List of Entries

Reader's Guide

The Reader's Guide provides an overview to all the entries in the *Encyclopedia* as well as a convenient way to locate related entries within an area of interest. Articles are arranged under headings, which represent broad categories of subjects. For instance, the heading Branches of Epidemiology lists the titles for the 20 main entries on fields of study and practice within epidemiology included in this *Encyclopedia*, from Applied Epidemiology to Veterinary Epidemiology. Similarly, under the heading Epidemiologic Data are listed the main entries on that topic, including types of data (e.g., Administrative Data), specific sources of data (e.g., the Behavioral Risk Factor Surveillance System), and issues related to data management (e.g., Biomedical Informatics). The guide is also useful for finding articles related to a particular topic. For instance, if you are interested in Genetic Epidemiology, you will find that topic under the heading Genetics, which also includes articles on topics such as Epigenetics, the Human Genome Project, and Linkage Analysis. Some topics appear under more than one heading (e.g., Genetic Epidemiology appears under both Branches of Epidemiology and Genetics), reflecting the interrelationships among the broad categories represented by the headings.

Statistics and Research Methods

About the Editor

Sarah Boslaugh, Ph.D., MPH, has more than 20 years of experience working in data management and statistical analysis. She is currently a performance review analyst in the Center for Healthcare Quality and Effectiveness of BJC HealthCare and an adjunct professor in the Washington University School of Medicine, both in St. Louis, Missouri. She previously worked as a biostatistician and methodologist at Montefiore Medical Center in New York City and for the School of Public Health of Saint Louis University. She is the author of two books, *Secondary Data Sources for Public Health* (2007) and *SPSS Programming: Using Syntax for Data Management* (Sage, 2004), and of numerous book chapters and professional articles. Her research interests include multilevel modeling, quality improvement in healthcare settings, and measurement theory. She received her Ph.D. in research methods and evaluation from the City University of New York and her MPH from St. Louis University.

About the Associate Editor

Louise-Anne McNutt, Ph.D., is an associate professor in the Department of Epidemiology and Biostatistics, University at Albany, State University of New York. Her areas of expertise include infectious disease epidemiology, violence intervention, epidemiologic methods, and quantitative methods. She primarily focuses her international research in the post-Soviet East studying transmission of bloodborne pathogens in health care settings and disease transmission affecting women of reproductive age. In the United States, she conducts research to inform policies on intimate partner violence screening and intervention in primary care settings and sexually transmitted disease interventions. After completing her graduate education, she joined the Epidemic Intelligence Service, Centers for Disease Control and Prevention (CDC). She has held many positions in national organizations, is currently cochair of the Associated Schools of Public Health's Biostatistics and Epidemiology Council, and will join the Editorial Board of the American Journal of Public Health in Fall 2007. Her funding sources for research activities include the National Institutes of Health, CDC, New York State Department of Health, and multiple foundations. She has an MS in biostatistics from the Medical College of Virginia and a Ph.D. in preventive medicine from the University of Iowa.

About the Advisory Board

Elena M. Andresen, Ph.D., is Professor and Chair, Department of Epidemiology and Biostatistics, at the University of Florida College of Public Health and Health Professions. Her training and research interests include chronic disease epidemiology among older adults, disability epidemiology, and outcomes research methods and measures. She has special expertise in research methods and measures regarding older adults and groups with disability and currently receives support for research from the Centers for Disease Control and Prevention, National Institute on Disability and Rehabilitation Research, National Institute on Aging, Department of Veterans Affairs, and the Komen Foundation. She has served as a member of the Institute of Medicine committees on issues of aging and disability and has numerous service activities for a number of federal agencies, including the Centers for Disease Control and Prevention, National Institute on Disability and Rehabilitation Research, and the Agency for Healthcare Research and Quality. She received her Ph.D. in epidemiology from the University of Washington in 1991.

Peter S. Arno, Ph.D., is a health economist and professor in the Department of Health Policy and Management at New York Medical College. He was a Pew Postdoctoral Research Fellow at the Institute for Health Policy Studies and the Institute for Health and Aging at the University of California, San Francisco (1984–1986); a scholar of the American Foundation for AIDS Research (1989–1992), and recipient of an Investigator Award in Health Policy from the Robert Wood Johnson Foundation (1998–2003); and coauthor of *Against the Odds: The Story of AIDS Drug Development, Politics & Profits*, nominated for a Pulitzer Prize. His recent work includes studies of regulation and pricing practices of the pharmaceutical industry; the economics of informal caregiving and long-term care; public health and legal implications of regulating tobacco as a drug; cost, access, quality, and outcome measures related to HIV disease; and the impact of income support policies on health. Based on this work, he has testified before numerous U.S. House and Senate committees.

Ross C. Brownson, Ph.D., is a professor of epidemiology and Director of the Prevention Research Center at Saint Louis University School of Public Health (SLU-SPH) in Missouri. As a chronic disease epidemiologist, he is involved in numerous community-based interventions designed to reduce modifiable risk factors such as physical inactivity and tobacco use. In particular, he is interested in the impacts of environmental and policy interventions on health behaviors. He also conducts research on dissemination of evidence-based interventions. His research is funded by the Centers for Disease Control and Prevention, the National Institutes of Health, and the Robert Wood Johnson Foundation. He is the author of 6 books, more than 200 peer-reviewed articles, and is on numerous editorial boards. His books include *Chronic Disease Epidemiology and Control, Applied Epidemiology,* and *Evidence-Based Public Health*. He has led in the development of the internationally recognized training course in evidence-based public health. He is the recipient of the Award for Excellence in Prevention Research and Research Translation in Chronic Disease (2000, from CDC) and the Abraham Lilienfeld Award for outstanding contributions in teaching and mentoring from the American Public Health Association. Prior to joining SLU-SPH, he was a division director (a cabinet-approved appointment) with the Missouri Department of Health. In this capacity, he wrote or cowrote bills on tobacco access to minors, state clean indoor air, and private insurance coverage of screening mammography and Pap smear testing.

Diane Sperling Lauderdale, Ph.D., is an associate professor in the Department of Health Studies and the College of the University of Chicago. She has been a member of the faculty at the University of Chicago

since 1996 and teaches courses in epidemiologic research methods and the history of public health in the United States. As a chronic disease epidemiologist, she carries out population-based studies of how chronic disease and health-related behaviors, including physical activity and obesity, receipt of preventive medical care, and sleep, vary in the population. She is the author of more than 60 papers in peer-reviewed journals. Her research is funded by the National Institutes of Health, the American Cancer Society, and the Robert Wood Johnson Foundation. Much of her research has focused on the health and health care of immigrant populations in the United States, including studies of birth outcomes, osteoporosis, mortality, and discrimination experiences in medical care. She received an AB in the comparative study of religion from Harvard University, MA degrees in divinity and library science from the University of Chicago, and a Ph.D. in public health (epidemiology) from the University of Illinois at Chicago School of Public Health.

William D. Shannon, Ph.D., is Associate Professor of Biostatistics in Medicine in the Department of Medicine, Washington University School of Medicine. As an applied biostatistician and statistical methodologist, he is involved with a broad range of biomedical data analysis problems, including the genetics of leukemia, field trials for the eradication of lymphatic filariasis in Egypt, developing new methods for sleep medicine in cardiovascular and HIV/AIDS research, designing clinical trials on the impact of automated computer alerting systems to improve physician compliance with medical guidelines, and developing prediction rules for sepsis in intensive care settings. As Director of the Washington University Department of Medicine's Biostatistical Consulting Center, he is continually presented with the challenges of analyzing biomedical data. Of particular interest to him are the statistical methods of cluster analysis and classification analysis. He is on the Board of Directors of the Classification Society of North America and Interface of Computing Science and Statistics and has organized and hosted three of their annual meetings at Washington University. He has received his Ph.D. from the University of Pittsburgh, Graduate School of Public Health, in 1995.

Introduction

The Field of Epidemiology

Epidemiology is the study of the frequency and determinants of morbidity and mortality in populations. Besides being a discipline in its own right, the science of epidemiology is one of the foundational sciences of public health and of evidence-based medicine. The Centers for Disease Control and Prevention (CDC) estimate that of the more than 30 years increase in life span experienced by Americans between the years 1900 and 1998, approximately 25 of those years can be attributed to improvement in public health. Epidemiology played a key role in these improvements by identifying risk factors and causal agents for disease and by aiding in the development and evaluation of public health and educational programs designed to reduce morbidity and mortality. Epidemiology has proved equally useful in the drive to prevent and control infectious disease through measures such as provision of clean water, the institution of widespread vaccination programs, and in the reduction of morbidity and mortality from chronic disease through identification of risk factors such as tobacco smoking, consumption of a high-fat diet, and lack of physical activity.

Epidemiologic studies often begin by describing variation in disease occurrence or other health outcomes according to the variables of person, place, and time. *Person* variables describe who is becoming ill—their gender, ethnic group, usual diet, and so on. *Place* variables may describe where the individual was exposed to the disease-causing agent, the location where they became ill, or where the agent (such as a rodent or mosquito) became infected with the disease. *Time* variables may relate either to measurements such as the age or birth cohort of those infected, the duration of an infection or disease, or to cyclical or secular trends in disease occurrence. Descriptive studies of disease occurrence often suggest hypotheses that may be investigated further in analytic studies that examine many variables to discover causal or risk factors related to disease occurrence.

Epidemiologic studies have led to massive improvements in public health, sometimes even before the mechanisms of disease causation are completely understood. For instance, Ignaz Semmelweis's observations of the differing rates of puerperal fever within different wards of the Vienna General Hospital in the mid-19th century led him to institute antiseptic procedures that drastically lowered both morbidity and mortality rates, years before the germ theory of disease was accepted. Similarly, Joseph Goldberger was able to demonstrate that pellagra, a disease epidemic in the American South in the early 20th century, was not an infectious disease but was related to poor nutrition. Goldberger was also able to prevent outbreaks of pellagra by having individuals consume small amounts of brewer's yeast, a breakthrough achieved a decade before niacin deficiency was definitively identified as the cause of pellagra. And the first recognition that cigarette smoking was a primary risk factor for lung cancer came from observational epidemiologic studies conducted by Sir Richard Doll and Sir Austin Bradford Hill in Great Britain in the 1950s, studies conducted before any specific mechanism relating smoking and lung cancer had been proposed.

The scope of epidemiology is continually widening to accommodate expanded definitions of health and to accommodate our ever-broadening understanding of the influence of diverse factors on health. Although epidemiologic thought may be traced back to ancient times, growth and development of epidemiology as a profession began in the 19th century, when the science of epidemiology was developed partly in response to public health concerns such as the cholera epidemics that regularly occurred in many large cities. So successful were the interventions devised in this early

period that many infectious diseases that still plague the developing world are almost unknown in the industrialized world, thanks to public health measures such as the provision of potable tap water, control of mosquitoes and other pests, and institutions of widespread vaccination programs. Infectious diseases still remain a concern in industrialized countries, however, and the emergence of diseases such as HIV and multidrug-resistant tuberculosis pose new challenges for the science of epidemiology.

The first great expansion in the scope of epidemiology was the inclusion of chronic as well as infectious diseases. This is a logical development since, partly due to greater control of infectious disease, the greatest causes of morbidity and mortality in developed countries today are chronic diseases such as cancer, cardiovascular disease, and stroke. These diseases are also significant health factors in the developing world: In fact, the World Health Organization estimates that 80% of deaths due to chronic disease now occur in developing countries. Increased study of chronic diseases has brought with it a massive increase in complexity, since most such diseases do not have a single causal factor or solution. While cholera is caused by ingestion of the bacterium *Vibrio cholerae* and effective prevention requires the public health measure of preventing the bacterium from polluting drinking water or removing or killing it through filtration, chemical treatment, or boiling, heart disease may be influenced by many things, including genetics, obesity, tobacco smoking, and comorbid conditions, and prevention and treatment are likely to require an individualized combination of behavioral and lifestyle changes as well as medical intervention. In fact, many of the risk factors for chronic diseases are individual behaviors, and epidemiology's growing awareness of the importance of individual health behaviors on morbidity and mortality led to the establishment, in the 1980s, of the Behavioral Risk Factor Surveillance System. It has also led to numerous public health campaigns aimed at lowering chronic disease morbidity and mortality by inducing individuals to make alterations in their lifestyle, such as increasing physical activity, eating more fruits and vegetables, and quitting smoking and moderating alcohol consumption.

An even newer focus of concern for epidemiology is the influence of social and geographical factors on health. We now realize that not only individual behavior but also the material facts of a person's life may be major determinants of their health. Geographical influence on health includes not only obvious factors such as living in a polluted region or in a high-crime area but also more elusive qualities such as the type and strength of social relationships that typify a given neighborhood. Social influences also range from the obvious to the remarkable: It's easy to see how poverty could negatively affect health through lack of access to health care or inability to purchase nutritious food, or how the regular experience of discrimination could harm one's mental and physical health, but recent studies indicate that even in affluent societies where health care is available to all, a person's place within the social hierarchy can be a major influence on their health. Sorting out the influence of the many variables involved remains a challenge for epidemiology.

Epidemiologists are concerned not only with disease but also with injury. This includes accidental injuries, such as those caused by motor vehicles or by falling off a ladder, as well as injuries deliberately caused by oneself or other persons. The inclusion of topics such as suicide, child abuse, and intimate partner violence within the scope of epidemiology represents a commonsense broadening of scope, as does the study of risk factors such as the presence of firearms in the home. War and terrorism have also been included within the scope of epidemiology, which is entirely appropriate given the great toll they extract in human life and suffering.

Another expansion of scope for epidemiology, which was originally concerned with the health of human populations, has been the development of the science of veterinary epidemiology that studies the occurrence of health and disease of animal populations. This expansion is entirely logical because not only are many diseases communicable between animals and humans, but animal husbandry also plays an essential role in securing both the food supply and economic welfare of many human populations.

Organization of the *Encyclopedia*

As the study of epidemiology may potentially incorporate information about anything that affects human health, it incorporates descriptive and analytical techniques borrowed from many areas of study. However, a two-volume encyclopedia cannot include detailed discussions of every topic relevant to epidemiology, so we took the approach of including overview articles on many topics relevant to epidemiology, with their length proportional to the centrality of the topic to epidemiology. Anyone studying epidemiology will need to know something about biostatistics, for instance, but not so much as a full-time biostatistician.

Similarly, a basic knowledge of health economics is relevant to the practice of many epidemiologists, although that knowledge need not be as extensive or detailed as someone working as a health economist. We have organized this material into almost 500 entries, which may be viewed as belonging to a number of broad categories. One way to look at the content of this *Encyclopedia* is by major topics and representative entries included within each:

Behavioral and Social Science. This deals with topics such as acculturation, community health, demography, health behavior, health communication, network analysis, and social epidemiology.

Branches of Epidemiology. This includes 20 fields of study, based on methodological approach or content studied, from applied epidemiology to veterinary epidemiology.

Diseases and Conditions. This deals with the incidence, prevalence, prevention, and control of 40 major infectious, chronic, and psychiatric diseases and conditions, from Alzheimer's disease to zoonotic diseases.

Epidemiological Concepts. This deals with topics that form the basis of the science of epidemiology, including fundamental concepts such as attack rate, attributable fractions, incidence and prevalence, effect modification and interaction, morbidity and mortality rates, herd immunity, and direct and indirect standardization.

Epidemiologic Data. This deals with topics related to important data sets and the acquisition and management of data, including administrative data, cancer registries, notable epidemiologic studies such as the Framingham Heart Study and the Harvard Six Cities Study, publicly available data sets, sampling techniques, and secondary data.

Ethics. This deals with standards of ethics in health care, public health and human subjects research, and when doing epidemiology in developing countries, and related topics such as definitions of health, eugenics, and genocide.

Genetics. This deals with topics related to the burgeoning science of genetic epidemiology, including epigenetics, family studies, genetic counseling, gene-environment interaction, linkage analysis, molecular epidemiology, and twin studies.

Health Care Economics and Management. This deals with topics such as biomedical informatics, economic evaluation, functional status, health economics, managed care, and quality-of-life measurement.

Health Risks and Health Behaviors. This deals with what is known about the influence of numerous agents and conditions on health and disease from Agent Orange to urban sprawl and individual health behaviors from alcohol use to tobacco.

History and Biography. This deals with the history of epidemiology and public health, and biographies of pioneers in the field, from William Budd to John Tukey.

Infrastructure of Epidemiology and Public Health. This deals with epidemiologic and public health organizations, governmental and nongovernmental agencies, major journals, and the publication process.

Medical Care and Research. This deals with topics at the intersection of medicine and epidemiology, including clinical epidemiology; evidence-based medicine; the International Classification of Diseases and the International Classification of Functioning, Disability and Health; medical anthropology; and screening.

Specific Populations. This deals with major threats to health and patterns of disease and disability within specific populations, as defined by race or ethnicity, gender, age category, urban or rural residence, immigrant or refugee status, and sexual identity.

Statistics and Research Methods. This deals with theoretical background and applied techniques of epidemiology and statistics, including categorical data analysis, bias, causation and causal inference, classification and regression trees, cluster analysis, factor analysis, geographical and spatial analysis, multilevel modeling, nonparametric statistics, qualitative methods, regression, sequential analysis, and structural equation modeling.

The Growth of the Field of Epidemiology

The demand for epidemiologists is growing faster than the available supply of trained personnel, although enrollment in both public health programs in general, and epidemiology programs in particular, has been steadily expanding for years. In the United

States, most formal epidemiologic study takes place at the graduate (master's and doctoral) level at one of 37 accredited schools of public health, who enroll students from all parts of the world. University study in epidemiology and public health is offered in many other countries as well, including Canada, Japan, and numerous European countries.

Epidemiology is truly an international science, and epidemiologic research today is conducted in all parts of the world. The international growth of epidemiology as a science is demonstrated by the expansion of the International Epidemiological Association, which began as an "International Corresponding Club" founded by three British and American researchers in 1954, that now has members from more than 100 countries and whose triennial Congress in 2002 was attended by more than 1,200 people. Regional epidemiologic conferences also regularly draw participants from outside their geographic region; for instance, the 2004 European Congress of Epidemiology accepted individuals from 38 countries, representing all six continents.

In 2004 to 2005, U.S. schools of public health produced 6,656 graduates, a 43.6% increase from 1994 to 1995. Epidemiology was the most popular field of study, with 19.5% of students choosing this concentration. Despite this increase in graduates, there is a shortage of epidemiologists in the United States and worldwide. Many people who are currently working in epidemiology without formal training, such as the Council of State and Territorial Epidemiologists (CSTE), estimates that almost half the individuals working as epidemiologists in state and territorial health departments are not academically trained in the subject, with the largest gaps in those working in infectious disease epidemiology and injury epidemiology. Of course, many of these individuals are not able to stop working and enroll in a full-time course of study; even if they were, there are not sufficient places in university epidemiology programs to accommodate them. This situation led to development by the CDC and the CSTE of the *Competencies for Applied Epidemiologists in Governmental Public Health Agencies,* which specify what topics should be included in competency-based, on-the-job training for epidemiologists in government public health agencies.

Rationale for the *Encyclopedia*

The extraordinary growth of the field of epidemiology in the past several decades, coupled with an ever-increasing demand for people with epidemiologic training, has created a void in the literature. There are several highly technical encyclopedias directed to trained epidemiologists and biostatisticians and basic dictionaries that define key terms in the field, but there is no single reference work that describes basic epidemiologic concepts in sufficient depth for practitioners and that is accessible to the nonspecialist also. In addition, there is no reference that combines technical information about the techniques used in epidemiology with substantive information about the epidemiology of specific diseases and conditions or about the health status of particular population groups.

The *Encyclopedia of Epidemiology* is designed to be comprehensive in its coverage of topics but not exhaustive in its treatment of any one topic. Basic information about epidemiology is presented in a manner that is appropriate for both a student beginning university study in the field and the interested general reader. Technical articles such as those on biostatistical techniques are presented in a nontechnical manner so that they may be understood without advanced statistical training. Particular emphasis has been placed on communicating with individuals outside the field. Epidemiology plays too important a role in the modern world to be left to epidemiologists alone, and many people working outside the field need a working knowledge of at least some aspects of epidemiology. Such persons include health care professionals such as nurses and physicians, researchers in other social science fields, social workers, and journalists.

Content and Organization

This *Encyclopedia* was designed to include every topic that would be of major concern to persons studying or working epidemiology; thus, many topics from related fields such as biostatistics, health psychology, and health economics are included. Because many topics are interrelated, and to avoid redundancy, all topics include cross-references to related topics. In some cases, a topic was completely covered within an article on another topic; in that case, the smaller topic is listed in its alphabetical position with a cross-reference to the entry in which it is discussed.

To help the reader navigate the *Encyclopedia*, a Reader's Guide is provided that organizes the content into the 14 large topics previously enumerated. Additionally, a list of the entries is presented in alphabetical order.

The content of each article is intended to provide a concise and nontechnical summary of the major aspects of the topic, providing the reader with a fundamental

A

Acculturation

Acculturation is the process of individual or group adjustment to a new culture. As a result of continuous contact with a culture that is different from his or her culture of origin, an individual typically undergoes psychological, behavioral, and attitudinal changes that can affect psychological and physical health. The relevance of acculturation to public health is an issue of national, and increasingly global, importance.

The process of acculturation can take many paths. Individuals may embrace new cultural beliefs and practices, strive to retain culture of origin, or develop bicultural identities. Acculturation in the United States, however, has repeatedly been associated with numerous adverse health behaviors such as increased smoking and drug use. Understanding acculturation processes and constructs that underlie acculturative change is central to developing effective public health practices and policies that promote healthy populations. This entry examines Latino acculturation to the United States to illustrate the importance of acculturation to epidemiology and to highlight the gains to public health that increased understanding of acculturation may bring. The processes discussed, however, may apply to other immigrant populations acculturating to new environments.

Definitions of Acculturation

Acculturation has traditionally been defined as a linear movement away from the culture of origin and toward a new culture. The process of acclimating to a new culture, however, is increasingly recognized to be a complex and multidimensional one, in which individuals retain the values and practices from their culture of origin and adopt the new culture's values and practices to varying degrees. Recent research on biculturalism, for example, suggests that two cultural identities can be retained simultaneously and with varying degrees of psychological ease. Newer measures of acculturation, such as the Acculturation Rating Scale for Mexican Americans-II (ARSMA-II), take this variation into account and can simultaneously generate measures of linear, multidimensional, and bicultural types of acculturation.

Measuring Acculturation

Acculturation measures ideally are tailored to the cultural adjustment experience that is being examined. For example, a researcher studying the health impact of Latino acculturation to the United States strives to measure the behaviors and beliefs that are most representative of Latino culture and U.S. European American culture. This type of measure, however, is not always practical in applied or epidemiologic settings. Thus, many researchers rely on proxies of acculturative change, such as an individual's country of birth, time spent in the new cultural environment, and the extent to which an individual prefers the language, media, and values of the new culture versus culture of origin. These proxies are often useful estimates of acculturation but lack the fine-grained distinctions of more multidimensional measures. Both direct

and proxy measures, however, may fail to address the underlying causes of change in disease risk.

Health and Acculturation

Acculturation is relevant to many health processes, including (1) reproductive health (e.g., sexual behavior, experience and outcomes of pregnancy), (2) disease risk and management (e.g., diabetes and various forms of cancer), (3) psychosocial processes that affect health (e.g., stress and coping patterns), and (4) the development of effective prevention and intervention procedures.

Cultural beliefs and practices surrounding sex and pregnancy are related to differences in how individuals manage their reproductive health. Relative to U.S.-born European Americans, for example, less acculturated Latina immigrants to the United States are known to delay sex longer, have fewer partners over their life course, and be less likely to engage in sexually risky behaviors. Once pregnant, these women are more likely to have a positive attitude toward pregnancy and motherhood and have comparable birth outcomes to U.S.-born European Americans. With greater acculturation to the United States, Latinas begin to show a more adverse pattern that includes earlier sex, more partners, less positive attitudes toward pregnancy and motherhood, and poorer birth outcomes.

Acculturation is also linked with changes in health behaviors that can influence risk factors for developing diseases such as diabetes and cancer. Less acculturated Latinos, for example, have lower mortality from all causes and lower rates of various cancers relative to the rest of the U.S. population. With greater time in the United States, Latinos acquire less nutritious dietary habits (e.g., greater reliance on fast food) and become more likely to smoke, drink alcohol, and use drugs than their less acculturated counterparts. Research suggests that these changes result from greater access to convenience food and from the acceptance of smoking, alcohol, and drugs in the United States.

Psychosocial processes, such as strategies for coping with stressful life events, are also associated with cultural beliefs and have been found to vary by acculturation and to play a role in health outcomes. For example, more acculturated Latinas in the United States report feeling more everyday stress and pregnancy-related anxiety than less acculturated counterparts. Researchers have suggested that the process of adjusting to a new culture accounts for increased perceptions of stress, but another possibility is that the culture of origin may be protective against stress or may promote more effective coping strategies.

Finally, the development of effective strategies for preserving health, such as obtaining and complying with prevention or intervention information, is linked to acculturation. Turning again to the example of Latino acculturation to the United States, understanding changes in norms for leisure-time activity and communication styles is important for developing effective prevention and intervention programs directed at the Latino community. For example, more acculturated Latinos appear to exercise more regularly than less acculturated counterparts and might be persuaded to use this behavior to compensate for a less nutritious diet. In terms of intervention, many cultures, including Latino culture, favor indirect communication and strive to give socially desirable responses. Intervention programs aimed at relatively unacculturated Latinos or members of similarly oriented cultures stand to benefit from taking these norms into account.

Additive and Multiplicative Models

Additive and multiplicative models are two alternative approaches to modeling effect of risk factors on disease. In additive models, risk—or disease incidence—changes by some fixed amount when a risk factor is present. The statement "If you take up *X*, you will increase your risk of *Y* by 10%" is an example of an additive model of risk. In contrast, multiplicative models represent the changes in risk as a proportion of the baseline risk. The statement "If you take up *X*, you will double your risk of *Y*" is an example of a multiplicative model of disease risk.

The distinction between additive and multiplicative models becomes especially important when considering the effect of multiple risk factors. For instance, consider the situation described in Table 1.

Table 1 Disease Incidence per 100,000

	No Exposure A	*Has Exposure A*
No Exposure B	10	20
Has Exposure B	30	?

The incidence of disease we expect to see in those with exposure to both A and B differs depending on whether we take a multiplicative or additive approach to disease risk. Under the additive model, we would expect to see 40 cases per 100,000 in those with both exposures, since exposure A increases incidence by 10 per 100,000, exposure B increases incidence by 20 per 100,000, and the baseline rate is 10 per 100,000 $(10 + 10 + 20 = 40)$. Under the multiplicative model, we expect to see 60 cases per 100,000 in the group with both exposures, since exposure A doubles the incidence, exposure B triples the incidence, and the baseline incidence is 10 per 100,000 $(10 \times 2 \times 3 = 60)$. When the observed incidence or risk of disease in people with multiple exposures differs from what is expected based on the model being used (whether additive or multiplicative), there is said to be *interaction* or *effect modification* between the exposures on that scale.

In the analysis of epidemiologic data, the choice of an additive or multiplicative model determines the type of regression analysis performed and the risk measures that will be reported. If an investigator is modeling risk as additive, he or she will generally use linear regression and report risk differences. An investigator who is modeling risk on a multiplicative scale will generally perform a logistic regression and report a relative risk or odds ratio. Epidemiologic investigations that are concerned with disease etiology usually use multiplicative models, while those focused on public health impact are more likely to use an additive risk model.

Administrative Data

Administrative data are collected by organizations and agencies expressly for the purpose of conducting administrative tasks and meeting administrative responsibilities for that organization or agency (e.g., evaluate program performance, agency accountability). These tasks and responsibilities may include contacting individuals within the system, tracking resource utilization, reporting counts to an oversight agency, and projecting trends for resource allocation. Examples of administrative data sources include health maintenance organizations, Medicare and Medicaid programs, vital records administrations, school health systems, hospitals, and

health insurance providers. Although administrative data are collected through a system designed for nonresearch purposes, they can be very useful in epidemiologic research and have been used extensively for this purpose. There are, however, limitations to using administrative data in epidemiologic studies.

The most apparent advantage of administrative data is their availability. Abstracting medical records or conducting surveys to collect the same data in a comparable sample size may not be possible due to time and financial constraints. Administrative data sets often contain records spanning decades. Such data are gathered prospectively by the organization or agency and, therefore, can then become a source for nonconcurrent prospective investigations by the epidemiologist. Access to these data is also relatively easy, since most administrative systems are now computerized and data can be transferred onto electronic media for sharing. Administrative data generally are not for public use and require a research proposal submitted to the agency or organization that collects and oversees use of the data, and sometimes a fee is associated with requests. Administrative databases also tend to be relatively large, allowing for subgroup analysis by various factors such as geographic subdivision, gender, ethnicity, and age. The size of a data set is due mainly to the inclusiveness of the administrative records—everyone in the system is included in an administrative data set. This inclusiveness is another advantage of administrative data as it minimizes the prospect of selection bias.

Although there are no data collection or data entry costs associated with administrative data, data cleaning can still be a time-consuming task on a very large administrative data set. In addition, an administrative data set will seldom have all the data elements needed for a specific epidemiologic study, raising concerns over residual confounding, and variables often need to be recoded. Another disadvantage can be the presence of missing data on key items, although this varies by data source. Finally, as most administrative data sets are not population based, study results from analyses of administrative data may not be generalizable to the larger population or community.

