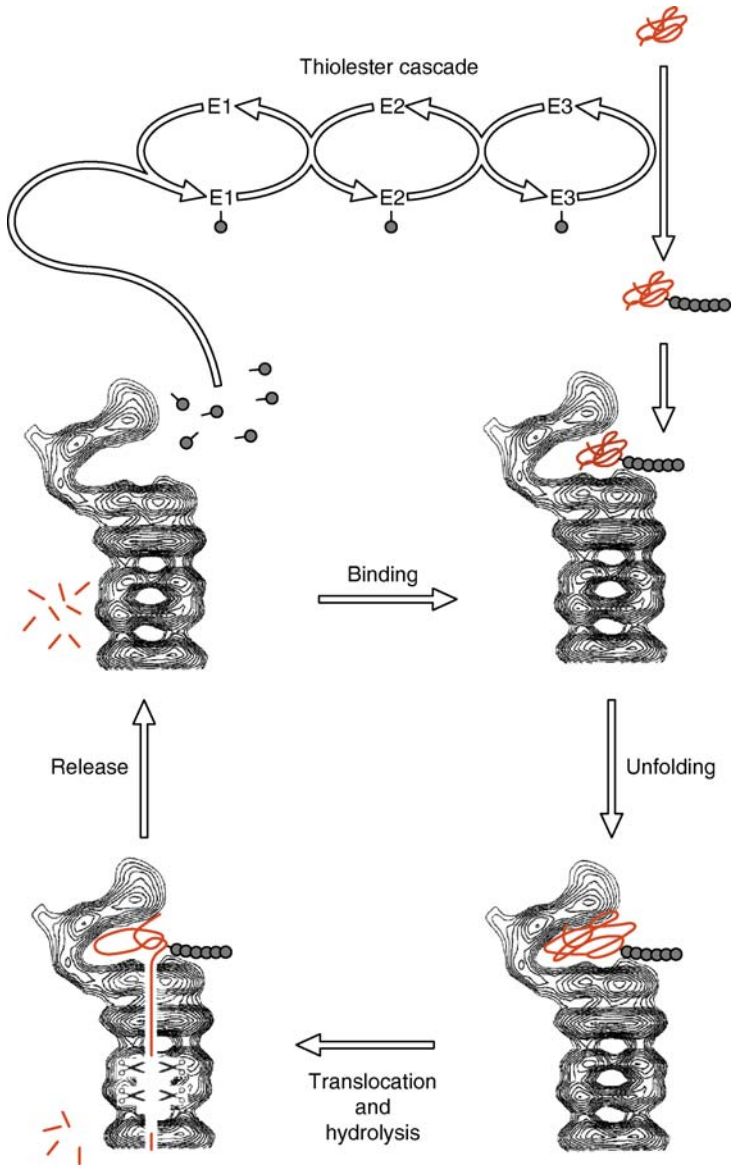
Intracellular proteins are degraded at rates that vary over 100,000-fold. While most proteins are relatively stable, critical regulatory proteins such as oncoproteins and tumor suppressor proteins are often short lived. Examples include ►p53, ►Mdm2, ►receptor tyrosine kinases, β-catenin (►E-cadherin), ►NFκB, ►Fos, ►Jun, cyclins (►cyclin D) and inhibitors of cyclin dependent kinases. The degradation of these proteins is subject to complex controls and is in many cases a dominant aspect of their regulation. For example, the cell cycle is driven principally by temporally controlled variations of cyclin levels, which are enforced by sudden periods of cyclin degradation. Exit from mitosis is marked by the deregulation of one cyclin, while other cell cycle transitions follow upon degradation of other cyclins and cyclin dependent kinase inhibitors.

Protein degradation has several advantages as a regulatory mechanism. As compared to regulated gene expression, it is capable of changing the level of a gene product very rapidly. Down-regulation by repressing gene transcription is very slow when the gene product is stable. As compared to phosphorylation, degradation allows a regulatory switch to function irreversibly. Regulation by degradation is a kind of ratchet mechanism, which in the case of the cell cycle or circadian cycle, for example, can prevent the possibility of reverse movement through the cycle.

Cellular Regulation

Two major systems for protein degradation have been identified in eukaryotic cells:

- The lysosomal pathway
- The ubiquitin-proteasome pathway



Ubiquitination. Figure 1 The proteasome cycle in protein degradation. Ubiquitin is shown as a large dot, and the peptidase sites are shown as scissors. For simplicity, the 26S particle is shown with a single regulatory particle and the 19S particle is shown without the protein mass that occupies the mouth of the wedge. Degradation of the substrate to oligopeptides is accompanied by the regeneration of free ubiquitin. The cycle begins when ubiquitin is activated at its carboxy terminus by the adenylyl transferase E1, then the activated ubiquitin is passed to an E2 enzyme. The E2 may the pass the activated, thiolester-bound ubiquitin to the active-site cysteine of an E3 enzyme (ubiquitin-protein ligase), as shown, or directly to substrate (not shown). For simplicity only one mechanism is shown. The former mechanism is exhibited by the HECT class of ligases and the latter by the RING class, which is the more common. The proteolytic substrate is linked to ubiquitin by an isopeptide bond. Multiple ubiquitin groups are added to the substrate sequentially to form a multiubiquitin chain, which finally targets the substrate for degradation (Figure taken from Ref. 4).

Short lived regulatory proteins, such as those discussed above, are degraded by the ubiquitin-proteasome pathway, with few exceptions. The ubiquitin-proteasome pathway is unusual in that it is a two-step pathway for protein turnover; attachment of the small protein ubiquitin to the substrate protein targets it to be recognized and degraded by the proteasome. Ubiquitin is attached to proteins via its C-terminus, which can form either an isopeptide bond with the ε-amino group of a protein lysine residue, or in rare

cases ubiquitin may be conjugated to the α-amino group at the N-terminus of the target protein. Efficient recognition by the proteasome requires multiple ubiquitin molecules to be ligated to the substrate, usually in the form of a multiubiquitin chain. Once bound to the target protein, ubiquitin itself becomes a preferential target of ubiquitination, and thus ubiquitin chains can be assembled on the substrate.

The ubiquitin-proteasome pathway is highly elaborate. The proteasome itself has over 30 subunits arranged in a remarkable self-compartmentalized structure. The active sites of the proteasome are thus inaccessible to the ubiquitinated substrate proteins unless the substrates are unfolded and translocated through an internal channel in the enzyme into its hydrolytic chamber for degradation. The initial attachment of ubiquitin to the substrate protein involves three classes of enzymes, known as E1, E2 and E3. E1 uses the energy of ATP to form a high energy thiolester linkage with the C-terminus of ubiquitin, thus "activating" ubiquitin for conjugation. E1 then transfers ubiquitin to any of a large number of E2 enzymes, which also bind ubiquitin covalently through a thiolester bond. Ubiquitin is finally donated to the substrate protein, either from the E2 enzyme or from the E3. In either case, the critical substrate recognition component of the machinery is generally the E3 enzyme. Many E3 enzymes are large protein complexes subjected to intricate controls. Substrate recognition by the E3 enzyme can be regulated by phosphorylation of either the substrate or E3 itself.

Ubiquitin conjugates are not always degraded by the proteasome. One alternative fate for such proteins is for the substrate-ubiquitin linkage to be reversed through the activity of any of a large family of ►de-ubiquitinating enzymes. De-ubiquitinating enzymes which probably number 75–100 in humans, can remove ubiquitin from ubiquitin-protein conjugates, thus sparing the protein from proteasomal degradation. These enzymes also break down abundant multi-ubiquitin chains that are not attached to any substrate, and produce mature ubiquitin from the precursor forms in which it is synthesized. A second alternative fate for ubiquitin-protein conjugates is that ubiquitinated cell surface proteins may be targeted for endocytosis and eventual degradation via the lysosome rather than the proteasome.

Still other deubiquitinating enzymes dismantle ubiquitin chains that, because they contain variant sites for ubiquitin-ubiquitin linkage, do not target their substrates for degradation, but rather perform other signaling roles. An example is the tumor-suppressor protein CYLD. Loss of function mutations in this deubiquitinating enzyme lead to multiple physiological defects, but notably inherited cancers of epidermal origin (cylindromatosis). The signal transducers NEMO and TRAF2 are prominent substrates of CYLD. Both NEMO and TRAF2 are positive regulators of the transcription factor NF-κB. Since signaling via NEMO and Traf2 is potentiated by attached ubiquitin chains, loss of CYLD results in enhanced signaling through the NF-κB pathway, which is largely proto-oncogenic.

The physiological importance of the ubiquitin pathway has only recently been recognized, and the field is now expanding rapidly. Cancer is one of the many diseases in which the ubiquitin pathway has been implicated, as might expected from a biochemical pathway that has myriad regulatory proteins as substrates. However, ubiquitination is particularly important for cancer because cancer results from aberrant growth regulation, and many growth regulatory factors are unstable substrates of the ubiquitin pathway. For example, the increased degradation rate of a particular tumor suppressor protein could confer a growth advantage on the affected cell over surrounding non-tumor cells. On the other hand, for oncoproteins whose degradation is perturbed, the opposite effect of stabilization and increased accumulation is generally observed. In each case, the physiological effect is to promote cell transformation. Some of the better established examples of the role of protein turnover in cancer are given below.

Clinical Relevance

p53 and HPV-Associated Cervical Carcinoma

p53 is a tumor suppressor protein, the levels of which rise rapidly after DNA damage. Increased p53 levels result in growth arrest or apoptosis. In normal cells, p53 is degraded through the ubiquitin-proteasome pathway and has a half-life of ∼30 min. p53 accumulation after DNA damage is thought to result principally from its stabilization. p53 is inactivated by mutation or constitutively destabilized in many transformed cells. One example of the latter is that of ►human papillomavirus (HPV)-associated anogenital carcinomas. Strains of HPV that confer high risk for cancer encode an E6 protein that targets p53 for degradation. Consequently, p53 levels are very low in cervical carcinomas associated with HPV. E6 acts in cooperation with the cellular factor known as E6-AP to bind p53. E6-AP is a member of a large class of E3 enzymes (the HECT domain E3′s) that are distinguished by the ability to form thiolester linkages with ubiquitin, in analogy to E2 enzymes. E6 acts as an ancillary factor to modify the specificity of E6-AP. It appears that the normal pathway of p53 turnover does not involve either E6-AP or a cellular homolog of E6. The oncoprotein Mdm-2, previously recognized as a negative regulator of p53, is apparently a ubiquitin ligase for p53. Mdm2 is overexpressed in many human soft tissue tumors, also occasionally in

►neuroblastomas, and elevated Mdm2 levels are associated with poor prognosis of several human cancers.

von Hippel Lindau (VHL) Disease

Like p53, the von Hippel Lindau (►VHL) gene is a ►tumor suppressor gene. In contrast to p53, however, the VHL protein is a component rather than a substrate of the ubiquitin-proteasome pathway. VHL disease affects 1 in 36,000 individuals and is characterized by a range of cancers, including (but not limited to) blood vessel tumors (hemangioblastomas) as well as tumors of the adrenal gland, kidneys, pancreas and lymphatic system. While the complete set of proteins that are stabilized when VHL activity is lost is not yet known, it appears that the major effect of the loss of VHL function is to potentiate angiogenesis and thus allow tumor outgrowth. VHL tumors are richly supplied with blood vessels due to their production of ►vascular endothelial growth factor (VEGF). VEGF is overproduced in these cells as a result of their expressing high levels of transcription factors for the VEGF gene, HIF-1α and HIF-2α. Under normal conditions these proteins are present at low levels as a result of their rapid degradation via the ubiquitin-proteasome pathway. However, under hypoxic conditions their degradation is inhibited, leading to VEGF induction. Even in the presence of normal oxygen levels, however, the HIF proteins are stabilized in VHL tumors. This stabilization is directly due to the loss of VHL in these tumors; the VHL protein binds HIF protein directly and functions as part of an E3 enzyme, the VBC complex, in the ubiquitination of HIF proteins. This complex is closely related to the SCF complex described below.

β-Catenin Turnover in Colorectal Tumors

Aberrant regulation of the Wingless/Wnt signal transduction pathway is a key event in the development of ►colon cancer. In the absence of the Wnt signal, ►glycogen synthase kinase-3β (GSK-3β) is active and phosphorylates β-catenin, causing it to be degraded. Upon Wnt signaling, phosphorylation of β-catenin is inhibited, and β-catenin accumulates and drives proliferation through the activation of downstream transcription factors. The ►APC (adenomatous polyposis coli) tumor suppressor promotes β-catenin degradation by assisting in its phosphorylation by GSK-3β. Among the most common genetic events leading to colorectal cancer are mutations in the APC gene.

The E3 enzyme that recognizes β-catenin and catalyzes its ubiquitination is known as β-TRCP. β-TRCP is an F-box protein and functions in the context of an SCF complex. In general, the key component in the SCF complexes is the F-box protein, which is the primary, if not always exclusive, mediator of substrate recognition. β-TRCP recognizes β-catenin only when it is phosphorylated by GSK-3β. In some tumors, β-catenin is found with substitutions in the serine residues, whose phosphorylation induces ubiquitination. These β-catenin mutants are stabilized as a result of their inability to be recognized by β-TRCP. Substrate recognition by F-box protein is often dependent on substrate phosphorylation.

Degradation of p27, a CDK Inhibitor

Cell-cycle progression is controlled through the activity of cyclin-dependent kinases (CDK enzymes). CDK activity is regulated by two major classes of factors; cyclins and CDK inhibitors. Both cyclins and CDK inhibitors are regulated through the ubiquitin-proteasome pathway (as well as by other mechanisms). Among CDK inhibitors, p27 has been found to be present at significantly reduced levels in common tumors, such as colorectal tumors and in breast cancer. The abundance of p27 is a valuable prognostic marker for epithelial cancers, brain tumors and malignant lymphomas. Reduction of p27 levels has been shown to be due to an increased rate of degradation in epithelial cancers, lymphomas and astrocytic brain tumors. It should be noted, however, that p27 mutations in human cancers are rare. The acceleration of p27 degradation may therefore reflect alterations of the ubiquitination machinery in tumor cells.

The mechanism of p27 ubiquitination is not fully understood, but recent data indicate the S-phase kinase-associated protein 2 (Skp2) and F-box protein functions as the E3 enzyme for p27, in the context of an SCF ubiquitination complex. Recognition of p27 by Skp2 requires phosphorylation of p27 at threonine-187. This phosphorylation event is catalyzed by specific CDK/cyclin complexes such as CDK2/cyclin E, the same kinase complex that p27 inhibits. Given that cyclin E levels fluctuate during the cell cycle, it is not surprising that degradation of p27 is normally under cell cycle control. The lowest rates of p27 phosphorylation and degradation are found during G1. Both p27 regulators, cyclin E and Skp2, are often found overexpressed in tumors.

Cbl and Receptor Tyrosine Kinase Degradation

c-Cbl is encoded by a ►proto-oncogene and negatively regulates signaling via cell surface receptor tyrosine kinases, such as receptors for ►platelet-derived growth factor, epidermal growth factor and colony-stimulating factor-1. Transforming variants of Cbl have been identified in transforming retroviruses and in pre-B cell lymphomas. These oncogenic forms of Cbl contain mutations affecting the RING finger motif of the protein (a zinc-chelating domain).

RING finger motifs have been implicated in the association of various proteins to E2 enzymes. As such,

the presence of a RING finger in a given protein could indicate that it functions as an E3, as an ancillary component of a ubiquitination complex, or even as a substrate for the E2 to which it binds. In the case of Cbl, the RING finger domain has been shown to mediate the association of Cbl to the E2 enzyme known as Ubc4, and to allow Cbl to function as an E3 for receptor tyrosine kinases. The RING finger is essential for ubiquitination and down-regulation of activated receptor proteins. Loss of the RING finger domain is presumably oncogenic because it results in an inactive and dominant negative form of Cbl.

Another domain in Cbl, the SH2 domain, is required for recognition of its substrates. In general, SH2 domains recognize phosphotyrosine residues that are produced upon ligand binding and receptor activation, and thus the involvement of an SH2 domain in receptor ubiquitination may explain the selectivity of down-regulation for active forms of receptor tyrosine kinases.

Fanconi Anemia

As mentioned above, ubiquitin modification can function nonproteolytically in some cases. Often this results from modification of a substrate with a single ubiquitin molecule. Such monoubiquitin modifications are apparently of widespread importance in the regulation of chromatin, in particular DNA repair and transcription. One such modification has been linked to ►Fanconi Anemia (FA), a rare inherited disease with hallmarks including genomic instability, high risk of cancer, and bone marrow failure. Most genes that when mutated can cause FA are involved in the monoubiquitination of chromatin proteins known Fanconi Anemia D2 (FANCD2) and its paralog FANCI. A complex multisubunit ubiquitin ligase is responsible for this ubiquitin event, which is stimulated by DNA damage and promotes proper repair of DNA crosslinks. How ubiquitination of FancD2 and FANCI promotes DNA repair is not yet clear.

Proteasome inhibitors

►Proteasome function is essential in cells, and strong proteasome inibition is unlikely to have any therapeautic utility. However, carefully graded doses of the proteasome inhibitor ►Bortezomib are effective against multiple myeloma in many patients. Bortezomib, also known as Velcade, has been approved by the FDA for this application, as well as for ►Mantle Cell Lymphoma, and is in widespread use in the US and tens of other countries at this time. Bortezomib is effective both in single-agent and combination therapies. Bortezomib inhibits the proteolytic active sites of the proteasome, within the hydrolytic chamber described above. There is considerable debate about why Bortezomib is so effective against certain cancers. Most likely a number of distinct physiological effects of proteasome inhibition underlie its anti-cancer activity.

Summary

Protein turnover pathways that are normally under tight regulation are converted by genetic defects to either constitutively active or inactive states. The protein turnover defects that can lead to cancer are various in nature. The primary defect can lie in:

- E3 enzymes, as in the case of Mdm2, Cbl and VHL
- An E3-associated ancillary factor, as in the case of E6
- A component that regulates phosphorylation, as in the case of APC
- The substrate itself, as for β-catenin

Given the large number of important substrates for the ubiquitin-proteasome pathway, it is likely that more examples of protein turnover defects underlying cancer will be found.

UCN-01 Anticancer Drug

Holger Bastians
Philipps University Marburg, Institute for Molecular Biology and Tumor Research (IMT), Marburg, Germany

Synonyms

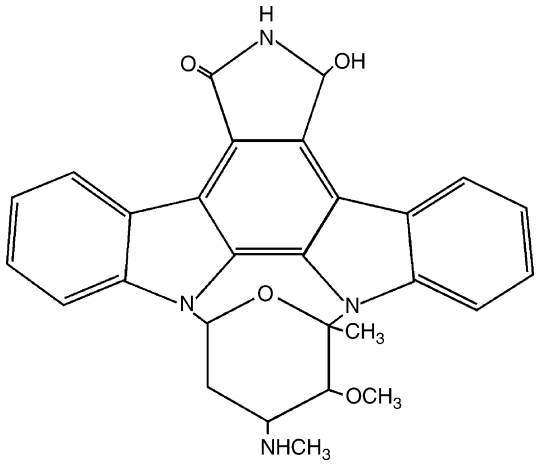
7-hydroxystaurosporine; NSC 638850

Definition

UCN-01 is an indolocarbazole compound originally isolated from *Steptomyces spec*. cultures, similar to ►staurosporine, but with an additional hydroxy group on the lactam ring (Fig. 1). It acts as an ATP competitive inhibitor targeting several kinases including protein kinase C (PKC), ►cyclin dependent kinases and ►Chk1 and shows high preclinical and clinical antitumor activity. UCN-01 can abrogate ►DNA damage induced cell cycle arrest in S and G2 phases of the cell cycle and thereby sensitize tumor cells to DNA damage-induced toxicity. Currently, several phase I/II clinical trials explore UCN-01 as a stand-alone therapy or in combination with various DNA damaging chemotherapeutic drugs.

Characteristics

UCN-01 was originally described as a potent inhibitor of ►protein kinase C (PKC). Its chemical name is: (3R, 8S, 9R, 10R, 12R)-3-hydroxy-9-methoxy-8-methyl-10-(methymamino)-8, 12.epoxy-2,3,9,10,11,12-hexahydro-1H, 8H-2, 7b, 12a-triazadibenzocyclononatrinden-1-one, $C_{28}H_{26}N_4O_4$. Since it acts as an ATP competitive inhibitor, it is not surprising that it is not specific for PKC, but inhibits several cellular protein kinases, although it exhibits a much greater selectivity as staurosporine. Nevertheless, UCN-01 has a high antitumor activity,



UCN-01 Anticancer Drug. Figure 1 The structure of UCN-01. UCN-01 is an indolocarbazole compound and derivative of staurosporine with an additional hydroxy group on the lactam ring.

inhibits growth and induces ►apoptosis in many cancer cells. These effects appear to be independent of PKC inhibition and are rather related to the inhibition of cell cycle kinases including cyclin dependent kinases (CDK), ►PDK1, which positively regulates the AKT/PKB survival pathway (►AKT Signal transduction pathway in oncogenesis) and the checkpoint kinase ►Chk1, which is inhibited by UCN-01 in a low nanomolar range.

Although efficient in several animal models, clinical pharmacology studies have revealed a low bioavailability of UCN-01 in humans, which is due to a high affinity to the α-1 acid glycoprotein in human plasma. Therefore, novel derivatives of UCN-01 with lower retention are currently being explored. However, recent clinical trials have demonstrated that despite the high binding capacity to human plasma proteins a schedule of 34 mg/m^2/d for 3 days is sufficient for antitumor activity.

UCN-01 has completed several phase I clinical trials in the United States and in Japan as a stand-alone therapy and phase II trials are currently underway to investigate the efficacy of UCN-01 in lymphomas (National Cancer Institute).

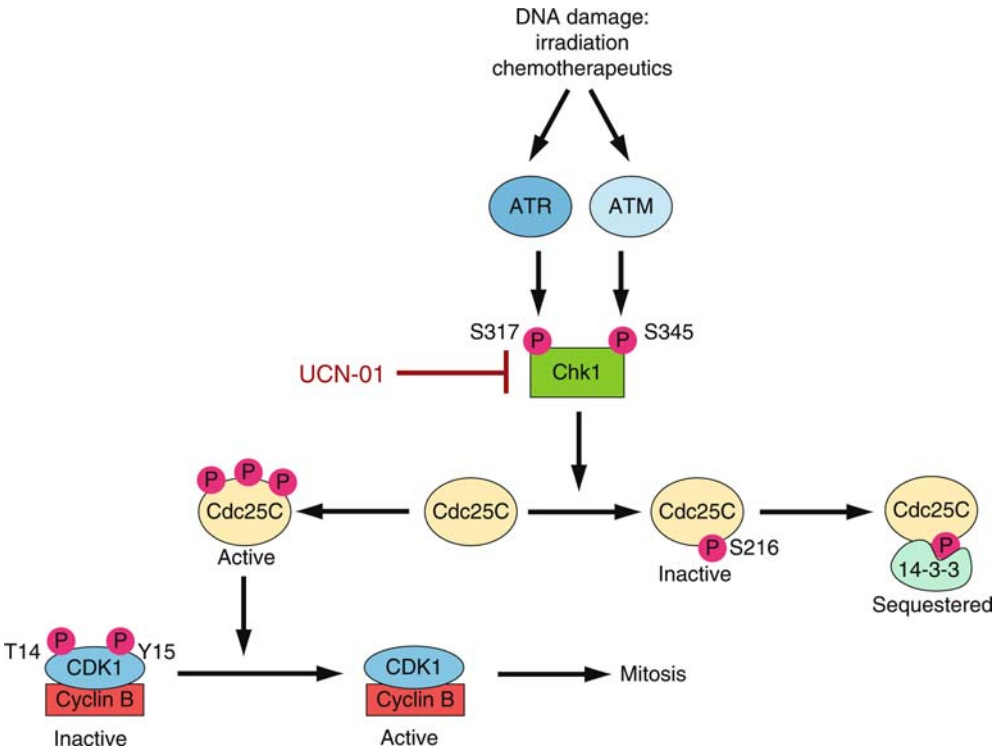
Inhibition of Chk1 Kinase and G2 Checkpoint Abrogation by UCN-01

An important cellular target of UCN-01 is the Chk1 kinase, which has an important function during a normal ►DNA replication. Recent results indicate that abrogation or inhibition of Chk1 results in replication stress followed by DNA damage, which might

contribute to the ability of UCN-01 to induce apoptosis as a stand-alone therapy.

The Chk1 kinase has also an important function in ►DNA damage response in human cells. Upon DNA damage, which is induced for instance by irradiation (►ionizing radiation therapy) or by treatment with ►platinum drugs (►Cisplatin) or topoisomerase inhibitors (e.g. etoposide, topotecan, doxorubicin), cells activate DNA damage checkpoints resulting in the halt of the cell cycle allowing DNA repair to occur. The first step of the DNA damage response is the recruitment of sensor complexes to the sites of DNA damage where the ATM/ATR (►ATM protein; ►ATM-related protein kinase) kinases are activated. These kinases can phosphorylate and activate either the transcription factor p53 (►P53 protein) directly or the Chk2 kinase, which in turn can phosphorylate and activate p53. The transcriptional activation of p53 results in an induction of its target gene *p21* (►p21 (WAF1/CIP1/SDI1), which encodes a CDK inhibitor protein that binds to and inhibits CDK-cyclin complexes in G1. This finally leads to a cell cycle arrest in G1 before cells enter S phase and is thus termed the G1 checkpoint. In addition, the ATM and ATR kinases can also phosphorylate and activate the Chk1 kinase, which is an essential component of the p53 independent G2 checkpoint (Fig. 2). Activated Chk1 kinase phosphorylates and inactivates the dual specificity phosphatase Cdc25C leading to its cytoplasmic sequestration. Cdc25C is the phosphatase responsible for removing two inhibitory phosphates from CDK1, which is required for activation of CDK1 and entry into mitosis. Thus, DNA damage induced inhibition of Cdc25C is mediated by Chk1 and prevents the entry into mitosis constituting the G2 DNA damage checkpoint.

Since many tumor cells lack functional p53 they activate only the G2 checkpoint in response to DNA damage, while p53 proficient cells predominantly arrest in G1, which still allows subsequent DNA repair. This circumstance gives rise to the therapeutic concept



UCN-01 Anticancer Drug. Figure 2 Inactivation of the G2-Checkpoint by UCN-01. In response to DNA damage, the ATM and ATR kinases are activated, which in turn phosphorylate and activate the Chk1 kinase. Chk1 phosphorylates the Cdc25C phosphatase on serine-216 and keeps it in an inactive state. Chk1 mediated phosphorylation of Cdc25C also facilitates the sequestration of Cdc25C into the cytoplasm by promoting complex formation with 14–3–3- proteins. Inactivation of Cdc25C prevents the dephosphorylation and activation of CDK1 at the G2/M transition and thus prevents entry into mitosis. Inhibition of Chk1 by UCN-01 in the presence of DNA damage results in an override of the G2 arrest and cells can enter mitosis in the presence of DNA damage.

of ►G2 checkpoint abrogation by small molecules (►Small molecule drugs), which is expected to target p53 deficient tumor cells selectively. UCN-01 is such a G2 checkpoint abrogator by potently inhibiting Chk1 (IC_{50} = 7–10 nM). Inhibition of Chk1 by UCN-01 in the presence of DNA damage results in an unscheduled activation of Cdc25C and of CDK1-cyclin B kinase and thus leads to entry into mitosis in the presence of DNA damage. The unscheduled entry into mitosis is associated with the induction of cell death, a process also known as "►mitotic catastrophe" or "mitotic cell death." Thereby, UCN-01 greatly enhances the efficacy of DNA damaging drugs selectively in p53 deficient tumor cells. Due to the promising preclinical results that support the concept of G2 checkpoint abrogation, several phase I and II clinical trials for leukemia, lung cancer and advanced solid tumors are now underway to explore the efficacy of UCN-01 in combination with various DNA damaging agents, including platinum compounds and topoisomerase inhibitors (National Cancer Institute, USA).

Mechanisms of UCN-01 Induced Tumor Cell Death

Entry into mitosis in the presence of DNA damage results in the induction of mitotic cell death, which significantly enhances the efficacy of DNA damaging drugs. Recent results have shed light on the mechanisms involved in mitotic cell death. UCN-01 mediated entry into mitosis leads to the activation of the mitotic ►spindle assembly checkpoint, which is responsible for a prolonged mitotic arrest. Subsequent to the activation of the spindle checkpoint, a mitotic form of apoptosis is initiated, which requires the function of the spindle checkpoint. Remarkably, the pro-apoptotic role of the mitotic spindle checkpoint is counteracted by the Aurora-B/►Survivin complex (►Aurora kinase), which possesses a pro-survival function during mitosis. Importantly, pharmacological inhibition of this pro-survival function by inhibitors of Aurora or CDK1 kinases greatly enhances the efficacy of UCN-01 mediated mitotic cell death. Due to this synergistic effect, clinical trials combining UCN-01 and Aurora or CDK1 kinase inhibitors are highly desired.

UDP

Definition

Uridine diphosphate glucose (uracil-diphosphate glucose, UDP-glucose) is a nucleotide sugar. It is involved in glycosyltransferase reactions in metabolism.

UDP-Glucuronosyl Transferase

Definition

Refers to a family of enzymes that catalyses conjugation of UDP-glucuronic acid with ►xenobiotics containing an electron-rich nucleophilic heteroatom (O, N or S), such as those bearing aliphatic alcohols, phenols, carboxylic acids, aromatic and aliphatic amides, and free sulfhydryl groups.

►Detoxification

UGT

Definition

UDP-glucuronosyltranferase, is a family of drug-metabolizing enzymes. It catalyzes the glucuronidation of lipophilic ►xenobiotics and endobiotics, giving rise to normally less electrophilic, more water soluble, and more disposable products.

►Phase 2 Enzymes

Ulcerative Colitis

Definition

A heterogeneous, idiopathic, chronic, relapsing, inflammatory condition that is immunologically mediated. Disease activity is triggered by environmental factors that transiently break the colonic mucosal barrier, stimulate immune responses or alter the balance between

beneficial and pathogenic enteric bacteria. There is also a genetic component that can be broadly characterized as causing defects in mucosal barrier function, immunoregulation or bacterial clearance. Over time, there is an increased risk of ►colon cancer.

►Inflammation

Ultimate Carcinogen

Definition

Activated, and chemically reactive, form of a carcinogen or procarcinogen that is capable of direct covalent binding to nucleic acid and/or protein macromolecules. The form of a carcinogen that directly interacts with a cell constituent (presumably DNA) to initiate carcinogenesis.

►Carcinogen Macromolecular Adducts
►Toxicological Carcinogenesis

Ultrasound

Definition

Acoustic waves with frequencies greater than 20 kHz, *i.e.*, frequencies higher than sounds audible to humans. Medical ultrasound imaging systems transmit acoustic waves at frequencies greater than 1 MHz to form images of tissue structures that reflect the transmitted waves. In cancer, the most common applications are in diagnostic imaging to create images of internal anatomy, and in ►hyperthermia as a mechanism for heating tissue.

►Ultrasound Micro-Imaging

Ultrasound Biomicroscopy

Synonyms

High-frequency ultrasound imaging; Micro-ultrasound imaging; Ultrasound biomicroscopy

Definition

►Ultrasound micro-imaging is imaging of small animals using ultrasound instruments capable of resolving features in a mouse at a level of anatomical detail comparable to clinical ultrasonography of human patients.

Characteristics

Ultrasound micro-imaging systems are an example of technology for ►preclinical imaging of small animals in biomedical research. Ultrasound micro-imaging systems, while similar in design to conventional clinical ultrasound systems, are distinguished by their use of ultrasonic frequencies from 20 to 60 MHz, *i.e.*, frequencies above the 1–15 MHz band typically employed for clinical ultrasonography. The use of high frequencies enables images to be acquired with finer spatial resolution than clinical ultrasound images, but reduces the depth of penetration within the subject because soft tissues absorb ultrasound at a rate approximately proportional to frequency. A typical high-frequency ultrasound system provides spatial resolution on the order of 50–100 μm and penetration depths from 5 to 15 mm. Those penetration depths are suitable for most mouse imaging applications and many rat imaging applications.

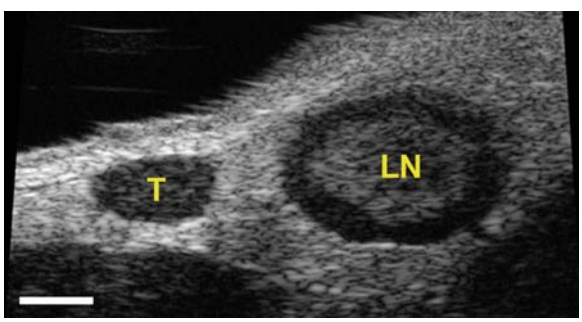
Preclinical imaging is a relatively new technology whose role in cancer research continues to expand due to the importance of ►mouse models in the discovery of biological mechanisms of human cancers and ►preclinical testing of new treatments. Preclinical imaging of small-animal cancer models can be performed using instruments analogous to any of the prominent medical imaging modalities, including x-ray computed tomography (CT), magnetic resonance imaging (MRI), radionuclide imaging, and ultrasound, as well as optical techniques such as ►bioluminescence imaging and optical coherence tomography. Preclinical imaging provides an alternative to research methods that require the use of subcutaneous tumor models with visible lesions or require animals to be sacrificed to obtain tissue specimens for analysis. Imaging facilitates evaluation of tumor progression and responses to

treatment in orthotopic (►Orthotopic model), metastatic, and ►genetically engineered models, where lesions develop in clinically relevant locations in internal organs. Imaging enables measurements to be made in live animals, which is valuable for studying the biological effects of dynamic processes such as blood flow. Imaging also permits data to be acquired from the same animal at multiple time points during an experiment, thereby reducing the number of animals needed for a study, which should accelerate and reduce the costs of developing new anticancer therapies.

Two- and Three-Dimensional Anatomical Imaging

Ultrasound micro-imaging is performed by positioning an ultrasound probe, which can be used while handheld or clamped to a support, against the skin of the mouse. The mouse is anesthetized during imaging so the animal will remain still. The probe transmits ultrasound pulses that reflect from tissue structures and the instrument detects the echoes returning to the probe. Images are displayed in shades of gray such that the brightness of a pixel represents the relative magnitude of the echo received from the corresponding location in the animal. Figure 1 shows an illustrative image of a murine breast cancer tumor and a nearby lymph node within a mammary fat pad. Ultrasound is best suited for imaging soft tissues, so, in addition to mammary fat pad tumors, ultrasound micro-imaging is typically used with subcutaneous or intradermal tumor models or tumors located at sites such as the abdominal organs or prostate.

Ultrasound micro-imaging systems are capable of two-dimensional (2-D) and three-dimensional (3-D) imaging. Two-dimensional imaging can be performed in real time, meaning at least 30 frames are acquired and displayed each second. In cancer studies, real-time imaging is valuable when a tumor is in a location such as the liver that experiences respiratory motion to prevent movement from degrading the images.



Ultrasound Micro-Imaging. Figure 1
Two-dimensional ultrasound micro-image of a murine mammary carcinoma tumor (T) and nearby lymph node (LN). Scale bar denotes 1 mm. (Image acquired by Graham KC and Wirtzfeld LA, University of Western Ontario.)

Ultrasound micro-imaging systems acquire 3-D images by mechanically sweeping the probe in the direction perpendicular to the 2-D imaging plane to acquire a set of parallel 2-D images that are combined to create a 3-D image. Acquisition of a 3-D image requires 20–30 s, but the image volume can be reconstructed as the planes are acquired and displayed immediately. This on-the-fly reconstruction is a significant advantage over other preclinical imaging technologies, which can require tens of minutes for 3-D image reconstruction.

One cancer research application of anatomical imaging is screening animals for tumor development. An investigator can thereby ensure that all mice receiving an experimental treatment actually possess tumors and that the treatment is administered when the tumors are at similar stages. Ultrasound's rapid acquisition and immediate display of images is beneficial because the presence or absence tumors can be determined in a few minutes, thereby permitting many animals to be screened in a reasonable amount of imaging time.

Imaging tumors repeatedly over the course of a study to measure their growth is a second important use of anatomical imaging. Delays in tumor growth and changes in the rate of growth are commonly used preclinical measures of treatment response. Tumor sizes can be determined in a variety of anatomical sites using 2-D or 3-D ultrasound micro-imaging. If 2-D imaging is used, the diameter of the tumor is measured along the long and short axes of the largest cross section through the tumor, and those diameters can be used to estimate tumor volume. Alternatively, the tumor can be outlined in parallel planes through a 3-D image and the total volume enclosed by those boundaries can be determined. Ultrasound is nonionizing and repeated exposure carries no risk to the animal, so it is an attractive technology for treatment studies that require repeated longitudinal measurements of tumor size.

Ultrasound possesses some disadvantages that make the technology inappropriate for some applications. Ultrasound waves traveling through tissue are strongly reflected by bone and by pockets of air, so ultrasound is not effective for imaging bony or air-filled organs. Ultrasound micro-imaging is therefore inappropriate for studies using brain, skeletal, or lung tumor models. Second, the field of view of an ultrasound micro-image is typically 10–15 mm along each side, which is much smaller than the area that can be depicted in an x-ray micro-CT or high-field MRI image. Ultrasound micro-imaging is therefore not an efficient method of searching for ►metastases if lesions are expected to be distributed throughout the animal's body. Third, acquisition of satisfactory images depends on the skill of the ultrasound system operator and the images can be challenging to interpret. For example, the accuracy of

tumor volumes estimated from 2-D images depends on the operator's ability to identify and image the plane containing the largest tumor cross section. Three-dimensional imaging ensures that the entire tumor is measured, but a significant amount of the investigator's time must then be invested in outlining the tumor because automated image analysis algorithms tend to be unreliable for identifying tumor boundaries in ultrasound images.

Doppler Blood Flow Imaging

Preclinical cancer studies often require information about the distribution of blood flow in different regions of a tumor or changes in vascularization as a tumor progresses or responds to treatment with an ►anti-angiogenesis or vascular disrupting agent. ►Doppler ultrasound is an attractive technology for imaging tumor blood flow because Doppler images are produced from echoes received from moving blood cells, which enables blood flow to be visualized without using injected ►contrast agents. Doppler micro-imaging systems provide sufficient spatial resolution to distinguish adjacent vessels separated by 100–200 μm, which is the spatial scale needed to depict tumor microvasculature. However, as in anatomical imaging, this resolution comes at the cost of reduced penetration depth. Furthermore, Doppler systems ignore echoes suggesting flow at velocities slower than a few millimeters per second to prevent the images from being overwhelmed by artifacts arising from tissue motion. Doppler micro-imaging is therefore more effective for imaging vessels 100 μm diameter and larger than for imaging microvessels, which tend to exhibit slower blood velocities.

Two methods for displaying 2-D or 3-D images of tumor blood flow are widely used. In the first method, called color Doppler imaging, pixels at locations where flow is detected are color-coded to represent the mean blood velocity averaged over the resolution volume. Color Doppler images enable discrimination between regions of slow and fast flow and between arterial and venous flow. However, accurate estimation of flow velocities requires knowledge of the angle between the flow direction and the ultrasound beam, which can be difficult to determine in the tortuous vessels frequently associated with tumors.

A second approach to blood flow imaging, termed power Doppler, color-codes images to indicate the total ultrasound power reflected from moving blood cells. Power Doppler images display a quantity proportional to the number of moving blood cells, rather than their velocity, at each point in the image. This approach avoids the angle dependence of the Doppler velocity measurement and reduces the sensitivity of the measurement to noise in the image. The reduced noise sensitivity can be beneficial when the echoes received from the blood are relatively weak, which is often the case when imaging tumor vasculature.

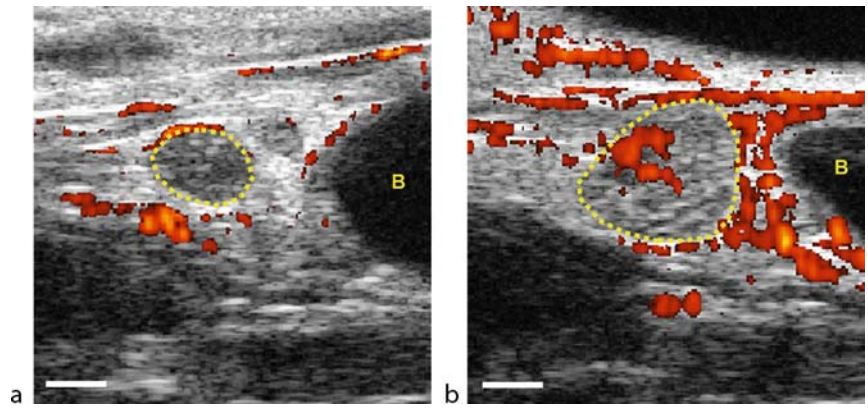
Most cancer research applications require a method of quantifying the vascularity depicted in color or power Doppler images so changes in blood flow can be assessed objectively. Color pixel density is an example of an uncomplicated but useful Doppler vascularity metric. Color pixel density is equal to the fraction of pixels within a region of interest that exhibit detectable flow. The region of interest is usually defined manually by the investigator and may encompass the entire tumor, the core or margin of a tumor only, or a nearby region of normal tissue. A change in color pixel density provides evidence of a change in tumor vascularity. For example, Fig. 2 compares power Doppler images of a genetically engineered mouse prostate cancer model acquired a few days before and during a period of rapid tumor growth. The color pixel density measured over the entire tumor volume increased from 0.7% at the first time point shown (Fig. 2a) to 30.9% at the second time point (Fig. 2b).

Contrast-Enhanced Imaging

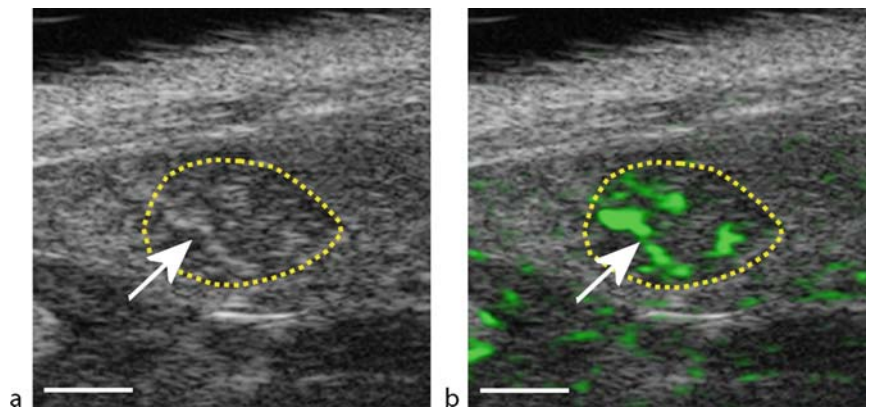
►Microbubble contrast agents provide another means of imaging tumor vascularity using ultrasound. Microbubbles injected intravenously circulate with the blood and increase the magnitude of echoes received from the blood pool. A single microbubble produces echoes several orders of magnitude more powerful than an echo from a single blood cell. Furthermore, scattering of ultrasound from microbubbles includes significant nonlinearity that permits microbubble echoes to be distinguished from tissue echoes using specialized signal processing. These aspects of microbubble physics improve the ability of ultrasound to detect the very slow flow characteristic of tumor vessels. This capability is obtained at the expense of increased experimental complexity, because administration of microbubbles to a mouse involves a tail vein cannulation or similar procedure.

Microbubbles can be used to enhance anatomical or Doppler images, or images can be colored to highlight locations where microbubbles are detected. Figure 3 shows a comparison of the first and third methods of displaying a contrast-enhanced image. Microbubbles appear as bright features in anatomical images, and the path of a microbubble along a vessel can be followed visually when real-time imaging is performed.

Quantification of contrast-enhanced images can be performed to analyze the spatial distribution of microbubbles (and, hence, blood flow) or to analyze the timing of contrast enhancement after injection of a microbubble bolus. The former type of quantification provides a measure of tumor vascularity similar to the Doppler color pixel density. Evaluating the timing of enhancement indicates whether a tumor receives a



Ultrasound Micro-Imaging. Figure 2 Two-dimensional power Doppler micro-images of a transgenic mouse prostate cancer model acquired in a sagittal plane through the bladder (B). Pixels where flow is detected are highlighted with an orange-yellow color scale, with brighter colors indicating regions where higher echo powers were received from moving blood. (a) Image acquired when the tumor (dotted yellow outline) was small and growing slowly. (b) Same tumor imaged 18 days later during a period of rapid growth. Scale bars denote 1 mm. (Figure Adapted from Xuan JW, Bygrave M, Jiang H et al (2007) cancer Res 67:2830–2839.)



Ultrasound Micro-Imaging. Figure 3 Contrast enhanced ultrasound micro-images of an experimental murine liver metastasis (dotted yellow outlines) model. (a) Microbubble contrast agents appear as moderately bright features in a gray-scale image. (b) Same 2-D image with green highlighting indicating regions where microbubbles were detected. A vessel running through the tumor (arrow) is evident in both images. Scale bar denotes 1 mm. (Image acquired by Graham KC, Mackenzie LT, and Wirtzfeld LA, University of Western Ontario.)

majority of its blood supply from the arterial or venous side of the circulation, which is, for example, an important aspect of the physiology of liver tumors. Microbubbles can also be used to perform relative measurements of perfusion by injecting a bolus of microbubbles, waiting a few minutes until the distribution of circulating agents reaches a steady state, temporarily increasing the transmitted power to burst all of the microbubbles within the 2-D image plane, and then reducing the ultrasound power to normal levels and measuring the time required for contrast enhancement to return to steady state. Parameters proportional to the blood volume, volume flow rate, and perfusion (volume flow rate divided by tissue mass) within a region of interest can be estimated from measurements of the change in ultrasound signal intensity as a function of time.

Microbubbles also enable ►molecular imaging using ultrasound. Ultrasound molecular imaging is performed by either modifying the shell composition or conjugating ligands to the shell of the microbubbles to create agents that are targeted to endothelial cell receptors specific to

a biological process. Imaging bound microbubbles provides an *in vivo* assay for the targeted receptor. In a cancer study, the agents are typically targeted to an ►angiogenesis marker such as a ►vascular endothelial growth factor or to a potential site of drug activity. Preclinical studies may be an effective means of developing targeted microbubbles for clinical use, assuming the receptors identified in mouse models are also expressed in humans.

Targeted microbubbles can also be formulated with a therapeutic agent incorporated in the shell or contained in the core of the agent. The therapeutic cargo can be released by bursting microbubbles with high-power ultrasound pulses. This technique is an attractive method of ►targeted drug delivery because ultrasound images can first be acquired to confirm that the tumor has bound the targeted agent, and then high-power pulses can be focused on the tumor only, thus reducing toxicity to healthy tissues by limiting the release of the drug to the immediate vicinity of the tumor.

Ultraviolet Light

Definition

UV light is that portion of sunlight in the 100–400 nm range. Sunlight contains three types of UV light: UVA (320–400 nm), UVB (280–320 nm) and UVC (200–280 nm). UVC rays are highly mutagenic but are blocked from reaching the planet's surface by the ozone layer surrounding the earth. Thus, only UVA and UVB rays reach the planet's surface and are responsible for essentially all nonmelanoma skin cancer. However, in areas without an ozone layer, UVC rays may reach the earth's surface and contribute to ►skin carcinogenesis.

Umbilical Cord Blood

Definition

Cord blood is a rich source of primitive hematopoietic ►stem cells that may be useful for cell therapies for a variety of diseases. Such cells may be as versatile as embryonic stem cells and it is becoming very popular to store newborn cord blood in a cord blood bank. The connective tissue surrounding the cord (Wharton jelly) is a rich source of mesenchymal stem cells.

Uncertain or Unknown Histogenesis Tumors

Pere Huguet, Santiago Ramón y Cajal
Department of Pathology, Vall d'Hebron University Hospital, Barcelona, Spain

Definition

Tumors of unknown histogenesis are those in which the normal cell counterpart has not as yet been identified. Recent advances in the molecular understanding of cancer have led to classification of these tumors in terms of differentiation, regardless of their location and the presumed cell of origin.

Characteristics

Tumors are classified as epithelial, mesenchymal, lymphoid or neuroectodermal depending on their cell of origin. Most tumors show the histopathological features of their normal cellular counterpart and can be classified accordingly. Currently, pathologists are attempting to classify tumors according to their patterns of gene expression and markers of differentiation. An important related discovery is the so-called cancer stem cell, which has the potential to self-renew and form additional cancer cells of a similar phenotype, and to give rise to phenotypically diverse cancer cells. These cancer cells can arise from mutational transformation of normal stem cells or from more differentiated cells that acquire the properties of cancer stem cells, such as self-renewal potential. This origin could explain the heterogeneity observed in tumors, as well as the diverse phenotypic patterns shown in some tumors.

In the majority of carcinomas, lymphomas, glial tumors and sarcomas, tumor cells show histopathological or genetic patterns of differentiation according to their location and normal cellular counterparts. Nevertheless, in approximately twenty types of tumors a normal cellular counterpart has not been identified, even though the tumor may show a clear line of differentiation. Most of these tumors arise in mesenchymal tissues and show mesenchymal, epithelial or even neuroectodermal markers of gene expression. These are known as tumors of uncertain histogenesis.

Many different tumors are included in the group of unknown histogenesis (Table 1). These can have a benign or malignant pattern, and several clinical and pathological characteristics. The following are the most important clinically: ►synovial sarcoma, ►epithelioid sarcoma, ►alveolar soft part sarcoma, ►clear cell sarcoma, ►extraskeletal myxoid chondrosarcoma, ►desmoplastic small round cell tumor, ►extrarenal rhabdoid tumor and ►neoplasms with perivascular epithelioid cell differentiation (PEComas). ►Myxoid tumors constitute a heterogeneous group with peculiar pathological features and clinical settings. ►Ewing tumors are now considered peripheral neuroectodermal tumors with a characteristic chromosomal translocation and varying degree of neuronal differentiation.

In brief, tumors of uncertain histogenesis harbor specific genetic alterations, usually chromosomal translocations, and their molecular signature is essential to establish the diagnosis. It is believed that these

Uncertain or Unknown Histogenesis Tumors. Table 1 Tumors of uncertain differentiation (OMS)

Benign	Intermediate (rarely metastasizing)	Malignant
Myxomas (intramuscular, juxta-articular and deep "aggressive" angiomyxoma)	Angiomatoid fibrous histiocytoma	Synovial sarcoma
Pleomorphic hyalinizing angiectatic tumor	Ossifying fibromyxoid tumor	Epithelioid sarcoma
Ectopic hamartomatous thymoma	Mixed tumor/ myoepithelioma/ parachordoma	Alveolar soft part sarcoma

tumors arise from mesenchymal stem cells or multipotential cells and that specific genetic alterations can induce the peculiar histopathological characteristics of each tumor. Hence, we now think in terms of lines of differentiation, which are determined by patterns of gene expression. In some neoplasms we can identify a line of differentiation, but we are unable to define a cellular counterpart among normal mesenchymal tissues.

Distinctive Tumors of Uncertain Histogenesis

Synovial Sarcoma

Synovial sarcoma (SS) is a mesenchymal spindle cell tumor that displays variable epithelial differentiation, including glandular formation. ►SS accounts for 5–10% of soft tissue sarcomas, and 90% of cases occur before the age of 50 years. These tumors can arise at any site, although about 80% of cases originate in the deep soft tissues of the extremities, particularly around the knees. The tumors display mesenchymal and epithelial markers and have a specific chromosomal translocation t(X; 18) (p11; q11). Five-year survival is around 40–70% (Fig. 1).

Epithelioid Sarcoma

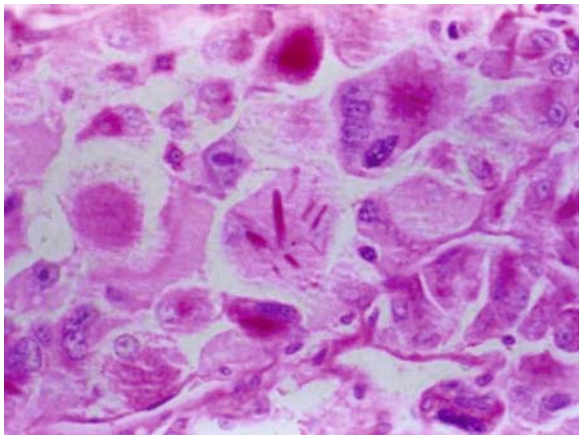
►Epithelioid sarcoma (ES) is a distinctive sarcoma of unknown lineage showing predominantly epithelioid cytomorphology, and affecting mainly adolescents and young adults. ►ES arises more frequently in the distal extremities, particularly the fingers, hands, forearms, knees and lower legs. Histopathologically, ES has a pseudogranulomatous appearance with a nodular growth pattern and mixed proliferation of eosinophilic epithelioid and spindle cells. These tumors are positive for epithelial markers and, in half of the cases, for CD4. The overall recurrence rate is around 80% at 10 years, and 5-year survival rates range from 50 to 80%, with an unpredictable clinical course. Moreover, there is a much more aggressive subtype called proximal-type ►epithelioid sarcoma that arises in the pelvis.

Alveolar Soft Part Sarcoma

►Alveolar soft sarcoma (ASPS) is a rare tumor affecting mainly adolescents and young adults. It is composed of large, uniform, epithelioid cells having abundant eosinophilic, granular cytoplasm arranged in solid nests and/or alveolar structures, separated by thin, sinusoidal vessels. ►ASPS is a rare tumor with a reported frequency of less than 1% of all soft tissue sarcomas. It can occur at any age, but is most common between 15 and 35 years. ASPS usually presents as a slow-growing lesion. Early metastasis is a characteristic feature of this tumor. Histopathologically, the large round or polygonal cells show light atypia and contain rod-shaped crystalline inclusions. Immunohistochemically, no consistent findings or markers have been described although muscle markers have been observed in some cases. In cytogenetics, these tumors harbor genetic alterations such as del (17), and t(x;17) (p11;q25) The 5-year survival rate is around 60% (Fig. 2).

Clear Cell Sarcoma of Soft Tissue

►Clear cell sarcoma (CCS) is a soft tissue sarcoma of young adults with melanocytic differentiation, typically involving tendons and aponeuroses. These rare tumors



Uncertain or Unknown Histogenesis Tumors.
Figure 2 Alveolar soft part sarcoma: PAS stain with diastase digestion demonstrates the presence of crystalline inclusions in the cytoplasm of tumor cells (PAS, ×600).

usually affect young adults, with a peak incidence in the third and fourth decade. The tumor usually presents as a slowly growing mass, being present for several weeks to several years. Histopathologically, the tumor displays a typical uniform, nested to fascicular growth pattern. The cells are epithelioid or spindle with a typical vesicular nuclei and prominent nucleolus. Tumor cells are positive for melanin stains in about 50% cases. The cytogenetic hallmark of this tumor is the presence of a t(12;22) (q13;q12) translocation. The 5-year survival is about 65% and 20-year survival only 10%.

Extraskeletal Myxoid Chondrosarcoma

►Extraskeletal myxoid chondrosarcoma (EMC) is a malignant soft tissue tumor characterized by multinodular architecture, an abundant myxoid matrix, and malignant chondroblast-like cells arranged in cords, clusters, or delicate networks. These tumors account for less than 3% of soft tissue sarcomas and mainly affect adults over 50 years of age. The thigh is the most common location. The tumors form cords or clusters and display an epithelial appearance with abundant eosinophilic cytoplasm, Despite the name, there is no convincing evidence of cartilaginous differentiation. The only marker found in all cases is vimentin. The t(9;22)(q22;q12) translocation is seen in around half of cases. Five-year survival is over 90%, although the tumor has a high potential for local recurrence and metastasis.

Desmoplastic Small Round Cell Tumor

►Desmoplastic small round cell tumor (DSRCT) is composed of small round tumor cells associated with prominent stromal desmoplasia and polyphenotypic differentiation. ►DSRCT primarily affects children and young adults, usually with abdominal serosal involvement. There is a male predominance. Histopathlogically, the tumor cells are small and arranged in nests. Immunohistochemistry can show multi-phenotypic differentiation with positive epithelial, mesenchymal, muscle, and even neuroectodermal markers. The t(11;22) (p13;q12) translocation is a consistent cytogenetic feature. Five-year survival is less than 20%.

Extrarenal Rhabdoid Tumor

►Soft tissue rhabdoid tumor (RT) is a malignant tumor of infants and children, characterized by neoplastic cells with large nuclei, prominent nucleoli, and abundant eccentric cytoplasm with variably prominent eosinophilic cytoplasmic "inclusions." RT can arise in the liver, heart, gastrointestinal system or soft tissues. The rhabdoid cell co-expresses mesenchymal and epithelial markers and, in many cases, neuroectodermal markers. Mutations, deletions or translocations of chromosome 22 involving the SMARCB1 gene are characteristic. Five-year survival is dismal. Since a rhabdoid phenotype can be present in a wide spectrum of tumors, particularly those occurring in adults, the diagnosis of rhabdoid tumor requires exclusion of underlying alternative lines of differentiation.

Neoplasms with Perivascular Epithelioid Cell Differentiation (Pecomas)

►Neoplasms with perivascular epithelioid cell differentiation (PEComas) are mesenchymal tumors composed of histologically and immunohistochemically distinctive perivascular epithelioid cells. The ►PEComa family of tumors includes angiomyolipoma (AML), clear cell "sugar" tumor of the lung (CCST), lymphangioleiomyomatosis (LAM), clear cell myomelanocytic tumor of the falciform ligament/ligamentum teres (CCMMT), and unusual clear cell tumors of the pancreas, rectum, abdominal serosa, uterus, vulva, thigh, and heart. Histopathologically, these tumors show epithelioid and spindle cells with clear or lightly eosinophilic cytoplasm surrounded by small arcing vessels. They are immunohistochemically positive for melanocytic and muscle markers. A consistent genetic alteration has not as yet been described in the few cases studied. Most PEComas have a relatively benign prognosis but malignant PEComas with aggressive clinical progression have been reported.

Ewing Sarcoma/Primitive Neuroectodermal Tumor (Pnet)

►Ewing sarcoma and ►PNET are defined as round cell sarcomas that show varying degrees of neuroectodermal differentiation. The term Ewing sarcoma has been used for tumors that lack evidence of neuroectodermal differentiation as assessed by light microscopy,

immunohistochemistry, and electron microscopy, whereas the term PNET has been applied to tumors that demonstrate neuroectodermal features. ►Ewing sarcoma/primitive neuroectodermal tumor (PNET) is relatively uncommon, accounting for 6–8% of primary sarcomas. It is the second most common bone and soft tissue sarcoma in children. Most cases arise in patients younger than 20 years. Histopathologically, Ewing tumors are composed of small round cells and are positive for neuroectodermal markers such as CD99. In cytogenetics, this family of tumors is characterized by a distinctive t(11;22)(q24;q12) chromosomal translocation in over 85% of cases. Other translocations are also described and interestingly, the prognosis differs according to the type of translocation (see Ewing tumor chapter).

Capillary Hemangioblastoma

►Capillary hemangioblastoma (CH) is a low-grade (WHO grade I) tumor of uncertain histogenesis, composed of stromal cells and abundant capillaries. ►CH occurs predominantly in the cerebellum, although multiple hemangioblastomas associated with Von-Hippel Lindau (VHL) disease arise at any site in the central nervous system. Approximately 25% of hemangioblastomas are associated with Von Hippel Lindau disease. The tumor cells are vacuolated and are negative for most of the markers studied, including endothelial markers. CH are well-circumscribed tumors; the prognosis depends on the surgical excision and the location.

Angiomatoid Fibrous Histiocytoma

A rare tumor (0.3% of soft tissue tumors), also known as angiomatoid malignant fibrous histiocytoma, which generally affects the deep dermis and subcutis of the extremities in children and young adults, simulating a hematoma. These tumors show multinodular proliferation of epithelioid or spindled eosinophilic cells (myoid cells), pseudoangiomatoid spaces, a thick fibrous capsule, and a pericapsular lymphoplasmacytic infiltrate. Cellular pleomorphism and increased mitotic activity have been identified, particularly in spindled tumors. Fifty percent of cases express desmin and/or EMA. These tumors have an indolent behavior with some local recurrence (10%) and a low metastatic potential (1%), generally to the regional lymph nodes.

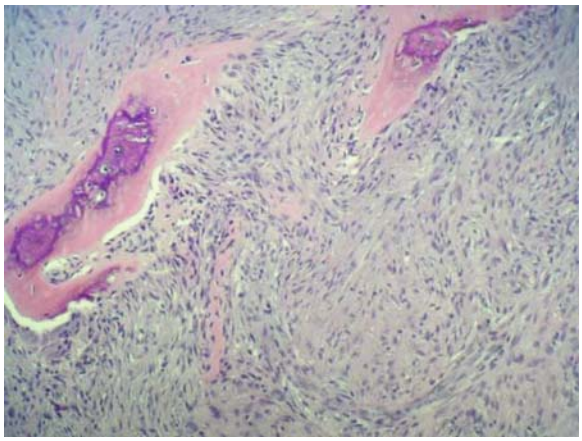
Myxoid Tumors

Within the large variety of predominantly ►myxoid tumors with peculiar clinico-pathological characteristics, we mention some having a generally benign pattern, with a tendency for local recurrence but no metastatic potential. Among these, there is intramuscular myxoma (IMM), which arises mainly in women (40–70 years) and has an excellent prognosis. Some IMM with hypercellular areas are defined as "cellular myxomas." The so-called Juxta-articular Myxoma has histological features similar to cellular myxoma; the majority occur in the vicinity of the large joints. Another myxoid tumor is the Deep "Aggressive" Angiomyxoma, which has a predilection for the pelvic and perirenal regions. And lastly, there is the Ossifying Fibromyxoid Tumor, which arises in the extremities in adults and occasionally acquires a malignant phenotype. It is important to identify myxoid tumors and differentiate them from malignant myxofibrosarcomas, a group of malignant fibrohistiocytic lesions with variable myxoid stroma and cellular pleomorphism that has a much poorer prognosis (Fig. 3).

Other (Benign) Tumors

Some rare, slow growing tumors of uncertain differentiation with tendency to local recurrence, but no metastatic potential, have been described. Pleomorphic hyalinizing angiectatic tumor of the soft parts (PHAT) occurs in adults and arises in the subcutis of the lower extremities. It is characterized by clusters of ectatic thin-walled vessels surrounded by spindled pleomorphic neoplastic stroma with a variable inflammatory component. The tumor cells occasionally express CD34.

Mixed tumor/myoepithelioma/parachordoma form a recently described group of benign tumors that arise in the subcutaneous or subfascial soft tissues of the extremities. Mixed tumors are similar to their salivary gland counterparts, with uniform epithelioid cells in a chondromyxoid stroma. Myoepitheliomas differ from mixed tumors in that they typically lack a definite ductal component. Parachordomas resemble mixed tumors, with the exception that there is prominent cytoplasmic vacuolation. All three tumors express myoepithelial markers: cytokeratin, vimentin and S 100 protein.



Uncertain or Unknown Histogenesis Tumors.

Uranium

Definition

A radioactive chemical element which is important for the nuclear fuel cycle and for atomic weapons. Naturally, two isotopes occur: 99.3% is ^{238}U and 0.7% is ^{235}U.

►Uranium Miners

Uranium Miners

Bernd Grosche
Department of Radiation Protection and Health, Bundesamt für Strahlenschutz (Federal Office for Radiation Protection), Oberschleissheim, Germany

Definition

In a very strict sense, uranium miners are those involved in uranium production, either in underground or in open pit mining. Further more, the term includes individuals in milling and processing, and in an even broader sense those persons who are employed by the mining company but working in unexposed areas.

The most important carcinogen to which uranium miners are exposed to is the radioactive noble gas radon and its progeny (henceforth called radon). Radon itself is a daughter product of uranium decay. And since uranium is not only part of those geological formations containing this metal in a content rich enough for mining but also in other geological environments, the term "uranium miners" does sometimes not only include miners working in uranium mines, but also miners exposed to elevated levels of radon.

The miners' exposure to radon is given in Working Level Months (WLM). A Working Level (WL) is defined as 1.3×10^5 MeV of potential alpha energy/L air. A Working Level Month equals an exposure to 1 WL for 170 h.

Characteristics

Uranium Mining

Uranium is needed for the nuclear fuel cycle and for the production of nuclear weapons. In the early years of large scale uranium mining it was mainly produced for developing and building nuclear weapons. Large scale uranium mining started in the mid 1940s. Before that, uranium production was low and the metal was used for other purposes.

In 2005, the largest share of uranium from mines came from Canada (28%), followed by Australia (23%). In terms of produced uranium, these countries are followed by Kazakhstan, Russia, Namibia, Niger, and 11 more countries. Overall, 41,595 tons were produced in 2005.

Miners' Cohorts

To date, there are 13 miners' cohorts with sufficient information on each individual miner to conduct epidemiological investigations into health effects, namely cancer. Twelve of these cohorts were jointly analyzed in two slightly different settings consisting of 11 cohorts each, whilst the thirteenth is new and has not been included in any of the joint analyses so far.

A pooled analysis was conducted for 11 cohorts with respect to radon-related lung cancer risk. The included cohorts are, in order of their individual size: Ontario, Canada (uranium); China (tin); Beaverlodge, Canada (uranium); Czech Republic (uranium); New Mexico, USA (uranium); Colorado Plateau, USA (uranium); France (uranium); Newfoundland (fluorspar); Radium Hill, Australia (uranium); Port Radium, Canada (uranium); Sweden (iron). Altogether, this analysis included 60,606 exposed miners with a cohort-depending follow-up from 1943–1991. The mean length of follow-up was 17.7 years. After the publication of the joint analysis, further follow-up was conducted for the French, the Czech, and the Newfoundland cohorts.

Again 11 cohorts were jointly analyzed in terms of radon-related risk for cancers other than lung cancer. In this case, the Radium Hill cohort was replaced by a tin miners' cohort from Cornwall, England. Overall, this pooled study included 64,209 miners with a follow-up from 1941 to 1990 and a mean length of follow-up of 16.9 years.

The largest single cohort is based on uranium miners having worked with the Wismut company in Saxony and Thuringia, Germany. Saxony and Thuringia are the southern part of the former GDR, and mining was stopped after the German unification. The cohort includes 59,001 miners. The follow-up covers the years 1949–1998 with a mean length of 30.5 years.

Exposures

Uranium miners are not only exposed to radon, but also to other agents. Depending on the geological

environment, this can be gamma radiation, long lived radionuclides, ►arsenic, ►asbestos, silica, and others. Nonetheless, the most important agent with respect to cancer induction is ►radon. Among the above mentioned cohorts, the exposure ranges from 0 WLM for unexposed cohort members, e.g., in the German cohort, to over several thousands of WLM as for the Colorado Plateau and the German cohorts. The highest average cumulative exposure of 579 WLM was observed among the Colorado Plateau miners.

The Risk of Lung Cancer

Of major health concern is the induction of ►lung cancer from radon exposure. Results from uranium miners' studies were the first to indicate that radon is the most important risk factor for lung cancer next to smoking. The analysis of the joint 11 cohorts revealed a linear increase of risk with increasing cumulative exposure. The Excess Relative Risk (ERR) per WLM was calculated as being 0.76%/WLM, i.e., the baseline lung cancer risk increases by 0.76%/WLM, but the risk estimates for each single cohort varied by more than one order of magnitude. For a more detailed analysis aimed to study the influence of effect modifiers, two models were used. While the first included time since exposure, attained age, and duration of exposure (the so-called exposure–age–duration model, EAD), the second model included time since exposure, attained age, and concentration (the exposure–age–concentration model, EAC). ERR/WLM decreased constantly with increasing time since exposure and increasing attained age. Furthermore, ERR/WLM was modified by either duration of exposure or concentration, i.e., depending on the model, ERR/WLM increased with increasing duration of exposure or with decreasing radon concentration. The effect of an increasing ERR/WLM with decreasing radon concentration is called the inverse dose-rate effect. For the 11 cohorts, it could be observed only at exposures exceeding 50 WLM. The inverse dose-rate effect might be explained on a microdosimetric basis. During the cell cycle, one or several periods might show a much higher sensitivity to irradiation than the others. Protracted exposure to α-emitters over a longer time subsequently leads to a larger proportion of these sensitive cells being irradiated compared with the same exposure occurred in a shorter time. Another explanation might be that a reduction of the dose-rate may allow for proliferation of cells being initiated by radiation earlier during exposure. A third suggestion is that this effect could be explained as a bystander effect.

The German cohort is as big as all the 11 cohorts put together, but less heterogeneous in various aspects: same societal and geographical background, same way of follow-up, and one system for exposure estimation. When applying those models used for the 11 cohorts to the Wismut miners, the overall estimated ERR per WLM was 0.21% with a 95% confidence interval of 0.18–0.24%. This is somewhat lower than the one observed in the 11 cohorts. For these, no confidence intervals were given. Thus, no clear answer can be given to whether or not there is a significant difference in the risk estimates derived from the two studies. Applying the EAD model to the German cohort revealed no meaningful results, but the EAC model gave results comparable to those from the 11 cohorts to that extended that the inverse dose-rate effect was in the same order of magnitude. Here, it could be observed only at exposures exceeding 100 WLM. The effects of time since exposure and attained age were less pronounced compared to the 11 cohorts. A synopsis of the results is given in Table 1. Though the results seem to be different to some extent, it has been shown that the estimates for the lifetime attributable lung cancer risks are comparable.

Histopathologic Findings

Those studies referring to radiation and cell type have provided conflicting results. Early investigations conducted in the 1960s announced that ►small-cell lung carcinoma (SCLC) was the characteristic cell type of radiation-induced lung carcinoma, whereas later it was suggested that radiation also was associated with other cell types, and that SCLC was simply the one that appeared first. Accordingly, a shift from the predominance of SCLC to squamous cell carcinoma (SqCC) was reported in the Colorado Plateau miners when the follow-up was extended. A short latency for SCLC was also reported for the Ontario uranium miners, amongst which there was a high proportion of SCLC especially 5–14 years after exposure. A study among Chinese tin miners found SqCC to be the predominant type, but SCLC appeared to be more strongly associated with radon exposure, namely among miners who developed lung carcinoma at younger ages. Results from two independent studies among German uranium miners suggest that SCLC and SqCC are more likely related to high radon exposure than adenocarcinomas (AC) and other cell types.

The Risk of Cancers Other than Lung Cancer

The radon-related risk for cancers other than lung cancer was analyzed based on 11 cohorts of radon exposed miners, most of them working in uranium mines. Twenty-eight individual cancer categories were analyzed. Among those, statistically significant increases in mortality were observed for stomach and liver cancer, while statistically significant decrease were observed for ►tongue cancer, mouth cancer, pharynx cancer, and ►colon cancer. For leukemia, an increased mortality was observed within the first 10 years since starting work, but not subsequently. Among the remaining individual categories, mortality

Uranium Miners. Table 1 Exposure–age–concentration model: comparison of BEIR VI parameters with parameters estimated from the WISMUT cohort

	BEIR VI	Wismut cohort
ERR/WLM (%)	0.83	0.25 (0.13–0.36)[a]
Time since exposure (years)		
5–14	1.0	0.66 (0.44–0.89)

15.0+	1.0	1.0

[a]95% confidence interval.

was related to cumulative exposure only for pancreatic cancer and for other and unspecified cancers. For this latter category, the finding again was restricted to the period less than 10 years after start of work. Overall, this analysis gave no evidence for a considerable risk for cancers other than lung cancer from radon. However, later studies from France and the Czech Republic revealed some indication for an increased risk for kidney cancer and leukemias, respectively. The risk for these causes of death can be considered as low, but further analyses based on new and/or extended cohorts are needed. Based on dosimetric assumption, a risk for pharyngeal cancer, cancer of the liver and the bone, and leukemias cannot be ruled out.

Conclusion

In conclusion, there is no doubt about the lung cancer risk deriving from radon exposure among uranium miners and other radon-exposed miners. The risk for other cancers cannot be ruled out, if at all it can be considered as small. Still, it needs further attention, since dosimetric models give hint that doses to some organs might be high enough for cancer induction. Another topic for further research is the analysis of combined effects. Some studies have looked at the interaction of smoking and radon. Results indicate that radon-related lung cancer risk exists both among smokers and nonsmokers. Little is known about combined effects of radon and arsenic or other cocarcinogenic substances.

Urea Cycle

Definition

Synonym ornithine cycle; Is a metabolic cycle of biochemical reactions occurring in many animals that produces urea from ammonia (NH_3). In mammals, the

urea cycle takes place only in the liver. Eliminating the excess nitrogen in this way prevents it from accumulating in the form of ammonia, which is toxic.

►Arginine-depleting Enzyme Arginine Deiminase (ADI)

Uridine Diphosphate-Glucuronosyltransferase

Definition

Microsomal uridine diphosphate-glucuronosyltransferase (UGT) enzymes catalyze the Phase II glucuronidation. The human UGT superfamily has been classified into the UGT1 and UGT2 families, further classified into three subfamilies (UGT1A, UGT2A, and UGT2B). All nine functional family-1 members of the UGT1A subfamily are encoded by a single gene locus on chromosome 2q37. UGT1A1 is highly expressed in the gastrointestinal tract and the liver and is the primary enzyme responsible for forming bilirubin glucuronides and for the detoxification of the active irinotecan metabolite SN-38.

►Irinotecan

Transitional cell carcinoma of the urinary bladder; Bladder cancer

Definitions

Urothelial carcinoma is a cancer arising from the urothelium, a specialized epithelium lining the urinary tract from the renal pelvis into the urethra, retaining

discernable morphological aspects and molecular markers of urothelial cells.

Characteristics

Distribution, Histology, and Clinical Course

Urothelial carcinomas are derived from the urothelium, an epithelium lining the urinary tract from the renal pelvis into the urethra. Most tumors initiate in the urinary bladder, but some are localized in the renal pelvis, the ureter and the urethra. Urothelial carcinoma is the most common histological subtype of ►bladder cancer, often retaining aspects of normal urothelial differentiation including markers like ►cytokeratins 7, 13, and 20, and ►uroplakins. Another histological subtype of bladder cancer, squamous cell carcinoma, is prevalent in selected countries, e.g. Egypt. It typically arises in the context of chronic inflammation, e.g. caused by ►Schistosomas hematobium infection. Limited squamous metaplasia is found in many, especially high-grade urothelial carcinomas. Adenocarcinomas are very rare in the urinary tract. Overall, bladder cancer incidences vary between 4–40/100,000 worldwide, with a two- to fourfold male predominance and a maximum in the over 70 age group.

About 70–80% of urothelial carcinomas exhibit a papillary morphology (Fig. 1a). Non-invasive papillary tumors are designated pTa. They can be removed by resection, but tumor recurrence is observed in 50–70% of the patients. The high recurrence rate and frequent multifocality of non-invasive urothelial tumors suggest a "field effect" in urothelial carcinogenesis. Indeed, multifocal urothelial carcinomas can arise independently, but also through intraluminal or intraepithelial spreading of one initial tumor. Clinical and molecular data suggest that a subset of well differentiated pTa tumors have a particularly low risk of recurrence and progression. These are now classified as a new subentity, PUNLMP (papillary urothelial neoplasia of low malignant potential). Low grade pTa tumors are rarely lethal, but high grade pTa tumors may progress to the invasive stages (Fig. 1b and c) pT1 (invading submocusal tissue), pT2 (invading the muscular layer), pT3 (invading the perivesical adipose tissue layer), or pT4 (invading neighboring organs). Most invasive urothelial cancers, however, develop from a different precursor stage, carcinoma in situ (pCIS), a highly dysplastic flat lesion. With increasing grade and stage of muscle-invasive tumors, metastasis to lymph nodes and distant organs, preferentially liver, lung, bone, and adrenal, becomes more frequent.

Causes

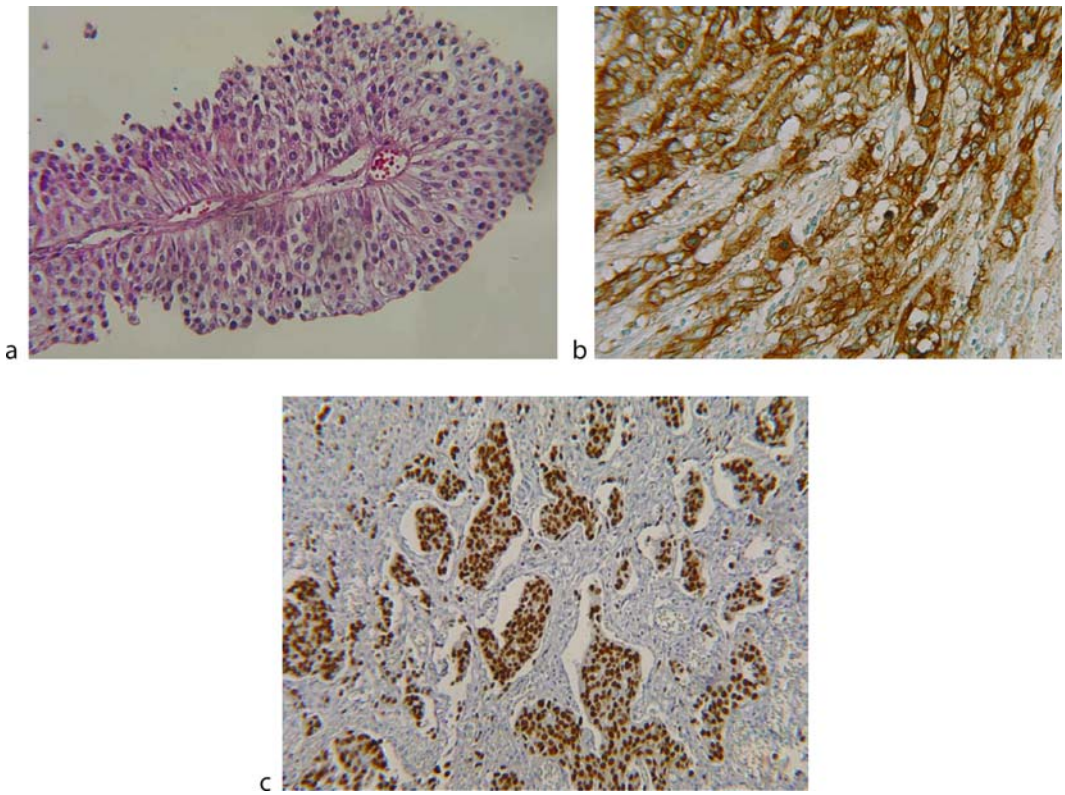
Urothelial carcinoma is caused by chemical carcinogens excreted in the urine, prominently arylamines, but also nitro-compounds, nitrosamines, polyaromates, arsenite, metabolites of drugs like phenacetin and cyclophosphamide, and of endogenous amines eg. from tryptophane. As tobacco smoke is a main source of carcinogens, smokers have an up to sixfold enhanced risk of bladder cancer. Specific exposures occur in certain occupations like, historically, aniline and azo-dye production. Less dramatic risks persist in some industries, e.g. those producing dyes, plastics, and rubber. Tobacco smoke is a source of many urinary carcinogens and together with occupational exposures may be responsible for the overall higher incidence of urothelial carcinomas in industrialized countries. There is little evidence for familial inheritance of urothelial carcinoma, but individual carcinogenesis risk is modulated by polymorphic xenobiotic metabolism enzymes. For instance, lack of GSTM1 (►Glutathione S-transferase M1) increases urothelial cancer risk ~1.5-fold, and more strongly in smokers. Hypomorphic alleles of NAT2 (►N-acetyltransferase 2) underlying the "slow acetylator" phenotype strongly increase the risk of individuals exposed to arylamine carcinogens. HNPCC (►Lynch syndrome) patients also have an increased risk of urothelial cancers, intriguingly only of the upper urinary tract.

Therapy

Nonmetastatic urothelial cancers can be successfully treated by surgery, either by transurethral resection for pTa and most pT1 tumors or by removal of the affected bladder (►Cystectomy), ureter, or kidney. Modern operation techniques have diminished the morbidity and the mortality of radical cystectomy. Continent techniques of urinary diversion allow patients to maintain a good quality of life. Chemotherapy is administered in an ►adjuvant or ►neoadjuvant fashion. Common chemotherapy regimes use MVAC (►methothrexate, ►vinblastine, ►adriamycin, ►cisplatin) or a ►cisplatin/►gemcitabine combination. Both regimes have similar, significant but limited efficacies. To prevent recurrences after transurethral resection nowadays postoperative intravesical chemotherapy is administered routinely. Patients with a high risk of tumor recurrence (due to big, multifocal, or high grade pTa or pT1 tumors or carcinoma in situ (►CIS)) are treated by the more efficacious ►BCG installation immunotherapy. All patients treated for urothelial cancers must be regularly monitored for recurrences. Due to its high recurrence rate and requirement for long-term monitoring and treatment, in many countries urothelial carcinoma is economically the most costly tumor type on a per patient basis.

Diagnosis and Monitoring

Definitive diagnosis of urothelial carcinoma requires endoscopy of the urinary tract. Resected tumors and biopsies from suspect areas are used for tumor staging



Urothelial Carcinoma. Figure 1 Histology of urothelial carcinoma. (a) Typical papillary tumor. (b) Invasive urothelial carcinoma immunostained for EGFR, which is detected at the membranes of the tumor cells growing as sheets and files. (c) Invasive urothelial carcinoma immunostained for TP53, which is detected in the nuclei of the tumor cells growing as clusters. All histological photographs were kindly provided by Dr. Christopher Kramer.

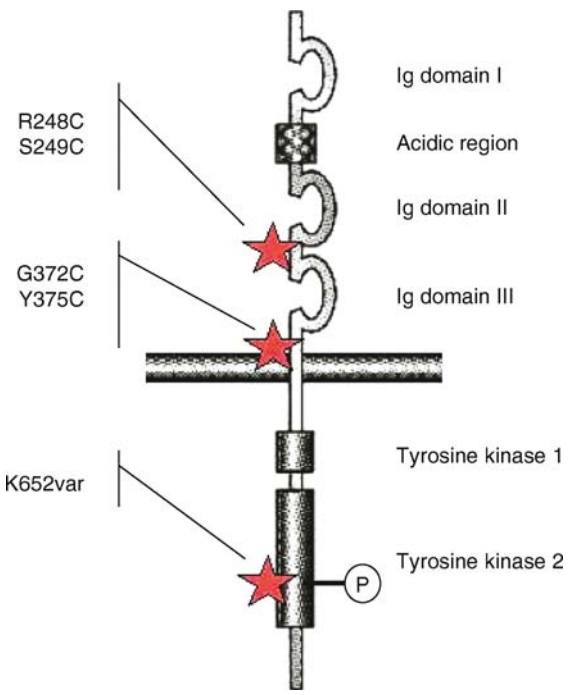
and grading. Visualization of flat lesions, in particular CIS, is improved by porphyrin fluorescence detection following instillation of aminolevulinic acid esters (►Photodynamic diagnostic). Urography is also helpful for diagnosis, especially for tumors in the upper urinary tract, i.e. ureter and renal pelvis. Computed tomography and magnetic resonance tomography are used to determine the extension of more advanced carcinomas and identify metastases. Monitoring for recurrences involves regular endoscopic investigations, as a minimum.

►Urine cytology, a noninvasive technique, is used for the initial diagnosis of urothelial carcinoma, but is more important for detection of recurrences. The technique is highly specific, but not very sensitive, especially for low grade tumors, and depends on observer experience. Therefore, cytogenetical, biochemical, and molecular assays of proteins and cells in the urine are entering clinical practice. Multicolor ►FISH analysis aimed at typical chromosomal changes in urothelial carcinoma is also highly specific, but not very sensitive. ►ELISA-based assays detect proteins released by urothelial carcinomas into the urine. They include the bladder tumor antigen assay (BTA) measuring complement factor H-related protein, ►NMP22 BladderChek measuring a nuclear matrix protein, and ImmunoCyt detecting mucin-like proteins and a ►carcinoembryonic antigen (CEA) isoform. Their specificity is limited by the fact that inflammatory processes common in individuals at risk for bladder cancer also increase urinary levels of these proteins. Novel assays measuring ►Survivin levels, ►telomerase activity, ►DNA methylation alterations, or ►microsatellite allelic loss are under development. These and future molecular diagnostic assays are expected to facilitate the long-term monitoring of patients with urothelial cancers by reducing the number of cystoscopies required, and to improve the classification of this highly diverse tumor type for individualized therapy.

Molecular Genetics

Invasive bladder carcinomas are characterized by pronounced ►chromosomal instability, with typically 7–10 gross aberrations. In contrast, low grade pTa tumors show few chromosomal aberrations and

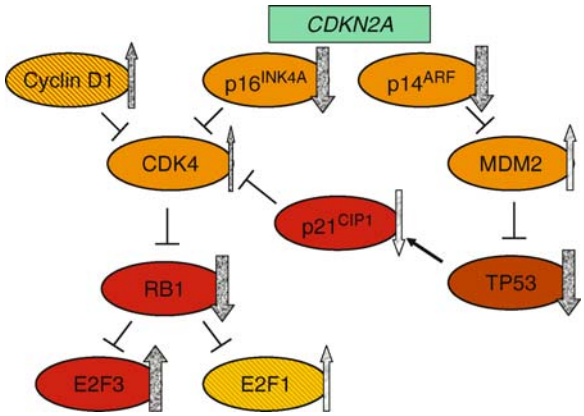
mutations. In such cases, losses affecting either or both arms of chromosome 9 are the only discernable chromosomal abnormality. Additional changes comprise i(5p) and trisomy 7. The 9p losses clearly target the twin gene ►*CDKN2A* which encodes two functionally and biochemically distinct tumor suppressors, $p16^{INK4A}$, and $p14^{ARF}$. Candidate tumor suppressor loci on 9q comprise ►*DBCCR1*, *PTCH1* (a negative regulator of ►hedgehog signaling), *TGFBR2* (a ►TGFβ receptor subunit), and *TSC1* (a component of the ►tuberous sclerosis complex). Many low grade pTa tumors harbor oncogenic missense mutations in a tyrosine receptor kinase, ►FGFR3, which are rare in invasive urothelial cancers and in other cancer types. The most frequent mutations are S249C, Y375C, S248C, and G372C (Fig. 2). They appear to stabilize and prolong the activated state of FGFR3 following binding of fibroblast growth factors or lead to growth-factor independent activation by formation of disulfide bonds. Possibly, they also increase FGFR3 protein levels. The prevalence of FGFR3 mutations decreases from PUNMLPs through pTa towards pT1 tumors and they are rare in muscle-invasive carcinomas. Thus, FGFR3 mutations appear to elicit a comparatively low malignant phenotype. Alternatively to those in FGFR3, oncogenic mutations are found in ►HRAS, but, like *CDKN2A* deletions, these are similarly frequent throughout all tumor stages. Apparently, FGFR3 mutations lead primarily to excessive urothelial cell proliferation, which otherwise resembles that during tissue regeneration after injury. Normal urothelial regeneration is also crucially dependent on autocrine ►EGF-like growth factors, especially HB-EGF and amphiregulin, and their receptors, especially ►EGFR, encoded by the *ERBB1* gene at 7p12. An increased dosage of chromosome 7 is frequent in early stage cancers and amplifications at 7p12 are found in later stages. Overexpression of the EGFR is accordingly common in urothelial carcinoma (Fig. 1b) and may deregulate autocrine stimulation of urothelial cell proliferation. Unlike FGFR3 mutations, EGFR overexpression is often associated with more aggressive cancers.



Urothelial Carcinoma. Figure 2 Common FGFR3 mutations in urothelial carcinoma.

Additional chromosomal changes accumulate in high grade papillary and in CIS tumors indicating the onset of genetic instability and the potential for progression towards invasive stages. In invasive cancers, multiple and variable changes are found. Among the more consistent additional alterations are losses at 3p, 8p, 10q, 11p, 13q, 17p, and 18q, and gains or amplifications at 1q, 6p, 8q, 11q, 17q, and 20q. Missense mutations of the ►p53 tumor suppressor leading to nuclear accumulation of the protein (Fig. 1c) are likewise characteristic of progressive urothelial carcinomas. Strikingly, the groups of tumors with p53 or FGFR3 mutations are almost distinct. In keeping with its precursor property, genetic changes in CIS resemble more those in invasive cancers than those in pTa tumors, although they are not as extensive. DNA methylation alterations also accumulate with tumor progression. In particular, hypermethylation of several genes including *RASSF1A* (an antagonist activated by ►RAS signaling), *SFRP1* (a ►WNT signaling antagonist), ►*APAF1*, and ►*APC* in various combinations becomes more frequent in invasive cancers, although beginning hypermethylation can be detected already in morphologically normal urothelium of cancer patients. Hypomethylation of repeat sequences is also prevalent in urothelial cancers, usually increasing with tumor stage.

All urothelial carcinomas show defects in two regulatory systems, cell cycle regulation and the p53 network, albeit to different extents (Fig. 3). Even low grade pTa tumors display losses of one or both *CDKN2A* alleles which impede both systems. In invasive carcinomas, cell cycle regulation is disturbed by inactivation of both ►RB1 alleles through mutations and allelic loss at 13q14, by amplification of *CCND1* at 11q13 encoding ►Cyclin D1, CDK4 (►Cyclin-dependent kinase 4) amplification, or most frequently complete *CDKN2A* inactivation by homozygous deletion, point mutation, or promoter hypermethylation. In more aggressive cancers, ►CDK inhibitors of the CIP/KIP family are additionally downregulated, usually by epigenetic mechanisms. In case of the imprinted



Urothelial Carcinoma. Figure 3 Common changes in cell cycle regulators in urothelial carcinoma. The direction of the arrows indicate the change in function (down: loss, up: increase), their width the frequency. Red color indicates changes associated with worse histopathological parameters, orange indicates distribution across all stages and grades. TP53 mutating correlate best with grade (indicated by the brown color). Increased expression of E2F1 is found in many cases, but has been postulated to indicate a better prognosis (thus yellow/orange). Overexpression of Cyclin D1 is typical of many low stage tumors (indicated by yellow), but can be caused by gene amplification in advanced cancers (indicated by red). *CDKN2A* encodes both $p16^{INK4A}$ and $p14^{ARF}$.

CDKN1C gene at 11p15 encoding $p57^{KIP2}$ loss of the active (maternal) allele is a further inactivation mechanism. Gains and amplifications at 6p22 lead to overexpression of ►E2F3 and at 8q24 to that of ►MYC, both of which aggravate cell cycle deregulation. Overall, the severity of cell cycle loss of control parallels the aggressivity of urothelial carcinoma. However, since so many different mechanisms contribute, it is difficult to employ this insight for prognostic purposes,. Similarly, defects in TP53 function appear to be associated with tumor progression and are brought about by different mechanisms, most commonly missense mutations in *TP53* and allelic loss of the gene at 17p and $p14^{ARF}$ loss by 9p21 deletions. Rarer cases show overexpression of the TP53 inhibitor ►MDM2. More commonly, mediators of TP53 action such as APAF1 and $p21^{CIP1}$ become downregulated by epigenetic mechanisms. The defects in TP53 function contribute to defective checkpoint function in urothelial carcinoma, which facilitates the accumulation of chromosomal alterations. Moreover, the concomitant loss of proper RB1 and TP53 function prevents hyperproliferation-induced ►senescence. In addition, almost all urothelial carcinomas reexpress active ►telomerase. Detection of hTERT RNA or active enzyme by the TRAP assay is therefore explored for diagnostic purposes.

Transitional cell carcinoma

Definition

The ►urothelium covers inner surface of almost the entire urinary tract, extending from the renal pelvis, through the ureter and bladder, to the proximal urethra. Usually it is composed of three to seven layers of cells. The luminal surface of the superficial cells is covered with an asymmetric unit membrane, which functions as the permeability barrier between urine and blood. Nearly 90% of the ►urothelial carcinoma arises in the bladder and renal pelvic and ureteral carcinomas account for only approximately 7% of the total. Worldwide, there are approximately 336,000 new cases of urothelial carcinoma and 132,000 deaths annually.

Characteristics

Morphological and pathological characteristics of urothelial carcinoma, mainly bladder carcinomas (►Bladder cancer), are a combination of ►papillary superficial ►carcinoma and ►nodular invasive carcinoma. Primary and/or associated ►urothelial carcinoma in situ (CIS) are occasionally seen. Papillary carcinoma is a basic pattern and consisting of approximately 70% of urothelial carcinoma; however, during repeated recurrences, 10–15% of them turn to nodular invasive carcinoma.

Another characteristic feature of the urothelial carcinoma is simultaneous or metachronous multifocal tumor development in the urinary tract (Fig. 1). (i) There are patients in which lesions in the renal pelvis, ureter, and bladder are observed simultaneously (Fig. 1a). (ii) When standard nephrectomy is performed for renal pelvic and ureteral carcinomas, approximately one-third of the lower ureter is left intact. In this remaining ureter, urothelial carcinomas develop subsequently in 20–50% of the patients (Fig. 1b). Consequently, at the present time, the state of the art surgery for renal pelvic and/or ureteral carcinomas is ►total nephroureterectomy, including removal of a small portion of the bladder with the ureteral orifice (bladder cuff) in the affected side. (iii) Even if total nephroureterectomy is carried out, however, 15–50% of patients exhibit subsequent carcinomas in the bladder (Fig. 1c). (iv) When superficial papillary urothelial carcinomas of the bladder are resected transurethrally (TUR), the rate for subsequent development of urothelial carcinomas of a similar biological nature in the normal-appearing bladder mucosa is reported to be 50–80% (Fig. 1d). (v) When cystoprostatectomy (i.e., removal of the bladder and prostate) is carried out for male bladder cancer patients, 4–17% incidences of urothelial carcinomas in the remaining urethra have been described (Fig. 1e). In female bladder cancer patients, involvement of the urethra is reported to occur in 1.4–36% of cases. This phenomenon is frequently called recurrences (as stated earlier) in a clinical setting. Two distinct concepts have been proposed to explain this phenomenon; the "►field cancerization" hypothesis indicating urothelial cells are equally exposed to the previous carcinogenic insults, the other hypothesis is "►clonal expansion or implantation" indicating that the multifocal development is caused by the seeding or implantations of originally transformed cells (►Carcinogenesis).

Diagnosis

Patients most frequently complain of gross hematuria. In some of the bladder carcinoma patients, vesical irritability is observed such as micturition pain, frequency, and sense of residual urine.

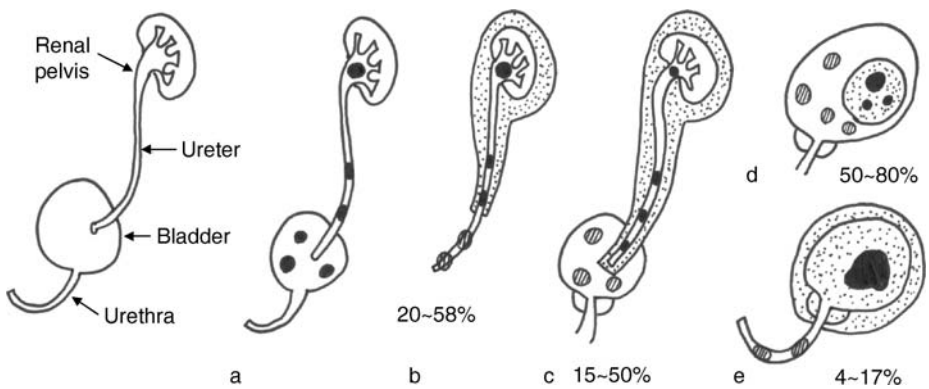
To diagnose urothelial carcinoma, urine cytology is essential, although in many low-grade papillary carcinomas, urine cytology is negative. On the contrary, nodular invasive carcinomas and CIS, usually exhibit positive cytology. For diagnosis of bladder carcinoma, cystoscopy during gross hematuria is particularly important to identify the presence and nature of bladder carcinoma and also to observe the possibility of gross hematuria from either side of the ureteric orifice. For diagnosis of renal pelvic and/or ureteral carcinomas, intravenous urography and enhanced CT are useful.

To evaluate the extent of urothelial carcinomas, chest X-ray, CT from the chest to the pelvic cavity, MRI of the pelvic cavity, bone scintigram, and blood counts/blood chemistry are done.

Biological nature and extent of disease are expressed by grade of tumors (G) obtained by biopsy and TNM staging (tumor, nodes, metastases by UICC) determined by imaging studies. Therapy of urothelial carcinoma is based on these information.

Therapy

In case of bladder carcinoma, treatment of papillary superficial bladder carcinoma is carried out by ►transurethral resection (TUR). Since papillary bladder carcinoma is notorious for its high rate of post-TUR intravesical recurrences, depending upon clinical stage and grade, various options are selected. For cTa, G1–2, just observation by cystoscopy and urinary cytology at 3 months interval at the initial year. For cTa, G3 or cT1, G1–2, one course of intravesical injection of ►Bacillus Calmette–Guerin (BCG) is preferred or just



Urothelial Carcinoma, Clinical Oncology. Figure 1 Clinical findings indicating multifocal tumor development in the urothelium. Hatched lesions are original tumors and oblique line lesions are recurrent tumors. Shaded area indicates the area of surgical resection.

observation. For cT1, G3, if cancer is completely resected, one course of intravesical injection of BCG is preferred. If primary or concomitant CIS is identified, intravesical BCG injection is definitely planned.

If the tumor has the nature of papillonodular or nodular invasive carcinoma indicating G2–3, cT2 or greater, as muscle invasive carcinoma, again, various options are selected such as radical cystectomy or partial cystectomy (if cancer is located at suitable part of the bladder and no associated CIS on multiple mucosal biopsies) or bladder sparing treatment after neoadjuvant ►chemotherapy and maximal TUR. If pathology reveals pT3 or more, positive lymph nodes, then, adjuvant chemotherapy is recommended.

After radical cystectomy, urinary tract is reconstructed by ileal conduit or neobladder. The former procedure needs appliance of pouch to the abdominal stoma to collect urine and the latter procedure ensures the patient to void from the urethra by replacing the bladder by ileal neobladder. In order to use neobladder to replace the bladder, cancerous lesions on the bladder neck and prostatic urethra should be denied by preoperative biopsies or intraoperative frozen section to avoid urethral recurrences of urotherial carcinoma after neobladder construction.

For metastatic urothelial carcinoma or neoadjuvant/adjuvant setting for deeply invasive or nodes positive bladder carcinoma, cisplatin-based combination chemotherapies such as methotrexate, vinblastine, actinomycin D, cisplatin (MVAC), or cisplatin/paclitaxel or gemcitabine/paclitaxel are used (►Cisplatin).

In case of urothelial carcinoma in the renal pelvis and/or ureter, total nephroureterectomy including bladder cuff is carried out because of multiple development of urothelial carcinomas (Fig. 1).

Genetics

Assessment of the risks of bladder carcinoma recurrence and of progression to invasive carcinoma is an important clinical task to plan the treatment and postoperative management of these patients. Genetic information in bladder carcinoma is indispensable for this purpose in addition to clinical grade and stage of bladder carcinoma.

Moreover, these information are essential to elucidate the pathogenesis of urothelial carcinoma.

Mutation in codon 12 of the *HRAS* oncogene was first identified in T24 bladder carcinoma cell line; however, in human bladder carcinoma, the frequency of *HRAS* mutations in codon 12, 13, and 61 was 6% and *HRAS* mutations are relatively infrequent genetic alterations in urothelial carcinoma of the bladder. Overexpression of c-erbB-2 has been observed in 37% of patients with muscle-invasive bladder carcinoma. *FGFR3* which encodes fibroblast growth factor receptor 3 is reported to be mutated as many as 74% of stage pTa superficial bladder carcinomas, 84% of G1, and 55% of G2 tumors which make clear contrast to only 7% of G3 tumors.

Retinoblastoma-associated protein (RB, encoded by ►*RB1*) and ►p53 are key proteins in cell-cycle regulations. *TP53* is located on chromosome 17p 13.1, where frequent lose of heterozygosity (LOH) has been reported in bladder carcinoma. Somatic mutation in *TP53* and its product p53 is regarded as the tumor suppressor being most frequently mutated in cancer. There are many reports on *TP53* mutations in bladder carcinoma; in G3 invasive carcinoma, approximately 50–70% are positive for *TP53* mutations.

RB protein is another key regulator of the cell cycle and ►LOH of the *RB1* locus is reported in 29–33% of bladder carcinomas, often observed in invasive carcinomas. Combination assays of RB and p53 protein are used to improve the accuracy of prognostic predictions.

Loss of chromosome 9 is the common genetic alteration in urothelial carcinomas. Approximately half of these carcinomas, all of the informative loci in both 9p and 9q demonstrate LOH. LOH of chromosome 9 is reported as high as 70% of bladder carcinomas more than pT1, and even 50% of G1 superficial carcinomas.

Promoter hypermethylation could be responsible for inactivation of genes which is called epigenetic alterations, and such inactivation can occur as a result of methylation or in combination with allelic loss and methylation. For example, promoter hypermethylation which encodes epithelial E-cadherin is reported to be associated with tumor recurrence.

Methylation and/or loss of the *CDH1* gene results in lack of E-cadherin, a cell-adhesion molecule. Reduced expression of E-cadherin is commonly observed in high grade G3 bladder carcinomas and CIS.

Loss of chromosome 9p and 9q are frequent early genetic events in the development of urothelial carcinomas, and involvement of chromosome 17p or the *TP53* locus is characteristic of invasive bladder carcinoma.

Molecular analysis including gene chip technology is now becoming a basic procedure in most laboratories; however, hard evidence of its benefit is still limited in the clinical setting. Genome-wide DNA analysis, using gene chips or complementary DNA arrays, are powerful tools for data mining; however, further statistical validation is required before these procedures are applied to the clinics for molecular staging of urothelial carcinoma.

Uterine fibroids; Fibromyomas; Fibromas; Myofibromas; Myomas

Definition

Uterine leiomyomata are benign tumors comprised of smooth muscle cells of the ►myometrium and of extracellular matrix components, such as collagen, proteoglycans and ►fibronectin. Commonly known as fibroids, uterine leiomyomata are the most prevalent pelvic tumor in women.

Characteristics

Clinical, Epidemiological, and Histological Characteristics. Uterine leiomyomata are symptomatic in ~20–25% of reproductive-aged women. However, the prevalence is likely to be much greater (>75%) as fibroids can be present but asymptomatic. Although uterine leiomyomata rarely (<0.1%), if ever, become malignant (►cell transformation), the symptoms are medically and socially significant and include prolonged and profuse uterine bleeding, pelvic pain, urinary incontinence, constipation, infertility, recurrent miscarriage and premature labor. Clinical diagnosis is typically made by physical examination and can be confirmed by imaging studies such as ultrasound. Small lesions, however, can go undetected.

Although leiomyomata primarily affect women during childbearing years, the only consistently curative therapy is ►hysterectomy. In fact, uterine leiomyomata are the most common indication for hysterectomy in the US, accounting for over 200,000 procedures, or more than one-third of procedures annually. Effective alternative treatment options are limited. For example, ►myomectomy is associated with a high rate of recurrence and medical therapies are not curative and are often ineffective. ►Uterine artery embolization (UAE) has been shown to be effective in reducing symptoms and tumor size and is less invasive than traditional surgical interventions; however, the effect on future fertility is uncertain. ►Magnetic resonance imaging-guided focused ultrasound surgery (MRgFUS), a new non-invasive thermoablative therapy that promises noninvasive, outpatient therapy, is not yet widely available and the long-term effects of the procedure are not known. Currently, non-surgical medical therapies are limited.

Histologically, uterine leiomyomata appear as whorled bundles of smooth muscle cells in well circumscribed masses. Generally, mitoses are rare and appear normal, which is consistent with the benign nature of these tumors. Uterine leiomyomata are classified by their location in the uterus. Tumors within the uterine wall are called intramural fibroids. Tumors located below the outermost uterine layer are termed subserosal fibroids. Alternatively, fibroids that expand toward the innermost uterine layer and distort the uterine cavity are termed submucosal fibroids. Subserosal and intramural locations comprise the majority (95%) of all leiomyomata; submucosal leiomyomata make up the remaining 5%. Tumor location and size correlate with symptoms such as bleeding, pelvic pain and infertility. For example, submucosal fibroids are more often associated with bleeding than are subserosal or intramural tumors.

Despite the major public health impact of uterine leiomyomata, little is known about their etiology. Cellular, molecular, cytogenetic and epidemiological studies have advanced our current understanding of fibroid biology.

Cellular characteristics. Until recently, the steroid hormones estrogen and progesterone were considered the most important regulators of leiomyoma growth. There is abundant evidence that sex steroids promote fibroid growth, including the clinical observations that fibroids grow in the presence of high levels of estrogen or progesterone, such as during the reproductive years or during treatment with synthetic progesterones; fibroids regress in the presence of low levels of estrogen

or progesterone, such as following menopause or during treatment with ►gonadotropin releasing hormone agonists (i.e. GnRHa) or with antiprogesterone agents (i.e. RU-486). Furthermore, fibroids have higher estrogen concentrations, bind more estrogen, have more ►estrogen receptors and progesterone receptors and convert ►estradiol (a more active form of estrogen) to estrone (a less active form of estrogen) more slowly than does normal myometrium. Other hormones, such as growth hormone and prolactin, are also thought to promote fibroid growth, but their roles are less well defined.

Growth factors, which are small proteins that affect cell growth, have been shown to mediate the growth-promoting effects of estrogen and to play an important role in the development of fibroid tumors. Potentially important factors in fibroid growth include ►transforming growth factor-β, basic ►fibroblast growth factor, ►epidermal growth factor, ►insulin-like growth factor and ►platelet-derived growth factor. Overall, estrogen, progesterone and growth factors likely promote tumor growth, but only after the initiation of tumor formation. This initiating event(s) remains largely unknown, although there is evidence to suggest there is a strong genetic component to fibroid development.

Molecular Genetic and Cytogenetic Characteristics. Uterine fibroids are considered to be independent monoclonal lesions as determined by X-inactivation studies using polymorphisms in either the glucose-6-phosphate dehydrogenase (G6PD) isoenzyme or the ►androgen receptor gene on the X chromosome.

Although 60% of fibroids studied cytogenetically have a normal karyotype, approximately 40% of fibroids have nonrandom chromosomal abnormalities. Analyses of these leiomyomata with abnormal karyotypes have revealed consistent cytogenetic rearrangements, which can be divided into several subgroups; ►chromosome translocation between chromosomes 12 and 14, trisomy 12, deletion on the long arm of chromosomes 3 or 7 and the short arm of chromosome 1, rearrangements of the short arm of chromosome 6, and rearrangements of chromosomes 1, 3, 10, 13, and X.

Translocation between chromosomes 12 and 14, t(12;14)(q14-q15;q23-q24), is the most common translocation in fibroids and occurs in approximately 20% of fibroids with karyotypic rearrangements. ►*HMGA2* (previously called ►*HMGIC*) is the critical gene on chromosome 12 involved in these translocations. Rearrangement of *HMGA2* is observed in many other ►mesenchymal tumors including angiomyxomas, breast fibroadenomas, endometrial polyps, hemangiopericytomas, lipomas (►adipose tumors), pulmonary chondroid hamartomas and salivary gland adenomas. However, the consistency of chromosome 14 as a translocation partner of chromosome 12 is notable in fibroids; chromosome 12 translocations in other mesenchymal tumors have a diverse number of partner chromosomes. *RAD51L1* on chromosome 14 has been identified to be involved in some fusion transcripts with *HMGA2*.

Rearrangements of the short arm of chromosome 6 (6p21) are present in fewer than 5% of karyotypically abnormal fibroids and include translocations with chromosomes 1, 2, 4, 10, and 14, as well as inversions and translocations with various other chromosomes. *HMGA1* (previously called *HMGIY*), a gene related to *HMGA2*, is involved in these rearrangements. Chromosome 6 abnormalities are also consistently present in other benign mesenchymal tumors such as lipomas, hamartomas, and endometrial polyps.

The HMGA genes play a role in cell growth. In general, the highest levels of *HMGA* expression are seen in tumor cells and during normal development in embryonic tissue, whereas expression is reduced or absent in adult tissues. Studies of chromosome 12 translocations in fibroids and other benign mesenchymal tumors have revealed various mechanisms of *HMGA2* dysfunction, including creation of fusion transcripts, truncation of *HMGA2*, disruption of *HMGA2* regulatory sequences, and creation of alternative splicing patterns. Interestingly, rearrangements within the coding region of *HMGA2* are frequently observed in lipomas, and rearrangements outside of the coding region are more common in fibroids. This suggests that dysregulation of *HMGA2* expression, not disruption of coding sequence, is a potential mechanism of fibroid growth.

Interstitial deletion of the long arm of chromosome 7, del(7)(q22q32), is present in approximately 20% of karyotypically abnormal fibroids as well as in other benign mesenchymal tumors, such as lipomas and endometrial polyps. Deletion mutations most often result in loss of gene function, and suggest the presence of a ►tumor suppressor gene in this area. Mapping projects have progressively narrowed the critical region, however none of the genes in this area have yet been shown to have a definitive role in the pathogenesis of the del(7q) subgroup of fibroids.

Other less common cytogenetic abnormalities in fibroids include trisomy 12 and rearrangements of chromosomes 1, 3, 10, 13, and X. In cases of trisomy 12, the presence of an extra copy of chromosome 12 may increase the level of *HMGA2* transcript and thus increase the gene product that is involved in fibroid growth.

Rearrangements of chromosome 1 frequently involve ring chromosome formation, as well as translocations with the short arms of chromosomes 2 and 6. Recently, fibroids with a specific deletion on chromosome 1 have been shown to exhibit gene transcription profiles similar to those of leiomyosarcomas, suggesting that subsets of fibroids may have differential potential to

progress to malignancy. In addition, attention has focused recently on rearrangements of chromosome 1 in fibroids since the gene, ►fumarate hydratase, was identified in the region 1q42-q44 and shown to be involved in two syndromes characterized by the development of fibroids. Fumarate hydratase is important in energy metabolism and also appears to act as a tumor suppressor. Cytogenetic analysis of fibroids with 1q42 rearrangements suggests that loss of fumarate hydratase may be important in the development of a subset of fibroids in women without inherited fibroid-related syndromes.

Rearrangements of chromosome 3 include insertions, long and short arm deletions and translocations with chromosome 7. To date, no candidate genes on chromosome 3 have been identified as having a role in fibroid growth or development. Rearrangements of chromosome 10 include loss of one copy of chromosome 10 (monosomy 10) and deletions affecting the long arm (especially band q22). *MORF*, a gene involved in chromatin remodeling, is disrupted in fibroids with translocations involving chromosome 10. Rearrangements of chromosome 13 include deletions and translocations. To date, no candidate genes on chromosome 13 have been identified as having a role in fibroid growth or development. Rearrangements of the X chromosome preferentially involve the region Xp11-p22 and include translocations with chromosomes 5 and 12, deletions, and inversions. Of interest, the region Xp11-p22 contains an *HMGA1*-like sequence, *HMGIYL1*, but aberrant expression of this gene in fibroids remains to be demonstrated.

In fibroids that are cytogenetically normal, genetic alterations that cannot be visualized by karyotype, such as point mutations, may be present. Genes that are differentially expressed in myometrium and fibroid cells include *WNT7A*, a gene involved in patterning in embryogenesis, and *CYP19*, which produces aromatase enzyme involved in estrogen metabolism. DNA polymorphisms that influence leiomyoma risk have been identified. Polymorphism are small sequence variations, often single nucleotide changes. They are commonly interpreted to be without, clinical significance, but, rarely, may result in a change in protein folding or in a change in codon for which there is limited tRNA availability. These changes in term could cause a change in clinical phenotype. The polymorphism of another steroid hormone metabolizing gene, *CYP17*, appears to increase risk of leiomyomata among black African women.

Even among karyotypically abnormal tumors, ~30–40% are mosaic with chromosomally normal cells. These chromosomally mosaic tumors also have been shown to be clonal by X-inactivation analysis as described above, suggesting that cytogenetic abnormalities may be secondary changes in tumor development and that other genetic changes may be primarily responsible for initial tumor growth in genetically susceptible cells.

Heritability and genetic epidemiological characteristics. A variety of epidemiological studies have assessed whether there might be a genetic basis for uterine fibroids, including ethnic predisposition, twin, and familial aggregation studies. For example, women of African origin experience an approximately threefold higher incidence of fibroids than women of other racial and ethnic groups, after adjustment for known risk factors, such as obesity and number of births, as well as socioeconomic status and access to health care. Identical twins have twice the rate for hysterectomy as compared to fraternal twins, which is consistent with the expected rates for a genetically influenced trait. In addition, fibroids are at least twice as common in women who have a first degree relative with fibroids than in women who have no relatives with fibroids. This increases about sixfold in women with early onset of fibroids (<45 years), an expected observation for a genetically influenced trait. Finally, two rare Mendelian disorders, Reed syndrome, characterized by fibroids in association with multiple cutaneous leiomyomata, and hereditary leiomyomatosis and renal cell cancer (HLRCC), a cancer syndrome characterized by fibroids and papillary renal cell carcinoma, are known to be inherited as autosomal dominant traits with reduced penetrance.

Together, these observations indicate that fibroids have a potentially significant heritable component to their development. This genetic predisposition is likely to involve a complex interaction of multiple genes. Future genome-wide studies among sister pairs affected by fibroids may identify susceptibility genes for uterine fibroids.

Overall, cytogenetic analyses, together with molecular clonality and epidemiological studies, suggest that karyotypic abnormalities in fibroids may be important in the pathobiology of these tumors and may represent secondary somatic changes in genetically susceptible cells. The susceptibility gene(s) that are crucial for fibroid pathogenesis remain mostly to be identified. Ultimately, understanding the mechanisms of fibroid tumor development could lead to innovative, less-invasive treatment options for this significant women's health problem.

Synonyms

Leiomyomata; Fibromyoma; Myoma; Fibroids

Definition

Uterine leiomyomas are benign neoplasms, composed of smooth muscle cells with variable amounts of fibrous stroma.

Characteristics

Leiomyomas are usually found in the myometrium of the uterine corpus; however, they can also originate in the smooth muscle organs. They are composed of smooth muscle and extracellular matrix (collagen, proteoglycan, fibronectin).

Incidence

Uterine leiomyomas are the most common neoplasms of the female pelvis. They occur in ~20–25% of women of reproductive age, but careful pathologic inspection of the uterus reveals that they are present in more than 80% of women. The neoplasm is more frequently found in the fourth and fifth decades of life and most commonly in patients of African descent. Age-standardized rates by race were 8.9 new cases per 1,000 woman per year for Caucasian women and 30.6 new cases per 1,000 woman per year for black women. Hispanic and Asian women had rates similar to those seen in Caucasian women: 11.0 and 8.0 new cases per 1,000 woman per year, respectively. There is an increased risk of leiomyomas in women with greater ►body mass index (BMI), but risk is decreased in women who smoke, who have given birth or who use oral contraceptive pills. Leiomyomas rarely occur before menarche and typically regress after menopause, indicating ►estrogen as a promoter of growth. Rarely, malignant changes may occur, usually in postmenopausal women. The most common warning sign is rapid enlargement of a ►fibroid with definitive diagnosis usually made at the time of surgery.

Gross Features

Uterine leiomyomas may have solitary nodule or multiple nodules ranging in size from microscopic to huge tumors weighing more than 100 lb. They are firm and well demarcated from the surrounding myometrium. On sectioning, the tumor bulges from the surface and the pseudocapsule, produced by compression of adjacent myometrium, is readily apparent. The surface is smooth and glistening white with a whorled, fasciculated pattern. Variations in this appearance include hemorrhage, hyalinization, hydropic, myxoid or mucinous degeneration, true ►necrosis and calcification. These variations are important because they may also be seen in ►leiomyosarcoma. Leiomyomas are characterized by their location in the uterus:

- Subserous leiomyoma (just under the uterine serosa)
- Interstitial leiomyoma (within the thick myometrium)
- Submucous leiomyoma (just under the uterine mucosa)

Microscopic Features

Histologically, uterine leiomyomas are bundles of interlacing smooth muscle fibers with varying amounts of collagenous fibrous tissue and few blood vessels. The nuclei have a uniform appearance, mitotic figures are infrequent, and there is never nuclear atypia. The variants of uterine leiomyoma listed in the International Society of Gynecological Pathologists' Classification are:

- Cellular leiomyoma
- Epithelioid leiomyoma
- Bizarre leiomyoma
- Lipoleiomyoma

Symptoms

It is estimated that only 10–40% of leiomyomas are symptomatic. Patients may complain of a self-detected mass, abnormal uterine bleeding, pelvic pain or pressure related symptoms.

Bleeding is the most common presenting symptom in uterine leiomyomas. The most frequent presentation includes the development of progressively heavier menstrual flow that lasts longer than the normal duration (menorrhagia). Although menorrhagia can occur in any women with leiomyomas, women with submucous leiomyomas appear to be particularly prone to this complication. Blood loss from this type of menstrual bleeding may be heavy enough to contribute to iron-deficiency anemia.

Another common presenting symptom is pelvic pressure. This is caused by slowly enlarging leiomyomas,

which may attain a massive size. Pressure on the bladder produces urinary frequency, urgency and rarely and the inability to void. Constipation may result from pressure on the rectum. Pressure of the uterine leiomyomas on the ureters may cause hydroureter and, on occasion, hydronephrosis.

Acute onset of pain in previously asymptomatic leiomyomas raises the possibility of necrosis, inflammation or torsion of a pedunculated subserous leiomyoma. Prolapse of submucous leiomyoma may present as intense cramping pain, often accompanied by discharge or bleeding. Pain in the low back or legs may reflect alterations in body posture or pressure on lumbosacral nerve trunks.

Uterine leiomyomas can also be associated with other kinds of reproductive dysfunction, including recurrent miscarriage, infertility, premature labor, fetal malpresentation and other complications of labor.

Diagnosis

The diagnosis of such tumors is usually made by the pelvic examination. A leiomyoma may be suspected based on a bimanual examination that reveals an enlarged, firm, nontender and irregularly shaped uterus. Ultrasonography is the most common method of confirming the diagnosis. A combination of transabdominal and transvaginal ultrasonography should provide information regarding uterine volume, the number of leiomyoma, their location relative to the endometrial stripe, and evaluation of the adnexa. Of other available imaging techniques, magnetic resonance imaging (MRI) may prove to be the most useful but does not improve the findings seen on ultrasonography and has much higher costs.

Treatment

The majority of patients with uterine leiomyomas do not require treatment. If the tumors are stable and slow growing, an annual follow-up including an optimized symptom control is a viable option. Symptomatic patients should usually be offered a trial of conservative management before considering surgery.

►Gonadotropin-releasing hormone (GnRH) agonists are analogs of gonadotropin-releasing hormone. With continuous administration, they induce a hypoestrogenic pseudomenopausal state. Because uterine leiomyomas are estrogen-dependent benign tumors, this causes shrinkage of these tumors and of the myometrial mass. In addition, treatment with a GnRH agonist induces amenorrhea, allowing women with menorrhagia-induced anemia to increase iron stores and hemoglobin concentrations leading to a technically easier surgery with markedly diminished blood loss. But once the treatment is stopped, the leiomyoma tends to regrow to pretreatment size. The major use of GnRH agonists is as a preoperative treatment to facilitate surgical procedures, either myomectomy or hysterectomy. This class of drug cannot be used long term (>6 months) because of the attendant risks of prolonged hypoestrogenism, such as osteoporosis and cardiovascular disease. Combinations of GnRH agonists and low doses of estrogen and progesterone (that is, "add-back" regimens) can minimize the adverse hypoestrogenic effects caused by GnRH agonist treatment.

Androgenic agents (danazol, gestrinone) and progestins (medroxyprogesterone acetate, depomedroxyprogesterone acetate, norethindrone) have also been used to minimize uterine bleeding in women with uterine leiomyomas. However, these kinds of medication do not consistently decrease uterine or leiomyoma volume and their mechanism of action is thought to be the induction of endometrial atrophy. If there is significant endometrial cavity distortion by interstitial or submucous leiomyomas, these agents are often not successful in controlling menorrhagia, because the excessive bleeding is usually related to profound anatomic and vascular distortion.

Hysterectomy is considered to be the definitive treatment for uterine leiomyoma in symptomatic women who have completed childbearing. If the tumors are small, the hysterectomy may be done vaginally, particularly if there is associated pelvic relaxation. The American College of Obstetricians and Gynecologists (ACOG) criteria for hysterectomy for uterine leiomyoma are as follows:

- Presence of 1–3 asymptomatic leiomyomas of palpable size abdominally and if they are a concern to the patient.
- Excessive uterine bleeding:
- Profuse bleeding with flooding or clots or repetitive periods lasting more than 8 days
- Anemia, due to acute or chronic blood loss
- Pelvic discomfort caused by myomas:
- Acute and severe pain
- Chronic lower abdominal or low back pressure
- Bladder pressure with urinary frequency not due to urinary tract infection

When women want to preserve childbearing potential, a ►myomectomy may be performed. Myomectomy has a higher complication rate than hysterectomy. These complications include excess intraoperative blood loss, risk of postoperative hemorrhage, adhesions and bowel obstruction. It is important to inform the patients that there is a 25–50% recurrence of leiomyomas after myomectomy. Therefore, a significant number of women undergoing a myomectomy will require a subsequent hysterectomy. Preoperative criteria for myomectomy published by ACOG are as follows:

- Failure to conceive or recurrent pregnancy loss
- Presence of leiomyomas of sufficient size or specific location to be a probable factor

- No other likely explanation for the failure to conceive or for recurrent pregnancy loss

The use of endoscopic resection will be more widely used for the surgical management of uterine leiomyomas. This technique causes less patient discomfort, less bleeding and has a shorter recovery time. Hysteroscopic resection of submucous leiomyomas can be done using a resectoscope with unipolar cautery loops or with a neodymium:yttrium-aluminium garnet laser (Nd:YAG). The use the Nd:YAG laser has its problems and the operating surgeon must have expertise not only with the hysteroscope but also with the intrauterine laser. Laparoscopic myomectomy and laparoscopically assisted vaginal ►hysterectomy (LAVH) are safe and reliable treatment options, but can be difficult to perform technically and are not available universally.

Uterine artery ►embolization is a new, investigational treatment of leiomyomas. The method involves the catheterization of both uterine arteries using a femoral arterial approach. Preliminary studies in women who had large, symptomatic leiomyomas have shown significant improvement in their symptoms. More trials need to be carried out to confirm the efficacy and safety of this surgical treatment.

Cytogenetic Changes

Evidence from glucose-6-phosphate dehydrogenase isoenzyme analysis and from polymorphism analysis in the androgen receptor demonstrate that uterine leiomyomas are monoclonal and that each tumor within the same uterus arises independently. Although the classic paradigm suggests that the sex steroid hormones (►estrogen and ►progesterone) are the only important modulators of leiomyoma growth and transformation, it is now clear that chromosomal abnormalities play a role in the pathogenesis of these neoplasms. In uterine leiomyomas, non-random chromosomal changes such as translocations, duplications and deletions have been identified in ~50% of tumors studied by cytogenetic analysis. The most frequent abnormalities are translocations between chromosomes 12 and 14, t(12;14)(q14–15;q23–24) and deletions on chromosome 7, del(7)(q22–32). The frequencies of these abnormalities are ~20% and 15%, respectively.