An archetypical example of a population-based administrative data resource that is commonly used in perinatal and pediatric epidemiology is state or provincial birth records. In addition to being able to identify and select a cohort from birth records, birth certificates have a variety of data elements that can be useful in studies of adverse neonatal and childhood outcomes. The content of birth records varies by state or province but usually includes the essential elements of name, date and time of birth, sex, race, parents' names, and place of birth. Some will also include birthweight, gestational age, and age, occupation, and race of the parents. Most epidemiologic studies using birth records for secondary data analysis are cross-sectional or case-control in design. Some have linked birth records of siblings to prospectively examine birth outcomes that may be associated with a previous adverse birth outcome, such as low birthweight. The quality and completeness of data items included on birth records are known to vary widely.

Hospital discharge data are another commonly used administrative data source in epidemiology. Hospital discharge data can be obtained on multiple levels of geographic area, from local hospitals to nationwide data sets. Researchers can work directly with specific hospitals to ascertain discharge records, and discharge data are available from state government agencies as well as the U.S. Agency for Healthcare Research and Quality. For example, the California Office of Statewide Health Planning and Development offers hospital discharge data for purchase by qualified researchers. Nearly every state in the United States has a system of collecting hospital discharge data, although there is a wide range in the data elements that are included and the quality of the data sets (as with birth records), and differences among states in whether reporting is voluntary or mandatory and their policies for making the data available to researchers.

Administrative data sets are sometimes combined with other data sets to allow more specific research questions to be examined. An example of a combined data set that is available to researchers is the SEER-Medicare Linked Database, created by linking the Surveillance, Epidemiology, and End Results (SEER) cancer surveillance data set with Medicare records. The SEER network covers approximately 26% of the U.S. population, while the federally funded Medicare program provides health insurance for the elderly (65 and above) and individuals with end-stage renal disease and certain disabilities. The linkage of SEER and Medicare records started in 1986 and has created a database that includes more than 2.4 million people with cancer for whom Medicare health care claims records are available.

African American Health Issues

Measures of health status highlight disparities in the health of African Americans compared with other racial and ethnic groups in the United States. African Americans are more likely to self-report that their health is fair or poor, and a higher occurrence of many health problems is reported among both lower- and higher-income African Americans. Statistics suggest that the situation is more critical for African American men. This entry provides an overview of the health status of African Americans, describes the nature of the health disparities observed, and discusses the factors most frequently associated with disparities in health outcomes.

African or Black Americans are the descendants of any of the black racial groups of Africa. In the United States, this group includes the descendants of African slaves who have lived here for generations, as well as recent immigrants from Africa, the Caribbean, and other countries. African Americans are currently the third largest ethnic group in the United States, with a population of 36.4 million or 12.9% of the total population. Of the total population, on the 2000 U.S. Census, 12.3% reported Black or African American as their only race. The remaining population, or 0.6%, reported this racial classification in combination with one or more races.

Overall Health Status

As is true of health in the United States in general, African American health has improved. In 2004, consistent with the trend for all subgroups, African American life expectancy reached a record high. Life expectancy at birth was 73.1 years compared with 78.3 for whites and 77.8 for all races combined. African American men have a lower life expectancy than men of other racial and ethnic groups and African American women (see Table 1). However, it is important to note that these statistics represent a narrowing of the black-white life expectancy gap.

Continuing the trend toward improved health, between 2003 and 2004 African Americans showed significant decreases in age-adjusted death rate. The relative magnitudes of these decreases were 3.7% for non-Hispanic African American men and 3.4% for women. The age-adjusted death rate for African Americans was higher than that of the general population, with African American men experiencing the highest rate among all racial and gender groups.

On one of the most sensitive indices of health status, infant mortality rate, African Americans have a rate that is approximately twice that of the general population. Maternal death also occurs at higher rates. African American elders also experience higher morbidity and mortality rates compared with the general population. Also, while unintended pregnancy rates in the United States have been declining, low-income African American women continue to have one of the highest rates.

In 2003, the 10 leading causes of death for African Americans were (in order) heart disease, cancer, stroke, diabetes, accidents and unintentional injuries, assault/homicide, kidney disease, respiratory disease, human immunodeficiency virus (HIV), and septicemia (bacteria in the blood). The top 3 causes of death are similar to those found in the general population, although the mortality rates observed among African Americans are higher. The most significant departures from the general population are deaths due to homicide and HIV. Despite a downward trend, homicide is still the leading cause of death among African American males 15 to 24 years of age. In a change from 2001 and 2002 data, kidney disease accounted for more deaths than HIV.

Table 1 African American Comparative Health Statistics

	All Races		*White*		*African American*	
Measure	*Male*	*Female*	*Male*	*Female*	*Male*	*Female*
Life expectancy at birth, 2004	75.2	80.4	75.7	80.8	69.5	76.3
Age-adjusted death rate per 100,000, 2004	955.7	679.2	936.9	666.9	1269.4	855.3
Adult smoking, 2002–2004	23.8	19.4	23.8	20.2	25.1	17.7
% Adult overweight, 1999–2002	68.8	61.6	69.4	57.2	62.6	77.1
% Adult obese, 1999–2002	27.5	33.2	28.0	30.7	27.8	48.8

Measure	*All Races*	*White*	*African American*
Adult age-adjusted percentage distribution: never exercised, 2005	61.3	57.2 61.3	65.7 76.6
10–14 years: birth rates per 1,000, 2004	0.7	0.2	1.6
15–19 years: birth rates per 1,000, 2004	41.1	26.7	63.1
Infant mortality rate, 2001–2003	6.79	5.66	13.6
Maternal mortality rate, 2002	7.6	4.8	22.9

Sources: National Center for Health Statistics, (2006) *Health, United States, 2006, With Chartbook on Trends in the Health of Americans*), Tables 19, 27, 35, and 43; Martin, J. A., Hamilton, B. E., Sutton, P. D., Ventura, S. Although African Americans are approximately 13% of the population, they currently account for the majority of new HIV infections in America. In addition, diseases such as asthma are higher among African American children and adults.

As is true in the general population, most causes of death have been declining among African American elders. However, lung cancer and deaths from other lung diseases have increased among older African American men and women. There has also been an increase in mortality associated with hypertension. The leading causes of death among African Americans aged 65 years and above are heart disease, cancer, stroke, diabetes, and pneumonia/influenza. The first four causes of death among African American elders are the same as those generally found in the African American population, and the top three causes of death are the same for elders of all ethnic groups. However, diabetes is a more common cause of death among African American elders than in other ethnic groups with the exception of American Indians.

Health behaviors also play a role in overall health. African Americans are more likely to have lower rates on positive and higher rates on negative health indicators. Among African Americans, mean fruit and vegetable intake was 3.7 servings per day, with only 23.7% of African American adults reporting that they ate three or more vegetables and 35.1% reporting eating two or more fruits per day. African Americans often report that they lack a usual source of care and are less likely to have a yearly dental exam. The trend toward increasing obesity is greater among African American adult females, with a 77.3% prevalence of overweight and obesity. African Americans tend to live in environments with poorer housing quality and disproportionately live in areas where the air contains one or more commonly found air pollutants, including ozone. Children from low-income groups and African American children are also at increased risk of lead poisoning.

Health Disparities

Definitions differ, but in general, the term *health disparities* refers to differences in a population's health status that are not based on biology and that are assumed to be related to differences in social status, including education, income, and access to care. Despite improvements in health care and access, African Americans have mortality rates that are higher than those of whites, and they have the highest rates of morbidity and mortality of any U.S. racial and ethnic group. According to the National Center for Health Statistics, the rate of diabetes among African Americans is greater than that found among whites, and heart disease is more than 30% higher. African Americans tend to have the highest rate of high blood pressure of all groups and tend to develop it younger than others. African Americans have higher rates of diabetes-related complications, such as kidney disease and amputations. Furthermore, the incidence of stroke is disproportionately high among African Americans and the mortality rate is higher than among whites. Age-adjusted death rates from asthma are higher among African Americans. African Americans and Hispanics have higher rates of sexually transmitted diseases than whites.

The poorer health status of African American men is well documented. Watkins indicated that African American men have a lower life expectancy than men in Bangladesh, Iran, Colombia, and Sri Lanka. African American men have a higher incidence of type 2 diabetes, are more likely to die from heart disease, have eight times the AIDS rate, and are nine times more likely to die of AIDS than white males. According to Ward et al., among all racial and ethnic groups, African American men had the highest cancer incidence and mortality rates for all sites combined. African American men had higher incidence and mortality rates for prostate, lung, colorectal, and other specific cancers.

Among African Americans, disparities also exist in the rates on several of the leading health indicators. For example, diets high in fat and calories and low in fruits, vegetables, and fiber, and physical inactivity increase the risk of diabetes, hypertension, heart disease, and cancer. Compared with whites, African Americans consume higher amounts of dietary fat and lower amounts of fruits, vegetables, and dietary fiber and are more likely to report no leisure-time physical activity. According to data from the National Health and Nutrition Examination Survey, overweight is more prevalent among African Americans than non-Hispanic whites. More African American girls aged 6 to 19 were considered overweight compared with white children of the same age. In contrast, the rate of overweight among non-Hispanic white and African American males between ages 6 and 19 is similar.

In addition, African American women are less likely to receive prenatal care in the first trimester of a pregnancy. The gap in vaccination rates among African American and white children has widened and fewer African American children are fully vaccinated.

Factors Associated With African American Health Disparity

While we cannot pinpoint the specific causes of health disparity for specific diseases among members of particular social categories, we can say that race, class, and gender do not in and of themselves produce health disparities. Disparities in African American health status are explained by a number of factors, including income, lack of education, unemployment, differences in lifestyles and health behaviors, differences in environmental and occupational risks and hazards, nutrition, and cultural beliefs about health, as well as discrimination and access to health care. There is evidence that each of these factors plays a role in health disparities.

Studies by the Commonwealth Fund indicate that Hispanic and African American working-age adults have lower access to health care and a higher probability of facing medical debt than white working-age adults. The rate of uninsured African Americans is higher than that of whites but lower than that of Hispanics. Individuals without insurance are more likely to delay care and screenings, less likely to obtain needed medications, and more likely to be diagnosed at later stages of illness. These patterns of access and use of health care are associated with increased morbidity and mortality from disease.

African Americans are less likely to report that they have seen a physician in the previous year. Data indicate that African American adults are more likely to visit an emergency room for a condition that could have been treated by a doctor in an office setting if routine health care were available. In addition, African Americans are less likely to receive preventive health screenings and immunizations. For example, African American and Hispanics are less likely than

whites to receive influenza or pneumonia vaccines and rates of cholesterol and blood pressure screenings are also lower. Studies suggest that African American youth are more likely to eat fast food, which may include more calorie-laden options, as well as watch more television than white children, which is associated with reduced rates of physical activity.

Targeted health promotion campaigns have resulted in positive trends in cancer-screening behavior. For instance, African American women's use of mammography and cervical-screening procedures and the rates of colorectal cancer screening have increased, and their screening rates are now similar to those of whites. African American youth are less likely to smoke than youth of other ethnic populations, and African American men between the ages of 18 and 24 are less likely than white men to be current smokers.

According to the U.S. Census Bureau, approximately 25% of African Americans lived in poverty in 2005, and unemployment is high in the African American community. Even better-off African Americans are often the first generation in their family to achieve middle-class status and are likely to lack the wealth accumulated by white families of similar economic status, meaning they have fewer economic resources to access during an extended illness or health care crisis. And while rates of high school graduation and college completion have increased, African Americans continue to be less well educated than whites. Because of decreased educational levels and personal resources, the awareness of health problems, knowledge of causes and risk factors, and capacity to access medical care may be greatly decreased. Low income and lack of education are associated with increased morbidity and mortality from disease, increased obesity, decreased physical activity, lack of insurance and health care access, and low rates of physical activity.

Studies indicate that the socioeconomic explanation of disparities is limited. Even when income and education are controlled, African Americans and other minorities are more likely to receive care in the lowest-quality facilities with the least likelihood of appropriate follow-up and have more difficulty than majority group members in locating a usual source of care. Similarly, African Americans are more likely to be hospitalized for asthma regardless of income level, and maternal mortality is higher at both lower and upper educational levels.

Discrimination may affect disparities through the historical existence of social inequity and injustice in American education, justice, and economic structures and the disadvantages that have accrued to African Americans based on these differences. In addition, discrimination may influence disparities through the biases of health care institutions and providers. It has been suggested that providers may offer less intensive and sophisticated treatment options to African American patients due to stereotyped beliefs about ability to pay and willingness or ability to engage in and/or accept these services. These biases have been most clearly observed and documented for cardiac care.

Lack of information may be another important factor in African American health disparities. Among African Americans seeking health information, primary care physicians and other professional medical personnel are often perceived as the most credible information sources. However, many African Americans do not maintain an ongoing relationship with a primary care physician. Thus, there may be limited knowledge of risks. For example, surveys have found that African Americans are often unaware of the risk factors associated with diseases and their own personal risk.

Culture can affect health attitudes and behaviors, and it has been argued that African Americans are a population for whom culture might be relevant. Differences in beliefs about the nature and cause of disease, appropriate treatment, and who should provide treatment may influence the rate at which members of different groups access and adhere to treatment, as well as the extent to which they accept and participate in health preventive behaviors. For example, the acceptance of larger body sizes may affect African American concern over the increasing rate of obesity in the population, and traditional foods may contribute to a diet higher in fat. Male gender-role norms may influence the negotiation of condom use among African American men and women.

Culture also affects the interpretation of communications between patient and provider. Recognition of and respect for the communication preferences and patterns of African Americans may improve provider-patient communication. Culturally sensitive care requires that the health care provider adjust to the special needs and circumstances of the patient. In the case of African Americans, this may mean adjusting assessment to accommodate the varying skin tones noted among

African Americans or particular attention to the need to convey respect in interactions.

Agent Orange

Agent Orange is a herbicide used by American forces during the Vietnam conflict to remove leaves and other plant life that provided cover to enemy forces. It is a formulation of the two commercially available and widely used herbicides: 2,4-dichlorophenoxy acetic acid (2,4-D) and 2,4,5-trichlorophenoxy acetic acid (2,4,5-T). Before the Vietnam conflict, commercial mixtures of the two herbicides were routinely used worldwide in rangeland, rights-of-way, and forest management programs. During the Vietnam War, the 50:50 mixture of esters of the herbicides was applied in jungle areas to clear vegetation and expose enemy infiltration routes, base camps, and weapons placements, and to clear vegetation from the perimeters of friendly military bases and along lines of communication. The objective of the herbicide spraying program was to defoliate thick jungles that provided cover and concealment for the enemy, who would engage in ambushes and other disruptive tactics. During the period from 1965 to 1970, the U.S. Air Force applied more than 44 million liters of Agent Orange in South Vietnam. In 1969, the contaminant 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD or dioxin) in the 2,4,5-T herbicide was found to be teratogenic (causing birth defects) in laboratory animals, and in April 1970, the U.S. Department of Defense terminated all uses of Agent Orange in Vietnam. Although exposure to Agent Orange was once considered to be the cause of a variety of physical and emotional problems suffered by American veterans and Vietnamese people exposed to Agent Orange, independent studies have not documented any association between Agent Orange exposure and the health conditions claimed to have been caused by it.

Veterans Health Concerns

Hundreds of studies have been conducted of groups exposed to TCDD and/or the phenoxy herbicides 2,4-D and 2,4,5-T, either in the production of the herbicides or as end users in agriculture or forestry. In addition, the U.S. Air Force and the Departments of Veterans Affairs (DVA) in the United States and Australia have conducted studies of Vietnam veterans. These studies include the Air Force Health Study of the men who sprayed the herbicide from fixed-wing aircraft in Vietnam (commonly referred to as "Ranch Hand" personnel after the Air Force Operation Ranch Hand); the DVA study of personnel who served in the U.S. Army Chemical Corps and sprayed herbicide on base perimeters using helicopters and ground equipment; and the Veteran Studies by the Centers for Disease Control and Prevention (CDC). The results of these long-term epidemiologic studies of Vietnam

veterans have consistently shown few, if any, health effects that were not also seen in veterans who did not serve in Vietnam, or in those who were not affiliated with defoliation programs in Vietnam. Moreover, no chloracne, the hallmark of substantial dioxin exposure, was identified in any of the veteran studies.

The Agent Orange Act of 1991

After many years of denials of benefits to Vietnam veterans for lack of evidence that the diseases claimed had been caused by exposure to Agent Orange, Congress passed, and the president signed, the Agent Orange Act of 1991, Public Law 102–4.

There is no test that can show if a veteran's health problems were caused by Agent Orange or other herbicides used in Vietnam, and thus, by law, the Veterans Administration must presume that all Vietnam veterans were exposed to Agent Orange.

Consequently, the Agent Orange Act of 1991 allows benefits to be awarded based on presumptions of exposure and diagnosis with a disease based on an ''association'' with Agent Orange, so that proof of medical causation is not required. Congress provided for a series of reports of the scientific literature by the National Academy of Sciences' Institute of Medicine (IOM) applying the statutory ''association'' standard to assist the Department of Veterans Affairs in establishing by regulation a list of diseases for which Agent Orange benefits would be paid. The IOM was directed by Congress to shift the burden of proof away from veterans, and the IOM reports clearly identify their findings as associations that do not amount to a causal association. In fact, most of the evidence considered by the IOM as providing a basis for an association is not present in most veterans' cases. In accordance with the IOM findings, the following health conditions are presumptively recognized by DVA for service connection, meaning that their occurrence in a Vietnam veteran is presumed to have been caused by Agent Orange:

- Chloracne (must have occurred within 1 year of exposure to Agent Orange)
- Non-Hodgkin's lymphoma
- Soft tissue sarcoma (other than osteosarcoma, chondrosarcoma, Kaposi's sarcoma, or mesothelioma)
- Hodgkin's disease
- Respiratory cancers, including cancers of the lung, larynx, trachea, and bronchus
- Prostate cancer
- Acute and subacute transient peripheral neuropathy (must have occurred with 1 year of exposure and resolved within 2 years of date of onset)
- Type 2 diabetes, *Diabetes mellitus*
- Chronic lymphocytic leukemia

In addition, spina bifida (except spina bifida occulta) is recognized for presumptive compensation in children of Vietnam veterans.

The Scientific Evidence: TCDD Levels in Vietnam Veterans

Notwithstanding the major epidemiologic studies of Vietnam veterans and Agent Orange over the years, the highly relevant data for the important questions of exposure and actual absorbed dose have not been sufficiently appreciated in the literature. The development of increasingly sophisticated methods for biomonitoring low levels of chemicals in human tissues is regarded as one of the premier achievements of environmental science. Beginning in 1986, the CDC collected serum TCDD in a group of 646 U.S. Army veterans who served as ground troops in the regions of Vietnam most heavily sprayed with Agent Orange and also from 97 veterans who had not served in Vietnam. The distributions of TCDD levels were ''nearly identical'' in the two groups, both having means and medians that were well within the range of background levels at that time; that is, the levels were those that everyone had as a result of small amounts of TCDD principally ingested from food.

The CDC study had a statistical power of 99% to detect differences, even if only a moderate proportion of Vietnam veterans had elevated TCDD levels while they were in Vietnam. Neither military and spraying records nor self-reported history of exposure could reliably identify either high- or low-exposure groups. The investigators concluded that most U.S. Army ground troops were likely not exposed to any detectable levels of TCDD.

About 1,200 U.S. Air Force personnel directly handled Agent Orange in support of Operation Ranch Hand, the aerial spraying of herbicides in Vietnam from Air Force planes during the period from 1962 to 1971, and another 1,000 men in the Army Chemical Corps were responsible for spraying the perimeter of bases in Vietnam. Serum TCDD levels confirmed that these individuals had measurable exposure and

that their exposure was often heavy. Yet the long-term epidemiologic studies of these men, when compared with their matched comparisons, do not indicate any major differences in health status.

The Air Force Health Study's results concerning Ranch Hand are particularly informative as to possible health effects of Agent Orange, because the study design incorporated a comparison group of military aircrews with similar duties operating similar types of aircraft in Vietnam and surrounding countries, whose planes were engaged in transporting cargo rather than spraying Agent Orange. Thus, researchers were able to control for other possible confounding causes of disease in Vietnam veterans more effectively than the other major studies.

Aging, Epidemiology of

The epidemiologic study of older people in the community has been pursued for many years. Although there is probably nothing unique about the application of epidemiologic methods to older populations, there are many important differences and special issues that merit separate consideration. Vital records, census counts, and demographic studies have documented the increased longevity of populations in nearly all developed countries over the past half century and the growth of the numbers of older persons. The increase in older populations has led to new opportunities for more detailed exploration of health and disease occurrence, risk factors for morbidity and mortality, and health outcomes. The growth in numbers of older persons has also caused a public health mandate for improved surveillance and control of important conditions in those populations, both in the community and in institutional settings. This entry examines differences between epidemiologic studies of older adults compared with other age groups. It also discusses issues in conducting population surveys among older persons.

There are a number of general differences in the epidemiologic study of older populations from young and middle-aged groups, including differences in the clinical manifestations of disease and conditions among older persons, alterations in medical practice, and variations of the "natural history" trajectories and outcomes. As a generalization, diseases that occur in young and middle-aged persons are single entities and have few complicating secondary conditions, at least early in their history. The natural conditions occurring in youth and middle age tend to have more genetic influence. Noninvolved bodily systems tend to be generally intact, and most treatments relate to the primary condition. Social support systems for coping with these conditions are more often well developed. In contrast, health and disease states among older people differ in many ways.

1. *Multiple, Simultaneous Health Conditions (Comorbidity).* The presence of multiple health conditions and physiological dysfunctions is the rule in older people, whether an acute or severe disease is present or not. This necessitates that epidemiologic assessment of older people contain detailed information on a wide range of organ systems. Otherwise, many will not be detected. Having one condition may lead to increased medical surveillance for other conditions ("detection bias"), thus altering the natural history of the latter condition. Also, the presence of comorbidity requires that studies of disease causation consider how the conditions other than the one of primary interest affect the risk factors. For example, if

one is exploring the role of tobacco use in Condition X, it is important to know if comorbid Condition Y, which may have clinically emerged earlier, had an effect on smoking habits.

2. *Increased Prevalence of Common Clinical Signs and Symptoms.* Surveys of older persons reveal that prevalence rates for common clinical signs and symptoms are higher than in younger populations, having several implications for understanding health status. First, even if there is no obvious major acute or chronic illness present, these clinical phenomena may negatively affect personal comfort and function. Pain syndromes are notoriously present at high rates and have important consequences. Chronic leg cramps is an important, if less well-studied, example. Another implication of common signs and symptoms is that there may be a loss of diagnostic specificity. For example, if dry and itching skin is a potential indicator of clinical or subclinical hypothyroidism, possibly leading to a diagnostic inquiry, a prevalence rate of 40% among older persons may preclude those skin symptoms as potential diagnostic indicators, because relevant thyroid conditions are much less common. This then becomes a challenge for the clinician and the epidemiologist, because there may be less intense diagnostic activity for thyroid disease.

3. *Atypical or Delayed Clinical Presentations of Many Conditions.* In older persons, for reasons that are only partly understood, certain diseases may present clinically in different ways among elders than in other age groups. An important example is the presentation of myocardial infarction (MI), which may be more clinically "silent" among older persons—that is, it may occur without classical signs of chest pain and related symptoms. This is known from the coincidental detection of MIs in clinical settings and from serial electrocardiographic studies of older community populations. Thus, determining the frequency of MI in population surveys, based on a physician's report to a survey respondent ("Has a doctor ever told you that you have ...?"), may disproportionately underestimate the burden of this condition among older persons, as well as fail to appreciate alterations in the manifestations of coronary disease in general.

Another important alteration in the way a disease may present is the case of acute infections. It has been reported classically that among the oldest old, pneumonia may not present in the usual manner of typical symptoms such as cough, expectoration, fever, and malaise. Rather, elders may present later than usual and with atypical problems such as confusion or falling. This is important to the accurate surveillance of such infections, particularly nosocomial pneumonia, among institutionalized patients. The altered clinical presentation of pneumonia among this age group has been attributed in part to comorbid dementia (see below), but the principal problem remains.

4. *An Altered Ability to Acquire Clinical Information.* In population epidemiology, the designation of a case of a particular disease or condition is rarely determined by extensive or elaborate testing procedures in the field. Rather, such designations usually depend on report and documentation of standard diagnostic practices within the health care system. Thus, ostensible disease rates will vary according to access to and utilization of health care and the diagnostic practices of individual health professionals. However, as suggested above, usual diagnostic and therapeutic processes may be especially challenging for older persons. Increased rates of cognitive impairment, as well as sensory impairments (particularly decreased hearing and vision), may impede the ability to take a full medical history, explain illnesses, and invoke optimal self-care. Some of this may be appropriately alleviated by caregivers, but such persons may not always be available. Such impediments to the clinical process may alter diagnostic and therapeutic outcomes, and thus spuriously alter estimates of diseases and conditions in population studies.

5. *Altered Variation in Physiological and Biochemical Measures.* Part of the diagnostic process, in addition to medical histories and physical examinations, depends on laboratory determinations, such as blood cholesterol or hemoglobin levels, and physiological measures, such as blood pressure and electrocardiograms. However, an important issue for such applications among older persons is that the "normal" ranges of these measures may be different from those in middle age. This highlights the question of what is "normal" and whether changes in the distributions of these measures represent "normal" aging or subclinical diseases, or even differences in environmental exposures, such as diet or sunlight. An important example is the change in diastolic blood pressure (DBP) with age; population DBP increases until around age 70 and then decreases back toward the normal range. But this may be due to arterial stiffening, which may have its own adverse effects and is not a return to decreased risk. The conundrum of what is normal, biologically

obligate aging versus disease makes designation of normal ranges of laboratory determinations for older persons a difficult and philosophical issue of great import, and demands careful consideration of what clinical questions are being addressed by the test. As in other parts of the basic diagnostic processes, this problem may lead to variation in disease designation and alter the epidemiology of the conditions at hand for definitional reasons.

6. *Increased Vulnerability to Environmental Challenges and Threats.* Whatever the conceptual challenges of defining normal aging versus disease, older persons clearly have a lesser capacity for homeostasis, the ability to return to the normal or previous physiological state after an important environmental challenge. For example, death rates are increased among elders when extremes of heat and cold temperatures occur, as well as in some acute infections or even adverse social occurrences. These challenges will change morbidity and mortality patterns and the relative contributions of the risk factors responsible for them.

7. *Increased Emphasis on Characterization of Functional Status.* One of the great contributions of geriatrics and clinical gerontology has been to incorporate and refine measures of human function, including social, physical, cognitive, and mental, into clinical and epidemiologic lore. This better helps describe and characterize how individuals fare in their social and physical environments. Summaries of these measures across individuals allow further characterization of the functional status of older persons, and hence levels of disability and dependence, in variously defined groups, including those that are geographically referent. Measures such as activities of daily living, instrumental activities of daily living, and mobility have added greatly to the understanding of population health states.

From a clinical perspective, functional characterization of individuals allows increased accuracy of clinical trajectories and outcomes, as well as more precise determination of the type and extent of intervention regimens and programs. From a community and public health perspective, incorporating measures and interventions of social function can improve both health status and quality of life. Epidemiologists are particularly interested in causative factors for ill health, and despite the many successful applications of function status measures in general, they present a problem for etiologic research. This is because functional impairments or decrements are complex syndromes that are multicausal and not single biological entities. Thus, finding the "causes" of dysfunction can be challenging without the specificity that comes with studying individual illnesses.

8. *Altered Medical Care.* Many of the categories noted above have discussed forces that alter medical practice and thus the designation of disease status among older persons. There are additional factors that frequently occur among older persons that alter diagnosis and treatment. One is that many drugs are metabolized differently in older persons, and thus, the therapeutic process on balance may be altered in ways not fully characterized. Another dimension of many comorbid conditions is that health practitioners may understandably prioritize the conditions to be addressed at any one confrontation and devote the most time to those that are most severe or immediate. This too will change the natural history of some medical conditions. Because of substantial comorbidity, older persons may receive care from many different practitioners and health care venues, and thus, coordination and thorough documentation of all relevant clinical activities is a challenge to both medical care and epidemiologic characterization. Elders also spend more time residing in institutions, and with this may come greater exposure to nosocomially generated conditions. This can add to elder morbidity and mortality. Finally, there are many ethical and moral issues tied to geriatric care, each potentially altering the nature history of conditions and their outcomes.

9. *Altered Clinical Outcomes.* While not universal, older persons may have worse clinical outcomes than middle-aged persons presenting with various medical conditions at a similar stage. This has been particularly studied for many cancers and various heart diseases. There may be many reasons for this, including those cited above. Comorbidity, including age-related degenerative conditions and accompanying frailty, poly-pharmacy, and altered medical care approaches may be among the important reasons. These altered outcomes, however mutable, lead, ceteris paribus, to altered prevalence rates of diseases and possibly to different approaches to community disease control. Age-related alterations in disease outcomes may also necessitate age-specific benchmarking when comparing health care outcomes among institutions and when creating quality-of-care standards.

10. *A General Absence of Scientific Studies With Which to Guide Clinical and Public Health Interventions.* Older persons are less likely to participate in clinical and population research studies, and for a variety of historical reasons, many studies in prevention and treatment did not include many persons above the age of 70 years. Thus, the scientific basis for clinical and public policy among older persons is much less secure, and it is one of the frontiers of epidemiologic research.