Recently, the ►high-mobility group protein gene HMGIC was identified as the target gene affected by the 12q14–15 aberrations. HMGIC is an architectural transcription factor in the nuclear scaffold, a function critical for the correct assembly of stereo-specific transcriptional complexes. The frequent rearrangement of the HMGIC gene in uterine leiomyomas suggests that this gene is directly involved in the aberrant growth control observed in these tumors. Gene-targeting experiments indicate that HMGIC plays an important role in mammalian growth and development, since inactivation of the murine HMGIC gene results in the pygmy phenotype. In uterine leiomyomas, the mitochondrial aldehyde dehydrogenase (ALDH2) gene in 12q24.1, the recombinational repair gene RAD51B in 14q23–24, and the cytochrome c oxidase subunit VIc (COX6C) gene in 8q22–23 were identified as translocation partners to HMGIC. Deletions of chromosome 7 imply that tumor enlargement in some leiomyomas is probably due to loss of tumor suppressor genes.

UV Radiation

Béatrice Secretan
IARC/WHO, Group Carcinogen Identification and Evaluation, Lyon Cedex, France

Definition

UV radiation belongs to the ►non-ionizing radiation part of the electromagnetic spectrum and spans between 100 and 400 nm. Conventionally UV radiation is further divided into three regions: UVA (>315–400 nm), UVB (>280–315 nm) and UVC (>100–280 nm).

Characteristics

Sunlight consists of visible light (400–700 nm), infrared radiation (>700 nm) and UV radiation. The quality (spectrum) and quantity (intensity) of sunlight are modified during its passage through the atmosphere. Solar UV radiation at ground level represents about 5% of the total solar energy; the radiation spectrum is between 290 and 400 nm, and is comprised of approximately 95% UVA and 5% UVB; UVC is completely filtered out by the Earth's atmosphere.

The spectrum of solar UV radiation to which an individual may be exposed varies with latitude, altitude, ground reflectance, season, time of day, weather, stratospheric ozone and other atmospheric components such as air pollution. For most individuals, solar radiation is the major source of exposure to UV radiation. ►Sunbeds and sunlamps used for tanning purposes are the main source of deliberate exposure to artificial UV radiation. Solar radiation is classified as a Group 1 carcinogen by the International Agency for Research on Cancer.

Cancers of the Skin

Skin cancer (see ►skin carcinogenesis) is the most frequent form of cancer worldwide. Skin cancers can be classified into three major histological types: ►malignant cutaneous melanoma and non-melanoma skin cancers, which comprise ►basal-cell carcinoma and ►squamous-cell carcinoma. Basal-cell carcinoma, which represents 70% of all skin cancers, develops from the basal cells of the epidermis, grows locally and never metastasizes. Squamous-cell carcinoma, which represents 20% of all skin cancers, develops from the epithelial cells of the epidermis, has a more aggressive behavior, can metastasize, but is rarely fatal. Cutaneous melanoma develops in the melanocytes within the basal layer of the epidermis; it is the least common form of skin cancer, but is the most serious as it readily metastasizes and is only curable if detected at an early stage.

Epidemiological Evidence of the Carcinogenic Potential of UV Radiation

Host Factors

There is a considerable range of susceptibility of the human skin to UV radiation. Susceptibility to UV radiation is closely related to pigmentary traits, and subjects who have the following characteristics are at increased risk for developing skin cancer (melanoma, squamous-cell carcinoma and basal-cell carcinoma):

- Red hair, followed by blond hair, followed by light brown hair.
- Skin phototype: subjects with a skin phototype I or II (always burn and never tan or always burn before developing a light tan) have a much higher risk for skin cancer than subjects with a skin phototype IV (never burn and always develop a deep tan). Intermediate risk categories are subjects who sometimes burn and always develop a tan (skin phototype III). Subjects with skin phototypes V and VI belong to populations with natural brown or black skin, and are resistant to sunlight.
- Freckles (ephelides) on the face, arms or shoulders. The risk for non-melanoma skin cancer increases with increasing sensitivity to freckling.
- Skin color: pale color, followed by increasing depth of pigmentation.
- Eye color: blue, followed by grey/green eyes, then by brown eyes.
- For melanoma, a large number of common naevi and the presence of a typical naevi.

Subjects with red hair, many freckles, fair skin and who never tan are at particularly high risk for skin cancer.

UV Radiation as an Environmental Risk Factor

The body of evidence from epidemiological studies indicates that there is a causal relationship between exposure to solar radiation and skin cancer.

1. These cancers affect more specifically individuals with fair skin.
2. These cancers occur predominantly on the parts of the body most commonly exposed to the sun such as the face, ears, neck and forearms; however, the distribution of melanomas and basal-cell carcinomas is not as closely related to the distribution of exposure to the sun as that of squamous-cell carcinomas.
3. There is a strong inverse relationship between latitude of residence and the incidence of and mortality from skin cancer.
4. There is a positive relationship between measured or estimated ambient UV radiation and the incidence of and mortality from skin cancer.
5. Migration to a country with high solar irradiation (e.g. Australia) is associated with an increase in risk.
6. There is a dose–response relationship between total cumulative dose and risk for skin cancer, although for melanoma this is not the only determining factor (see below).
7. Actinic keratosis, a sun-induced skin damage, is a precursor lesion of squamous-cell carcinoma.
8. Treatment with PUVA therapy (UVA radiation) increases the risk for melanoma and squamous-cell carcinoma.

However, the type and conditions of exposition (chronic or intermittent exposure, high exposure of short duration, exposure at young age) influence the type of skin cancer induced.

- Squamous-cell carcinoma develops at the sites of the body that receive chronic exposure; in contrast, basal-cell carcinoma and melanoma are associated with intermittent exposure.
- The risk for squamous-cell carcinoma is cumulative; consequently, people who work outdoors tend to have a higher incidence of squamous-cell carcinoma.
- For melanoma, the cumulative dose is not the only determining factor. In particular, the risk is correlated with ambient UV radiation at the place of residence during childhood. In fact, exposure to UVB during childhood is a necessary event for the development of melanoma.
- The risk for melanoma is inversely correlated with intense and continuous exposure to UV.
- Squamous-cell carcinoma is induced by UVB radiation. The wavelengths primarily involved in the development of melanoma and of basal cell carcinoma have not been firmly established.

Intraocular Melanoma

The results of studies on exposure to solar radiation and ocular melanoma would suggest that there is an association, but the data are inconsistent and their interpretation is difficult.

Biological Effects of UV Radiation Relevant to Carcinogenesis

DNA Damage

The biological effects of UV radiation vary enormously with wavelength. In addition, there is an estimated 1,000-fold variability in DNA repair capacity after exposure to UV radiation in humans (►photocarcinogenesis).

UVB is a complete carcinogen that is absorbed by DNA and can damage DNA directly. The DNA damage induced by UVB irradiation typically includes the formation of ►cyclobutane pyrimidine dimers (CPD) and 6–4 photoproducts. If these lesions are not repaired correctly, mutations are likely to occur. These mutations are C ⇒ T and CC ⇒ TT ►transversions, commonly referred to as "UVB fingerprint" or "UVB signature" mutations. UVB can also induce oxidative stress and the formation of singlet oxygen species (O_2^-), and can thus also cause DNA damage indirectly.

UVA is not readily absorbed by DNA and thus has no direct impact on DNA. Instead, UVA induces DNA damage indirectly through the absorption of UVA photons by ►chromophores, with the formation of ►reactive oxygen species (such as singlet oxygen and hydrogen peroxide [H_2O_2]) that can transfer the UVA energy to DNA via mutagenic oxidative intermediates such as 8-hydroxydeoxyguanosine (►8-OHdG). DNA damage by UVA radiation typically consists of T ⇒ G transversions, called "UVA fingerprint" or "UVA signature" lesions. The possibility that indirect DNA damage induced by UVA could play a major role in the development of melanoma is underlined by reports showing that patients who are genetically highly susceptible to oxidative agents develop multiple cutaneous melanomas.

Cellular Damage

Both UVA and UVB lead to altered expression of ►p53 and ►bcl-2 proteins, which may play an important role in regulating UV-induced apoptosis. Irradiation of melanocytes with UVA or UVB leads to the alteration of different intracellular proteins, which suggests that UVA and UVB may initiate the development of melanoma via separate intracellular pathways.

Differential Effects of UVA and UVB

UVA radiation is of longer wavelength and is therefore weaker but more penetrant. In humans, UVA penetrates deeper into the skin than UVB. The basal layer of the epidermis receives 50% of the total UVA and 10% of the total UVB to which the skin is exposed. Since solar radiation at ground level comprises a maximum of 5% UVB, the basal cells receive approximately 100 times more UVA than UVB from exposure to the sun. In contrast, the induction of an erythemal response requires 100–1,000 times more UVA than UVB.

As a result, UVA fingerprint mutations are mostly detected in the basal germinative layer of these lesions, whereas UVB fingerprint mutations are found predominantly more superficially in these lesions. In addition, UVB produces numerous immediate mutations whereas UVA produces fewer immediate mutations and more delayed mutations than UVB.

Consequently, squamous-cell carcinoma is clearly associated with the carcinogenic effects of UVB. In contrast, UVA could play a significant role in the causation of melanoma and basal-cell carcinoma.

Changes in the Immune Response

Both UVA and UVB can affect the immune system, but the two types of radiation seem to act differently. UVB can induce immune suppression at both local and systemic levels whereas UVA does not suppress the systemic immune response. In addition, UVA radiation may affect the local immune response differently from UVB.

Drug-Induced Photosensitivity

A variety of commonly used drugs such as diuretics, antibiotics and non-steroid anti-inflammatory drugs (►NSAIDs) increase cutaneous sensitivity to UV radiation, and are therefore predicted to increase the risk for skin cancer. Most drugs have a phototoxic rather than a photo-allergenic effect. Topical agents that have a

phototoxic effect include plant-derived photosensitizers (psoralens) such as bergamot, which is widely used in perfumed products.

Cancer Preventive Effects of UV Radiation

Several ecological studies have suggested that exposure to UV radiation may reduce the incidence of or the mortality from certain cancers (breast, colon, prostate) and of lymphomas. UV radiation induces the formation of vitamin D from its precursor in the body. Daily exposure of the face, forearms and hands to moderate sunlight for 10–15 min is generally sufficient to maintain vitamin D levels. Any vitamin D deficiency should be alleviated through dietary supplements.

Indoor Tanning and Cancer

The UV spectrum of indoor tanning facilities has varied over the years. The first fluorescent tubes designed for tanning purposes emitted up to 5% of the UV output as UVB. As a result of the growing concern about the carcinogenic potential of UVB, the UV output was then shifted towards UVA. Lamps that produce large quantities of long-wave UVA (>335–400 nm) per unit of time were marketed; these lamps can emit up to 10 times more UVA than that present in sunlight. More recently tanning appliances have been equipped with fluorescent lamps that achieve a balance between total UV, UVB and UVA similar to tropical sun.

The UV output and spectral characteristics of tanning appliances vary considerably as a result of differences in tanning appliance design (e.g. type of fluorescent tubes, materials that compose filters, distance from canopy to the skin), tanning appliance power and tube ageing.

A ►meta-analysis of epidemiological studies showed that ever-use of sunbeds is positively associated with an increased risk for melanoma (relative risk, 1.15; 95% confidence interval, 1.00–1.31), and there is a prominent and consistent increase in risk for melanoma in people who first used sunbeds in their twenties or teen years (relative risk, 1.75; 95% confidence interval, 1.35–2.26). Limited data suggest that the risk for squamous-cell carcinoma is similarly increased after first use as a teenager (relative risk, 2.25; 95% confidence interval, 1.08–4.70). Data also suggest detrimental effects from the use of sunbeds on the skin's immune response and possibly the induction of ocular melanoma.

Radiation emitted by lamps used in tanning appliances (mainly UVA) significantly increase the carcinogenic effect of broad-spectrum UV radiation, which indicates the possibility of a complex interplay between UVA and UVB radiation in human skin. The few studies that have addressed the biological changes in the skin induced by indoor tanning have shown that they are similar to those induced by sunlight.

Uveal Melanoma

Justis P. Ehlers, J. William Harbour
Department of Ophthalmology and Visual Sciences, Washington University School of Medicine, St. Louis, MO, USA

Synonyms

Choroidal melanoma; Ciliary body melanoma; Intraocular melanoma

Definition

Uveal melanoma is an intraocular melanocytic neoplasm that originates from within the ►uveal tract of the eye. The tumor is thought to arise most frequently from melanocytes within a nevus, but may also occur de novo. It is the most common primary intraocular malignancy in adults.

Characteristics

Epidemiology

Worldwide, the incidence of uveal melanoma is highest in northern Europeans. Uveal melanoma has an incidence rate of around 6/1,000,000 in the United States. Similar to cutaneous melanoma, the incidence of uveal melanoma is much higher in whites than nonwhites. There is a slight male preponderance. The average age at diagnosis is 50–60, but any individuals of any age can be affected.

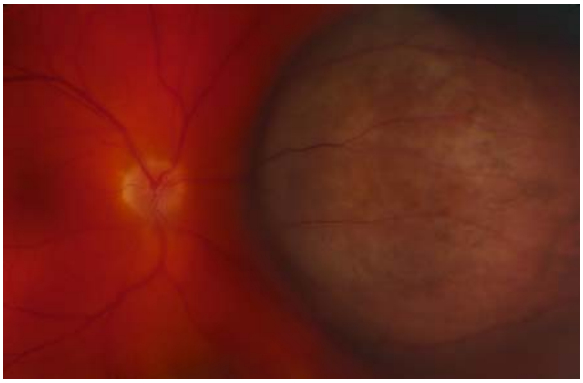
Risk Factors

Certain patient characteristics have been associated with increased risk of uveal melanoma, including light eye color, light skin color, and ability to tan. Individuals with ocular and ►oculodermal melanocytosis (nevus of Ota) are at increased risk of uveal melanoma. Interestingly, although these conditions can occur in any race, the increased rate of uveal melanoma appears to be primarily in whites.

Clinical Diagnosis

Signs and Symptoms

Uveal melanoma can be asymptomatic or associated with a variety of symptoms including blurred vision, visual field defects, distorted vision, flashes and floaters. On clinical examination, uveal melanomas can range in pigmentation from light tan to dark brown, and they are typically dome- or mushroom-shaped (Fig. 1). Features associated with uveal melanoma on fundus examination include orange lipofuscin pigmentation on the tumor surface, exudative retinal detachment, and "collar button" formation where the tumor herniates through the overlying Bruch's membrane, which can cause intraocular hemorrhage. Ciliary body melanomas are located near the crystalline lens and can induce subluxation, cataract formation, and astigmatism (from tilting the lens). Dilated episcleral feeder vessels, so-called "►sentinel vessels," can be associated with an underlying ciliary body melanoma. In larger tumors, neovascular glaucoma and necrosis may occur. Pain may be present if these complications develop. Clinical features associated with increased risk of metastasis include advanced patient age, increased tumor size, and ciliary body involvement.



Uveal Melanoma. Figure 1 Elevated choroidal melanoma adjacent to the optic nerve.

Diagnostic Modalities

Ophthalmoscopy remains the mainstay of diagnosis. Several adjunctive modalities can be used to further characterize the tumor and aid in diagnosis for ambiguous cases. Both ►A-scan and B-scan ultrasonography are critical for the complete evaluation of a suspected uveal melanoma. A-scan provides a single dimensional image characterizing the echogenic interfaces within the tumor. This provides an accurate way to measure the tumor height as well as confirming the typical homogenous characteristics of uveal melanoma. B-scan provides a two-dimensional image that allows for a cross-sectional view of the tumor. Most tumors are dome- or mushroom-shaped, the latter being nearly pathognomonic for uveal melanoma (Fig. 2).

►Fluorescein angiography is also a useful adjunct in to further characterize the tumor exclude other mimicking disorders. Common angiographic findings include early hyperfluorescence, pinpoint leakage and occasionally a double circulation pattern from vessels within the tumor (Fig. 3).

Fine needle aspiration biopsy (FNAB) is required in about 5% of intraocular tumors for the purpose of confirming the diagnosis of a melanocytic tumor. In the setting of an experienced surgeon and cytopathologist, FNAB can yield a diagnosis in over 90% of cases. In addition, FNAB is increasingly being used to assess the metastatic potential of melanomas using molecular tools described below.

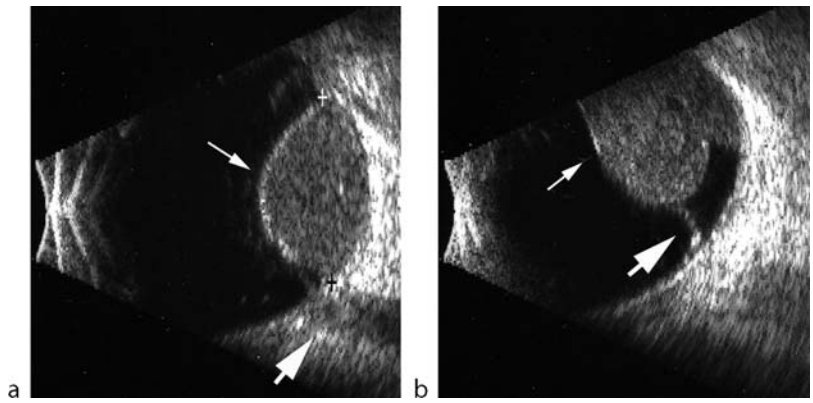
Other imaging modalities such as CT and MRI may provide further information in selected settings, such as when orbital or optic nerve invasion of an intraocular tumor is suspected.

Treatment Options

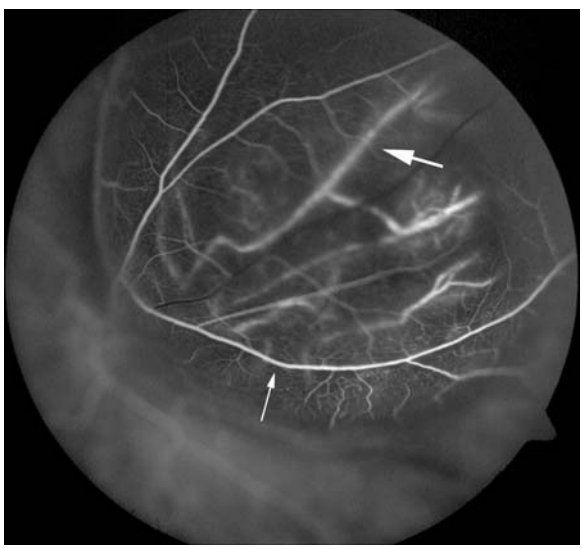
Several treatment options exist for uveal melanoma. The appropriate choice is based on patient age, health and preference, and on tumor characteristics.

Observation may be appropriate for small lesions where the diagnosis is in doubt, and in elderly or infirmed individuals with limited life expectancy. Choroidal melanocytic tumors less than about 3 mm in thickness and less than about 12 mm in diameter are usually considered suspicious nevi until growth is documented, at which point treatment is usually recommended. Serial fundus photography and ultrasonography are used to detect tumor growth.

►Transpupillary thermal therapy (TTT) has been advocated as primary therapy for smaller tumors and as an adjunctive treatment following radiotherapy. In



Uveal Melanoma. Figure 2 Ultrasound (B-Scan) of dome-shaped (a) and mushroom-shaped (b) melanoma. Thin arrows identify the tumor; thick arrows identify (a) the optic nerve and (b) the detached retina.



Uveal Melanoma. Figure 3 Fluorescein angiogram showing double circulation. The thin arrow shows a normal retinal arteriole; the thick arrow shows the intrinsic tumor vessel.

recent years, enthusiasm for primary TTT has waned as longer follow-up has revealed a high rate of local tumor recurrence. Most centers now reserve primary TTT for small tumors in patients who are unable to undergo surgery. The most widespread use of TTT today is as an adjunctive treatment following plaque or charged particle radiotherapy in tumors that are at high risk for recurrence, such as those located adjacent to the optic disc. In this setting, TTT appears to be effective at hastening the regression and reducing local recurrence risk compared to radiotherapy alone. Complications from TTT include retinal vascular occlusion, retinal fibrosis, retinal neovascularization, cystoid macular edema, retinal tears, retinal detachment and vitreous hemorrhage. These complications are much more common with primary TTT than with adjunctive TTT.

►Enucleation was once the mainstay of treatment for uveal melanoma. Today, however, enucleation is usually reserved for tumors that are very large or have demonstrated extensive local invasion (e.g., transscleral or optic nerve invasion). Enucleation may also be preferred in eyes with poor visual potential. At the time of enucleation surgery, a spherical implant is placed in the orbit and attached to the extraocular muscles to imitate the movement of the eye. Subsequently, the patient is fit with a prosthetic eye, which is a shell painted to match the other eye.

Plaque radiotherapy is the most common treatment for uveal melanoma. This treatment approach allows a large dose of radiation (85–100 Gy) to be delivered to the tumor over 4–5 days while minimizing radiation toxicity to the rest of the eye and surrounding structures. Various radioisotopes have been used, including ^{125}Iodine, ^{106}Ruthenium, ^{103}Paladium, but ^{125}Iodine is the most common choice. The medium tumor trial of the Collaborative Ocular Melanoma Study compared ^{125}Iodine plaque radiotherapy to enucleation and found no difference in survival. The plaque is surgically implanted on the scleral surface of the eye overlying the tumor. Treatment outcomes are significantly enhanced when intraoperative ultrasound is used to verify accurate placement of the plaque over the tumor. Local tumor control following plaque radiotherapy is greater than 90% in most centers. Complications include cataract, radiation retinopathy and papillopathy, neovascular glaucoma, vitreous hemorrhage, and rarely scleral necrosis. Incidence and severity of these complications are dose and location dependent.

Focal delivery of high dose radiotherapy can also be achieved with ►proton beam radiotherapy and other forms of charged particle therapy. A surgical procedure is required to place tantalum rings on the scleral surface overlying the tumor to direct the charged particle beam. Local tumor control appears to be slightly better with charged particle therapy than with plaque radiotherapy, especially in centers that do not use intraoperative

ultrasonography to localize their plaques, but complications are also more common with charged particle therapy. Complications include eyelash loss, dry eye, cataract, neovascular glaucoma, and radiation retinopathy and papillopathy. Newer radiosurgery techniques such as Gamma Knife and CyberKnife are being evaluated for their role in uveal melanoma.

Local tumor resection was once a popular alternative treatment that avoided radiotherapy and its attendant complications. However, as more experience has been obtained, it has become clear that local resection has its own set of serious side effects, including a high rate of local tumor recurrence, retinal detachment, vitreous hemorrhage and proliferative vitreoretinopathy. Today, local resection is usually reserved for selected tumors with small basal diameter and anterior location. There are many variations on this surgical technique, but most involve the creation of a partial thickness scleral flap, through which the tumor is resected en bloc. Adjunctive radiotherapy is often used postoperatively.

Pathology

The Callendar classification is the most widely accepted histopathologic grading system for uveal melanoma and is based on the spindle and epithelioid cell types (Fig. 4). Spindle A cells have narrow nuclei with a longitudinal fold. Spindle B cells have larger nuclei with a defined nucleolus. Epithelioid cells are larger and polygonal in shape with large nucleoli. Uveal melanomas are usually described as predominantly spindle, epithelioid, or mixed. Spindle cells portend a better prognosis, and epithelioid cells a worse prognosis. Other pathologic features that have been associated with worse prognosis include transscleral extension, increased number of mitotic figures, increased nucleolar area, and presence of looping extracellular matrix patterns.

Systemic Evaluation and Metastasis

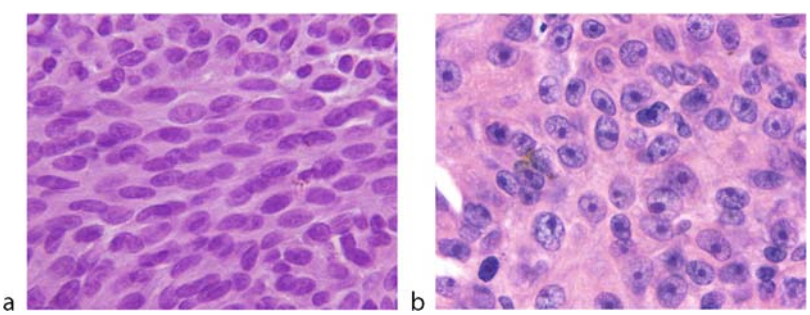
Metastatic uveal melanoma involves the liver in approximately 90% of cases. Other sites include lung, subcutaneous tissues, and bone. Systemic evaluation and monitoring should include liver function tests (especially lactate dehydrogenase, alkaline phosphatase, and gamma-glutamyl transpeptidase), and imaging of the abdomen with CT or MRI. Median survival after clinical diagnosis of metastasis is about 5–7 months. Metastatic disease limited to the liver can occasionally be treated with partial hepatectomy or hepatic arterial chemoembolization. Systemic chemotherapy and immunotherapy have met with limited success.

Prognostic Factors

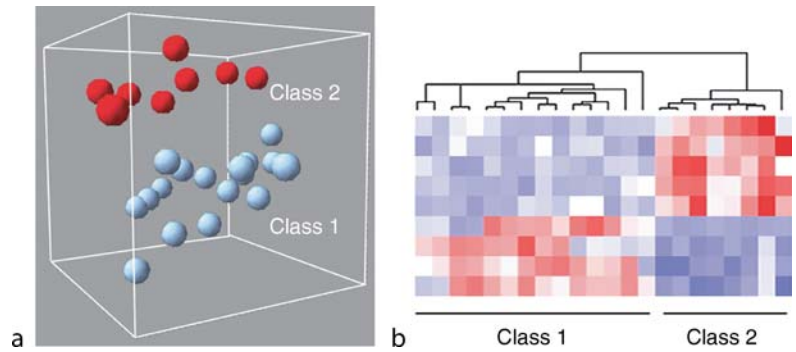
As mentioned in the previous sections, there have been many clinical and pathologic features of uveal melanoma that are statistically associated with metastasis. However, none of these features has demonstrated predictive accuracy sufficient for use in making treatment decisions in individual patients. This has led many researchers to investigate genetic features of the primary tumor that may predict metastasis with greater accuracy. The chromosomal alteration that is most closely linked to metastasis is loss of one copy of chromosome 3 (monosomy 3), which is found in about half of primary uveal melanomas. Various techniques have been employed to assess chromosome 3 status in clinical settings, including karyotype analysis, comparative genomic hybridization, fluorescence in situ hybridization, and loss of heterozygosity for polymorphic markers across the chromosome. More recently, ►microarray gene expression profiling has identified two molecular subgroups of primary uveal melanoma, referred to as class 1 and class 2 (Fig. 5). Virtually all of the metastatic deaths occur in class 2 tumors. The class 2 gene expression signature is closely linked to monosomy 3, but there are some exceptions, and the former outperforms the latter in terms of predictive accuracy. Consequently, the gene expression-based classifier has been refined to require less than ten genes and a small number of tumor cells that can be obtained by FNAB. Clinical studies are now underway to determine the best combination of molecular testing approaches for stratifying patients based on metastatic risk for inclusion in clinical trials and implementation of preemptive, adjuvant systemic therapy.

Systemic Therapy and Future Directions

Recent work on tumor doubling times, disease-free interval and metastasis strongly imply that those uveal



Uveal Melanoma. Figure 4 Uveal melanoma histopathology showing spindle cells (a) and epithelioid cells (b).



Uveal Melanoma. Figure 5 Gene expression profiling is the most accurate predictor of metastasis currently available for uveal melanoma. (a) Unsupervised principal component analysis showing clustering of tumors (spheres) in to class 1 (blue) and class 2 (red), with low and righ risk for metastasis, respectively. (b) Heatmap with supervised analysis with only nine discriminating genes (rows), which classify all tumors correctly (columns). Since a small number of genes can be used, this test is being adapted for use as a clinical test that can be applied to enucleation and biopsy samples.

melanomas that have the capacity to disseminate (e.g., class 2 tumors) have already done so prior to ocular treatment in most cases. This would explain why successful local treatments have not been associated with a demonstrable improvement in survival. Consequently, it may only be possible to improve survival in uveal melanoma by identifying high risk patients and treating them preemptively with systemic therapies that delay or prevent the development of clinical metastasis by maintaining micrometastases in a dormant state. The centerpiece of such a preventative strategy will be the newly emerging molecular prognostic tests described here. This strategy will also require the identification of new therapeutic approaches targeting the micrometastatic cell population.

Vaccine Therapy

Definition

Is an active, specific immunotherapy (ASI) mediated by stimulating the host's immune system to generate antibodies and/or immune cells (►cytotoxic T-cells) specifically against the target antigen to destroy a tumors or infectious microorganisms. A therapeutic (treatment) vaccine is given after the onset of disease and is intended to reduce or arrest disease progression. A preventive (prophylactic) vaccine is intended to prevent the initial onset of disease. Tumor vaccines include both native and artificial (mimic) tumor-associated antigens or tumor markers.

►Immunotherapy

Valproic Acid

Marta Kostrouchova
Laboratory of Molecular Biology and Genetics, Institute of Inherited Metabolic Disorders, 1st Faculty of Medicine, Charles University, Prague, Czech Republic

Synonyms

2-Propylpentanoic acid; Dipropyl-acetic acid

Definition

Valproic acid is a short chain branched fatty acid. It was first synthesized by B.S. Burton in 1882. During the last 40 years valproic acid has been extensively used for the treatment of epilepsy, bipolar and other neurological disorders. In the human brain, valproic acid affects the function of the neurotransmitter ►gamma aminobutyric acid (GABA) (mainly as a GABA transaminase inhibitor). Valproic acid has ►histone deacetylase inhibitory activity and affects behavior and growth of various cancers and ►cancer cell lines. Valproic acid induces cell differentiation and ►apoptosis of diverse cancer cell lines, increases ►recognition of cancer cells by the immune system, inhibits cell proliferation, decreases ►metastatic and angiogenic potential of cancer cells. The anticancer effect of valproic acid is based on its histone deacetylase inhibiting activity, modulation of ►MAPK signaling and ►beta-catenin pathway. Other mechanisms of action of valproic acid were also proposed. The relative safety of administration of valproic acid and its involvement in multiple pathways are making it a valuable lead in search for more potent and more specific drugs with anti-cancer activities.

Molecular Formula: $(CH_3CH_2CH_2)_2CHCOOH$
Molecular Mass: 144.21

Characteristics

The name valproic acid originates from its descriptive chemical name 2-propylvaleric acid (valeric acid is a synonym for pentanoic acid that was isolated from the flowering plant valerian (*Valeriana officinalis*)). Valproic acid was used as a solvent of neurologically active compounds and its therapeutic potential was discovered by chance. Valproic acid is a relatively safe drug, with only infrequent major side effects that include hepatotoxicity, thrombocytopenia, and prolonged ►coagulation time. In about 5% of pregnant users, valproic acid can cause congenital anomalies such as ►spina bifida.

Valproic acid inhibits proliferation and induces differentiation of neuroectodermal tumor cells.

Valproic acid and its analogs modulate the behavior of various tumor cell types by inducing apoptosis and differentiation, inhibiting proliferation, decreasing

►angiogenetic potency and increasing immunogenicity of cancer cells.

Valproic acid induces apoptosis in two ways: through the effect on ►caspases and ►chromatin fragmentation and trough its effect on membranes linked to phosphatidylserine externalization and release of cytochrome c from mitochondria. Valproic acid induced apoptosis in various animal cell lines including rat hepatoma cell line FaO, many human leukemia cell lines of B-, T-, and myeloid lineage, murine B-lymphoid cell lines, MV4-11 and KOCL-44, prostate carcinoma cell line, human thyroid cancer cells and other cells.

Treatment with valproic acid leads to inhibition of cell proliferation and induction of cell differentiation in different cell lines, mainly of neuroectodermal and leukemic origin. Valproic acid increased differentiation of human ►neuroblastoma cells (SJ-N-KP, AF8), which was documented by neurite extension and up-regulation of ►neuronal markers. The decreased net proliferation rate after valproic acid administration was observed in ►prostate cancer cells – androgen receptor positive (LNCaP and C4-2) and androgen receptor negative (DU145 and PC3). In leukemic cell lines HL-60 and MOLT-4, valproic acid induced cell differentiation was marked by an increase of CD 11b and co-stimulatory/adhesion molecule CD86. ►Hepatocellular carcinomas (HCC) that are resistant to conventional ►chemotherapeutics showed decreased proliferation in response to the treatment with valproic acid. A down regulation of anti- and up regulation of pro-apoptotic factors indicated that modulation of intracellular pro- and anti-apoptotic proteins is a key event in valproic acid induced tumor cell death. The influence of valproic acid in the ►cell cycle was determined to be in the G1 phase.

Valproic Acid is a Potent Inhibitor of Tumor ►*Angiogenesis*. Valproic acid caused inhibition of proliferation, migration and tube formation of endothelial cells and also caused a decrease of endothelial nitric-oxid synthase (eNOS) protein level. The inhibition of angiogenesis in vivo was documented on the chicken chorioallantoic membrane assay and the matrigel plug assay in mice. Valproic acid also caused disturbed vessel formation.

The indirect effect of valproic acid was observed in neuroblastoma cells. A higher production of anti-angiogenic-molecules thrombospondin-1 and ►activin A were detected. Similarly the treatment of colon adenocarcinoma cell line Caco-2 caused significant reduction of ►vascular endothelial growth factor (VEGF) secretion, down-regulation of protein expression and mRNA of VEGF, basic fibroblast growth factor (bFGF) protein level and inhibition of the ►ubiquitin-proteasome proteolytic system activity.

Valproic Acid Increases Immunogenicity of Cancer Cells. Treatment of human ►hepatocellular carcinoma cells with valproic acid mediated recognition of cancer cells by cytotoxic lymphocytes via the immunoreceptor NKG2D. Valproic acid induced transcription of MICA and MICB in hepatocellular carcinoma cells, leading to increased cell surface, soluble and total MIC protein expression. The induction of MIC molecules increased lysis of hepatocellular carcinoma cells by natural killer cells. In primary human hepatocytes, valproic acid treatment did not induce MIC protein expression indicating that valproic acid mediates specific priming of malignant cells for innate immune effector mechanisms.

Valproic Acid was Shown to Modulate Behavior of Numerous Tumors. Valproic acid was repeatedly used in patients with acute myeloid leukemia (AML) and combined with all-trans retinoic acid (ATRA). In some subtypes, the AML is connected with translocations that generate fusion genes including ►retinoic acid receptor alpha (RARα) which functions as an oncoprotein that inhibits differentiation pathways of myeloid lineage. ATRA was shown to partially release the differentiation block by binding to the RARα part of the fusion protein with subsequent increased expression of target genes (likely connected with disruption of binding of transcriptional co-repressors and induced degradation of the fusion protein). Valproic acid markedly increased the efficacy of the treatment by ATRA and resulted in transient disease control in subsets of patients with AML.

The antitumor efficacy of valproic acid was observed in ►medulloblastoma and supratentorial primitive neuroectodermal tumor (sPNET), which are the most common malignant brain tumors in children with poor prognosis. Two medulloblastoma (DAOY and D283-MED) and one sPNET (PFSK) cell lines were treated with valproic acid with resulting potent growth inhibition, cell cycle arrest, apoptosis, senescence, differentiation, suppressed colony-forming efficiency and tumorigenicity in a time- and dose-dependent manner at clinically safe concentrations (0.6 and 1 mmol/l).

Valproic Acid Affects Cell Behavior by Multiple Mechanisms

Valproic Acid Inhibits Histone Deacetylase Activity

The effect of valproic acid on behavior of cancers and cancer cell lines initiated studies directed at its mode of action. Behavior of cells depends on their gene expression that in turn is regulated by the basic transcription machinery, cell and tissue specific ►transcription factors and ►co-factors and by the organization of chromatin. ►Post-translational modification of chromatin, including histone acetylation, methylation, phosphorylation, ubiquitination and other modifications is a critical part of regulation of gene expression. Valproic acid was shown to down-regulate the HDAC activity in ►teratocarcinoma and neuroblastoma cells. Nevertheless, this effect may have been caused by a

direct action of valproic acid on enzymes involved in adding or removing acetyl residues on lysines of nucleosomal histones (mostly histones H3 and H4) or by a modulation of other targets. It was shown that valproic acid affects the in vitro deacetylation assay and acts as an HDAC inhibitor. Inhibition of HDAC activity was analyzed by measuring the acetylation of core histones H3 and H4 in the leukemic K562 and U937 cell lines. Valproic acid and its analogs (2-methyl-2-n-propylpentanoic acid (2M2PP), 4-pentenoic acid (4PA), 2-methyl-pentenoic acid (2M2P), 2-ethylhexanoic acid (2EH), and valpromide (VPM)) were shown to inhibit class I HDAC (HDACs 1–3), and class II HDAC (HDACs 4, 5, and 7). Valproic acid was the strongest inhibitor. The mechanism by which valproic acid affects behavior of cancer cells differs from its antiepileptic effect since the efficacy of antineoplastic and antiepileptic effects differ between particular analogs.

Valproic acid did not inhibit the activity of class II HDAC 6 and 10, in contrast to another HDAC inhibitor, ►trichostatin A (TSA). This implies a more selective effect of valproic acid on HDAC inhibition compared to ►TSA. Although valproic acid affects both class I and class II HDACs, the effect on these two classes differs. Valproic acid has been shown to inhibit the catalytic activity of class I HDACs and induce the proteasomal degradation of class II HDACs in contrast to TSA.

Valproic acid and its analogs induce expression of multiple exogenous reporter genes which are associated with HDAC inhibition, i.e. SV40, p21 and gelsolin.

Studies directed at the genome wide expression pattern showed that valproic acid affects expression of selective groups of genes (by their induction or repression).

Valproic Acid Interferes with MAPK Signaling

Valproic acid increases the DNA binding and transactivation activity of the transcription factor ►AP-1. In vitro studies showed that valproic acid specifically triggers the phosphorylation of ►ERK, the upstream modulator of AP-1, but does not act via the JNK (c-jun N-terminal kinase) and p38 pathways. Valproic acid and its derivatives (named above) activate MAPK. In clear contrast to their effect on inhibition of class I HDACs, the analogs of valproic acid have a stronger effect on MAPK activation than valproic acid itself. This may reflect a possibility that the effect on MAPK is not mediated by HDAC inhibition.

Therefore valproic acid-induced increases in AP-1 binding and function are likely due, at least in part, to activation of ERK followed by phosphorylation and increase in expression of c-Jun. Expression and phosphorylation of c-Jun in ERK pathway is required to direct cellular differentiation in poorly differentiated cells. Nevertheless, it seems likely that the way valproic acid affects cell behavior may to a large extent depend on the particular cell type.

Valproic Acid Affects the Beta-Catenin Pathway

GSK-3beta (►glycogen synthase kinase-3 beta) is a negative regulator of the ►Wnt signaling pathway, which regulates numerous processes, including cellular proliferation, cell migration, cell polarity, organo- and carcinogenesis. GSK-3 beta phosphorylates beta-catenin and this leads to its rapid degradation. Inhibition of GSK-3 beta by Wnt signaling leads to stabilization and accumulation of the beta-catenin protein. Consequently, beta-catenin translocates to the nucleus where it activates transcription of Wnt dependent genes by binding to factors ►Tcf/Lef (T cell factor, Lymphoid-enhancer factor).

Valproic acid has been reported to inhibit GSK-3 beta-mediated phosphorylation of a peptide derived from ►CREB protein in human embryonic kidney 293T and murine Neuro2A ►neuroblastoma cells and increase levels of beta-catenin in human neuroblastoma cells. Nevertheless, it was also proposed that valproic acid activates Wnt-dependent gene expression through the inhibition of histone deacetylase activity. The involvement of histone deacetylase inhibition by valproic acid in beta-catenin dependent regulation is supported by its effect on the expression of E-cadherin. Expression of numerous ►tumor suppressor genes including E-cadherin is linked to hypermethylation of specific regions of DNA and may be partially reverted by ►increased histone acetylation.

Valproic Acid may Influence Additional Pathways

Valproic acid was shown to be involved in other regulatory pathways. In many of them, it is likely that the effect is mediated primarily by the inhibition of histone deacetylase activity but some may be distinct. Valproic acid increases the levels of 5-►lipoxygenase (5-LOX) protein in murine hippocampus. 5-LOX produces ►leukotrienes from ►arachidonic acid and this is likely to be involved in the regulation of ►chromatin remodeling. Since increased levels of 5-LOX are linked to aging and neurodegeneration, it may be expected that the increase of 5-LOX expression may contribute to tumor cell aging and differentiation through chromatin remodeling.

Valproic acid is likely to inhibit invasiveness of cancer cells at concentrations lower than those necessary for its anti-proliferative effect. Increased expression of genes that inhibit invasiveness of cancer cells was observed in response to treatment with relatively low doses of valproic acid (150 μmol/l). These genes included ►signal transducer and activator of transcription 6 (STAT6), Ring1, RYBP and PCDHGC3.

Valproic acid may affect the regulation of gene expression by ►nuclear receptors which is critically

influenced by ►HDACs. Moreover, some members of this superfamily of genes may be affected by valproic acid more directly. PPARδ and PPARγ (but not PPARα) were activated by valproic acid in Chinese hamster ovary cells and F9 teratocarcinoma cells. At least in the case of PPARδ, this effect was not based on the binding and activation of the receptor by valproic acid as an agonistic ligand since it did not induce formation of heterodimers of PPARδ with retinoid X receptor on DNA response elements. Activated expression of PPARγ dependent genes may significantly contribute to the anticancer activity of valproic acid. PPARγ regulates the expression of the tumor suppressor gene PTEN (phosphatase and tensin homologue deleted from chromosome 10) that is often mutated in cancers. ►PTEN, a lipid phosphatase, dephosphorylates phosphatidylinositol (3,4,5)-triphosphate (PIP-3) to phosphatidylinositol (4,5)-diphosphate (PIP-2) and antagonizes the regulation by phosphatidylinositol-3 kinase (PI-3K).

Vanadium

Malay Chatterjee
Department of Pharmaceutical Technology, Jadavpur University, Calcutta, West Bengal, India

Definition

Vanadium, a member of group VB and in the 4th period of the periodic table is a first transition series, d-block, grayish metallic element with an atomic number of 23 and forms different oxidation states of –1, 0, +2, +3, +4 and +5. The oxidation states +3 (vanadic), +4 (vanadyl) and +5 (vanadate) being most common, the oxidation state +4 is most stable in biological systems. Vanadium is an endogenous constituent of most mammalian tissues and is further considered a ►dietary micronutrient. It is an essential element for the proper growth and development of mammals owing to its diverse physiological and biochemical functions.

Characteristics

The uniqueness of vanadium is that it is included in the list of 40 essential micronutrients required in small amounts for normal cell metabolism. Accordingly, it has been incorporated into many multinational pharmaceutical preparations for maintenance of normal health. Although micronutrients never have had pharmacological potencies, they can prevent the minor wear and tear of the essential critical molecules of the cell; vanadium may thus have a role in DNA maintenance reactions and may prevent genomic instability leading to ►cancers. The main source of vanadium intake for the general population is food, such as chicken, fish, grains, cereals, ►liver, spinach, black pepper, parsley, fruits, and vegetables. The total body pool of vanadium in humans is about 100 μg, with the actual daily dietary intake estimated to be 10–60 μg, depending on individual human diet.

Studies have established vanadium as a novel biological regulator and have confirmed the biphasic effect of this trace element in biological systems, that is, essentiality at low concentrations, and toxicity at higher concentrations. Vanadium compounds can influence the behavior of enzymes, mimic growth factor activities, regulate carbohydrate and lipid metabolisms, modulate gene expression and signal transduction pathways, and in particular exhibit anticarcinogenic/antineoplastic activities. The diverse biological action of vanadium results from its capacity to function as an oxyanion, oxycation, or prooxidant.

Vanadium in Cancer Treatment

Vanadium has a potential role in tumor growth inhibition and in prophylaxis against ►carcinogenesis in different experimental cancer models namely ►liver cancer, ►colon cancer, ►breast cancer and others and in various types of malignant cell lines. Vanadium compounds have been found potentially effective against murine ►leukaemia, fluid and solid Ehrlich ►ascites tumor, murine mammary ►adenocarcinoma, HEp-2 human epidermoid carcinoma cells and human ►lung cancer, ►breast cancer, and ►gastric cancer. Synthetic complexes of vanadium with amino acids, peptides, proteins, organometallic and inorganic ligands, and pharmacologically active moieties are an area of current interest in anticancer research. A cytostatic effect is observed with vanadium(III)–L-cysteine complex on chemically-induced ►leiomyosarcoma bearing Wistar rats. [VIII (Hcys)3].2HCl.2.5H2O or compound 1 exhibits significantly greater total antioxidant capacity along with inhibition of neutral endopeptidase activity as potent as thiorphan. Moreover, compound 1 prevents lung

►metastasis, thus proving its role as an antimetastatic agent. These beneficial effects of the above complexes, in combination with their low toxicity, provide evidence for their possible application in the treatment of human malignant diseases. A good candidate for the development of new vanadium derivatives with organic ligands is the flavonoid quercetin because of its own anticarcinogenic effect. The quercitin-vanadyl complex [VO(Quer)(2)EtOH](*n*) (QuerVO) stimulates ►extracellular signal-regulated kinase (ERK) phosphorylation and this seems to be involved as one of the possible mechanisms for the biological effects of the complex. Organometallic vanadocene complexes have been found to be potent antiproliferative and antimitotic agents and block cell division at the G2/M phase of cell cycle in human cancer cells by disrupting bipolar spindle formation. Furthermore, vanadocenes as potent ►apoptosis-inducing cytotoxic agents against human ►testicular cancer cells in vitro as well as in experimental mice model in vivo may therefore have potential utility in the treatment of testicular seminomas in humans. Vanadyl complexes of 1,10-phenanthroline [$VO(Phen)^{2+}$] and related derivatives possess strong antitumor chemopreventive activities against human nasopharyngeal carcinoma, and the observed effects are found to be superior to the chemotherapeutic drug, ►cisplatin. Bis(4,7-dimethyl-1,10-phenanthroline) sulfatooxovanadium(IV) or Metvan [VO(SO4)(Me2-Phen)2] has been identified as the most promising multitargeted anticancer bisperoxovanadium (bpV) complex with apoptosis-inducing activity in human leukaemia cells, ►multiple myeloma cells and solid tumor cells derived from ►breast cancer, ►glioblastoma, ►ovarian cancer, ►prostate cancer and ►testicular cancer. It is highly effective against cisplatin-resistant ►ovarian cancer and testicular cancer cell lines. Metvan inhibits the constitutive expressions of [►Matrix metalloproteinases (MMPs)] -2 and 9 proteins and its gelatinolytic activity in HL-60 cells, and leukemic cells from patients, and also inhibits the leukemic ►cell adhesion to the extracellular matrix proteins laminin, type IV collagen, vitronectin, and fibronectin and the invasion through Matrigel matrix. Metvan exhibits significant antitumor activity in severe combined immunodeficient mouse xenograft models of human malignant glioblastoma and breast cancer. The broad spectrum anticancer activity of Metvan together with favorable pharmacodynamic features and lack of toxicity of this oxovanadium compound may represent the first vanadium complex and a novel anticancer agent as an alternative to ►platinum-based ►chemotherapy.

Chemopreventive/Anticancer Mechanisms

Several mechanisms for the cancer chemopreventive role of vanadium have been proposed. The biochemical basis of the chemoprotective effect of vanadium may primarily be attributed to the substantial elevation of phase II conjugating enzymes, which may lead to a move and shift of the metabolic profile that may reduce the intracellular concentration of carcinogen-derived reactive intermediates. However, it is not yet clear whether the activity of specific ►CYP isoforms is directly influenced/modulated by vanadium treatment. Ortho- and meta- vanadate have been found to drastically reduce the mutagenicity of metabolically activated carcinogens by modulation of protein phosphorylation through the inhibition of protein phosphotyrosine phosphatases (PTPases). This micronutrient is able to exert in vivo anticlastogenic effect through suppression of ►micronucleus formation, sister-chromatid exchange, and structural, numerical and physiological chromosomal aberrations and may thereby prevent genomic instability. In aqueous solution, vanadium is found predominantly as oxo-anions (e.g., VO_4^{3-}) and as such may exhibit nucleophilic character for the electrophilic agents to attack, thereby preventing DNA ►alkylation damage as per the "carcinogen interception mechanism." although at the moment we cannot say if such processes take place within cells.

Experiments on various cell lines reveal that vanadate exerts its antitumor effects through activation of protein tyrosine kinases (PTKs) and/or inhibition of cellular PTPases leading to an accumulation of phosphotyrosine residues in cellular proteins. Both effects activate signal transduction pathways leading either to apoptosis and/or to activation of tumor suppressor genes. The stimulatory effect of vanadate on the cellular phosphorylation status of cytosolic proteins may be mediated in a dose-dependent manner probably via a ►protein kinase C-dependent mechanism. Vanadyl state is readily converted to vanadate in presence of H_2O_2, and thus vanadate seems to be the species that inhibits specific PTPase, and correspondingly increases the steady states of phosphorylation and thereby activates cytosolic PTKs at relatively low concentrations. Vanadium compounds have been shown to inhibit cell proliferation by limiting the expressions of several potential marker proteins, such as proliferating cell nuclear antigen, Ki-67 nuclear antigen, etc. In vitro antiproliferative activity of a variety of vanadium compounds may be exerted by their ability to interfere with the molecular interactions between GATA binding protein 1 and ►Nuclear Factor kappa B (NF-kappaB) transcription factors and target DNA elements. Vanadium complexes with a +5 oxidation state and their discrete anionic units appear essential for inhibition of tumor cell growth with induction of apoptosis, whereas a +4 oxidation state appears to be important in inhibiting transcription factors/DNA interactions.

Vanadium-induced apoptogenic signals are mediated through upregulation and overexpression of ►p53 tumor suppressor and proapoptotic Bax and by down-regulation of Bcl2. Reactive oxygen species generated

by Fenton-like reactions and/or during the intracellular one-electron reduction of V(V) to V(IV) by, mainly, NADPH participate in the majority of the vanadium-induced intracellular events. ROS/H_2O_2 generated by vanadate triggers ►DNA damage, and also activates ►mitogen-activated protein kinases (MAPKs) signal transduction pathways leading to an increased p53 protein expression and p53 phosphorylation, respectively. This in turn induces p53 transactivation, which subsequently leads to cell apoptosis. p53 is also an important transrepressor of inducible ►nitric oxide-synthase expression and thereby attenuates excessive nitric oxide production in a regulatory negative feedback loop.

Future Direction

Given what is known of vanadium effects on animal physiology, individual responses to vanadium treatment might be influenced by plasma- and cellular- binding proteins and genetic predisposition. Nonetheless, the potential therapeutic advantage of vanadium compounds and the available options for mitigating toxicities suggest that further development should yield safe and effective pharmacological formulations as antineoplastic agent.

VDAs; Vascular targeting agents; Vascular targeted therapies

Definition

Vascular Disrupting Agents (VDAs) disrupt tumor blood flow by specifically targeting vascular abnormalities associated with solid tumor development. The

result is tumor vessel occlusion followed by extensive tumor necrosis.

Characteristics

Tumor growth is limited by the diffusion of oxygen and nutrients from blood vessels into the surrounding tissue. In order to grow beyond a size of ~1 mm^3, tumors are dependent upon their ability to induce ►angiogenesis (the formation of new blood vessels). As the tumor outgrows its blood supply, angiogenic factor (i.e. ►VEGF and ►bFGF) expression is induced, which stimulates the formation of new blood vessels.

The growth rate of tumors is such that angiogenesis must be continuously induced to keep a steady supply of oxygen and nutrients to the tumor tissue, resulting in a state of endothelial proliferation not normally present in the adult body. The vessels produced by this elevated angiogenic state are also abnormal in structure: tortuous vessels that experience transient interruptions in blood flow, and are often leaky with reduced or non-existent ►pericyte.

The abnormality of the tumor vasculature provides a novel target for anticancer therapy, with the idea of interfering with tumor growth through the pharmaceutical disruption of the tumor blood supply (termed ►vascular targeting). Several vascular targeting agents have since been identified and have begun entering clinical trials. The vascular targeting approach can be broadly divided into categories: the antiangiogenics and the Vascular Disrupting Agents (VDAs). The anti-angiogenic agents prevent the formation of new blood vessels thereby slowing tumor growth, while VDAs target and disrupt the existing tumor vasculature, which results in acute destruction of tumor tissue.

The angiogenic process is a multi-stage event including the upregulation of pro-angiogenic factors, increased endothelial cell proliferation, degradation of the vessel basement membrane, and endothelial cell migration and new tube formation. Each of these stages is a potential target for antiangiogenic agents, but agents inhibiting pro-angiogenic factors are perhaps the most common. The most studied angiogenic factor involved in tumor pathophysiology is VEGF, and several agents have been developed which either prevent the binding of VEGF to its receptors or inhibit activation of the receptor. The agent Bevacizumab is an anti-VEGF antibody that prevents VEGF from binding and activating its receptors and has had therapeutic success in clinical trials. The tyrosine kinase ZD6474 has been shown to inhibit angiogenesis by selectively preventing activation of the ►VEGFR-2 receptor and is also undergoing testing in clinical trials.

Vascular Disrupting Agents

The VDAs can be further divided into two basic categories: biological agents and small molecules. Biologic approaches, such as antibodies and fusion proteins, utilize antigens specific to tumor endothelium to target and destroy these cells, while the small molecules rely upon physiological differences to selectively destroy tumor, not normal, endothelial tissue.

The Biologic Approach

The concept of using fusion proteins to target and disrupt tumor vasculature relies upon two necessary components: a ligand that selectively binds tumor endothelium and a conjugated toxin. The result is precise delivery of the toxic agent to only the tumor endothelium and not normal tissues. Two fusion protein VDAs that have produced positive preliminary results have utilized angiogenic proteins to specifically target the tumor endothelium. Testing of a $VEGF_{121}$/rGelonin fusion toxin in nude mice bearing ►PC-3 tumors revealed specific localization of the conjugate to the tumor vasculature and resulted in tumor vessel thrombosis. The fusion complex of antibody against fibronectin conjugated to Tissue Factor was also shown to specifically target the tumor endothelium and treatment of tumor bearing mice with this agent resulted in disruption of tumor blood flow.

Small Molecule VDAs

►Flavonoids and ►tubulin binding agents are two classes of small molecule VDAs that are currently being evaluated. The flavonoids are believed to induce endothelial cell death primarily through the induction of ►inflammatory cytokines such as ►TNF-α. The tubulin binding agents' primary mechanism of action is the disrupting of the ►microtubule network of the tumor endothelium.

Flavonoids Agents

Flavonoids such as flavone acetic acid (FAA) and its fused tricyclic analogue 5,6-dimethylxanthenone-4-acetic acid (DMXAA) have been shown to induce extensive hemorrhagic necrosis in tumors as a result of vascular collapse. Mechanistically, the action of this class of agent is believed to be largely indirect, through the induction of cytokines, particularly TNFα. This view is supported by experimental evidence showing that antibodies to TNFα could inhibit FAA-induced vascular collapse. It is of interest to note that although both FAA and DMXAA selectively damage tumor blood vessels in pre clinical tumor models, only DMXAA induces TNFα in both human and mouse macrophages. Consequently DMXAA is currently considered to be the lead agent of this class of VDAs.

Tubulin Binding Agents

The tubulin binding agents ►colchicine and the ►vinca alkaloids were recognized to have anti-vascular

properties as early as the 1930s. However, the high toxicity of these agents limited their usefulness as vascular targeting therapies. More recently, agents with much more favorable therapeutic indexes, such as Combretastatin-A4-Phosphate (CA4P) and ZD6126, have rekindled interest in the use of this group of VDAs. These agents have shorter half-lifes and bind tubulin in a reversible manner, which reduces their toxicity to normal tissues.

Tubulin binding agents bind tubulin subunits and prevent their polymerization. The result is depolymerization of the microtubules, reorganization of the actin cytoskeleton, and increased cellular permeability, which has been shown to be particularly destructive to dividing endothelial cells. In vivo, VDA treatment induces rapid disruption of blood flow and collapse of the vascular network. Although the precise mechanism of tumor blood flow shut down and vessel disruption is not fully understood, in vitro experiments have demonstrated endothelial cell shape changes and interruption of vascular endothelial-cadherin (►VE-cadherin) signaling as a result of tubulin binding agent treatment. In vivo endothelial cell shape changes could augment vessel occlusion, while disruption of VE-cadherin results in reduced endothelial cell adhesion and could lead to vessel disruption. The tumor cells downstream of the disrupted blood vessels die due to a lack of oxygen and nutrients and the build up of toxic biological byproducts. After VDA treatment, necrosis is induced throughout the central portion of the tumor.

The tubulin binding VDAs should not be confused with other microtubule binding anticancer agents such as the ►taxanes. These agents bind to ►microtubules and prevent depolymerization, contrasting with the VDAs which bind the tubulin subunits to prevent microtubule elongation. Treatment with these agents has not been shown to result in tumor vascular collapse, and, consequently, anticancer therapies like taxanes are designed to directly target and destroy tumor cells, not the tumor vasculature.

VDAs as Adjuvants to Conventional Therapy

A common characteristic observed after VDA treatment is the presence of a so-called "►viable rim" of tumor cell existing at the tumor periphery. This thin layer of viable tumor tissue remains at the tumor periphery, presumably because this tumor tissue is supported by the normal vasculature, which is not affected by VDA treatment. The cells of this region are able to survive regardless of VDA dose or treatment schedule. These tumor cells continue to divide and rapidly repopulate the tumor, limiting the success of VDAs as single agents.

While VDA treatment does not entirely eradicate the tumor, a large proportion of the center of the tumor is killed. In an untreated tumor, the cells of this central region are typically hypoxic, slowly dividing, poorly perfused, and located in a high interstitial fluid pressure and low pH environment, making them more resistant to conventional anticancer therapies. As VDAs destroy this typically resistant region, addition of VDAs to current treatment regimens could improve treatment outcome when used in combination with this therapies.

Several VDA and conventional therapy combinations have been tested in the pre-clinical setting and demonstrated beneficial treatment outcome over either therapy alone. These studies found improved treatment outcome when the VDAs CA4P or ZD6126 were combined with radiation. VDA combination with radiation was also found to effectively treat large tumors successfully, more so than smaller tumors. The combination of ZD6126 with the antiangiogenic agent ZD6474 produced improved treatment outcome in the ►HT29 and ►OW1 tumor models over either treatment alone. A few combinations are currently being tested in various clinical trials.

VDAs such as ZD6126 and CA4P have been shown to produce maximum effective at doses well below the maximum tolerated dose. Neither does treatment with these agents alone result in significant growth delay, presumably due to the rapidly dividing tumor cells at the tumor periphery which survive VDA treatment. Consequently, there have been difficulties evaluating VDA treatment efficacy in the clinical setting. Preclinical evaluations of efficacy centered on the percent induced tumor necrosis, but these measurements are not practical in the clinical setting as they require highly invasive procedures that are not applicable to tumors in all locations. The viable tissue that causes difficulties with the evaluation of treatment efficacy also limits the usefulness of VDAs as single agents.

However, while the effects of these VDAs have been extensively studied for the tumor as whole, little data exists that describes how the characteristics of the tissue that survives VDA treatment change during the phase of VDA-induced damage. Changes induced in this region by VDA treatment have the potential to negatively impact the efficacy of agents used in combination with VDAs. By understanding the VDA effects upon the surviving tumor tissue, insight may be obtained into possible means of overcoming these limitations. For example, decreases in perfusion as a result of VDA treatment that do not result in tumor death may inhibit the delivery of chemotherapeutic agents to the affected region and decrease the ►radiosensitivity of tumors cells in the affected area. A few studies have reported varying combination treatment efficacies with differing treatment schedules. Therefore, a better understanding of the effects of VDA treatment on the surviving tumor tissue could lead to more effective combination treatment strategies.

Vascular Endothelial Growth Factor

Dieter Marmé
Tumor Biology Center, Institute of Molecular Oncology, Freiburg, Germany

Synonyms

VEGF; vascular endothelial growth factor; VPF; vascular permeability factor

Characteristics

VEGF Family

Four VEGF family members have been described in mammals, VEGF-A through VEGF-D. VEGF-E, the fifth member of the family is coded by the Orf virus. An additional relative is the placenta-derived growth factor, PlGF. Whereas the VEGFs are potent growth promoting and vascular permeability enhancing factors, PlGF is incapable of inducing permeability. All members exert their biological functions as homodimers. VEGFs act almost exclusively on endothelial cells. VEGF is expressed by almost all cell types with the exception of endothelial cells which express only marginal amounts of the growth factor. Expression is controlled by a number of different mechanisms. Extracellular signals such as growth factors and cytokines are able to induce transcription of the VEGF gene. Activated oncogenes, such as ras, raf, or src, as well as inactivated tumor suppressor genes, such as ►p53 or ►von-Hippel-Lindau (VHL), contribute to enhanced transcription. The newly identified p53 analogue p73 in its wildtype form can cause repression of VEGF transcription. Hypoxia, a physiological signal in early embryonic development and a pathophysiological signal in many tumors, causes enhanced production of VEGF mRNA and also stabilizes the VEGF mRNA. The pattern of VEGF expression is strictly controlled by some of these factors in a time- and tissue-specific fashion during embryonic development and physiological angiogenesis. In pathological situations VEGF expression proceeds with no specific control, exceeds physiological concentration and occurs at wrong times and locations.

VEGF-Receptor Family

All VEGF family members mediate their signals through a family of distinct high affinity receptors; VEGF-R1 through VEGF-R3. All three VEGF receptors are tyrosine kinases that become stimulated upon ligand binding, with VEGF-R1 tyrosine kinase being much less activated than VEGF-R2 and VEGF-R3. VEGF-R1 is expressed as two distinct forms; the entire transmembrane receptor VEGF-R1 and a soluble variant sVEGF-R1 generated by alternatively spliced mRNA. VEGF-R1 and its soluble variant bind VEGF-A, VEGF-B and PlGF. VEGF-R2 has high affinity for VEGF-A, VEGF-C, VEGF-D and VEGF-E. VEGF-R3 binds VEGF-C and VEGF-D. All three VEGF receptors are exclusively expressed on the surface of endothelial cells. VEGF-R2 is the most important VEGF receptor mediating a proliferative response to endothelial cells. Upon transfection into non-endothelial cells VEGF-R2 becomes autophosphorylated in response to VEGF binding, but is no more mitogenic. This indicates the involvement of cell type-specific signaling mechanisms. The endothelial cell proliferation and survival in response to VEGF requires the association of cell surface adhesive molecules. Activated VEGF-R2 associates with integrins $\alpha v\beta 3$. VE-cadherin colocalizes with VEGF-R2 and upon stimulation by VEGF becomes associated with VEGF-R2, β-catenin and PI-3-kinase. This leads to activation of PKB/Akt and initiation of a survival signal. Disruption of VE-cadherin leads to prevention of VEGF-mediated cell survival. VEGF-receptor expression is under tight control in embryo development and normal physiology. In pathological situations, such as tumor angiogenesis, VEGF-R1 and VEGF-R2 are transcriptionally upregulated in response to VEGF and thus generate an amplification mechanism to enhance this fatal process.

VEGF in Vasculogenesis and Physiological Angiogenesis

VEGF is widely and abundantly expressed in many tissues during fetal development and has been implicated in the process of vasculogenesis, i.e. the de novo formation of the vascular system. Mice deficient for VEGF die at day 8.5–9.0 and show a delayed differentiation and an impairment of both vasculogenesis and angiogenesis, i.e. the sprouting of new capillary vessels from pre-existing vasculature. Similarly, the receptors VEGF-R1 and VEGF-R2 are strongly expressed in the developing embryo. In particular, VEGF-R2 is expressed in the hemangioblasts, the common precursor to both endothelial cells and hematopoetic lineages. VEGF-R1, being non-essential for endothelial development, is required

at a later stage of the organization of the embryonic vasculature. Disruption of the VEGF-R2 gene interferes with endothelial cell development, leading to death of embryos at day 8.5–9.5. Disruption of the VEGF-R1 gene permits endothelial cell differentiation but results in thin walled vessels of larger than normal diameter, and the embryos die at day 9.

In the adult organism, large amounts of VEGF are also found in the female reproductive tissues in association with hormonally regulated angiogenesis that takes place in the ovary and endometrium at specific stages of the menstrual cycle and in pregnancy. Strong expression of VEGF can be detected in several tissues of the adult in the absence of angiogenesis, particularly kidney, lung, adrenal gland and heart. However, some of these tissues express only low levels or no VEGF receptors which might explain the absence of angiogenesis. As VEGF has been shown to be a survival factor for vascular endothelial cells it might also be that this function, requiring only low levels of VEGF receptors, is important for maintaining vascular homeostasis without angiogenesis to occur.

Clinical Relevance

VEGF in Pathophysiological Angiogenesis

VEGF, as well as its receptors VEGF-R1 and VEGF-R2, are strongly overexpressed at both the mRNA and protein levels in almost all malignant tumors. Tumor metastases exhibit overexpression of VEGF similar to that found in the primary tumors from which they arose. Elevated VEGF levels have been found in the blood of tumor patients, correlating in many cases with poor clinical prognosis of the disease. Accordingly, the soluble variant of the VEGF-R1 is also found to be elevated in the blood of tumor-bearing patients indicating the presence of activated tumor endothelium in the diseased areas. Thus, VEGF and the soluble variants of VEGF-R1 could be regarded as surrogates for pathological tumor ►angiogenesis. In addition to the intimate involvement of VEGF and its receptors in tumor angiogenesis, VEGF is also capable of increasing vascular permeability. VEGF-induced leakage of plasma from hyperpermeable microvessels results in fluid accumulation within tumors. This is also favored by the fact that tumors in general lack lymphatic vessels and hence are unable to drain extravasated proteinaceous fluid effectively. This is in particular obvious in ►brain tumors, showing increased intracranial pressure and in tumors metastasizing to body cavities leading to substantial accumulation of fluid.

VEGF and both of its receptors are also overexpressed in a number of pathological entities that involve angiogenesis, but are not associated with neoplasia. These include diabetic and other retinopathies, rheumatoid arthritis and psoriasis. In all of these examples, overexpression of VEGF and its receptors is accompanied by increased microvascular hyperpermeability and pathological angiogenesis.

VEGF/VEGF Receptor System: Therapeutic Opportunities

As VEGF and its receptors are intimately involved in the pathology of many diseases, such as cancer, rheumatoid arthritis, diabetic retinopathies, considerable efforts have been made to interfere therapeutically with this signaling system. Monoclonal antibodies against VEGF and the binding domain of its receptor VEGF-R2 have been generated. Animal experiments show efficacy against tumor vascularization, tumor growth and metastases formation. Both antibodies have been humanized (►humanized antibodies) and are being evaluated in the clinic. Low molecular weight compounds were developed to inhibit the tyrosine kinase activities of VEGF-R1 and VEGF-R2. These compounds show considerable activity against growth of highly vascularized tumors and also inhibit metastasis formation. Some of these inhibitors also show activity against other non-VEGF receptor tyrosine kinases. Clinical evaluation is being carried out to demonstrate whether the additional non-VEGF receptor related activity is beneficial or not. Furthermore, combination of anti-VEGF strategies together with low dose cytotoxic strategies have revealed synergistic effects in animals. This indicates that anti-angiogenic therapy could be useful to enhance the therapeutic potential of conventional chemo-therapeutic drugs.

Synonyms

Structural vascular stabilization; Functional vascular stabilization; Vascular maturation; Vascular remodeling

Definition

Vascular stabilization stands for the basic steps of the morphogenetic processes, finally leading to vascular maturation such as establishment of inter-endothelial contacts, development of a regularly structured basement membrane enveloping both endothelial cells and pericytes, and integration of one layer of peri-endothelial cells (pericytes or smooth muscle cells) into the vascular wall.

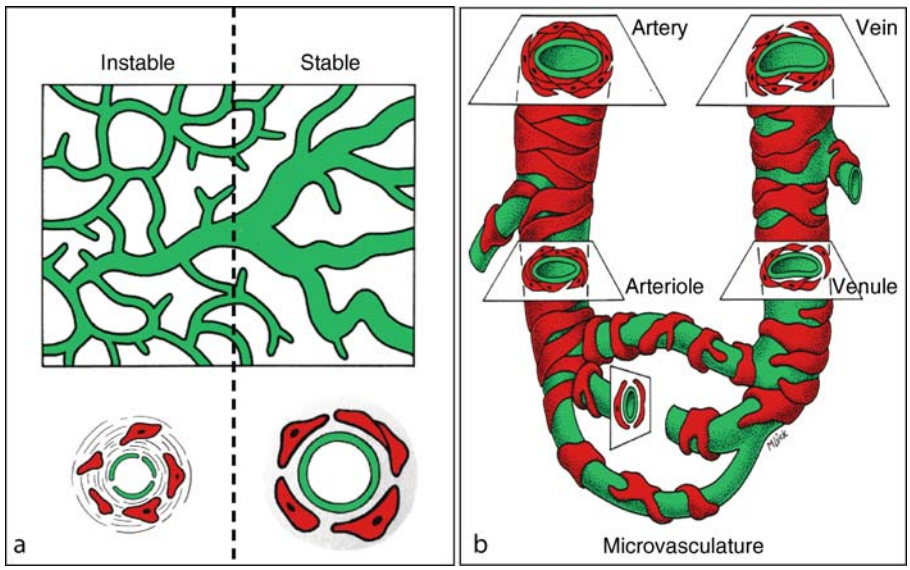
Characteristics

Normal Vascular Hierarchy

The adult vascular system is hierarchically organized in large, middle sized, and micro vessels at both the arterial and venous sides. The lumen of all blood vessels is lined by endothelial cells (EC). EC are of mesodermal/mesenchymal origin and differentiate from hemangioblasts; they are probably the common precursor of endothelial and hematopoietic cells. The first hemangioblasts are visible in the blood islands of chorionallantoic membrane and the peripheral cells of these islands differentiate to endothelial cells, while the rest serve as the source for hematopoiesis. The primitive vascular network developed in the chorionallantoic membrane subsequently connects to the cardiac system and serves as the basis for a functioning blood circulation. However, this system comprising nascent blood vessels will undergo enormous remodeling processes containing several sequential steps which are precisely coordinated timely and spatially. The essential step of the vascular remodeling in the early phase of vascular development is structural stabilization, which involves the development of inter-endothelial contacts and basement membrane and integration of peri-endothelial cells into the vascular wall (Fig. 1). Accompanied by organogenesis and the demand on blood perfusion, further processes of vascular maturation will lead to the development of the vascular wall containing several layers of smooth muscle cells and connective tissue, depending on perfusion pressure and exchange processes between the vascular and interstitial compartments. The factors and mechanisms regulating these processes are also involved in the regulation of vascular permeability, which also depends on organ-specific requirements. The end of these processes is the construction of a vascular hierarchy comprised of large and mid-sized arteries and veins macroscopically visible, as well as arterioles, capillaries and venules making up the micro vascular part of the blood vessels (Fig. 1). As far as we can observe, the vascular stabilization and the final vascular maturation result in a decrease of vascular density as blood vessels which are not included in the organ perfusion by blood undergo regression and successively disappear (Fig. 1).

Vascular Destabilization and Activation of Angiogenesis

The initiation of ►angiogenesis is marked by structural destabilization of the vascular wall, generally accompanied by an abnormal vascular permeability. This is also a common sign of the tumor vascular bed. Looking at the structure of tumor vessels, a structural instability marked by the loosening of pericytes/smooth muscle cells from the endothelial layer, opening of inter-endothelial junctions (►Tight junctions), development of endothelial fenestration and/or transendothelial gaps



Vascular Stabilization. Figure 1 From the primitive vascular plexus to the hierarchy of normal vascular system: the primitive dense vascular plexus is mainly composed of unstable nascent blood vessels of approximately equal state of vascular stabilization (a, *left*). Cross section shows that BM is not regularly structured and pericytes (*red*) are not tightly connected to the endothelial layer (*green*). Vascular stabilization during embryogenesis and fetal development have led to a decrease of vascular density (a, *right*). In cross section (a, *right*) a dense BM (*gray*) is visible, endothelial cells (*green*) build a closed layer and mural cells (*red*) are enclosed by the same BM and are tightly organized around the endothelial layer. These processes serve as the basis for the first step of vascular hierarchy in the adult as demonstrated in b.

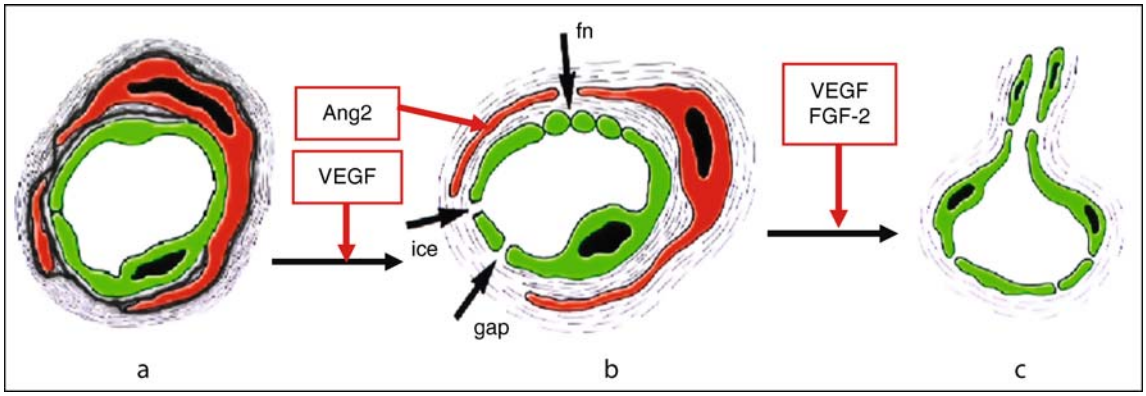
and degradation of the vascular basement membrane are frequently observed alterations of the vascular wall in this initial phase of angiogenesis (Fig. 2). This initial destabilization is probably induced by a switch of the angiogenic balance towards the activation of angiogenic sprouting. The further duration of this process is mediated by pro-angiogenic factors such as VEGF (►Vascular endothelial growth factor), FGF-2 (►Fibroblast growth factors) and Ang2. It would lead to complete destabilization and disintegration of the endothelial layer. The detachment of endothelial cells from the basement membrane results in the migration and subsequent proliferation of these cells. Finally, new capillary sprouts formed by the new endothelial cells are nascent and structurally unstable. The maintenance of pro-angiogenic activation would hold these new vessels in structural instability and in an abnormal leaky state. This phenotype of vessels dominates in the tumor vascular bed. Particularly, the concerted action of VEGF and Ang2 at certain sites of tumor vasculature has been shown to be very effective in keeping the blood vessels unstable and angiogenesis ongoing.

Vascular destabilization accompanied by abnormal vascular leakiness is also frequently observed during inflammation. It is well known that several cell types involved in the inflammatory process such as macrophages or lymphocytes produce high amounts of pro-angiogenic factors including VEGF and bFGF. Also Ang2 which is involved in vascular destabilization has been detected in several inflammatory processes. Thus, inflammation seems to provide high amounts of VEGF and Ang2, and the concerted action of both is the main mediator of vascular destabilization.

Vascular Stabilization

While it has been assumed for several years that new vessels provided by angiogenesis are lined only by endothelial cells and would not be able to enter further steps of vascular maturation, detailed studies in the last decade have revealed without doubt that some of the new vessels developed by physiologic or pathologic angiogenesis as in tumors (►cancer) do exhibit a basement membrane and mural cells such as pericytes and/or smooth muscle cells. As of now, only a few factors have been characterized as being involved in these processes. To give a systematic overview of the vascular stabilization, it makes sense to evaluate the following morphogenetic steps.

1. *Inter-endothelial contacts:* Like cell-cell contacts between epithelial cells, TJ or ►zonula occludens, adherence junctions (AJ) or zonula adherens and ►gap junctions (GJ) are the main cell-cell contact types between endothelial cells, but in contrast to



Vascular Stabilization. Figure 2 Vascular destabilization and initiation of angiogenesis: a normal stabilized capillary with a dense BM (*gray*) enclosing both endothelial cells (*green*) and pericyte (*red*) (a) will be destabilized by the action of pro-angiogenic factors as shown by VEGF and Ang2 leading to endothelial fenestration (fn), opening of inter-endothelial contacts (iec), development of transendothelial gaps (gap), degradation of BM and finally detachment of pericytes from the endothelial layer (b). These morphogenetic events are accompanied by an abnormal vascular leakiness. The further duration of pro-angiogenic action would finally lead to the sprouting of new nascent and unstable blood vessels (c), a process defined as angiogenesis.

epithelial cells, ►desmosomes are absent between endothelial cells. Also, in endothelial cells, TJ are localized at the boundary between the apical and basolateral sides of endothelial cells and thus, they are important for the barrier function. The members of the claudin family, occludin and junctional adhesion molecule-A (JAM-A) as well as their cytoplasmic interaction partners such as the members of the ZO (zonula occludens proteins) are the main players that govern the establishment of endothelial TJs. Also ESAM, the endothelial cell-selective adhesion molecule, is localized at the TJ and regulates the paracellular permeability of the endothelial barrier. VE-cadherin (vascular endothelial cadherin) (►Adherens junctions) is essential for the establishment of adherence zones between endothelial cells. The main intracellular partners of VE-cadherin are β- and γ-catenin. They link α-catenin, which anchors this complex to actin. A further intracellular partner of VE-cadherin is p120, a substrate of src. Of particular impact for vascular stabilization versus destabilization is the interaction of VE-cadherin with endothelial signaling proteins. VE-cadherin, VEGFR-2 (VEGF receptor type 2, KDR) and Src-kinase form a complex which is obviously essential for the maintenance of the endothelial barrier controlling the paracellular transport of molecules and cells through the endothelial layer. In contrast, the interaction of VE-cadherin with VE-PTP (vascular endothelial-specific receptor-protein tyrosin phosphatase) strengthens the AJ between endothelial cells. Gap junctions (GJ) represent intercellular channels mediating exchange of ions and small molecules between neighboring cells by diffusion. The establishment of GJ is governed by ►connexins; ~20 connexins (Cx) have been identified until now. Expression studies demonstrate the presence of Cx37, Cx40 and Cx43 between endothelial cells but the role of connexins in the inter-endothelial communication is not sufficiently understood. Considering the fact that the expression pattern of these connexins in the blood vessels depends on the vessel type and the position in the vascular tree a regulating role of the connexins in differentiation or maturation of blood vessels can be postulated. Although there are several excellent studies regarding the expression and the role of each factor involved in cell-cell contact between endothelial cells, it is not clarified at exactly which stage of vascular morphogenesis these contacts are established. Particularly the determination of temporary and spatial sequences of these processes needs to be evaluated. Based on recent studies it can be postulated that in the first step of vascular morphogenesis, where the nascent vessels are lined only by endothelial cells, the first provisional inter-endothelial contacts are mediated by ►cell adhesion molecules like integrins, VCAM, ICAM and ►CEACAM1. Particularly, CEACAM1 has been shown to be involved in vascular stabilization in a dual way: CEACAM1 overexpression in endothelial cells induces a signaling leading to vascular stabilization, while its down-regulation in epithelial cells as it occurs in several tumors leads to vascular destabilization. In a second step the special cell-cell contacts mentioned above will be established between

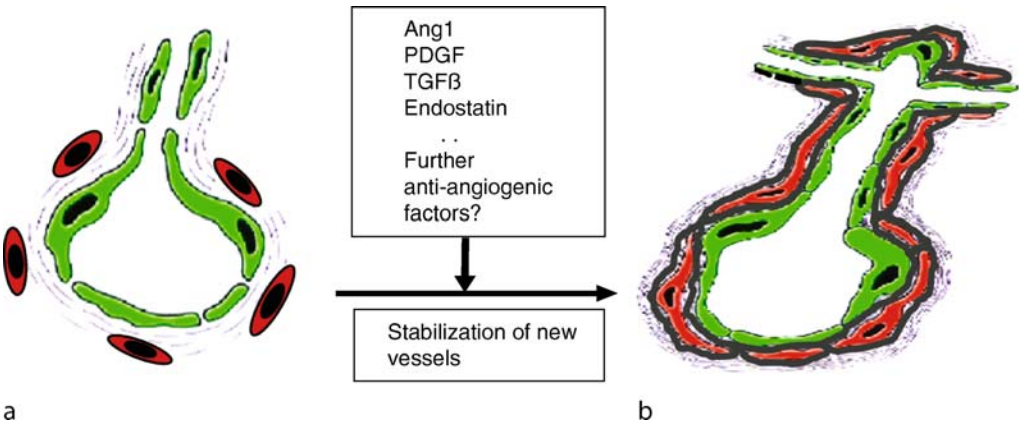
endothelial cells serving the basis for the entering of nascent and still unstable vessels into the stabilization process.

2. *Construction of the vascular* ►*basement membrane (BM):* The BM (or electron microscopically basal lamina) is an extracellular matrix structure of flexible thickness of 40–120 nm underlying all epithelial cell sheets and tubes formed by endothelial cells. In general, the assembly of BM is mainly provided by collagen type IV and laminin, which have the capacity to self-assembly, but several other molecules like perlecan, nidogens, and collagen type XVIII are identified components of BM and necessary for its regular construction. In transmission electron microscopic studies of the normal vasculature, the basal lamina (corresponding structure to basement membrane) shows an amorphous and dense structure. In small blood vessels BM encloses both endothelial cells and pericytes. The dense structure of BM is mostly not present in the basal lamina of tumor blood vessels, indicating a degradation or insufficient construction of the BM. This is one of the essential parameters leading to the loss of endothelial anchoring to the extracellular matrix and to detachment of pericytes from the endothelial layer with subsequent migration and proliferation of endothelial cells. The components of well structured BM signal an inhibitory effect on angiogenesis while the direct contact of endothelial cell to the "provisional" matrix components such as collagen type I, fibronectin and vitronectin accelerates the proliferation and migration of endothelial cells. BM collagens contain cryptic domains with anti-angiogenic activity (►Antiangiogenesis) if they are released from their mother substance as demonstrated by ►endostatin, a fragment of collagen type 18, and tumstatin, a fragment of collagen type IV. Endostatin has been shown to stabilize newly formed endothelial tubes and to strengthen the endothelial barrier by protecting the basement membrane and interendothelial contacts in normal structure. Taken together, these data suggest that a well constructed vascular basement membrane stabilizes the newly formed endothelial tubes and reduces the angiogenic potency. Indeed, in experimental models and in preclinical treatment with different types of angiogenic inhibitors (►Antiangiogenesis) ►stabilization of the vascular wall and the decrease of vascular leakiness are frequently observed phenomena.
3. *Integration of vascular mural/peri-endothelial cells into the vascular wall:* The assembly of pericytes or smooth muscle cells to the vascular wall is an essential step of vascular stabilization. Factors involved in this process are Ang1 and Tie-2-system, TGFβ, PDGF and their receptors. Although the vascular mural cells are of multiple origins, their presence and interaction with endothelial cells are crucial for vascular stabilization. Ang1 is not only involved in the assembly of pericytes into the vascular wall but it also mediates cell-cell and cell-matrix interaction, leading to a significant reduction of vascular leakiness. Ang1- and Tie-2 knock-out mice are lethal because they lack vascular plasticity and remodeling resulting in disorganization of the primitive vascular plexus and apoptosis of endothelial cells. In contrast, Ang1 overexpression in mice blocks the VEGF-induced vascular leakiness and increases the diameter of blood vessels. To reduce the role of pericytes in vascular morphogenesis only to a mechanical supportive function for the endothelial cells would be very simplifying and not appropriate. Via direct signaling facilitated by cell-cell contacts between endothelial cells and pericyte processes through the basement membrane, pericytes influence the maturation and quiescence of endothelial cells. But these actions of pericytes on endothelial cells can only be effective when pericytes are well integrated into the vascular wall enclosed by the same basement membrane as endothelial cells (Fig. 3).

Clinical Implications

In several diseases the vascular dysfunction is either an accompanied clinical problem making therapeutic handling much more difficult such as in diabetic retinopathy and microangiopathy, or it is an essential prerequisite for the full development of diseases such as cardiovascular failure or tumor growth and metastasis. Since cardiovascular diseases rank first and tumor second in the list of fatal diseases world wide, the therapeutic managing of vascular morphogenesis is a big challenge in medicine. The role of vascular stabilization in the process of vascular morphogenesis, plasticity and remodeling is still not sufficiently understood because it was neglected for a long time. In the last few years, the mechanisms of vascular stabilization, particularly the interaction between endothelial and vascular mural cells, have received more attention in both cardiovascular and tumor angiogenesis research. While anti-angiogenesis targets the tumor vasculature to cut blood supply to the tumor tissue, the pro-angiogenic therapeutic strategies deal with the creation of new vessels, which should have the capacity, as far as possible, to achieve a structural stabilization and functional normalization.

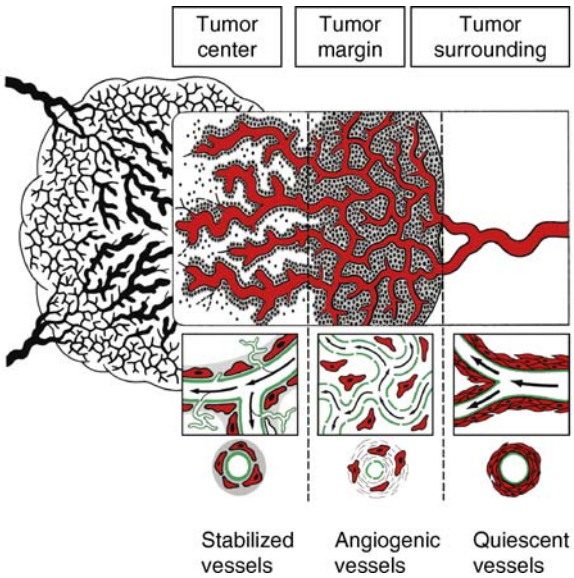
Therapeutic angiogenesis and vascular stabilization: "One is as old as one's arteries" is a frequently cited statement from Virchow and underlines the impact of the arteries in determining the life span, and also the quality of life. Cardiovascular disorders such coronary artery disease or the sclerotic changes of the peripheral



Vascular Stabilization. Figure 3 Vascular stabilization: the wall of a newly formed unstable blood vessel is constructed by endothelial cells (green) with provisional interendothelial contacts, provisional BM without the regular dense organization and mural cells (red) which are present but not regularly integrated into the vessel wall (a). Several endogenous factors as shown by Ang1, TGFβ, PDGF and endostatin, promote the structural stabilization and serve in a concerted interplay with other factors such as VE-cadherin, occludin, claudins, collagen IV, laminin and integrins as the basis for establishment of durable interendothelial contacts, a regular BM and mural cells tightly integrated into the vascular wall, a process named vascular stabilization.

arteries are mostly caused by degenerative alteration of the vascular wall at the arterial part of the vascular system. In all these disorders the formation of new vessels, for example the initiation of the growth of collateral vessels, is desirable, but it is difficult to bring the new vessels in a stable state, fulfilling the specific tissue demands on vascular perfusion and permeability. Although therapeutic angiogenesis in preclinical studies shows promise, no clear success has been achieved in controlled clinical phases II and III studies until now. These results demonstrate how complex the processes are which govern the morphogenesis of blood vessels, but they also show how difficult the way is from experimental models to human trials. Despite these ups and downs, the therapeutic angiogenesis still remains a fascinating perspective, highly promising for the treatment of cardiovascular and ischemic disorders.

Anti-angiogenic tumor therapy and vascular stabilization: The destabilization of blood vessels accompanied by abnormal vascular leakiness is one of the earliest signs of angiogenic activation. This vascular phenotype dominates the tumor vascular bed. Although it was believed for a long time that tumor vessels lack BM and ►pericytes, detailed studies in the last 5–6 years have revealed that in tumor vessels also, endothelial tubes are underlined by a BM and that pericytes are organized around these tubes. But in contrast to normal vasculature, the BM of tumor blood vessels is not well structured, the interendothelial contacts are not strong enough, and the pericytes are not tightly connected to the endothelial tubes. This vascular phenotype has a high plasticity, making it highly susceptible to pro-angiogenic factors such as VEGF and Ang2. While the link between vascular destabilization and angiogenic activation, as well as tumor vascularization, has been known for several years, well studied and understood to a great extent, the impact of vascular stabilization on tumor vascularization, tumor growth and metastasis (cancer) was mostly neglected until a few years ago. Based on emerging data from anti-angiogenic therapy, a "normalization" of tumor vessels has been postulated. According to this hypothesis, the anti-angiogenic therapy would create a "therapeutic window," enabling a more effective use of chemo- or radiation therapy for tumors. This suggests an indirect relation between vascular stabilization and tumor therapy, but what is the role of vascular stabilization per se on tumor angiogenesis and tumor growth and metastasis? The best known factor leading to vascular stabilization is Ang1. Ang1 overexpression blocks the VEGF-induced vascular leakiness by stabilization of blood vessels. In mice overexpressing Ang1, tumor vascularization was seen to be less active than those overexpressing Ang2 or tumor growth was suppressed. But there are also studies suggesting that vascular stabilization, for example by Ang1, results in the acceleration of tumor growth. These controversial findings demonstrate clearly that this aspect of tumor angiogenesis has not been studied sufficiently. Hypothetically, one would expect that vascular stabilization reverses the angiogenic phenotype of blood vessels to a more quiescent phenotype by reducing susceptibility of tumor vessels to pro-angiogenic factors. This in turn would cause a reduction of vascular density and part



Vascular Stabilization. Figure 4 Vascular stabilization and tumor growth: Stabilization of tumor vessels occurs mostly in the tumor center but significantly extends to the marginal zone under anti-angiogenic therapy, e.g. with endostatin. This is accompanied by a dramatic regression of a part of the blood vessels, resulting in a significant reduction of vascular density. This process apparently changes the perfusion of tumor tissue. In the marginal tumor zone with unstable blood vessels, there is a nearly equal perfusion of the whole vascular bed as marked by arrows. In contrast, in the tumor center, the main route of blood flow is served by stabilized vessels while unstable blood vessels were successively cut of function and underwent regression. This may result in further necrosis of tumor tissue. Green: endothelial lining, grey: vascular basal lamina.

starvation of tumor tissue, resulting in tumor necrosis (Fig. 4). This has been observed in several experimental tumor models and experimental tumor treatments with different anti-angiogenic substances. It is imaginable that we principally need a two-step approach of anti-angiogenic tumor therapy: the first step should aim to achieve a disruption of new nascent and unstable blood vessels and a suppression of endothelial proliferation, and the second would deal with the stabilization of tumor vessels switching tumor vasculature from the angiogenic to quiescent phenotype. Both these steps would serve the basis for a therapeutic "window" enabling the combination of angiogenesis inhibitors and chemotherapeutic drugs (►Chemotherapy) and/or radiation (►Radiation oncology) in the final step of tumor therapy. Taken together, emerging data recommend a stronger consideration of mechanisms that govern vascular stabilization in future anti-angiogenic tumor therapy strategies.

VTAs; Vascular targeted therapies; Angiogenesis inhibiting agents; Vascular disrupting agents

Definition

Vascular targeting agents (VTAs) are primarily cancer therapies that are specifically designed to target the vasculature of tumors and as a consequence will inhibit tumor growth and development. They may also be used to treat other pathophysiological conditions in which the tissue vasculature plays a role.

Characteristics

Background

In cancer, the vascular supply to tumors is critical. For most solid tumors to grow beyond a size of a few

millimeters it is necessary for them to develop their own functional blood supply, which they do from the already established normal tissue vasculature by a process called ►angiogenesis. This process begins with the tumor cells secreting various angiogenic growth factors. These factors are upregulated by different environmental changes such as ►hypoxia, loss of ►tumor suppressor function or ►oncogene activation. Of these angiogenic factors, the most potent and specific is ►vascular endothelial growth factor (VEGF), which is not only crucial for endothelial cell proliferation and blood vessel formation, but also induces significant vascular permeability and plays a key role in endothelial cell survival signaling in newly formed vessels. These growth factors react with various receptor kinases on the endothelial cells and then put in motion a series of physical events that include destruction of the basement membrane of the normal endothelial cells, migration of endothelial cells into the extracellular matrix in the form of a sprout, division of endothelial cells away from the sprout tip, the formation of solid strands of endothelial cells in the extracellular matrix, the development of a lumen within the strands, fusion with other sprouts to form loops, and the formation of new sprouts and loops from these primary loops. All this ultimately results in the establishment of a functional vascular supply for the tumor. Once this occurs not only can the primary tumor begin to grow, but the tumor cells have a means of entering the systemic circulation and so move to other areas in the body and then ultimately form ►metastases.

This importance of the tumor vasculature makes it an excellent target for therapy and two major VTA approaches have now evolved. The first is based on controlling the development of the tumor blood vessels by inhibiting the angiogenesis process, while the second involves a disruption of the already established tumor blood vessels. It has been demonstrated that vascular effects are involved in the action of other therapies, including certain types of ►chemotherapy, radiotherapy, and inhibitors of epidermal growth factor receptors or cyclooxygenase-2. But, in these situations the vasculature is far from being their principal target and as such it is technically incorrect to classify them as VTAs.

Mechanisms

Although angiogenesis inhibiting agents (AIAs) and ►vascular disrupting agents (VDAs) both target the tumor vascular supply they are two distinct approaches. AIAs are designed to prevent further development of the tumor neovascular network. The complex process of tumor angiogenesis offers many possible targets for ►antiangiogenesis strategies. These strategies vary from regulation of angiogenic factor expression in tumors to endogenous inhibitors of angiogenesis. Based on their biological activities, these strategies can be categorized into several broad classes. One class of agents specifically targets the angiogenic growth factors, which play the most significant role in neo-vascularization, especially VEGF. VEGF has been targeted by a variety of strategies, including inhibitors of endothelial cell receptor signaling that interfere with associated ►receptor tyrosine kinase activities (e.g., SU5474, SU6668, ZD6474 and PTK787/ZK 222584), as well as monoclonal antibodies directed against pro-angiogenic growth factors (e.g., Bevacizumab/Avastin and DC101). Bevacizumab/Avastin, a recombinant humanized monoclonal antibody to VEGF, is the first anti-angiogenic therapy to have demonstrated a survival advantage when given to patients with cancer. It is currently being investigated in a variety of tumor types. A second class of agents includes those designed to inhibit endothelial cell functions, basement membrane degradation, endothelial cell migration, proliferation, and tube formation. One example is ►Endostatin, a naturally occurring fragment of collagen XVIII, which has been identified as a potent endogenous inhibitor of endothelial cell function. A third class consists of agents that target survival factors of neovascular blood supply, such as integrin antagonists. Integrins are heterodimeric transmembrane proteins that control cell motility, differentiation and proliferation via interactions with extracellular matrix molecules. The αvβ3 integrin is an attractive target for anti-angiogenic therapy because it is almost exclusively present on the cell surface of activated endothelial cells and is considered a survival factor for angiogenic vessels in tumors. Finally, non-specific therapies that impact new vessel development are also being actively considered. ►Thalidomide and its analogues are one such group of agents that inhibits angiogenesis, but the mechanism of action is poorly understood.

VDAs are agents that cause direct damage to the already established tumor endothelium. These include physical treatments like hyperthermia or ►photodynamic therapy, which have been well documented to induce direct tumor cell killing and an indirect effect through the induction of vascular damage. They also include biological response modifiers or cytokines like tumor necrosis factor (TNF) and interleukins; certain established chemotherapeutic drugs such as vinka alkaloids and arsenic trioxide; and various ligand-based approaches that use antibodies, peptides or growth factors that can selectively bind to tumor vessels. But, more commonly VDAs involve the use of small molecule drugs, of which there are two major classes of agents. The first includes flavone acetic acid (FAA) and its derivative DMXAA, which have a complex mechanism of action that is poorly understood, but their main effect on vascular endothelial cells is thought to involve a cascade of direct and indirect effects, the latter

involving the induction of cytokines, especially TNF-α, leading to the induction of hemorrhagic ►necrosis. A second group includes the tubulin-binding agents CA4P, ZD6126, AVE8062, NPI2358, MN-029, and OXi 4503. These tubulin depolymerizing agents are believed to selectively disrupt the cytoskeleton of proliferating endothelial cells, resulting in endothelial cell shape changes and subsequent thrombus formation and vascular collapse. Since they preferentially target dividing endothelial cells this accounts for their tumor specificity. Both types of small molecular drugs have been shown to have potent anti-vascular and anti-tumor efficacy in a wide variety of preclinical models and the lead agents are undergoing clinical evaluation.

Since AIAs and VDAs induce vascular effects by very different mechanisms their anti-tumor activity and optimal application will be very different. Generally, AIAs are given as a chronic administration and essentially slow tumor development. There are examples where tumor growth can be completely inhibited or the treatment of established tumors can result in tumor regression, but these tend to be exceptions rather than the norm. As a result AIAs are probably best suited for early stage or metastatic disease. With VDAs the administration is of a more acute type to induce substantial vascular shut down. Anti-tumor effects should also be possible with lower doses given over a prolonged period, but that would probably increase the risk of normal tissue vessel damage and defeat the potential benefit. Following treatment with VDAs tumor shrinkage has been observed, but this appears to be tumor and drug dependent and although significant it is generally modest and thus tumor growth is only temporarily delayed. There is good evidence that VDAs have a superior effect on bulky disease. Given the key differences between AIAs and VDAs it should be clear from a therapeutic perspective that targeting the tumor vasculature with AIAs and VDAs is complimentary and not redundant. Such approaches are being actively pursued.

Clinical Aspects

It is clear that neither AIAs nor VDAs, whether given alone or even in combination, can induce tumor control. Therefore, their clinical potential as anti-cancer therapies requires that they must be combined with other cancer therapies, and numerous pre-clinical studies have demonstrated that when this is done significant improvements in tumor response are possible. For AIAs, this has been demonstrated when they have been combined with conventional treatments like radiation (►ionizing radiation therapy) and chemotherapy, including ►alkylating agents (e.g., ►cisplatin, carboplatin, melphalan, cyclophosphamide and dacarbazine), nitrosoureas (e.g., BCNU), antimetabolites (e.g., ►gemcitabine, 5-►fluorouracil, and pemetrexed), anthracyclines (e.g., doxorubicin), topoisomerase inhibitors (►topoisomerase enzymes as drug targets) (e.g., ►irinotecan, topotecan and etoposide), taxanes (e.g., ►paclitaxel and ►docetaxel), corticosteroid hormones (e.g., prednisone) and ►bioreductive drugs (e.g., ►mitomycin C). AIAs have to a lesser extent also been combined with hyperthermia and photodynamic therapy. With VDAs the combinations have also included radiation and various chemotherapy agents, such as alkylating agents (e.g., cisplatin, carboplatin, melphalan, cyclophosphamide and chlorambucil), antimetabolites (e.g., 5-fluorouracil), anthracyclines (e.g., doxorubicin), topoisomerase inhibitors (e.g., irinotecan and etoposide), taxanes (e.g., paclitaxel and docetaxel), vinka alkaloids (e.g., vincristine and vinblastine) and bioreductive drugs (e.g., mitomycin C, tirapazamine and AQ4N). Less conventional therapies combined with VDAs include hyperthermia, radioimmunotherapy, and antibody/clostridia directed enzyme prodrug therapy.

One important issue here concerns the pathophysiological effects induced by VTAs. As a result of targeting tumor vasculature, VTAs modify the tumor pathophysiology and these include changes in vascular density, blood perfusion, oxygenation, metabolic activity, intracellular/extracellular pH and interstitial fluid pressure. Many of these pathophysiological changes can have a profound influence on the activity of the other combination therapy, and since the reported changes include both increases and decreases the effects can be in both a negative and positive fashion. For example, increasing tumor oxygenation status will enhance tumor radiation response, while decreasing oxygenation will reduce it. With the AIAs these pathophysiological changes can be highly variable between the different drug types. The same AIA can also produce completely opposite pathophysiological affects in different tumor types, even when administered using similar drug doses and treatment schedules. VDAs are more consistent in the pathophysiological changes induced. Essentially they all decrease tumor blood perfusion and as such will make the microenvironmental conditions, especially oxygenation and pH, worse. These effects suggest that timing and sequence between the different treatments must be considered in any clinical application, especially when combining VTAs with therapies that already have some beneficial effect in patients. Despite these potential limitations, preclinical studies with VTAs in combination with other therapies do show an enhanced tumor response without any significant increased damage in dose limiting normal tissues.

Numerous VTAs are currently under clinical evaluation. With AIAs these include both specific and non-specific inhibitors of angiogenesis, and the phase of testing ranges from Phase I to IV. The most popular agents in clinical testing are the anti-VEGF antibodies

(e.g., Avastin), followed by receptor kinase inhibitors (e.g., Bay 43–9006, SU 11248, PTK 787/ZK 222584), and the non-specific inhibitor thalidomide. Far fewer trials are underway with the VDAs, and those agents that are being investigated are either in Phase I or II. The lead agent in this series is CA4P. Experimental studies strongly support the concept that the application of angiosuppressive and vascular disrupting strategies as adjuvants to standard anticancer therapy can improve treatment outcomes. Lead vascular targeting agents are now under active investigation in such settings in patients. Ultimately, it is possible to envisage future treatment protocols consisting not only of the current mainstays of cancer management, surgery, radiotherapy, and chemotherapy, but will also include a "vascular targeted therapy" consisting of a battery of tumor vessel directed agents.

Definition

The generation of microvascular channels by genetically deregulated, aggressive tumor cells was termed "vasculogenic mimicry" (VM) to emphasize their de novo generation without participation by endothelial cells. VM is thought to represent a vascular channel formation without the involvement of endothelial cells, in contrast to ►angiogenesis. Vasculogenic mimicry refers to a blood supply pathway in tumors that is formed by tumor cells and that is independent of endothelial cell-lined blood vessels. Three factors are thought to govern the formation of functional and patterned microcirculation channels by VM: (i) plasticity of highly malignant tumor cells, (ii) remodeling of the ►extracellular matrix (►ECM), and (iii) connection of the VM channel with host blood vessels to acquire blood supply from the host tissue. Formation of VM in tumors may have substantial impact on clinical outcome of tumor patients. Tumor patients in the presence of VM have a poorer prognosis than those without VM, and ►VM-targeted therapy is a perspective for tumors showing VM. At this point, VM is a new concept originally described for ►melanoma that needs to be studied further in detail.

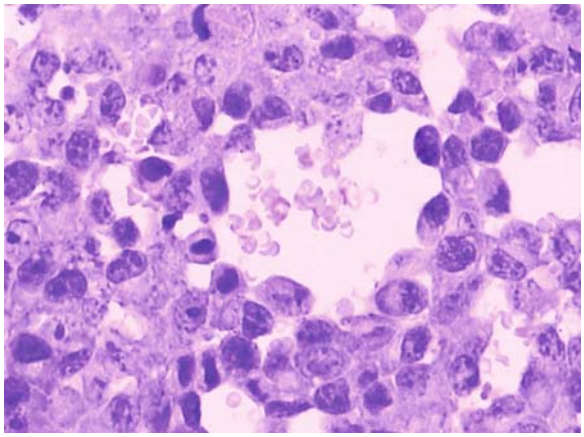
Characteristics

Introduction

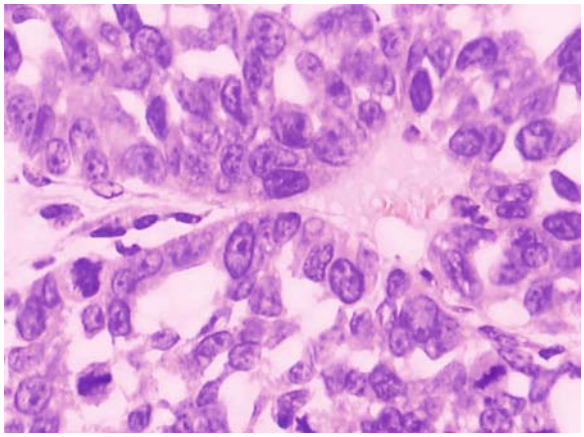
Tumor angiogenesis is a key for tumor growth, ►invasions, and metastasis. Tumor growth is ►angiogenesis-dependent, and angiogenic switch is an essential step for a small and noninvasive tumor to transit into a tumor with invasive and metastatic ability. Blood vessels are assembled by two processes: (i) ►vasculogenesis, the reorganization of randomly distributed cells into a blood vessel network, and (ii) ►angiogenesis, the sprouting of new vessels from preexisting vasculature in response to external chemical stimulation.

Current Status of Studies on VM in Tumors

It is believed that VM consists of tumor cells and PAS-positive ECM on the inner wall of channels. The constituents of PAS-positive ECM are ►laminin, collagens IV and VI, mucopolysaccharide, and heparin sulfate glucoprotein (HSPG). Initially, PAS-positive ECM was considered as an absolutely indispensable element. However, VM channels in the absence of



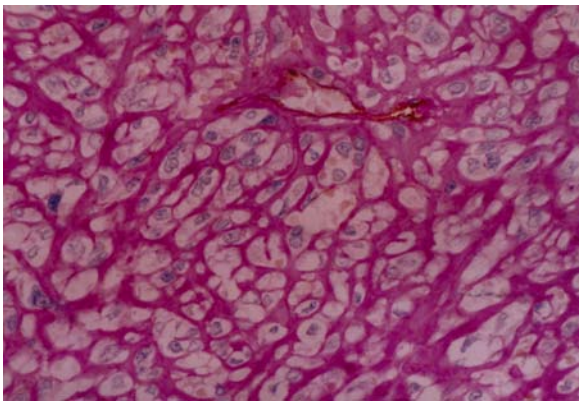
Vasculogenic Mimicry. Figure 1 Vasculogenic mimicry (VM). Melanoma cells form VM channels, and red blood cells (RBC) flow into the channel. Necrosis and inflammatory cells are not observed in tumors undergoing VM.



Vasculogenic Mimicry. Figure 2 The connection of VM channel and endothelium-dependent vessel shows VM is a functional microcirculation.

PAS-positive ECM were observed in a melanoma mouse model.

VM is an independent blood supply pattern in tumors (Figs. 1–3). Compared with endothelium-dependent vessels, it has several characteristics as follows: (i) VM channels are lined by tumor cells but not endothelial cells. (ii) There is red blood cell (RBC) leakage into tumor tissue near to endothelium-dependent vessels, while leaking RBCs are lacking in tumors with VM. (iii) Necrosis and inflammatory cells are not observed in tumors undergoing VM.



Vasculogenic Mimicry. Figure 3 VM consists of tumor cells and PAS-positive ECM on the inner wall of channels. The PAS-positive patterns are lined by tumor cells, and there are red blood cells in the center of the pattern.

Molecular Mechanisms Underlying VM

Compared with less aggressive melanoma cells, highly aggressive melanoma cells express higher levels of ►matrix metalloproteinases (►MMP-1, 2, 9, and 14) and the 5γ2 chain of laminin. This increases expression of MMPs and presence of the laminin receptor on the surface of tumor cells help cells adhere to more laminin. The activated MMPs cleave laminin into several short chains and eventually promote the formation of VM. Phosphoinositide-3-kinase modulates the function of MMP-14 (MT1-MMP), which activates MMP-2 with the help of tissue inhibitor of MMP-2 (TIMP2), and the activated MMP-2 then cleaves 5γ2 chain into γ2′ and γ2x chains. The two chains facilitate the formation of VM. The cleavage fragments of 5γ2 can be secreted by highly malignant melanoma cells directly.

VE-cadherin has been proved to be closely related to the formation of VM channels. Highly aggressive melanoma cells express VE-cadherin but less aggressive ones do not and inhibition of VM formation by downregulating the expression of the VE-cadherin gene.

Dedifferentiation of Tumor Cells is the Key to Formation of VM Channels

Much information on VM has come from studies of highly malignant melanomas. Tumor cells having the ability of VM formation show an embryonic phenotype. A ►cDNA microarray study of 5,000 genes from a patient with poorly and highly aggressive melanoma cells revealed that there was a differential expression in 210 genes, including some genes associated with the phenotypes of endothelial and hematopoietic stem cells.

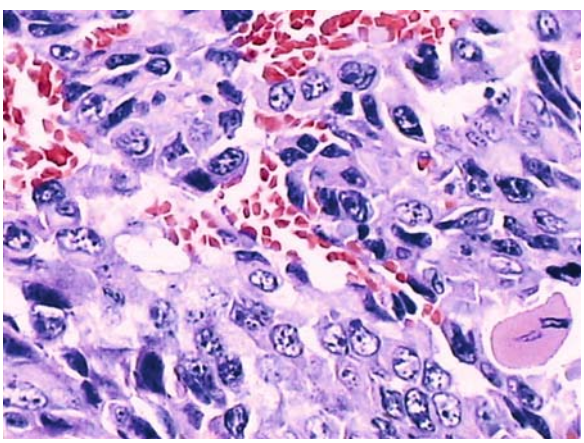
Except for embryonic genotypes, cells of tumors with VM express various angiogenesis-related cytokines. Flt-1 and Tie-2 are expressed by tumor cells of naked

mice bearing human inflammatory breast carcinoma cells. Ovarian ►cancer cells with high aggressivity express the vascular endothelial growth factor (VEGF) and other angiogenesis-related cytokines (e.g., Ang-1 and Ang-2), whereas those with low aggressivity express VEGF only.

The expression of tyrosine kinase (an enzyme that catalyzes the phosphorylation of several signal transduction proteins) is upregulated in highly aggressive melanoma cells than in less aggressive melanoma cells. Aggressive melanoma cells show an increased activity of tyrosine kinase around VM channels. ►Epithelial cell kinase (►EphA2), a tyrosine kinase receptor, is specifically expressed in highly aggressive melanoma cells. Inhibitors of tyrosine kinase activity hinder VM channel formation, and a transient knockout of EphA2 shows reduced VM channel formation.

Linearly Patterned Programmed Cell Necrosis and Three-Stage phenomenon

►Linearly patterned programmed cell necroses (►LPPCN) and ►three-stage phenomenon are thought to play essential roles in the blood supply for melanoma. At the early stage of tumor generation, endothelium-dependent vessels do not sprout into tumor center. Under the pressure of hypoxia, some tumor cells activate ►apoptosis-associated genes, and lacunas left by dissolving LPPCN cells connect with each other and form channel networks (Fig. 4). The channels coming from LPPCN cells face two opposite ends. If they connect with endothelium-dependent vessels, blood will flow into these channels lined by tumor cells and the channels will be a functional microcirculation. In contrast to this, the mass of tumor cells will undergo necrosis if these channels fail to link to endothelium-dependent vessels.



Vasculogenic Mimicry. Figure 4 LPPCN. Cells undergoing LPPCN have spindle-like figure and dark blue nuclei. They connect with each other as lines and some cells enter the wall of VM channels.

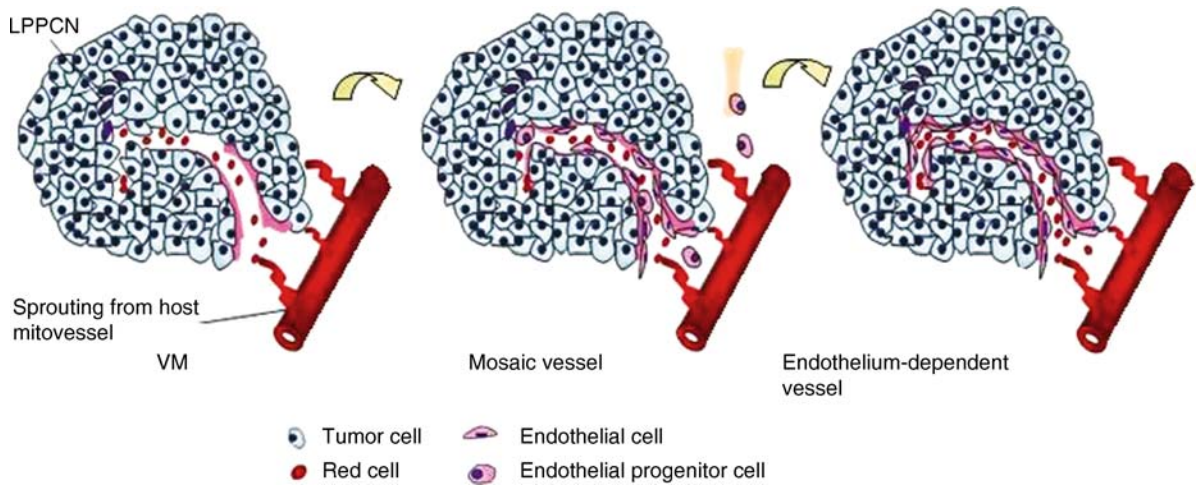
Three microcirculation patterns – VM, ►mosaic vessels, and endothelium-dependent vessels – coexist in melanoma tissue. Angiogenesis requires the recruitment of normal endothelial cells, which may not be efficient and/or sufficient enough for sustaining aggressive tumor growth at the initial stage of rapid growth. Some tumor cells dedifferentiate, connect with other tumor cells or endothelium, and finally line the wall of tube. They are vasculogenic mimicry and mosaic vessels.

Mosaic vessel may be a transition between VM channel and endothelium-dependent vessel. The three-stage phenomenon on tumor blood supply pattern assumes that there is a transformation among VM channels, mosaic vessels and endothelium-dependent blood vessels (Fig. 5). In the stage of rapid tumor growth, endothelium-dependent vessels sprout from normal tissue but are insufficient to support the rapid tumor growth. VM occurs on the base of LPPCN and acts as the major blood supply pattern for tumor growth. As tumor size becomes bigger, endothelial cells from peripheral blood home, proliferate on the wall of VM, and cover some tumor cells forming VM. Mosaic vessels appear and become the major microcirculation pattern in tumors. Finally, endothelium-dependent vessels take over the dominant role in tumor blood supply.

The Effect of Local Tumor Microenvironment on the Formation of VM Channels

Tumor growth and evolution are regulated by a good many factors and tumor cells display distinguished blood supply pattern and biological behavior to adapt different microenvironment. The environmental factors impacting VM channel formation include oxygen pressure, interstitial fluid pressure (IFP) in tumor tissue, pH, focal concentration of cytokines, and ECM.

►Hypoxia is a two-edge sword for tumor generation and development. Hypoxia and ischemia induce tumor cells to necrosis and tumor suppression, whereas hypoxia actives metastasis-related genes to promote tumor invasion. The hypoxic condition enhances the formation of VM channels, which exerts its function though ►HIF-1α and its downstream molecules. In the hypoxic environment, accumulated HIF-1α in tumor cells induces ►MMP-2, MMP-9, and VEGF expression and activation. MMP-2 and MMP-9 proteinases degrade the ECM components and facilitate VM formation, tumor invasion, and metastasis. VEGF secreted by tumor cells results in permeability of blood vessels, resulting in an increase and leaking-out of many serum proteins. Such a milieu provides a temporary matrix for VM channel formation. Under the stimuli of hypoxia, LPPCN-associated genes can be triggered and some tumor cells undergo LPPCN. Interspaces left by



Vasculogenic Mimicry. Figure 5 Three-stage phenomenon on tumor blood supply pattern. During rapid tumor growth, endothelium-dependent vessels sprouting from normal tissue can not satisfy the need for growth. VM occur on the base of LPPCN and acts as the major blood supply pattern for tumor growth. As endothelial cells from host microvessels migrate and endothelial progenitor cells from peripheral blood home into the wall of VM, endothelial cells cover some tumor cells forming VM. Mosaic vessels appear and become the major microcirculation pattern in tumors. Finally, endothelium-dependent vessels get the dominant role in tumor blood supply.

dissolving cells connect with each other as networks to provide the space basement for VM.

Interstitial fluid pressure (IFP) is another important factor affecting tumor microcirculation patterns. Increased IFP is a characteristic of malignant tumors because of its rapid proliferation. It is similar to hypoxia and has double impact on tumor development. High IFP inhibits both endothelial cells of blood vessels and lymphatic vessels to migrate into the tumor center, with the result of tumor hypoxia. Elevated IFP stimulates tumor cells to secret invasion-associated proteins. High IFP is a barrier for endothelium-dependent vessels sprouting into tumor tissue, but hypoxia induced by it is an inducer for VM. Moreover, the expression of MMP-2, MMP-9, ►integrin, ►selectin, and ►kinesin increase significantly in tumor cells growing in the ►microenvironment with high IFP, which promote VM formation to provide sufficient nutrition and oxygen for tumor growth.

Clinical Significance of VM

VM has been observed in several human malignant tumor types, such as highly aggressive uveal ►melanomas, ►breast cancer, ►liver cancer, ►glioma, ►ovarian cancer, ►melanoma, ►prostate cancer, malignant ►astrocytoma, and ►bidirectional differentiated malignant tumors. Tumor cells lining on the inner surface of VM channels are directly exposed to blood flow, may move into the bloodstream and metastasize to other organs.

VM is associated with poor prognosis in patients. Tumors with VM have a higher rate of metastasis compared with tumors without VM, and the patients have a lower 5-year survival rate. Routine ►antiangiogenic drugs, such as angiostatin and ►endostatin, which target endothelial cells, have not achieved a therapeutic effect on tumors that exhibit VM because of the absence of endothelium-dependent vessels (Fig. 6).

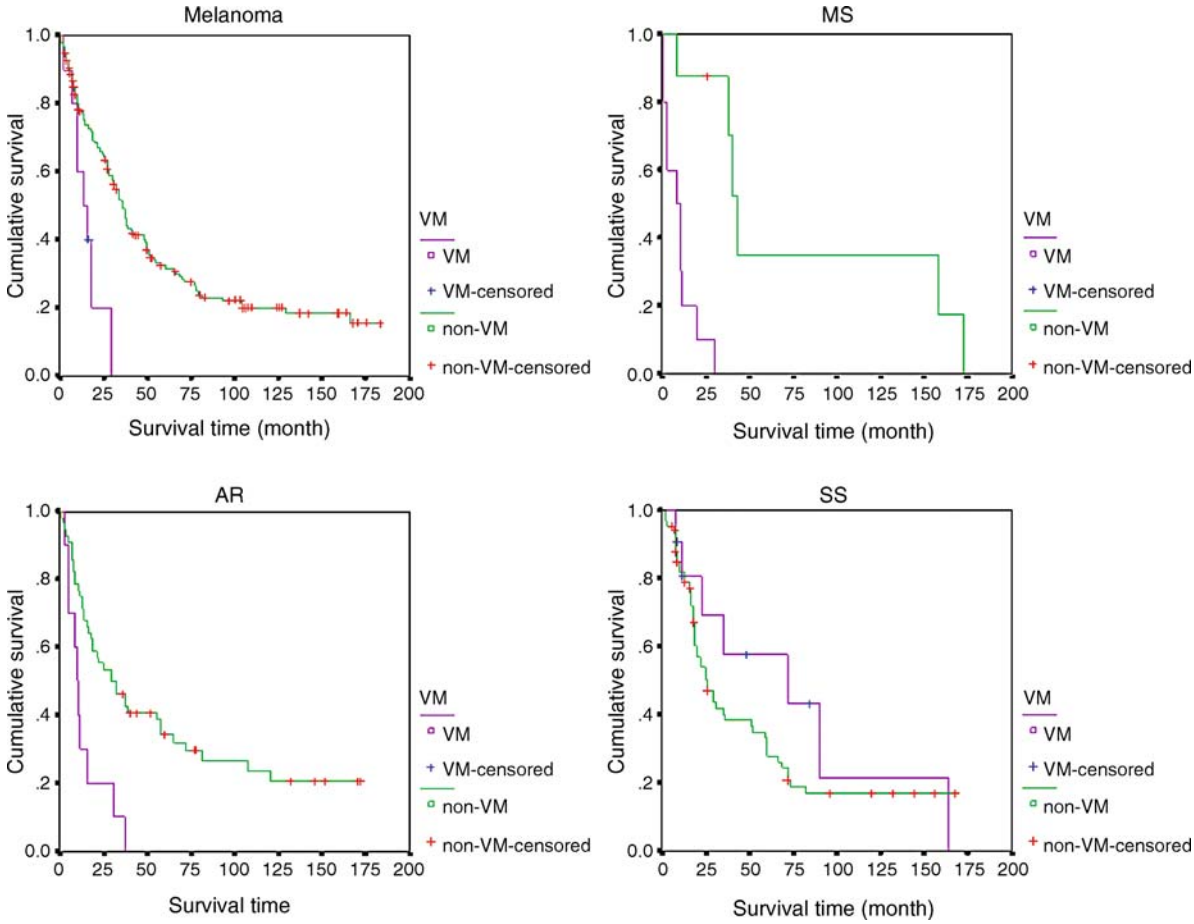
Advances and Challenges

VM and Lymphagenesis in Tumors

VM, a new pattern of blood supply to the tumors, has attracted the attention of many researchers, but many phenomena unique to VM channel formation remain to be elucidated. As a functional tumor microcirculation, VM channels need to be studied with regard to their connection with endothelium-dependent vessels, their relationship with lymphatic tubes, and their dual function as vessels and lymphatic tubes. Uveal melanoma cells have a specific vortex vein but no lymphatic tube. Highly aggressive melanoma expresses lymphatic-vessel endothelial hyaluronan receptor1 (LYVE1) and VEGF-C, a lymphatic tube-related growth factor.

VM-Targeted Therapy

Given the important role of angiogenesis in tumor growth and metastasis, therapies aiming at endothelial cells represent promising antitumor strategies. As VM has a different structure from endothelium-dependent vessels, traditional antiangiogenic agents targeting at endothelial cells, such as anginex, TNP-470, and ►endostatin, have no remarkable effects on malignant tumors with VM.



Vasculogenic Mimicry. Figure 6 Comparison of overall survival time of patients with bidirectional differentiated malignant tumors. A Kaplan–Meier algorithm reveals that the survival time of melanoma, mesothelial sarcomas (MS), alveolar rhabdomyosarcomas (AS), and synovial sarcomas (SS) without VM are both significantly longer than that of patients with VM.

One of the distinguished features of tumors with VM is that cell adhesion molecules, tumor invasion-related proteinases and ECM synthesis and secretion-associated proteins are overexpressed by tumor cells. These molecules represent potential targets for anti-VM strategies of highly aggressive and blood metastatic tumors with VM. Suppressing tyrosine kinase activity, using a knockout ►EphA2 gene, downregulating VE-cadherin, using antibodies against human MMPs and the laminin 5γ2 chain, and using anti-►PI3K therapy are strategies that have been employed to inhibit VM.

Vasoactive Intestinal Contractor

►Endothelins

Vasoconstrictor

Definition

Any factor that causes the constriction of blood vessels, which increases blood pressure.

►Endothelins

Vasodilation

Definition

Is the regulated widening of blood vessels by a controlled relaxation of the surrounding smooth muscle cells, thus permitting a higher blood flow at a lower pressure.

►Relaxin

Vasostatin

Definition

Refers to the N-terminal domain of ►calreticulin (CRT) (amino acids 1–180), is an endogenous inhibitor of ►angiogenesis and tumor growth. The potency of vasostatin in mice is 4- to 10-fold that of ►endostatin or ►angiostatin.

VCAM-1

Definition

Is a ►cell adhesion molecule that belongs to the immunoglobulin superfamily. It mediates the ►adhesion of lymphocytes to endothelial cells, thereby being involved in various inflammatory diseases including ►angiogenesis and atherosclerosis.

►Minodronate

V(D)J Recombination

Markus Müschen
Leukemia and Lymphoma Program, Norris Comprehensive Cancer Center, University of Southern California, Los Angeles, CA, USA

Synonyms

Somatic recombination of V, D and J segments; Immunoglobulin- or T cell receptor-gene rearrangement

Definition

Surface immunoglobulin (expressed on B lymphocytes) and T cell receptors (expressed on T lymphocytes) represent the central molecules for antigen recognition in adaptive immune responses. Variable (V), diversity (D) and joining (J) gene segments, which together encode immunoglobulin or T cell receptor variable chains, are present in every somatic cell. However, in order to acquire coding capacity, V, D and J gene segments need to be assembled in a functional configuration. The mechanism for the assembly of V, D and J gene segments, termed V(D)J recombination, represents a unique capacity of both B and T lymphocytes.