Population Survey Research on Older Populations

Conducting surveys in communities to ascertain health states and their causes, as well as community needs and policy directions, requires special consideration and preparation. The following is a brief review of selected issues. Challenges in sampling older populations begin with deciding whether those in institutional or quasi-institutional settings are part of the target. In the United States, about 5% of persons live in long-term care settings, and many are disabled. Access to these settings for epidemiologic study may be difficult. Similarly, access to retirement or assisted living communities may require special techniques and resources beyond what is normally available.

Even when conducting interviews and related data collection activities in usual community settings, there are special problems. In general, community participation rates for epidemiologic studies decrease with increasing age; enhancing completeness of data collection often requires the use of surrogate respondents. Increased levels of disease and disability with increasing age lead to reluctance or inability to participate, only partly offset by the greater likelihood that these individuals may be more likely to be at home. Elders may be more embarrassed by their appearance or that of their households because of disabilities, further deterring participation. Elders with substantial illnesses are more likely to have caregivers and gatekeepers who may (appropriately) deny access, leading to the higher rates of proxy interviews and data collection with increasing age. Increasing rates of cognitive impairment among older respondents may decrease the quality of the information collected from such respondents and, equally important, raise issues on the ability of such persons to provide informed consent. This latter issue needs to be clarified with institutional review boards before embarking on data collection.

Consideration of the mode of data collection for older persons is important. Having increased levels of sensory or cognitive impairment may deter various types of data collection and increase the possibility that the collection activity will be assisted by others; this would be true of mailed questionnaires as well as telephone and personal interviews. Older people are increasingly likely to have access to computers and the Internet, and data collection by this means is increasingly feasible. However, such access rates are still lower than those for young and middle-aged adults, necessitating consideration of mixed-mode approaches. In telephone and personal interviews, attention to ability to hear and see collection materials, the possibility of fatigue, and disruptions due to illnesses or caregiving chores by the respondent are important. In the general interview setting, item nonresponse is generally not different from that in surveys of other age groups. However, the increased utilization of brief cognitive testing in surveys may cause some increased resistance compared with other health-related items.

Alcohol Use

Beverage alcohol results from fermentation of substances containing simple sugars and is catalyzed by yeast. Given that substances containing sugar and yeast occur widely in nature, alcohol was "discovered" early and often in the development of civilization. The intoxicating properties of alcohol have contributed to its widespread use, as have its medicinal properties. However, alcohol is one of few substances voluntarily consumed in amounts approaching those causing coma and death. Acute overconsumption can lead to unintentional alcohol poisoning and increase the likelihood of accidental injuries. Chronic overconsumption can cause social, legal, and medical problems, including psychiatric disorders. Thus, misuse of alcohol represents substantial suffering by individuals and a major societal burden. This entry reviews the epidemiology of alcohol use, alcohol problems, alcohol abuse and dependence, and alcohol-related health consequences.

Physiological Properties of Alcohol

Alcohol is rapidly absorbed from the gastrointestinal tract, enters the bloodstream, and is distributed in the body water compartment. Most alcohol is metabolized to acetaldehyde by alcohol dehydrogenase in the liver. However, chronic heavy drinking may induce added metabolic capacity by the microsomal ethanol-oxidizing system, an enzyme sited predominantly within hepatocyte microsomes that degrades a number of drugs. Acetaldehyde, 100 times more toxic than alcohol, is rapidly metabolized by acetaldehyde dehydrogenase to water and carbon dioxide in most people, but it may accumulate in those who have inherited a less efficient form of acetaldehyde dehydrogenase, giving rise to a dysphoric "flushing syndrome" most prevalent in Asians and often associated with abstention and light drinking patterns.

In general, alcohol has a biphasic effect on mood. As it is absorbed from the gastrointestinal tract, rising blood alcohol levels (BALs) are usually associated with elevated mood. In contrast, as alcohol is metabolized and BALs fall, people are more likely to feel dysphoric and, in some cases, drink more, seeking to regain initial feelings of well-being. Within these broad parameters, there is substantial individual variability in response to alcohol. Studies of subjective response to alcohol indicate that nonalcoholic sons of alcoholics are less affected by a given alcohol dose than nonalcoholic sons of nonalcoholics. Paradoxically, innate tolerance (experiencing fewer effects during initial drinking) appears to be a risk factor for developing alcohol dependence.

Monitoring Alcohol Use

Per capita alcohol consumption, based on alcohol sales and census data, is a standard ecological measure of alcohol use. It provides both cross-jurisdictional (across states and nations) and cross-time-series data for epidemiologic studies of alcohol's impact on rates of morbidity and mortality. Efforts to improve state-specific estimates in the United States include adjusting for abstention rates and taking into consideration the ethanol content of specific beverage types and their market shares in each state.

National surveys dating from the early 1940s provide individual-level data on alcohol use to complement ecological data, and the number, size, and sophistication of alcohol surveys have increased dramatically in recent decades. The National Institute on Alcohol Abuse and Alcoholism (NIAAA) was established in 1973 to lead national efforts to reduce alcohol-related problems. The Alcohol Research Group, an NIAAA Alcohol Research Center, has conducted periodic National Alcohol Surveys since 1964 at approximately 5-year intervals with standardized measures since 1979. Special Alcohol Supplements have been administered in conjunction with several National Health Information Surveys, and the National Health and Nutrition Examination Surveys also include questions on alcohol use. Similarly, questions on alcohol use are asked in the annual National Household Survey on Drug Abuse, sponsored by the National Institute on Drug Abuse. The largest U.S. alcohol surveys today are those conducted by NIAAA's intramural program—the National Longitudinal Alcohol Epidemiologic Survey and the National Epidemiologic Survey of Alcohol-Related Conditions.

Self-report measurement of consumption, though known to underreport alcohol sales, has been

improving with increased methodological rigor. The addition of questions on patterns of drinking providing information on heavy drinking episodes and assessing ethanol content of beverages consumed improves both coverage and estimates of alcohol exposure. Comparability of survey findings is hampered by variability in the measures employed, and relatively little information is available on lifetime patterns of alcohol use.

Factors Influencing Alcohol Use in the United States

Long-Term Trends

The use of alcohol over the past century has been characterized by oscillating secular trends characterized by increases in consumption until this produces negative consequences severe enough to precipitate a backlash in policy enactments and preventive measures that, it has been argued, lead to the subsequent periods of declining drinking. In the United States, an extreme example is the passage and ratification of the Prohibition Amendment, taking effect in January 1920. Although this greatly reduced consumption and alcohol-related problems such as cirrhosis mortality, alcoholic psychosis, and "drunk and disorderly" arrests, increases in criminal activity associated with the production and sale of illegal liquor and social discontent led to repeal in 1933. Per capita consumption increased in subsequent decades, particularly after the 1960s as postrepeal laws were eroded, reaching a peak of nearly three gallons of absolute alcohol per person aged above 14 by 1981.

In the 1980s, concern regarding drunk driving mobilized advocacy groups such as Mothers Against Drunk Driving and Students Against Drunk Driving. Effective campaigns for stronger penalties, more stringent law enforcement, and policies limiting youth access to alcohol followed. A result was federally enacted incentives leading all states to raise the legal drinking age to 21 years, and more recently to reduce the threshold defining driving while intoxicated to a uniform .08 BAC (blood alcohol content). By the late 1990s, per capita consumption reached a new nadir close to that seen in the 1950s, just above two gallons of alcohol. Since then it has been inching up again, starting an apparent new wave. Lifetime drinking patterns of birth cohorts are influenced by these secular fluctuations in the "wetness" or "dryness" of prevailing alcohol attitudes and policies.

Alcohol Use Over the Life Course

Most U.S. individuals who drink alcohol begin in adolescence or early adulthood. Among those who drink regularly, frequency of consumption tends to increase and quantity (i.e., drinks per drinking day) tends to decrease with age. Thus, drinking by older teens and young adults is often characterized by heavy episodic consumption. The overall amount of alcohol consumed, sometimes referred to as volume and expressed as average drinks per day, is often used to summarize measures of alcohol intake. However, it has the disadvantage of obscuring drinking patterns; for example, frequent heavy drinkers who have seven drinks per drinking day once a week have the same volume as moderate drinkers who have one drink per drinking day seven times a week. The importance of taking drinking patterns into account when assessing the consequences of alcohol use is being increasingly recognized. Such patterns can interfere with important developmental achievements and are associated with automobile crashes and other injuries. Although the majority "mature out" of risky drinking patterns as they take on adult social roles involving work and family responsibilities, others maintain or increase heavy intake, thus increasing their risk of social, legal, and work-related alcohol problems, as well as acute and chronic health problems. In addition to the typical moderation seen with aging (i.e., more frequent consumption of smaller quantities), abstention rates increase. Factors associated with these reductions in alcohol intake include age-related changes in body composition (i.e., greater percentages of body fat relative to body water, resulting in higher BALs associated with a given alcohol intake), increased use of medications that contraindicate alcohol use, chronic conditions that impair the ability to cope with alcohol effects, and fewer social opportunities for drinking. In addition, some people attempt to stop abusive use of alcohol as they get older.

In the United States, as in virtually all countries, men drink more than women and suffer more alcohol-related problems. However, women tend to be more vulnerable to alcohol effects, both socially,

because of gender-related stigmas regarding intoxication, and physiologically. In general, for a given alcohol intake, women achieve higher BALs than men but may offset this by tending to drink more slowly. Some metabolism of ethanol takes place in the gastrointestinal lining, preventing it from reaching the bloodstream, a process more efficient in men than women. More important, women tend to have smaller cellular water compartments in which to distribute the alcohol they absorb, both because they tend to be smaller and because of a higher percentage of body fat. Finally, there is some evidence to suggest that even when BALs are held constant, women may respond more strongly than men to alcohol.

Race and ethnicity play an important role in overall consumption and in the time course of drinking. African Americans, Asian Americans, and Hispanics have higher abstention rates (especially for women) than Caucasian counterparts. African Americans and Hispanics who do drink tend to drink more heavily and may less often reduce consumption in middle age, shifting upward the age distribution of alcohol problems. Certain American Indian and Alaska Native groups have extremely heavy and dependent drinking patterns, which seem to be influenced by genetic as well as current and historical environmental factors. As indicated earlier, Asian Americans may be partially protected by the flushing response. Although broad generalities are often made about drinking patterns of minority groups, these patterns vary markedly with sociodemographic characteristics, Indian tribal affiliation, and Hispanic and Asian country of origin, acculturation, and immigrant status.

Alcohol Use Around the World

In countries where wine is traditionally part of the diet (e.g., France and Italy), high cumulative alcohol intakes have been associated with high rates of chronic alcohol-related disease such as cirrhosis but with relatively low rates of social problems related to drinking. In contrast, Nordic drinking is characterized by heavy episodic drinking on weekends and festive occasions, relatively low total consumption, and high rates of acute problems such as injuries and violence. In Russia, lax controls over drinking and a tradition of drinking to excess led to a dramatic increase in alcohol-related mortality in the period after perestroika. Italy has reduced per capita consumption considerably in recent years, and today more young people are consuming beer, leading to some homogenization of European drinking cultures.

With the proliferation of "new" products as part of the global expansion of alcohol multinationals, there is concern about rising rates of alcohol use in developing countries. In general, consumption of traditional beverages, while often continuing, has been overlaid with heavily marketed manufactured products, mostly beer and spirits. Increasing heavy episodic drinking conjoined with economic development and burgeoning vehicular traffic has led to sharp increases in accidents and injuries.

Alcohol Misuse

Alcohol-Related Problems

The burden represented by chronic and acute health effects associated with alcohol abuse is roughly equivalent to the burden represented by social, mental, and emotional consequences. These include violence, vandalism, public disorder, interpersonal difficulties, financial and work-related problems, and reduced educational performance. In U.S. surveys, it has long been noted that higher problem rates are seen among drinkers who consume very large quantities fairly often (e.g., 12+ drinks on a single day, at least monthly) and those who engage in frequent heavy drinking (e.g., 5+ drinks on a single day, on a weekly basis).

According to the *USDA Dietary Guidelines for Americans 2005*, moderate drinking is defined as the consumption of up to one drink per day for women and up to two drinks per day for men. Twelve fluid ounces of regular beer, 5 fluid ounces of wine, or 1.5 fluid ounces of 80 proof distilled spirits count as one drink for purposes of explaining moderation. This definition of moderation is not intended as an average over several days but rather as the amount consumed on any single day. Although heavy drinkers have higher problem rates, the so-called moderate drinkers contribute most to the total number of alcohol problems because there are so many more of them. This has been termed *the prevention paradox* because prevention efforts targeting heavy drinkers may not have as great an impact on the overall

number of alcohol-related problems as interventions targeting moderate drinkers.

Alcohol Abuse and Dependence

Alcoholism was defined as a disease in the 1950s, having previously been thought of as a bad habit by many. Alcohol abuse and dependence are psychiatric disorders described in the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, published by the American Psychiatric Association in 2000. Impairment of self-control is still regarded as a key element of alcohol use disorders. In the psychiatric epidemiologic tradition, survey methods assess alcohol abuse and dependence using structured interviews. A classic example is the Diagnostic Interview Schedule, developed in the 1980s for use in the NIMH-sponsored Epidemiologic Catchments Area studies. It allowed lay interviewers to obtain measures of alcohol abuse and dependence. These surveys revealed that the general adult household population prevalence of meeting criteria for an alcohol disorder was vastly greater than the number in alcohol treatment. People so diagnosed were much younger than clinical cases, giving rise to the term *the two worlds of alcoholism*—the world of untreated alcoholics and the world of alcoholics who enter treatment. These discrepancies directed attention to the phenomenon of ''natural recovery'' from alcoholism (i.e., recovery without formal treatment) and stimulated the development of programs to increase screening and referral for alcohol problems, for example, through emergency departments, employee assistance, and drunk driving programs. More recently, the U.S. Preventive Services Task Force has recommended screening and brief counseling interventions addressing alcohol abuse in primary care settings, and NIAAA has published guidelines to aid such providers.

Numerous risk factors for alcohol disorders have been investigated (e.g., genetic, neurological, psychological, social, and environmental availability). Several alcohol typologies have been proposed based on findings from these studies, and the life course of alcohol disorders is highly variable. Many individuals who have alcohol experiences consistent with a diagnosable disorder appear able to respond by abstaining or moderating their drinking, usually with no formal treatment. In contrast, others struggle for years, need a great deal of support to abstain or cut down, and continue to be at risk of relapse when stressed. Early onset of alcohol use and early intoxication are associated with a greater likelihood of later alcohol dependence; however, prior conditions such as family disruption, conduct disorder, multiple-risk-taking dispositions, and genetic factors probably contribute to this relationship.

Alcohol-Related Health Consequences

Heavy drinking for years is a necessary and sufficient cause of conditions such as alcoholic liver disease and fetal alcohol syndrome, and it increases the likelihood of numerous other health problems. Causal relationships have been demonstrated between alcohol consumption and more than 60 disease conditions and disabilities, including traffic fatalities and other kinds of injuries, homicide, and suicide. In one method of estimating the burden of disease caused by alcohol in a given population, epidemiologic studies identify the fraction of a given disease that can be attributed to alcohol, the alcohol-attributable fraction (AAF). Thus, 100% of alcoholic liver disease is attributable to alcohol, but a relatively small percentage increase in breast cancer is associated with alcohol use. To estimate burden, AAFs may be applied to subsets of the population having the relevant diseases and summed. Another measure of alcohol's impact on society sums years of potential life lost (YPLL)—age at death from an alcohol-related cause subtracted from 65 years. Because many alcohol-related deaths, such as those resulting from automobile crashes and even cirrhosis, occur in relatively younger individuals compared with victims of heart disease and cancer, alcohol-related YPLLs are higher than would be expected given their mortality rates. Contemporary work sponsored by the World Health Organization has quantified the burden of disease attributable to alcohol and other factors, finding that the total global burdens of disease for alcohol (4.0%) and tobacco (4.1%) are on a par.

Alcoholic Liver Disease

Mortality data on liver cirrhosis serve as a surrogate for monitoring alcoholic liver disease because alcohol abuse is often omitted from death certificates to spare the family. Age-adjusted cirrhosis mortality rates dropped during Prohibition, peaked during the 1970s, and have fallen since then. That mortality rates began falling before per capita alcohol consumption decreased has been attributed to improved

access to and effectiveness of alcoholism treatment. Cirrhosis mortality was substantially higher among blacks compared with whites in 1970, but age-adjusted rates have fallen more rapidly among blacks, such that rates are now similar. In contrast, cirrhosis mortality rates remain higher among white Hispanics than blacks or whites. Not only is heavy drinking a primary cause in alcoholic liver disease, it also exacerbates liver damage from other factors such as chronic hepatitis C virus (HCV) infections and obesity, often co-occurring with these conditions. Increases in liver cirrhosis are anticipated as the cohort most affected by the HCV epidemic between the 1960s and 1980s reaches ages at which liver disease usually manifests, exacerbated by the epidemic increases in early onset obesity.

Cardiovascular Disease

The relation of alcohol use to cardiovascular disease (CVD) is complex. Numerous studies have reported J-shaped or U-shaped alcohol dose-response curves with CVD endpoints, suggesting that drinking moderately may be protective. Others have argued that such curves may be artifacts related to unadjusted confounding factors (e.g., a generally healthier lifestyle among moderate drinkers compared with abstainers, a tendency of sicker persons to abstain or reduce intake, and failure to take drinking patterns and lifetime drinking trajectories into consideration).

Allergen

An allergen is a molecule that stimulates an allergic response in a sensitive individual. Allergens are almost always proteins; however, not all proteins are allergens. A protein that acts as an allergen displays two fundamental properties: induction of an IgE immune response on first exposure and induction of a clinical response to the same or similar protein on subsequent exposures. Some examples of allergens include dust mites, peanuts, pollen, and pet dander; however, a comprehensive list of allergens is impossible to assemble, as the list of possible substances is extensive (i.e., food, air particles, drugs, animal products, and insect stings). Sensitivities vary greatly from one person to another; and the response to allergens also varies in severity from allergic rhinitis and hives to asthma and anaphylaxis. Allergen sensitivity testing is used in epidemiology studies to characterize atopy and its association with allergic diseases in populations.

An allergen provokes an allergic response in the immune system by acting as a substance that stimulates an IgE-mediated antibody response. On first exposure to the allergen, IgE antibodies are developed that specifically recognize the allergen. These antibodies are then bound to mast cells, a cell type that is very common in our gastrointestinal and respiratory systems. If the body is exposed to the allergen again, the mast cell-bound IgE antibody recognizes the antigen and causes the mast cells to release substances (e.g., histamine, leukotrienes, and interleukins) that cause cell damage and inflammation, resulting in the symptoms we commonly associate with allergies such as a runny nose, congestion, hives, and swelling. Atopy refers to the condition of

raised IgE antibody levels following exposure to common allergens.

Exposure to an allergen can occur through inhalation (e.g., pollen), ingestion (e.g., peanuts), or direct contact (e.g., latex gloves). If the allergen is in the air, the allergic reaction will likely occur in the eyes, nose, and lungs. If the allergen is ingested, the allergic reaction will likely occur in the mouth, stomach, and intestines. An allergic reaction can occur throughout the body, such as hives or analphlaxis, if the reaction is severe enough. Many protein allergens have been sequenced, but there are only a handful of common characteristics associated with these allergenic proteins. Several allergen types (food and plant) belong to only a few of the thousands of protein families, suggesting common structural features. Other common features include a high dose of the protein in the ingested or inhaled substance and resistance to digestion, two features that make immunologic resistance more difficult.

The goal of diagnosing an allergy is identifying the causative allergen; IgE antibodies specific to a particular allergen are measured in the blood in RAST (radioallergosorbent) testing, or skin-prick testing (SPT) is performed. SPT involves the controlled application of a variety of allergens and positive and negative controls to the skin. Itchy, red skin indicates a positive response to the applied allergen—that is, an IgE-mediated reaction. SPT has been used in a variety of ways in epidemiologic studies to characterize atopy in populations, including to identify the prevalence or incidence of reactivity to specific allergens in predisposed populations such as asthmatics; to identify a sensitive population for use in a case-series or case-control study; to examine the trend of skin test reactivity over a particular time frame in a population; to calculate the association of specific skin reactivities with particular allergy types (e.g., asthma or chronic obstructive pulmonary disorder) or the severity of those allergies; and to calculate the association between reactivity to an allergen and the levels of that allergen in an environment (e.g., pollen reactivity and pollen counts).

Allergic diseases are common, with an estimated 40 million persons in the United States suffering from some type of allergic disease. Correspondingly, the reported prevalence of positive skin test responses to common allergens is relatively high in epidemiologic studies. For example, the National Health and Nutrition Examination Survey (NHANES), a survey designed to be representative of the general U.S. population, conducted SPT testing using 10 common allergens among participants interviewed from 1988 through 1994. The majority of the participants (i.e., 54.3%) had at least one positive skin test response, with the most common positive responses occurring with exposure to dust mite, cockroach, perennial rye, and short ragweed allergens. Males tend to be more likely to have a positive skin test response and higher IgE levels, compared with females. Also, skin test reactivity and IgE levels tend to peak in young adulthood and decline in later years.

The vast majority of asthmatics are sensitized to at least one common allergen, including pet, rodent, and dust mite allergens. Allergen sensitization is a condition that is highly associated with prevalent asthma, as well as a risk factor for the future development of asthma. Allergen sensitization is thought to be an intermediate factor in the causal pathway leading to asthma. Also, allergen sensitization appears to modify the effects of other exposures, meaning that atopic persons are more likely to develop asthma symptoms than nonatopic persons, given the same level of allergen exposure.

The treatment for allergies involves avoidance or controlled exposure to the offending allergen, the administration of drugs that counteract the effects of the substances released by mast cells (e.g., antihistamines), and allergen immunotherapy (AIT). AIT is the controlled, systemic administration of an ''allergy vaccine'' composed of a specific mixture of allergens that is designed to modify the allergic mechanisms and ultimately desensitize the person to the allergen.

Alzheimer's Disease

Alzheimer's disease (AD) is a progressive, degenerative brain disease that impairs memory, thinking, and behavior. AD, named after Alois Alzheimer, a German neurologist who published his observations of a patient, Augusta, D., in 1906, is the most common form of dementia, comprising 60% of all dementias. AD has been previously known as dementia of the Alzheimer type, senile dementia of the Alzheimer type, and Alzheimer's dementia.

AD currently affects about 4.5 million men and women in the United States, with an annual cost of $100 billion, and the number of persons with AD is expected to rise to 16 million by the year 2050. The incidence of AD increases with age, affecting up to 50% of people above the age of 85, although rare in those below the age of 60. There are other forms of dementia not related to AD, such as dementia with Lewy bodies (20%), vascular dementia (15%), and rare forms such as frontal-temporal dementia (5%) with women at greater risk for AD than vascular dementia. There is no known cause of AD, although it appears likely that a combination of factors, including age, genetic inheritance, environmental factors, diet, and overall general health, is responsible.

Although the first symptoms of AD are often confused with the changes that take place in normal aging, AD is not a normal part of aging and is caused by brain pathology. The brain of an affected individual may begin to deteriorate as much as 10 to 20 years before any visible signs or symptoms of AD appear. Typical symptoms of the early stages of AD may be attributed to many causes, making initial diagnosis difficult; they include memory loss, behavioral symptoms, emotional changes, and changes in judgment and decision making.

Over time, AD progresses through three main stages: mild, moderate, and severe. Memory impairment is a necessary feature for the diagnosis of AD or any type of dementia. Change in one of the following areas must also be present: language, decision-making ability, judgment, attention, and/or other areas of mental function and personality. The rate of progression is different for each person. If AD develops rapidly in an individual, it is likely to continue to progress rapidly. If it has been slow to progress, it will likely continue on a slow course.

Generally, the onset of AD is insidious, with failure of memory of recent events, emotional changes, depression, anxiety, and unpredictable behaviors being the earliest symptoms, appearing up to 3 years prior to diagnosis. Functional and behavioral problems may be evident and may increase anytime within 1.5 to 6 years after diagnosis, followed by progressive apathy, space perception disorders, a shuffling gait, slow and awkward movements, jerky muscle contractions (myoclonus), and irreversible loss of speech and memory. AD eventually progresses to a late vegetative phase consisting of complete inability to think, move, or speak. The patient usually dies of pneumonia, heart attack, or stroke.

While clinical symptoms and a thorough examination resulting in a diagnosis of probable AD are highly correlated with postmortem examination, a definitive diagnosis is made only after a postmortem examination. Postmortem examination of an AD patient will reveal a loss of cells in all cortical layers except the motor cortex and a degeneration of neurofibrils, the filaments found in and around nerve cells. Neurofibrillary degeneration and plaques, composed of amyloid protein, are distinctive histopathological features of the cerebral cortex in AD. The amyloid deposition is thought to be due to an abnormality in the amyloid precursor protein. This abnormality is influenced by several factors, including higher levels of stress hormones and the four alleles of the apolipoprotein E (APOE) genotype.

Risk Factors

Several factors may protect against AD, while others increase susceptibility to AD. Genetic differences appear to play a role in susceptibility to AD. The fact that a high percentage of Down syndrome patients develop AD suggests a possibility of involvement of chromosome 21 in the development of AD. Familial clustering and apparent generation-to-generation transmission are suggestive of autosomal dominant inheritance in rare cases such as familial Alzheimer's disease. Other genetic traits that are associated with higher rates of AD are the presenilin 1(PS1) gene, APOE polymorphisms, and alpha-1-ntichymotrypsin (ACT), an inflammatory protein. APOE polymorphisms occur in either homozygous (3/3) or heterozygous

(2/3) form. The polymorphism containing the four alleles in either heterozygous or homozygous form tends to increase susceptibility to AD and can interact with ACT and amyloid precursor protein to increase the risk and clinical progression of AD.

In addition to genetic factors, interaction between genes and environment can lead to increased risk. One such factor is chronic stress leading to glutamate excitotoxicity and increased amyloid precursor protein. Other factors associated with increased susceptibility to AD include depression, cerebrovascular disease, history of head injury, high cholesterol levels, a prolonged inflammatory response, and oxidative free radicals.

Several factors have been identified that may be protective for AD. These include consumption of antioxidant foods such as curcumin, found in the spice turmeric; exercise; use of nonsteroidal anti-inflammatory medication (NSAIDS) such as aspirin; and the APOE 2 allele.

Diagnosis

To obtain a diagnosis of AD, a person must meet several criteria. These include dementia confirmed by medical and psychological exams; problems in at least two areas of mental functioning; progressive loss of memory and other mental functions; and no other disorders that might account for the dementia, such as hypothyroidism, depression, overmedication, drug-drug interactions, and vitamin B_{12} deficiency.

Tools used to diagnose AD include the Mini-Mental State Examination (MMSE), Clock Test, Functional Assessment Staging (FAST), Alzheimer's Disease Assessment Scale, Cognitive Subscale (ADAS-Cog), Severe Impairment Battery (SIB), Modified Alzheimer's Disease Cooperative Study (ADCS), Neuropsychiatric Inventory (NPI), and the Clinical Rating Scale.

One of the tools frequently used to screen for overall cognitive decline is the MMSE (scored 0 to 30; mild decline is indicated by a score of 21 to 25, moderate 9 to 20, and severe 0 to 8) consistent with the Clinical Dementia Rating (CDR) scoring of 1.0 for mild and 2.0 for moderate dementia. The MMSE consists of 11 questions that cover five cognitive areas: orientation, registration (ability to recognize and name specific items), attention, recall, and language.

The Clock Test, an easy-to-administer indicator of cognitive decline, is used to differentiate between depression and stages of AD. Patients are asked to draw a clock, including all the numbers and a specific time. Scoring for this test includes the numbers drawn, location of the numbers, and location and size of clock hands.

The FAST is used to determine the stage (mild, moderate, or severe) of AD rather than for diagnosis. It assesses a range of activities, including dressing, continence, and ability to speak, sit up, and smile.

Several tests are used more commonly in clinical research regarding AD. The ADAS-Cog, used to gauge change in cognition with a focus on memory and language, is a highly accurate scale in diagnosing and staging mild to moderate AD. One of the limitations of this scale is a "floor effect" (the inability of the test to identify worsening conditions after patients reach the bottom of the scale), which makes it ineffective in measuring severe AD.

The SIB is used to assess the cognitive functioning of severely impaired persons who are unable to take other standardized cognitive scales. It consists of 40 questions (some with multiple parts) that measure cognitive range in orientation, language, memory, and attention. This test is used to assess patients in the moderate to severe stages of AD.

Developed through the modified ADCS, the Activities of Daily Living Inventory (ADCS-ADL) is used to measure functional capacity over a broad range of dementia severities. Patients are evaluated on their response to questions designed to determine their ability to perform specific ADLs, such as bathing, dressing, eating, and walking.

The Behavioral Rating Scale for Geriatric Patients (BGP) assesses both functional and behavioral disturbances in geriatric patients. Assessments include physical disabilities, abilities to perform ADLs, and level of activity versus inactivity.

The NPI evaluates behavioral and psychiatric disturbances with a 12-item questionnaire. Items include delusions or paranoia, hallucinations, agitation or aggression, depressed mood, anxiety, elation or euphoria, apathy or indifference, disinhibition, irritability, motor disturbance, nighttime behaviors, and appetite problems.

The Clinicians' Interview-Based Impression of Change Plus Caregiver Input (CIBIC-Plus), used to interview both patient and caregiver, measures the overall improvement or decline of a patient's cognitive function through a series of interview questions.

Treatment

Treatment of AD is symptomatic and is directed toward preventing further deterioration, given the current pathophysiologic understanding of the disease. Pharmacologic agents for cognitive symptoms include cholinesterase inhibitors and NMDA receptor antagonists. Cholinesterase inhibitors are directed toward increasing the concentration of the chemical messenger acetylcholine and keeping it high so that neural transmission will proceed in the face of the loss of cholinergic neurons found in mild to moderate AD.