Characteristics

More than 30 years ago, Hozumi and Tonegawa discovered that immunoglobulin genes in B lymphocytes as opposed to any other somatic cell type undergo a complex rearrangement process in order to assemble a functional immunoglobulin variable region. This process, later termed V(D)J recombination, is in fact unique for B and T lymphocytes and critical for the expression of immunoglobulins and T cell receptors, respectively. Immunoglobulin and T cell receptor genes represent gene families in mammalians that are arranged in segments and, hence require somatic recombination of individual variable (V), diversity (D) and joining (J) gene segments to assemble a coding immunoglobulin or T cell receptor gene. V(D)J-recombination defines an early step during B- or T-lymphocyte development within the bone marrow or the thymus, respectively. In humans, three immunoglobulin and four T cell receptor gene loci are known (see Table 1). Each locus carries gene segments that together encode one protein chain. Immunoglobulins or T cell receptors typically represent the assembly of two heterodimers: For instance, immunoglobulins expressed on the cell surface of B lymphocytes comprise of two identical heterodimers of each one immunoglobulin heavy chain and one immunoglobulin κ or λ light chain molecule.

V(D)J Recombination. Table 1 Immunoglobulin and T cell receptor gene loci in the human

Locus	V segments	D segments	J segments	Gene product

TCRB, 7q34	64	2	13	TCRβ chain
TCRG, 7p14	14	None	5	TCRγ chain
TCRD, 14q11.2	8	3	4	TCRδ chain

Mechanism

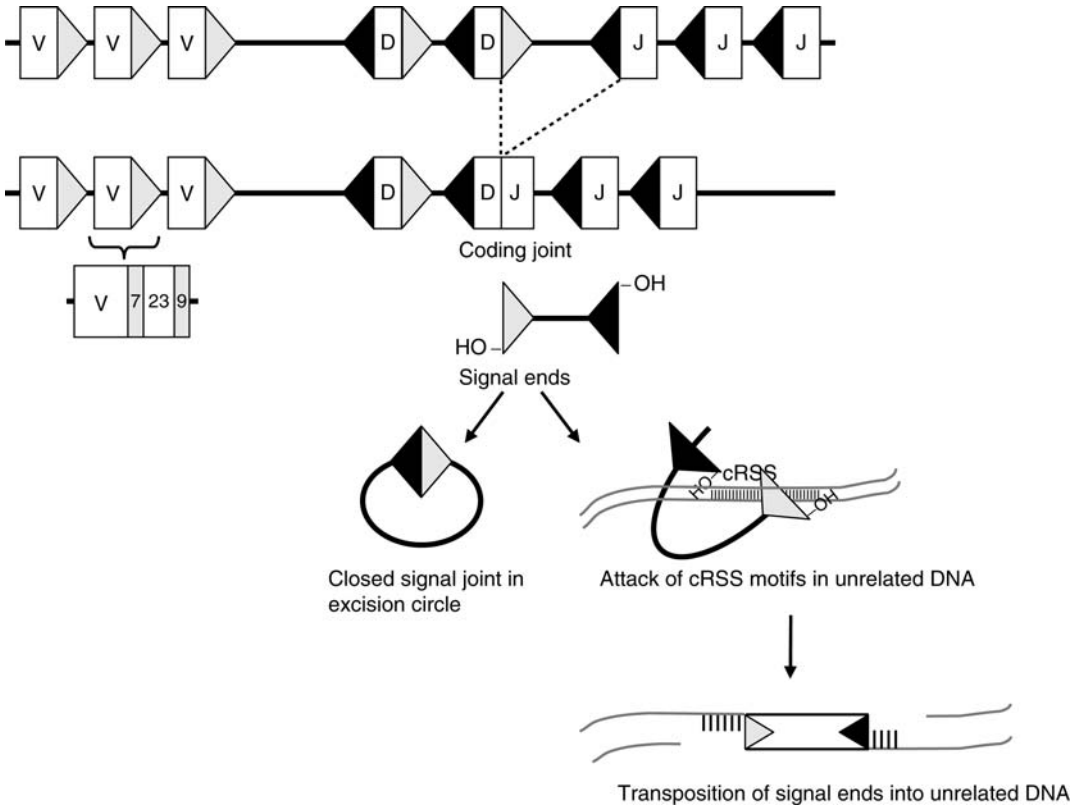
As opposed to meiotic recombination, V(D)J recombination represents a site-specific DNA recombination event in B or T lymphocytes. Site-specific recombination is conferred by recombination signal sequences (RSS) immediately flanking V, D and J gene segments. RSSs are composed of a conserved heptamer and nonamer and a non-conserved spacer of 12 or 23 bp in length. The length of the spacer determines the pairing of RSS-motifs, which only allows synapse formation between RSS motifs of different spacer-length. For the recombination process, RAG1 and RAG2 proteins (encoded by the recombination activating genes 1 and 2) are essential. RAG1 and RAG2 proteins are only expressed in B and T lymphocytes and their expression is tightly controlled during their development. RAG1 and RAG2 form a heterodimeric complex that only recognizes synapses between two RSS motifs of different spacer length, i.e. only 12/23 RSS pairs. The 12/23 rule for RSS pairing ensures that V, D and J segments are recombined in a coordinated manner to prevent mispairing of gene segments.

The RAG1/RAG2 complex then introduces a DNA double-strand break exactly at the border of the heptamer element (Fig. 1). These DNA double strand-breaks are blunt ended and 5′-phosphorylated for signal ends, which facilitates self-ligation and formation of signal joints within so-called excision circles (Fig. 1). In contrast, the broken-ended DNA of gene segments (coding joint; Fig. 1) are protected against immediate re-joining by the formation of a closed hairpin-structure. Of note, even though the targeting by the RAG1/RAG2 complex is very precise, the sequence of coding joints, i.e. the junction between two rearranged gene segments, is extremely variable. This variability of coding joints is owed to further processing of the hairpin structure by the enzymes Artemis and DNA ligase IV. The diversity of coding joints is further increased by the activity of the lymphoid-specific terminal deoxynucleotidyl-transferase (TdT): TdT is able to introduce additional nucleotides, the so-called N-nucleotides, into the junction between two gene segments in a template-independent manner.

Classical RSS motifs containing the conserved heptamer (CACAGTG) and nonamer (ACAAAAACC) sequences and a non-conserved 12 or 23 nucleotide spacer are exclusively found adjacent to immunoglobulin and T cell receptor gene segments. However, RSS-like motifs, so called cryptic RSS sites, have been identified in a number of genes outside the immunoglobulin and TCR loci. Functional assays have shown that these cryptic RSS motifs (cRSS, Fig. 1) can indeed be targeted by the V(D)J recombinase machinery. Given that many genes, among them tumor suppressor and proto-oncogenes, harbor cryptic RSS sites, targeting by the V(D)J recombinase may predispose early B and T lymphocyte precursors to malignant transformation. In this regard, it is important to note that the RAG1 and RAG2 enzymes also possess transposase activity. Thereby, 5′-phosphorylated signal ends carrying a complete RSS motif on each end may attack unrelated DNA, preferentially at cryptic RSS sites (cRSS; Fig. 1). If both RSS motifs of the excised signal ends participate in this attack, this may lead to the integration of the RSS-flanked DNA fragments at positions staggered by 3–5 bp, resulting in target site duplication at the integration site (Fig. 1, bottom). It is obvious that integration of DNA that was excised during V(D)J recombination into unrelated loci carries the risk of oncogenic transformation. Even though classical transposition events are rarely seen in lymphoid malignancies, chromosomal translocations and deletions bearing the hallmarks of illegitimate V(D)J recombination are frequent events during malignant transformation of lymphocytes.

Clinical Aspects

Malignant transformation of human B and T lymphocyte precursors towards ►acute lymphoblastic leukemia (ALL) often coincides with the timing of activity of the V(D)J recombinase machinery. Therefore, it was an obvious hypothesis that aberrant or "illegitimate" V(D)J recombination may be the causative mechanism for many if not all subtypes of ALL. In many cases, ALL cells carry ►chromosomal translocations. The breakpoints of these gene rearrangements, however, exhibit the hallmarks of



V(D)J Recombination. Figure 1 Schematic representation of RSS pairing during D-J segment joining. A simplified model of the *IGH* locus is shown including a group of V, D and J gene segments. Each of these segments are flanked by either a recombination signal sequence (RSS) with a spacer length of 23 bp (V, *light gray*) or 12 bp (J, *dark gray*) or both types of RSS motifs (D). During the RAG1/RAG2-mediated recombination process, two types of break-intermediates are generated: a coding joint (*top*) with a junction between two rearranged gene segments and signal ends (*bottom*) containing a fragment of excised DNA between two RSS motifs. These signal ends are processed by self-ligation to a signal joint within a closed excision circle. These excision circles are very stable in lymphocytes but are not replicated during mitosis. On the other hand, broken ended RSS motifs may attack unrelated DNA, preferentially at cryptic RSS sites (cRSS). Thereby, RAG1 and RAG2 can act as transposases, in that they catalyze the integration of the intervening DNA between two signal ends into the attacked unrelated DNA.

V(D)J recombination in only a few cases (Table 2). For instance, targeting to immunoglobulin (*IGH*, *IGK* or *IGL*) or T cell receptor (*TCRA*, *TCRB*, *TCRG*, *TCRD*) loci would argue for involvement of V(D)J recombination. While *BCL1* and *BCL2* gene rearrangements typically target the *IGH* locus, rearrangements of the *CCND2*, *HOX11*, *LMO2*, *TAL1*, *TAL2* and *TTG1* gene target at least one of the four *TCR* loci (Table 2). In addition, one would expect that breakpoints reflecting illegitimate V(D)J recombination exhibit traces of site-specific targeting in that they precisely flank RSS or RSS-like motifs. Virtually all genes involved in an *IGH*- or *TCR*-specific gene rearrangement show targeting of an RSS or RSS-like motif at least for one of the two translocation partners. In addition, genetic abnormalities were found, in which RSS or RSS-like motifs were targeted even though no immunoglobulin or *TCR* locus was involved. This applies mainly to intragenic/interstitial deletions. Such deletions often occur in T cell lineage ALL cells and deletions of the INK4 family genes *CDKN2A*, *CDKN2B*, *CDKN2D* and within the *HPRT*, *NOTCH1* and *SIL/SCL* loci (Table 2) are examples for such a second type of genetic aberration induced by illegitimate V(D)J recombination. Finally, addition of N-nucleotides (i.e. a junction sequence that cannot be attributed to either of the two fusion partners) by enzymatic activity of TdT represents a unique feature of V(D)J recombination. Indeed, junctional diversity compatible with the introduction of N-nucleotide was found in many cases, in which a gene rearrangement was mediated by V(D)J recombination, but not in all.

Applying these three criteria (involvement of *IGH* or *TCR* loci, site-specific targeting of RSS- or RSS-like motifs and presence of N-nucleotides) to B and T cell lineage ALL, it appears that T cell lineage as opposed to

B cell lineage ALL frequently arises through genetic aberrations that were caused by aberrant V(D)J recombination. With the exception of the ►*E2A-PBX1* gene rearrangement, none of the classical chromosomal translocations in B cell lineage ALL are compatible with V(D)J recombination: ►*BCR-ABL1*, *MLL-AF4* and ►*TEL-AML1* gene rearrangements are not related to the *IGH* locus, do not show site-specific targeting at RSS-like motifs and do not carry intervening nucleotides within the junction between the two fusion partners. The case of *E2A-PBX1* is complicated because only the breaks of the *E2A* gene are site-specific and localized at RSS-like motifs, while the breaks within the *PBX1* gene are scattered over a large genomic region. Unlike *BCR-ABL1, MLL-AF4* and *TEL-AML1* gene rearrangements, however, the *E2A-PBX1* fusion carries N-nucleotides in almost all instances, which argues for a contribution of the V(D)J recombinase.

►Chromosomal translocations affecting one of the immunoglobulin loci in mature B cell lymphomas may also be owed to somatic hypermutation and/or immunoglobulin class-switch recombination. These two mechanisms are active in mature B cells during affinity maturation within germinal centers of tonsils, lymph nodes and spleen. Indeed, frequent recurrent gene rearrangements in germinal center-derived B cell lymphoma most likely result from somatic hypermutation and/or class-switch recombination and not from V(D)J recombination.

V(D)J recombinase-related genetic aberrations indeed seem to have distinct mechanisms in B cell lineage (pre-B ALL and B cell lymphoma) and T cell lineage (T cell precursor ALL) malignancies. According to a recently proposed model, chromosomal translocations in T cell lineage ALL are more frequent and are mainly caused by illegitimate V(D)J recombination between a TCR locus and a proto-oncogene locus, i.e. both loci were targeted by V(D)J recombination. Conversely, for translocations in B cell lineage malignancy, involvement of the V(D)J recombinase machinery is rare. In these rare cases, in which aberrant V(D)J recombination contributes to B cell lineage malignany, V(D)J recombination typically targets only one of the two translocation partners: In t(1;19)((q23;p13) pre-B ALL, the *E2A* locus is targeted by the V(D)J recombinase but

not its fusion partner *PBX1*. In both ►Mantle cell lymphoma and ►Follicular lymphoma, the *IGH* locus is targeted by aberrant V(D)J recombinase activity but not the *BCL1* and *BCL2* genes on the respective partner chromosome.

VE-Cadherin

Definition

Vascular endothelial cadherin is a ►adhesion molecule important in maintaining endothelial permeability. Inhibition of VE-cadherin by antibodies increases both permeability and neutrophil transmigration in vivo.

►Vascular Disrupting Agents

Vector

Definition

Genetic information encoding e.g. a therapeutic gene, plus those sequences required for gene expression and for integration into the host genome where applicable. In some situations, the term “vector” denotes the vector sequences in the context of a gene transfer vehicle (viral or non-viral).

►Gene Therapy

VEGF

Definition

►Vascular endothelial growth factor; Is a cytokine made by cells that stimulates new blood vessel formation, by mediating numerous functions of endothelial cells including proliferation, migration, invasion, survival, and permeability. VEGF is also known as vascular permeability factor. VEGF naturally occurs as a glycoprotein and is critical for ►angiogenesis.

►Vascular Endothelial Growth Factor

VEGF-C

Definition

A member of the ►VEGF growth factor family that stimulates lymphangiogenesis and is required for lymphatic vessel development.

►Lymphangiogenesis

VEGFR

Definition

►Vascular endothelial growth factor receptor; ►VEGF.

VEGFR-2

Definition

►Vascular endothelial growth factor receptor 2 gene is transcriptionally regulated during ►angiogenesis.

►Vascular Disrupting Agents

VEGFR-3

Definition
A member of the ►VEGF receptor family that recognizes the VEGF-C and VEGF-D isoform.

►Lymphangiogenesis

Verapamil

Definition
A calcium ion influx inhibitor (calcium entry blocker or calcium ion antagonist). Verapamil is used for reduction of blood pressure and for treatment of cardiac diseases.

►ABC-Transporters
►Fluoxetine

Verner-Morrison Syndrome

Definition
Is a clinical syndrome characterized by a profuse watery diarrhea that results in massive loss of water, potassium, sodium, and bicarbonate, leading to dehydration, electrolyte deficiency, and metabolic acidosis. It is associated with endocrine pancreatic tumors that produce excessive amounts of the vasoactive intestinal polypeptide (VIPomas).

►Neuroendocrine Carcinoma

Vesicle Trafficking

Definition
The process through which membrane-bound molecules are routed to various cellular compartments. Cell surface receptors and their associated signaling complexes are routed to internal endosomal organelles through this process. Signal transduction and vesicle trafficking processes are coordinated and trafficking events can generate discrete cellular signals.

V-Gene

Definition
Variable regions of ►immunoglobulin genes that encode light and heavy chains.

VHL

Definition
Is the gene involved in von Hippel-Lindau disease (renal carcinoma).

►von Hippel-Lindau Tumor Suppressor Gene

Video-assisted Thoracoscopic Surgery

Definition
VATS; Minimaly invasive surgical technique used to diagnose and treat problems in the chest. One or more small incisions are made in the chest and a fiberoptic camera called thoracoscope is inserted through one incision and surgical instruments are inserted through this or other small incisions.

►Pleural Effusion

Villin 2

►ERM Proteins

Vinblastine

Definition
Vinblastine is a ►chemotherapy drug of the group of ►vinca alkaloids that is used as a treatment for some

types of cancer including ►leukemia, ►lymphoma, ►breast cancer and ►lung cancer. It binds ►tubulin, thereby inhibiting the assembly of ►microtubules. It is M phase ►cell cycle specific since microtubules are a component of the ►mitotic spindle and the ►kinetochore.

Vinca Alkaloids

Definition

A class of chemotherapeutic drugs that disrupts ►mitosis by binding to ►tubulin, thus preventing ►microtubules from forming. These are also known as anti-mitotic, antimicrotubule agents, or mitosis inhibitors. Common vinca alkaloids include ►vinblastine, ►vincristine, ►vindesine, and ►vinorelbine.

Vincristine

Definition

Chemotherapeutic agent; ►vinca alkaloid; inhibits ►tubulin polymerization.

Vinorelbine

Definition

Chemotherapeutic agent; ►vinca alkaloid; inhibits ►tubulin polymerization.

VIPoma

Definition

Is a functioning ►islet cell tumor that produces excessive amounts of the vasoactive intestinal polypeptide (VIP) that can result in the ►Verner-Morrison syndrome.

►Neuroendocrine Carcinoma

Viral Oncogene

Definition

A viral gene that contributes to malignancies in vertebrate hosts.

►Gastrointestinal Stromal Tumor

Viral Oncology Epigenetics

James Flanagan
Wolfson Institute for Biomedical Research, University College London, London, UK

Definition

►Viral oncology epigenetics can represent the ►epigenetic alterations that occur within the host cell genome as a result of viral infection or virally induced ►carcinogenesis. Alternatively, viral oncology ►epigenetics can refer to epigenetic alterations of the viral genome during latent or lytic infection or during carcinogenesis.

Characteristics

One of the emerging concepts in cancer biology is that epigenetic alterations are important in the initiation and early progression of the majority of human cancers. However, differentiation of the early cancer causing epigenetic alterations from later consequences is difficult. Oncogenic viruses are typically very small and with very few genes and yet can induce transformation. Therefore, investigations into the epigenetic alterations that viruses make to the host cell genome may provide an indication of which epigenetic alterations are critical for early carcinogenesis.

Oncogenic viruses include any virus that has been identified as the causative agent for cancer. They can induce cellular alterations that enable transformed cells to evade host responses, including the immune system and apoptosis. In vitro, oncogenic viruses induce cellular transformation creating cells capable of unrestrained proliferation and are often tumorigenic in athymic mice. Oncogenic viruses in humans include DNA viruses, such as ►hepatitis B viruses (HBV), ►human papillomavirus (HPV), polyomaviruses (BKV, JCV, and ►SV40) and the gamma-herpesviruses ►Kaposi sarcoma-associated herpesvirus (KSHV) and ►Epstein-Barr virus (EBV) as well as ►retroviruses, such as ►human T cell lymphotrophic viruses 1 and 2

(►HTLV1/HTLV2), the RNA flavivirus ►hepatitis C virus (HCV).

Epigenetics is a term used to describe the regulation of gene expression and genomic stability by heritable, but potentially reversible, changes in ►DNA methylation and chromatin structure. DNA ►methylation is controlled in the genome by various epigenetic regulators, including the DNA methyltransferases (*DNMT1*, *DNMT3A* and *DNMT3B*), methylated DNA binding proteins (e.g. *MECP2*, *MBD1-MBD4*) and DNA demethylases (e.g. *GADD45A*, *GADD45B*). Chromatin structure is regulated by posttranslational modifications to the tails of the core histones that make up the ►nucleosome including lysine acetylation, lysine and arginine methylation, lysine ubiquitination, serine phosphorylation and proline isomerization. The enzymes that catalyze these modifications (►histone deacetylases, histone acetyltransferases, histone demethylases and histone methyltransferases) interact with other chromatin structure regulators, such as the polycomb group (repression) and trithorax group (activation) genes, ATP-dependent chromatin remodeling complexes and ►microRNAs and the RNAi machinery to coordinate together the regulation of gene expression.

In normal cells transcriptionally active genes typically contain unmethylated promoter ►CpG islands, gene-wide histone hyperacetylation and a number of specific histone modifications, such as H3 lysine 4 (H3K4) methylation, H3K79 methylation, H3 arginine methylation, H3S10 phosphorylation and H2B ubiquitination. Transcriptionally repressed genes often contain methylated promoter CpG islands, histone hypoacetylation and H3K27 and H3K9 methylation. In cancer cells, however, there are marked differences in the epigenetic landscape of the genome. Genome-wide, there is an overall ►hypomethylation associated with repetitive DNA in cancer cells, as well as promoter hypermethylation of specific tumor suppressor genes and hypomethylation of ►oncogenes. In addition to altered DNA methylation, ►chromatin remodeling in cancers is also considered a common epigenetic alteration, including loss of H4K16 acetylation fand H4K20 tri-methylation and gains in H3K4 di- and tri-methylation, H3K79 methylation and H3 and H4 hyperacetylation.

Host Epigenetic Changes Due to Viruses and Virus-Associated Cancers

Differentiating epigenetic causes of cancer from epigenetic consequences is one of the more challenging goals of current research in the epigenetics field. This conundrum can equally be applied to virally induced cancers. It is challenging to differentiate epigenetic changes that are directly due to viral infection, due to the anti-viral response of the host or due to downstream effects of the virally induced transformation. Important early epigenetic changes in cancer may be distinguished from consequences via the identification of specific interactions between epigenetic regulators and the viral proteins effecting those changes and then determining the downstream effects of these interactions.

Kaposi Sarcoma Associated Herpesvirus

►Kaposi sarcoma associated herpesvirus (KSHV) is an oncogenic gamma-herpesvirus identified as the causative agent of the endothelial tumor Kaposi sarcoma (KS) and associated with the lymphoproliferative disorders primary effusion lymphoma (PEL) and multicentric Castleman disease (MCD). Like other gamma-herpesviruses KSHV has both a lytic and latent phase of its life cycle. In the majority of tumor cells the more restricted set of latent genes are often expressed. Recent evidence suggests that KSHV can reprogram the cellular gene expression profiles of both blood and lymphatic vessel endothelial cells, although the mechanisms behind this reprogramming remain unclear.

A direct link between the KSHV protein latency associated nuclear antigen (LANA) and the de novo methyltransferase DNMT3a was examined in a study revealing recruitment of DNMT3a by LANA to the chromatin possibly via its interaction with histones H2A and H2B. This targeted repression of ~80 cellular genes, many of which are typical targets of epigenetic inactivation in numerous cancers. KSHV has been shown to hypermethylate the ►*CDKN2A* gene promoter in the majority of PEL cell lines harboring KSHV and in primary PEL samples. This is not unexpected, given that *CDKN2A* is probably the gene most commonly hypermethylated in cancers. This suggests that KSHV has the ability to invoke DNA methyltransferase activity, via the LANA protein, and may inactivate numerous cellular genes by promoter hypermethylation. In addition, LANA has numerous other roles in epigenetic gene regulation via interactions with a methylated DNA binding protein MECP2, as well as the mSin3 repression complex and the SUV39H1 histone methyltransferase. Numerous studies have also proposed a direct interaction between the KSHV encoded interferon regulatory factors (viral IRF 1, IRF2 and IRF3) and the histone acetyltransferase complex ►p300/CBP. The binding of CBP by the cellular IRF3 is thought to be a necessary interaction for transcriptional upregulation of the antiviral cytokine interferon-β (IFN-β). In effect, the interactions of the viral IRFs with CBP inhibit histone acetyltransferase activity and promote histone hypoacetylation, altered chromatin structure and reduction of cytokine gene expression. Presumably other genes that are activated by p300/CBP would also be down regulated.

Epstein Barr Virus

Epstein Barr virus (EBV) is another gamma-herpesvirus that has been identified as the causative agent of

numerous lymphoproliferative diseases such as ►Burkitt lymphoma (BL), ►Hodgkin Disease (HD) and post-transplant lymphoproliferative disease (PTLD). EBV is also involved in carcinogenesis of epithelial origin tumors, particularly ►nasopharyngeal carcinomas (NPC) and some gastric cancers. The EBV latent membrane protein 1 (►LMP1) increases DNA methyltransferase activity by upegulating the maintenance methyltransferase DNMT1 as well as both de novo methyltransferases, DNMT3b and DNMT3a. In EBV-related epithelial cancers this causes increased promoter methylation and reduction of e-cadherin expression, resulting in increasing cell migration, an important step during carcinogenesis. Other cellular genes that are methylated by EBV are yet to be identified. The EBV latent nuclear antigens EBNA 2 and 3c appear to alter histone acetylation via their interactions with either the p300/CBP complex or with histone deacetylases, respectively.

One of the interesting observations regarding the EBV proteins that coordinate epigenetic regulation (EBNA2, EBNA3c, and LMP1) is that they are all latent genes that are not expressed in most Burkitt lymphoma, EBV-associated gastric cancer or nasopharyngeal carcinomas. This may lead one to conclude that the role of the virus induced host epigenetic alterations may be limited in these cancers. However, in these cancers and in other virally induced cancers it cannot be ruled out that the early cancer precursor cells may have been infected with the virus expressing these proteins that could alter the host epigenome. Epigenetic fingerprints such as histone modifications and DNA methylation are mitotically heritable and therefore even if the progeny cancer cells no longer express these latent genes, the epigenetic history of the cell may remain.

Hepatitis B Virus

The hepatitis B virus (HBV) is a DNA virus from the hepadnavirus family and is the causative agent of viral hepatitis, a chronic inflammation of the liver, which can develop into ►hepatocellular carcinoma. The hepatitis B virus oncogenic protein HBx has been shown to increase the activity of DNMT1, and similar to EBV related cancers, this results in increased DNA methylation of e-cadherin (*CDH1*) and an increased cell migration. Whether this can be attributed directly to increased activity of the maintenance methyltranserase, DNMT1, is not clear as EBV also activates the de novo methyltransferases, DNMT3a and DNMT3b which HBV does not. The tumor suppressor gene *CDKN2A* and the glutathionine-S-transferase (*GSTP1*) genes are both commonly hypermethylated in ►hepatocellular carcinomas associated with HBV, however, there is currently no direct evidence that the virus causes the increased DNA methylation of these genes.

Human Papillomavirus

The human papillomavirus (HPV) family is a large family of DNA viruses of which some subtypes (particularly HPV 16 and 18; ►early genes of human papillomaviruses) are associated with ►cervical cancer and rarer epithelial origin cancers. The two important HPV oncoproteins E6 and E7 have both been implicated in epigenetic alterations during carcinogenesis. HPV E7 protein increases the DNA methyltransferase enzymatic activity by direct interaction with DNMT1 and E6 can bind and inhibit the histone acetyltransferase activity of p300 and CBP similarly to KSHV. This transcriptional repression by HPV is supported by E7 protein interaction with the Nurd ATP-dependent chromatin remodeling complex and ►histone deacetylase 1 which are both involved in transcriptional repression. Numerous cellular epigenetic alterations have been described in ►cervical cancers including hypermethylation of tumor suppressor genes *RB*, *CDKN2A*, *MLH1*, *VHL* and *CDH1*. Whether the E7 mediated increase in DNA methyltransferase activity is responsible for methylation of these genes is yet to be established.

Polyomaviruses (SV40, BK Virus and JC Virus)

Polyomaviruses are very small DNA viruses (~5kb) encoding only six genes. In humans the BK virus is associated with some brain tumors and the JC virus has been associated with gliomas, medulloblastomas and a minority of colorectal carcinomas, however, neither virus has been implicated as direct causative agents in these tumors. The simian virus SV40 is not a causative agent of any human tumors, but has been found in some mesotheliomas. These three polyomaviruses encode the T-antigen oncoprotein which is involved in inducing DNA methylation alterations. The SV40 virus upregulates the de novo methyltransferase DNMT3b which results in increased DNA methylation and increased tumorigenicity in normal human bronchial cells. Abberrant methylation of *RASSF1A*, *HPP1*, *CCND2*, *DCR1*, *TMS1*, *CRBP1*, *HIC1* and *RRAD* have all been detected in SV40 associated malignant mesotheliomas or SV40 infected human mesothelial cells. The BK virus increases transcription of DNMT1 through the pRB/E2F pathway in cells that have pRB inactivated, however, this has not yet been linked to increased methylation of any specific genes. The JC virus T antigen expression is associated with the methylator phenotype in colorectal cancer, however this link with methyltransferase is still rather speculative.

Adenovirus

The ►adenovirus protein E1A can induce transformation in vitro and can induce tumors in animal models but the virus does not in itself cause any human cancers. E1A interacts with the p300/CBP complex and is likely to result in a loss of histone acetylation across the

genome. It has been proposed that this interaction could be one of the key events in E1A induced cellular transformation. Another important role could be its capability of increasing DNMT1 activity, although which cellular genes are hypermethylated as a result of this increased activity is yet to be determined.

Human T Cell Lymphotrophic Viruses

Human T cell lymphotrophic viruses (►HTLV1 and HTLV2) are single stranded RNA retroviruses that are causative agents of adult T-cell leukemias. While there is little data on host DNA methylation alterations directly mediated by this virus, the HTLV1 Tax protein does interact with the ►p300/CBP complex to mediate transcriptional repression.

Epigenetic Alterations in the Virus Due to the Host

The opposite side of viral oncology epigenetics is the epigenetic alterations that occur on the viral genome during the lytic and latent stages of infection and during carcinogenesis. In addition to regulation of their own genome, DNA methylation of viral genes has also been proposed as a mechanism for silencing potentially highly immunogenic proteins that would otherwise elicit an immune response.

Due to spontaneous deamination of methylated cytosines to thymine there is a reduced rate of CpG dinucleotides (►CpG island) in the genomes of organisms that use DNA methylation as a mechanism of gene silencing. This mechanism, known as CpG suppression, is seen in the human genome with an observed CpG dinucleotide rate of ~1% where the statically expected rate would be 1/16 (6%) of the total bp. The genomes of many gamma-herpesviruses, including EBV, show CpG suppression suggesting that their genomes have been methylated similarly to the DNA of the host cells in which they reside. In this way the epigenetic state of the viral genome can be considered due to the host in which they reside. KSHV on the other hand only shows CpG suppression at the lytic switch promoter, ORF50, suggesting that the rest of the viral genome is not extensively methylated. KSHV in fact controls its entry into the lytic phase by employing both demethylation and chromatin remodeling of the lytic switch gene Rta (ORF50) promoter and its latent cycle replication is controlled by hyperacetylation of the replication origin. The EBV C promoter which drives the expression of the latent gene transcripts is often methylated and silenced in most EBV associated tumors. This prevents the expression of highly immunogenic Epstein Barr nuclear antigen (EBNA) proteins that would elicit a cytotoxic T-cell response and provides a very good example of how viruses exploit epigenetic mechanisms to evade the immune system.

Conclusions

It is clear that oncogenic viruses increase the activity of DNA methyltransferases and have the ability to decrease ►histone acetylation via ►p300/CBP. These are both likely to be essential for the inactivation of tumor suppressor genes. That both of these events occur in many non-viral cancers as well suggests that they may be some of the earliest epigenetic alterations in carcinogenesis. The common pathways utilized by viruses to effect these epigenetic changes suggest that perhaps very few changes are required to initiate epigenetic misregulation in cancer. For example the BK virus increases transcription of DNMT1 through the pRB/E2F pathway in cells that have pRB inactivated, however this has not yet been linked to increased methylation of any specific genes. The HPV E7 protein, KSHV LANA, polyomavirus T antigen and adenovirus E1A are all known to inactivate pRB as well as increase DNA methyltransferase activity, suggesting that inactivation of pRB may be a critical step towards epigenetic alterations in carcinogenesis. It is also interesting to note that many of the viral proteins described here, LMP1, E6 and E7, LANA, E1A, large T antigen and Tax, are all often portrayed as the viral "oncoproteins" as they are often either essential components of viral transformation or oncogenic on their own. This is often used as evidence that the functions of these proteins, in this case the epigenetic interactions, are indeed essential for carcinogenesis induced by these viruses.

Viral Vector-mediated Gene Transfer

Yuanan Lu[1], Lynn Sniderhan[2]
[1]Department of Public Health Science, University of Hawaii, Honolulu, HI, USA
[2]Department of Microbiology and Immunology, University of Rochester, Rochester, NY, USA

Synonyms

Virus vector; Oncolytic virus; Virus vector-mediated gene transfer

Definition

Refers to the process by which virus vectors are used to deliver functional genes of interest into target cells and tissues, either *in vitro* or *in vivo*.

Characteristics

Viruses have evolved natural mechanisms to efficiently transport their own genetic materials into host cells while also commandeering host cell machinery for replication. Therefore, the use of viruses for the introduction of therapeutic genes and stimulation of the immune system has become an attractive and promising method for the treatment of a variety of diseases, including cancer.

The genomes of a wide array of viruses can be modified and used as a tool for the efficient transfer of exogenous genes into living cells or organisms. In broad terms, two types of virus vectors exist: replication-competent, and replication-defective. Replication- competent vectors are exemplified by live-attenuated strains of many common viruses, including both DNA viruses (such as ►adenovirus, herpes simplex virus type-1 (HSV-1) and vaccinia virus) and RNA viruses (such as recombinant derivatives of vaccine strains of measles virus, poliovirus and vesicular stomatitis virus (VSV)).

Replication-defective vectors have an intrinsically more favorable safety profile than replication-competent vectors, but can be more difficult to engineer and manufacture. Commonly used replication-defective vectors include both small (adeno-associated virus (AAV)) and large (adenovirus, HSV-1) DNA viruses, as well as RNA viruses (including alphaviruses such as Venezuelan equine encephalitis virus (VEE), lentiviruses and other retroviruses). In all cases, the vectors are designed such that one or more genes essential for viral replication or assembly have been deleted or otherwise rendered defective.

Some viral vectors combine aspects of both replication-competent and replication-defective vectors. These include vectors that are fully competent for replication in cells of one type or species, but not in cells of a different type, or from a different host species. Widely used examples include baculovirus vectors, which are able to transduce mammalian cells but which can replicate only in insect cells, and certain poxviruses such as the Modified Vaccinia Ankara (MVA) strain of vaccinia virus, which replicates efficiently in chick embryo fibroblasts, but undergoes abortive infection in human cells. Conditionally replicating virus vectors, such as oncolytic viruses, are another example – and are especially attractive as potential therapeutic agents for cancer treatment, as will be discussed later in this essay.

Finally, there is considerable interest in the development of artificial virus-like vectors, including virus-like particles (VLPs). VLPs offer potential advantages for vaccine delivery or display of vaccine antigens due to the densely repetitive nature of the surface of many VLPs. These properties explain, in part, the tremendous effectiveness of the recently licensed VLP-based vaccines for oncogenic human papillomavirus (HPV) subtypes. Completely synthetic gene transfer vectors have particular appeal because of the potential to mass-produce such agents using conventional chemical technologies, rather than the more complex and cumbersome biological production methods required to manufacture conventional virus vectors. However, the efficiency of gene transfer by completely synthetic vectors currently remains far inferior to that of conventional virus vectors.

Detection of Viral Vector-Mediated Gene Expression and Vector Distribution. In order to analyze the success of viral vector-mediated gene transfer, it is important to be able to monitor both the distribution of the vector and the effectiveness of vector-mediated gene expression. This can be achieved by subcloning a reporter gene into the viral vector backbone. Several reporter genes are commonly used for this purpose including: fluorescent proteins of various colors (Including green fluorescent protein, GFP), *E. coli* β-galactosidase (*LacZ*), and various forms of luciferase *(Luc)*. It is simple to detect and quantitate cells expressing these marker genes *in vitro*, using FACS analysis or fluorescence microscopy. Detection of vector-transduced cells *in vivo* often requires a different approach. Modified luciferase reporters such as the Gaussia luciferase can generate a very bright light emission that can be detected and localized to specific tissues by using highly sensitive light detection methods in combination with 3D tomography.

For in vivo imaging applications, a number of marker genes are compatible with the use of currently available gamma cameras or ►positron emission tomography (PET) instruments. These include the sodium iodide symporter (NIS), which has been used to target radioisotopes of iodine to cancer cells. This allows both *in vivo* imaging of the distribution of the vector, quantitation of gene expression, and also delivery of therapeutic radiation to cancer cells. The ►HSV-1 thymidine kinase (TK) gene has also been a successful tool for imaging when coupled with PET tracers. Furthermore, in the case of cancer therapy, the TK gene can be combined with ►prodrugs, such as ►ganciclovir (GCV), which become activated by TK and exert cytotoxic effects on rapidly dividing cancer cells.

Viral Vectors for Cancer
►*Gene Therapy*. A number of vectors, including AAV, adenovirus, HSV, measles virus and ►retroviruses have been developed to promote the selective elimination of tumor cells. Cancer gene therapy approaches include

immunotherapy and suicide gene therapy. In addition, naturally oncolytic viruses such as reovirus (exemplified by Reolysin) and oncolytic viral vectors that result in the destruction of transduced tumor cells are also being pursued. For reasons of space, we will focus the rest of this review on the latter. Virus platforms that are being used to develop oncolytic vectors include adenovirus, HSV-1, measles virus and vaccinia virus. The field of ►oncolytic virotherapy has made rapid progress in the past decade, resulting in human clinical trials of multiple agents based on all of the above vector platforms. Clinical trials have included phase III studies, and in 2005, the field received a major boost when the Chinese government approved the first oncolytic virus therapy for cancer treatment. This is a significant landmark that likely presages the approval of other oncolytic virus therapies elsewhere in the world.

There are several approaches that can be taken in the use of oncolytic vectors for cancer therapy. One approach simply utilizes the replicating virus itself as therapy. As the virus replicates within the tumor cells, the cells are lysed and destroyed. Considerable efforts are being made to improve tumor-selectivity, and to ensure that the ►virotherapy spares surrounding healthy tissue. This can be accomplished by: (i) placing viral genes under the control of tumor-specific promoters (such as the PSA promoter in ►prostate cancer); (ii) altering the receptor binding properties of the vector in order to target tumors; (iii) utilizing the oncolytic properties of the vector in conjunction with "arming" of the virus with therapeutic genes. The use of "armed" vectors is attractive due to the fact that it draws on multiple mechanisms to achieve the desired effect. For example, engineering oncolytic HSV vectors to deliver a therapeutic gene, such as an antiangiogenic factor, has been shown to enhance the therapeutic efficacy of the vector in small animal model systems. It is also possible to introduce a tumor suppressor gene, such as ►p53, into cancer cells via an oncolytic vector in order to exert control over the cell cycle of the tumor cells while also subjecting the cells to the oncolytic activity of the virus itself.

The success of oncolytic vectors as anti-cancer therapies can be further enhanced by combining the virotherapy with either chemotherapy or radiation treatment. Not only is it possible to use radiation-inducible promoters to direct the expression of essential viral genes, but also it has been shown that radiation and chemotherapy are able to enhance the replication of certain oncolytic vectors. For example, in the case of oncolytic HSV-1 vectors, the induction of DNA repair genes by chemotherapy actually augments viral replication. Also, the use of a reporter gene, which has therapeutic effects when combined with radiation, such as NIS, offers the promise of an effective synergistic approach to tumor treatment.

Overall, the field of cancer gene therapy has made important advances within the past few years, and while oncolytic virotherapy may not offer a simple "magic bullet," it has considerable potential to synergize with, and enhance the effectiveness of, other established therapies such as chemo- and radio-therapy.

Viral Vector Cancer Gene Therapy – Pitfalls. While important advances have been made, concerns remain. First, oncolytic virotherapies may not be sufficiently effective to provide optimal therapeutic benefit as a stand-alone treatment. Therefore, the effectiveness of the vectors needs to be increased. In addition, the issue of pre-existing immunity to common viruses such as HSV-1 and adenovirus serotype 5 may need to be overcome, in order to make most effective use of oncolytic viruses based on these agents. Second, biosafety questions must be addressed. These include the potential for vector replication in normal tissues, such as rapidly dividing stem cells, and the inherent genetic instability of certain viruses. For example, it was recently found that an oncolytic HSV-1 vector being used in human clinical trials contained a previously unrecognized mutation (a truncation in the UL3 open reading frame).

In conclusion, virus vector-mediated gene transfer holds significant promise as a potential therapeutic approach for many human diseases, including cancer. The recent approval of the world's first oncolytic virus for human tumor therapy is indicative of the rapid and exciting progress in the field. Moreover, evolving success in combining oncolytic virotherapies with sophisticated tumor-targeting and gene transfer approaches, as well as conventional chemo- and radio-therapy, provide a compelling reason to anticipate new cancer treatments that more effectively exploit the potential of viral vector systems.

Virilization

Definition

Refers to the process of normal male sexual development (puberty) regulated by the production of testosterone. In adrenocortical carcinoma, ►virilization can occur in boys (precocious puberty) or girls (pseudo-precocious puberty) as a result of excessive amounts of androgens.

►Childhood Adrenocortical Carcinoma

Virology

Paul G. Murray
CRUK Institute for Cancer Studies, Molecular Pharmacology, Medical School, University of Birmingham, Edgbaston, Birmingham, UK

Definition

Virology addresses the molecular nature of viruses, their genetic content, the pathway by which they enter cells and multiply using the molecular machinery of the host cell, and the mechanisms by which they elicit diseases. Tumor virology is a specialized discipline analyzing the association of particular virus types with cancers in animals and humans.

Characteristics

In 1964 the first human tumor virus, the ►Epstein-Barr virus (EBV), was isolated from tumor samples of a patient with African ►Burkitt lymphoma. Subsequently, EBV was linked to the development of other forms of cancer. In the 44 years since the discovery of EBV, other human tumor viruses have been identified (Table 1).

Tumor Virus Epidemiology

The development of cancer is an infrequent consequence of viral infection and often occurs many years after any initial infection. Therefore, tumor viruses often infect individuals without adverse effects. For example, approximately 95% of the World's adult population are infected with EBV. The majority of these individuals carries the virus asymptomatically and will not develop cancer as a consequence of EBV infection. Likewise, tumors associated with the human T lymphotropic virus-1 (HTLV1) arise infrequently in populations where the virus is endemic. Thus, presumably alone tumor viruses are usually insufficient to cause malignancy; virus infection is only one step in the multistep process leading to a cancer. Although virus infection may be linked to a particular cancer type, in order to establish a clear association between the virus and the development of a cancer it is usually necessary to detect the virus within the tumor cells.

Immunosurveillance and Viral Oncogenesis

Virus-associated cancers occur in both immunocompetent and immunodeficient patients. However, the latter group has a particularly high risk for the development of these tumors, suggesting that the immune system can prevent the development of virus-associated cancers. ►Cytotoxic T cells (CTLs) are particularly important in the recognition and elimination of virus-infected tumor cells. CTLs recognize virus-derived peptides that are presented by the infected cell in association with MHC class I. The development of virus-associated cancers in immunocompetent individuals suggests that the virus-infected tumor cell or its progenitor has developed mechanisms to escape immune recognition. In some cases virus-specific CTLs have been used to treat virus-associated cancers (►adoptive immunotherapy). In some cases gene therapy may be used to modify CTL function (►CTL therapy).

Tumor Viruses

There are a number of different viruses that have been associated with the development of cancer. The acutely transforming ►retroviruses cause cancer in animals but to date none have been associated with the development of human tumors. The following sections consider some of the important human tumor viruses.

Herpesviridae

The major oncogenic herpesviruses are the Epstein-Barr virus (EBV) and the Kaposi sarcoma-herpesvirus (KSHV).

Epstein-Barr Virus

EBV (Epstein-Barr virus) is a double stranded DNA virus of the gamma herpesvirus family. EBV infects the majority of the World's adult population and following primary infection the individual remains a lifelong carrier of the virus. In poorly developed countries, primary infection with EBV usually occurs during the first few years of life and is often either asymptomatic or produces only a mild febrile illness. However, in developed populations primary infection is frequently delayed until adolescence or adulthood, in many cases producing the characteristic clinical features of infectious mononucleosis (also known as glandular fever) including sore throat, fever, malaise, lymphadenopathy and mild hepatitis. EBV is often transmitted from one individual to another in saliva and the oropharynx is

Virology. Table 1 Major oncogenic viruses

Virus family	Virus	Natural host	Host in which virus is oncogenic	Tumor	Major oncogenic protein (s)
Adenoviridae	Human Adenoviruses A, B, D	Man	Hamster, rat	Various	E1A, E1B
Polyomaviridae	Polyoma	Mouse	Mouse	Various	Middle T antigen, Large T antigen
	SV40	Monkey	Hamster, rat	Various	Large T antigen
Papillomaviridae	HPV 16,18	Man	Man	Skin cancer, cervical cancer, anal cancer	E6, E7
Herpesviridae	EBV	Man	Man	Burkitt lymphoma, nasopharyngeal carcinoma, Hodgkin lymphoma	LMP1
	KSHV	Man	Man	Kaposi sarcoma, multicentric Castleman disease, primary effusion lymphoma	
Hepadnaviridae	Hepatitis-B virus	Man	Man	Hepatocellular carcinoma	Hepatitis-B x-antigen
Flaviviridae	Hepatitis C virus	Man	Man	Hepatocellular carcinoma	HCV core, NS3, NS4B, NS5A
Retroviridae	HTLV1	Man	Man	Adult T cell leukaemia	Tax

believed to be both the primary site of infection and where virus replication occurs. Virus replication in the oropharynx ensures the production of new virions for transfer in saliva to other susceptible hosts. Because EBV is transmitted in this way infectious mononucleosis is often referred to as the 'kissing disease'.

Soon after primary infection EBV infects B-lymphocytes through an interaction of the viral envelope glycoproteins, gp350/220, with the cellular EBV receptor, CD21. EBV does not usually replicate in B-lymphocytes but instead establishes a latent infection during which no new virions are produced and only a subset of viral genes are expressed. As a consequence of the host immune response, the number of latently infected B-lymphocytes in the peripheral blood falls to approximately 1 in 106 during the months following primary EBV infection. This low number is maintained in healthy carriers by the continual elimination of proliferating EBV-transformed B-lymphocytes by virus-specific CTLs.

The EBV genome usually exists in cells as extrachromosomal pieces of circular DNA, known as episomes. During latency only a limited number of viral genes are expressed; these include six nuclear proteins, referred to as the Epstein-Barr nuclear antigens (EBNAs), two latent membrane proteins (LMPs), two non-translated RNA molecules known as the Epstein-Barr encoded RNAs (EBERs 1 and 2), and transcripts from the BamH1A region of the viral genome (BamH1A rightward transcripts; BARTs). Three major forms of viral latency exist in tumors (Table 2). The restricted forms of latency have evolved partly to prevent expression of the immunodominant EBNA proteins and are controlled by differential ▶methylation of viral promoters. Demethylating agents can induce

Virology. Table 2 Three major forms of viral latency are associated with EBV-positive malignancies

Latency	Viral genes expressed
I	EBERs, BARTs
	EBNA1
II	EBERs, BARTs
	EBNA1,
	LMP1, LMP2A, & LMP2B
III	EBERs, BARTs
	EBNA1, EBNA2, EBNA3A, EBNA3B, EBNA3C & EBNA Leader Protein (LP)
	LMP1, LMP2A, & LMP2B

During EBV latency only a limited number of viral genes are expressed; these include six nuclear proteins, referred to as the Epstein-Barr nuclear antigens (EBNAs 1, 2, 3A, 3B, 3C and EBNA-LP), two proteins found in the cell membrane of infected cells known as the latent membrane proteins (LMPs), two non-translated RNA molecules known as the Epstein-Barr virus encoded RNAs (EBERs) and the BARTs.

expression of these EBNAs and in some cases can also induce lytic cycle; this has been proposed as an alternative treatment for some EBV-associated cancers (►epigenetic therapy).

Many viruses, including EBV, are able to subvert the cellular epigenetic machinery, not only to regulate virus gene expression, but also potentially to influence cell growth by silencing ►tumor suppressor genes).

LMP1 is the major transforming protein of EBV; it is a transmembrane protein which mimics a constitutively activated ►tumor necrosis factor receptor (TNFR). In normal cells binding of the appropriate ligand to these receptors causes intracellular signaling and a number of effects including either proliferation or ►apoptosis, depending upon the nature of the signal and the cell type involved. In contrast, LMP1 requires no ligand for its activation and delivers constitutive intracellular signals leading to cell proliferation and protection from apoptosis, which in turn accounts for the transforming properties of this protein. Signaling pathways activated by LMP1 include ►NF-κB, JNK/AP-1, p38/MAPK, and JAK/STAT (►signal transducers and activators of transcription). Several of these pathways are aberrantly activated in EBV-associated tumors, such as ►Hodgkin lymphoma. LMP1 can decrease ►ATM expression, and may represent one of a number of ways in which EBV can disable DNA repair.

The malignant diseases associated with EBV include Burkitt lymphoma, ►nasopharyngeal carcinoma, Hodgkin lymphoma and a variety of other cancer types.

EBV-Encoded microRNAs

►MicroRNAs (miRNA) are a class of small RNAs that are probably major regulators of gene expression. miRNA are complementary to their cognate mRNA sequences; their interaction in the RNA-induced silencing complex (RISC) results in the cleavage of the target mRNA or in some cases inhibits its translation. The first virus-encoded miRNAs that were discovered were those of EBV, from which five miRNAs were cloned. EBV miRNAs are clustered in two distinct regions; the first is located within the 5′ and 3′ UTR of the BHRF1 transcript and the other within the BART region. The precise functions of these and other viral miRNAs are yet to be defined but are likely to play key roles in the regulation of virus and cellular gene expression, with potential involvement in oncogenesis.

Burkitt Lymphoma

►Burkitt lymphoma (BL) is an aggressive tumor of B-lymphocytes. There are two main types of BL. The endemic (African) type occurs with high frequency (5–20 cases/100,000 children/year) in equatorial Africa and Papua New Guinea and with a distribution that matches that of holo-endemic malaria. Almost all cases of endemic BL are EBV-positive. On the other hand, sporadic BL occurs world-wide with a much lower incidence and only around 15% of cases are EBV-positive. A third form of BL occurs in AIDS patients and approximately one-third of these tumors harbor EBV.

The cells of EBV-infected BL tumors usually display a latency I phenotype – that is they only express one viral protein, EBNA1. More recently variant forms of BL have been described in which expression of some of the other EBNA genes is observed. These are known as Wp using BL since they use a distinct viral promoter (Wp) to drive EBNA expression. Although infected BL tumor cells could process peptides from the EBNA1 protein and present them to specific CTLs, the processing of endogenous EBNA1 through the Class I pathway is inhibited. This, together with the down-regulation of MHC class I and ►adhesion molecules that is a feature of BL cells, contributes to their ability to evade immunodetection.

BL is characterized by reciprocal translocations that result in deregulation of the ►myc gene. In endemic BL, EBV-driven proliferation of B-lymphocytes, together with a general polyclonal stimulation of B cells induced by malaria infection, is thought to increase the chances of one of these specific translocations occurring in the B lymphocytes that will eventually give rise to BL.

Nasopharyngeal Carcinoma

►Nasopharyngeal carcinoma (NPC) is an epithelial tumor of the nasopharynx that is rare in the West but endemic in China, South East Asia, and North Africa. There are three main types of NPC; undifferentiated, non-keratinizing and squamous NPC. EBV is strongly associated with the undifferentiated type (UNPC). UNPC is an aggressive tumor with ►metastasis early to bone, liver, and lung and to the lymph nodes of the neck. The exact contribution of EBV to the pathogenesis of NPC has yet to be established, although recent studies suggest that EBV infection is preceded by genetic changes which include deletions of chromosome regions rich in tumor suppressor genes. Dietary factors, including nitrosamines from preserved fish, as well as EBV, are important risk factors for UNPC.

Hodgkin Lymphoma

►Hodgkin lymphoma (HL) is characterized by relatively low numbers of malignant, so-called ►Hodgkin/Reed–Sternberg cells (HRS cells) surrounded by a mass of ‘reactive’ non-malignant cells. HL is classified into four major subtypes on the basis of the relative proportions and morphology of the HRS cells, the nature of the reactive component, and the degree of fibrosis. In most cases the HRS cell is believed to derive from germinal centre (GC), or post-GC B-lymphocytes.

The frequency of the EBV association in HL is dependent upon a number of factors. EBV is most often associated with the mixed cellularity form and less commonly with the other subtypes. In North America and Europe, fewer (20–40%) tumors are EBV-associated, compared to developing countries where the association approaches 100%. Males also seem to be more at risk than females for EBV-positive HL. In EBV-positive cases, HRS cells express EBNA1, LMP1 and LMP2 (latency II pattern, Table 2). Epitopes from both LMP1 and LMP2 can be processed and presented to CTLs by infected cells. Thus, EBV-infected HRS cells should be recognized by EBV-specific CTLs; however, their survival in immunocompetent patients suggests that they, like BL cells, can escape the immune response. EBV-infected HRS cells express interleukin-10 (IL-10) which can inhibit EBV-specific CTL responses. Regulatory T cells have are also detected in the microenvironment of HL. It is likely that EBV and other persistent virus are able to recruit regulatory T cells to inhibit virus-specific T cell responses.

Lymphoproliferative Disease in Immunosuppressed Patients

In immunosuppressed patients the lack of EBV-specific CTLs can lead to an increase in the numbers of EBV-infected B-lymphocytes. In persistent ►immunosuppression states, such as in post-transplant patients or in AIDS sufferers, EBV-infected B-lymphocytes can proliferate to produce tumor like masses. Later, the acquisition of other genomic changes, such as those that affect ►p53, ►MYC or ►BCL-6 can lead to the formation of a classic ►lymphoma. Therefore, these lymphoproliferative diseases constitute a spectrum of disorders ranging from relatively benign atypical lymphoproliferations which will regress if the immunosuppressive therapy is withdrawn through to highly aggressive lymphomas which do not respond to immune reconstitution.

Other Tumors

EBV is associated with a number of other tumors, including some T cell lymphomas, such as nasal T/natural killer cell lymphomas (►NK cell lymphomas). EBV is also associated with some gastric cancers and with smooth muscle tumors that arise in some immunodeficient patients. Thus, EBV is apparently able to infect and contribute to neoplastic growth in a number of different cell types.

Kaposi Sarcoma Herpesvirus

►Kaposi sarcoma (KS), originally described in 1872, is a malignancy of endothelial cells that usually presents as a brown/purple skin tumor with more aggressive forms involving the lungs, lymph nodes, and gastrointestinal tract. Until the advent of the AIDS epidemic it was a relatively rare disease whose etiology remained obscure. KS occurs frequently in ►HIV-positive individuals, particularly in homosexual/bisexual males. Suspicions that KS might be due to an infectious agent were confirmed when a new human herpesvirus, known as Kaposi Sarcoma herpesvirus or KSHV (also referred to as human herpesvirus-8, HHV8), was discovered in KS tumors from AIDS patients. In fact, viral sequences are present in all types of KS including KS that arises in HIV-negative individuals. Serological assays to detect antibodies to KSHV were developed and showed a higher prevalence of infection in those groups at high risk for the development of KS. KSHV is also associated with primary effusion lymphomas and a rare lymphoproliferative disease known as multicentric Castleman disease.

KSHV is a double stranded DNA virus that is closely related to EBV. Its genome encodes many genes with homology to human genes (Table 3). Some of these are involved in the regulation of both innate and adaptive immune responses; many of them function to inhibit the immune responses to viral infection. For example, several virus-encoded ►interferon (IFN)-regulatory

Virology. Table 3 KSHV encodes many homologues of cellular proteins, some of these viral proteins and their effects upon the infected cell are summarized

Cellular gene	KSHV gene	Effect of virus gene expression
Cyclin gene (cyclin D2)	v-Cyclin D	Phosphorylates Rb and releases cell from cell cycle arrest
IL-6	v-IL-6	Autocrine stimulation of cell growth
IL-8R	v-GPCR	Constitutive activation of phosphatidylinositol pathway leading to cell growth
FLICE inhibitor protein (FLIP)	v-FLIP	Inhibits CD95-mediated apoptosis
Interferon regulatory proteins (IRFs)	v-IRFs 1–4	Inhibits interferon signaling
Bcl-2	v-Bcl-2	Protects infected cell from apoptosis

factors (IRFs) negatively influence anti-viral interferon responses, while others protect cells from apoptosis (e.g. v-►FLIP, v-►Bcl-2).

Polyomaviridae

Polyomaviruses are DNA viruses with small circular genomes encoding only six proteins. They include the mouse polyoma virus, the ►simian virus 40 (SV40), and the human viruses, ►BK virus and ►JC virus. With the exception of the mouse polyoma virus, these viruses do not cause cancer in their natural hosts but do induce tumors in newborn animals, including hamsters and rats. Polyomaviruses do not themselves encode replication proteins and must drive cells into S-phase where host DNA replication proteins can be utilized for virus replication. The large T (tumor) antigen (T-Ag) and the small t antigen (t-Ag) are major effectors of this. T-Ags bind to pRb encoded by the ►RB gene and displace ►E2F thereby promoting cell cycle progression; this is a major mechanism by which T-Ag promote the inappropriate cell proliferation leading to oncogenic transformation. The release of E2F from pRb activates p14ARF which can stabilize p53. However, SV40, JCV and BKV T-Ags can bind to and inactivate p53 and thus prevent inhibition of the cell cycle or apoptosis.

Apart from their well established role in the binding and inactivation of p53 and pRb, T-Ag can influence other pathways leading to oncogenesis. Thus, JCV T-Ag can interact with insulin receptor substrate-1 (IRS-1); this is associated with transformation and might be involved in the development of childhood medulloblastomas. JCV T-Ag can also bind β-catenin, causing it to translocate to the nucleus where it can stimulate the expression of genes such as c-myc and cyclin D1. SV40 t-Ag binds and inhibits protein phosphatase 2A (PP2A), a major serine/threonine specific protein phosphatase; this leads to the activation of several pathways that promote cell proliferation, including the MAPK pathway.

Although the polyomaviruses can transform cells in culture and under certain conditions are oncogenic in laboratory animals, their association with clinical human tumors has yet to be definitely proven (►association of polyomaviruses with human cancers).

Papillomaviridae

►Human papillomaviruses (HPVs) are small DNA viruses that commonly infect epithelial tissues. At present there are over 100 known subtypes of HPV and the majority are responsible for benign lesions of the genital, upper respiratory and digestive tracts. However, some HPV subtypes are associated with malignant diseases of the skin and cervix (►cervical cancers). Cutaneous HPV infection normally results in the appearance of benign warts, however in the rare but lifelong skin disease, ►epidermodysplasia verruciformis (EV), these multiple benign warts can progress to malignant squamous carcinoma when exposed to ►ultraviolet light. The tumor cells often contain HPV 5 or 8. These two HPVs are also associated with the skin carcinoma observed in long-term immunosuppressed renal transplant patients.

Virtually all squamous cancers of the cervix are HPV-positive; HPV16, followed by HPV18 are the commonest subtypes found in this disease. HPV18 is the type most strongly associated with adenocarcinoma of the cervix. HPV is sexually transmitted and the association of HPV with cervical cancer explains many of the risk factors for this disease including early age at first sexual encounter and multiple sexual partners. Although most women will have been infected with HPV at some time, very few will develop invasive cancer.

In cancers, integration of HPV18 is almost universally observed, whereas integration of HPV16 is less common. Integration usually disrupts the E1 or E2 viral genes (►early genes of human papillomaviruses); this results in the loss of negative feedback control of E6 and E7 expression by the viral regulatory E2 protein. Overexpression of E6 and E7 proteins is important in oncogenesis; E6 binds to and inactivates p53 and E7 binds to Rb.

A bivalent HPV16/18, and a quadrivalent HPV 6/11/16/18 vaccine are being evaluated in phase III clinical trials. Preliminary data suggest that these prophylactic HPV virus-like particle vaccines are effective in preventing infections and also in reducing epithelial abnormalities (►human papillomavirus vaccines).

Hepadnaviridae

Hepatitis B Virus

►Hepatitis B virus (HBV) is associated with the development of ►hepatocellular carcinoma (HCC) where integrated HBV DNA can been detected in the majority of tumors. The exact role of HBV in the development of HCC is yet to be established. However, the HBx protein is likely to be important since it can induce a number of cellular changes that contribute to transformation, including the activation of several intracellular signaling pathways, including NF-κB. Other factors in addition to HBV status contribute to the risk of developing HCC; these include smoking, dietary components such as ►aflatoxin, and exposure to other hepatotoxic agents, including ►hepatitis C virus.

Flaviviridae

Hepatitis C Virus

►Hepatitis C virus is a ►blood-borne RNA virus that can cause chronic hepatitis and later ►cirrhosis and hepatocellular carcinoma. HCV is spread by

blood-to-blood contact. Many people with HCV infection have no symptoms and are unaware of the need to seek treatment. An estimated 150–200 million people worldwide are infected with HCV. At least four HCV gene products, namely HCV core, NS3, NS4B and NS5A, have been shown to exhibit transformation potential in tissue culture. Both HCV core and NS5A induce the accumulation of wild-type β-catenin.

Retroviridae

Human T lymphotropic Virus-1

Human T lymphotropic virus-1 (HTLV1) (►human T cell leukaemia virus) infects ►CD4-positive T-lymphocytes and is associated with the development of adult T-cell leukaemia/lymphoma (ATLL). Like other retroviruses, the HTLV1 genome consists of gag, pol, and env genes, which encode important structural and functional proteins, flanked by long terminal redundancies (LTRs). HTLV1 has an additional 3Y region which encodes several proteins implicated in transformation; these include Tax, Rex, p12, p13, p30, and HBZ. ►Tax has been shown to be necessary and sufficient for transformation by HTLV-1. Tax activates both the canonical and non-canonical NF-κB pathways, in turn leading to increased expression of many ►cytokines and their receptors, including ►interleukin-2 and the interleukin-2 receptor, which leads to polyclonal proliferation of HTLV-1-infected cells by ►autocrine and ►paracrine mechanisms. Additional potentially transforming effects are contributed by some of the other HTLV1 genes.