NMDA receptor antagonists regulate levels of glutamate, an excitatory messenger chemical that the brain uses to process, store, and retrieve information. However, an excess amount of glutamate excitotoxicity has been implicated in increased susceptibility to AD. This class of medications is used most extensively to treat those with moderate to severe AD, slowing the progression and maintaining functional ability.

Most herbal therapies are directed toward the antioxidant effect that these substances provide in an attempt to reduce oxidative free radicals. While they may be effective in several individuals with AD, these substances are not regulated, and their efficacy has not been established. Two commonly used treatments are coenzyme Q10 and *Ginkgo biloba*. Neither of these can be recommended at this time to decrease or prevent further decline in AD. In addition, *Ginkgo biloba* may be dangerous for some individuals as it has anticoagulant properties and may compromise blood clotting. AD patients often display behavioral symptoms such as irritability, anxiety, sleep disturbances, agitation, restlessness, and pacing, all of which are distressing to the patient and their caregivers, frequently resulting in institutionalization. Events that may trigger these behaviors include a change in caregiver or living arrangement, travel, and bathing.

Given the side effects and limited efficacy of pharmacologic interventions such as antipsychotics used to treat these symptoms, the American Neurological Association currently recommends the use of nonpharmacologic interventions. Several of these interventions have met with varying success and are directed toward increasing relaxation and decreasing stressful environments. These include music therapy, therapeutic touch, aromatherapy such as lemon balm, pet therapy, increased pleasant activities, and simulated presence. Simplifying the environment and providing predictable structure and routine can decrease these behaviors. In addition, improving the therapeutic communication and decreasing the stress of formal and informal caregivers can help to decrease these symptoms.

American Cancer Society Cohort Studies

The American Cancer Society has conducted numerous cohort studies that provide a wealth of data to help in the fight against cancer. The first of these, the Hammond-Horn Study, was initiated in 1952. It was a prospective cohort study designed to research the effects of tobacco smoking on cancer death rates, as well as death rates from other diseases. With the help of volunteers, 188,000 adult men were recruited for this study and followed yearly through 1955. The Hammond-Horn Study paved the way for the cancer prevention studies (CPS-I, CPS-II, and CPS-3), which began in 1959 and are continuing today. The CPS-I, CPS-II Baseline, and CPS-II Nutrition cohorts studies have produced at least 117, 163, and 34 publications, respectively.

Cancer Prevention Study I

For the CPS-I, which focuses on mortality as an endpoint, approximately 1 million male and female adults in 25 states were recruited between October 1, 1959, and February 1, 1960, and completed extensive baseline questionnaires covering demographic characteristics, height, weight, diet, occupation, alcohol and tobacco use, menstrual and reproductive history (females), and personal and family disease history, including that of cancer. Supplemental questionnaires on changes in tobacco use and cancer were mailed to participants in 1961, 1963, 1965, and 1972 to confirm vital status. Vital status of participants was determined annually from 1960 to 1965, 1971, and 1972 through personal inquiry. Vital status, as well as date and place of all deaths, was recorded in the study, and death certificates were obtained from State Health departments.

Cancer Prevention Study II

For the CPS-II, approximately 1.2 million male and female adults in 50 states, the District of Columbia, and Puerto Rico were recruited in 1982 for the Baseline Cohort and also completed extensive baseline questionnaires covering topics similar to those of CPS-I. Vital status of participants is updated in conjunction with the National Death Index through computerized linkage. Follow-up on vital statistics of the cohort is completed through 2002, and cause of death for more than 98% of all deaths for the cohort has been documented. As of 2002, more than 385,000 deaths have occurred in the CPS-II Baseline Cohort.

In 1992, a subgroup of 184,194 males and females from the CPS-II Baseline Cohort was mailed a new questionnaire covering additional detailed information on diet, updates on aforementioned lifestyle factors, and self-reported cancer diagnoses, which constitutes the CPS-II Nutrition Cohort. The Nutrition Cohort allows cancer diagnosis to be studied as an endpoint in addition to mortality. Participants of the Nutrition Cohort are aged 50 to 74 and reside in 21 states that have population-based state cancer registries, including California, Connecticut, Florida, Georgia, Illinois, Iowa, Louisiana, Maryland, Massachusetts, Michigan, Minnesota, Missouri, New Mexico, New Jersey, New York, North Carolina, Pennsylvania, Utah, Virginia, Washington, and Wisconsin. The Nutrition Cohort is mailed this additional questionnaire biennially starting in 1997. Self-reported cancer diagnoses are verified with medical records when consent is given, and self-reported cancer diagnoses are supplemented using computerized linkage with the state cancer registries.

Beginning in 1998, blood samples were obtained from a subgroup of 39,371 surviving males and females from the CPS-II Nutrition Cohort, comprising the CPS-II Lifelink Cohort. The Lifelink Cohort allows for future epidemiologic research on potential nutritional, hormonal, and genetic risk factors for cancer and other diseases. In June 2001, collection of blood samples was completed. Additionally, in January 2001, collection of buccal, or cheek, cells from 70,000 males and females of the CPS-II Nutrition Cohort using a mailed collection kit began as an alternative to donation of blood. All biospecimens are being stored in liquid nitrogen for future research.

Cancer Prevention Study 3

Recruitment for the Cancer Prevention Study-3 is currently under way. The goal is to enroll 500,000 males and females aged 30 to 65 years from various races/ethnicities. Nearly 25 years have elapsed since recruitment of the CPS-II Baseline Cohort in 1982 so that this new CPS-3 Cohort likely has new lifestyles and behaviors compared with the previous cohorts that need to be researched and captured.

American College of Epidemiology

The American College of Epidemiology (ACE) was incorporated in 1979 with the purpose of addressing the professional concerns of epidemiologists and developing criteria for their professional recognition.

Goals of the ACE include advocating for policies and actions that enhance the science and practice of epidemiology, promoting the professional development of epidemiologists, recognizing excellence in epidemiology, issuing timely policy statements for the profession, and developing and maintaining an active membership base representing all aspects of epidemiology. The first president of the ACE was Abraham M. Lilienfeld, who was also one of the signatories of the ACE Articles of Incorporation, along with Cedric F. Garagliano and Curtis L. Meinert.

The ACE is a professional membership organization for people working in epidemiology or closely related fields: Individuals must apply for membership and have their application reviewed by the ACE Board of Directors. A recommendation for admission is based on credentials, including training, education, experience, and contributions to the profession. There are three main categories of membership: associate member, member, and fellow. Associate members are individuals who are enrolled in training, which, when completed, would qualify them for admission into the ACE. Members are individuals who have a doctoral degree in epidemiology, a doctoral degree in a related field and a master's degree in epidemiology, or a doctoral or master's degree plus related experience in epidemiology. Fellows are individuals who meet the requirements to be a member and have also demonstrated significant and sustained contributions to epidemiology through research or leadership in the field.

The ACE holds an annual scientific meeting and every 5 years holds the American Congress of Epidemiology in conjunction with the Epidemiology Section of the American Public Health Association, the Canadian Society for Epidemiology and Biostatistics, and the Society for Epidemiological Research. The First Congress of Epidemiology was held in 2001 in Toronto, Ontario, and the second in 2006 in Seattle, Washington.

Annals of Epidemiology is the official journal of the ACE. It is a peer-reviewed, international journal published 12 times per year by Elsevier. *Annals of Epidemiology* focuses on epidemiologic research and methodological development and encourages the use of epidemiology in a multidisciplinary approach to studying disease etiology. The ACE has issued official statements on several major topics within epidemiology, including minority representation in epidemiology and within the ACE; ethics; health data control, access, and confidentiality; data sharing from epidemiologic studies; and a statement of opposition to Proposition 54 in California, which would have restricted the collection and use of racial, ethnic, and national origin data within California.

American Indian Health Issues

North Americans indigenous to the lands of the 48 contiguous states refer to themselves variously as Indians, American Indians, Native Americans, or as members of their tribes (e.g., Menominee, Cherokee, Navajo) or cultural groups (e.g., Ojibwe), and at times simply as Americans. The term *American Indian* is used in this entry. Alaska Natives will be included as North American continental indigenous peoples with distinct political ties to the United States. Similarities and differences in tribal origins, cultures, and traditions are a backdrop to understanding health and health beliefs. European Columbian contact in 1492 precipitated abrupt changes in life ways and initiated a political history felt as historical trauma. American Indians today experience health disparities that reflect the cultural disruption and political disadvantage of the past. Culturally acceptable, culturally supportive health services, American Indian–initiated and –conducted research, and strengths inherent in traditional ways of life are identified as pathways to optimal health in the future.

Tradition and Culture

American Indians and Alaska Natives are the descendants of the indigenous peoples of the lands now

occupied by the 48 contiguous states and Alaska in the United States. Anthropological evidence suggests an Asian origin for native North American people, with migration waves across Bering Strait land bridges beginning well over 15,000 years ago. Hundreds of distinct tribes each with their own unique and overlapping traditions have been located on North American lands from time immemorial. Well over 200 distinct languages have been distinguished.

Over the centuries, American Indian cultures have reflected local geographic and climatic conditions. Migrating societies thrived through subsistence hunting, fishing, and gathering of plant materials, while sedentary groups relied largely on cultivation of crops and hunting and lived in villages both large and small. Groups appeared, shifted, and regrouped over the centuries. For example, around 1250 AD to 1540 AD, there were significant shifts during what is termed the Southwest Pueblo IV period. Through migration, the entire Pueblo world's demography shifted east from the Four Corners region, causing dramatic demographic, social, economic, and political reconfigurations.

Complex tribal social and religious structures included clans, clan families, birth families, father's clan, kiva groups, and other medicine and priest societies, and other connections such as a spiritual father. Social and religious roles and duties were carried out through dance, music, and storytelling. In some groups, music was reserved for sacred activities and rites. A common thread was a holistic integration of practical day-to-day life with nature-based spirituality.

In the past and continuing today, most tribal groups recognized physical, emotional, mental, and spiritual balance in harmony with nature as the core of health. Sacred medicine wheels, hoops, or other symbols portray tribal beliefs about health across the life cycle. Illness reflected imbalance with self, relationships, or nature. Healers were recognized as medicine people, midwives, bone pressers, stomach massagers, or members of medicine societies. Each had special knowledge of practical and spiritual methods for treating injury, illness, and emotional disturbances. Ceremonies, botanicals, including herbs and tobacco, visions, stories, and songs were used to restore balance and health.

European Contact

The American Indian population in 1492 is estimated broadly by historians and demographers to have been from 1 to 18 million. It declined precipitously following European Columbian contact. The decline was due to deaths from epidemic disease and warfare. Entire villages and tribes were annihilated as smallpox, measles, and other infectious diseases for which American Indians had no immunity and no effective treatment swept across the continent. Epidemics weakened the ability of American Indian communities to respond politically or militarily to early European settlement pressures and subsequent U.S. actions for removal to designated Indian Territory west of the Mississippi River.

The Cherokee Trail of Tears (1838–1839), Navajo Long Walk (1864), and other operations were brutal death marches where disease and starvation were commonplace. Those who survived faced harsh living conditions, sociocultural disruption, and poverty that continue to affect Indian life today. That impact has been termed *historical trauma* and is regarded as a factor in the emergence of health disparities in life span and the modern plagues of chronic illness. It is thought that loss of identity, grief, guilt, and other posttraumatic symptoms lead directly or indirectly to diabetes, stroke, heart disease, liver disease, cancer, and maladies impairing social functions, such as depression, alcoholism, substance abuse, and injury.

Political Status

The U.S. Constitution (Article II, Section 8), treaties, federal statutes, and seminal Supreme Court decisions serve as the basis for federal recognition of the 569 Indian tribes and Native Alaska corporations and for policy guiding government-to-government interaction with them, termed the *federal trust responsibility*. Political recognition of tribes as sovereign nations sets the American Indian experience uniquely apart from that of other U.S. minority groups. The U.S. government provides health services to members of recognized tribes in fulfillment of the federal trust responsibility. The Indian Health Service, Tribal Health Services, and Urban Health Services (ITU) are components of the federal system of care. The Indian Health Service (IHS) is a national system of hospitals, clinics, and satellite offices providing a widely varying range of health services for enrolled members of federally recognized tribes.

In the 20th century, an increased birth rate and slow but steady improvement in life expectancy

contributed to a rebound in the American Indian/Alaska Native population from its 1900 nadir of about 250,000 individuals. According to the 2000 census, approximately 2.5 million individuals (0.9%) of the U.S. population self-identified as only American Indian/Alaska Native and 4.4 million (1.5%) reported mixed ancestry. The number of U.S. citizens reporting some Indian ancestry or cultural identification is increasing. American Indians are U.S. citizens and citizens of the states in which they reside, but in addition can be citizens of their tribe if they become enrolled members. Tribal governing bodies set criteria for citizenship, which vary among Indian Nations. For example, Navajo Nation requires a blood quantum level of 1/4, whereas Cherokee Nation requires direct descent from individuals on the Dawes Rolls (closed in 1907) rather than a minimum blood quantum. Enrolling as a tribal member is not automatic, and one must apply for the privilege.

Most of today's American Indian/Alaska Native population is located west of the Mississippi River, with the greatest number in California (mostly urban Indians) and high concentrations in Alaska, Oklahoma, Arizona, and New Mexico. Navajo Nation has the largest reservation-based population at about a quarter of a million, while Cherokee Nation has the largest nonreservation-based population. Approximately 40% of the American Indian/Alaska Native population continues to reside on or near reservation lands. Following federal policy encouraging nonreservation relocation during the World War II era, most of the American Indian/Alaska Native population now lives in urban areas. Among Indian elders, there is a trend toward remigration from cities to reservation residence.

Modern Diseases

Today, life expectancy overall equals that of whites, but the change is distributed unequally across the American Indian population. Males and females residing near reservations in 2001 had a life expectancy of 5.9 and 4.3 years less than whites with slightly above-average income and education living in areas other than the upper Midwest, Appalachia, and the Mississippi Valley and some Asian Americans.

Quality data are an essential foundation for describing the burden of disease in a population, planning effective health services, and setting research agendas. Obtaining data about American Indian health is challenging due to inconsistencies and difficulties in defining, identifying, and accessing the American Indian/Alaska Native population. Nevertheless, it is clear that the American Indian population is younger than the U.S. overall population, with 8.6% below 5 years as compared with 6.8% for the U.S. overall in 2000. There are fewer elders above 54 years (11.9% compared with 21%). Life expectancy at birth increased from 63.5 in 1972 to 73.2 in 1992. Yet American Indian/Alaska Native teens and young adults residing on or near reservations have among the highest mortality rates of groups in the United States.

Despite lower rates of low birthweight, American Indian/Alaska Native infant mortality rates are higher than U.S. overall (9.7 vs. 6.8 per 1,000 in 2001 data). Elevated postneonatal death rates account for the discrepancy. Sudden infant death syndrome (SIDS; the sudden death of an infant younger than 1 year of age that remains unexplained after a thorough case investigation that includes autopsy, death scene investigation, and review of clinical history) is the leading cause of postneonatal death. The IHS Aberdeen Area (North Dakota, South Dakota, Nebraska, Iowa) reported rates ranging from 3.46 to 3.66/1,000 live births from 1992 to 1998 (compared with 0.7/1,000 live births for all U.S. races in 1999). The disparity persisted in 2003, when American Indian/Alaska Native SIDS deaths occurred at 2.3 times the rate for infants of non-Hispanic white mothers, even as SIDS rates for all U.S. groups were falling. Reasons for the elevated incidence of SIDS in American Indian/Alaska Native infants are uncertain. Risk factors are the same as those in other populations (smoking, delayed prenatal care, nonsupine sleep position, low socioeconomic status, layered clothing), although smoking occurs at relatively high rates in the American Indian/Alaska Native population. Serotonergic brainstem abnormalities found in non-Indian and American Indian/Alaska Native victims of SIDS may play a role. Until a more complete understanding of SIDS pathogenesis is available to guide effective prevention, treatment is directed toward reduction of risk factors and compassionate support of families whose babies died of SIDS.

Alcoholism appeared in American Indian populations during early days of European contact when ammunition, alcohol, and tobacco were primary trade goods. Now, a constellation of alcoholism, injuries (homicide, suicide, motor vehicle accidents,

traumatic brain injury), substance abuse, domestic and community violence, and depression disproportionately affects American Indian/Alaska Native youth and young adults. Accidents and homicide are among the top three causes of death for American Indian/Alaska Natives from 1 to 24 years of age. Suicide among American Indian/Alaska Native youth occurs over 2.5 times more frequently than among the U.S. all races group. The alcoholism death rate for Indians from 15 to 24 years of age is 5.5 per 100,000 compared with 0.3 for all U.S. races. Many Indian youth rate their health status as low. The social toll is enormous, affecting all aspects of life for affected individuals, their families, and tribal communities. Poverty, lack of educational opportunity, isolation, and cultural disruption are all thought to be etiologic factors. Among adults, perceived discrimination is associated with higher levels of depression, and practice of traditional life ways appears protective. A sense of social competence, positive school achievement, and avoidance of substance use are related to well-being among youth. Many American Indian communities view elimination of substance abuse as a key to reducing the spectrum of social pathologies and draw on their cultural strengths to design interventions ranging from programs for individual treatment to community-wide prevention.

Epidemic type 2 diabetes emerged in the American Indian/Alaska Native population in the mid-20th century. It is recognized as a ''white man's disease'' resulting from disruption of traditional life ways, including diet and activity patterns. Prevalence is markedly higher, onset occurs at younger ages, and renal, cardiovascular, and retinal complications develop at higher rates than in the general population. Depression comorbidity is high as well. Genetic and behavioral factors have been implicated in the increasing incidence and prevalence of type 2 diabetes in the American Indian/Alaska Native population. The highest prevalence of diabetes in the world occurs among the Pima Indians of Arizona. The diabetes burden of disease is expected to grow as today's youthful American Indian/Alaska Native population with diabetes ages with longer exposure to risk factors for complications. Increased physical activity, improved diet, and weight management are key aspects of both primary and secondary prevention because they may prevent or delay onset of diabetes and mitigate its debilitating complications.

Access to effective care is critical to the monitoring required for early identification and treatment of diabetes complications. A challenge in diabetes prevention and control is altering beliefs that the disease is inevitable. Awakening the Spirit, an American Indian/Alaska Native program sponsored by the American Diabetes Association, emphasizes that diabetes did not occur in the past and that people with diabetes can manage the disease, live full lives, and be well enough to watch their grandchildren grow up. Within ITU programs, community diabetes interventions reflect local priorities. In an expression of hope and responsibility for the well-being of future generations, many programs focus on diabetes prevention efforts for children.

There is also a disparity between health problems of elderly American Indians and Alaska Natives compared with the United States at large. Chronic diseases and resulting functional declines appear earlier than in the general population, are of greater severity, and usually result in a shorter life span. For these reasons, American Indian elders are often eligible for IHS, tribal health care services, or urban Indian health services at age 50. The service base is spare, however. The elderly on reservations have almost no formal services because long-term care is not a principal function of IHS or tribal health care. There are only 12 reservation-based nursing homes in the country. Due to moratoriums on building new nursing home beds in 32 states, many needed beds will never be built. Clashing health beliefs and traditions and laws are barriers that keep American Indian elders from obtaining off-reservation long-term care, which perpetuates a cyclical wheel of disparity.

Pathways to Optimal Health

Beginning in the early 1800s, military physicians provided public and personal health services aimed at control of infectious disease among Indian people. After 1849, the Bureau of Indian Affairs in the Department of the Interior administered medical care. Through the Snyder Act of 1921, Congress authorized funds for health services to federally recognized tribes. Responsibility was moved to the U.S. Public Health Service in 1954, with the IHS serving 12 areas. The IHS, headquartered in Rockville, Maryland, comprises a national health system operating 33 hospitals, 59 centers, 34 urban health clinics, and 50 stations. Under the Indian Self-Determination Act

(PL 93–638), tribes receive direct IHS services or operate health services using funds allocated through IHS.

The mission of the IHS, in partnership with the American Indian/Alaska Native people, is to raise physical, mental, social, and spiritual health to the highest level. Improvements in Indian health across the 20th century have been attributed, in part, to efforts of the IHS. However, the IHS faces continuing challenges in providing services.

Many American Indian/Alaska Natives eligible for services lack access to IHS or tribal facilities. Of the estimated 3.3 million members of federally recognized tribes and their descendents who are eligible for care, only about 1.8 million receive IHS services. Intertribal urban health clinics decrease geographic barriers by providing services in some major metropolitan areas with high Indian populations.

The IHS employs more than 15,000 health care professionals. Yet the system is strapped by ongoing shortages of personnel, estimated at 12% in 2003. Remote locations are an employment disincentive, as is unfamiliarity of many health care providers with Indian culture. American Indian/Alaska Natives are underrepresented among health professionals. Health professions awareness programs beginning in elementary schools and scholarship/mentoring programs supporting American Indian students in higher education are designed to ease the shortage.

Traditional Indian medicine and Western care are used to varying degrees by many American Indian/Alaska Native people. American Indian/Alaska Native health professionals are leaders in encouraging use of tribal healers. The American Association of Indian Physicians includes as part of its mission the honoring of traditional healing practices. The National Alaska Native American Indian Nurses Association logo incorporates bear claws to signify strength and medicine for healing. IHS policy directs local service units to collaborate with tribes in provision of traditional healing to their patients.

American Indians are sometimes characterized as among the most overstudied and underserved of U.S. populations. Yet the need for research is recognized even though there are daunting challenges in implementing research and converting findings to action. While the American Indian/Alaska Native population shares some commonalities, tribes are also culturally distinct. Research procedures acceptable with one group may be anathema to another, and findings may not generalize. Research tools such as survey questionnaires developed in the majority population may appear peculiar to American Indian/Alaska Native respondents. For example, depression-screening tools may include language and symptoms inconsistent with interpretation among American Indians.

Indian-initiated and -conducted research is one pathway to the elimination of American Indian health disparities. The Native Research Network links American Indian/Alaska Native investigators to promote excellence and integrity in research. The National Institutes of Health, Minority Access to Research Careers, and Bridges to the Future programs (including the University of Minnesota M.S. to Ph.D. Nursing Science Bridge Program) reflect a federal commitment to developing a cadre of researchers from underrepresented minority groups including American Indians. The Resource Centers for Minority Aging Research (including the Native Elder Research Center at the University of Colorado) emphasize postdoctoral training. The Native American Research Centers for Health program is a mechanism for linking tribes with resources, including technical expertise from collaborating research universities, to carry out their research agendas. American Indian health scientists have firsthand appreciation of the complexity of health and illness experiences among American Indians and Alaska Natives, and they know the importance of combining tribal self-determination, traditional spiritual values, and the highest-quality science for the resolution of disparities.

American Public Health Association

The American Public Health Association (APHA), founded in 1872, is the oldest public health association in the world. It is also the largest, with more than 50,000 members in 2006, representing many different occupations related to public health. The APHA engages in a variety of activities to promote public health, including disseminating information through press releases, books and journals, holding an annual meeting, providing opportunities for professional development and continuing education, and bestowing a number of awards on individuals who have aided in public health efforts.

The APHA was founded by Stephen Smith, then Commissioner of the Metropolitan Health Board in New York City. The first annual meeting was held in 1873 and, as is still the rule today, combined presentation of scholarly papers with inclusion of more popular speakers. This format reflects APHA's interests in garnering support for public health among politicians and the general public as well as providing a forum for the exchange of ideas among people working in public health. APHA has held annual meetings every year from 1872 to the present, except for 1945; most have been held in the United States, but a few have taken place in Mexico, Canada, or Cuba.

As membership grew, members with common interests began forming sections to discuss topics of mutual interest. Among the first founded were the sections devoted to laboratory investigation (1899), health administration (1908), statistics (1911), and sanitary engineering (1911). Currently, there are 24 sections representing interests from alcohol, tobacco, and other drugs through Vision Care. APHA currently has 17 caucuses, which are formed around either members with common backgrounds, such as ethnicity or occupation, or common concerns and outlooks, such as Socialism or Peace.

The official journal of APHA is *The American Journal of Public Health*, which began publication in 1911 and publishes primarily scholarly research articles. APHA also publishes the monthly newspaper *The Nation's Health*, which carries articles written in a more popular style, often summarizing current research and reporting on public policy issues. Books relating to a number of public health concerns are also published through APHA.

The APHA fosters awareness of public health through presentation of a number of awards honoring individuals and organizations. The William Thompson Sedgwick medal has been awarded annually since 1929, to honor distinguished service by those working in public health. The Presidential Citation of the American Public Health Association is awarded on an irregular basis for service to public health by someone not working specifically in public health: Recipients have often been politicians or journalists. Other awards bestowed by the APHA include the David P. Rall Award for Advocacy in Public Health, the Milton and Ruth Roemer Prize for Creative Public Health Work (awarded to a health officer working at the city, county, or other local governmental level), and the APHA Distinguished Public Health Legislator of the Year (awarded to a local, state, or federal lawmaker).

Analysis of Covariance

Analysis of covariance (ANCOVA) is a combination of analysis of variance (ANOVA) and regression analysis because the model contains both quantitative and qualitative independent variables. The idea is to enhance the ANOVA model by adding one or more quantitative independent variables that are related to the dependent variable. These variables are called concomitant variables or covariates. Increasing the precision of the model results in reducing the error terms. Without a covariate, the error mean square may be so high that a simple ANOVA may not detect differences between treatments. Covariates can also be used to remove the effect of an extraneous variable from the dependent variable. An extraneous variable influences the outcome of an experiment but is not of particular interest to the researcher.

Consider the study of a new weight-loss medication. In a double-blind study, weight is measured on subjects who have been randomly assigned to one of two treatment groups. One group receives the new medication, and the other group receives a placebo. The researcher wants to know whether the new medication produces significant weight-loss results. Since the effect of the medication may be related to the individual's initial weight, initial weight is used as a covariate in the analysis to reduce within-treatment variability. The ability to detect differences between treatments is now strengthened.

ANCOVA is also used to explore the nature of treatment effects rather than for increasing the precision of the model. In a study of the effect of two different cognitive therapy treatments, children with behavioral problems are assessed by a mental health professional using a questionnaire. Each child is given a total problem score. Parents are asked to fill out a questionnaire to establish a socioeconomic status (SES) score for each child as well. The SES score is used as a covariate in the analysis. In this case, the relationship between total problems and SES score for each treatment is of primary concern rather than the effect of the treatments on total problem score.

ANCOVA is often used as a means of correcting for bias when treatment groups are noticeably different from each other. In the double-blind study of a new medication to reduce blood pressure, subjects are randomly assigned to one of two treatments: those treated with a placebo or those treated with the medication. Suppose it is found that by chance the initial blood pressure for subjects in one group is found to be substantially higher than that of the other group. Adding initial blood pressure as a covariate in the model helps remove that bias. Using ANCOVA for this purpose must be done with caution, however. If the covariate is related to the treatment variable, any conclusions are questionable at minimum. For instance, in a study of attitudes toward two different blood glucose monitors for diabetics, it is found that older patients tend to like one monitor while younger patients tend to like the other. With little regard, age is a covariate in an ANCOVA in an attempt to remove the bias. As it turns out, however, age is related to monitor preference. Therefore, using age as a covariate could actually lead to the wrong conclusion.

Selecting the right covariate requires careful thought and consideration. If the covariate is not related to the dependent variable, nothing is gained by adding it to the model. An ANOVA is more appropriate and less complicated in this situation. Covariates are usually observed before the study begins and should be independent of any effect of the treatments to obtain meaningful results. If the covariate is measured during the study, it is important to ensure that it is not influenced by the treatments. Examples of covariates are prestudy attitudes toward treatments, questionnaire scores, and prestudy health condition measurements, such as weight and blood pressure.

The ANCOVA model starts with an analysis of variance model. One or more terms are added to the model to reflect the relationship between the dependent variable, Y, and the independent variable, X.

The model for one covariate is as follows:

$$Y_{ij} = \mu + \tau_i + \gamma(X_{ij} - \bar{X}_{..}) + \varepsilon_{ij},$$

where

μ is an overall mean;
τ_i are fixed treatment effects subject to the restriction $\Sigma\tau_i = 0$;
γ is a regression coefficient for the relationship between Y and X;
X_{ij} are covariate values;
ε_{ij} are independent and normally distributed with mean 0 and variance σ^2;
$i = 1, \ldots, r$ treatments; and
$j = 1, \ldots, n_i$, n_i is the number of subjects in treatment i.

The basic properties of the ANCOVA and the ANOVA models are the same. However, since there is more to the ANCOVA model, it has additional properties.

In ANOVA, all observations of the ith treatment have the same mean response (μ_i). In ANCOVA, however, the mean response depends on the treatment as well as the value of the covariate, X_{ij}. Therefore, the mean response for the ith treatment is given by

$$\mu_{ij} = \mu_{.} + \tau_i + \gamma(X_{ij} - \bar{X}_{..}),$$

which is the mean response for treatment i at any value of X. When $X_{ij} - \bar{X}_{..} = 0$, the value of Y is $\mu + \tau_i$ and γ is the slope of each regression line.

Since the slope of the regression line is the same for all treatments, the difference between the mean responses is the same at any value of X. Figure 1 shows three regression lines for three treatments using hypothetical data. Treatment 1 has a higher mean response than Treatments 2 and 3, and Treatment 3 has a higher mean response than Treatment 2. The difference between the mean responses for Treatments 1 and 3 is the same regardless of the value of X because the slopes are parallel. This property of the ANCOVA model is referred to as *constancy of slopes.* It allows for comparison of treatment effects at any convenient level of X, such as $X_{ij} = \bar{X}_{..}$. Without constancy of slopes, ANCOVA is inappropriate. A test for parallel slopes should be conducted before proceeding with ANCOVA.