Virosomes

Definition

Are vesicles mimicking the envelopes of various viruses, such as influenza virus, Sendai virus, and human immunodeficiency virus. These vesicles lack the functional viral nucleocapsid, including the viral genetic material, but can still be used to incorporate low molecular weight drugs, proteins, and nucleic acids. Virosomes can introduce these molecules into target cells by the same mechanism as viral infection because they retain the cell entry and membrane fusion properties of the parent virus.

Synonyms

Oncolytic virotherapy

Definition

►Virotherapy utilizes ►oncolytic viruses, which may occur naturally or more commonly be engineered, such as conditionally replicative ►adenoviruses (►CRAds), to selectively infect tumor cells and replicate within them, thus causing their demise while sparing surrounding normal cells in the host. ►Oncolysis results from the replicative life cycle of the virus, which lyses infected tumor cells and releases viral progeny for propagation of infection and resultant lysis of neighboring cancer cells whereby normal host cells are spared.

Characteristics

Virotherapy represents an exciting and novel interventional strategy for a range of neoplastic disorders. In this strategy a virus is rendered conditionally replicative for tumor cells whereby direct oncolytic target killing is achieved. A variety of viral species have been adapted as virotherapy agents with the majority of human clinical trials exploiting conditionally replicative ►herpes simplex virus (HSV) and adenovirus. Of these, adenovirus has emerged as a promising model oncolytic

vector to target tumor cells. Over 40 different human serotypes of adenoviruses have been identified with types 2 and 5 being the most extensively used in developing oncolytic constructs.

Oncolytic Adenoviruses and Cancer Gene Therapy

The concept of using conditionally replicative adenoviruses (CRAds) for the treatment of cancer, also known as ►oncolytic virus therapeutics, originated in the 1950s. The knowledge that adenoviruses could eliminate cancer cells *in vitro*, as a consequence of their reproducitive cycle leading to cell lysis ("oncolysis"), resulted in clinical studies in which various wild-type adenoviral serotypes were examined for their effect on ►cervical cancer patients. In these studies, no significant toxicity was reported after intratumoral injection (i.p.) or intravenous (i.v.) administration and a moderate tumor response was observed. The most studied CRAd is the one originally generated (*dl*1520) by Arnold Berk and used initially by Frank McCormick as a selective vector, named ONYX-015. This viral vector originally was believed to only replicate in p53-defective cells (present in ~50% of human tumors). It is now recognized that these agents have beneficial properties for cancer ►gene therapy when compared with their nonreplicating counterparts, although this mechanism has subsequently been questioned. The adenovirus-based vectors have maintained their positions as the leading candidates for *in vivo* oncolytic virotherapy because they are safe, produced in high titers, do not integrate into the host chromosome, and have a wide tropism in neoplastic cells. While adenoviral transfection is efficient, the expression of the transferred gene is transient, as the viral genome remains episomal. To maximize CRAd mediated cell killing, one needs to achieve an amplification effect for transduction, via replication of the delivered viral vector post-infection, resulting in lateral spread of the progeny vector and cell killing via viral oncolysis. In addition, viral proteins expressed late in the course of infection are indirectly cytotoxic, including the E3 11.6 kDa adenovirus death protein, E4ORF4.

CRAds in Human Clinical Trials and the Limitations

Significant antitumor activity has been demonstrated using ONYX-015 both *in vitro* and *in vivo* using murine models. The preclinical potential of CRAds led to their rapid translation into human clinical trials, including those targeting recurrent head and neck, pancreatic, colorectal, ovarian, and ►hepatobiliary cancer. The overall conclusion was that adenoviral virotherapy is a safe method when applied via various routes, thus validating the concept *in vivo*. In clinical practice, however, employing CRAd as a single agent has demonstrated limited efficacy. This is due, in part, to relatively inefficient gene transfer to tumor cells. The replicative Ad system of ONYX-015, although demonstrating promise in preclinical studies, yielded no clinical effect in 16 patients with ►ovarian cancer treated intraperitoneally with up to 1×10^{11} plaque-forming units of adenovirus daily for 5 days. Important in this regard, cancer cells have been specifically shown to be profoundly resistant to Ad infection. The results obtained in these studies have been helpful in determining the limitations of the current generation of CRAds. The critical problems that have been encountered involve two main limitations: (i) poor infectivity of cancer cells by adenovirus at the transductional level due to the lack of native adenoviral receptor, the coxsackievirus-adenovirus receptor (CAR), on the surfaces of tumor cells; (ii) poor tumor selectivity of CRAd agents at the transcriptional level due to the lack of tumor specific promoters to selectively drive the viral replication in tumor cells.

CAR-Deficiency on Tumor Cells Results in the Poor Infectivity of Ad Agents

Cancer cells have been specifically shown to be profoundly resistant to Ad infection because of their lack of the primary receptor for viral entry, the coxsackievirus-adenovirus receptor (CAR). As these primary tumor cells often express relatively low levels of the CAR, this results in the poor infectivity of CRAd agents and the difficulty of lateral dispersion of virus in tumor tissue. This has been demonstrated by the fact that low CAR levels strongly reduced viral replication and oncolysis in monolayer cultures and murine models. On this basis, it was proposed that delivery be achieved via a heterologous entry pathway, or CAR-independent pathway to circumvent this key aspect of tumor biology.

Infectivity Enhanced CRAd Agents-Retargeting CRAds to Tumor Cells

Native adenoviral tropism is mediated by two capsid proteins, fiber and penton base. These proteins bind to the primary, high-affinity cellular receptor, CAR, and the integrins $\alpha v\beta 3$ and $\alpha v\beta 5$, respectively. Manipulation of these molecular interactions has been carried out to modify adenovirus tropism by routing entry through either a heterologous entry pathway or a CAR-independent pathway. Many approaches have been described to enhance the viral infectivity. These include: (i) Ad capsid modification for circumventing tumor cell CAR deficiency. Specifically, Dmitriev et al. (1998b) reported that construction of modified adenoviral vectors containing the RGD peptide in the HI loop region, which targets integrins $\alpha v\beta 3$

and αvβ5 instead of CAR, increased gene transfer to ovarian cancer cell lines (30–600 fold) and to primary ovarian cancer cells obtained from patients (2–3 fold). Many other approaches have been reported which include targeting Ad to the serotype 3 receptor with a chimeric fiber protein, such as F5/3, targeting Ad to tumor cells with the non-human canine Ad type 2 knob, targeting Ad to a heparin sulfate-containing receptor with a Ad fiber incorporating polylysine (pK7) and targeting Ad to the junction adhesion molecule 1 (JAM1) with an Ad fiber incorporating reovirus sigma 1 fiber. All these fiber modifications enhanced the viral infectivity of Ad vectors but with different levels of success dependent upon the tumor types. (ii) Transductional retargeting using heterologous targeting adapters. In adapter-mediated targeting, the tropism of the virus is modified by an extraneous targeting moiety, the ligand, which associates with an Ad virion either covalently or non-covalently. Zhu et al. described in 2004 that an adenoviral vector was successfully induced to transport itself across polarized epithelial monolayers by use of a fusion protein (sCAR-transferrin), a bi-functional adapter, which bound to the knob of Ad through a sCAR (secretory CAR) domain and to the transferrin receptor on cell surfaces through a transferrin domain. In addition, sCAR-EGF, sCAR-SCF, and sCAR-scFv have all been reported as having successfully targeted EGF receptor-positive cells, c-Kit(+) and CAR(–) hematopoietic cells and ovarian carcinoma cells, respectively. The genetic fusion proteins of single-chain variable fragment (scFv) antibodies directed against the fiber knob and receptor on the surfaces of tumor cells have also been used in virotherapy. In this schema, an anti-fiber-knob Ab has been employed to attach to the cell recognition motif of the fiber knob and, importantly, ablate the native tropism determinants. An Ab, or Fab derivative, was then conjugated to a second moiety, which provided targeting specificity. To that end, receptor ligands such as folate and basic fibroblast growth factor-2 (FGF-2) have been used to successfully target tumor cells. Thus, the strategy of tropism modification either using bispecific conjugates or scFv molecules allowed dramatic augmentation in gene delivery to tumor targets, with a specificity that would predict an improved therapeutic index.

Tumor Specific CRAd Agents – Using a Tumor Specific Promoter to Drive Specific Viral Replication

Although viral replicative specificity is not the main limit of CRAd efficacy, our work and those of others have also sought to address this aspect to improve the overall therapeutic index. The method used to direct CRAd vector specificity is by regulation of viral replication via cellular promoters that are over expressed or reactivated in selected tumor cells, sometimes referred to as "tumor specific" promoters. A number of CRAd agents have been developed, which harbor the essential Ad E1A gene under the control of such promoters. They include the alpha-fetoprotein promoter, Cox-2 promoter, DF3/MUC1 promoter, midkine promoter, PSA/PSMA enhancer, secretory leukocyte protease inhibitor (SLPI) promoter, CXCR4 and survivin promoters, human telomerase reverse transcriptase (hTERT) promoter, and the tyrosinase promoter/enhancer. Most of these agents have demonstrated remarkable preclinical results in eradicating tumors in xenograft mouse models.

A Double Targeted CRAd for Ovarian Cancer

Based on the foregoing considerations, we have developed a CRAd agent which addressed the limits of the current systems. As previously discussed, CAR deficiency in the context of the target tumor would clearly confound this process, thus undermining the overall efficacy of CRAd agents. Previous studies have demonstrated that incorporation of an Arg-Gly-Asp (►RGD)-containing peptide in the HI loop of the fiber knob domain results in the ability of the virus to utilize an alternative receptor during the cell entry process. In the context of ovarian cancer, the RGD modified nonreplicative adenovirus mediates enhanced gene transfer *in vitro* in both established cell lines and freshly cultured ►ovarian cancer cells. It exhibits preferential gene transfer to primary ovarian cancer cells when compared to non-transformed human mesothelial tissue, thus, indicating a degree of specificity for tumor cells. In addition, the RGD modified nonreplicative adenoviral vector demonstrated enhanced infectivity of primary ovarian tumor cells where infectivity was known to be inhibited by preformed neutralizing antibodies against adenovirus found in the ascites fluid in which the tumor cells float. Investigators at the University of Alabama at Birmingham (UAB) and the University of Texas-MD Anderson Cancer Center have constructed a novel infectivity enhanced CRAd, designated Ad5-Δ24RGD, that has a 24 bp deletion in the E1A gene and that incorporates the RGD modification in its fiber. The deletion in the E1A gene is from Ad5bp923 to 946 which corresponds to the amino acid sequence L122TCHEAGF129 of the E1A protein known to be necessary for host cell Rb protein binding. Adenoviruses having this partial deletion cannot induce resting cells to pass the ►G2/M checkpoint and progress to mitosis and lysis. In contrast, most human tumor cells bypass the Rb/p16 pathway, thus allowing for selective replication of adenoviruses with this deletion. Preliminary experiments demonstrated that Ad5-Δ24RGD propagated more efficiently than Ad5-Δ24 in

A549 cells. Specifically, A549 cells transfected with Ad5-Δ24RGD yielded 43 fold times increase in viral progeny (3.75×10^9 pfu/ml) when compared to Ad5-Δ24 infected cells (8.74×10^7 pfu/ml). Cell lysis in Ad5-Δ24RGD infected A549 and LNCap cells was 7 and 3.5 times higher, respectively, compared to that achieved with Ad5-Δ24. Validation of the potential benefits of incorporating infectivity enhancements into a CRAd provided the rational to translate this into clinical trials which has been recently approved by FDA.

Future Directions for Improvements

CRAd human trials were historically limited by lack of useful information regarding the biologic basis of adenovirus efficacy barriers. Absent "surrogate endpoints," imaging could potentially provide this information. We have thus developed an imaging system which addresses this problem, based upon fluorescently labeled adenovirus carrying EGFP (enhanced green fluorescent protein) on the pIX minor surface protein of Ad for vector detection. Furthermore, positron emission tomography (PET) scanning has been used to detect herpes simplex virus type 1 (HSV-1) thymidine kinase (TK) which was fused to this same Ad protein IX (pIX). Other conventional imaging systems for virotherapy have been designed for the detection of transgene expression of reporters such as sodium iodide symporter, somatostatin receptor type 2 (SSTR-2), and luciferase. The combination of a noninvasive imaging modality with a genetic adenoviral labeling system for detection of viral replication and progeny localization has begun to provide a powerful means of real-time monitoring of CRAd function *in vivo*.

Virus Vector-mediated Gene Transfer

►Viral Vector-mediated Gene Transfer

Viruses

Definition

Viruses are pathogens composed of a nucleic acid genome enclosed in a protein coat. They can replicate only in a living cell, as they do not possess the metabolic machinery for independent life.

►Virology

Vital

Definition

Crucial or extremely important.

Vitamin A

Definition

Is an essential human nutrient. It exists not as a single compound, but in several forms. In foods of animal origin, the major form of vitamin A is ►retinol.

►All-Trans Retinol
►Retinoids

Vitamin C

Definition

A water-soluble vitamin found in fruits and vegetables and used as an ►antioxidant.

►Chemoprotectants

Vitamin D

Laura P. Zanello
Department of Biochemistry, University of California-Riverside, Riverside, CA, USA

Definition

The biologically most active form of vitamin D, 1α,25-dihydroxy-vitamin D_3, and many synthetic analogs exert anti-proliferative actions on different cancer cell types, most typically breast, colon, and prostate. Recent clinical studies indicate a potentially important role for vitamin D in the prevention and treatment of cancer.

Characteristics

1α,25-dihydroxy-vitamin D_3 (1,25D), or ►calcitriol, the biologically most active form of vitamin D, is essential to bone and mineral metabolism. 1,25D deficiency has been traditionally associated with bone diseases characterized by decreased bone mass and reduced mineralization, such as rickets, osteomalacia, and osteoporosis. In addition to its well known actions on bone and calcium homeostasis, this ►secosteroid hormone exerts a number of effects on many different target organs and systems. 1,25D actions include regulation of ►cell cycle, cell proliferation and differentiation in breast, colon, and prostate, among others. 1,25D binds to the nuclear ►vitamin D receptor (VDR), which acts as a ►transcription factor for the regulation of gene expression. In addition, 1,25D stimulates signal transduction cascades implicated in non-genomic responses of target cells such as modulation of the electrical state of the plasma membrane, secretory activities, cell survival, and establishment of the apoptotic phenotype.

Mechanisms

In recent years, natural compounds and synthetic analogs of vitamin D have proved to have significant effects on cell cycle, differentiation, survival and ►programmed cell death. More specifically, 1,25D has been shown to act as a powerful anti-proliferative agent on certain cancer cell types expressing the VDR, including breast, colon and prostate, both *in vitro* and *in vivo*. Typically, cell cycle arrest promoted by physiological doses of 1,25D is linked to cell differentiation, and therefore reduction in the probability of cells to become cancerous.

Human trials on anti-cancer properties of calcitriol and synthetic analogs have increased in recent years, with ►prostate cancer being the most studied one. Calcitriol and numerous analogs have shown potential to become therapeutic agents for the treatment of certain cancer types in the future. However, the molecular mechanisms by which 1,25D inhibits cancer cell proliferation remain only partially understood. To date, more

than 1,000 vitamin D analogs have been synthesized, and many of these analogs have shown to have significant anti-proliferative effects.

The earliest evidences on a relationship between vitamin D and cancer come from epidemiological studies conducted in the 1990s. An inverse relationship was discovered between sunlight exposure –which is lower as latitude increases– and ►prostate cancer cases in the United States over 45 years of data (1950–1994). A main source of vitamin D in our bodies is by means of production of vitamin D_3 or cholecalciferol, a hormone precursor, in the skin by ►UV radiation. The second main source is vitamin D_2 or ergocalciferol in the diet. However, these products are biologically inactive. They require two sequential hydroxylations, first in the liver (to produce 25-hydroxy-vitamin D_3, or 25D), and then in the kidney (to render 1α,25-dihydroxy-vitamin D_3). The major circulating source of the secosteroid hormone is 25D, therefore measurement of circulating concentrations is a good indicator of the overall vitamin D_3 status of the individual. In addition, many tissues express 25-hydroxy vitamin D_3 1α- hydroxylase, the enzyme that transforms 25D into 1,25D, which indicates that local production of the biologically active form may play an important role in ►autocrine and ►paracrine functions. Early epidemiological studies suggested that elevated circulating levels of 25D main protect against cancer, and that ingestion of vitamin D supplements may be helpful in the treatment of tumors.

In addition to case studies, extensive *in vitro* work has demonstrated that high concentrations of 1,25D (10^{-9}–10^{-7} M) inhibit the growth and induce differentiation of tumor cells, including malignant ►melanoma, myeloid leukemia, ►prostate cancer, ►breast cancer, ►glioma cancer, and ►colon cancer. Clinical trials and treatment of cancer patients with high doses of 1,25D or synthetic analogs have been limited due to the fact that, at these high vitamin D_3 doses, there is a significant risk to develop ►hypercalcemia with fatal side effects. This has encouraged the pharmaceutical industry to develop new synthetic analogs with high potency for cell growth inhibition and low hypercalcemic effects (for example, analog EB1089).

The highly conformationally flexible 1,25D molecule offers a broad source of possibilities for the design of chemical compounds with high affinity for the VDR. These are ideally capable of potentiating the genomic regulation of the cell cycle, while inducing only low calcium effects more likely to develop via non-genomic mechanisms. Recently, an alternative binding site for non-genomic analogs has been proposed on the basis of molecular modeling of the crystal structure of the VDR. This new hypothesis for the binding of ligands to the VDR brings an even higher potential for the design of analogs with more specific anti-proliferative actions and reduced hypercalcemic side effects.

Additional aspects that contribute to the tumor suppressive activity of vitamin D compounds include the ability of 1,25D and analogs to reduce ►angiogenesis and ►metastasis. While use of 1,25D and analogs with low calcemic effects for the treatment of cancer offers high promise, combination therapy with other anti-tumorigenic drugs may signify even higher beneficial effects. *In vitro* studies have demonstrated, for example, that 1,25D in combination with the antiestrogen ►tamoxifen has greater efficacy in the inhibition of breast cancer cell lines. Different combinations of vitamin D_3 and ►retinoids, ►cytokines, and a number of cytotoxic compounds including ►adriamycin, ►carboplatin, ►cisplatin have proven to act synergistically on the suppression of cancer cell growth.

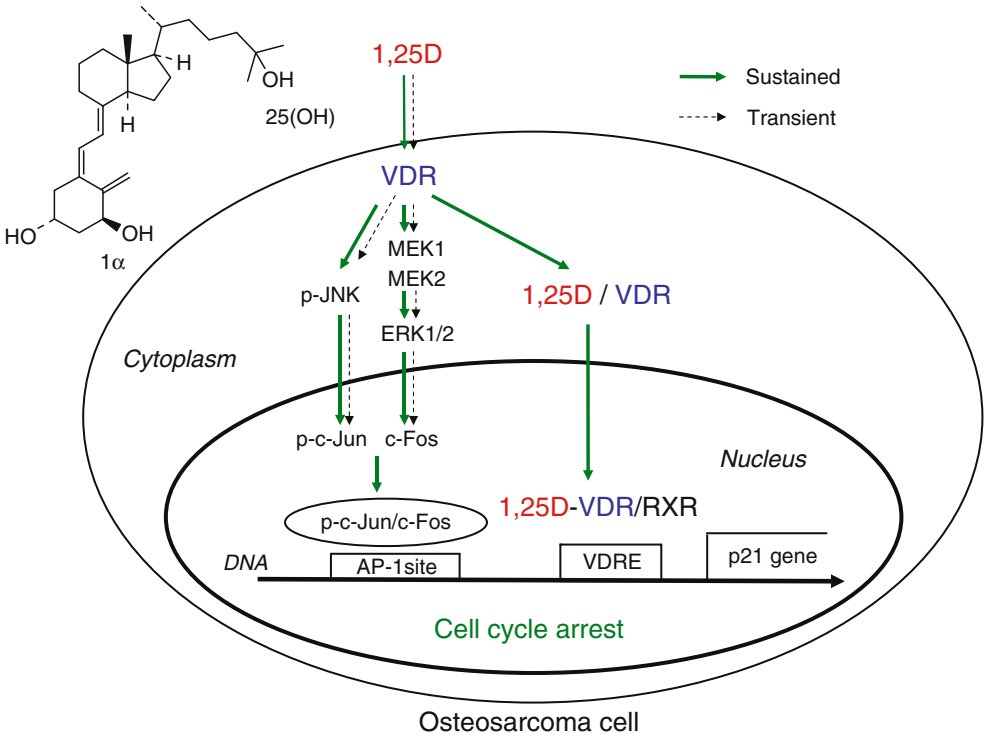
The anti-cancer effects of vitamin D compounds and analogs can be explained on the basis of different aspects of cancer cell biology. More specifically, 1,25D effects on tumor cells include:

1. Regulation of the ►cell cycle
2. Induction of ►apoptosis or programmed cell death
3. Modulation of the expression of ►oncogenes and ►tumor suppressor genes
4. Induction of cell differentiation

Studies performed with 1,25D and analogs on different cancer cell lines *in vitro* have shown that cells grown in the presence of the steroid significantly reduce their growth rate mostly by blockade of the transition from the G_0/G_1 phase (differentiated, non dividing cells) to the S phase (DNA synthesis). In addition to promoting cell cycle arrest and inhibition of cell division, 1,25D and related compounds have proved to induce apoptosis in glioma, breast, leukemia and colon cancer cells. It is not clear, however, how a cell follows its path to either cell cycle progression or apoptosis once it reaches early G_1 phase. Vitamin D_3 compounds appear to act at this point through different molecular mechanisms, depending on whether they induce cell death or stop cells from dividing.

In human ►osteosarcoma, for example, 1,25D treatment reduces cell proliferation *in vitro* by approximately 25% after 3 days. The mechanisms involve sustained activation of ►MAP kinase/►AP-1/p21(waf1) pathways. Upregulation of *p21* gene expression led to control over the cell cycle and subsequent cell cycle arrest (Fig. 1).

The modulation of the expression of certain oncogenes and tumor suppressor genes has been also shown to be affected by 1,25D treatment of cancer cell lines. Among genes that modulate cell growth and apoptosis, the ►*bcl-2*, ►*c-myc*, and retinoblastoma gene products are the most widely studied. The *bcl-2* oncogene product protects against apoptosis, therefore inducing cell survival. In MCF-7 breast cancer cells, 1,25D and analogs KH1060 and EB1089 decreased *bcl-2*



Vitamin D. Figure 1 1,25D reduction of human osteosarcoma cell proliferation occurs via sustained activation of mitogen activated protein kinases ►JNK and MEK1/MEK2 downstream of non-genomic VDR signaling, leading to upregulation of a c-Jun/c-Fos (AP-1) transcription factor complex, which in turn modulates *p21(waf1)* gene expression. Transient refers to 1,25D treatment for 15 min; sustained implicates a treatment with hormone for 3 days. RXR: ►retinoic acid receptor, VDRE: vitamin D responsive element, p: indicates phosphorylation of the protein.

expression, and cells progressed through apoptosis. The expression of the oncogene *c-myc* has also been shown to be reduced by 1,25D treatment of breast cancer cells, and resulted in reduction of cell proliferation. Finally, induction of cell differentiation by vitamin D_3 compounds has been widely described in combination with its anti-proliferative effects. Typically, 1,25D inhibits cell proliferation and induces differentiation in the hematopoietic system, osteoblasts, and keratinocytes.

Currently, the safe upper limits for vitamin D intake as supplements have been set in the US by The Institute of Medicine to be 1,000 IU/day for children under 1 year of age, and 2,000 IU/day for adults. Although rare, vitamin D intoxication may develop if intake of higher doses happens over significantly prolonged periods of time, and lead to hypercalcemia, hyperphosphatemia and hypercalciuria. A recent clinical trial conducted on patients with premalignant colon and rectal tissues showed that a treatment with 1,500 mg of calcium carbonate and 400 IU of vitamin D_3 per day significantly decreased the levels of expression of markers of cell proliferation in polyp tissues, which is an indicator of tumor size reduction. In Europe, fortification of milk and other food products with vitamin D has been prohibited because of an increase in hypercalcemia cases in infants after World War II. However, in consideration that vitamin D deficiency is widely recognized as a cause of impaired bone formation in children, and that there are clear beneficial effects of the hormone in cases of cancer and osteoporosis, many European countries currently fortify margarine and cereals with vitamin D.

Conclusions

In vitro and *in vivo* studies on anti-cancer effects of 1,25D and synthetic analogs have indicated that the steroid has high potential for therapeutic applications in a wide range of cancers. Of special interest is the development of future combination therapies with other anti-tumor drugs with synergistic effects on cell growth. However, it is imperative that the precise molecular mechanisms by which 1,25D modulates cell proliferation and death be investigated. In addition, more clinical studies are needed in order to establish whether 1,25D and analogs can be used as an effective treatment of cancer.

Vitamin D Receptor

Definition

Member of the family of nuclear receptors transcription factors. The vitamin D receptor is activated upon binding of the active form of vitamin D to its ligand binding site. Once activated, the ligand-bound VDR interacts with a vitamin D responsive element in the DNA to modulate the expression of specific genes in target cells.

von Hippel-Lindau; VHL; tumor suppressor gene

Definition

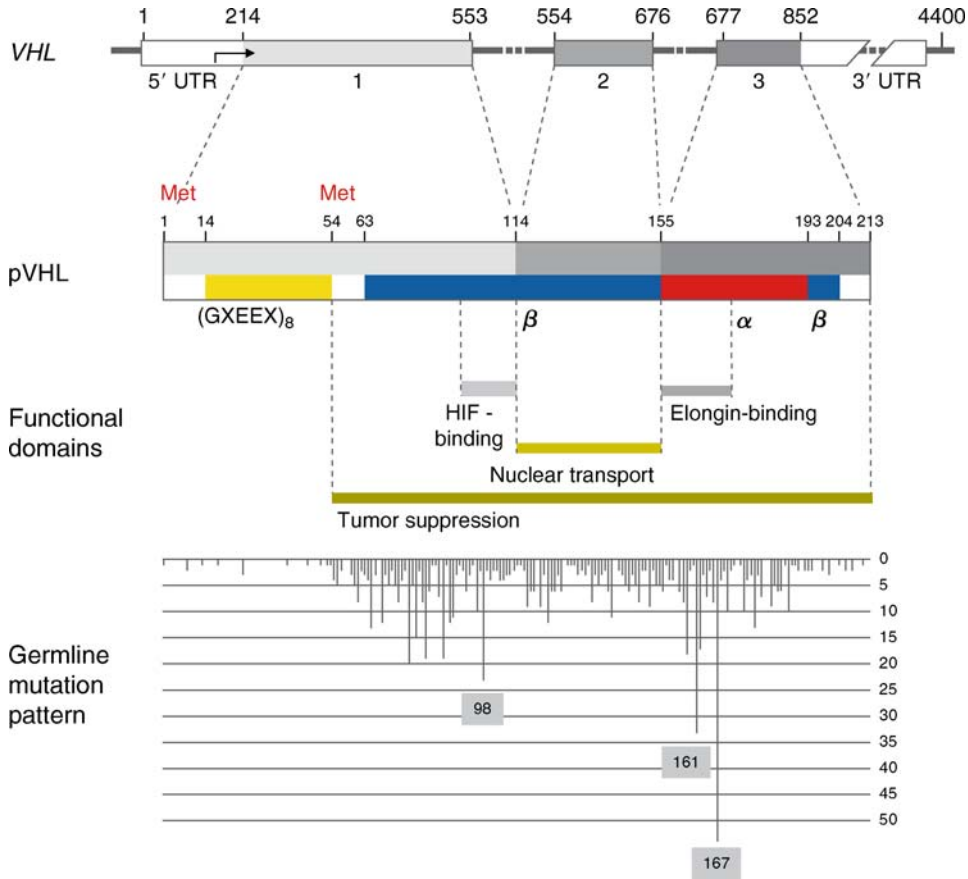
The von Hippel-Lindau ►tumor suppressor gene (VHL) is a cellular gene that is required for normal development, differentiation and cellular stress response (hypoxia, lack of glucose). VHL was discovered in families with the hereditary von Hippel-Lindau (VHL) syndrome by virtue of its two-hit mechanism of inactivation, and identified in 1993 following a positional cloning strategy. The VHL gene may be subject to mutation either in the germline giving rise to VHL disease or in somatic renal epithelial cells giving rise to sporadic renal conventional (clear cell) carcinoma (CCRCC) functioning as a ►gatekeeper. VHL mutation patterns suggested two functional domains within the protein pVHL. Current knowledge indicates similarities to the SCF (Skp1-Cul1-F-box protein) ubiquitin ligase complex that targets proteins for degradation. Therefore, pVHL may function as a molecular adaptor in a similar proteolytic pathway. Today's best understood function of pVHL is its role in the VHL/HIF (►Hypoxia inducible factor 1 α) pathway.

Characteristics

Molecular Features

- Gene located at 3p25.3, single copy locus: NCBI GenBank, range: bp 10.158.319–10.168.762, as published in Nature 431(7011):931–945 (2004) (Fig. 1)
- 639 Nucleotides in three exons (originally reported sequence contained 852 nucleotides with 213 untranslated base pairs at the 5′ end)
- Exon 1 is a CpG island (G + C content is 70%, CpG/GpC > 1)
- TATA-less and CCAAT-less promoter
- Two transcription initiation codons (amino acid 1 and amino acid 54)
- Follows a two-hit mechanism of inactivation characteristic for tumor suppressor genes
- Evolutionarily highly conserved
- No homologies known
- The full length protein pVHL contains 213 amino acids
- Known isoforms result from tissue specific and developmentally selective alternative splicing (skipping of exon 2)
- Differentially phosphorylated at serin 68 by casein kinase 2 or glykogen synthase kinase 3
- Expressed in a variety of adult and fetal tissues including those of VHL target organs
- There are two protein binding domains that allow pVHL to function as an adaptor molecule in a proteolytic pathway
- The gene may be subject to mutations at almost any nucleotide of the 470 bp COOH terminal sequence
- Phenotypic variation may result from confounding effects of modifier genes
- No imprinting reported
- Posttranslational negative regulation by E2-EPF UCP (E2-EPF ►ubiquitin carrier protein)

Structure of the von Hippel Lindau gene (*VHL*), and protein, indicating the functional domains. The pattern of germ line mutations published so far, reflects the functional importance of the binding sites to the target as well as to the multimeric protein complex.



von Hippel-Lindau Tumor Suppressor Gene. Figure 1 Structure, Function, and Germ Line Mutations of the VHL gene.

Role in Diseases – Clinical, Molecular and Cellular Characteristics

von Hippel-Lindau (VHL) disease (OMIM 193300) is an ►inherited tumor susceptibility syndrome predisposing gene carriers to a variety of benign and malignant tumors. VHL segregates in affected families as an autosomal dominant inherited trait. Phenotypic expression is highly variable.

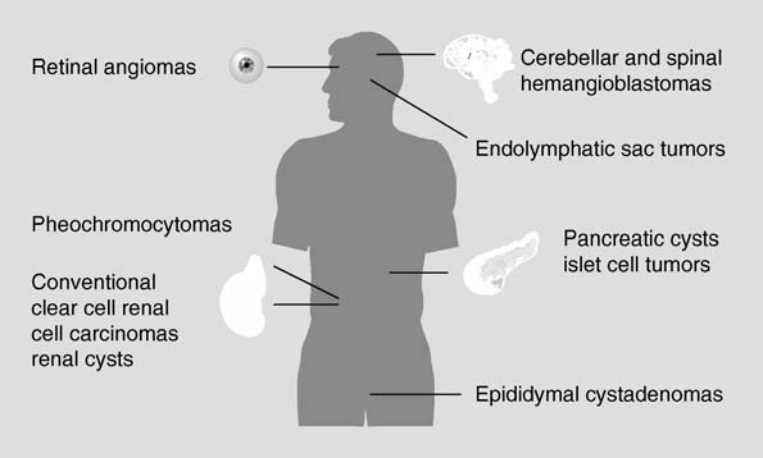
Clinical and Molecular Features

Lesions Associated with von Hippel-Lindau Disease. (Fig. 2) VHL patients may present with a variety of tumors affecting eye, central nervous system, inner ear, adrenal gland, kidney, pancreas, epididymis. Most frequent tumors include retinal angiomas, and ►hemangioblastoma of the cerebellum and of the spinal cord which are usually benign. Other benign lesions include ►pheochromocytoma, renal and pancreatic cysts. Renal clear cell carcinomas are malignant.

- Tumors and cysts are frequently bilateral and/or multiple in origin.
- All ethnic groups are involved, there is no sex bias.
- Birth incidence is estimated 1/39,000 (Germany) to 1/53,000 (East Anglia).
- Prevalence is 1/85,000–1/31,000.
- Incidence of *de novo* mutations is about 5% (up to 20%).
- Mean age at diagnosis is 26 years.
- Penetrance by age of 65 years more than 90%.
- Most severe complications are hemangioblastomas due to unrestricted growth in the confined space of skull or vertebral canal, and CCRCC due to metastasis.
- Major cause of death are hemangioblastomas.

Classical Clinical Definition

- Known family history of retinal or cerebellar ►hemangioblastoma: the presence of a single hemangioblastoma or a visceral manifestation, i.e. diagnosis of a CCRCC in a family member will define this patient as a disease gene carrier.
- Isolated cases, possibly indicating a *de novo* mutation: two or more hemangioblastomas (spinal,



von Hippel-Lindau Tumor Suppressor Gene. Figure 2 Lesions associated with von Hippel-Lindau disease.

cerebellar or retinal) or a single hemangioblastoma in association with a visceral manifestation, i.e. CCRCC) are sufficient to establish the diagnosis.

It is possible in most cases to determine VHL carrier status by mutation testing of DNA derived from nuclear blood cells. This can either be performed to assist clinical diagnosis or to establish carrier status presymptomatically in at risk individuals. Based on the presence or absence of pheochromocytoma, VHL disease is phenotypically subclassified into VHL type 1 (without pheochromocytoma, applies to the majority of all families) and VHL type 2 (with pheochromocytoma, about 7–20% of all families). The VHL type 2 syndrome is further subdivided into type 2A (without CCRCC), type 2B (with CCRCC), and type 2C (pheochromocytomas as the sole manifestation). In VHL type 2C disease, it is especially important to carefully establish the molecular diagnosis in affected patients since pheochromocytoma is also a manifestation of other inherited syndromes such as multiple endocrine neoplasia type 2, neurofibromatosis type 1, and others.

Germline Mutations

Comprehensive germline mutation analysis allows the detection of more than 95% of VHL predisposing mutations in gene carriers (Fig. 1). As of today as many as 1,000 VHL mutations have been described in data bases, of which some 140 have been described as unique mutations. About 50–60% are missense mutations, 20–30% large intragenic deletions, 12–20 microdeletions, or insertions and 7–11% nonsense mutations. Most mutations can be readily identified by sequencing analysis. Large genomic and intragenic deletions may be identified by Southern blotting including quantitative Southern blotting, pulsed field gel electrophoresis (PFGE) or/and fluorescence *in situ* hybridization (►FISH), and more recently by Q-RT-PCR (quantitative real time polymerase chain reaction) and MLPA (multiplex ligase probe amplification). In those rare cases where germline mutations escape detection it is possible that an affected individual may be a mosaic, with some cells carrying the VHL mutation and others that don't. Although it may be difficult to find a VHL mutation in a mosaic individual, offspring are at high risk to develop the disease. Once the mutation is passed on into the next generation, due to affected germ cells, it should be easily identified in the affected offspring who now will carry the germline mutation in all of the body cells.

Most germline mutations cluster within exon 1 and exon 3 suggesting two functional protein domains. In particular, there is a mutational hotspot affecting codon 167, either changing an arginine to tryptophane or to glutamine. The affected amino acid is located within a 35 residue domain necessary for ElonginC binding for the formation of the ternary pVHL/ElonginC/ElonginB complex (VCB). Another frequently identified mutation causes a change of histidine to tryptophane at codon 98. The frequency of this mutation also known as Black Forest mutation is due to a founder effect. The affected amino acid is located within the HIF binding domain. Other commonly described mutations are delPhe76, Asn78Ser, Arg161Stop, and Leu178Pro. A VHL mutation data collection is available at http://www.umd.necker.fr (Beroud C, INSERM).

A unique hematological hereditary disease has been identified as a subtype of VHL germline mutations (Type Chuvash, OMIM 263400). Specific homozygous missense mutations C598T (Arg200Trp), and C571G (His191Asp) present exclusively with clinical features of polycythemia vera with elevated ►erythropoietin level. Interestingly, so far no other typical VHL complications have been seen in any carrier of these homozygous

von Hippel-Lindau Tumor Suppressor Gene. Table 1 Lesions associated with von-Hippel-Linder Disease

Affected Organs	Clinical Symptoms	Frequency
Eyes	Angiomatosis retinae	50–57%
Central nervous system	Cerebellar hemangioblastomas	55–59%
	Spinal hemangioblastomas	13–14%
Adrenal glands	►Pheochromocytomas	7–19%
Kidneys	Renal cysts	76%
	Conventional (clear cell) renal cell carcinomas (CCRCC)	24–52%
Pancreas	Pancreatic cysts	22%
	Serous cystadenomas	Occasionally
	Islet cell tumors usually asymptomatic	Infrequent
Inner ear	Endolymphatic sac tumors	<10%
Epididymis	Cystadenomas	10–15%
Broad ligament	Benign adnexal papillary tumors	Occasionally
Liver	Cysts	Occasionally

mutations. Of note, these mutations have also been observed as compound heterozygote alterations.

Genotype/Phenotype Correlation

There is a difference of frequencies of the types of germline mutations between VHL type 1 and VHL type 2 families. With few exceptions, most VHL type 2-associated germline mutations are of the ►missense type. The predicted consequence of any ►missense mutation is a single amino acid change in an otherwise full length protein. Although these mutations seem to cause minor damage to the VHL protein, they have a tendency to compromise pVHL function in a tissue specific manner, which may explain their frequent association with the formation of pheochromocytoma. The spectrum of VHL type 1-associated germline mutations is much more diverse and includes large deletions, microdeletions, insertions, nonsense, frameshift and missense as well as splice site mutations. Most of these mutations cause severe damage and most likely loss of VHL function due to the destruction of the domain required for VCB complex formation.

A high prevalence of CCRCC was seen in patients with partial germline VHL deletions relative to complete deletions. Deletion mapping revealed that development of CCRCC had an even greater correlation with retention of HSPC300 (C3orf10), located within the 30-kb region of chromosome 3p, immediately telomeric to VHL (52.3 vs. 18.9%, $p < 0.001$).

Sporadic Tumors

There are sporadic equivalents to all VHL tumors. For example, CCRCC is not only a feature of the rare hereditary VHL disease, but more frequently occurs sporadically in the general population. Likewise, hemangioblastomas frequently develop sporadically.

Tumor suppressor genes by definition are subject to a two-hit inactivation mechanism. There are two possibilities to achieve homozygous mutation. For example a germline mutation accompanied by a somatic mutation at the homologous allele will result in a hereditary tumor. Alternatively, two somatic mutations at homologous alleles will result in a sporadic tumor. Thus the same tumor suppressor gene accounts for both hereditary and sporadic tumors. Functional evidence for the tumor suppressor activity of VHL comes from transfection experiments that showed inhibition of tumor proliferation upon reintroduction of wild-type VHL into the $VHL^{-/-}$ tumor cells.

Somatic Mutations

Homozygous somatic VHL mutations were identified in sporadic CCRCC (up to 80%), sporadic cerebellar hemangioblastomas (up to 25%) but only in a few sporadic pheochromocytomas (<10%). Mutation types and locations in sporadic tumors differ from those in the germline. Most mutations in sporadic CCRCC are predicted to severely compromise the VHL protein structure and may therefore cause loss-of-function. About 20% of the cases show epigenetic events, such as abnormal ►methylation of the ►CpG islands (exon 1), which accounts for gene silencing with the predicted consequence of loss of pVHL function. Also, exon 2 is more frequently affected in sporadic tumors than in the germline. In particular, a mutational hotspot was identified in patients with CCRCC, which may reflect possible environmental factors to be involved in tumorigenesis. Altogether, differences in the VHL mutation pattern may reflect the influence of as yet unknown carcinogens, which on their way to become excretable compounds may target the VHL gene in kidney epithelial cells at preferential target sites. One

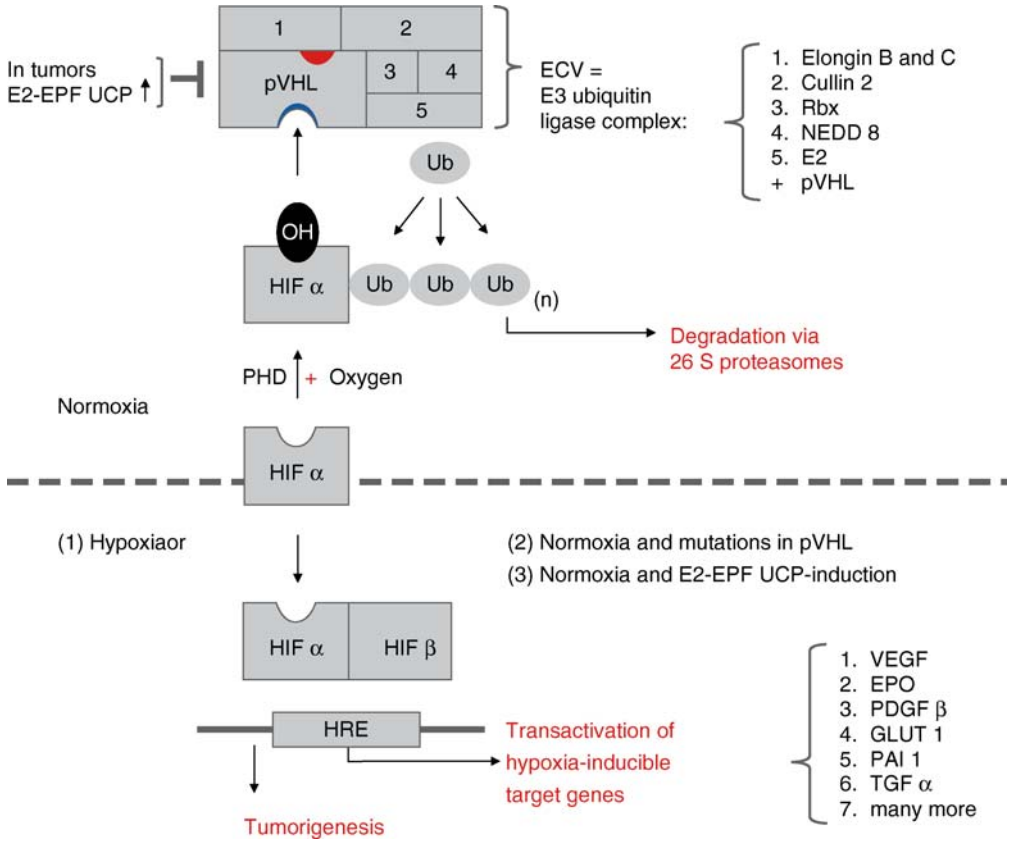
such carcinogen was identified to be trichloroethylene, an important industrial solvent. Somatic VHL mutations and alterations are detectable at all stages of tumor growth, however the presence of somatic VHL alterations may provide a growth advantage to any tumor and therefore indicate a bad prognosis. With the exception of a subgroup of papillary (chromophilic) renal cell carcinomas other pathological entities of renal epithelial tumors, such as chromophobe and the majority of papillary (chromophilic) renal cell carcinomas as well as benign renal oncocytomas, are not associated with VHL mutations.

Somatic VHL mutations have also been found in CCRCCs in members of families with a rare hereditary form of these tumors segregating with a constitutional chromosome 3 rearrangement. These patients had no VHL alterations in their germ line.

The upper part (Fig. 3) illustrates the physiological cellular situation: under normal oxygen conditions (normoxia) HIF α is hydroxylated on conserved prolyl residues (PHD). The pVHL complex polyubiquitinates (Ub) HIF α which is then destroyed by ►proteasomes. The lower part reflects the today known three conditions when HIF α is not degradated and thus will activate a large number of hypoxia-inducible genes: (i) ►hypoxia, or ►normoxia and inactivation of pVHL (ii) via *VHL* mutations, or (iii) via inhibition of pVHL by E2-EPF UCP-induction.

Cellular/Functional Features

Subcellular localization: pVHL localizes mostly to the cytoplasm at steady state but engages in a dynamic transcription-dependent nucleocytoplasmic shuttle. VHL does not carry a classical nuclear export signal. Therefore, shuttling may be facilitated by a sequence that may function as nuclear export domain. VHL-►ElonginC-ElonginB (VCB) complex formation and transcription elongation control: pVHL binds to ElonginC and ElonginB forming the ternary protein complex VCB. Initially, it was proposed that by binding to the Elongins, pVHL may be involved in the control of transcription elongation. Whereas association of Pol II (RNA polymerase II) with the ternary complex ElonginA/ElonginC/►ElonginB allows transcription of downstream genes, the heterotrimer VCB, in which ElonginA is replaced by pVHL, is responsible for the pausing of Pol II at attenuation sites. In normal cells, transcription elongation is controlled by these adverse activities. Mutated forms of



von Hippel-Lindau Tumor Suppressor Gene. Figure 3 VHL/HIF pathway.

V

pVHL are no longer able to associate with ElonginC/ElonginB, consequently resulting in amplified transcription of genes involved in tumorigenesis.

Data of the three-dimensional structure of the VCB complex provided insight into the spatial distribution of amino acids, the α- and β-domain structure of pVHL, and its interactions with ElonginC/ElonginB. Tumorigenic mutations cluster in two surface patches on the molecule; the 35 residue domain responsible for ElonginC binding and a separate remote domain containing the target capture site.

Multimeric complex formation and protein degradation: pVHL forms multimeric complexes with ElonginC and ElonginB, Cul2 and Rbx1. These complexes resemble so-called SCF ubiquitin ligase complexes (Skp1/Cdc53/F-box protein). Thus, by analogy, pVHL is expected to play a role in ►ubiquitination, a biological process that allows a cell to identify proteins in a timely and specific manner in order to destroy them. Cells that lack pVHL are unable to degrade members of the HIF (►hypoxia inducible factor) transcription factor family. Whereas pVHL associated ubiquitination activity depends on ElonginC and Cul2 binding via the α-domain, the β-domain is responsible for target capture, stressing the adaptor function of pVHL between target and the protein degradation machinery. The ability of pVHL to recognize and ubiquitinate HIF can be prevented by mutations in the α-domain. Mutations in the β-domain interfere with the ElonginC/ElonginB binding site.

Role in tumor ►angiogenesis: VHL-related tumors including CCRCC overexpress ►VEGF (Vascular endothelial growth factor), one of the most potent angiogenic factors. This upregulation of VEGF is likely to be responsible for the highly vascular presentation of VHL-related tumors. VEGF expression is under the control of hypoxia inducible transcription factors (HIF). In normal cells, HIF is stable only under hypoxic conditions. pVHL co-immunoprecipitates with the HIF-1 α-subunit, suggesting that pVHL is necessary for the oxygen dependent proteolysis of the HIF-1 α-subunit. Further, cells lacking pVHL are no longer able to degrade members of HIF. Thus, due to the presence of VHL mutations, cells lacking pVHL mimic oxygen deprivation and consequently may unleash HIF. Downstream consequences are the activation of the transcription of a large number of hypoxia responsive genes, such as VEGF, ►EPO (erythropoitein), ►PDGF (platelet derived growth factor), TGFα (transforming growth factor), and GLUT-1 (glucose transporter 1) as well as more than 60 other genes.

Other up-regulated target genes and role in maintenance of extracellular pH: HIF also controls expression of the carbonic anhydrases CA9 and CA12. These enzymes are involved in the reversible reaction of carbon dioxide hydration. They are overexpressed in VHL tumors and in CCRCC due to absence of pVHL, suggesting a role in glycolytic acidification of tumors and a role for pVHL to regulate the maintenance of extracellular pH. CA9 is identified by the antigen binding monoclonal antibody mAbG250, that reacts with CCRCC. This antibody is currently under investigation for an application in the treatment of kidney cancer.

Other capture targets and functions: Other likely target proteins for pVHL are transcription factor Sp1, fibronectin and two isoforms of protein kinase C. Thus, additional proposed functions of pVHL include regulation of the correct assembly of the extracellular matrix and controlled exit from cell cycle.

Animal models: There are VHL homologues in rodents (rat and mouse), Drosophila and worm. Homology to the predicted human pVHL is 50% in Drosophila, 87% in rats and 98% in mice. Homology is highest in the protein binding motifs.

Observations during tracheal development of Drosophila suggests that the Drosophila homologue of VHL (*dVHL*) plays a role in halting of cell migration at the end of vascular tube outgrowth. Considering a common evolutionary origin of the Drosophila tracheal system and the mammalian vasculature, this observation may be helpful to explain the loss-of-function phenotypes in knockout mice and human tumors. In the mouse embryo, loss of VHL activity may lead to uncontrolled cell movement, causing disruption of major vasculature in the placenta. In the adult human with a completely laid out vasculature, lack of VHL activity may be involved in extensive cell migration and vessel branching, leading to overvascularization, as observed in VHL associated tumors.

In homozygously VHL deleted knockout mice, embryos die at day 9–9.5 of gastrulation, due to lack of placental vascularization. Heterozygotes do not show any specific phenotype within the observation period of 2 years. Current scientific efforts focus on the development of a conditional knockout mouse model (deletion of VHL in kidney cells only) to provide a model for the study of kidney tumor initiation and progression and to test gene therapies.

Applications in Diagnosis and Clinical Management

Molecular diagnosis and implications: Patients with VHL disease should be subjected to molecular analysis to determine their family-specific VHL germline mutation. Once a mutation has been identified, all family members need to be tested for VHL mutation carrier status, that is to identify gene carriers and family members not carrying the mutation. Only family members with a VHL germline mutation should then be subjected to clinical diagnostic procedures. This approach significantly reduces the psychological stress of unnecessary clinical screening examinations for the non-carrier. Also, by this approach, costs will be reduced. Affected patients should be tested according

to a standard protocol ((Maher ER (1993) VHL disease. In: Hodgson SV, Maher ER (eds) A practical guide to human genetics. Cambridge Press, pp 157–162; American Cancer Society (1999)). Good clinical practice includes genetic counseling prior to molecular testing and prior to disclosure of tests results. Patient information on all aspects of VHL disease are available online from patient support groups: http://www.vhl.org/ and http://www.hippel-lindau.de/.

Clinical Management. Molecular testing of VHL disease today is used to sustain clinical diagnosis. In many cases, the disease will be discovered presymptomatically. Early detection allows treatment of lesions prior to the onset of symptoms. For retinal hemangioblastomas, adequate laser treatment significantly reduces the risk of blindness. Cerebellar or spinal hemangioblastomas are benign tumors and need to be removed prior to the onset of neurological impairment. Pheochromocytoma should be treated when symptomatic. Renal lesions require specific attention. Cysts may be critical, as their lining epithelium may be the origin of malignoma. Thus, any cysts in VHL patients should be regarded as potentially malignant, especially when they are accompanied by solid and/or fast growing tumors. With respect to the size and location, nephron sparing surgery is the treatment of choice for renal conventional (clear cell) carcinoma. The involvement of a variety of different organ systems requires interdisciplinary cooperation of experts from different medical fields for the appropriate management of VHL disease.

Today an increasing number of drugs are clinically applied in advanced renal cell carcinoma, hemangioblastomas, and age-related macula degeneration that have been developed based upon the detailed understanding of the VHL/HIF/VEGF pathway. This includes administration of small molecule inhibitors of HIF-responsive growth factors, an approach that holds the potential of target-specific treatment that might improve treatment efficacy while minimizing adverse effects.

Remaining Questions

Current knowledge of VHL and the VHL regulatory pathway still leave many questions unanswered. It is still unclear why VHL mutations cause this highly restricted subset of tumor types and whether specific VHL mutations are associated with different site-specific tumor risks. Finally, it will be of interest to know whether VHL in addition to its capacity to inhibit HIF exerts additional tumor suppressor functions.

Definition

Vorinostat is a small molecule (MW 264) inhibitor of ►histone deacetylase (HDAC) activity (see Fig. 1).

Characteristics

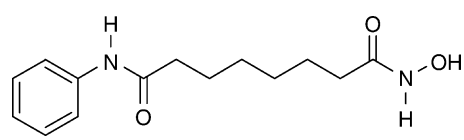
Background

HDACs are enzymes that catalyze the removal of acetyl groups from the lysine residues of proteins, most notably the ►histones contained within ►nucleosomes. Three classes of HDACs have been identified. Class I human HDACs are homologous to the yeast HDAC Rpd3, and include HDAC1, HDAC2, HDAC3 and HDAC8. Class II HDACs are subdivided into Class IIa enzymes (HDAC4, HDAC5, HDAC7 and HDAC9) and Class IIb enzymes (HDAC6 and HDAC10). Class II HDACs are homologous to the yeast HDAC Hda1. The key catalytic residues have been conserved in both the Class I and Class II HDACs. The third class of human HDACs consists of homologues of yeast Sir2. The catalytic site of this third HDAC class is not similar to the catalytic site of the Class I and Class II enzymes. Class III HDACs require nicotinamide-adenine dinucleotide (NAD+) for activity.

Vorinostat inhibits the enzymatic activity of Class I HDACs, (HDAC1, HDAC2, and HDAC3) and the Class II HDAC, HDAC6, at low nanomolar concentrations (IC50 < 86 nM). Vorinostat is approximately tenfold less potent in inhibiting HDAC8, a Class I HDAC, and ~100-fold less potent in inhibiting the Class IIa HDACs, HDAC4, 5 and 7. Vorinostat does not inhibit the activity of the Class III HDAC, SIRT1, at concentrations up to 100 μM. Thus, vorinostat demonstrated potent selective inhibitory activity against specific Class I and Class II HDACs.

Mechanism of Antitumor Action

Vorinostat is active in inducing differentiation, cell growth arrest, or apoptosis in a wide variety of transformed cells in culture. Vorinostat was originally identified as an inducer of differentiation of murine ►erythroleukemia (MEL) cells. Vorinostat has also been found to inhibit proliferation of cultured transformed cell lines derived from lymphoma, leukemia, myelomas, non small cell lung carcinoma, colon carcinoma, central nervous system tumors, melanoma, ovarian carcinoma, renal cell carcinoma, prostate cancer, and breast cancer.



Vorinostat. Figure 1 Vorinostat.

The molecular mechanisms of vorinostat-induced growth arrest, differentiation and ►apoptosis have yet to be fully clarified. The acetylation of nucleosomal histones plays an important role in the transcriptional regulation of gene expression. Hypoacetylation of histones is associated with a condensed ►chromatin structure (►Chromatin Remodeling) and repression of gene transcription. Conversely, acetylated histones are associated with a more open chromatin structure and activation of transcription. Defects in the enzymes regulating histone acetylation have been found in a variety of cancers. These defects can cause an imbalance in histone acetylation that may lead to changes in chromatin structure and transcriptional dysregulation of genes involved in the control of cell cycle progression, differentiation, and apoptosis. A potential mechanism for the anti-tumor action of vorinostat is that vorinostat inhibition of HDAC activity, and subsequent accumulation of acetylated histones, leads to the activation of genes whose expression causes the observed anti-proliferative effects. This model is based on the finding that the expression of a finite number of genes is regulated following exposure to vorinostat. One of the most commonly induced genes is the cell cycle kinase inhibitor $p21^{WAF1/CIP}$.

Vorinostat-induced apoptosis occurs through the intrinsic apoptotic pathway, characterized by the release of mitochondrial membrane proteins such as cytochrome c and the subsequent activation of caspases. Apoptosis mediated by vorinostat can be inhibited by overexpression of ►Bcl-2. Depending on the cell type, caspase activation may or may not be necessary for vorinostat-induced cell death. One study has demonstrated a dependence of ►p53 for vorinostat-induced apoptosis, however, it is generally believed that vorinostat can function in the absence of wild-type p53. Vorinostat has also been cited to induce autophagic cell death. This mode of cell death is characterized by massive degradation of cellular contents by means of intracellular membrane/vesicle reorganization and lysosomal activity.

While most models suggest that histone hyperacetylation leads to transcriptional activation of genes, expression profiling studies have revealed that vorinostat treatment can also lead to repression of gene expression (►Histone Modification in Cancer Biology). Possible mechanisms to explain vorinostat inhibitor-mediated transcriptional repression involve both direct and indirect effects resulting from histone acetylation, or alternately, may involve the hyperacetylation of non-histone proteins. For example, a recent study has demonstrated that vorinostat prevented the transactivation of cytokine-induced signal transducer and activator of transcription (►STAT) 5 target genes. A second study demonstrated that vorinostat

suppressed the induction of c-jun transcription by inhibiting the recruitment of the preinitiation complex to the c-jun promoter resulting in reduced COS-2, cyclin D1 and collagenase-1 transcription.

Vorinostat may affect cancer growth independently from its direct action on tumor cell proliferation and survival by regulating the expression of genes involved in tumor angiogenesis and ►inflammation processes. Vorinostat is a potent anti-angiogenic agent that can alter vascular endothelial growth factor (►VEGF) signaling. The anti-angiogenic activities of vorinostat may arise through its ability to suppress the expression of VEGF receptors 1 and 2, and ►neuropilin. In addition, vorinostat induces expression of the VEGF competitor ►semaphorin III and is likely to suppress angiogenesis by preventing endothelial cells from responding to the angiogenic stimulus generated by VEGF. A separate study found that vorinostat exhibits anti-inflammatory properties in vivo and in vitro and that vorinostat may stimulate the expression of genes that control the synthesis of cytokines and ►nitric oxide or hyperacetylate other targets.

HDAC inhibitors, such as vorinostat, may also affect cell cycle progression by altering the ability of tumor cells to enter and exit mitosis. Histone acetylation is tightly regulated during the cell cycle and may be important for proper deposition of histones during DNA synthesis and chromosome segregation during mitosis. For example, an increase in acetylated histones during S and G2 phase could activate a G2 checkpoint and induce G2 arrest. Loss of this checkpoint, a frequent event in cancer cells, may result in the inability to arrest in G2 phase leading to aberrant mitosis and induction of apoptosis. Likewise, a similar disruption of the mitotic spindle checkpoint may also predispose tumor cells to HDAC inhibitor-induced apoptosis.

While results from mechanistic studies support the hypothesis that the effects of vorinostat on histone acetylation play an important role in its biological activities, the activity of a number of other proteins is regulated, at least in part, by ►histone acetyltransferases (HATs) and HDACs and may be targeted by vorinostat. Several nonhistone proteins, (e.g., ►tubulin, ►Hsp90 and ►p53) are known to be reversibly acetylated on lysine residues and undergo hyperacetylation following exposure to vorinostat. Acetylation of these proteins may also contribute to the antitumor activity of vorinostat.

Studies on the activity of vorinostat in combination with other cancer therapies have demonstrated synergistic or additive activity in a variety of cultured human transformed cell lines. Vorinostat has been tested in combination with other cancer therapies including radiation, kinase inhibitors, cytotoxic agents, and differentiating agents.

Vorinostat has demonstrated anti-tumor activity in a variety of in vivo rodent tumor models whether administered by the intraperitoneal, intravenous, or oral route in both carcinogen induced tumor formation and established tumor models. Administration of vorinostat causes significant tumor growth inhibition in human breast, colon and prostate carcinoma xenografts in mice. Tumor growth inhibition is observed at doses of vorinostat that do not produce toxic side effects.

Clinical Studies

The initial phase I trial (►phase I and II clinical trials) of oral vorinostat was conducted in patients with advanced hematologic malignancies or solid tumors. Seventy-three patients received treatment once or twice daily on a continuous basis or twice daily for three consecutive days per week. The median age was 60 years (range, 20–79) and the majority of patients had received at least three prior systemic therapies. Patients received a total of 416 vorinostat treatment cycles (median, 2; range, 1–37+). The pharmacokinetics were linear from 200 to 600 mg, the mean apparent half-life was 1.5–2 h, and the estimated bioavailability was 43%. Accumulation of acetylated histone H3 was observed in patient peripheral blood mononuclear cells at all dose levels. One patient with transformed diffuse large ►B-cell lymphoma achieved a complete response for 17 months, three patients (diffuse large B-cell lymphoma, laryngeal cancer, ►papillary thyroid carcinoma) had partial responses, and two (metastatic mesothelioma) had unconfirmed partial responses. An additional 16 patients achieved stable disease for 4–37+ months. The major dose-limiting toxicities were anorexia, dehydration, diarrhea, and fatigue. The maximum tolerated dose was 400 mg once daily or 200 mg twice daily for continuous dosing or 300 mg twice daily for three consecutive days per week.

A phase II trial of oral vorinostat in patients with refractory ►cutaneous T-cell lymphoma (CTCL) was conducted. Thirty-three patients were enrolled and received vorinostat 400 mg daily, 300 mg twice daily for 3 days with 4 days rest, or 300 mg twice daily for 14 days with 7 days of rest followed by 200 mg twice daily. The median age was 67 years (range, 26–82), the median number of prior systemic therapies was 5 (range, 1–15), and 85% of patients had Stage IIB or higher CTCL. Eight of 33 patients (24%) achieved a partial response, including 4 of 13 (31%) who received 400 mg daily dosing. The median time to response was 11.9 weeks (range, 3.6–21.9) and the median duration of response was 15.1 weeks (range, 9.4–19.4). The median time to progression was 12.1 weeks overall and 30.2 weeks for responders. One patient who was enrolled on two consecutive dose regimens was treated for 1.4 years. Fourteen of 31 patients (45%), including

73% of those who received 400 mg daily dosing, had symptomatic pruritus relief. The most common adverse experiences were fatigue, thrombocytopenia, diarrhea, nausea, and dysgeusia. Grade 3/4 drug-related adverse experiences included thrombocytopenia and dehydration. Serious adverse experiences and discontinuations due to adverse experiences were least common in patients who received 400 mg daily dosing. These findings supported further investigation of vorinostat 400 mg daily in patients with refractory CTCL.