The question of interest in ANCOVA is similar to that in ANOVA: Are there significant treatment effects and, if so, what are they? ANCOVA uses regression procedures to adjust the dependent variable for the

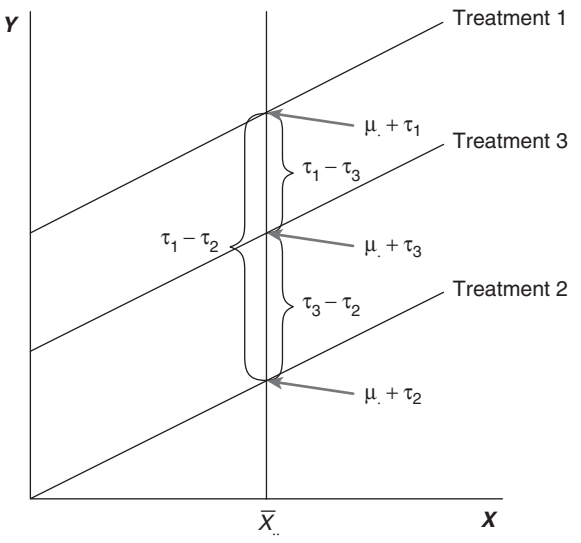

Figure 1 Regression Lines for Three Treatments in ANCOVA

effect of the covariate. In ANCOVA, therefore, the question is modified: Are there significant differences between treatments if the covariate is held constant? If the treatment regression lines are parallel, the hypothesis to test for differences between treatments, as in ANOVA, is that the population means for each treatment are equal:

$$H_0 : \tau_1 = \tau_2 = \cdots \tau_r = 0.$$

The alternative hypothesis is that at least one τ_i is not equal to zero. In other words, are the regression lines at the same level or is at least one of them higher than the others? If there is a significant difference between treatments, pairwise comparisons of treatment effects $\tau_i - \tau_i'$ can be made. This amounts to comparing the vertical distance between two regression lines. If necessary, more general contrasts of the τ_i can be made as well.

When there is no relationship between Y and X, the error mean square is the same as for ANOVA, and one degree of freedom for the error is lost. Therefore, testing whether the regression coefficient γ is zero is generally not done.

The ANCOVA model can also be expressed in terms of a regression model. In this model, $r - 1$ dummy variables are used to represent the treatments:

$$Y_{ij} = \mu + \tau_i I_{ij1} + \cdots + \tau_{r-1} I_{ij,r-1} + \gamma(X_{ij} - \bar{X}_{..}) + \varepsilon_{ij},$$

where I_{ij1} is the value of dummy variable I_1 for the jth observation from treatment i. The treatment effects $\tau_1, \ldots, \tau_{r-1}$ are regression coefficients for the dummy variables. Interaction terms $I_1(X_{ij} - \bar{X}_{..})$, $\ldots, I_{r-1}(X_{ij} - \bar{X}_{..})$ can be added to this model to allow for nonparallel slopes:

$$Y_{ij} = \mu_{.} + \tau_i I_{ij1} + \cdots + \tau_{r-1} I_{ij,r-1} + \gamma(X_{ij} - \bar{X}_{..}) + \beta_1 I_{ij1}(X_{ij} - \bar{X}_{..}) + \cdots + \beta_{r-1} I_{ij,r-1}(X_{ij} - \bar{X}_{..}) + \varepsilon_{ij}.$$

The regression form of the ANCOVA model is useful for testing for parallel slopes:

$$H_0 : \beta_1 = \cdots = \beta_{r-1} = 0.$$
$$H_a : \text{ at least one } \beta \text{ is not equal to zero}$$

An F test is used to compare the error mean squares of the models with and without interaction terms.

There may be situations where more than one covariate is appropriate. Extending the ANCOVA model is fairly straightforward. In the case of two covariates, X_1 and X_2, the model becomes

$$Y_{ij} = \mu_{.} + \tau_i + \gamma_1(X_{ij1} - \bar{X}_{..1}) + \gamma_2(X_{ij2} - \bar{X}_{..2}) + \varepsilon_{ij}.$$

The relationship between Y and X discussed in this article is linear, but linearity is not required. A linear model is preferable, since it is easier to interpret. In some cases, nonlinear data may be transformed so that a linear model can be used. When it is not reasonable to use a linear model, a nonlinear model may provide more meaningful results. The relationship, for instance, could be a quadratic one:

$$Y_{ij} = \mu_{.} + \tau_i + \gamma_1(X_{ij} - \bar{X}_{..}) + \gamma_2(X_{ij} - \bar{X}_{..})^2 + \varepsilon_{ij}.$$

When using a nonlinear model, parallel curves fit to each treatment are of interest.

Analysis of Variance

Most analyses of relationships between variables involve the use of independent and dependent variables. Analysis of variance (ANOVA) is a collection of methods where the independent variable(s) are categorical (nominal) and the dependent variable is quantitative (metric, interval/ratio) with a numerical scale. The analysis compares the means of the dependent variable for the groups defined by the independent variable(s). A more appropriate name might be analysis of means, but variances are used to determine whether means are different.

The simplest case has one independent variable with two categories and one dependent variable. For example, ANOVA can be used to analyze the relationship between the independent variable gender (categorical) and the dependent variable blood pressure (quantitative). The analysis compares the mean blood pressures for females and males. This comparison can also be made using a t test for the comparison of two means, and such a t test is a special case of ANOVA. Furthermore, the comparison can be made using regression analysis with a dummy variable for gender, and such a regression analysis is also a special case of ANOVA.

ANOVA and regression analysis are special cases of the general linear model, and there are mainly historical reasons why the two methods are seen as distinct. ANOVA grew out of analysis of experimental data in agriculture, where yields were compared for different treatments, such as type of fertilizer. Most of this took place in England under the leadership of the great statistician Ronald Fisher (1850–1921). Much of regression analysis has its foundation in economics with its many quantitative variables. Regression analyses used by economists are often called econometrics. The answer to which method of performing ANOVA is the proper approach can itself be analyzed using regression analysis with the dummy variables, but the construction of such variables can be cumbersome. Most statistical software programs still distinguish between ANOVA and regression, and regression analysis typically provides less detailed output than does ANOVA.

With one independent variable, we perform one-way ANOVA, with two independent variables we perform two-way ANOVA, and so on. Introducing location as a second independent variable with values

urban and rural, we can use a two-way ANOVA to study whether there are differences in blood pressure for females and males as well as between an urban and a rural location, using both gender and location as the two variables in one analysis. We could do a one-way analysis for gender and then separately do a one-way analysis for location, but it is more efficient to use both gender and location at the same time in one analysis. With more than one dependent variable, we perform multivariate ANOVA.

Main Results of an Analysis of Variance

ANOVA provides a measure of how strong the relationship is between the dependent and the independent variable(s) on a scale from 0 to 1. The strength of the relationship is measured by the quantity R^2, which takes on the role of a squared correlation coefficient. Such a number is also known as the size of the effect of the independent variable, measured on a scale from 0 to 1 or a percentage from 0 to 100. With several independent variables, we can get such a coefficient for each variable, telling us how strong the relationship is between that particular independent variable and the dependent variable. We can even get an overall coefficient, which sometimes is simply the sum of the coefficients for the individual variables.

Also, the analysis can test whether the relationship is statistically significant—that is, whether the group means are different from each other. A typical null hypothesis is that the group population means are equal. We will reject the null hypothesis if our analysis returns a small p value, meaning it is unlikely that if the population means were equal, results would be as extreme as they were. The p value is found using the theoretical statistical F variable, named for Fisher. If the group means are different, we can also ask whether they are all different from each other or whether only some of them are different from each other. An alternative to a null hypothesis stating that all means are equal is that at least some of them are not equal but not necessarily that they are all different.

One-Way Analysis of Variance

Suppose we think a variety of socioeconomic variables have an impact on obesity. Using census tracts of a city as a substitute for these variables, we ask whether average weight varies for residents living in different city census tracts. Weight as the dependent variable is quantitative, and census tract as the independent variable is categorical. The data set is drawn from random samples of women, one sample from each census tract.

In this analysis, any person's weight may be explained by either of two factors. One is location (census tract of residence) and the other is the combined, net effect of all variables other than location. Such a variable is known as the residual variable. Suppose the residual variable has no effect—weight is determined by location only. In that case, all women in a given census tract will have the same weight. The best estimate of that common value is the mean weight in that census tract. But this is not a realistic premise; we would not expect all the women in any sample to have the same weight. The difference between an individual woman's weight and the mean weight in her census tract is therefore taken to be the effect of the residual variable. Thus, for each woman we can measure the effect of the residual variable. We then need some way to summarize these residual values. It is tempting to take their mean, but that is not feasible as some of the residuals will have negative values and some will have positive values, and by definition their mean will equal zero.

One way around this problem is to square all the residuals to make them positive. The overall effect of the residual variable can then be defined as the sum of all these squared terms. This gives the residual sum of squares (RSS) as

$$\text{Residual variable sum of squares} = \text{Sum (Observation} - \text{Group mean)}^2.$$

The larger the effect of the residual variable is, the larger this sum will be. This sum looks like the numerator in a variance.

Similarly, if no variables influenced the weight of individual women, then all women in the study would have the same weight. The best estimate of this common weight is the overall mean weight of all the women. Thus, the difference between the weight of a woman and the overall mean becomes the effect of all variables. One way to summarize these differences is to take their squares and add all the squares. This gives the total sum of squares (TSS) as

$$\text{Total sum of squares} = \text{Sum}\,(\text{Observation} - \text{Overall mean})^2,$$

as a measure of the effects of all variables.

Now we have the effect of all the variables and the effect of the residual variable, but not the effect of the location variable. If location did not have an effect, then the means in the census tracts would all be equal and equal to the overall mean. Thus, the difference between a census tract mean and the overall mean tells the effect of the location variable. We can find this difference for every woman, square all the differences, and add the squares. This gives the effect of the independent variable (ISS) as

$$\text{Independent variable sum of squares} = \text{Sum}\,(\text{Group mean} - \text{Overall mean})^2.$$

The more the group means are different, the larger this sum will be. This also looks like the numerator in a variance, and we can now begin to see how we use variances to tell if means are different.

The way these sums have been defined gives the identity:

$$\text{Total sum of squares} = \text{Independent sum of squares} + \text{Residual sum of squares}.$$

This equality always holds and is a mathematical consequence of the definitions above.

These sums are often displayed in a table. Sometimes ISS is called the between-group sum of squares, and the RSS is called the within-group sum of squares. The sums of squares are interpreted as the magnitude of effect, and the proportion R^2 tells the effect of the independent variable on a scale from 0 to 1 or as a percentage from 0 to 100.

The effects are based on the variation in the data. If all the data points are equal, then there are no effects and there is no variation. The TSS gives the total variation in the data, and this variation is broken down into two parts: one for the independent variable and one for the residual variable. Thus, we can say the independent variable explains the proportion R^2 of the total variation in the data. Multiplying R^2 by 100 gives the percentage of the variation in the dependent variable that is explained or accounted for by the independent variable.

Finally, what about the populations from which the data came? Most analyses of variance include test(s) of significance. The null hypothesis states that all the population means are equal versus the alternative hypothesis that at least one population mean is different from the others. It may not be surprising that the null hypothesis is not rejected when R^2 is small and most of the effect is accounted for by the residual variable—that is, when the RSS is large in comparison to the ISS. But the RSS, to a large extent, depends on how many observations there are, and the ISS, to a large extent, depends on how many groups there are.

Table 1 Magnitude of Effects

Variable	*Magnitude of Effect*	*Proportion*
Independent variable	ISS	$R^2 = \frac{\text{ISS}}{\text{TSS}}$
Residual variable	RSS	$1 - R^2 = \frac{\text{ISS}}{\text{TSS}}$
Total	TSS	1.00

Notes: ISS, independent sum of squares; RSS, residual sum of squares; TSS, total sum of squares.

We compensate for this by normalizing both sums of squares before comparing them. This is done by dividing RSS by the quantity $n - k$, where n is the total number of observations and k is the number of groups (this is analogous to what we do in the computation of the variance for a set of observations when we divide the sum of squares by $n - 1$). This gives the residual mean square (RMS) as

$$\text{RMS} = \frac{\text{RSS}}{n - k},$$

which then is the variance of the residual terms. Similarly, ISS is divided by $k - 1$ to give the independent mean square (IMS),

$$\text{IMS} = \frac{\text{ISS}}{k - 1}.$$

The two quantities $n - k$ and $k - 1$ are the so-called degrees of freedom for the corresponding sums.

When the null hypothesis is true, the two mean squares are estimates of the same variance and therefore approximately equal. When the null hypothesis is not true, then the IMS is a good deal larger than the RSS. To compare the two mean squares, we take their ratio

$$F = \frac{\text{IMS}}{\text{RMS}}.$$

Table 2 Analysis of Variance

Sources of Variation	*Sums of Squares*	*Proportions*	*Degrees of Freedom*	*Mean Squares*	*F Ratio*
Independent variable	ISS	$R^2 = \frac{\text{ISS}}{\text{TSS}}$	$k - 1$	$\text{IMS} = \frac{\text{ISS}}{k-1}$	$F = \frac{\text{IMS}}{\text{RMS}}$
Residual variable	RSS	$1 - R^2 = \frac{\text{RSS}}{\text{TSS}}$	$n - k$	$\text{RMS} = \frac{\text{RSS}}{n-k}$	
Total	TSS	1.00			

Notes: IMS, independent mean square; ISS, independent sum of squares; RMS, residual mean square; RSS, residual sum of squares; TSS, total sum of squares.

This is the F ratio with $k - 1$ and $n - k$ degrees of freedom. If the observed value is close to 1, then there is very little difference between the means. When F is much larger than 1, there is typically a significant difference between the means. Most statistical software gives p values for the observed values of F. There are also extensive published tables of the F distribution. For example, with 1 (2 groups) and 50 (52 observations) degrees of freedom, the .05 value of $F_{1,50} = 6.30$. Thus, we need a larger value of F than 6.30 to reject the null hypothesis of equal means. This test is valid only when the data in each group are approximately normally distributed.

These computations are often summarized in an ANOVA table, as seen in Table 2. There are times when the column with the proportions is not included in the table.

Finally, when a large F value results in a small p value, such that the null hypothesis of equal group means is rejected, we may also want to determine which of the means are different and which are not different from each other (assuming there are more than 2 groups). The answer is typically found using methods known as multiple comparisons.

Two-Way Analysis of Variance

When there are two independent, categorical variables, it would be possible to do two separate one-way analyses. With an analysis using the first variable, the effect of the second variable would be included in the residual variable, and the same for the second variable. However, if we can take the variance explained by both variables out of the residual variable simultaneously, the effect of the residual variable will be less. Since the effect of the residual variable is used in the denominator for the F tests, a smaller residual effect will result in a larger F and therefore (holding all other facts constant) a better chance to find a significant result for each independent variable.

Two new issues arise. First, the two categorical independent variables themselves define a contingency table. Suppose there are two treatments A and B, and the dependent variable is level of blood sugar. Some subjects would get both A and B, some would get A but not B, some would get B but not A, and some subjects would get neither A nor B. This gives a contingency table with two rows and two columns. How many subjects should we have in each of the four cells? With the same number of observations in each cell, it will be possible to get unique effects for both treatments, using ANOVA. In experiments, we have control over how many subjects there are in each cell. Thus, ANOVA has a close relationship to how experiments are designed.

But if we had a sample survey and categorized people by gender and urban/rural residence, there is no reason to expect there would be the same number of observations in each cell. Thus, if gender and residence are themselves related, we will not be able to get unique measures of the effects of gender and residence. If we did the analysis using multiple regression with two dummy variables, those variables would probably be correlated. With collinearity in the independent variables, we do not get unique sums of squares for each variable.

Second, there may be a so-called interaction effect present. There may be an additional effect of A and B, over and beyond their separate effects. Suppose we are testing two treatments intended to lower blood sugar, A and B, and the subjects that get both treatments show a reduction in blood sugar larger than the combined effects of A and B. This shows that there is an interaction between the two treatments. Fortunately, the strength of this interaction is easily quantified in an ANOVA. The typical output from

a two-way ANOVA will have a row for the first variable, a row for the second variable, a row for the interaction variable, a row for the residual variable, and a total row. There will be sums of squares for each variable that can be used to establish R^2s for each variable, degrees of freedom for each variable, mean squares, and F values for the two independent variables and the interaction variable. If the ANOVA table does not show the interaction variable, it may be that the interaction effect was found to be small and statistically insignificant. It is then common to combine the original RSS and the interaction sum of squares into a new RSS and use this for the basis of the F tests for the two categorical variables.

More Than Two Independent Variables

ANOVA generalizes directly to cases with more than two independent categorical variables. The main difference is that more interaction effects are possible. With three independent variables A, B, and C, there are main effects for each of the variables and two-way interaction effects for A and B, A and C, and B and C. We also get a three-way interaction effect ABC. Higher-order-interaction effects are often difficult to interpret. If they are not statistically significant, their sums of squares and degrees of freedom are often combined with the original RSS and degrees of freedom, and the new RSS and degrees of freedom are used for the F tests for the remaining variables.

Random Versus Fixed Variables

The distinction between random and fixed variables refers to whether we use all the values of the variable in question. Gender is an example of a fixed variable, because we use all the values (female and male) of the variable in the analysis. As an example of a random variable, consider a situation in which we want to take random samples of people in the almost 70 counties in Pennsylvania and compare the counties on some characteristic such as weight, in anticipation of a statewide antiobesity campaign if there are county differences. If there are no differences in weight across counties, the campaign will not take place. Taking a random sample within each county is a large undertaking; it is easier first to take a random sample of counties and then to take a random sample of people within the chosen counties. Since we are not using all the values of the county variable, county becomes a random as opposed to a fixed variable, because the values included represent a random selection of all the values to which we wish to generalize. For more complicated studies, it makes a difference in the analysis whether we have fixed or random variables.

Anxiety Disorders

Anxiety disorders are the most common mental disorders among adults with a peak in incidence during young adulthood. Anxiety disorders are associated with high rates of psychiatric comorbidity, physical illness, social and occupational disability, suicidality, and high rates of health service utilization in the United States and worldwide. There are mounting data to suggest that anxiety disorders begin early in life, are common among youth and adults, frequently persist throughout development, and increase the risk of subsequent psychosocial and psychiatric morbidity, including suicidal behavior, from early childhood into adulthood. Moreover, despite rapid increases in availability of efficacious psychotherapeutic and

psychopharmacologic treatments for anxiety disorders in the past three decades, evidence to date suggests that few with anxiety disorders seek and receive treatment.

The prevalence of anxiety disorders has been documented in a number of cross-sectional psychiatric epidemiologic studies that suggest that the lifetime prevalence of anxiety disorders ranges from 24.9% to 44% among adults in the community.

Risk Factors

In recent years, there has been increasing interest into factors that influence an individual's risk of developing an anxiety disorder. In contrast to heavy research investment into a number of other mental disorders, including conduct, mood, and psychotic disorders, there has been comparatively little research into the risk factors for anxiety disorders. Available evidence to date suggests that demographic factors, a history of childhood physical or sexual abuse, family history of anxiety disorders, disruption in parenting, and certain perinatal factors may increase the risk of anxiety disorders. In addition, individual factors associated with risk of anxiety disorders include evidence of mental disorders in childhood and certain genetic and personality factors.

Numerous studies have documented an association between specific demographic factors and increased risk of anxiety disorders. These studies variously show that factors such as female gender, lower socioeconomic status, minority racial status, marital status, and age are associated with increased risk of anxiety disorders in adulthood.

Childhood physical abuse has been associated in numerous studies with increased risk of mental disorders, though there is notably less research investigating these linkages compared with the impact of sexual abuse on later mental health. These studies variously show that exposure to childhood sexual abuse, especially severe abuse, is related to a significantly increased risk of a wide range of mental disorders, including anxiety disorders, in adulthood. Recent studies have shown linkages between childhood abuse and increased rates of panic disorder, panic attacks, social phobia, specific phobia, generalized anxiety disorder (GAD), and post-traumatic stress disorder (PTSD) among youth and adults. In sum, the evidence to date suggests a link between exposure to childhood physical abuse and increased risk of anxiety disorders.

Several studies have documented an association between childhood sexual abuse and increased risk of anxiety disorders. These studies variously show that exposure to childhood sexual abuse, especially contact sexual abuse, is related to a significantly increased risk of anxiety and anxiety disorders in adulthood. In a recent review of this literature, Fergusson and Mullen identified more than 30 studies that found that children known to have been sexually abused are vulnerable to a wide range of behavior problems, mental health disorders, and adjustment difficulties, including anxiety, fear, depression, and other negative attributes.

Family history of anxiety disorders has been shown to be a significant risk factor for the onset of anxiety disorders in offspring in clinical and high-risk samples. Results consistently suggest that having a parent with an anxiety disorder is associated with a significantly increased risk of anxiety disorders in offspring. For instance, Goldstein and colleagues found that panic disorder is more common among offspring of parents with panic and other anxiety disorders, compared with children with parents without anxiety disorders. Similarly, family studies have shown that the individual family member examined with first-degree relatives who have anxiety disorders have significantly higher rates of anxiety disorders, including social phobia, specific phobias, and agoraphobia, compared with those with never mentally ill relatives. Results on familial linkages of obsessive compulsive disorder (OCD) are relatively consistent but remain more mixed, while studies consistently show that panic is familial.

Previous clinical and cross-sectional studies of adults have shown that divorce/early parental separation and loss are associated with increased rates of anxiety disorders, compared with those who have not been exposed to these events. For instance, Davidson and colleagues found that adults with PTSD had significantly higher rates of parental separation before age 10, compared with those without PTSD.

Allen and colleagues examined the relationship between a range of prenatal and perinatal factors in the risk of anxiety and depressive disorders in a prospective, longitudinal study of 579 adolescents in the community. They found that fever and illness during the first year of life, as well as maternal history of miscarriage and stillbirth, were associated with an increased risk of anxiety disorders as were not being

breast-fed and maternal emotional problems during pregnancy.

Numerous studies have documented an association between psychiatric symptoms and mental disorders and increased risk of anxiety disorders, for instance, by Johnson, Cohen, and Brook. These studies variously show that the appearance of symptoms and mental disorders in early childhood, especially anxiety symptoms, is related to a significantly increased risk of anxiety and anxiety disorders in adulthood. Previous studies also show that depression in adolescence is associated with increased risk of anxiety disorders during young adulthood and suggest that anxiety disorders evident at an early age (ages 14 to 16) were associated with increased risk of later anxiety disorders. These associations persist after adjusting for differences in potentially confounding risk factors.

Genetic Factors

A recent meta-analysis by Kendler's group was performed to assess the level of heterogeneity between studies of the genetic epidemiology of anxiety disorders, as well as to combine data from multiple studies for a more powerful estimate of the heritabilities and familial risks of anxiety disorders. The results of this study confirmed that the relative risk of a later family member's developing most anxiety disorders ranges between 4 and 6. Analysis of twin studies suggests that the source of the risk is primarily genetic and found little support for common environment as the source of risk. The heritabilities for anxiety disorders are estimated at 30% to 40%. A number of genomic screens for panic disorder have been performed, with some modest evidence for linkage to several genomic regions. A single genome for OCD suggests linkage to a region on chromosome 9. A large number of candidate gene association studies have been performed for anxiety disorder, with the large majority being carried out in panic disorder data sets. Although generally underpowered, these studies have suggested some association between panic disorder and the genes for catechol-*O*-methyltransferase (COMT), monamine oxidase A (MAOA), the 2A adenosine receptor, and the Type B cholecystokinin receptor. Although these studies have not been adequately replicated, they provide interesting candidate genes for studies of anxiety phenotypes. Fewer such studies in OCD populations suggest the involvement of MAOA and COMT, the serotonin transporter, and the 1B serotonin receptor.

Previous clinical and cross-sectional studies of community samples have also shown linkages between specific personality traits (e.g., neuroticism) and increased rates of anxiety disorders, as well as increased severity, impairment, and poorer response to treatment associated with specific personality factors among patients with anxiety disorders. Moreover, cross-sectional community-based studies of adults have shown that personality traits are associated with increased rates of comorbidity among anxiety disorders, and depressive and substance use disorders, compared with those without these traits.

Outcomes Associated With Anxiety Disorders

Comorbidity is common among patients with anxiety disorders, and there is a relatively large literature on the comorbidity of anxiety disorders among adults in clinical and community samples. Clinical data suggest that comorbidity of mood and substance use disorders occurs among 50% to 80% of adult patients with anxiety disorders with similar rates suspected for pediatric patients; however, fewer data are available as information to investigate this speculation. Clinical data suggest that comorbid cases are more severe in terms of number of lifetime disorders, earlier onset, greater family history of anxiety and other mental disorders, poorer response to treatment, increased number of life events, and longer duration of disorder. Epidemiologic studies to date are largely consistent with these findings and are based on data from cross-sectional studies of population-based samples of adults in the community.

Previous studies have shown cross-sectional associations between anxiety disorders and a range of negative psychosocial outcomes. These include suicidal ideation and suicide attempts, occupational disability, higher rates of medical and psychiatric service utilization, physical morbidity, premature mortality, victimization, crime, poor partner relations, educational achievement, lower socioeconomic status, and others.

A small number of studies have documented an association between early anxiety problems and anxiety disorders and poorer educational achievement. These studies variously show that anxiety problems and anxiety disorders in childhood and adolescence

are related to a significantly lower level of educational achievement in youth and young adulthood.

A number of studies have documented an association between anxiety disorders and impairment in occupational functioning and occupational disability. These studies variously show that anxiety disorders, including panic disorder, social phobia, and generalized anxiety disorder, are related to a significantly increased risk of occupational disability compared with those without.

There have been several studies documenting an association between anxiety disorders and increased risk of suicidal ideation and suicide attempts. These studies variously show that anxiety disorders, especially panic attacks and panic disorder, are related to a significantly increased risk of suicidal ideation and suicide attempts. In addition, a recent literature review showed a significant association between panic and risk of suicide behavior.

Apgar Score

The Apgar score was devised in 1952 by Dr. Virginia Apgar (1909–1974) as a quick and simple method of assessing the condition of newborn infants. Typically an infant is assessed at 1 and 5 min after birth in five areas of functioning, each of which is assigned a score from 0 to 2. The five scores are summed, and a higher score indicates better health; a score of 7 or higher (out of a possible 10) indicates good to excellent health. The five areas of functioning, with their mnemonic in parentheses, are skin color (**a**ppearance), heart rate (**p**ulse), reflex irritability (**g**rimace), muscle tone (**a**ctivity), and respiration (**r**espiration). These areas were selected from a larger list of objective signs of infant health because delivery room personnel could be easily taught to evaluate them using the 0 to 2 scale.

The first use of the Apgar scale in research was a review in 1953 by Virginia Apgar of 1,025 infants born alive at Columbia Presbyterian Hospital in New York City. She found that Apgar score was related to the type of birth (higher scores were associated with vaginal births with the occiput presenting, and lower scores with breech extraction and version) and the use of anesthesia (which was associated with lower scores). Lower scores were also associated with higher neonatal death rates: Mature infants with scores of 0 to 2 had a 14% death rate, those scoring 3 to 7 a 1.1% death rate, and those scoring 8 to 10 a 0.13% death rate.

The Apgar score was quickly adopted for both infant assessment and research purposes, and the 5-min evaluation became common after a study of more than 54,000 births occurring during 1959 to 1966, in which the Apgar score at 5 min was found to be more predictive of neonatal mortality than the 1-min score. This was confirmed in an analysis of more than 150,000 infants born in Texas in the years 1988 to 1998, which found a strong correlation between the 5-min Apgar score and neonatal mortality. Preterm births with 5-min Apgar scores of 0 to 3 had 315 neonatal deaths per 1,000, those with scores of 4 to 6 had 72 neonatal deaths per 1,000, and those with scores of 7 to 10 had 5 deaths per 1,000.

For full-term births (37 weeks of gestation or later), those with 5-min Apgar scores of 0 to 3 had 244 neonatal deaths per 1,000, those with scores of 4 to 6 had 9 deaths per 1,000, and those with scores of 7 to 10 had 0.2 deaths per 1,000.

The Apgar score has been criticized because it has been used for purposes for which it was never intended—for instance, to predict the neurologic development of the infant or to serve as an indicator of hypoxia. Apgar scores are also influenced by several extraneous factors, including the maturity of the infant (a healthy preterm baby may receive a low score because of its immaturity) and maternal use of certain medications. However, the usefulness of the Apgar score for its original purpose, to quickly evaluate the health of a newborn infant, has been reaffirmed in recent studies and it is used all over the world for this purpose.

Applied Epidemiology

The term *applied epidemiology* has been defined according to five core purposes: (1) the synthesis of the results of etiologic studies as input to practice-oriented policies; (2) the description of disease and risk-factor patterns as information used to set priorities; (3) the evaluation of public health programs, laws, and policies; (4) the measurement of the patterns and outcomes of public health and health care; and (5) the communication of epidemiologic findings effectively to health professionals and the public.

Many in epidemiology and public health view the linkage between etiologic research and public health intervention as implicit. However, it was observed more than two decades ago that the discipline of epidemiology has become increasingly divorced from activities in the real world that result in the improvement of public health. The concept of applied epidemiology has developed in an attempt to address concerns that epidemiology is not responding adequately to the concerns of public health practitioners. A major challenge for applied epidemiology is to improve overall health status by encouraging and measuring the effects of policy change, economic incentives, and behavioral interventions. There is also a shortage of epidemiologists in public health settings. Making epidemiology more relevant to public health practice will require training programs that provide practicing professionals with at least a basic understanding of epidemiologic methods and ways of accurately interpreting the large body of scientific literature.

Background and Historical Evolution

Epidemiology is often considered the key scientific underpinning of public health practice. The pivotal role of epidemiology was emphasized by the Institute of Medicine in its definition of the substance of public health as ‘‘organized community efforts aimed at the prevention of disease and promotion of health. It links many disciplines and rests upon the scientific core of epidemiology’’ (Committee for the Study of the Future of Public Health, 1988, p. 41).

Since 1927, dozens of definitions of epidemiology have been put forth. A widely accepted version is the study of the distribution and determinants of health-related states or events in specified populations, and the application of this study to control of health problems. Perhaps the most comprehensive definition, and the one most relevant to public health practice, and applied work was crafted by Terris (1992):

> Epidemiology is the study of the health of human populations. Its functions are:
>
> 1. To discover the agent, host, and environmental factors which affect health, in order to provide the scientific basis for the prevention of disease and injury and the promotion of health.

2. To determine the relative importance of causes of illness, disability, and death, in order to establish priorities for research and action.
3. To identify those sections of the population which have the greatest risk from specific causes of ill health, in order that the indicated action may be directed appropriately.
4. To evaluate the effectiveness of health programs and services in improving the health of the population. (p. 912)

Each of these four functions has a direct application toward improving the overall health of the population. Recognition of epidemiology's role in improving the overall health of the public was not consistently present in early definitions.

Critics of modern epidemiology acknowledge that the science has produced information essential for understanding disease etiology and decreasing the burden of disease, yet many important public health issues are left unaddressed, and the potential role of communities has been inadequately considered. The so-called risk-factor epidemiology approach involves the search for multiple antecedent factors at the individual level (e.g., smokers at high risk of lung cancer), without necessity for determining intervening factors (e.g., the policies that lead to high smoking rates). To some degree, this approach ignores the multilevel, environmental determinants of disease (or health) and may obscure opportunities for intervention.

Using Epidemiology in Applied Settings

Epidemiologists have at their disposal an increasingly large array of tools that can enhance the application of epidemiology within public health practice. These include methodological advances that offer us more sophisticated ways to evaluate the health risks associated with many exposures and environmental contaminants in modern society. New information technologies, including the rapid evolution of microcomputers, software, and the Internet, offer exciting possibilities and quick access to data. In addition, changes in how health care is delivered, particularly the growth of managed care, provide new chances for epidemiologists to become involved in the assessment of health care utilization and quality. Despite these vast possibilities, there are many examples where decision making and health policy making in public health and health care occur in the absence of sound epidemiologic data and scientific reasoning. While epidemiology contributes greatly to the discovery of new knowledge for public health, it falls short in translating existing knowledge to improve practice and the health of the public.

Epidemiology is an important discipline to aid in bridging the gap between science and practice. Various reports and survey data support the importance of epidemiology in the public health setting. A survey of 40 state health agency directors found that among 11 key areas, epidemiology was rated as having the highest importance to respondents (a mean of 9.5 on a 10-point scale). In contrast, the percentage of respondents who believed that research needs in epidemiology were being met by universities was much lower (a mean of 4.4 on a 10-point scale).

Personnel and Training Needs

Although obtaining accurate estimates of personnel needs is difficult and relatively little empirical data exist, it is widely accepted that a shortage of trained epidemiologists has existed in public health agencies for several decades. It is also likely that the continually growing demand for quality measurement in health care will increase the need for epidemiologists in the private and nonprofit sectors. In a recent study of 37 state health agencies, 40.5% identified a shortage of epidemiologists. The shortage of master's- and doctoral-trained epidemiologists may be most acute for noninfectious disease epidemiologists. As of 2003, 43% of responding states did not appear to have a state chronic disease epidemiologist or person recognized as such even if not formally titled.

Training of epidemiologists occurs through a variety of mechanisms. Many epidemiologists at the master's and doctoral levels are trained by schools of public health. Other important sources include schools of medicine and the Epidemic Intelligence Service of the Centers for Disease Control and Prevention Survey data, and expert groups have also shown the need for expanded and perhaps different formal training in epidemiology. Successful educational programs need to maintain close contact with public health practice. Training and job categories in epidemiology are inconsistent. For example, 42% of the current epidemiologic workforce lacks formal academic training in epidemiology. There are promising developments in training across the globe, including Field Epidemiology Training Programs and Public Health

Schools Without Walls. The current epidemiologic and technologic advances provide unprecedented opportunities for practicing health professionals. To take full advantage of these opportunities, continued skill enhancement will be necessary.

Arthritis

Arthritis is a general term that technically means inflammation of the joint(s), but the terminology is somewhat misleading because arthritis also refers broadly to a wide range of joint-related conditions—not all of which involve inflammation per se. Joints have six major components: (1) cartilage, (2) synovial membrane, (3) bursa, (4) muscle, (5) tendon, and (6) ligament. Problems with the functioning of any of these joint components may be described as "arthritis." This entry examines the epidemiology, clinical management, and social and cultural impact of arthritis, focusing in particular on osteoarthritis, rheumatoid arthritis, and juvenile rheumatoid arthritis.

Epidemiology and Clinical Manifestations

The term *arthritis* covers more than 100 different medical conditions, and approximately one third of the population in the United States is affected by arthritis, which is the leading cause of disability. The primary causes for most forms of arthritis are not completely known, but arthritis occurs more commonly in women than in men, and the prevalence of most forms of arthritis increases with advancing age. Nevertheless, arthritis can affect all age groups, including children. Common subtypes of arthritis include osteoarthritis, rheumatoid arthritis, and juvenile rheumatoid arthritis.

Osteoarthritis

Osteoarthritis (OA), sometimes called degenerative joint disease, is the most common form of arthritis and is closely associated with the aging process. OA is associated with worn or frayed cartilage, which subsequently fails to properly cushion the joint. The typical clinical manifestations include painful joints, stiffness, and difficulty with mobility. Prevalence estimates for OA are highly dependent on the criteria used to define it, such as symptomatic pain, radiographic evidence, or self-reported symptoms. However, the incidence of hip arthritis is approximately 88 cases per 100,000 person-years; the incidence of knee arthritis is approximately 240 cases per 100,000 person-years; and the incidence of hand arthritis is approximately 100 per 100,000 person-years. Due to the implications for weight bearing, the presence of radiographic evidence of OA in the knees or hips is often associated with substantial functional impairment. The known risk factors for OA include advancing age, female gender, obesity, major joint trauma, repeated overuse, heredity, prior inflammatory disease, and developmental abnormality. A role for heredity in OA, although

complex, also is suspected because persons whose parents had OA are at higher risk for developing OA themselves. Occupations that involve high physical demands or repetitive movements are associated with a higher incidence of OA.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) affects about 1% of the worldwide population, and approximately 75% of those affected are female. RA is a condition involving chronic inflammation of the synovial membrane that lines the joint. As a result, the joint becomes swollen, tender, and warm; inflammatory activity may eventually cause irreversible damage to cartilage and/or bone. RA typically presents in a symmetrical manner with both sides of the body being similarly affected; the joints of the wrists and knuckles are almost always involved. Persons with RA also commonly experience systemic symptoms such as fatigue, aching muscles, and even a low-grade fever. The major risk factors for RA are advancing age and female gender. Onset is most commonly in the fifth and sixth decades of life, but it can occur at any age. Both genetic and hormonal factors are thought to play a role in the development of RA. Family studies reveal a higher risk for RA among first-degree relatives as compared with persons who are unrelated, although this relationship is not pronounced. With regard to hormonal risk factors, the picture is not entirely clear, but symptoms of RA often remit during pregnancy, and recurrence is likely after birth. Studies have been mixed regarding the role of oral contraceptives and postmenopausal estrogens, but some investigations have suggested that these therapies may lower the risk for development of RA.

Juvenile Rheumatoid Arthritis

As the name implies, juvenile rheumatoid arthritis (JRA) affects children prior to age 16. Population-based studies indicate that the prevalence of JRA is approximately 1 to 2 per 1,000 children; the incidence is 11 to 14 new cases per 100,000 children. The cause of JRA is unknown, but several subsets of the condition exist. Interestingly, onset prior to age 6 typically involves females; onset at an older age typically involves males. As is the case with most other forms of arthritis, the risk factors are unclear, but heredity appears to play a role due to the notably higher incidence in monozygotic versus dizygotic twins. Infectious agents (e.g., rubella virus and Lyme disease) also have been suggested as possible triggering agents for JRA. Life expectancy for adults with JRA is lower than for the general population.

Clinical Management

Due to the wide range of conditions that are subsumed under the term *arthritis*, no single treatment regimen will apply to all. However, for most forms of arthritis, a multimodal approach is employed, which may involve patient education, especially in the form of "self-management" programs. Other common clinical interventions include pharmacologic management, exercise (both strengthening and aerobic), physical modalities (heat and cold), splinting, surgery (including joint replacement), and cognitive-behavioral training, among others. Clinical intervention is also frequently directed at secondary problems such as pain, fatigue, sleep disturbance, mood disorders, deconditioning, treatment adherence, and work disability.

Social and Economic Impact

Arthritis, in all forms, exacts a heavy toll in terms of physical, social, and psychological consequences. The physical consequences include pain, joint stiffness, and limitations of mobility, which can secondarily affect personal care, household activities, and occupational status. Social consequences can include role limitations, increased social isolation, and loss of leisure activities. Psychological consequences can include a higher incidence of depression, anxiety, and perceptions of helplessness, particularly in the context of a frequently unpredictable disease course. These collective physical, social, and psychological impacts all conspire to make arthritis the leading cause of disability in the United States. Lower levels of formal education and lower income levels, possibly due to less adaptive resources, have been identified as risk factors for arthritis-related disability. The economic impact of arthritis is enormous due to the high prevalence of the various conditions, the chronicity of the symptoms, the implications for high health care utilization, and the frequency of losses in gainful employment. The economic impact of arthritis in the United States has been estimated

to be approximately 2.5% of the gross national product.

Asbestos

Asbestos, a mineral used as an insulator and fire retardant during much of the first half of the 20th century, is now a nearly ubiquitous environmental contaminant. Found frequently in buildings, asbestos may be present in a broad range of construction materials, from concrete blocks to flooring.

Asbestos is a human health threat because a single submicroscopic fibril, thousands of which make up a single asbestos fiber, can cause severe lung disease. Only when asbestos is pulverized are the dangerous fibrils released into a dust cloud, which may be inhaled or ingested. The safe removal of asbestos is therefore a delicate and time-intensive process and presents a high risk of exposure. Current practice is typically to leave asbestos undisturbed. It is estimated that billions of dollars would be required to eliminate asbestos from all affected buildings.

Asbestos exposure is most commonly associated with occupational exposure, though persons living in areas with naturally occurring asbestos or man-made mines may also be exposed. Historically, high-risk occupations have included mining, milling, working with insulation, shipbuilding/repairing, and working in the textile industry. Men are more commonly exposed to asbestos and, therefore, are more frequently affected by negative sequelae associated with exposure.

The most common diseases caused by asbestos exposure are mesothelioma, asbestosis, and lung cancer. If ingested, asbestos fibrils may also cause stomach cancer. Mesothelioma is a very rare form of cancer of the mesothelium, the membrane lining the various body cavities, which most commonly affects the mesothelium of the lungs or chest cavity, but may also affect the mesothelium of the abdomen or heart. Mesothelioma is nearly always associated with asbestos and is not related to smoking. Asbestosis occurs when asbestos fibrils irritate and scar lung tissue. This damage decreases the ability of the lungs to oxygenate blood, causing shortness of breath. There is no treatment for asbestosis, a progressive disease. The many diseases associated with asbestos exposure have a long latency period, typically many decades. Thus, studies assessing the risk of various health outcomes among asbestos-exposed persons require adequate follow-up time.

Asbestosis is a member of the group of diseases termed *pneumoconioses*. These diseases—coal workers' pneumoconiosis (CWP), silicosis, asbestosis, mixed dust pneumoconiosis, graphitosis, and talcosis—all result from inhaling mineral particles, result in changes in lung tissue, and have no current treatment. From 1968 to 2000, deaths due to pneumoconioses decreased overall and for all specific subtypes except asbestosis. Rather, mortality due to asbestosis increased steadily from 77 to 1,493 during this period. The annual age-adjusted death rate for asbestosis increased from 0.54 per million population in 1968 to 6.88 per million population in 2000. Asbestosis increased throughout the United States during this time, though the coastal states saw the most marked rise, likely due to the shipbuilding industry. Since asbestosis mortality usually occurs 40 to 45 years after exposure, this upward trend in asbestosis mortality likely dates back to the post–World War II era. However, it is not expected that this trend will begin to reverse for at least several years, since asbestos use peaked in the United States in 1973. The peak in asbestosis deaths in the United States will likely be seen around 2013 to 2018.

Beginning in the 1970s, studies indicated that the risk of lung cancer among people exposed to asbestos was increased beyond what would be expected by cigarette smoking (synergism). While is remains clear that lung cancer risk among asbestos-exposed persons differs by smoking status (effect modification), the underlying relationship has been debated recently—namely, whether this model is additive or multiplicative. According to the U.S. Environmental Protection Agency (EPA), cigarette smoking and asbestos exposure interact synergistically in the development of lung cancer. Estimates

of lung and pleural cancer risk following asbestos exposure have ranged from 1.9 to 28.0.

Asbestos is still used worldwide, though it has been limited to primarily commercial uses in the United States and most Western European countries; some European countries have banned its use altogether. In the United States, asbestos use peaked in 1973 at 719,000 metric tons. In 1999, when asbestos use was limited to commercial roofing materials, gaskets, and friction products such as brake shoes and clutches, 15,000 metric tons were used in the United States. Worldwide, 1.93 million metric tons of asbestos were produced in 1999, compared with a 1975 peak global production of 5.09 million metric tons. Many countries rely on asbestos for inexpensive building materials, made by combining cement with asbestos for added strength. Asbestos cement products tend to carry a lower risk of exposure since the cement is relatively effective at securing the asbestos fibers within the solid.

Asbestos may also be found in vermiculite, a mineral used for its fire-resistant and absorbent properties. One of the most recent and most publicized cases of asbestos exposure involved a vermiculite mine in Libby, Montana. In late 1999, following public concern and media reports of asbestos contamination, the EPA and other federal agencies began environmental assessments in Libby, the site of a vermiculite mine and two former vermiculite processing plants. Mining of asbestos-contaminated vermiculite occurred in Libby from the 1920s until the mine's closure in 1990. It is estimated that 80% of the world's vermiculite came from the mine in Libby. Libby was added to the National Priorities List (NPL) in 2002, after which 3,500 properties in the area were inspected. Cleanup work has already begun in Libby, with an expectation that as many as 1,400 properties will require remediation.

In 1989, the United States passed a ban on asbestos-containing materials (ACM). Because the ban was overturned in 1991, however, much of this ban was never implemented. Several categories of ACM were banned after the 1991 decision: flooring felt, rollboard, and corrugated, commercial, or specialty paper. In addition, no new uses of asbestos are permitted in the United States. The EPA primarily regulates asbestos use under the Clean Air Act and the Toxic Substances Control Act.

Asian American/Pacific Islander Health Issues

Persons in the United States with ancestral origins in Asia or the Pacific Islands (Polynesia, including Hawaii, Micronesia, Melanesia, and other islands) have often been grouped together for the purpose of gathering health information and calculating statistics. However, this is an extremely heterogeneous group, with national origins that cover one third of the globe. Until recently, there have been relatively few persons in the United States from Asia, and grouping them together was a way to fit these populations into the racial classification system used in data collection in the United States. There is widespread recognition that describing the group in

aggregate might mask important health issues that are particular to one or more subgroups. The Asian American and Pacific Islander population (AAPI) comes from very diverse environments, and their experiences in the migration process and living in the United States have also varied greatly. The economic status of these groups varies greatly: The Japanese and Asian Indians are among the wealthiest ethnic groups in the United States, while persons from Southeast Asia have very high rates of poverty. Pacific Islanders have lower average educational attainment and income than Asian Americans. Ideally, health issues would describe each national origin population separately, such as the Thai, Filipino, or Samoan. Practically, though, data are rarely available to do this, and an important health issue for Asian Americans and Pacific Islanders is the inadequacy of the data.

Data Issues

The aggregate AAPI category is a relatively recent invention, recommended in a 1977 federal document as part of a new effort to collect uniform statistics by race and ethnicity across all federal agencies. The 1980 census was the first census to use the AAPI category. In the 1990s, there were two changes in federal recommendations for race and ethnicity data collection that are important for the AAPI category, both of which are seen in the 2000 census and some other recent data sources. First, Asian Americans and Pacific Islanders were separated into two race categories. Second, persons were allowed to check more than one race code. The multiracial provision has a large impact on AAPI data because about 15% of persons who checked an Asian American race code and 55% of persons who checked a Pacific Islander race code also selected another race code in the 2000 census. Pacific Islanders are the race group most likely to check more than one category. Because it is unclear how to count the multiracial persons, it is difficult to track the size of the Asian American or Pacific Islander populations or to use the census as a denominator when calculating a health indicator when the numerator data source lacks multiple race codes. The inconsistency across data sources in racial or ethnic classification is a serious limitation in comparing data over time or across different study populations; some data are reported with one race category (AAPI), some with two race categories (Asian American and Pacific islander), and some with ethnic subgroup categories (such as Chinese). Sometimes, identification by ethnically distinctive surname is used to infer subgroup in data sources that provide only aggregate racial identification or no racial identification.

There is another important limitation to health data for AAPI. Asian Americans constituted 4.2% of the population in 2000 and Pacific Islanders 0.3%. Nationally representative health surveys, even large ones with several thousand respondents, do not include adequate numbers of participants in the individual AAPI subgroups to permit estimates of health factors, and they may not even have enough participants to calculate stable rates for the aggregate race categories. This is the case for the National Health and Nutrition Examination Surveys. Beginning in the 1980s, many health-related data collections oversampled African Americans and Latinos to ensure adequate numbers for analysis, and there were also a number of epidemiologic studies that exclusively targeted these groups. However, Asian Americans were perceived as a ''model minority'' without health problems requiring special research and public health efforts, and until very recently, there was neither oversampling in large data collections nor targeted studies. A notable exception is the Honolulu Heart Program initiated in 1965 by the National Institutes of Health as a prospective cohort study of environmental and biological causes of cardiovascular disease among Japanese Americans living in Hawaii. More recently, a few large epidemiologic studies have oversampled Asian American populations, including the National Longitudinal Study of Adolescent Health (Add Health), the Multi-Ethnic Study of Atherosclerosis (MESA), and the Study of Women's Health Across the Nation (SWAN). Chinese Americans are best represented in these studies.

Asian American Health Issues

By many standard health indicators, Asian Americans are indeed a very healthy population. Age-specific death rates reported by the National Center for Health Statistics are much lower for Asian Americans than for any of the other race categories and life expectancy is higher, although there are concerns with the completeness and accuracy of Asian American identification on the death certificates used to calculate the death rate numerators. Asian Americans are less likely

to die of heart disease, diabetes, and stroke than non-Hispanic whites. Infant mortality is also lower for Asian Americans than for non-Hispanic whites, although average birthweight is also lower. Because a high proportion of adult Asian Americans are foreign-born, the "healthy immigrant effect" is often cited when discussing the health of this group. The healthy immigrant effect comes from the observation that recent immigrants tend to be in very good health, presumably because of the powerful selection factors associated with their motivation to migrate and their success in the difficult migration process.

Nonetheless, there are several health issues specific to Asian American populations. Since a high proportion of adults are migrants, they may face significant cultural and linguistic barriers accessing health care. Limited English proficiency is common among the adults in some subgroups, particularly persons from Southeast Asia and China. There are also high rates of noninsurance of health among Asian migrants.

Infectious Diseases

The infectious diseases recognized as particular concerns among Asian Americans are tuberculosis and hepatitis B. Many adult Asian Americans are migrants from countries where these infections have a much higher prevalence than in the United States.

Asian Americans have the highest tuberculosis rate of all race groups in the United States, estimated to be as high as 20 times the rate among non-Hispanic whites. Almost one fourth of new tuberculosis cases in the United States occur among Asian Americans, mostly among the foreign-born.

Hepatitis B is more common among Asian Americans than any other race group. Hepatitis B virus can lead to cirrhosis (scarring) of the liver and liver cancer. Hepatitis B is transmitted through bodily fluid, including blood. One mode of transmission is from an infected mother to her infant in childbirth, and this is a common mode of transmission in regions with high prevalence of hepatitis B, such as Southeast Asia, China, and Korea. The vaccine against hepatitis B, introduced in most countries in the 1990s, is effective at blocking mother-child transmission when administered to the infant at birth. However, persons born in some parts of Asia before that have a high likelihood of hepatitis B infection. There have been estimates that chronic infection with hepatitis B may be as high as 15% among some Asian American populations. Asian Americans may also have relatively high rates of hepatitis C, but data are limited.

Cancer

Cancer is the leading cause of death for Asian Americans, although it should be noted that more Asian Americans die of cancer than of heart disease not because the cancer death rate is so high but rather because the heart disease death rate is low. However, there are several cancer sites for which Asian Americans do have high risk compared with most other race groups. These are liver cancer, cervical cancer, and stomach cancer—all cancers of infectious origin. The few studies that allow the disaggregation of Asian Americans, though, suggest that risk is not uniformly high across all Asian American subgroups for these cancers. Liver cancer rates are particularly high for Vietnamese, Koreans, and Chinese. Stomach cancer rates are very high for Japanese and Koreans and somewhat high for Chinese and Vietnamese. Cervical cancer risk is high for Vietnamese women and may be high for Asian Indians. Because cervical cancer is preventable through early detection, there have been concerted efforts to increase rates of screening with a Papanicolaou smear, particularly among women from Southeast Asia.

Coronary Heart Disease

Heart disease rates are very low among all Asian American groups except Asian Indians. Asian Indians, whether living in South Asia or elsewhere, have among the highest rates of coronary heart disease in the world. Although the Asian Indian population is the most rapidly growing subgroup in the United States, increasing by more than 100% from 1990 to 2000, there has been little epidemiologic research in the United States. Many Asian Indians have very high levels of the blood fat triglyceride and low levels of high-density lipoproteins (the "good cholesterol"), both well-recognized risk factors for coronary artery disease. There are also high rates of diabetes among Asian Indians, another risk factor for coronary heart disease. Some recent research suggests that genetic factors may play a role in coronary heart disease risk for Asians Indians.

Diabetes

Some Asian American subgroups appear to have a risk of type 2 diabetes as high or higher than

non-Hispanic whites. These groups are Asian Indians and possibly Japanese and Filipinos. Higher body mass index is associated with increased risk of type 2 diabetes in all populations, but there is some evidence that the relationship is different for Asians, regardless of geographic location. Because of greater percent body fat and visceral adiposity at the same level of body mass index, Asian Americans may have increased diabetic risk at lower levels of body mass index than white populations.

Health Behaviors

Data are limited on health behaviors for Asian American subgroups. The difference between smoking rates for men and women is much larger for Asian Americans than other race groups, reflecting the high prevalence of smoking among men in East and Southeast Asia (but not South Asia) and very low prevalence of smoking among women with the same background. Men from Southeast Asia, Korea, and China have high rates of smoking in the United States. Several studies suggest that more than half of men from Southeast Asia smoke. While smoking is more prevalent among Asian American women born in the United States than among migrants, it is still less common than among non-Hispanic white women.

Asian Americans have lower rates of obesity than other race groups. However, obesity risk is not uniform across subgroups; limited data suggest that Asian Indian women and Japanese men have rates of obesity similar to non-Hispanic whites. Foreign-born Asian Americans are less likely to engage in leisure-time physical activity than persons born in the United States and are no more likely to engage in nondiscretionary physical activity (for transportation or employment-related), which would compensate for lower levels of discretionary activity.

Mental Health Issues

Many small studies have investigated mental health issues among specific populations of Asian Americans, particularly depression and stress related to acculturation. However, cultural differences in the expression, recognition, and description of depression and other mental health problems make it difficult to develop multilingual survey instruments that will function similarly across different populations. Asian Americans appear to have relatively low rates of utilization for mental health services, and there is concern that this represents underutilization. Refugees from Southeast Asia have a high risk of post-traumatic stress syndrome.

Acculturation and Health

Many studies have examined how acculturation affects the health of Asian Americans. The conceptualization and measurement of acculturation are not consistent across studies, with some using a single measure, such as years in the United States or home language use, and others using instruments that include several questions and try to measure an underlying construct of cultural orientation. In general, studies of physical health find declining health and worsening health behaviors with increasing years since migration, or other measures of acculturation. Studies of mental health have conflicting findings.

Pacific Islanders

While data are limited for describing Asian American health, they are much more limited for Pacific Islanders. Pacific Islanders have been nominally included in studies of AAPI, but there is often little information specific to them. Most Pacific Islanders in the United States originate in islands that are part of the United States (Hawaii, Guam, and Samoa) and are therefore not international migrants, even if they have moved to the mainland. They have not experienced the selection pressures that probably account for the good health of migrant Asian Americans.

Pacific Islanders generally experience poorer health than both Asian Americans and non-Hispanic whites. Available data suggest generally high rates of both infectious and noninfectious diseases among Pacific Islanders. They are more likely to develop and die from cancer, heart disease, and diabetes. Obesity rates are very high among native Hawaiians and Samoans. Factors contributing to poor health may include limited access to health care, cultural barriers, and poor nutrition. Rates of hepatitis B and tuberculosis are high for Pacific Islanders, as they are for Asian Americans, and HIV/AIDS may also be higher than among non-Hispanic whites.

Association, Genetic

Analytical epidemiologic studies investigate potential associations between exposures (e.g., risk factors) and outcomes (e.g., as identified in quantitative data on traits or diseases) of interest. Genetic association studies are a special type of analytical epidemiologic studies in which the exposure of interest is represented by a genetic factor. Genetic factors are usually represented by common forms of genetic variation, such as single nucleotide polymorphisms (i.e., genetic loci for which different DNA variants can be present among different individuals) or deletions or insertions (i.e., losses or additions of a sequence of DNA in a chromosome).

Identification of genetic associations can have important implications in the prevention, diagnosis, and treatment of diseases, including complex diseases such as cancer and cardiovascular illnesses. For example, identification of specific polymorphisms related to the development of disease may lead to prevention programs targeted to specific subgroups of individuals at high risk. Similarly, genetic variation that affects response to specific medications may be taken into account in selecting the most effective and least toxic pharmacologic treatments for individual patients.

Genetic associations can be investigated within several epidemiologic study designs, including the classic case-control study design. In a case-control study of genetic risk, individuals with and without a specific disease are compared according to their exposure to a specific genetic risk factor, usually whether they have or do not have a particular genetic variant. However, the genetic nature of the exposure influences the methodological approach used in these studies in several respects. One reason for this influence is that even in the simplest case of diallelic loci (i.e., genetic loci at which only two possible alternative alleles are present in the population), double copies of most polymorphisms are present in humans (with the exception of loci on the sex chromosomes), and they are located in proximity to other polymorphisms; therefore, genetic risk factors can be linked to disease in several different ways. For example, the disease of interest can be associated with

1. the frequency of a specific allele among chromosomes from cases (allele analysis);
2. the frequency of a specific combination of alleles at one locus among cases (genotype analysis);
3. the frequency of specific haplotypes (i.e., the sequence of alleles at different loci on the same chromosome) among chromosomes from cases (haplotype analysis); and
4. the frequency of specific combinations of haplotypes among cases (diplotype analysis).

In addition, because at the population level alleles can have different frequencies in different groups (e.g., ethnic groups) and can be assorted at different loci in a nonrandom fashion (i.e., they can be in linkage disequilibrium), the validity of associations between polymorphisms and disease in epidemiologic studies can be confounded by associations related to

population stratification across ethnic groups and/or by the existence of linkage disequilibrium between these polymorphisms and other nearby polymorphic loci. Despite these limitations, genetic association studies are usually less vulnerable to confounding and bias than classic epidemiologic studies. For example, in genetic case-control studies, the risk of recall bias is minimized and the temporal sequence between exposure and outcome is resolved because individual genomic variation is established from conception and, thus, must precede the outcome of interest (e.g., onset of disease).

Yet in the years following the completion of the Human Genome Project, most studies investigating genetic associations for complex diseases have produced variable results. The genetic dissection of complex diseases is proving quite challenging. One possible explanation for these inconsistencies is that the effects of genetic variation on disease risk are influenced by interactions between genes and the environment. Thus, capturing the complexity of these interactions will need to precede the identification of the genetic components of complex diseases.

Association of Schools of Public Health

The Association of Schools of Public Health (ASPH) was founded in 1953 and is the only U.S. public health organization representing deans, faculty, and students of ASPH-accredited and associate schools. It is governed by its members and board of directors and currently has 39 member schools. It was created in response to the growth of graduate education programs in public health during the early 20th century, which led to a need to formalize a periodic accreditation process of national programs. The comprehensive accreditation process for schools of public health is now conducted by an independent agency, the Council on Education for Public Health (CEPH), which is recognized by the U.S. Department of Education.

ASPH schools prepare students for entry into careers in public health with a well-rounded approach that includes the major facets of public health. Member schools must be independent academic institutions that have a doctoral degree program and offer degrees in the core areas of public health. These areas include epidemiology, environmental health, biostatistics, health service administration, and health education/behavioral sciences.