An international, multicenter, phase IIb trial of oral vorinostat 400 mg daily in patients with persistent, progressive, or recurrent CTCL was conducted. Seventy-four patients were enrolled, including 61 with Stage IIB or higher disease. The median age was 60 years (range, 39–83) and the median number of prior systemic treatments was 3 (range, 1–12). Twenty-two of 74 patients (30%) achieved a partial response, including 18 of 61 (30%) with Stage IIB or higher disease. The median time to response was 55 days (range, 28–171). The median duration of response and time to progression for responders were not reached but estimated to be at least 165 and 256 days, respectively. Response to vorinostat did not appear to be impacted by response to last prior therapy. Eleven patients who did not meet the response criteria had stable disease for at least 24 weeks. Twenty-one of 65 patients (32%) with baseline pruritus scores of at least 3 (scale, 1–10) had pruritus relief. The most common adverse experiences were diarrhea, fatigue, nausea, and anorexia and were mostly mild to moderate in severity. Grade 3/4 adverse experiences included fatigue (5%), pulmonary embolism (5%), thrombocytopenia (5%), and nausea (4%). Fifteen patients received vorinostat for at least 1 year (range, 12.0–34.2+ months). Eighty-five percent of patients did not require dose reduction and 9% discontinued due to a drug-related adverse experience.

Vorinostat (Zolinza™) was approved on October 6, 2006 by the US Food and Drug Administration for the treatment of cutaneous manifestations in patients with cutaneous T-cell lymphoma who have progressive, persistent or recurrent disease on or following two systemic therapies. Further investigation of vorinostat in phase II and III trials for patients with other hematologic malignancies and solid tumors is ongoing. Clinical activity has thus far been observed in patients with acute myeloid leukemia, multiple myeloma, non-Hodgkin lymphoma, glioblastoma multiforme, and metastatic mesothelioma, as well as breast, laryngeal, nasopharyngeal, papillary thyroid, ovarian, and non-small cell lung cancer.

Activity of Vorinostat in Non-oncology Indications

Vorinostat has also shown activity in preclinical studies in indications beyond cancer, including neurodegenerative disorders such as Huntington disease and as an anti-inflammatory agent. Clinical studies in non-oncology indications will be required to determine whether vorinostat may be used for the treatment of a variety of human diseases in addition to cancer.

WAGR Syndrome

Definition

Acronym for **W**ilms tumor, **A**niridia, **G**enitourinary malformations, and mental **R**etardation; is an unusual complex of congenital developmental abnormalities, such as aniridia, genitourinary (GU) malformations, and mental retardation. Individuals are at high risk (>30%) of having a Wilms tumor. At birth, the association is aniridia, GU malformations, and mental retardation (AGR) syndrome. With the discovery of a ►Wilms tumor in these patients, the association is referred to as WAGR syndrome. These syndromes result from the loss or mutation of the ►Wilms tumor gene from the short arm of chromosome 11.

Waldenstrom Macroglobulinemia

Definition

Is a low grade ►B-cell lymphoma that is characterized by the secretion of IgM. The tumors are also called lymphoplasmacytoid lymphoma in the REAL classification. The absence of CD5 and CD10 expression is useful for its distinction from ►chronic lymphocytic leukemia.

►B-cell Tumors

Walker A Motif

Definition

A consensus sequence of amino acids observed in the nucleotide binding fold among distantly related sequences of ►ABC transporters, ATP synthase, myosin, kinases, and other ATP-requiring enzymes.

Warburg Effect

Synonyms

Aerobic glycolysis; Tumor glucose metabolism

Definition

Warburg Effect describes the propensity for cancer cells to convert ►glucose to ►lactate even when oxygen is ample. This effect, also known as aerobic ►glycolysis, contrasts with the anaerobic glycolysis that occurs as an adaptive response to low oxygen tension or ►hypoxia. Adaptive responses through the induction of the ►hypoxia-inducible factor 1 (HIF-1) and cell autonomous changes that activate ►AKT, ►HIF-1, ►MYC or ►RAS oncogenes or inactivate the ►tumor suppressor P53 or ►VHL could all contribute to the Warburg effect.

Characteristics

In reports of pioneering studies, which were translated from German by Frank Dickens in 1930 and made accessible to English readers as a monograph entitled "The Metabolism of Tumors," Otto Warburg described the propensity for cancer cells to convert glucose to

lactate even in the presence of oxygen. The experiments described by Warburg were prescient in determining the maximum allowable thickness of normal and cancer tissue sections to be studied without interference from diffusion limitations. The maximum tissue section thickness was calculated from differential equations and determined to be 2.1×10^{-2} cm, which correlates remarkably well with modern experimental microprobe measurements indicating that oxygen becomes limited for cells >150 μm away from ambient oxygen. By studying human and animal cancer tissues, Warburg reached the profound conclusion that tumors prefer to convert glucose to lactate and speculated that "If the respiration of a growing cell is disturbed, as a rule the cell dies. If it does not die, a tumor cell results."

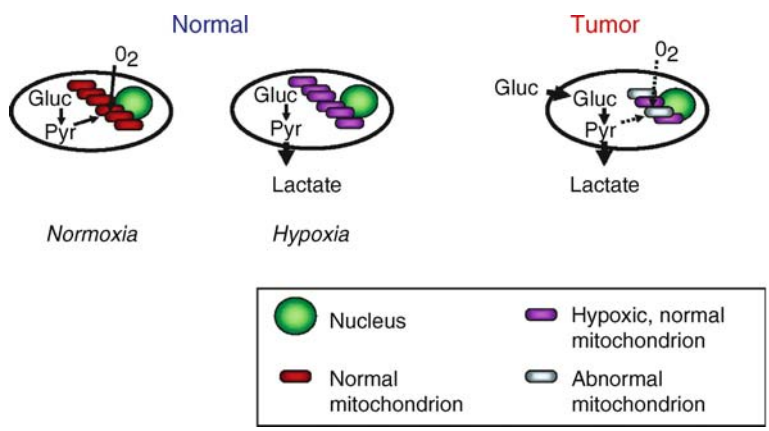
Through the glycolytic pathway, normal tissues convert glucose to pyruvate and generate ATP and NADH. Pyruvate is taken up and then further metabolized by mitochondria through the Krebs or tricarboxylic acid (TCA) cycle. From a single pyruvate molecule, the TCA cycle donates eight high-energy electrons to the mitochondrial transport chain, which creates a proton gradient across the inner mitochondrial membrane, with oxygen as the terminal electron acceptor. Dissipation of the proton gradient produces ATP through ►oxidative phosphorylation. In the absence of oxygen, pyruvate is instead converted to lactate. Cancer cells, in contrast to normal cells, tend to convert glucose directly to lactate even when oxygen is available (Fig. 1).

Mitochondrial DNA Mutations and the Warburg Effect

Warburg's postulation that mitochondrial dysfunction or disturbance contributes aerobic glycolysis is now partially supported by studies of cancer mitochondrial DNA (mtDNA) mutations. Mitochondrial components are encoded by both nuclear and mtDNA, whose mutations can be heritable through maternal transmission, resulting in specific muscle diseases, blindness or deafness. Acquired somatic mtDNA mutations have been discovered in large fractions of human tumors; however, the functional consequences of these mutations are not firmly established. While many mtDNA mutations have unknown effects, some mutations may diminish components of the respiratory chain thereby cause disturbances in respiration. Cell fusion experiments support a functional role of defective mitochondria, which enhance tumorigenicity of prostate cancer cells.

Tumor Suppressors and the Warburg Effect

Since the mitochondrion plays a central and crucial role in programmed cell death or ►apoptosis, it is possible that acute disturbances of respiration could result in cell death as a means to rid the organism of defective cells. However, as proposed by Warburg, if a growing cell with disturbance in respiration does not die presumably as the result of activation of anti-apoptotic pathways, then a tumor cell results. Intriguingly, the tumor suppressor protein ►P53, which plays an intimate role in ►apoptosis, was recently shown to directly activate genes that enhance cellular respiration, such that loss of P53 favors the conversion of glucose to lactate and cell survival. In particular, ►P53 activates Synthesis of Cytochrome c Oxidase 2 (SCO2) which is critical for positively regulating the cytochrome c oxidase (COX) complex, a major site of oxygen consumption by the mitochondrion. Additionally, P53 activates TIGAR, which shares sequence similarity with the bisphosphatase FBPase-2 and diminishes fructose-2,6-bisphosphate



Warburg Effect. Figure 1 The Warburg Effect. In contrast to normal cells that utilizes glucose through mitochondrial oxidative phosphorylation in the presence of oxygen (normoxia) and undergo anaerobic glycolysis in hypoxia, Warburg hypothesized that tumor cells with disturbances in respiration, presumably due to defective mitochondria, have the propensity to convert glucose to lactate even in the presence of oxygen. In tumor cells oxygen and pyruvate are presumably inefficiently utilized (dashed arrows) by the mitochondria. Gluc, glucose; Pyr, pyruvate.

levels, thereby blocks glycolysis. Hence loss of the tumor suppressor P53 would be expected to diminish respiration and unblock glycolysis.

Several ►familial cancer syndromes have been linked to mutations of tumor suppressors that are enzymes in the TCA cycle enzymes or proteins involved in metabolism. Mutations of succinate dehydrogenase are associated with paragangliomas, while mutations of fumarate hydratase are linked with ►renal carcinoma and uterine leiomyomatosis. These mutations result in high levels of succinate, which inhibit prolyl hydroxylase (PHD) function resulting in increased stability of the hypoxia inducible factor HIF-1 protein. PHDs hydroxylate HIF-1 and target it for recognition by the von Hippel-Lindau protein (vHL) and subsequent proteasomal degradation. Hence inactivating mutations of vHL also stabilize HIF, which is important for tumorigenesis through ►transcriptional regulation and stimulation of glycolysis and angiogenesis. These observations indicate that mutations of tumor suppressors may not only decrease mitochondrial function, but may also activate glycolysis directly or through the stabilization of HIF-1.

Mutations of the LKB1 tumor suppressor result in the rare autosomal dominant form of Peutz-Jeghers syndrome that is characterized by early age onset of gastrointestinal polyposis. LKB1 is a kinase that phosphorylates and activates AMP kinase (AMPK) in the presence of AMP when intracellular levels of ATP are low. AMPK, in turn, increases ATP production through stimulation of pathways including fatty acid oxidation. AMPK also activates two other tumor suppressors, TSC1 and TSC2, which are mutated in the familial syndrome ►tuberous sclerosis complex characterized by benign tumors commonly affecting the brain, but also affecting the kidneys, heart, eyes, lungs, and skin. TSC1 and TSC2 form heterodimers that inhibit ►mTOR, the ubiquitous kinase which stimulates cell growth and protein synthesis in response to growth factors. Hence, loss of LKB1, TSC1 or TSC2, activates the mTOR pathway. Hyperactivation of the mTOR pathway through loss of tumor suppressors also appears to increase translation of HIF-1α mRNA and thereby stimulates the Warburg effect.

Oncogenic Activation of the Warburg Effect

In vivo and *in vitro* studies have demonstrated that many tumors are severely hypoxic due to a disordered, inefficient neo-vascular system. Hypoxia results in the stabilization of HIF, which in turn transcriptionally activates genes encoding glucose transporters, glycolytic enzymes, and angiogenic factors. As a result, tumor uptake of glucose is avid and lactate production is robust. It is apparent however, that not all areas of a tumor that are highly glycolytic are necessarily hypoxic, suggesting that cell autonomous oncogenic alterations could also cause the Warburg effect. In one scenario, oncogenes could stabilize HIF itself or alternatively directly inhibit cellular respiration or activate glycolysis.

Since HIF-1 has been found in non-hypoxic areas of tumors, it is likely that HIF-1 could be stabilized by non-hypoxic factors, such as loss of vHL. HIF-1 levels are increased by insulin-like growth factor stimulation, activated v-►Src, ►c-Src or ►Ras oncogenes. Signaling through the EGF receptor, ►HER2, or ►PI3 kinase also promote increased synthesis of HIF-1 protein. Another view contends, however, that the PI3-kinase/AKT and HIF1 are independent pathways. Hence, oncogenic activation of a number of pathways could result in the stabilization of HIF-1 under normoxic conditions. However, oncogenic activation of glycolysis also occur independent of HIF.

Additional insights into the Warburg effect are provided through a novel HIF-1 target gene that actively inhibits mitochondrial function. Pyruvate dehydrogenase kinase 1 (PDK1) is one of four PDK family members and was identified as a direct transcriptional target of HIF-1. PDK1 inactivates the mitochondrial pyruvate dehydrogenase (PDH) complex by phosphorylating the PDH E1α catalytic subunit. Suppression of PDH inhibits the conversion of pyruvate to acetyl-CoA, thereby decreases mitochondrial respiration. As such, it is expected that the non-hypoxic oncogenic stabilization of HIF would increase PDK1 levels, which divert pyruvate from PDH and enhance lactate production. These studies indicate that PDK1 activation could be a key regulatory switch contributing to the Warburg effect.

The ►MYC oncogene is over-expressed in 20–70% of commonly occurring human cancers (www.myccancergene.org). Myc directly binds and transactivates the promoters of several key glycolytic genes (HK2, ENO1, and LDHA), which have highly evolutionarily conserved Myc binding sites, as well as many other glycolytic genes and glucose transporters. The activation of glycolytic genes by Myc could be physiological or pathological under non-hypoxic conditions. It is notable that Myc is also implicated in stimulation mitochondrial biogenesis and hence could normally play a role in driving glucose metabolism toward oxidative phosphorylation in non-transformed cells. In tumor cells with defective or suppressed respiration, however, constitutive activation of Myc is expected to contribute to aerobic glycolysis by directly activating glycolytic genes. Hence, in certain tumors Myc may contribute to a cell autonomous state of converting glucose to lactate even in non-hypoxic conditions.

The ►AKT oncogene, which encodes a protein serine-threonine kinase, also activates a cell autonomous state of aerobic glycolysis in a seeming HIF-independent fashion through mobilization of glucose

transporters to the cell surface, and activation of hexokinase 2 and phosphofructokinase 2. Intriguingly, Akt increases glycolytic conversion of glucose to lactate without an increase in oxidative phosphorylation. Similar to Bcl-X_L, a ►Bcl-2 family member, Akt is anti-apoptotic such that its ability to increase aerobic glycolysis is coupled with suppression of cell death. However, unlike Bcl-X_L, Akt is able to transform cells. Hence, activation of Akt appears to be sufficient for the Warburg effect and tumorigenesis under certain conditions.

The Warburg effect has also intriguingly emerged in a model of ►tumor progression triggered by serial transduction of normal human cells with immortalizing and oncogenic genes. By multidimensional metabolic profiling of primary human fibroblasts transformed step-wise by ►hTERT, ►SV40 large T antigen, small T antigen, and H-Ras, the highly tumorigenic cells were observed to display the Warburg effect with high rates of lactate production and low mitochondrial mass. Cells transformed by the other three genes but lacking H-Ras had high mitochondrial mass and a high oxygen consumption rate with lower lactate production. These observations suggest that a certain stage in tumorigenesis could be associated with increased respiration, but H-Ras appear to be associated with the final conversion of human fibroblasts to a highly tumorigenic phenotype associated with aerobic glycolysis. In fact, Ras is implicated in the regulation of PFKFB3, a 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase, which diminishes the intracellular concentration of the activator, fructose-2,6-bisphosphate (F2,6BP). Paradoxically, while increased PFKFB3 appears to be necessary for Ras transformation of fibroblasts, the associated diminished levels of F2,6BP, which allosterically activates the rate-limiting phosphofructokinase 1 does not appear to correlate with cellular transformation. In this regard, the effects of Ras on PFKFB3 contrasts with the activation of TIGAR by P53 discussed above.

In summary, many studies support the activation of glycolysis and lactate production as an adaptive response to hypoxia as well as a result of direct oncogenic activation. Although, distinction between these two possible mechanisms of activation of tumor aerobic glycolysis is necessary for our understanding of tumor metabolism, it is the cell autonomous oncogenic activation of glycolysis that appears to substantiate Warburg's original observations.

Does the Warburg Effect Contribute to Tumorigenicity?

If aerobic glycolysis mediated by the Warburg Effect is much less efficient for ATP production as compared to oxidative phosphorylation, then what are the selective pressures for tumor aerobic glycolysis? Hypoxia is pervasive in tumors in vivo and likely to be a selective pressure on cancer cells. Although independence from oxygen requirement through the Warburg effect could be advantageous to a cancer cell, there must be additional advantages since an adaptive hypoxic response of activated glycolysis should also confer the same advantage to normal cells. Yet, hypoxia diminishes the growth potential of normal cells, except endothelial cells. Several glycolytic enzyme genes, including glucose phosphate isomerase (GPI) and phosphoglucomutase, were found capable of immortalizing primary fibroblasts in an expression cloning study. The associated increases in glycolytic rates are hypothesized to suppress mitochondrial reactive oxygen species production, which has been implicated in cellular senescence and apoptosis. In this regard, ►immortalization by glycolytic enzymes could be a step in tumorigenesis that is poised for additional oncogenic conversions. It should be noted that there are non-glycolytic functions, such as the roles of LDH and GAPDH in transcriptional regulation, of these enzymes that may participate in tumorigenesis.

The multi-functional roles of glycolytic enzymes, which include the anti-apoptotic roles of glucokinase and hexokinase through direct interactions with the mitochondria, could contribute to tumorigenesis. In addition, GPI is also known as autocrine motility factor that was isolated as a factor capable of stimulating motility of cells in an ►autocrine or ►paracrine fashion. The increased motility could contribute to the malignant phenotype of metastasis. How these non-glycolytic functions directly contribute to tumorigenesis remains to be further studied.

Clinical Aspects and Summary

The characteristics of cancer cells including the avid consumption of glucose and robust lactate production were first described by Warburg about 80 years ago. Over the past two decades, the molecular basis for tumorigenesis unfolded in the discovery of oncogenes and tumor suppressor genes that are now linked to altered glucose metabolism. While the analogies of a defective automobile brake to loss of tumor suppressor and a stuck accelerator to oncogene activation are touted as central mechanisms in tumorigenesis, the fuel line or tumor energy metabolism has been an overlooked, yet critical aspect of tumorigenesis. In fact, the avid uptake of glucose by tumors, observed by Warburg decades ago, is now the foundation for the detection and monitoring of human cancers by 2-fluorodeoxyglucose ►positron emission tomography (FDG-PET). Although Warburg suggested that cancer cells underwent aerobic glycolysis as a result of mitochondrial disturbances, more recent studies suggest that both cell autonomous genetic alterations as well as adaptation to hypoxia through the stabilization of HIF-1 contribute to this characteristic tumor metabolic adaptation. This common metabolic perturbation of aerobic glycolysis or the

Warburg effect in cancers appears attractive as a therapeutic target pathway, although the true therapeutic window remains to be established.

WD Repeats

Definition

A motif of approximately forty amino acids that commonly ends with a tryptophan and aspartic acid dipeptide. These motifs often occur as tandem repeats. Many of the proteins containing WD repeats are subunits of protein complexes. WD proteins commonly have 4–16 repeating WD units. WD proteins are a large family found in all eukaryotes and are implicated in a variety of functions, such as signal transduction, regulation of transcription, cell cycle control, and apoptosis. The underlying function of WD proteins is the assembly of multimeric protein complexes with the repeating units serving as a rigid scaffold for protein interactions that are mediated by non-WD repeat regions. The specificity of the protein's function is usually determined by its sequence that lies outside of the tandem repeats.

Wild-type

Definition

Refers to the most prevalent gene variant (encoding a protein, or an active enzyme) in the population. If a variant is predominant in one population, but has a low frequency in another population, the terminology usually refers to the population in which the variant was first described. For this reason, it is advisable to refrain from using this terminology on its own because it may easily create confusion in a number of cases.

Wilms Tumor

Kathy Pritchard-Jones
Institute of Cancer Research/Royal Marsden Hospital, Sutton, Surrey, UK

Definition

Wilms tumor (synonym nephroblastoma) is a childhood embryonal cancer of the kidney. It was named after a German physician, Max Wilms, who described the first large collection of cases of this tumor in a paper published in 1899. The term Wilms tumor used to be applied to other types of childhood kidney cancer (clear cell sarcoma of kidney and malignant rhabdoid tumor of kidney) but these are now recognized as distinct entities with different clinical behavior and requiring different treatments.

Characteristics

How Common is Wilms Tumor?

Wilms tumor affects ~1 in 10,000 children before their fifteenth birthday, typically at around age 3–4 years. Ninety percent of cases will have been diagnosed before the age of 7 years. There is a degree of ethnic variation; it is commoner in blacks and relatively rare in Asians. Usually only one kidney is affected, but in 5–8% of cases there are tumors in both kidneys (bilateral disease).

What Causes Wilms Tumor?

Although the majority of cases of Wilms tumor are "sporadic" with no obvious cause, it is known that genetic predisposition to Wilms tumor can occur. One to two percent of affected children inherit a defective gene from a parent. There are at least four such "familial Wilms tumor genes," only one of which has been identified to date. More commonly, in ~5% of all cases, a child has a developmental defect associated with genetic predisposition to Wilms tumor and sometimes other forms of cancer. The first of these to be defined at a molecular level was the association of Wilms tumor with aniridia, a lack of development of the iris in the eye. Such children usually have other defects including abnormal genital development and variable mental retardation, and hence the acronym, WAGR syndrome (for Wilms tumor, Anividia, Genitourinary malformations, and mental retardations). This defect is due to a chromosomal deletion that deletes one copy of the ►Wilms tumor gene, WT1, and the adjacent ►PAX6 gene at 11p13. Loss of one allele of PAX6 is dominant, but development of the tumor requires loss or mutation of the remaining WT1 allele in one or more kidney cells (i.e. tumor development is recessive, hence WT1 belongs to the class of ►tumor suppressor genes). Heritable mutations in WT1 are also responsible for the predisposition to Wilms tumor associated with abnormal kidney development seen in ►Denys-Drash syndrome, where children lose large quantities of protein in their urine (nephrotic syndrome) and often have abnormal genital development. Thus, Wilms tumor provides a fascinating example of how normal development of an organ can be intimately linked to cancer predisposition in that organ. Indeed, Wilms tumor can bear an uncanny resemblance to cell types seen during normal embryonic kidney development, hence the term "embryonal tumor."

There are an increasing number of children recognized with nephrotic syndrome with underlying germline WT1 mutations who do not develop Wilms tumor. Hence, it is possible that inheriting a mutation in WT1 provides only a relatively weak stimulus to developing Wilms tumor (i.e. the gene is of low ►penetrance).

A second category of genetic predisposition to Wilms tumor occurs in the overgrowth syndromes of childhood, of which ►Beckwith-Wiedemann syndrome (BWS) is the best recognized. The genetics of BWS are complex, involving several different genes within the 11p15.5 chromosomal locus and the phenomenon of ►genomic imprinting, whereby expression of a gene depends from which parent it was inherited. The overall tumor risk is ~10%, of which half are Wilms tumors. It appears that children with early nephromegaly (i.e. overgrowth of the kidneys) or asymmetrical overgrowth (hemihypertrophy) are at greatest risk.

Finally, there is some evidence from case control studies that the risk of Wilms tumor may be somewhat increased by certain parental occupations or exposures. However, the relative risk to the child is usually small, of the order of two- to tenfold.

Clinical Characteristics

Wilms tumor is one of the most curable of childhood cancers, even when it has spread beyond the kidney to distant sites. The commonest site of such metastases

is the lung, followed by lymph nodes and liver. Wilms tumor rarely metastasizes to bone, bone marrow or brain. The treatment consists of chemotherapy with one to three different drugs (usually ►vincristine, ►actinomycin D+/– ►adriamycin) together with surgical excision of the affected kidney. Radiotherapy is also used when there is residual or spilt tumor in the abdomen or metastasis to the lungs. With these regimens, ~90% of children with a tumor confined to the kidney (stages I and II) are cured, as are over two-thirds of patients with metastatic disease (stage IV). There is a different philosophical approach to the organization of treatment between different national and international childhood cancer study groups. The National Wilms Tumor Study Group (►NWTSG) of North America favors immediate surgical excision of the affected kidney, followed by chemotherapy with or without radiotherapy, according to the tumor extent found at the time of surgery. The approach of the International Society of Paediatric Oncology (►SIOP) is to use pre-operative chemotherapy to shrink the tumor prior to surgery. This study showed a reduction in the risk of tumor rupture during operation and also reduction in the tumor stage, hence allowing less intensive post-operative treatment. The two groups have comparable cure rates, but the NWTSG approach uses slightly more radiotherapy whereas the SIOP approach uses more anthracyclines (adriamycin). Both these treatments have the potential for long term side effects on growth and fertility and on the heart muscle, respectively. The majority of children with Wilms tumor are cured without the need for either of these agents and are unlikely to suffer any long term sequelae.

Is Wilms Tumor One Disease?

As with most cancers, various "prognostic factors" can be recognized in Wilms tumor. The most obvious adverse factor is increasing tumor ►stage. However, a distinct histological subtype called ►Wilms tumor anaplasia carries a poor prognosis, especially when associated with advanced stage disease. Anaplasia is associated with mutations in the ►p53 gene, which can occur focally as part of clonal evolution of a tumor. Other molecular characteristics that may be associated with worse outcome are allele loss or ►loss of heterozygosity for markers on chromosome 16q, 1p and possibly 22q and 11q. Some of these are being tested prospectively in the current NWTS 5 clinical trial, which aims to use molecular characteristics of a tumor to better define risk groups.

Molecular Characteristics of Wilm Tumor

As soon as the WT1 gene was isolated in 1990 it became clear that it was not mutated in the majority of sporadic Wilms tumors. Among over 600 published cases analyzed for intragenic mutations, WT1 mutation occurs in only ~10%. In some tumors, mutation of both WT1 alleles appears to be sufficient for tumorigenesis, in accordance with ►Knudson hypothesis of two hits. However, in other tumors, either only one WT1 allele is mutated or other genetic events are clearly interacting. The molecular biology of the WT1 protein is fascinating and has led to insights into both tumor and normal development and their inter-relationship. Although it is known that several different genetic loci exist for other Wilms tumor genes, their relative contribution to sporadic Wilms tumor is not yet known. A database of WT1 mutations is maintained (http://www.umd.necker.fr).

Treatment of Relapsed Wilms Tumor and Future Therapeutic Possibilities

Although Wilms tumor is one of the most curable of childhood cancers at initial diagnosis, those cases that relapse carry a much worse prognosis, even with intensive retreatment. Less than a third of relapses are due to the anaplastic variant. Hence, one of the goals of current Wilms tumor clinical studies is to identify factors present at diagnosis that are predictive of outcome. Future treatment intensity could then be stratified according to predicted risk of relapse using molecular characteristics of individual tumors. Another potential avenue is to use knowledge of the biology of the Wilms tumor genes to devise novel therapeutic approaches. In the future this might also lead to preventative strategies for children at increased genetic risk of Wilms tumor.

Heritability and Screening

By clinical criteria it appears that <10% of children with Wilms tumor have a potentially "heritable" form of the disease. Approximately 1–2% have a family history of Wilms tumor, a further 1–2% have the WAGR syndrome, ~3% have either Beckwith Wiedemann syndrome or some degree of asymmetrical overgrowth. However, it now appears that there are several genes that may be responsible for familial Wilms tumor and they may be of relatively low ►penetrance. This means that a proportion of patients with apparently sporadic Wilms tumors may transmit a germline mutation to their offspring predisposing them to Wilms tumor. However, even if the proportion of heritable cases is larger than previously believed, the absolute risk to offspring must be low; only four cases among 362 offspring of 462 survivors of unilateral Wilms tumor have been reported.

Early detection of Wilms tumor has the potential to increase survival and reduce treatment morbidity. Children known to be genetically predisposed to Wilms tumor, such as those with WAGR, Beckwith-Wiedemann or Denys-Drash syndromes, are candidates for screening. This is usually done by regular

abdominal ►ultrasound scanning, although teaching the parents to perform regular palpation of the abdomen is an acceptable alternative. Since Wilms tumors can grow very rapidly, ultrasound screening is recommended at intervals of no >3–4 months. However, there are no definitive clinical trials to determine which screening method or interval is superior for detecting tumors at a low stage (I or II). In the future, if a larger proportion of children are shown to be carriers of one of the familial Wilms tumor genes, then more information should become available on the efficacy of screening. A further benefit of the application of molecular genetics is that children with germline WT1 mutations appear to be at risk of late renal failure and hence require appropriate monitoring.

Wilms Tumor Anaplasia

Definition

The term "anaplasia" in ►Wilms tumor is used to describe a histological pattern defined as the presence of all of the following three features:

- Cells with a nuclear diameter at least three times of adjacent nuclei of the same cell type;
- Marked hyperchromatism of these cells, indicative of increased chromosome numbers;
- Abnormal mitotic figure.

►Anaplasia may be focal or diffuse and is associated with mutation of the ►p53 gene. Anaplasia is felt to be a marker of cellular resistance to therapy but not of increased tumor aggressiveness as anaplasia in stage I tumors has no adverse prognostic significance.

Wilms Tumor Suppressor Gene

Definition

WT1 gene; Is located at 11p13 and consists of ten exons spanning approximately 50 kb of genomic DNA. The gene encodes a zinc finger protein that has two alternative splice sites affecting the whole of exon 5 and a three amino acid insertion (KTS) between the third and fourth zinc fingers. The WT1 protein is multifunctional and the various isoforms can act as transcription factors or may be involved in RNA processing or splicing. WT1 is essential for formation of the kidney and gonad in the mouse. There is a genotype-phenotype correlation, with germline missense mutations as seen in ►Denys-Drash syndrome having a more pronounced effect on genitourinary development than complete deletion of one allele, as seen in WAGR syndrome. Germline intronic mutations affecting splicing of the KTS linker also act in a dominant fashion on genitourinary development.

WIN

►Forkhead Box M1

Wiskott-Aldrich Syndrome

Definition

WAS; is a rare X-linked ►recessive disease with variable expression, but commonly includes immunoglobulin M (IgM) deficiency. WAS always causes persistent ►thrombocytopenia (low platelet counts), and, in its complete form, also causes small ►platelets, atopy, cellular and humoral immunodeficiency, and an increased risk of ►autoimmune disease and ►hematologic malignancies. The exact function of the WAS protein is not fully elucidated, but it seems to function

as a bridge between signaling and movement of the actin filaments in the cytoskeleton. WAS is also sometimes called the eczema-thrombocytopenia-immunodeficiency syndrome.

Withaferin A

Chendil Damodaran
Department of Clinical Sciences, University of Kentucky, Lexington, Kentucky, USA

Synonyms

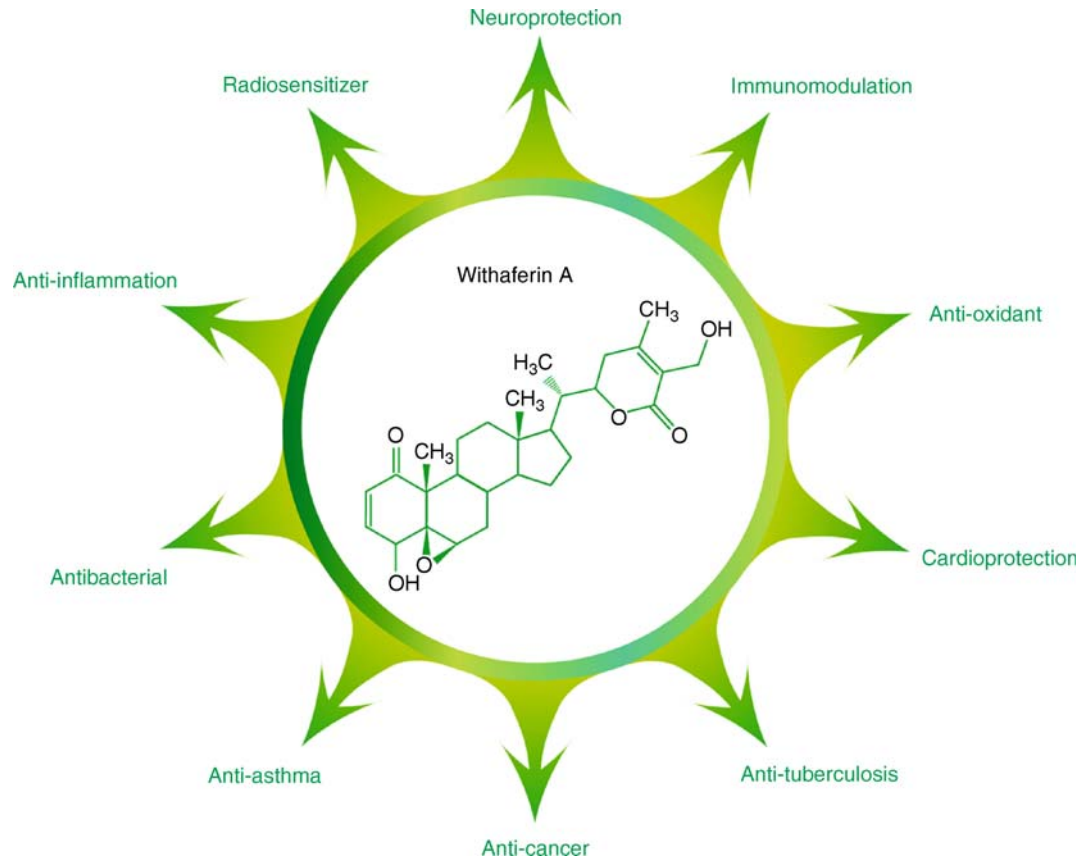
WA

Definition

The natural product Withaferin A (WA) is an important bioactive component of *Withania somnifera* (WS), a medicinal plant of the Solanaceae family that is used in the Indian Ayurvedic medical system, as well as many other indigenous medical practices. A structural analysis of WA indicates that it is a highly oxygenated C-28 ergostane-type steroid with a 22, 26-lactone and a 1-oxo-group (Fig. 1).

Characteristics

WA has been used in several ethnobotanical medical practices (►Natural products) to treat a variety of ailments, including cancer, inflammatory conditions, and cardiac and neurological disorders (Fig. 1). With respect to cancer, seminal *in vivo* and *in vitro* studies have revealed that WA possesses chemopreventive, chemotherapeutic, and radiosensitizing character (►Adjuvant therapy). The chemopreventive properties of WA were first identified in a Swiss albino mice tumor model, and were subsequently confirmed in mice using *Withania spp.* root extracts, as well as several withanolides isolated from these extracts. Similarly, early studies also revealed the chemotherapeutic utility of WA, as it potently inhibited mouse Ehrlich ascites carcinoma *in vivo* and induced G_2/M arrest (►G_2/M Transition) of the cell cycle in Chinese Hamster V79 cells. This WA-mediated G_2/M arrest has been shown to result in significant radiosensitization in cell culture



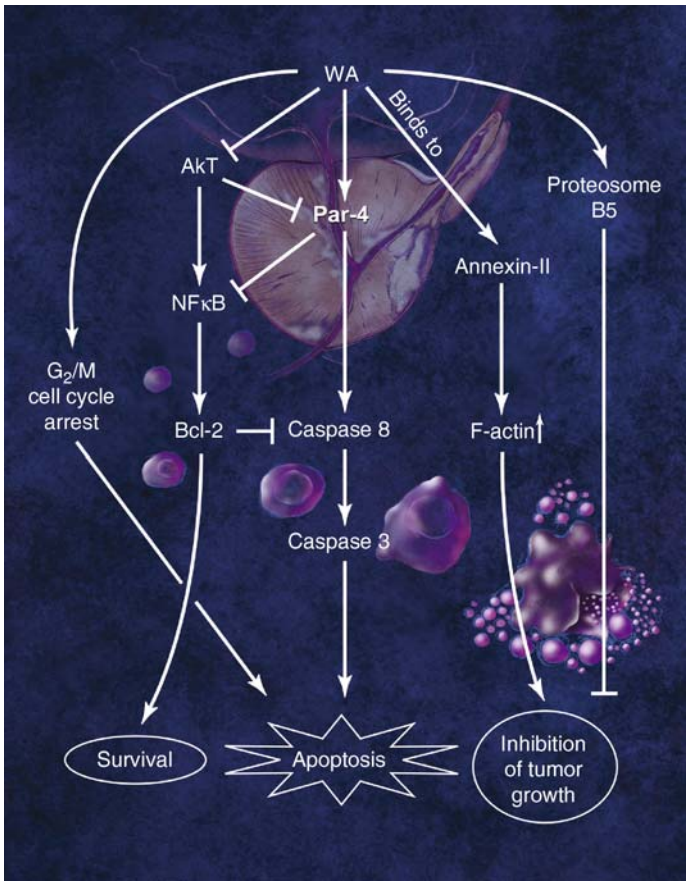
Withaferin A. Figure 1 The diverse spectrum of Withaferin-A activity.

models, as well as in mouse fibrosarcoma and melanoma when administered prior to radiotherapy. Notably, when used in combination with radiotherapy *in vivo*, WA increased tumor cure and disease-free survival. Several reports substantiate these findings and support the activity of WA against various cancer models, including prostate, colon, breast, and lung cancer.

The mechanistic details of WA anti-cancer activity have been extensively studied in prostate cancer (►Prostate cancer, clinical oncology) models *in vitro* and *in vivo*. WA induces ►apoptosis in androgen refractory prostate cancer cells, and causes regression of PC-3 xenografts in mouse models. These studies also reveal that WA alone fails to induce apoptosis in androgen-responsive prostate cancer, but the combination of WA and an anti-androgen induces apoptosis in androgen-responsive cells (►Androgen receptor). Published reports from several labs confirm these selective effects of WA on prostate cancer. Given that androgen-responsive prostate cancer often progresses to an androgen-refractory phenotype, which is resistant to current therapeutic approaches, these findings are significant.

WA targets multiple signaling pathways in prostate cancer cells to induce its apoptotic effects (Fig. 2). In prostate cancer cells, WA up-regulates the gene expression of prostate apoptosis response-4 (Par-4), which induces p53- and phosphatase and tensin homolog (PTEN)-independent cancer-selective apoptosis. The pro-apoptotic effects of WA are dependent on Par-4 expression and action. In normal and malignant cells, Par-4 is phosphorylated and inactivated by Akt (also known as Protein Kinase B), which is an evolutionarily conserved regulator of the cell cycle. However, as shown in prostate, breast, and lung cancer cells, WA inhibits Akt-mediated pro-survival signaling (►BCl-2) and initiates G_2/M cell cycle arrest (unpublished data).

WA also negatively regulates NFκB activity in variety of cancer cell lines. NFκB is a transcription factor, a regulator of key cellular processes, such as apoptosis, immunoresponse, differentiation, and proliferation, and its constitutive activation has been linked to cancer. Under normal conditions, NFκB activity is held in check in the cytoplasm by IκB. Upon phosphorylation of IκB by IκB kinase (IKK), NFκB translocates to the nucleus to effect gene transcription. Importantly, WA inhibits IκB kinase activity, thereby blocking NFκB nuclear translocation, and targets various cysteine residues of multiple kinases and phosphotases.



Withaferin A. Figure 2 Withaferin-A mechanism of action in prostate cancer.

As a consequence, WA alters the phosphorylation status of p38, MEK/ERK, JNK, and IKKβ, thereby inhibiting the pro-survival machinery and triggering apoptosis.

Beyond WA effects on Par-4 and pro-survival signaling pathways (►Apoptosis Signaling), it has been reported that WA "function both as a ►proteasome" and ►angiogenesis inhibitor. The proteasome is a proteinase complex that selectively degrades ubiquitinated proteins, and is considered to be a potential target for cancer chemotherapy. WA targets the proteasome β5 subunit, inhibiting cell survival *in vitro* and tumor growth *in vivo*. Structural modeling analysis indicates WA contains two conjugated ketone bonds that target the hydroxyl group of the N-terminal threonine of the proteasomal chymotrypsin subunit β5. With respect to angiogenesis, a recent study demonstrates that WA binds to annexin II to promote F-actin polymerization and growth inhibition in Prostate cancer cells. This observation complements a study that shows WA inhibits angiogenesis through its ability to negatively regulate NFκB signaling, in addition to ►cyclin D1.

Although preclinical studies reveal that WA impacts multiple signaling cascades associated with cancer cell proliferation and survival, careful analyses are needed to establish the clinical merit of WA in treating human cancers. The precise mechanism by which WA elicits such diverse biological effects remains unclear, thus additional studies are required to identify unknown targets of WA, and clarify the molecular nexus that directs this broad spectrum of WA activity.

Wnt

Definition

The name comes from the *Drosophila* gene wingless and the proto-oncogene *int-1*. The wnt/β-catenin pathway is highly conserved and regulates gene expression by ►TCF/LEF transcription factors. The pathway is of importance in embryonic development, stem cell differentiation, cell death, and tumor progression.

►Wnt Signaling

Wnt/beta-Catenin Pathway

Definition

In the canonical Wnt/beta-catenin pathway, Wnt ligand binding to its cell surface receptor triggers changes of cytoplasmic effector activities and stabilization of beta-catenin protein. Beta-catenin then accumulates in the nucleus where it interacts with ►high mobility group (HMG) box transcription factors to regulate gene expression.

►APC/β-Catenin Pathway
►Wnt Signaling

Wnt Signaling

Robert M. Kypta
Cell Biology and Stem Cells Unit, CIC bioGUNE, Derio, Bilbao, Spain; Imperial College London, London, UK

Definition

The name ►Wnt comes from wingless (Wg) and Int-1. Wingless is a *Drosophila* gene important during development and Int-1 is a gene into which the mouse mammary tumor virus (MMTV) *int*egrated to cause tumors. Wg and Int-1 were subsequently found to be related in sequence. Wnt signaling is the result of binding of Wnt proteins to cell surface receptors. Wnt family members exist in all multicellular organisms.

Characteristics

Wnt Proteins

Vertebrate Wnts comprise a family of 19 hydrophobic cysteine-rich secreted glycoproteins of ~350 amino acids in length. Their hydrophobicity stems from lipid modification – cysteine palmitoylation and serine palmitoleoylation – that is essential for signaling activity and secretion. Wnt proteins are quite insoluble and associate with ►HSPGs (heparan sulfate proteoglycans) in the extracellular matrix, so they often signal only over short distances. Long-range Wnt signaling does take place, however, for example, when Wnts form gradients to pattern developing tissues. Long-range Wnt signaling is mediated by ►lipoprotein particles and facilitated by the ►retromer. Wnt signals can elicit a number of cellular responses including proliferation, differentiation and migration (►Migration). The nature of the response is dictated by the responding cell and the specific Wnts and Wnt receptors present.

Mutations of Wnt genes are rare and have not been found in human tumors. However, Wnt gene expression patterns are often altered in tumor cells and inhibition of Wnt activity using antibodies or siRNA (►siRNA) induces apoptosis (►Apoptosis) in some tumor cell types (see Table 1). Both increases and decreases in Wnt5a expression have been observed in cancer, perhaps because Wnt5a plays different roles in different tissues or at different stages during tumor progression.

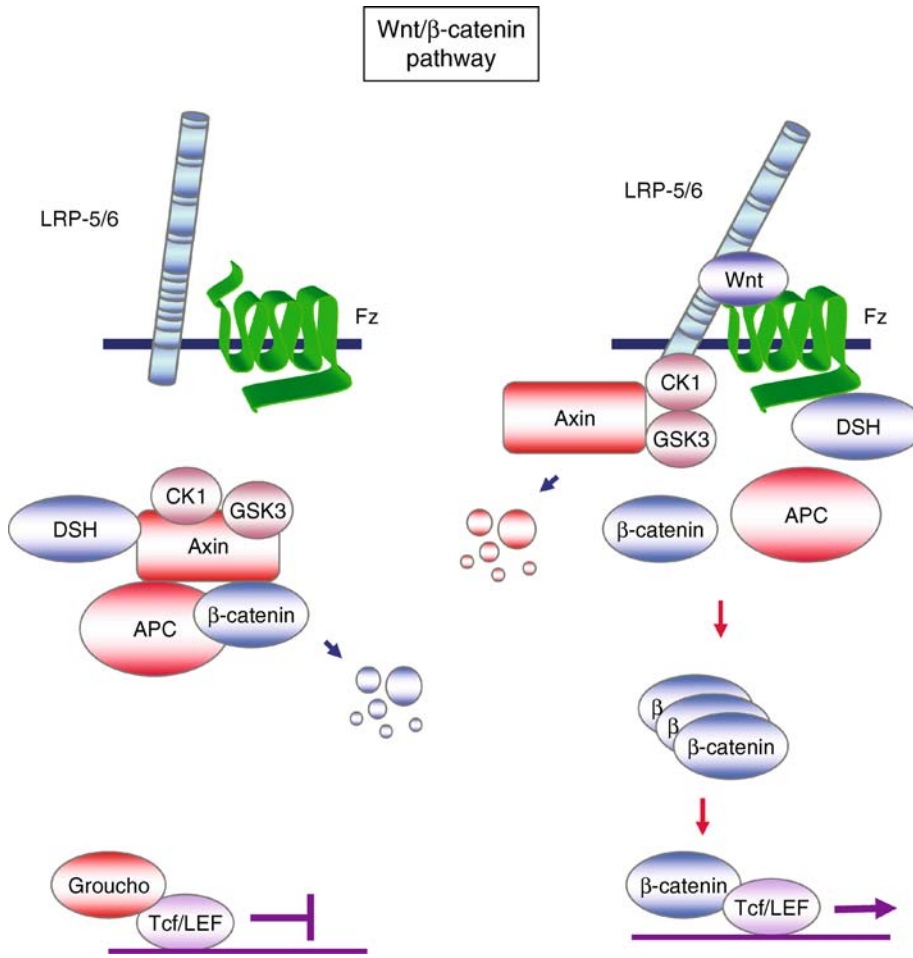
Wnt Signaling Pathways

Wnt proteins normally bind to cell-surface receptors of the frizzled (►FZD) family, which activate intracellular disheveled (►DVL) family proteins. At this stage the Wnt signals bifurcate and can activate distinct pathways. The best understood of these is the Wnt/►β-catenin pathway, also referred to as the canonical pathway (►APC/β-catenin pathway) (Fig. 1). In this pathway, Wnt proteins also bind to ►LRP5/6, which interact with the β-catenin-binding protein ►Axin. In the absence of Wnts, a so-called β-catenin destruction complex controls the level of β-catenin in the cytoplasm. This complex, which includes Axin, glycogen synthase kinase-3(►GSK-3), casein kinase-I (►CKI) and adenomatous coli polyposis protein (APC) (►APC in familial adenomatous polyposis), facilitates β-catenin phosphorylation, ubiquitination (►Ubiquitination), and ultimately degradation in the ►proteasome. Canonical Wnt signals disrupt this complex by eliciting changes in Axin localization and stability, resulting in the stabilization of β-catenin in the cytoplasm. Stabilized β-catenin enters the nucleus and binds to transcription factors, primarily of the ►Tcf/LEF family, thereby regulating gene expression. The Wnt/β-catenin pathway is permanently active in many tumor types, in particular in colon cancer (►Colon cancer), as a result of mutations in APC, β-catenin or Axin. In rare cases, inactivation of Wnt/β-catenin signaling leads to tumor formation, for example, in sebaceous tumors with LEF-1 mutations (Table 2).

Non-canonical Wnt signals do not stabilize β-catenin. Instead, they overlap with other known signaling pathways. The planar cell polarity (►PCP) pathway is a noncanonical pathway that was first defined in *Drosophila*, where it controls the uniform orientation of hairs and bristles on the body. PCP signaling has also been studied extensively in frogs and zebrafish, where it regulates ►convergent extension. In mammals, the best example of PCP is the uniform orientation of the hair cell stereociliary bundles within the cochlea. PCP pathway proteins include FZD, DVL and several proteins not involved in other Wnt signaling pathways; those relevant to cancer include ►VANGL, which is overexpressed in tumors and promotes metastasis (►Metastasis), and PTK7, a catalytically inactive transmembrane tyrosine kinase (►Receptor tyrosine kinase) that is overexpressed in tumor-derived cell lines. The PCP pathway activates the small GTPases Rac and Rho (►Rho family proteins) and the protein kinases c-Jun NH2-terminal kinase (►JNK) and Rho-associated kinase (►ROCK) to induce changes in the cytoskeleton. Whether Wnt ligands activate the PCP pathway is still unclear; there is no strong evidence for this in flies or humans, but mutations

Wnt Signaling. Table 1 Examples of Wnt genes with altered expression in cancer

Wnt	Tumor type	Change in expression	Comments
Wnt1	Several	Increase	Anti-Wnt1 antibody induces apoptosis
Wnt2	Mesothelioma (mesothelioma), melanoma (melanoma)	Increase	Anti-Wnt2 antibody and siRNA apoptosis
Wnt5a	Gastric cancer, melanoma, leukemia	Increase (gastric cancer, melanoma) decrease (leukemia)	Increase probably linked to metastasis
Wnt16	Leukemia, basal cell carcinoma	Increase in expression of alternatively-spliced isoform b	Anti-Wnt16 antibody induces apoptosis



Wnt Signaling. Figure 1 A simplified view of Wnt/β-catenin signaling. In the absence of Wnt (*left*), a protein complex that includes Axin, APC, GSK-3 and CK-Iα promotes the phosphorylation, ubiquitination and subsequent degradation of β-catenin in the proteasome; Tcf/LEF proteins associate with Groucho to repress target gene expression. On the *right*, Wnt binds to FZD and LRP5/6 receptors resulting in DVL and LRP5/6 phosphorylation and Axin recruitment/degradation. This allows accumulation of β-catenin, which then enters the nucleus and associates with Tcf/LEF to activate gene expression. For simplicity several other components of the pathway are not shown.

Wnt Signaling. Table 2 Wnt/β-catenin pathway mutations in cancer

Intracellular component	Common tumor types	Effect of mutations

	Liver cancer	
	Colon cancer	
LEF-1	Sebaceous tumors	Reduced Wnt/β-catenin signaling

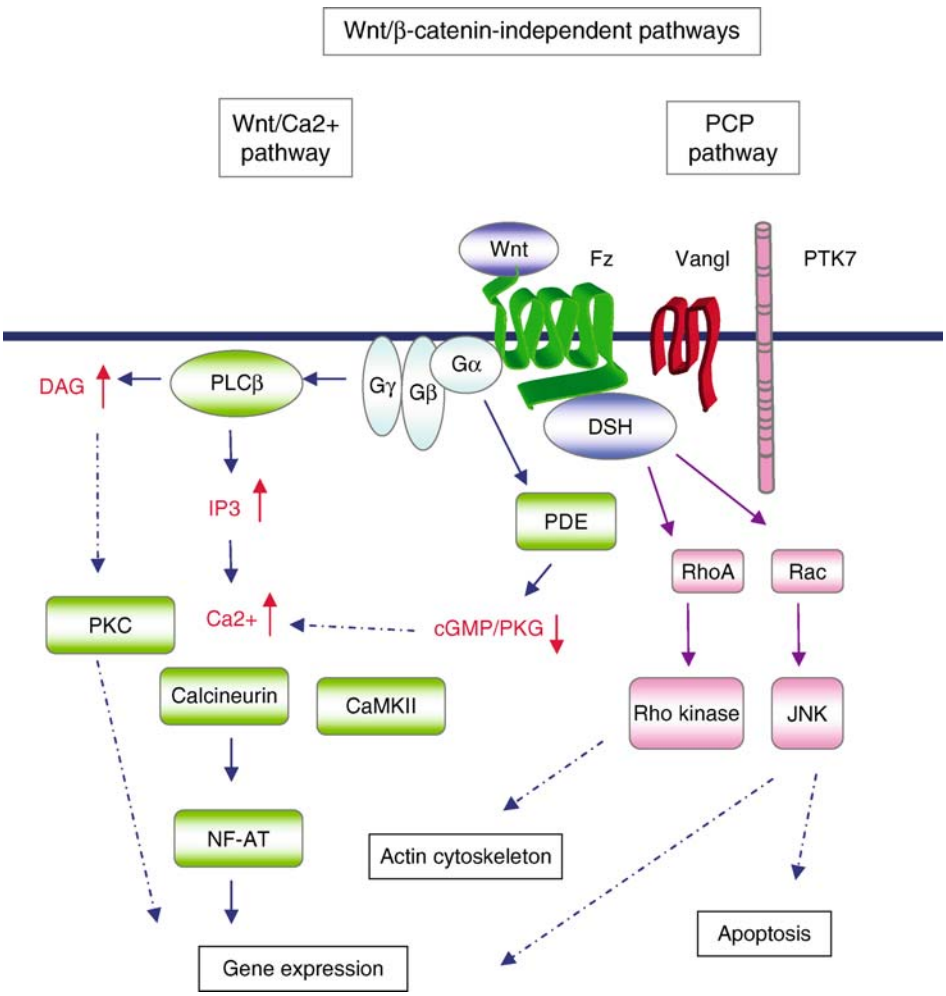
in *Wnt5* and *Wnt11* disrupt convergent extension in zebrafish.

In the Wnt-calcium (Ca2+) pathway, binding of Wnt to FZD leads to activation of ►G proteins that then activate phospholipase C and phosphodiesterase, leading to increased concentrations of free intracellular Ca2+. These events result in activation of ►protein kinase C (PKC) and Ca2+/calmodulin-dependent

protein kinase II (CaMKII) and the Ca2+-sensitive protein phosphatase ►calcineurin. PKC and calcineurin directly and indirectly regulate various transcription factors such as nuclear factor of activated T cells (NF-AT). The Wnt-Ca2+ pathway has been studied extensively in frogs and zebrafish, where it can be activated by Wnt4, Wnt5a and Wnt11 (Fig. 2).

There is increasing evidence for the involvement of heterotrimeric ►G-protein α subunits in canonical and noncanonical signaling pathways. For example, Gαo and Gαt2 participate in Wnt/Ca2+ signaling by activating a phosphodiesterase that lowers cGMP levels, thereby inactivating protein kinase G; Wnt3a signals through Gαq to activate PKCδ; and prostaglandin E2 receptors stimulate proliferation of colon cancer cells through the β-catenin pathway by association of Gαs with ►Axin. The existence of Wnt-Ca2+ and Wnt/G protein signaling pathways in mammalian cells is largely supported by overexpression studies using cell lines and still requires confirmation using genetic approaches.

Just how important non-canonical Wnt signaling is in cancer is still not clear. Wnt5a is probably the most studied non-canonical Wnt and its roles in cancer are complex. For example, Wnt5a expression is reduced in human leukemia and Wnt5a heterozygous mice (►Haploinsufficiency) develop B-cell lymphoma. In contrast, the expression of Wnt5a is increased in gastric cancer (►Gastric cancer), where it correlates with tumor aggressiveness. Wnt5a is likely to have more than one function, controlling cell proliferation and/or differentiation in some tissues and promoting cell migration in others. At the molecular level these differences might



Wnt Signaling. Figure 2 A simplified view of Wnt/β-catenin-independent signaling. In the Wnt-Ca2+ pathway, Wnt binding to FZD activates G proteins, thereby activating a number of downstream signals. The PCP pathway involves activation of FZD and DVL, which together with several additional proteins including VANGL and PTK7, affect Rac/Rho signaling pathways. See text for more details. For simplicity several other components of the pathway are not shown.

Wnt Signaling. Table 3 Examples of ligands and receptors involved in Wnt signaling

Ligand	Receptor	Key events	Examples of changes in cancer
Wnt ligands			
Wnt (several)	FZD	FZD recruits DVL	FZD7 overexpressed in hepatocellular carcinoma (►hepatocellular carcinoma)
Wnt (several)	LRP5/6	LRP5/6 recruits Axin	–
Wnt5a	Ror2	Inhibits Wnt/β-catenin signal	–
Wnt (several)	Ryk	Ryk also binds FZD8 and DVL; activates Wnt/β-catenin signal	Ryk overexpressed in ovarian cancer (►ovarian cancer)
Non-Wnt ligands			
sFRP family	(FZD family)	Inhibit Wnt signals by binding to Wnt	Reduced expression (CpG methylation) (►CpG islands)
DKK family	LRP5/6	Inhibit Wnt/β-catenin signal	Reduced expression (CpG methylation)
WIF1	–	Inhibits Wnt signals by binding to Wnt	Reduced expression (CpG methylation)
Norrin	FZD4	Activates Wnt/β-catenin signal	–
Sclerostin	LRP5/6	Inhibits Wnt/β-catenin signal	–
R-spondin	LRP6, FZD8	Activates Wnt/β-catenin signal	Reduced expression

be explained by the ability of Wnt5a to activate discrete signaling pathways through distinct receptors. For example, in transfected cells Wnt5a inhibits Wnt/β-catenin signaling by binding to the tyrosine kinase Ror2 and activates Wnt/β-catenin signaling by binding to FZD4. There are also examples of canonical Wnts that activate β-catenin-independent signals, such as Wnt3a activation of PKCδ. Moreover, although Wnt1 is best known as an activator of Wnt/β-catenin signaling, anti-Wnt1 antibodies can induce apoptosis in cells that do not express β-catenin, suggesting that Wnt1 noncanonical signals are important for cancer cell survival.

Other Ligands and Receptors that Directly Regulate Wnt Signaling

There are several other proteins that modulate Wnt signaling by binding to Wnts themselves, binding to Wnt receptors or by acting as Wnt receptors (Table 3). Most of the secreted proteins are so-called Wnt antagonists that normally inhibit Wnt signals. The secreted frizzled related protein (►sFRP) family and Wnt inhibitory factor-1 (WIF1) have the potential to inhibit all Wnt signals, since they interact with Wnt proteins themselves. sFRP proteins also bind to FZD receptors and in some cases have been shown to augment rather than inhibit Wnt/β-catenin signaling. The expression of sFRP proteins and WIF1 is downregulated in many tumors as a result of promoter methylation. In contrast to sFRP proteins, dickkopf (►DKK) family members and Sclerostin interact with LRP5/6 and so are thought to inhibit only Wnt/β-catenin signaling. The expression of DKK family members is often reduced in tumors as a result of promoter methylation. However, DKK1 is highly expressed in myeloma (►Multiple myeloma), where it contributes to osteolytic bone disease by inhibiting the differentiation of osteoblasts. Although DKK1 and DKK4 inhibit Wnt/β-catenin signaling, DKK2 can activate Wnt/β-catenin signaling, while DKK3 does not directly affect Wnt signaling at all since it cannot bind to LRP5/6. DKK1 is itself a β-catenin/Tcf target gene that provides a negative-feedback loop for Wnt/β-catenin signaling. Finally, Norrin and R-spondin are secreted proteins that activate Wnt/β-catenin signaling. Examples of proteins that act as Wnt receptors are Ryk, a catalytically inactive receptor tyrosine kinase that binds Wnt proteins using a domain related to WIF1, and Ror2, which binds to Wnt5a.

WW Domains

Definition

Named after two highly conserved tryptophan residues within the sequences of small protein modules (~30 amino acids in length) that recognize and bind to proline-rich peptide motifs in interacting proteins.

►WWOX

WWOX

Kay Huebner, Rami Aqeilan
Molecular Virology, Immunology and Medical Genetics, The Ohio State University, Comprehensive Cancer Center, Columbus, OH, USA

Synonyms

FOR; Wox1

Definition

Wwox, a 414 amino acid protein of 46 kDa, mapping to a common ►fragile site at chromosome region 16q23.3, exhibits two N-terminal ►WW domains and a central short chain oxidoreductase-like domain. Wwox is a cytoplasmic protein that binds other proteins containing PPxY-containing ligand proteins through the first Wwox WW domain. Through binding of its ligands, Wwox controls transcriptional activation and repression of nuclear genes and thus controls signaling pathways that affect aspects of cell growth and ►apoptosis. Wwox expression is nearly ubiquitous in normal tissues but is lost or decreased in many cancers due to genomic or ►epigenetic modification, and its restoration causes apoptosis of Wwox deficient cancer cells; thus *WWOX* is the second known fragile ►tumor suppressor gene.

Characteristics

The Gene

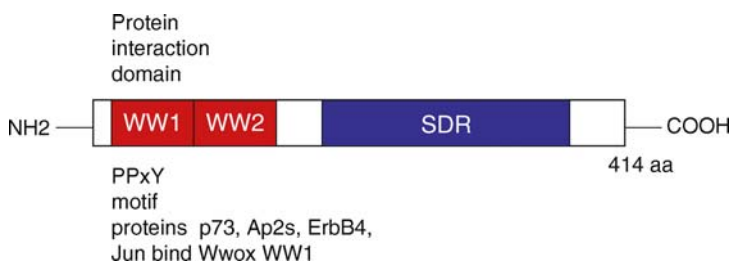
The *WWOX* gene spans a genomic locus of >600 kb and is composed of nine exons encoding an open reading frame of 1,245 bases; the protein sequence includes two WW domains and a short chain dehydrogenase/reductase domain that may be involved in sex-steroid metabolism, considering its sequence homology to 17β-hydroxysterol reductase 3 (Fig. 1).

The *WWOX* gene also spans fragile site ►FRA16D, encompasses a region involved in ►loss of heterozygosity (LOH) in cancers, is associated with ►homozygous deletions in cancer-derived cell lines, with chromosome translocations in ►multiple myelomas, and its promoter region is frequently hypermethylated in cancers (Fig. 2).