At present, 15 types of degrees in specific areas of public health are offered. New areas of study include international and global health, biomedical and laboratory practice, and maternal and child health. Distance learning methods are becoming more popular, with several ASPH member schools offering degrees through distance learning alone.

The ASPH performs a number of functions to further public health and public health education. Its goals, as enumerated on the ASPH Web site, include facilitating communication among member schools, providing a focus and a platform for the enhancement of emerging academic public health programs, cooperating with the federal government to strengthen public health education and the public health profession, assisting in the development and coordination of national health policies, serving as an information center for governmental and private groups and individuals whose concerns overlap those of higher education for public health, and assisting in meeting national goals of disease prevention and health promotion.

Not all educational institutions for public health and health education in the United States are members of ASPH, because they have not gone through the formal review process administered by CEPH. The issues of accreditation, accountability, and cost-effectiveness are controversial, and there is an ongoing dialogue among various public health agencies concerning how to improve the quality of services to the public and how to raise the standard of public health services on a local and national level.

Asthma

Asthma is an obstructive airway disorder characterized by reversible airway narrowing, mucus hypersecretion, chronic inflammation, and episodic shortness of breath. Severe recurrent bouts of asthma lead to airway scarring, termed *remodeling*, which is not reversible and can lead to an increased frequency and severity in asthma exacerbations and lung infections. Asthma can be allergen provoked, which is termed *atopic*, or asthma may be due to unknown factors and termed *intrinsic*. There is a broad consensus that the prevalence of asthma has increased dramatically in most industrialized countries over the past several decades, prompting the development of several asthma study cohorts that have attempted to address asthma incidence, etiology, prevention, and control. What has come to be appreciated in the past decade due to the use of conditional gene expression systems, and transgenic animals, is the true complexity of the multiple molecular pathways that are involved in the development and progression of asthma and the understanding that asthma is more accurately characterized as a collection of diseases comprising a syndrome rather than a distinct homogenous entity. Therefore, in terms of a cure, there is no single "magic bullet" with regard to the treatment or the prevention of asthma.

Incidence, Prevalence, and Cost Burden

In 2004, the incidence of asthma worldwide was estimated at 300 million people, and it was predicted that by the year 2025, this number would increase to 400 million. In the United States, it has been estimated that as many as 11% of the population may be afflicted. Asthma often develops in childhood, although incident adult cases are not uncommon. Estimates indicate that 28% to 78% of young children with asthma ultimately have symptom resolution once adulthood is reached, while 6% to 19% continue with severe forms of the disease. Asthma is the third leading cause of hospitalization among persons less than 18 years of age in the United States, and according to the Centers for Disease Control and Prevention, the prevalence of asthma among U.S. children increased from 3.6% in 1980 to 5.8% in 2003. Not surprisingly, there is a significant cost burden associated with health care for asthma. In 2002, the total direct medical costs relating to asthma were estimated to be $9.4 billion, with indirect costs comprising an additional $4.6 billion. Of these direct costs, 33.0% were due to hospitalization, and 39.4% were related to prescription drug costs.

Diagnosis

Asthma is a complex disease to diagnose with a single parameter. The definitive diagnosis of asthma is a clinical one made on the basis of a patient's medical history, physical examination, and assessment of the reversibility of airway obstruction. In most studies, questionnaires are used to assess whether subjects have had symptoms of asthma or have ever received a diagnosis of asthma from a physician. This type of assessment is highly subjective to a patient's and a physician's understanding and awareness of asthma and has brought speculation as to whether the number of asthma cases has really increased so dramatically or whether there is simply a higher public awareness of the disease coupled with a greater willingness on the part of physicians to diagnose patients as having asthma. One study that illustrates this conundrum well is a study in Scotland that showed that the proportion of children reporting asthma symptoms who also received a diagnosis of asthma increased from 28% in 1964 to 64% in 1999.

Risk Factors for Incidence and Exacerbations

The risk factors associated with asthma appear to involve both genetic and environmental components. Clinical population studies have shown that the risk of allergic disease such as asthma is inherited. In families in which one parent has allergic disease, including asthma, at least 30% of the children will

also be allergic; if both parents have the disease, the risk rises to 50%. In children, risk factors for asthma have been identified as wheezing, familial history of asthma, atopy, obesity, being male, an increase in eosinophils in the peripheral blood, severe infections of the lower respiratory tract, and increased IgE. In adults, the risk factors for asthma include cigarette smoking, rhinitis, atopy, familial history of asthma, and being female. The susceptibility to asthma that may be attributable to genetic predisposition has been estimated to be as high as half of all cases. Chromosome linkage studies have shown that regions on chromosome 6p and 12q are involved in susceptibility to allergy and asthma. However, studies involving monozygotic twins raised in different environments and having differing degrees of asthmatic disease have illustrated the complex interaction of the environment and genetics.

Several environmental factors have been studied for their impact on allergy and asthma sensitization. In urban areas, air pollution, especially diesel exhaust, nitrogen dioxide, and sulfur dioxide have been shown to be major contributors to the development and severity of asthma through the augmentation of previous allergen-specific IgE responses and the capacity to promote the primary sensitization to a new allergen. Exposure to tobacco smoke is highly associated with susceptibility to asthma, and a meta-analysis concluded that parental smoking is very likely to be causally related to both acute respiratory tract illnesses in infancy and the incidence of childhood asthma. There are also studies that have shown that active smoking is associated with the onset of asthma in adolescents and adults.

The environmental impact of living in rural areas has long been known to confer a protective influence against the development of asthma. This is thought to be due to the concurrent exposure of children to bacterial proteins called endotoxins, and potential allergens, while the immune system is still developing. This serves to confer an immunologic tolerance to classic allergens rather than promote an asthmatic response. The ''hygiene hypothesis'' relates to this phenomenon. According to this theory, our largely indoor and hygienic Western lifestyle has decreased our exposure to outdoor environmental allergens and bacterial proteins and, therefore, has increased our likelihood of developing asthma.

Psychological stress has also been shown to play a role in both the incidence and exacerbation of asthma, and there is an association between depressive disorders as well as anxiety disorders and asthma. The mechanism by which stress influences asthma is by altering hormonal components of the endocrine system, such as cortisol and catecholamines, which in turn alters the polarization of the immune response toward an allergic phenotype.

Epidemiologic studies continue to identify and evaluate risk factors for the development or exacerbation of asthma. Episodic exposures to toxicants will continue to be evaluated by documented studies of adverse health effects with comparisons to measured exposures, hospital admissions, or lost school days. Prospective cohort studies or population-based surveys will also continue to evaluate chronic exposures to toxicants and the incidence or prevalence of asthma. Future trends in asthma epidemiology are likely to focus on the combination of specific genetic and environmental factors in the etiology or contribution of the disease and will continue to be challenged by the difficulties of characterizing chronic exposures, multiple contaminant exposures, and study design limitations. It is clear that there are multiple contributing factors to asthma for which epidemiologic studies have been invaluable as far as their contribution to better understanding the syndrome as a whole.

Attack Rate

The attack rate is the proportion of people who become ill with a disease. These rates are used in the investigation of an acute outbreak of disease to determine what exposures contributed to the illness. It is calculated as the number of people who became ill divided by the number of people at risk for the illness:

$$\frac{\text{Number of people who became ill}}{\text{Number of people at risk of becoming ill}}.$$

A case definition must first be developed. Case definitions may be based on a constellation of clinical signs (e.g., fever with vomiting and/or diarrhea) or on serology (e.g., the presence of antibodies to the etiologic agent). Those people who meet the case definition are identified; the number of people who meet the case definition is the numerator of the attack rate. The denominator of the attack rate is the number of people at risk of becoming ill. As the attack rate is used in the investigation of an outbreak, those at risk are the people who had the opportunity to be exposed such as those who attended the same event as those who became ill.

The time over which cases are collected is defined by the specifics of the outbreak: those who develop the symptoms over a set period after an event. The period over which new cases occur can be a clue to the identification of the causative agent.

Those who did or did not get sick are interviewed to determine their exposures, and attack rates for those who were or were not exposed are calculated. It may be impossible to determine the causative exposure from exposure-specific attack rates alone, as many of the subjects will have exposure to multiple potential agents. A relative attack rate must be calculated for each exposure:

$$\frac{\text{Attack rate}_{\text{exposed}}}{\text{Attack rate}_{\text{unexposed}}}.$$

An Example of Analysis Using Attack Rates

An outbreak of Group A β-hemolytic streptococcal pharyngitis occurred among prisoners in a jail. Of 690 inmates, 325 were affected. A survey of 314 randomly selected inmates was conducted and a significant association between sore throat and both consumption of egg salad sandwiches and of a beverage was found.

As Table 1 shows, the attack rate among those who ate the egg salad is higher than among those who did not, but the attack rate among those who drank the beverage is also higher than among those who did not drink the beverage. One way to determine which is more likely to have been the vehicle is to examine the relative attack rates. For the beverage, the attack rate for those who drank compared with those who did not is 1.5, while for the egg salad the relative attack rate is 2.1.

A more definitive way to distinguish is to cross-classify the subjects by whether they did or did not eat egg salad and did or did not drink the beverage, as shown in Table 2.

From Table 2, it is clear that whether or not the subjects drank the beverage did not greatly alter the

Table 1 Attack Rates for Pharyngitis in Prisoners Who Consumed a Beverage or Egg Salad

	Ate			*Did Not Eat*			*Relative*
	Sick	*Total*	*Attack Rate (%)*	*Sick*	*Total*	*Attack Rate (%)*	*Attack Rate (%)*
Beverage	179	264	67.8	22	50	44.0	1.5
Egg salad	176	226	77.9	27	73	37.0	2.1

Source: Adapted from Saslaw et al. (1974).

Table 2 Cross-Classified Attack Rates for Pharyngitis in Prisoners Who Consumed Either Egg Salad, a Beverage, or Both

	Ate Egg Salad			*Did Not Eat Egg Salad*		
	Sick	*Total*	*Attack Rate (%)*	*Sick*	*Total*	*Attack Rate (%)*
Drank beverage	152	201	75.6	19	72	26.4
Did not drink beverage	12	15	80.0	7	28	25.0

Source: Adapted from Saslaw et al. (1974).

attack rates for those who ate the egg salad (75.6 vs. 80.0) or who did not eat the egg salad (26.4 vs. 25.0), whereas eating the egg salad did increase the attack rate both for those who drank the beverage (26.4 to 80.0) and for those who did not drink the beverage (25.0 to 80.). This table makes it clear that the egg salad was the most likely vehicle for the infection.

Attributable Fractions

The attributable fraction is one of a class of measures used by epidemiologists to quantify the impact of an exposure or intervention on the occurrence of a disease or other outcome events in a population. These measures can be used, for example, to examine the impact of obesity on disease risk and the potential or expected impact of weight-reduction programs on disease rates. The origin of this concept is a measure proposed by a cancer epidemiologist, Morton Levin, in 1953. In describing the association between cigarette smoking and lung cancer, Levin (1953) offers the following definition of the new measure:

> The third index (S) is the . . . maximum proportion of lung cancer attributable to smoking. This index is based on the assumption that smokers, if they had not become smokers, would have had the same incidence of lung cancer as that found among non-smokers. (p. 536)

Although Levin did not give this measure a name, many epidemiologists now call it the *attributable fraction.* It should be noted, however, that this term has several synonyms in the epidemiologic literature, including attributable risk,* attributable proportion, excess fraction, etiologic fraction,* impact fraction,* and Levin's measure.

This article conceptually defines the attributable fraction and other impact measures, shows how they are estimated from population data, discusses how they are interpreted and sometimes misinterpreted, and demonstrates their use in public health practice. Before discussing these concepts in more detail, it is necessary to provide some background on the theory of causal inference in epidemiology.

Causal Inference in Populations

Measures of Effect and Counterfactuals

Much of epidemiologic research is aimed at making inferences about the net (causal) *effect* of one or more exposures on disease occurrence in a population. The dominant paradigm for defining such effects is the *counterfactual* or potential-outcomes model in which we contrast the frequency of disease (usually incidence) in the population under two or more exposure conditions such as everyone being exposed versus everyone being unexposed. Since individuals cannot be both exposed and unexposed simultaneously, at least one of those conditions is counter to fact or counterfactual. For example, suppose a group of N_e exposed persons at risk are followed without

*These terms also have other meanings as noted later.

loss for a given period during which A new (incident) cases of the disease occur. Thus, the risk (R_e) of disease in this exposed group is A/N_e. The central causal question is how many cases would have occurred during that period if no one in that population had been exposed. Suppose that counterfactual number is A_0. Therefore, the counterfactual risk in the exposed group is A_0/N_e, and the *causal risk ratio* ($\mathcal{RR}_e$), a measure of the exposure effect, is $(A/N_e)/(A_0/N_e) = A/A_0$. If $\mathcal{RR}_e > 1$, the exposure is called a causal or positive *risk factor* for the disease in that population; if $\mathcal{RR}_e < 1$, the exposure is called a protective or negative risk factor. It should be noted that without knowledge of biological mechanisms, this distinction between a causal and protective risk factor is generally arbitrary since exposure statuses can be reversed. For example, inferring that an active lifestyle is a protective risk factor for coronary heart disease is equivalent to inferring that a sedentary lifestyle is a causal risk factor.

Measures of Association and Confounding

Unfortunately, the causal risk ratio cannot be observed or estimated directly because we cannot observe A_0. To deal with this inherent limitation in not being able to observe effects, epidemiologists compare the exposed group with another group of unexposed individuals to observe the statistical *association* between exposure status and disease risk. This approach is the epidemiologic method. Suppose, for example, that a comparison group of N_0 unexposed persons at risk is followed for the same period as the exposed group and B new cases occur. A measure of the exposure-disease association is the ratio of risks in the exposed (R_e) and unexposed (R_0) groups; that is, the risk ratio (RR_e) or relative risk is $R_e/R_0 = (A/N_e)/(B/N_0)$. Unlike the effect measure, this association measure is an observable quantity. Another measure of association is $R_e - R_0$, which is called the risk difference or attributable risk.

For the epidemiologist to infer that $RR_e = \mathcal{RR}_e$, a key assumption is needed: The risk of disease in the unexposed group (B/N_0) must be equal to the counterfactual risk in the exposed group had that group been entirely unexposed (A_0/N_e). The implication of this assumption is that the two groups are comparable or that RR_e is unconfounded. If the assumption is not true, RR_e is confounded (biased) and will not equal $\mathcal{RR}_e$.

Control for Confounders

In nonrandomized studies, it is important for researchers to examine the comparability assumption and, whenever possible, attempt to control for possible confounding. Since the no-confounding assumption is also not observable, epidemiologists address the problem indirectly by attempting to identify and control for *confounders*—that is, extraneous risk factors that are associated with exposure status in the population and that are not intermediate in the causal pathway between exposure and disease. For example, in a study of the association between high blood pressure and stroke, we would expect age to be a confounder because it is a risk factor for both stroke and high blood pressure. There are two statistical methods to control for confounders in the analysis: *stratification*, in which the exposure-disease association is examined within categories or strata of measured confounders, and *covariate adjustment*, in which a regression model, including predictors for the exposure and confounders, is fit to the data.

In stratified analysis, the stratum-specific measures are combined by computing a weighted average. The special stratification method used to estimate effect (a counterfactual contrast) in a particular target population is called *standardization.* In this method, the stratum-specific risks in the exposed and unexposed groups (R_{ej} and R_{0j}, where j refers to the jth stratum) are weighted separately by the numbers of persons in the strata of the target population (N_{sj}), called the standard population (s). That is, the risks in the two exposure groups are mutually standardized to the covariate distribution of the same population. The *standardized risk ratio* ($RR_{e.s}$) is the ratio of the two mutually standardized risks ($R_{e.s}$ and $R_{0.s}$). These operations can be expressed mathematically as

$$RR_{e.s} = \frac{R_{e.s}}{R_{0.s}} = \frac{\sum N_{sj}R_{ej}/\sum N_{sj}}{\sum N_{sj}R_{0j}/\sum N_{sj}} = \frac{\sum N_{sj}R_{ej}}{\sum N_{sj}R_{0j}} = \frac{\sum N_{sj}R_{0j}RR_{ej}}{\sum N_{sj}R_{0j}}, \qquad [1]$$

where $RR_{ej} = R_{ej}/R_{0j}$; and summation is across strata ($j = 1, \ldots, J$). Note that the standardized risk ratio can also be interpreted as a weighted average of the stratum-specific risk ratios (RR_{ej}). If the exposed group is chosen as the standard population (so that $N_{sj} = N_{ej}$) and there is no residual confounding (within strata), then

$$RR_{e.e} = \frac{R_{e.e}}{R_{0.e}} = \frac{R_e}{R_{0.e}} = \frac{\sum A_j}{\sum N_{ej} R_{0j}} = \frac{A}{A_0} = \mathcal{RR}_{\mathrm{e}}, \quad [2]$$

where $R_{e.e}$ is the risk in the exposed group standardized to its own covariate distribution, which is equivalent to the crude (unstandardized) risk in the exposed group $= R_e = A/N_e$. In other words, under these conditions, the risk ratio standardized to the covariate distribution of the exposed group (which is also called the standardized morbidity/mortality ratio, SMR) can be interpreted as the causal risk ratio in the exposed population.

Attributable Fractions for Causal Risk Factors

Impact measures reflect the number of new cases either attributable to the exposure or prevented by the exposure during a given period in a particular population. Thus, there are two basic types of impact measures: *attributable fractions*, which are used for causal risk factors, and *prevented fractions*, which are used for protective risk factors. Since these measures represent another way of expressing counterfactual contrasts, they are closely related to effect measures.

For a causal risk factor, where $\mathcal{RR}_{\mathrm{e}} > 1$, the *attributable number* (A^*) is the excess number of cases in the exposed population that would not have occurred during a given period in the absence of exposure (or exposed at some designated reference level), where $A^* = A - A_0$. It is customary to express this number as the proportion of exposed cases (A) in the population or as a proportion of all exposed plus unexposed cases (M). Thus, the *exposed attributable fraction* (AF_e) is A^*/A, that is, the proportion of exposed cases attributable to the exposure. The *population attributable fraction* (AF_p) is $A^*/M = (A/M)AF_e$, that is, the proportion of all cases attributable to the exposure.

Attributable fractions also have applied interpretations that make them very useful in public health practice. The AF_e is the probability that a randomly selected exposed case would not have developed the disease during the follow-up period in the absence of exposure. The AF_p is the proportion of cases that is potentially preventable, that is, the maximum proportion of cases that could be prevented during a given period if an intervention were implemented to make everyone in the population unexposed. For example, if the AF_p for the impact of cigarette smoking on lung cancer in the United States is 90%, the maximum proportional reduction in the incidence of lung cancer that could be achieved by eliminating smoking in the United States would be 90%.

Estimating the AF_e

Since A^* is a counterfactual quantity, attributable fractions cannot be observed or estimated directly from the conceptual formulas above. By comparing exposed and unexposed groups and assuming no confounding, however, the exposed attributable fraction can be expressed in terms of the observable risk ratio or exposure-specific risks:

$$AF_e = \frac{A^*}{A} = \frac{A - A_0}{A} = \frac{A/A_0 - A_0/A_0}{A/A_0} = \frac{\mathcal{RR}_{\mathrm{e}} - 1}{\mathcal{RR}_{\mathrm{e}}} = \frac{RR_e - 1}{RR_e} = \frac{R_e - R_0}{R_e}. \quad [3]$$

To control for confounders by stratification, the AF_e is standardized to the covariate distribution of the exposed group since the AF_e involves a contrast of the exposed population with that same population in the absence of exposure. Using the same principles as described for standardized risk ratios, the standardized AF_e is

$$AF_{e.e} = \frac{R_{e.e} - R_{0.e}}{R_{e.e}} = \frac{R_e - R_{0.e}}{R_e} = \frac{RR_{e.e} - 1}{RR_{e.e}}, \quad [4]$$

where $R_{e.e}$ is the risk in the exposed group standardized to its own covariate distribution = the crude risk in the exposed group (R_e).

Estimating the AF_p

Assuming no confounding and noting that $A^* = AF_e \times A$, the population attributable fraction can be expressed as a function of AF_e, RR_e, or risks:

$$AF_p = \frac{A^*}{M} = \frac{AF_e \times A}{M} = f_e\left(\frac{RR_e - 1}{RR_e}\right) = \frac{p_e(RR_e - 1)}{p_e(RR_e - 1) + 1} = \frac{R_p - R_0}{R_p}, \quad [5]$$

where $f_e = A/M =$ the proportion exposed among cases; $p_e = N_e/N_p =$ the proportion exposed in the total population (of size N_p); and $R_p = M/N_p =$ the risk in the total population $> R_0$. Note that the AF_p,

unlike the AF_e, is a function of two parameters: the magnitude of effect ($\mathcal{RR}_e = RR_e$, assuming no confounding) and the frequency of exposure in the total population (p_e) or in cases (f_e). In practice, these parameters are often estimated from different sources, for example, RR_e from observational studies of exposure effects and f_e from surveys of the target population. When the exposure is a polytomous variable (more than two categories), two of the expressions in Equation 5 can be extended as follows:

$$AF_p = 1 - \frac{1}{\sum_{i=0}^{I} p_i RR_i} = 1 - \sum_{i=0}^{I} f_i / RR_i, \qquad [6]$$

where i refers to the ith category of the exposure ($i = 0, 1, \ldots, I$); $i = 0$ is the reference category; p_i and f_i are the proportions exposed in the total population and cases, respectively; $RR_i = R_i/R_0 =$ the risk ratio for the ith exposure category; and $RR_0 = 1$. Equation 6 is equivalent to combining all nonreference categories ($i > 0$) into one exposed group and applying one of the expressions in Equation 5.

To control for confounders by stratification, the AF_p is standardized to the covariate distribution of the total target population since the AF_p involves a contrast of the total population with that same population in the absence of exposure. Using the same principles as described for standardized risk ratios, the standardized AF_p can be expressed in terms of standardized risks ($R_{p.p}$ and $R_{0.p}$), the standardized risk ratio ($RR_{e.e}$), or as a weighted average of stratum-specific population attributable fractions (AF_{pj}):

$$AF_{p.p} = \frac{R_{p.p} - R_{0.p}}{R_{p.p}} = \frac{R_p - R_{0.p}}{R_p} = f_e\left(\frac{RR_{e.e} - 1}{RR_{e.e}}\right) = \frac{\sum M_j AF_{pj}}{\sum M_j}, \qquad [7]$$

where j refers to the jth stratum; and R_p is the crude risk in the total target population = the risk standardized to its own covariate distribution ($R_{p.p}$). The target population in Equation 7 is the total population from which cases arose, but it could be another population of interest. With a polytomous exposure, one of the expressions in Equation 7 becomes

$$AF_{p.p} = 1 - \sum_{i=0}^{I} f_i / RR_{i.i}, \qquad [8]$$

where $RR_{i.i} = R_{i.i}/R_{0.i} =$ the risk ratio for the ith exposure group standardized to its own covariate distribution (analogous to $RR_{e.e}$); and $RR_{0.0} = 1$.

AF_p for Multiple Exposures

The methods described above can be extended to analyses in which the researcher's objective is to estimate the combined impact of two or more exposures on disease risk. Suppose, for example, a study objective is to estimate the proportion of oral cancer cases that is attributable to cigarette smoking and/or alcohol consumption in the population, that is, the proportion of cases that would not have occurred if no one in the population had smoked cigarettes or consumed alcoholic beverages. A common mistake is to assume that the population attributable fractions for these two exposures are additive. For example, if the unconfounded AF_p is 35% for smoking and 45% for alcohol, the AF_p for both risk factors is not necessarily 80%, and the AF_p for all remaining risk factors is not $100\% - 80\% = 20\%$. The main reason for these misconceptions is that there may be a biological interaction (e.g., synergy) between the two exposures; that is, the risks attributable to smoking and drinking are not additive, as in this example. In addition, attributable fractions for different risk factors are not additive whenever there are causal effects between the risk factors. In general, the sum of AF_p for multiple risk factors can be greater than 1, but the combined AF_p for any set of risk factors, by definition, cannot be greater than 1.

A correct method for estimating the combined population attributable fraction for K exposures (AF_{pK}) is to cross-classify the population by all K exposures, choose one joint category as the reference group ($i = 0$), and apply the method for polytomous exposures in Equation 6 or 8. Thus, in the previous example, if both smoking and alcohol are categorized into three groups, there would be nine joint categories with nonsmokers and nondrinkers treated as the reference group. This method is equivalent to collapsing all nonreference categories ($i > 0$) into one exposed group and applying Equation 5 or 7.

Prevented Fractions for Protective Risk Factors

For a protective risk factor, where $\mathcal{RR}_e < 1$, the *prevented number* (A^o) is the number of cases that

would have occurred in the exposed population during a given period in the absence of exposure but did not occur—that is, the number of cases prevented by the exposure, where $A^\circ = A_0 - A$. It is customary to express the prevented number as the proportion of potential exposed cases ($A_0 = A + A^\circ$) in the population or as the proportion of all potential cases ($M + A^\circ$). Thus, the *exposed prevented fraction* (PF_e) is $A^\circ/(A + A^\circ)$, that is, the proportion of exposed cases prevented by the exposure. The *population prevented fraction* (PF_p) is $A^\circ/(M + A^\circ)$, that is, the proportion of all cases prevented by the exposure. When the exposure is an intervention such as a vaccine, PF_e is also called the efficacy of that intervention, and PF_p is also called its effectiveness.

Although attributable and prevented fractions are analogous, note the difference in these two concepts: Whereas the denominators of attributable fractions are observable numbers of cases, the denominators of prevented fractions are nonobservable (counterfactual). The implication of this difference, for example, is that the proportion of all coronary heart disease cases prevented by active lifestyles in a particular population during a given period is not equal to the proportion of cases attributable to sedentary lifestyles in the same population.

Estimating the PF_e

By comparing exposed and unexposed groups and assuming no confounding, the PF_e can be expressed in terms of the observable risk ratio or exposure-specific risks:

$$PF_e = \frac{A^\circ}{A + A^\circ} = \frac{A_0 - A}{A_0} = 1 - RR_e = \frac{R_0 - R_e}{R_0}. \quad [9]$$

To control for confounders, the PF_e is standardized to the covariate distribution of the exposed group. Using the same principles as described for attributable fractions, the standardized PF_e is

$$PF_{e.e} = \frac{R_{0.e} - R_{e.e}}{R_{0.e}} = \frac{R_{0.e} - R_e}{R_{0.e}} = 1 - RR_{e.e}. \quad [10]$$

Estimating the PF_p

Assuming no confounding and noting that $A^\circ = A \times PF_e/(1 - PF_e)$, the population prevented fraction can be expressed as a function of observable parameters:

$$PF_p = \frac{A^\circ}{M + A^\circ} = \frac{f_e(1 - RR_e)}{f_e(1 - RR_e) + RR_e} = p_e(1 - RR_e) = \frac{R_0 - R_p}{R_0}, \quad [11]$$

where $R_p < R_0$. When the exposure is a polytomous variable, the expressions in Equation 11 become

$$PF_p = 1 - \sum_{i=0}^{I} p_i RR_i = 1 - \frac{1}{\sum_{i=0}^{I} f_i/RR_i}, \quad [12]$$

where i refers to the ith category of the exposure ($i = 0, 1, \ldots, I$); and $RR_0 = 1$.

Standardizing the population prevented fraction to the covariate distribution of the total population to control for confounders yields

$$PF_{p.p} = \frac{R_{0.p} - R_{p.p}}{R_{0.p}} = \frac{R_{0.p} - R_p}{R_{0.p}} = \frac{f_e(1 - RR_{e.e})}{f_e(1 - RR_{e.e}) + RR_{e.e}}, \quad [13]$$

where $R_p < R_{0.p}$. For a polytomous exposure, the last expression in Equation 13 becomes

$$PF_{p.p} = 1 - \frac{1}{\sum_{i=0}^{I} f_i/RR_{i.i}}. \quad [14]$$

Preventable Fraction

With protective risk factors, researchers and policy analysts are often interested in how much of the current disease risk in the total target population is potentially preventable if everyone in the population were exposed. This measure, called the *preventable fraction* (PaF_p), should be distinguished from the population prevented fraction (PF_p): Whereas the PF_p reflects the previous impact of being exposed in the population, the PaF_p reflects the potential impact in the future if everyone were to become exposed. The PaF_p would be of interest, for example, to predict the maximum proportion of coronary heart disease cases that could be prevented if everyone in the population were to have active lifestyles.

To estimate the PaF_p, it is helpful to recognize this measure as the proportion of cases that was attributable to being *un*exposed. Thus, the PaF_p is equivalent to the population attributable fraction (AF_p) in which "exposed" and "unexposed" categories are reversed; that is, the PaF_p is estimated with one of the expressions in Equation 5 or 7. Suppose, for example, that

the unconfounded risk ratio (RR_e) for coronary heart disease risk, comparing active with sedentary lifestyles, is 0.50, and 20% of the population is active (p_e). Therefore, from Equation 11, the PF_p is $0.20(1-0.50)=10\%$. Reversing the exposure categories, RR_e becomes $1/0.50=2.0$, and p_e becomes $1-0.20=0.80$. Therefore, from Equation 5, the PaF_p is $0.8(2-1)/[0.8(2-1)+1]\approx 0.44$. That is, approximately 44% of the cases that currently occur could potentially be prevented if everyone were to have an active lifestyle.