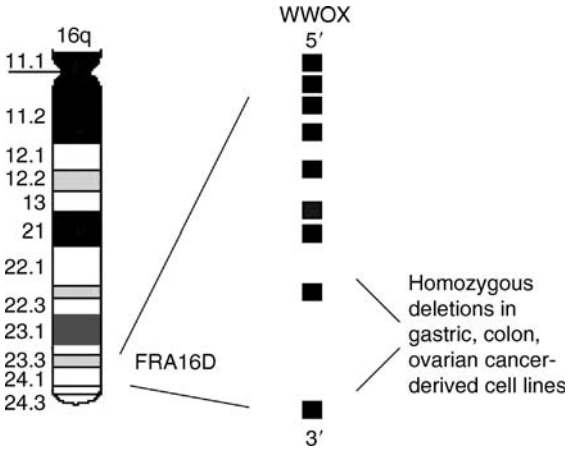
Most cancer cell lines with FRA16D homozygous deletions also exhibit deletions in ►FRA3B and the ►*FHIT* gene, consistent with the finding that common fragile sites or regions are highly susceptible to ►DNA damage and recombination. The mouse ortholog, *Wwox*, at murine chromosome region 8E1, is also fragile and is highly homologous to the human locus. Internally deleted *WWOX* transcripts have been observed in human breast, ovarian and other tumor types, though *bona fide* point mutations have not been observed. The highest level of *WWOX* expression in normal tissues occurs in hormonally regulated tissues. The *WWOX* promoter is hypermethylated in many cancers in association with loss of Wwox expression, and detection of the ►methylation status by ►methylation-specific PCR (MSP) amplification may serve as a marker of cancer development or prevention.

The Protein

Wwox protein binds the proline-rich ligand PPxY and a number of proteins interacting with the first WW domain, WW1, have been identified. WW domains are grouped by binding preference for specific types of proline-rich ligands and the Wwox WW1 domain belongs to group I, that binds PPxY ligands; among



WWOX. Figure 1 Schematic of the Wwox protein showing the WW and short chain dehydrogenase/reductase domains. Proteins with a PPxY motif that interact with Wwox through its first WW domain are listed.



WWOX. Figure 2 Schematic of the WWOX gene. The long arm of chromosome 16 is shown on the *left*. The dark boxes on the *right* represent WWOX exons. Many of the deletions detected in tumor cell lines are within WWOX intron 8.

these ligand-containing proteins are p73, Ap2α, Ap2γ, ErbB4, Jun and the SIMPLE protein; ►p53 has also been reported to bind Wwox or Wox1, the murine ortholog, but other studies have not confirmed this ligand. The Cytogen Corporation has developed, through informatics and binding studies, a proprietary database that lists all potential Wwox ligands among known gene products, and the first three ligands listed above were selected from the database and confirmed as Wwox-interacting proteins by *in vitro* analyses.

The cytoplasmic Wwox protein binds its ligands and prevents the interacting proteins from entering the nucleus, where some have roles in transcriptional activation or repression. There are thus far unconfirmed reports of Wwox subcellular location also in mitochondria and nuclei of some cells.

Biological Role

In normal cells: human tissue samples of more than 30 organs have been analyzed by immunohistochemistry for expression of Wwox; Wwox is expressed in most organs but is expressed at highest levels in secretory epithelial cells such as those of breast, ovary, testes and prostate. Wwox is also expressed in various cells of neural origin.

►Targeted deletion of the mouse *Wwox* gene revealed important roles of Wwox in tumorigenesis and metabolism. Using ►homologous recombination, a mouse lacking exons 2, 3 and 4 of the mouse *Wwox* gene was generated. Progeny from *Wwox* heterozygous (*Wwox*+/–) intercrosses resulted in offspring of all three genotypes with ratios consistent with ►Mendelian distribution. At birth, homozygous Wwox-deficient (*Wwox*–/–) pups were indistinguishable from wild type or heterozygous littermates up to 3 days postpartum; after 3 days, homozygous pups were easily identified by their smaller size. *Wwox*–/– pups continued to grow more slowly than littermates, and all homozygous knockout mice died by 4 weeks after birth. Serum chemistry analysis of *Wwox*–/– mice showed marked hypoproteinemia, hypoalbuminemia, hypoglycemia, hypocalcemia, hypotriglyceridemia and hypocholesterolemia, indicating that *Wwox*–/– pups suffered severe metabolic defects.

Macroscopic and histological examination of the organs confirmed atrophy of many organs in *Wwox*–/– animals without significant microscopic lesions, though *Wwox*–/– mice are born with gonadal abnormalities and display bone growth retardation. Juvenile *Wwox*–/– mice displayed impaired steroidogenesis; levels of steroid biosynthesis enzymes, including Cyp11a1 (cytochrome p450 side-chain cleavage enzyme) and Hsd3b (3-β-hydroxysteroid dehydrogenase), were reduced in mutant testis and ovary compared to wild type and heterozygous testis. Radiography and high-resolution microtomography (μCT) of limb bones showed that *Wwox*–/– mice develop less dense bones with slow growth rates.

Analysis of the *Wwox*-mutant mice demonstrated that Wwox functions as a *bona fide* tumor suppressor. Spontaneous ►osteosarcomas in juvenile *Wwox*–/– and lung papillary carcinoma in adult *Wwox*+/– mice were observed, and *Wwox*+/– mice developed significantly more ethyl nitrosourea (ENU)-induced lung tumors and ►lymphomas in comparison to wild type littermates. These tumors still express Wwox protein, suggesting ►haploinsufficiency of Wwox is cancer-predisposing.

In cancer cells: Esophageal squamous cell carcinoma, ►non-small cell lung cancer and ►breast cancer showed high ►LOH rates, low mutation rates and expression of aberrant transcripts of the *WWOX* gene. Wwox expression is reduced in 63% of invasive breast carcinomas and is correlated with ►estrogen receptor alpha level, and prognostic features; Wwox and Fhit expression is coordinately lost in breast cancers. The *WWOX* gene is also inactivated in breast and lung cancers by regulatory region DNA methylation; promoter methylation was also detected in tissues adjacent to breast cancer, and methylation in *WWOX* exon 1 distinguished breast cancer DNA from DNA of adjacent and normal tissue. Wwox restoration in lung cancer cells *in vitro*, and in ►xenografts, suppressed growth. Wwox-deficient breast cancer cells, by treatment with ►5′-Aza-2′-deoxycytidine to demethylate the *WWOX* promoter, was associated with effective induction of apoptosis *in vitro* and suppressed breast cancer xenograft growth *in vivo*, without affecting the Wwox-sufficient cells or causing persistent changes in global methylation levels.

►Tamoxifen is commonly used for treatment of ►estrogen receptor alpha positive breast cancers, but

de novo or acquired tamoxifen resistance occurs frequently. Wwox protein, which binds and retains Ap2α and γ transcription factors in the cytoplasm, may mediate tamoxifen sensitivity *in vitro*; Wwox loss initiates tamoxifen resistance through release of Ap2 factors to the nucleus where Ap2γ up-regulates ErbB2 (►Her2) expression. Restoration of Wwox in tamoxifen-resistant breast cancer-derived cells restored tamoxifen sensitivity and abrogated ErbB2 expression.

Wwox expression was significantly (p = 0.013) reduced in tamoxifen resistant breast cancers, and a reliable marker of tamoxifen resistance, especially in premenopausal and stage 3 patients. Thus, the Wwox signaling pathway may provide new targets for therapeutic intervention in antiestrogen-resistant breast cancers.

X Chromosome Inactivation

Definition

A gene dosage compensation mechanism by which one of the two X chromosomes in female cells becomes transcriptionally silenced early in embryonic development through a process understood to be controlled by an inactivation centre located on the X chromosome. The X-inactivation centre determines the X chromosome to be inactivated in each individual cell and produces a noncoding Xist transcript that coats the X chromosome in *cis*, triggering its silencing and further inducing a cascade of chromatin and ►methylation changes completing the ►epigenetic silencing process.

►LINE-1 Elements

Xanthine Oxidase

Definition

Is a ►flavoprotein enzyme catalyzing the oxidation of certain purines; it is normally found in the liver of humans and it is released to blood during liver damage and can cause renal failure.

►Polyphenols

Xanthophylls

Definition

Are ►carotenoids where some of the double bonds have been oxidized, such as lutein and zeaxanthin.

Xenobiotics

Pavel Soucek
Group for Biotransformations, Center of Occupational Medicine, National Institute of Public Health, Prague, Czech Republic

Synonyms

Foreign substances; Exobiotics

Definition

Xenobiotics are chemicals present in an organism or environment, which did not produce them. Some naturally occurring chemicals (endobiotics) become xenobiotics when present in an environment at excessive concentrations. The word "xeno" is derived from the Greek word "*xenos*," meaning a guest, friend, or foreigner.

Characteristics

Origin of Xenobiotics

Xenobiotics are mostly produced by human activities and excite public awareness due to their ability to interact with the living environment. Some organisms may also form them as a part of their defense system, e.g., mycotoxins, bacterial, and herbal toxins, etc., and xenobiotics become harmful when entering the alimentary chain. Contemporary human exposure to xenobiotics is unavoidable, as xenobiotics are omnipresent. Human exposure to some xenobiotics is voluntary because of their anticipated beneficiary effects on human health (e.g., drugs, antibiotics, dietary supplements as antioxidants, etc.). Daily use of xenobiotics as food ingredients (dyes, stabilizers, emulsifiers, salt compounds, preservatives, etc.), cosmetics and personal care products (makeup, hair dyes, soaps, perfumes), and household products (chlorine bleach, bug sprays, cleaners, etc.) further increases exposure extent. Nevertheless, the positive role of xenobiotics as components of modern technologies enabling further progress of human civilization is inevitable. At present time, it is not possible to divide xenobiotics into straightforward categories as, e.g., good versus bad ones and simply eliminate the latter from living environment.

Metabolism of Xenobiotics

Metabolism or in other words biotransformation leads to conversion of xenobiotics in the organism. After entering the human body, blood vessels transport xenobiotics to the liver as the main ►detoxification site. Hepatocytes (liver cells) contain xenobiotic-metabolizing enzymes (XMEs). The major task of XMEs is to convert xenobiotics soluble in fat into water-soluble products and thus facilitate their elimination from the cell and excretion from the body. XMEs are divided into three groups: ►phase I enzymes (activation), ►phase II enzymes (conjugation), and phase III (transport) enzymes (Table 1). ►Cytochromes P450 (P450s) represent a major player in the field of phase I biotransformation. P450s and other phase I enzymes as NAD(P)H:quinone oxidoreductases (NQOs) usually perform activation reactions aiming at formation of reactive ►intermediates. Such highly electrophilic intermediates efficiently conjugate with ►nucleophiles, e.g., glutathione in reactions catalyzed by phase II enzymes as ►glutathione S-transferases (GSTs). The majority of conjugated xenobiotics undergo transport outside of the cell by ►efflux pumps driven by ►membrane ATP-binding casette transporters (ABC), e.g., ►P-glycoprotein. Main routes of elimination of hydrophilic conjugates are urine, feces, sweat, or breath. Xenobiotics are often highly lipophilic and thus may accumulate in fat tissues and slowly drain into blood circulation long time after exposure event occurred. The typical example may be exposure to organic solvents as styrene or polychlorinated biphenyl ►dioxin. Various physiological factors, e.g., age, gender, nutritional status (starving), or pathological factors, e.g., hypertension, diabetes mellitus, liver cirrhosis, renal failure, etc., significantly affect metabolism. An understanding of xenobiotic metabolism is critical for the pharmaceutical industry because it is responsible for the activity but also for the toxicity of drugs.

Effects of Xenobiotics

Common concern about xenobiotics is due to their toxicity toward living organisms and potential to cause environmental effects on global level. ►Acid rains and production of glasshouse gases increase global warming. Sea pollution or soil contamination by agricultural chemicals facilitates incorporation of heavy metals into highly toxic organic compounds. High concentration of metropolitan transport and local heating enhances concentration of particulate matter containing ►polycyclic aromatic hydrocarbons, ►polychlorinated biphenyls, dioxins, etc. Toxicity classification concerns the grouping of chemicals into general categories according to their most important toxic effect. Such categories can include allergens, neurotoxins, carcinogens, mutagens, teratogens, ►immunotoxins, etc. Xenobiotics act either directly as parent compounds or indirectly as intermediates or products of their metabolism. ►Oxidative stress presents another secondary product of metabolism of xenobiotics. ►Reactive oxygen species may then attack DNA, proteins, or stimulate ►inflammation. In some cases, an inactive conjugated metabolite is reactivated, for example, by enzymatic cleavage and causes tissue-specific toxic effect, e.g., tumor promotion. Certain xenobiotics entering human body deregulate important cellular and organ signaling pathways because they mimic physiological substrates. Xenoestrogens or endocrine disruptors, e.g., phthalates or polychlorinated biphenyls (DDT, dioxin), etc., impair reproductive functions, disturb wildlife, and may cause sterility by decreasing sperm count in males. Another important issue is the widely discussed oncogenic potential of xenoestrogens. Evaluation of environmental exposure to xenobiotics complicated by the fact that combined exposures to several xenobiotics simultaneously occur rather than separate simple exposures. Chemicals acting via the same mechanisms produce ►additive effects. However, interaction between chemicals may result in an

Xenobiotics. Table 1 Major xenobiotic-metabolizing enzymes

inhibition (►antagonism) or in ►synergism, a more pronounced effect than would be expected by addition. Estimation of effects of combined mixtures by animal experiments and computer modeling belongs to the most difficult tasks of modern toxicology.

Interactions

Xenobiotics are able to enhance their own metabolism by ►induction of XMEs. Induction of battery of XMEs through ►arylhydrocarbon receptor (AhR) was the first proved example. Expression of XMEs is regulated also through other nuclear receptors, e.g., constitutive androstane receptor (CAR), ►peroxisome proliferator-activated receptor (PPAR), pregnane X receptor (PXR), and others. Some xenobiotics cause inhibition of XMEs by covalent binding to active site or other functionally important part of enzyme or by competition for enzyme with physiological substrates or other xenobiotics. Interactions between xenobiotics and XMEs may cause severe health effects. Induction of P450 2E1 by ethanol consumption enhances metabolism of acetaminophen (paracetamol) by P450 2E1 to hepatotoxic intermediates leading to death of sensitive individuals. Inhibition of P450 3A4 by components of grapefruit juice may either decrease effect of P450 3A4-activated ►prodrugs or/and prolong toxicity of P450 3A4-detoxified drugs. P450 3A4 metabolizes about 50% all currently prescribed drugs, e.g., amiodarone, budesonide, codeine, digitoxin, ►irinotecan, lidocaine, midazolam, simvastatin, ►tamoxifen. Drug–drug interactions may of course have similar consequences as interactions between drugs and nutrition.

Individual Variability

XMEs are highly genetically variable and contain a number of functionally relevant polymorphisms (►metabolic polymorphisms). These inherited DNA variations may influence both level and activity of expressed XMEs. Altered enzyme then lacks critical detoxifying activity or gains activating properties, which may form excess of toxic metabolites and impair important physiological functions. Thus, genetic variability may explain why certain individuals are more susceptible to

toxic effects of xenobiotics than others are. Various populations differ in frequencies of XMEs polymorphisms, e.g., GSTT1-null polymorphism conferring lack of enzyme activity affects 10–20% of Caucasian populations but 30–60% of Oriental ones. Thus, depending on exposure type and extent this polymorphism may be more important for Orientals. Polymorphisms in alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH) converting ethanol to acetaldehyde cause unpleasant adverse effects in large group of Orientals and are suspected to modify acetaldehyde-induced ►carcinogenesis. Polymorphisms in pharmacologically important P450 2D6 belong to the most studied ones and progress in science and technology enabled genotyping individuals to assess so-called poor metabolizer phenotype (persons with weak metabolizing ability), medium, and rapid phenotype (persons with high metabolizing ability). Such effort pays off both to society on the cost-benefit basis and to individual patient whom physician prescribes the most efficient drug with least adverse effects without blind tests of different medications with potential danger of longer periods of illness or even hospitalization. However, individual variability still greatly complicates assessment of drug–drug interactions and presents a challenge for contemporary pharmacology. Among possible solutions of this puzzle, design of new generation of drugs, which are not subjects to metabolism by polymorphic XMEs will soon play pivotal role.

Xenobiotics and Cancer

Various xenobiotics promote carcinogenesis or cause genotoxicity by interaction with genetic information. The majority of procarcinogens undergo metabolic conversion to become ultimate carcinogens. The extent of carcinogen production is dependent on ratio between activation and detoxification capacity. Thus, understanding the individual variability in XMEs may shed more light on the molecular basis of diseases apparently caused by interaction between genetic background and environment. Experts in molecular epidemiology now evaluate prognostic value of reported associations between genetic variants in genes coding XMEs and various diseases, especially cancer. Although the concept of association between metabolic capacity modified by genetic variation in XMEs and disease caused by metabolically activated procarcinogens seemed reasonable, ►meta-analysis shows that the task will be extremely difficult. Association studies usually use very limited numbers of patients due to problems with recruiting. Moreover, each cancer type presents distinct disease with distinct etiology, so pooling of patients with different diagnoses is questionable. Quite often, the identification of individual chemicals and levels of exposure in studied individuals is very complicated by the long latency period from exposure to onset of cancer (usually decades). Finally, interplay between different groups of low-penetrance genes (such as XMEs) most probably multiplies the effect of associations. The final goal of molecular epidemiology is to predict cancer susceptibility based on individual variability and prevent interacting exposures. In individuals already suffering from cancer, individualized therapy tailored to XMEs overexpressed in tumor cells will be available soon.

Exploitation of Knowledge about Xenobiotics and XMEs

Besides the use in pharmacology and ►cancer epidemiology, the knowledge gained through intensive research on xenobiotics, their origin, and fate in living organisms over last decades suggested promising applications in many commercial areas. Genetically engineered XMEs are evolving tools for selective production of chemicals with valuable properties including drugs whose production by chemical synthesis is impossible or connected with overwhelming costs. Sewage is increasingly contaminated with xenobiotics of all sorts including human waste. Sorting of sewage is becoming extremely expensive and for its bioremediation treatment systems based on immobilized XMEs seem to be the most natural choice. After obtaining solution for some technical aspects broader applications of XMEs and their optimization for commercial needs will soon be performed.

Xenogeneic

Definition

Derived or obtained from an organism of different species and, therefore, immunologically incompatible.

Xenograft

Definition

The engraftment of cells or tissue originating from one species into the body of a different, often immune-suppressed, host species. In the field of oncology, a commonly used term to describe small rodent tumor cell implantation models. For example, human breast cancer cells injected into nude mice.

Xeroderma Pigmentosum

Rob J. W. Berg
University Medical Center Utrecht, Utrecht, The Netherlands

Definition

Xeroderma pigmentosum (XP) is a genetic disease with clinical and cellular hypersensitivity to ►ultraviolet radiation and defective ►repair of DNA. XP patients display a marked increase in the frequency of skin malignancies. XP, thus, serves as a model disease to study the relationship between defects in DNA repair and (skin) cancer. It is a skin cancer prone disorder, due to defective ►nucleotide excision repair (NER).

Characteristics

Xeroderma Pigmentosum (XP) Subgroups

The DNA repair pathway that deals with the removal of DNA damage induced by UV radiation is NER (nucleotide excision repair). In 1972 it was demonstrated by using cell fusion techniques that fibroblasts from one patient were able to compensate the repair defect in fibroblasts from another patient. Heterokaryons (cells with nuclei from different donors in a common cytoplasm) were found to exhibit mutual correction of the defective removal of UV radiation-induced DNA damage. Such cells were said to be in different ►complementation groups. If both nuclei in a heterokaryon have the same genetic defect, then the heterokaryons show defective repair of DNA damage and the patients are in the same complementation group. Such studies have revealed the existence of at least seven complementation groups in XP (XP-A through XP-G). Each complementation group may represent a gene that, if mutated and in homozygous condition, causes XP. In addition, a subgroup exists with the clinical symptoms of XP but with normal NER of UV-induced DNA damage. Patients in this subgroup have a defect in an alternative repair process, viz., in postreplication repair. Such patients are called XP-V (XP variants).

Clinical Aspects

XP is clinically characterized by photosensitivity, pigmentary changes, premature skin ageing and a high incidence of ►skin cancer. In the majority of cases the first symptoms are noticed between 6 months and 3 years after birth. Freckling, sensitivity to sunburn and an increased dryness on sun-exposed skin are usually the earliest manifestations. The first malignant tumors may develop as early as the third or fourth year. ►Basal cell carcinoma, ►squamous cell carcinoma, and ►melanoma, are common and may be multiple. Besides the skin, the eyes and the nervous system may be affected. In the large majority of patients, photophobia and conjunctivitis are early symptoms. Neurological abnormalities occur in ~20% of the cases, which are predominantly patients in the XP-A and XP-D complementations groups. These abnormalities may comprise mental retardation, spacticity, ataxia, dysphasia and areflexia. Two-thirds of XP patients die before 20 years of age from metastases, neurological complications or infections, to which they are also abnormally susceptible. Table 1 summarizes the clinical features of the different XP complementation groups.

Cellular Parameters

The two major types of DNA damage induced by UV radiation are CPD (cyclobutane pyrimidine dimers) and [6–4]PP (6-pyrimidine-4-pyrimidone photoproducts). Both CPD and [6–4]PP are formed between two adjacent pyrimidines (cytosine and/or thymine) on a DNA strand. Both lesions lead to a considerable distortion of the three-dimensional structure of the double helix. CPD and [6–4]PP are removed from the genome by nucleotide excision repair (NER), which comprises two subpathways:

- GGR (global genome repair)
- TCR (►transcription-coupled repair)

The GGR subpathway is responsible for the removal of lesions from the transcriptionally inactive DNA and from the non-transcribed strand of active genes.

Xeroderma Pigmentosum. Table 1 Clinical properties of the separate XP complementation groups

Group	Skin cancer	Neurological abnormalities	Relative frequency
XP-A	+	++	High
XP-B	±	++	Very rare
XP-C	+	–	High
XP-D	+	+	Intermediate
XP-E	±	–	Rare
XP-F	±	–	Rare
XP-G	±	++	Rare
XP-V	+	–	High

In the TCR subpathway, the repair machinery is directed preferentially to the transcribed strands of active genes to avoid unrepaired lesions interfering with transcription. Generally, the transcribed strand is corrected up to 5–10 times as fast as the nontranscribed strand. As different mutations in the same gene can lead to different levels of impairment, patients within the same complementation group can vary quantitatively in their residual GGR and/or TCR capacity. All NER-defective XP complementation groups are more or less defective in both GGR and TCR, with the exception of XP-C and XP-E, which are defective in GGR only.

Molecular Parameters

►NER is the process in which damaged DNA is removed and replaced with new DNA using the intact strand as a template. This complex system involves the concerted action of multiple proteins. The first step in mammalian NER is damage recognition. The XP-C and the XP-E protein play a role in recognition of UV-damaged DNA in nontranscribed DNA. In transcriptionally active DNA, the arrest of transcription at the site of a DNA lesion serves as the damage-recognition signal. Subsequently, the XP-A protein and a protein complex called ►TFIIH are recruited to the lesion, and the double helix is opened around the site of damage. It is assumed that in both transcription and NER the function of TFIIH is the unwinding of the double-stranded DNA helix. Both the XP-B and the XP-D protein are part of the TFIIH complex. After damage recognition and partial unwinding of the double helix the actual removal of DNA damage is identical for the GGR and TCR subpathways. The XP-F and XP-G proteins play a role in cutting the DNA on either site of the damage, thereby releasing a 24- to 32-residue oligonucleotide. Subsequently, the gap is filled in by a DNA polymerase and sealed by a DNA ligase.

XP-V cells have normal removal of UV-induced DNA damage from both transcribed and nontranscribed DNA. Cells can tolerate unrepaired damage in their genome and removal of damage does not have to be complete before DNA replication takes place. As CPD and [6–4]PP are effective blocks to the progression of replicative DNA polymerases, cells have developed specialized DNA polymerases that can bypass DNA damage and extend replication forks through damaged sites. One of these DNA polymerase can bypass CPD at thymine-thymine sites and usually correctly inserts two A residues opposite the lesion. In XP-V cells this specialized polymerase is defective. Consequently, in XP-V cells lesions are bypassed by polymerases that insert incorrect residues, leading to a high level of mutations in XP-V cells.

Animal Models

Experimental studies on the relationship between NER defects and clinical phenotype are difficult to carry out as XP is a rare disease, which consists of at least seven NER-defective subgroups. In addition, experimental studies with UV radiation in XP patients can be considered questionable for obvious ethical reasons. Therefore, mouse models for XP have been developed, which are well suited to study the relationship between deficiencies in NER and susceptibility to skin cancer. The first viable animal models for XP were XP-A-deficient and XP-C-deficient transgenic mice (XP-A and XP-C knockouts). These animals develop normally, are fertile and do not show signs of a NER-disorder. However, after exposure to UV radiation both animal models strongly mimic the phenotype of humans with XP, i.e., they show a severely increased susceptibility to skin cancer. Neurological disorders, common in XP-A patients, were not found in XP-A knockout mice. A direct comparison in skin cancer susceptibility between XP-A and XP-C ►knockout mice has shown that XP-A knockouts are more cancer prone than XP-C knockouts. Hence, skin cancer susceptibility is determined by both GGR and TCR, and defective GGR contributes more prominently to skin cancer development than defective TCR. However, acute UV effects

appear to be related primarily to TCR; the minimal dose required to induce a slight sunburn is strongly reduced in XP-A knockouts but not in XP-C knockouts. Probably blockage of RNA synthesis during transcription, by persistent CPD or [6–4]PP, triggers the influx of pro-inflammatory molecules leading to sunburn.

As parents of XP patients usually are clinically normal, inheritance of XP is considered to be autosomally recessive. Whether carriers of XP genes (heterozygotes) have a subtle increase in skin cancer risk can easily be addressed by XP mouse models. Heterozygous XP-A animals did not show a higher skin cancer susceptibility than wildtypes, whereas heterozygous XP-C animals have been reported to have a higher susceptibility to UV carcinogenesis than their wildtype litter mate controls. The reason for this difference has not yet been elucidated.

Other NER-Related Syndromes

In addition to XP, two other rare genetic diseases have been associated with a defect in NER. The first is CS (Cockayne syndrome), which comprises at least two complementation groups (CS-A and CS-B). CS patients have a defect in TCR and they exhibit a severe clinical phenotype. CS patients show growth failure, progressive neurological degeneration, retinal degeneration, photosensitive skin and deafness, and most CS patients die at an early age. The second NER-related disease is a photosensitive form of ►trichothiodystrophy called PIBIDS. This is an acronym for photosensitivity, ichthyosis, brittle hair and nails, intellectual impairment, decreased fertility and short stature. Patients with PIBIDS have mutations in the XP-B or XP-D gene, which are both components of the ►TFIIH complex. It has been suggested that specific mutations that preserve the transcription function of TFIIH leads to XP, whereas mutations that also modify the transcription function lead to PIPIDS.

Xiphophorus

Manfred Schartl
Biozentrum, Universität Würzburg, Würzburg, Germany

Synonyms

Gordon-Kosswig melanoma system; Platyfish-swordtail melanoma

Definition

Small aquarium fishes of the genus Xiphophorus are known by the common name of platyfish (*X. maculatus*) and swordtail (*X. hellerii*). Introgressive hybridization results in offspring that develop melanoma according to Mendelian principles. This represents the first animal model, described in 1927, systematically employed for studies of genetic factors in cancer and to show induction of melanoma by ultraviolet light (►UV-A).

Characteristics

Genetics of Melanoma Formation

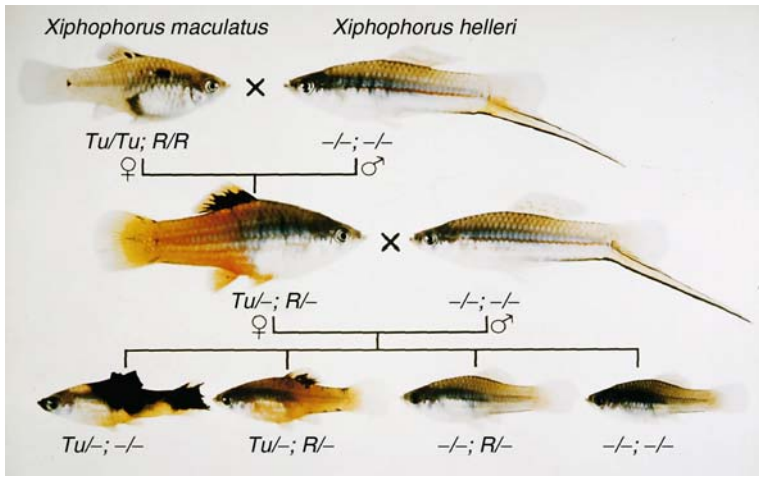
The genetic basis of melanoma formation after introgressive hybridization is explained by the independent

segregation of a pigmentation locus (Sd), which contains a dominantly-acting ►oncogene, designated Tu, and a trans-acting regulatory gene R (also termed Diff, *MelSev* or R_{Diff}) that suppresses the oncogenic activity of *Tu* (Fig. 1). Independent segregation is possible because *Tu* and *R* reside on different chromosomes. Crossing and backcrossing the fish carrying both *Tu* and *R* (platyfish) to the swordtail results in the progressive replacement of platyfish chromosomes bearing the R by swordtail chromosomes lacking *R*. The stepwise elimination of *R* from the hybrid genome allows expression of the *Tu* phenotype, leading to a benign hyperpigmentation in cases where one functional allele of *R* is still present (F1 and 25% of backcross) or to malignant melanoma in cases where *R* is completely absent (25% of backcross).

The *Xmrk* Oncogene

The melanoma oncogene from the *Tu* locus is referred to as *Xmrk* (Xiphophorus melanoma receptor tyrosine kinase, also termed *Xmrk-2*). It encodes a transmembrane ►receptor tyrosine kinase (RTK) that is an oncogenic version of the epidermal growth factor (EGF) receptor. During evolution, *Xmrk* was generated by gene duplication from its corresponding proto-oncogene. The new copy was fused to the 5′ non-coding region of another (anonymous) sequence. This process generated a novel promoter for the oncogenic version (called *Xmrk* to distinguish it from the proto-oncogenic copy *Xegfrb*) of the gene.

As a consequence of this rearrangement, the proto-oncogene and the oncogene are subject to different transcriptional regulation. Specific overexpression of the *Xmrk* oncogene in the pigment cell lineage of hybrid fish is responsible for melanoma formation. An *R* locus-dependent transcriptional control of the oncogene promoter allows high levels of expression exclusively in pigment cells of certain hybrid genotypes but not in non-hybrids. This explains why the dominantly-acting *Xmrk* oncogene is ineffective in the pure bred parental Xiphophorus fish and is a non-hazardous constituent of the genome in natural populations for many generations. This is reminiscent of the situation found for the ►RET and ►MET oncogenes in humans, where dominantly-acting mutations are transmitted through the germ line and elicit ►multiple endocrine neoplasia type 2 (MEN2A, MEN2B) and hereditary papillary renal-cell carcinomas (HPRCC), respectively. Transcriptional control of *Xmrk* by *R* involves the suppression of an Sp1 transcription factor-mediated constitutive promoter activity in non-melanoma cells and a specific hypomethylation of the oncogene promoter, compared to the proto-oncogene promoter. The *Xmrk* oncogene is necessary for melanoma formation since transposon inactivation of the oncogene in one



Xiphophorus. Figure 1 Genetic tumors in Xiphophorus. The classical cross-breeding experiment: a female platyfish (*X. maculatus*), which is homozygous for the X-chromosomal locus *Sd*, encoding the pigment pattern "spotted dorsal" (small black spots in the dorsal fin composed of a specific type of pigment cells – so-called macromelanophores) is mated to a swordtail (*X. hellerii*), which does not have the corresponding locus. The F1 hybrids show enhancement of the *Sd* phenotype. Backcrossing of F1 hybrids to *X. hellerii* results in offspring that segregate. Fifty percent do not inherit the *Sd* locus and are phenotypically like the *X. hellerii* parental strain. The other 50% carry the *Sd* locus and develop melanoma. Here, in approximately half of the fish, the severity of melanoma ranges from very benign (phenotype like the F1 hybrids) to extremely malignant in the others. Highly malignant melanomas become invasive and exophytic, and are fatal to the individual. These melanomas grow progressively, following transplantation into thymus-aplastic "nude" mice. Symbols below the fish describe their genotypes in respect to the *R* and *Tu*-loci.

mutant strain results in loss of melanoma formation. However, overexpression of the receptor is not the only reason for tumor induction. Mutations in the extracellular domain that create covalently linked receptor dimers with constitutive activity and a cell type-specific signal transduction machinery downstream of *Xmrk* are necessary for tumor formation in transgenic fish and for transformation of cells in tissue culture.

Signal transduction by Xmrk affects all cellular events needed for a full transformation. Some, though not all of the pathways induced by the oncogene are also shared by mammalian EGFR. It starts with the parallel activation of the ►Ras/Raf/MAP kinase pathway, the ►PI3 kinase pathway, the ►signal transducer and activator of transcription STAT5, the small src kinase fyn and the ►focal adhesion kinase. These events result in the transcription of numerous target genes belonging to different functional categories (secreted proteins, anti-apoptotic effectors, cell cycle regulatory proteins etc.). Finally, an induction of cellular proliferation, protection from ►apoptosis, ►migration and contact-independent survival takes place. In addition, transcriptional and post-translational regulation of the differentiation and survival factor MITF impairs the final differentiation of the pigment cell. Consequently, *Xmrk* alone is able to elicit all the processes that are necessary for establishing the full malignant neoplastic phenotype of a melanoma cell.

UV-Induced Tumors

Melanoma in certain hybrid crosses can be induced by UV-B and photoreactivation can reverse this melanoma incidence to background levels. When young backcross hybrids were irradiated with wavelengths from 365–436 nm, melanomas could be induced. This led to the appreciation that UV-A, and perhaps the visible light spectrum as well, are important in the etiology of human melanoma. Research on UV-induced melanoma uncovered *CDKN2* a/b as a candidate gene for *R*.

Carcinogen-Induced Tumors

Besides the propensity to develop melanoma on a hereditary basis, certain backcross strains have a susceptibility to develop cancer after exposure to carcinogens. While fish of wild type strains resist the development of tumors after exposure to N-methyl-N-nitrosourea (MNU) or to X-rays, certain hybrids are highly sensitive and respond to treatment by developing a large spectrum of tumors.

Yin and Yang

Definition

Is a philosophical concept developed in ancient China. According to the theory of yin and yang, things and phenomena in the natural world oppose and complement each other. Yin and yang not only means two things opposing each other, but they also means two opposite components in the same thing. The contradiction movement between unity and opposite of yin and yang exists universally within everything and its consequence is the occurrence, development, and changes of all things in the universe. The theory of yin and yang has been widely used in Chinese medicine to refer to various antitheses in anatomy, physiology, pathology, diagnosis, and treatment, such as feminine, interior, cold, and hypofunction being yin while masculine, exterior, heat, and hyperfunction being yang.

Z-Factor

Ji-Hu Zhang[1], Kevin R. Oldenburg[2]
[1]Lead Discovery Center, Novartis Institute for Biomedical Research, Cambridge, MA, USA
[2]MatriCal, Inc., Spokane, WA, USA

Synonyms

Z′ factor

Definition

The data quality of an assay can be estimated by the Z′-factor formulae:

$$Z' = 1 - (3\sigma_{c+} + 3\sigma_{c-})/(|\mu_{c+} - \mu_{c-}|),$$

where (σ_{c+}) and (σ_{c-}) is the data standard deviation for the high reference control and low reference control, respectively, and $|\mu_{c+}-\mu_{c-}|$ is the absolute value of the difference of the two control signal means and it defines the *usable* dynamic range (usually the linear range) of the assay.

Characteristics

Z factor (Z′ factor) is a statistical data quality indicator for a bioassay, particularly that used in the field of high throughput screening (HTS). In most HTS programs in drug discovery, each compound from a chemical library is only evaluated in a single test during primary screening. A high degree of accuracy and sensitivity in the assay is therefore critical for identifying active compounds (or "hits"). Due to various unavoidable sources of errors, the measurements from any assay will contain a certain degree of variability. Yet hits need to be identified in the presence of such variations in signal measurement. Reducing the measurement variation will give higher fidelity of the screening data. Therefore, in the design and validation of HTS assays, assessment of the screening data variability, by metrics such as the standard deviation (SD) and coefficient of variation (CV) of the replicate data set, is critical in determining whether an assay can identify hits with high confidence.

The quality of an assay has also been loosely expressed as signal-to-noise ratio (S/N) and/or signal-to-background ratio (S/B). Both ratios reflect the assay signal strength and therefore are useful parameters in assay quality assessment. In HTS, the compound activity is normally expressed as a percentage measured against some selected reference control signals, usually a high reference control and a low reference control. However, both S/N and S/B ratios fail to simultaneously take into account all of the data variability information of the sample and reference controls, as well as the assay dynamic range. To overcome some of the pitfalls of S/N or S/B ratios, Zhang and Oldenburg (1999) proposed a new, simple statistics, the Z factor (Z′ factor) as defined above, for use in evaluation of assay performance and assay signal robustness in HTS.

The Z′-factor contains data variability information of both the high and low reference controls (the same high and low reference controls usually used for normalization of the measured raw data to a percentage activity) as well as the dynamic range information. Therefore, compared to CV, S/B or S/N, the Z′-factor is more

appropriate for evaluating overall assay quality. It is a useful tool for the evaluation, comparison, and validation of any assays in general and has been widely used for quality control (QC) of HTS assay quality.

As originally proposed, the Z-factor refers to the specific Z′-factor when the mean and standard deviation of one of the corresponding reference controls are replaced by those of the testing samples. Therefore, the Z-factor is affected by the screening conditions such as the compound concentration. Z-factor has been used as a screening quality assurance parameter for assay plates owing to its sensitivity toward signal strength and data variability of test samples on the plate as well as the hit rates on the plate.

Generally, a assay with Z′-factor value of close to 1 is an ideal assay for HTS, with Z′ values between 0.5 and 1 are considered good quality, and with values between 0.5 and 0 are considered to have a moderate to poor quality. An assay with $Z' < 0$ can not be used in HTS. These are, however, only rough categorizations of assay quality for HTS and should not be regarded as absolute rules. Also, this metric applies to single point screening only. When multiple measurements (n replicate) of a testing sample are taken, the standard error (SE) should be used instead of the standard deviation and consequently the assay quality will be improved by a factor of square root of n.

There are several caveats and limitations in using the Z′-factor statistics in HTS. First, the Z′-factor should be assessed only when using large data sets, and both the high and low reference control signals should approximate a normal distribution. In some rare cases where either the data distributions deviate severely from a normal distribution or (σ_{c+}) and (σ_{c-}) values are hugely different, e.g., >10-fold, the Z′-factor values can become less effective in indicating the assay data quality. Another limitation is that, due to its dependence on two reference control states of the assay, sometimes the Z′-factor becomes a less defined measure of assay quality for stimulator or agonist screens when there is no known stimulator/agonist reference control available. When there is a strong or natural agonist/stimulator available as reference control, the Z′-factor can be rightfully defined.

Connections to Other Assay Data Quality Indicators

Besides the commonly used Z′-factor, S/B and S/N ratios, there are several other assay performance statistical parameters used in the HTS literature. A "signal window" (SW) ratio had been reported to evaluate the performance of HTS assays. The so called assay variation ratio (AVR) was also used to evaluate assay quality. AVR and Z′-factor are inter-related and inter-changeable to one another, except that the original recommended values for the acceptable and unacceptable assay for screening were somewhat discrepant. Some simulation studies compared the performance of the Z′-factor with both the SW and AVR and recommended the Z′-factor as a preferred assay performance measure. The power analysis is another approach for assay quality indication. However, the power analysis is usually based on one reference state of the assay signal distribution, and may not reflect the quality of the assay over the entire usable signal dynamic range. Compared to the power analysis, the Z′-factor is a much simpler statistical parameter to use. Z′-factor can be used in conjunction with CV, S/B or S/N to give a more comprehensive assessment of the assay variation and performance.

Z′-factor and Lower Limit of Detection of an Assay

The assay sensitivity can be evaluated by the lower limit of detection (LLD) of the assay measurement. The LLD as assay sensitivity limits are evaluated in terms of signal strength versus variability. The S/N ratio is a good indicator for strength of signal. The concentration of an analyte that gives a S/N = 3 is conventionally regarded as the LLD of the assay measurement with regard to that analyte. Similarly, one can use an analyte concentration that gives $Z' = (-1)$ as LLD of the assay.

Zoledronic Acid

Dominique Heymann
Physiopathologie de la Résorption Osseuse et Thérapie des Tumeurs Osseuses Primitives, University of Nantes, Nantes, France

Definition

Zoledronic acid is a stable synthetic derivative of the naturally occurring endogenous pyrophosphate, which acts as a powerful anti-bone degradation drug and exhibits anticancer activities.

Characteristics

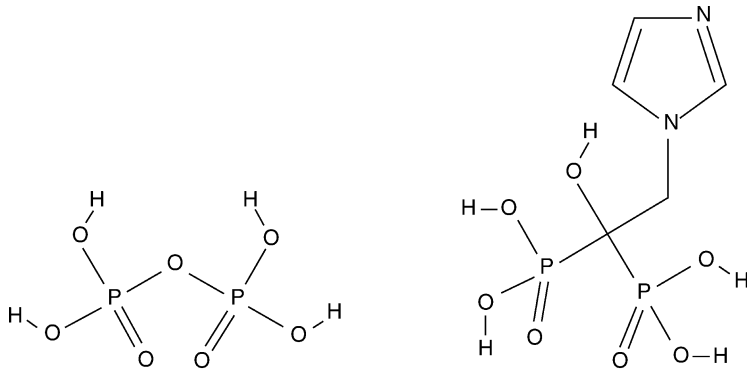
Structural Characteristics

Zoledronic acid belongs to a large drug family named ►bisphosphonate derived from endogenous ►pyrophosphate (Fig. 1). In contrast to pyrophosphate, bisphosphonates have a carbon atom replacing the central oxygen which is associated with two additional substituents. There are three main generations of bisphosphonates: (i) the first generation, including compounds called clodronate and etidronate, possess simple substituents attached to the central carbon; (ii) the second generation such as pamidronate, alendronate, and ibandronate are characterized by aliphatic side chain containing a single nitrogen; (iii) the third generation such as risedronate and zoledronic acid is composed by a heterocycle side chain containing one or two nitrogen atoms. Thus, zoledronic acid is a nitrogen bisphosphonate composed by two nitrogen atoms in an imidazole ring (Fig. 1). Zoledronic acid, like the other bisphosphonates, possesses a high affinity for calcified matrix such as bone tissue via its phosphate groups.

In vitro Activities of Zoledronic Acid and Mechanisms of Action

Due to the high tropism of bisphosphonates for ►hydroxyapatite crystals in bone and the ability of ►osteoclasts to release bone-bound bisphosphonates, osteoclasts represent the main target of zoledronic acid. Thus, after administration, zoledronic acid selectively concentrates on the bone surface at the interface with the active osteoclasts where bone tissue is most exposed. Zoledronic acid is one of the most potent bisphosphonates in terms of anti-bone resorptive activity. While the first generation of bisphosphonates has a relative potency of 1–10, the potency of the second generation reaches 10–10,000, and zoledronic acid has a relative potency more than 10,000. To exert its activities, zoledronic acid must be internalized by the cells. Although the internalization of zoledronic acid is still controversial, two mechanisms have been proposed to explain its entry into the cells: in the first case, the cellular uptake of zoledronic acid would require fluid-phase endocytosis, and in the second case, ►integrins located at the cell membrane would represent the binding site of zoledronic acid which could explain why zoledronic acid is able to inhibit cell adhesion. The main targets of nitrogen-bisphosphonates are the two enzymes involved in the ►mevalonate pathway: farnesyl diphosphate synthase (FPP) and geranylgeranyl diphosphate synthase (GGPP). FPP and GGPP are required for the ►prenylation of small GTPases (i.e., Ras, Rho, and Rac), a biochemical reaction essential for the anchorage of small GTPases to cell membranes and to protein–protein interactions. In fine, their inhibition by zoledronic acid results essentially in the blockade of osteoclast function and also osteoclastogenesis decreasing the proliferation, viability, and recruitment of preosteoclasts.

In addition to their powerful anti-►bone resorption effects, recent in vitro studies evidenced a direct antitumor activity exerted by zoledronic acid on several cancer cells including breast and prostate ►carcinomas, ►osteosarcoma, ►neuroblastoma, ►multiple myeloma.



Zoledronic Acid. Figure 1 Zoledronic acid structure compared with pyrophosphate and basic bisphosphonate structure, characterized by a central carbon substituted by two phosphate groups and two other substituents R1 and R2.

Similar to its effects on osteoclasts, zoledronic acid treatment impairs protein geranyl-geranylation in these cancer cells. The main biological effects of zoledronic acid on malignant tumor cells include the inhibition of cell adhesion (associated with an alteration of cytoskeleton organization), of cell proliferation, and induction of cell death. Indeed, zoledronic acid treatment results in the cell cycle arrest in S and G2/M phases through the control of the intra-S DNA checkpoint and induces cell death independently of ►caspase activation but via the mitochondrial pathway, in particular, the apoptosis-inducing factor and endonuclease G translocation. Furthermore, zoledronic acid exerts its antitumor activity independently of the ►p53 and ►retinoblastoma (Rb) protein status of the cells. This point is of paramount importance, because several mutations or inactivations of the ►antioncogenes *p53* and *Rb* are detected in high percentage of patients suffering from malignant pathologies. Zoledronic acid also exerts synergistic effects in vitro with conventional ►chemotherapy (carboplatin, cisplatin, YDFUR, docetaxel, epirubicin, fluvastatin, gemcitabine, imatinib, paclitaxel, trastuzumab, or vinorelbine, etc) on cancer cells.

Antitumor and Bone Resorption Activity of Zoledronic Acid in Preclinical Models

Although nitrogen-bisphosphonate has been widely used to treat ►osteoporosis and to limit the decrease of bone mineral density, zoledronic acid has been successfully used to reduce the skeletal complications (►osteolysis, hypercalcemia) associated with bone ►metastases. According to the in vitro studies, several animal models demonstrated that zoledronic acid can reduce skeletal-tumor burden in prostate, breast, and renal carcinomas, multiple myeloma, osteosarcoma, chondrosarcoma. For instance, zoledronic acid inhibits the development of ►osteoblastic bone lesions, as well as osteolysis in a murine model of ►prostate cancer. The efficacy of zoledronic acid can be explained by several mechanisms. First, a "vicious cycle" has been described in osteolytic tumors consisting in the activation of osteoclasts by mediators produced by tumor cells, which in turn release osteoclastic factors and/or bone-stocked factors favorable to the proliferation of cancer cells. In this context, zoledronic acid inhibits osteoclastogenesis and bone degradation and then reduces tumor growth. Second, zoledronic acid can affect directly the growth of tumor cells (induction of tumor-cell apoptosis and/or inhibition of tumor-cell proliferation and/or inhibition of tumor-cell spreading and invasion). Indeed, such direct activity can be underlined in nonosseous tumor models such as lung metastases. Thus, zoledronic acid diminishes osteosarcoma-induced lung metastasis in a murine model, thereby prolonging the animal survival. Third, zoledronic acid exerts an antiangiogenic activity and inhibition of tumor cell bone invasiveness by a transient reduction of circulating levels of several growth factors and matrix metalloproteinase. Moreover, it also sensitizes endothelial cells to cytokine-induced, caspase-independent programmed cell death. Fourthly, zoledronic acid exerts a variety of immunomodulatory effects that might contribute to its antitumor activities. It stimulates the proliferation of a specific γδ T-cell subpopulation which exhibits cytotoxicity against numerous tumor cells. Taken together, the published studies demonstrated that zoledronic acid must be considered as a multifunctional molecule exerting both antiresorption and tumor activities.

Therapeutic combinations of zoledronic acid and chemotherapeutic agents have also been assessed in animal models. Thus, in murine models of bone metastases, zoledronic acid combined with UFT (a combination drug of tegafur and uracil) decreases not only bone metastases but also lung metastases and

visceral metastases. In a rat osteosarcoma model, zoledronic acid associated with ifosfamide enhances tumor regression and tissue repair and increases animal survival by inhibiting lung metastases. Similarly, zoledronic acid associated with ►Glivec increases the survival of the leukemia animals. In light of these preclinical data, the main benefit of combined treatment with zoledronic acid and anticancer drugs is to prolong significantly the life of cancer-bearing animals.

Clinical Aspects

On the basis of results obtained from randomized phase III clinical trials, zoledronic acid was approved in the United States for the treatment of patients with documented bone metastasis from solid tumors in conjunction with conventional chemotherapy and patients suffering from multiple myeloma. Zoledronic acid was also approved in Europe for the prevention of ►skeletal-related events (hypercalcemia, osteolysis, bone pain, fractures, etc) in patients suffering from advanced malignancies implicating bone. Thus, zoledronic acid as the other bisphosphonates has became the standard treatment for metastatic disease spread to the bone from prostate, breast, lung, and renal cancers and for multiple myeloma. Zoledronic acid therapy is generally well-tolerated, is safe for long period, and provides durable therapeutic benefits but can be associated with an upmodulation in serum creatinine. In this context, patients must be adequately hydrated, monitoring of renal function being required for all patients receiving zoledronic acid treatment. Caution must also be exercised for patients receiving other potentially nephrotoxic treatment. The current treatment guidelines recommend intravenous administration of 4 mg zoledronic acid diluted in calcium-free solution (approximately 100 ml of saline or 5% dextrose) and infused over 15 min, every 3–4 weeks. This recommended 15 min infusion time is significantly shorter than other i.v. bisphosphonate such as pamidronate (90 mg infusion for 2 h). As the optimal duration of the zoledronic acid treatment is not really documented, the treatment should be continued as far as it is well-tolerated or until significant effects on pathologic bone tissues are observed. Plasmatic concentrations of zoledronic acid quickly increase and reach their maxima at the end of infusion. Thereafter, these concentrations rapidly decrease (<10% of zoledronic acid infused detectable after 4 h, <1% after 24 h) and a very low level of zoledronic acid (<0.1%) can be measured after 20 days, date corresponding to the next administration. In the blood, around 60% of zoledronic acid is associated with albumin, and 60% of the injected molecule binds to the bone calcified matrix before being slowly released in to systemic circulation. Zoledronic acid is not metabolized but is mainly excreted by kidney pathway under its native form. Similarly to the other bisphosphonates, zoledronic acid induces some side effects in approximately 30% of the patients. The adverse reaction includes especially a influenza-like syndrome with fever, fatigue, nausea, vomiting, arthralgia or myalgia, bone pains, and conjunctivitis. Symptoms will generally occur within 24 h and disappear within 48 h. Moreover, these adverse events are less severe with the second injection and do not occur anymore with the third infusion. Alterations of renal function (23% of the patients) have also been reported in the literature. Furthermore, clinical trials using zoledronic acid also pointed out the potential risk (but rare) of osteonecrosis of the jaw in the treated patients, length of exposure appearing to be the most important risk factor for this complication. The effects of zoledronic acid on the reproductive function have been evaluated only in animal models. Thus, low doses (0.01mg/kg) induced dystocias in rat; however, this potential risk is unknown in human. In this context, the main counter indication of zoledronic acid is pregnancy and breast feeding.

Recent advances evaluated the therapeutic interests to combine zoledronic acid with ►taxanes, thalidomide, or with bioactive compounds such as interferon-γ or ►somatostatin in patients with metastatic androgen-refractory ►prostate cancer ►hormone-refractory prostate cancer or with ►renal carcinoma. These combinatory therapies that have synergistic effects offer ►palliative clinical responses to zoledronic acid alone.

Zonula Adherens

►Adherens Junctions

Zonula Occludens Protein-1

Keiran S. M. Smalley, Meenhard Herlyn
The Wistar Institute, Philadelphia, PA, USA

Synonyms

Tight junction protein-1; TJP-1; ZO-1

Definition

The zonula occludens (ZO-1) protein-1 is a membrane-associated component of both ►tight junctions (TJ) and ►adherens junctions (AJ) found at the site of cell-cell contact. Functionally, ZO-1 is an intracellular adaptor protein and is known to interact with claudins, occludin, the cadherins, the actin cytoskeleton and downstream signaling pathways and transcription factors (such as ZONAB).

Characteristics

In order for organs to perform their diverse functions, the constituent cells that make up a tissue must be able to arrange themselves in an organized fashion. The complex architecture of a given tissue is regulated by the differential expression of cell-cell adhesion molecules. Epithelial cells adhere to each other through a set of intercellular junctions that consist of adherens junctions (AJ), tight junctions (TJ) and ►desmosomes. These different types of junctions perform discrete adhesion, organizational and transport functions. TJs typically form a "belt" that circles the apical end of the cell to form a paracellular barrier regulating the flow of growth factors, ions, and other macromolecules. The ability of TJs to regulate molecular traffic in this manner is one way of ensuring that the apical/basolateral ends of the cell inhabit different microenvironments and allows for the maintenance of epithelial polarity. The extracellular portion of TJs consist of either claudins (Claudin 1–24), occludin, or the junctional adhesion molecule (JAM) proteins. Of these, the claudins and occludin are four trans-membrane domain proteins that polymerize with their counterparts on adjacent cells to form the physical barrier. JAMs are different from claudins and occludin and instead associate with the TJ strands rather than directly constituting them.

AJs and ►desmosomes do not regulate molecular transport and are primarily involved in cell-cell adhesion. Although AJs are often found in close proximity to tight junctions they are instead cadherin-based, and link directly to the actin cytoskeleton. Unlike AJs, desmosomes are distributed along the cell membrane and link to intermediate filament proteins. The cytoplasmic portions of both AJs and TJs consist of many adaptor scaffolding proteins. These proteins serve many functions such as linking the claudins/occludin and the cadherins (►E-cadherin) to the actin cytoskeleton, as well as serving as molecular docking sites for signaling proteins involved in junctional regulation and cell proliferation. One major adaptor protein is the zonula occludens (ZO-1) protein-1, which has close homology to the rat synaptic protein PSD-95, and the discs large (dlg) drosophila tumor suppressor gene. The ZO-1 protein is part of a larger family that also includes the closely related ZO-2 and ZO-3.

Molecular Biology of ZO-1

ZO-1 was first identified as a ~220 kDa antigen with a monoclonal antibody raised against a cell-cell junction enriched liver extract. The close association of ZO-1 with the claudins and occludin led to the initial identification of ZO-1 as a tight junction protein. Sub sequent work showed that ZO-1 is also expressed in many non-epithelial cells, such as fibroblasts, astrocytes, Schwann cells, glioma (►Glioblastoma multiforme) and sarcomas, where it instead associates with AJs. In cadherin-based adherens junctions, ZO-1 facilitates cell-cell adhesion through its function as a cross-linker between α-catenin and the actin cytoskeleton. ZO-1 exists in at least two alternately spliced isotypes, ZO-1^{+} and ZO-1^{-}, which confer differences in cell-cell junction dynamics. Although most epithelial and endothelial cells express both the + and − forms of ZO-1, some specialized cells, such as the endothelia of the glomerular, the peritubular capillary and the eye's trabecular meshwork express only the ZO-1^{-} form.

Sequence analysis has shown that ZO-1 is a membrane associated guanylate kinase (MAGUK) protein. The molecular structure of ZO-1, with its many protein-protein binding sites facilitates its role as a molecular scaffold. Structurally ZO-1 is composed of three PDZ domains (so named after being identified in *P*SD-95/*D*lg/*Z*O-1 proteins), one SH3 domain (►SH2/SH3 domains) and one guanylate kinase (GUK) domain.

The ►PDZ domains are protein binding motifs that are located almost exclusively at synapses and cell-cell junctions. PDZ domains facilitate the direct interaction of ZO-1 with the C-terminal domain of the claudin/occludin proteins. The SH3 (►SH2/SH3 domains) domain of ZO-1 is thought to be critical for the recruitment of a specialized serine protein kinase called ZO-1 associated kinase (ZAK) that phosphorylates a region immediately C-terminal to the SH3 domain. The guanylate kinase domain of ZO-1 is thought to be catalytically inactive, and is instead more likely to also mediate protein-protein interactions (Figs. 1 and 2).

Regulation and Function of ZO-1

The cellular localization of ZO-1 is determined by the level of confluency. In a sub-confluent monolayer, most ZO-1 is localized in the nucleus. As the cells become more confluent, ZO-1 migrates, and becomes associated with the cell-cell contacts of fully confluent cells. Because of this, there is evidence that ZO-1 plays a role in sensing and regulating the extent of cellular confluency by controlling cell proliferation at the level of gene transcription. In accordance with a gene transcription role, ZO-1 associates with its own SH3 motif binding Y-Box transcription factor ZONAB. The ZO-1/ZONAB interaction appears to be critical for controlling cell density in Madin-Darby canine kidney (MDCK) cell monolayers. In these cells, ZO-1 regulates proliferation both at the G_1/S transition checkpoint by sequestering cyclin-dependent kinase (CDK)-4 (►cyclin dependent kinases) and by directly binding to ZONAB to regulate transcriptional initiation. The ZO-1/ZONAB interaction is also regulated by cellular stress. Apg-2 is a novel member of the heat shock protein (HSP)-70 family that directly competes with ZONAB at the SH3 domain of ZO-1 to regulate ZO-1/ZONAB binding. Other studies have shown that ZO-1 can also regulate cell-cell junction formation through interaction with AF-6, which is a target of the small GTPase ►Ras.

ZO-1 in Cancer

Disruption and alteration of both AJs and TJs are major hallmarks of cancer, and it is likely that altered ZO-1 expression contributes to this phenomenon in an important fashion. Under normal tissue homeostasis, the behavior of an individual cell is tightly controlled by the immediate tissue ►microenvironment. The loss of this local cellular control is associated with epithelial disorganization, invasiveness and hyperproliferation. Many epithelial tumors lack functional TJs, and this is often associated with loss of polarity and de-differentiation. Loss of TJ integrity may be particularly important for allowing the free diffusion of nutrients and other factors responsible for the growth and survival of cancer cells. Another important driving force for behind the enhanced motility and invasiveness of early tumor cells is the loss of AJ function. Loss of E-cadherin, which is often also accompanied by a switch ►N-cadherin expression, is a key early event in tumor formation and is characteristic of the ►epithelial-to-mesenchymal transition (EMT). The critical function of ZO-1 as a scaffold for both claudin/occludin-based TJ and E-cadherin-based AJ is highly suggestive of its role in cancer.

Membrane ZO-1 expression is often reduced or lost in breast, gastric, pancreatic and esophageal ►squamous cell carcinomas (SCC) as well as in SCC of the skin. In breast cancer, high ZO-1/E-cadherin expression is associated with strong cell-cell adhesion and reduced invasiveness. Consequently, loss of ZO-1 expression correlates with a more invasive breast cancer phenotype. Reduced ZO-1 levels are also associated with invasion in other tumor types, such as pancreatic cancer

Zonula Occludens Protein-1. Figure 2 Structure of ZO-1 based plaque at a tight junction. The ZO-1 is scaffold molecule linking the extracellular tight junction proteins (claudin and occludin) to both gene transcription (ZONAB) and the actin cytoskeleton.

(►Pancreatic cancer, Basic and Clinical Parameters). Altered ZO-1 expression is not the only indicator of aberrant behavior. Mislocalization of ZO-1 from the membrane to the cytoplasm/nucleus is also an important factor in determining the oncogenic behavior of the protein. A loss of membrane-bound ZO-1 and its translocation to the cytoplasm upregulates expression of membrane type-1 matrix metalloproteinase (MT1-MMP) and increases breast cancer cell invasion. A further role for ZO-1 in oncogenic behavior arises from the deregulation of the ZO-1/ZONAB axis. Some epithelial tumor types such as ►hepatocellular carcinoma and pancreatic cancer overexpress the human homolog of ZONAB (Dbpa), which is known to drive the proliferation of epithelial cells through regulation of ►PCNA and ►cyclin D1. Depletion of Dbpa, using an ►shRNA against symplekin, reduced the growth of human adenocarcinoma cells, suggesting that ZONAB could be a potential therapeutic target.

The role of ZO-1 in cancer seems to depend on whether the cancer in question is epithelially-derived or not. As such, some tumor types actually exhibit markedly increased levels of ZO-1 that are not usually found in the non-transformed parent cell. In ►melanoma, which arises from a non-epithelial cell type (the melanocyte), there is an association between high ZO-1 expression and tumor progression. In this instance, ZO-1 associates with N-cadherin leading to increased melanoma cell invasion. In a similar vein, melanomas often exhibit aberrant expression of TJ proteins such as claudin-1. Another tumor type with aberrant ZO-1 expression is ►Merkel Cell carcinoma, although in this instance the precise function of the overexpressed ZO-1 protein is unknown.

At present, knowledge about ZO-1 protein expression in cancer is best used as a diagnostic tool. Loss of ZO-1 expression in epithelial tumors is strongly associated with loss of epithelial organization and increased invasion. In non-epithelial tumors, such as melanoma, the opposite is true and increased ZO-1 expression may contribute to increased tumor invasion.

ZRP1

Definition

Zyxin-related protein 1 is a member of the ►zyxin family of proteins

► TRIP6
►Lipoma Preferred Partner

Zymogen

Definition

Inactive enzyme precursors that require a biochemical change (such as the hydrolysis of a fragment that masks an active enzyme or configuration change) in order to become active

►Protease Activated Receptor Family

Zyxin

Definition

Is an 82-kDa protein that is localized at cell-substratum and cell-cell adherens junctions. It is the founding member of the zyxin family of proteins which includes seven members: zyxin, TRIP6/ZRP-1, LPP, Ajuba, LIMD1, WTIP and FBLP-1/migfilin/Cal. The name "zyxin" is derived from the New Latin combining form "zyxi," a derivative of the Greek word "zeuxis" meaning "a joining" to indicate that it is found at regions where extracellular ligands are structurally and functionally joined to the cytoskeleton. Under certain circumstances, zyxin accumulates in the nucleus. Zyxin is an ►adaptor protein containing three carboxyterminal copies of the ►LIM domain and a proline-rich pre-LIM region harboring several protein-protein interaction domains. Interaction partners include: CRP1, α-actinin, VASP, Vav, warts/LATS1, E6 protein from ►human papillomavirus type 6, p130Cas, TES, LIM-nebulette, Lasp-1, and myopodin. In humans, the gene encoding the zyxin protein is localized at chromosome bands 7q34-q35.