Covariate Adjustment by Model Fitting

A major limitation with stratification to control for confounders is that the method is inefficient when the sample size is small or when the number of strata is large—that is, when the data are "sparse." In this situation, estimation is imprecise, resulting in wide confidence intervals, and sometimes invalid. To deal with this problem, analysts usually rely on covariate adjustment to control for confounders by fitting regression models to the data. The advantages of model fitting are that continuous variables such as age need not be categorized, and model fitting involves additional parametric assumptions that improve estimation efficiency.

Unfortunately, covariate adjustment for confounders is often done improperly when estimating attributable or prevented fractions. For example, by fitting a logistic model that contains a dichotomous exposure (coded 0 or 1) and potential confounders as predictors, the adjusted odds ratio—an approximation of the risk ratio with a rare disease—is estimated by e^b, where b is the estimated logistic coefficient for the exposure. The incorrect method involves substituting this adjusted risk-ratio estimate for RR_e in one of the expressions in Equation 5 or 11. The main problem is that this method does not properly standardize for the covariates whenever RR_e is heterogeneous across covariate levels; that is, the risk ratios are not weighted to reflect the covariate distribution in the target population.

To standardize for confounders in a cohort study, the fitted logistic model can be used to estimate the disease risk (r_i) for the ith subject, that is,

$$\hat{r}_i = 1 - \frac{1}{1+e^{-(b_0+b_e x_{ei}+\sum_k b_k x_{ki})}}, \qquad [15]$$

where x_{ei} is the value of the dichotomous exposure for the ith subject (0 = unexposed and 1 = exposed); x_{ki} is the value of the kth covariate for the ith subject; and b_0, b_e, and b_k are the estimated logistic coefficients. Then, using the expression in Equation 7, the estimated population attributable fraction, standardized to the covariate distribution of the total population, is

$$\widehat{AF}_{p.p} = \frac{\hat{R}_p - \hat{R}_{0.p}}{\hat{R}_p} = \frac{\sum_{i=1}^{N_p}\hat{r}_i - \sum_{i=1}^{N_p}\hat{r}_{0i}}{\sum_{i=1}^{N_p}\hat{r}_i}, \qquad [16]$$

where $\hat{r}_{0i}$ is the estimated risk for the ith subject, setting exposure status (x_{ei}) equal to the reference value (0). It should be noted that this method may yield invalid results if the model is not properly specified or does not adequately fit the data—for example, if important interactions are ignored. The statistical method for estimating $AF_{p.p}$ from case-control studies differs from Equations 15 and 16 because this design does not include exposure data on the entire population at risk.

Methodological Issues of Interpretation

Risks Versus Rates

It is important to recognize that attributable and prevented fractions, such as risks, are cumulative measures; they have a well-defined period referent during which cases may occur. For example, we might be interested in the 1-year or 10-year AF_p for the impact of an exposure in a fixed cohort initially at risk for the disease and followed for 1 or 10 years. Thus, all observable expressions for the impact measures were expressed in terms of risks. In many epidemiologic studies, however, disease incidence is measured as a *rate*—that is, a person-time measure that has units of time^{-1} (e.g., 5 new cases occurring during 100 person-years of follow-up yield an incidence rate of 0.05 per year). When incidence or mortality rates and rate ratios are substituted for risks and risk ratios in the expressions for attributable fractions, the resulting measures have been called *rate fractions* (RF_e and RF_p). In general, the rate fraction will approximate the corresponding attributable fraction if the disease is rare in both exposure groups and the exposure has only a negligible effect on the changing number of people at risk during follow-up. (Note that the person-time denominator

of a rate changes during follow-up as the number of people at risk changes.)

Choice of the Reference Group

The choice of the reference group for estimating the impact of an exposure is critical to the interpretation of that estimate whenever the exposure is not an inherent dichotomy such as gender. For example, with obesity as the exposure, the proportion of all cases of coronary heart disease that is attributable to a body mass index (BMI) greater than 25 is likely to differ from the proportion of cases attributable to a BMI greater than 30. The choice of a reference group is also critical when comparing the proportions of cases attributable to different exposures. For example, a comparison of population attributable fractions for obesity and smoking in a particular population during a given period depends on how we define the reference categories or levels for these two exposures.

Etiologic Fraction Versus Attributable Fraction

It is common for attributable fractions to be misinterpreted as the proportion of cases *caused by* the exposure—that is, the proportion of cases in whom being exposed contributed to the development of the disease or when it occurs. This latter measure is known as the *etiologic fraction* (EF_e or EF_p). It is important to appreciate that the number of cases caused by the exposure (the etiologic number) is not the same as the number of cases attributable to the exposure (the attributable number). This distinction can be explained in counterfactual terms. The EF_e, for example, can be expressed as $(A_1 + A^*)/A$, where A_1 is the number of exposed cases that would have occurred later during follow-up in the absence of exposure; and A^* is the number of exposed cases that would not have occurred at all during follow-up in the absence of exposure (as previously defined). In contrast, AF_e is A^*/A. Thus, in general, the AF_e is less than or equal to the EF_e. Unfortunately, the EF_e cannot be readily estimated from epidemiologic data without making certain restrictive biological assumptions that cannot be assessed empirically.

The distinction between the etiologic fraction and the attributable fraction has important legal implications that can be used in favor of defendants in toxic tort litigation. In this type of civil case, the plaintiff is claiming injury that was "more likely than not" caused by an exposure for which the defendant is being held responsible. Therefore, using this criterion for legal causation, the court would like to know whether the probability of causation, EF_e, is greater or less than 50%, where e refers to the plaintiff's exposure level, compared with no exposure or some designated background exposure. This probability, however, is likely to be underestimated by the AF_e, as noted above. To the extent that A_1 is greater than zero, EF_e will be greater than AF_e. Suppose that RR_e is greater than 2. According to Equation 3, AF_e will therefore be greater than 50%; thus, it follows logically that EF_e is greater than 50%. On the other hand, if RR_e is less than 2, so that AF_e is less than 50%, it does not follow that EF_e will be less than 50%. Consequently, it is often to the benefit of defense attorneys to underestimate EF_e with AF_e.

Attributable Fraction for Covariates

The concept of the attributable fraction can be extended to "explain" a difference in disease risk or rate between groups in terms of differences in the distribution of one or more covariates (Objective 1) or to "explain" a trend in disease risk or rate over time in terms of changes in the distribution of one or more covariates (Objective 2). For example, an epidemiologist might want to know the extent to which the difference in lung cancer rates between whites and blacks is attributable to differences in cigarette smoking or the extent to which the increasing rate of infant mortality in a low-income population was attributable to a decline in prenatal care. A measure to address these objectives is called the *attributable fraction for covariates* (AF_c).

For Objective 1, the AF_c is the proportion of the difference in risk between groups that is attributable to a difference in the distribution of one or more covariates—that is, the proportion of the crude risk difference that is explained by the covariates. The AF_c can be expressed as a function of risks, risk differences (RD), or risk ratios (RR), as shown below.

$$AF_c = \frac{R_e - R_{e.0}}{R_e - R_0} = \frac{RD_e - RD_{e.0}}{RD_e} = \frac{RR_e - RR_{e.0}}{RR_e - 1}, \quad [17]$$

where e and 0 refer to the two groups (such as exposed and unexposed); RD_e is the crude risk

difference $= R_e - R_0$; and $RD_{e.0}$ is the risk difference standardized to the covariate distribution of the unexposed group $= R_{e.0} - R_0$. If $RD_{e.0} = RD_e > 0$, then $AF_c = 0$, meaning that covariate differences do not explain any of the crude risk difference between groups. If $RD_{e.0} = 0$ and $RD_e > 0$, then $AF_c = 1$, meaning that covariate differences completely explain the crude risk difference between groups.

For Objective 2, the AF_c is the proportion of the change in risk that is attributable to a change in the distribution of one or more covariates—that is, the proportion of the crude risk change that is explained by the covariates. AF_c is computed from one of the expressions in Equation 17, where time is treated as the exposure, letting the first follow-up period be the reference group (0) and the second period be the exposed group (e).

Impact Estimation

As noted earlier, population attributable fractions (and preventable fractions) can be interpreted in terms of the potential for prevention. For example, an AF_p of 80% for a causal risk factor implies that a maximum of 80% of all cases could be prevented if everyone in the population were unexposed. In practice, however, the expected proportional reduction in disease risk due to an actual intervention designed to eliminate the exposure is usually less than 80% because not every exposed (high-risk) person receives the intervention and because the intervention is not 100% efficacious in reducing risk. Impact estimation is a method for estimating the expected impact of a planned intervention on disease risk in a target population by changing the distribution of one or more risk factors. Specifically, the *impact fraction* (*IF*) is the expected proportional reduction in disease risk following the intervention, taking into consideration the limited effectiveness of the intervention. Expressed mathematically,

$$IF = \frac{R_p - R'_p}{R_p} = AF_p \times q_e \times E, \qquad [18]$$

where R_p is the risk in the total population before the intervention; R'_p is the risk in the total population after the intervention; q_e is the success rate of the intervention—that is, the proportion of exposed persons who receive the intervention; and E is the relative efficacy of the intervention—that is, the extent to which participation in the intervention results in a risk reduction to the level of those unexposed persons before the intervention $= (R_e - R'_e)/(R_e - R_0)$. Substituting this expression for E and the expression for AF_p from Equation 5 into Equation 18 yields

$$IF = \frac{p_e q_e RR_e(1 - RR')}{p_e(RR_e - 1) + 1}, \qquad [19]$$

where $RR_e > 1$; and RR' is the risk ratio corresponding to the effect of the intervention among the exposed < 1. Equation 19 assumes that participation in the intervention is unrelated to disease risk. This method has been used to estimate the expected impact of various cholesterol-lowering strategies on the reduction in risk from coronary heart disease. When all four parameters in Equation 19 cannot be reliably determined from existing data, the researcher may estimate *IF* for different sets of reasonable assumptions regarding the values of those quantities.

Impact estimation has recently become popularized as a component of *health impact assessment* (HIA), which is a systematic approach for assessing the expected health impact of a proposed project, program, or policy and communicating the results to decision makers and stakeholders. This approach is often applied to proposals for which health effects are not intended and typically involves identifying relevant health outcomes, defining the causal pathways linking the proposed action with those health outcomes, and developing an analytic strategy. For example, an HIA was conducted to assess the expected impact of a city living wage ordinance on total mortality.

Conclusion

Attributable fractions are important theoretical measures that underscore the counterfactual foundation of the epidemiologic method in populations. These and related impact measures discussed in this article can be applied in a number of informative ways to public health practice and policy making. The estimation of impact measures and their interpretation require explicit specification of a reference population and period referent, attention to the principles of confounder control by standardization, and careful assessment of other sources of bias.

Autism

Today, common usage of the term *autism* refers to the following subset of clinical diagnoses falling under the *Diagnostic and Statistics Manual*, fourth edition, revised (American Psychiatric Association) heading of *Pervasive Developmental Disorders*: autistic disorder, Asperger's disorder, and pervasive developmental disorders not otherwise specified (PDD-NOS). However, some still reserve usage of the term *autism* to refer only to the diagnosis of autistic disorder. Because of the potential for confusion, most epidemiologists now prefer to use the term *autism spectrum disorder* (ASD) to refer to the group of three diagnoses collectively and rely on the specific *DSM-IV-R* term when referring to a specific diagnosis. The use of the term *spectrum*, however, should not be taken to imply that this is one etiology with gradations of severity. It is quite possible that the ASDs actually comprise a number of etiologically distinct conditions.

ASDs are neurodevelopmental disorders characterized by deficits in reciprocal social interaction and communication along with the presence of restricted, repetitive, and stereotyped patterns of behaviors, interests, or activities. Individuals with a clinical diagnosis of autistic disorder must have 6 of 12 core symptoms with at least 2 in the social interaction domain, at least 1 in each of the other two domains, and emergence of impairment prior to age 3. A PDD-NOS diagnosis requires some impairment in each of the three core domains where impairment in at least one of the domains does not meet criteria for autistic disorder. An Asperger's disorder diagnosis requires impairment in social interaction and the presence of restricted and repetitive behaviors or interests without communication impairment. In practice, children receiving Asperger's diagnoses typically have no overt language

delays, but, in fact, they often have other deficits in communication. Approximately half of the children with ASDs have cognitive impairment ($IQ \leq 70$). Children with Asperger's disorder tend to have average to above-average IQs, though this is not part of the formal diagnostic criteria. ASDs are approximately four times more common in boys than in girls. Children with ASDs often present with other medical symptoms, including GI dysfunction, disordered sleep, as well as sensory and motor issues. Etiologic or pathophysiologic mechanisms underlying any of the ASDs are yet to be confirmed, and no biological test is available that can inform diagnosis.

In research and specialty clinic settings, two diagnostic tools have become increasingly accepted: the Autism Diagnostic Observation Schedule (ADOS) and the Autism Diagnostic Interview—Revised (ADI-R). The ADOS involves direct observation of the child interacting with an assessor who creates multiple, standardized stimuli to elicit behavioral responses from the child. The ADI-R is an in-person interview of the primary caregiver and focuses on the child's behaviors in various types of settings and responses to certain types of social and emotional stimuli. These tools are less reliable in children less than 3 years of age, and new tools are currently being developed and validated to identify signs of ASD in younger children. In most community clinical settings today, diagnosis, though informed by standard instruments, is still typically based on judgment of a clinician following *DSM-IV* diagnostic criteria.

Since clinical diagnoses of ASDs are based strictly on behavioral criteria, the prevalence of ASDs can be influenced by changes in the conventional wisdom surrounding the types and severity of behavior meeting criteria. Over the past two decades, general awareness of ASDs has increased markedly, and the conception of the behavioral deficits meeting diagnostic criteria has broadened. The prevalence of ASDs in the United States has recently been estimated to be approximately 65 per 10,000. This is considerably higher than estimates from past decades, although much of the early prevalence data were limited to estimates of autistic disorder. Undoubtedly, the increasing secular trend in ASD prevalence is due, at least in part, to this increasing awareness and changes in diagnostic tendency. However, it is exceedingly difficult to determine whether these factors account for all the increase in prevalence observed, and, consequently, there continues to be interest in exploration of environmental risk factors that could explain, in part, increasing ASD prevalence over time.

Although specific causes of ASDs are not yet known, it is understood that there is a strong genetic component to their etiology. The prevalence of autistic disorder among children with an older sibling who also has autistic disorder is several-fold greater than population prevalence, and autistic disorder concordance among monozygotic twins has been estimated to exceed 65%, which is far greater than concordance in dizygotic twins. Studies have also suggested that a less-severe broader autism phenotype appears more frequently in family members of individuals diagnosed with an ASD than in control families. ASDs also occur at greater than expected frequencies among individuals with other known genetic conditions such as fragile X, Down syndrome, tuberous sclerosis, Prader-Willi syndrome, and Angelman syndrome. Studies designed to identify autism risk genes have suggested chromosomal regions and candidate genes of potential interest, but as yet, no specific putative risk gene has been found. The lack of conclusive genetic findings most likely is attributable to complexity of the genetic mechanism, likely involving multiple interacting genes, combined with the fact that studies completed to date have not been able to account for etiologic heterogeneity because good markers of etiologically distinct groups are unknown.

Some features of the complex inheritance of autism, for example, the lack of 100% concordance among monozygotic twins and the wide variation in phenotype among concordant monozygotic twins, also point to the possible involvement of nongenetic factors. Neuropathologic studies of autism, although falling short of identifying anomalies in brain structure, organization, or function definitively linked to autism, do indicate that pathologic changes in the brains of individuals with ASDs likely begin prenatally suggesting that the critical window for any etiologically significant exposures may, in fact, be in utero. To date, there has been fairly limited exploration of nonheritable ASD risk factors in epidemiologic studies. Those factors that have been, or are currently being, considered include those related to infection and immune dysfunction, endocrine factors, obstetric factors, xenobiotic exposures, and lifestyle factors. Of course, obtaining valid and reliable measures of exposures and events during prenatal periods is quite challenging

in retrospective studies. At present, there are no nonheritable risk factors that have been conclusively linked to autism. Because of concerns about childhood immunization as a potential risk factor for ASDs, several epidemiologic studies have examined associations between vaccination and autism risk and are consistent in finding no evidence of an association. Studies are just now beginning that will investigate the potential role of environmental risk factors in the context of heritable mechanisms. These include studies of gene-environment interaction and investigations of how nonheritable risk factors may modify a gene's effect via epigenetic mechanisms, such as imprinting.

Although the cause or causes of ASD are unknown, treatment can be effective in ameliorating symptoms. Behaviorally based educational interventions are considered fundamental to an intervention strategy, although optimal approaches are still debated and many believe that different techniques may be more effective in certain, as yet undefined, subgroups of children with ASDs. Evidence does exist, however, indicating that the earlier the initiation of educational interventions, the greater the potential for impact. A variety of pharmacologic treatments are also used to address behavioral symptoms associated with autism, although the evidence supporting their effectiveness is generally limited. At present, only one drug is FDA-approved to treat behaviors (those related to irritability) in children with autism. A number of other intervention approaches are offered to families of children with ASDs in the absence of scientific evidence for their effectiveness and even their safety. These range from strict dietary modification to removal of heavy metals from the body by chelation. Effective provision of accurate information surrounding intervention strategies for ASDs remains a public health priority.

Avian Flu

Avian influenza, also known as avian flu, bird flu, or fowl plague, is an animal disease of viral etiology that ranges from a mild or even asymptomatic infection to an acute, rapidly fatal disease of chickens, turkeys, guinea fowls, and other domestic poultry, as well as wild birds, migratory waterfowl, and other avian species. Inasmuch as the avian influenza viruses can be occasionally transmitted to humans, avian flu is a zoonotic disease. Due to its potential to cause worldwide epidemics in humans (i.e., pandemics), and the current A/H5N1 avian flu outbreak—that is, an epizootic or *epornithic* (the nonhuman equivalent of an epidemic in bird populations) in some parts of the world, particularly Southeast Asia—avian influenza has been identified as a major public health concern worldwide. Indeed, under the revised International Health Regulations, any novel (i.e., different from currently circulating human flu H1 and H3 viruses) human influenza A virus infection must be reported immediately to the World Health Organization (WHO). In fact, the chief and foremost strategy in addressing the current pandemic threat entails diminishing the pandemic likelihood by controlling highly pathogenic influenza viruses in animals, expressly the epizootic caused by A/H5N1 virus in poultry, through improved detection, surveillance, and control by way of strengthening veterinary public health structures and competencies.

The natural reservoirs of influenza A viruses—the etiologic agents of avian flu—are the aquatic birds of the world, particularly ducks, in which the viruses appear to be in evolutionary stasis or equilibrium with their natural host, causing no disease. All known influenza A subtypes exist in the aquatic bird reservoir (i.e., the 16 hemagglutinin and 9 neuraminidase surface glycoprotein subtypes); due to this fact, influenza is reckoned as not an eradicable disease. In wild ducks, flu viruses replicate preferentially in the cells linings of the intestinal tract, cause no disease signs, and are excreted in high concentrations in the feces. As much as 30% of the large number of susceptible young ducks hatched each year can shed flu

virus before fall migration for as long as 30 days. Avian flu viruses have been isolated from fecal material and lake water, and it has been shown that viruses retained infectivity in fecal material for as long as 30 days at 4°C. Waterfowl, therefore, may have a very efficient mode of virus transmission: by fecal material in the water supply. Flu viruses of avian origin have been implicated in outbreaks of influenza in mammals, such as seals, whales, pigs, mink, and horses, as well as in domestic poultry. Ducks and wading birds may play a unique and very important role in the natural history of influenza.

As striking as the apparent genetic stability of avian flu viruses in aquatic reservoirs is another conspicuous characteristic: the continued evolution and extent of genetic variation of their mammalian strains. The gene pool of influenza A viruses in aquatic birds provides all the genetic diversity required for the emergence of annual epidemics and occasional pandemics of disease in humans, lower animals, and birds. In humans, pigs, and horses, influenza A viruses show both antigenic drift and genetic shift—that is, point mutations and gene reassortment, respectively—two mechanisms of molecular changes in the two surface glycoproteins and in the eight RNA segments of the viruses that keep accumulating their genetic variability. Another notable characteristic is the lack of proofreading among RNA polymerases, contributing to replication errors of the order of 1 in 10^4 bases (in contrast with the much higher replication fidelity found among DNA polymerases, with errors of the order of 1 in 10^9 bases). Antigenic and genetic evidence show that the 1957 H2N2 Asian and the 1968 H3N2 Hong Kong pandemic strains were generated by genetic reassortment between human and avian flu viruses. Pigs seem to play an important role in interspecies reassortment and subsequent transmission of influenza viruses.

Of the different subtypes of influenza A viruses, two of them H5 and H7 subtypes, are classified as highly pathogenic avian influenza (HPAI) viruses; the reason for this specificity remains unknown. Disease signs vary, depending mainly on the species and age of poultry, virus strain, and superimposed bacterial infections. Typical clinical signs of HPAI in chickens or turkeys are decreased egg production, ruffled feathers, respiratory signs, rales, excessive lacrimation, sinusitis, cyanosis of unfeathered skin, edema of head and face, diarrhea, and nervous disorder. HPAI viruses can cause quick death without clear previous clinical signs.

The Asian H5N1 avian flu virus that infected humans in 1997 acquired all eight gene segments from Eurasian avian sources. This virus was first detected in Guangdong Province, China, in 1996, when it killed some geese, but it received little attention until it spread through live poultry markets in Hong Kong to humans in May 1997, killing 6 of 18 infected persons. The culling of all poultry in that city ended the first wave of H5N1, but the virus continued to circulate among apparently healthy ducks and geese in southeastern China, and the 1997 H5N1 virus was soon replaced by additional genotypes. The most remarkable property of the H5N1 genotype from late 2002 was its high pathogenicity for ducks and other aquatic birds, a property hardly ever found in nature. In early February 2003, H5N1 virus reemerged in a family in Hong Kong and since then has produced 288 confirmed cases and 170 deaths in 12 countries (Azerbaijan, Cambodia, China, Djibouti, Egypt, Indonesia, Iraq, Lao People's Democratic Republic, Nigeria, Thailand, Turkey, and Vietnam), as reported by the WHO as of April 2, 2007. All available evidence on this ongoing situation suggests that human-to-human transmission of H5N1 virus is still highly inefficient and that close contact with sick birds has been a common epidemiologic feature among H5N1 human cases so far.

The unprecedented magnitude of the current avian flu epidemic has resulted in the destruction of hundreds of millions of poultry, mainly chickens, ducks, turkeys, and geese; coupled with export bans on affected countries, the disease is so far representing an enormous impact on the poultry industry and the economies of many countries. In the meantime, multiple opportunities for the successful mammalian transmission of H5N1 influenza viruses—including those taking place in huge live bird markets—are provided by their continuing evolution in Asia, their propensity for reassortment, the generation of multiple lineages and genotypes, and the acquisition of high pathogenicity for aquatic birds. If an opportunity for reassortment with human influenza strains occurs, then the likelihood of successful transmission between humans will be high.

Bar Chart

A bar chart is a pictorial representation of the information in a frequency distribution. It displays the classes on the horizontal axis and the frequencies or relative frequencies of the classes on the vertical axis. The height of a bar represents how common a particular value or category is in a distribution. A frequency is the number of observations that fall in a class—that is, counts. A relative frequency is the ratio of the frequency of a class to the total number of observations—that is, the proportion or percentage of cases that fall into a class.

One may create either a *frequency* or a *relative frequency* bar chart. A *frequency* bar chart is a graph that displays the classes on the horizontal axis and the frequencies on the vertical axis. The frequency of each class is represented by a vertical bar whose height is equal to the number of times that class occurs in the data set. A *relative frequency* bar chart is a graph that displays the classes on the horizontal axis and the relative frequencies of the classes on the vertical axis. The only necessary difference between the two types of bar charts is the label on the *y*-axis: For a frequency bar chart, it will be counts, while for the relative frequency bar chart, it will be percentages.

It is also possible, although less common, to create a *horizontal bar chart*, which may display either frequency or a relative frequency. A horizontal bar chart displays the classes on the vertical axis and the frequencies or relative frequency on the horizontal axis.

Bar charts are distinguished in two primary ways from histograms:

1. Bar charts are customarily used for discrete or categorical data, while histograms are used only for quantitative data. When histograms are used for continuous data, it usually needs to be grouped into categories.
2. In a bar chart, space is left between the bars, that is, they do not touch each other, while in a histogram, bars may be connected to each other without space.

The second rule emphasizes the discrete or categorical nature of the data presented by the bar chart.

Consider the data given in Table 1, which were collected in a survey from a class of 26 students at Columbus State University.

The classes for grouping the data of sex are "Male" and "Female," while the classes for grouping the data of siblings are numbers from 1 to 5. Tallying the data sets in Tables 2 and 3, we obtain the frequency and relative frequency distributions for sex and siblings, respectively.

A frequency bar chart and relative frequency bar chart for sex and siblings are displayed in Figures 1 and 2.

Barker Hypothesis

David Barker, of the University of Southampton, England, was among the first to argue that impaired fetal growth is an important contributor to coronary heart disease and its metabolic precursors. In the original formulation of the hypothesis, maternal malnutrition in pregnancy was the underlying determinant of suboptimal birth size, and Barker hypothesized that the effect of prenatal malnutrition was trimester-specific, producing different later metabolic consequences depending on when in pregnancy nutrition was impaired. Small size at age 1 year was also found to be associated with later coronary heart disease, implying a causal role in heart disease of both infant and fetal malnutrition. Barker and his colleagues made ingenious use of several old databases, most notably the records of birthweights and infant weights collected during the 1920s and 1930s in Hertfordshire by a dedicated nurse, which were then linked to contemporary death records. Critics of the Barker opus have asserted that large losses to follow-up; inadequate attention to socioeconomic, environmental, and genetic confounding; and other methodological problems weaken the evidentiary base of the hypothesis.

The hypothesis has broadened beyond its nutritional origins, but it still focuses principally on the relationship of impaired fetal growth to elevated blood pressure, glucose intolerance, and other contributors to coronary heart disease and stroke. The hypothesis has stimulated a great deal of research, both in the laboratory and in human populations. In animal studies, components of the Barker hypothesis have been confirmed; dietary restrictions in pregnancy producing smaller offspring have been accompanied by elevations in cardiovascular risk factors, although at times these nutritional effects have not been dependent on alterations in birthweight. A relatively common model involves halving caloric intake in pregnant animals. How closely these experimental interventions parallel the common human experience is uncertain. This laboratory work has in turn led to the concept of "fetal programming," that is, that some of the cardiovascular risk profile may be determined by subtle alterations in nutrition or metabolism occurring at critical periods in development, especially in fetal life. In human studies, the Barker hypothesis has been studied in many different settings across the globe. It has been broadened by several investigators to include other components of early social and environmental disadvantage, producing what has sometimes been termed the *life course* hypothesis that posits a major role for many kinds of experiences in fetal, infant, and child life in shaping risk of adult disease. Many of these critical experiences are hypothesized to be social and environmental in origin, with biological effects (such as small size) operating as mediators of subsequent cardiovascular risk.

The net contribution of the Barker hypothesis to public health has as yet been modest. Birthweight is notoriously resistant to change in human populations, and the effects of birthweight are modest in determining blood pressure and glucose levels, especially when compared with current weight. But the hypothesis has made many investigators more conscious of the possibility that fetal, infant, and child experiences may have long-lasting consequences for human health.

Bayesian Approach to Statistics

The Bayesian approach to statistics is a general paradigm for drawing inferences from observed data. It is distinguished from other approaches by the use of probabilistic statements about fixed but unknown quantities of interest (as opposed to probabilistic statements about mechanistically random processes such as coin flips). At the heart of Bayesian analysis is Bayes's theorem, which describes how knowledge is updated on observing data.

In epidemiology, diagnostic testing provides the most familiar illustration of Bayes's theorem. Say the unobservable variable θ is a subject's true disease status (coded as 0/1 for absence/presence). Let q be the investigator-assigned probability that $\theta = 1$, in advance of diagnostic testing. One interpretation of how this probability statement reflects knowledge is that the investigator perceives the pretest odds $q/(1-q)$ as the basis of a "fair bet" on whether the subject is diseased. If the subject is randomly selected from a population with known disease prevalence, then setting q to be this prevalence is a natural choice. Now say a diagnostic test with known sensitivity *SN* (probability of positive test for a truly diseased subject) and specificity *SP* (probability of negative test for a truly undiseased subject) is applied. Let q^* denote the probability that $\theta = 1$ given the test result. The laws of probability, and Bayes's theorem in particular, dictate that the posttest disease odds, $q^*/(1-q^*)$, equals the product of the pretest odds and the likelihood ratio (*LR*). The *LR* is the ratio of probabilities of the observed test result under the two possibilities for disease status, that is, $LR = SN/(1-SP)$ for a positive test, $LR = (1-SN)/SP$ for a negative test. Thus, postdata knowledge about θ (as described by q^*) is an amalgam of predata knowledge (as described by q) and data (the test result).

More generally, any statistical problem can be cast in such terms, with θ comprising all relevant unobservable quantities (often termed *parameters*). The choice of q in the testing problem generalizes to the choice of a *prior distribution*, that is, a probability distribution over possible values of θ, selected to represent predata knowledge about θ. A *statistical model* describes the distribution of data given the unobservables (e.g., *SN* and *SP* describe the test result given disease status). Bayes's theorem then produces the *posterior distribution*, that is, the distribution of θ given the observed data, according to

$$\frac{\Pr(\theta = a|\text{Data} = d)}{\Pr(\theta = b|\text{Data} = d)} = \frac{\Pr(\text{Data} = d|\theta = a)}{\Pr(\text{Data} = d|\theta = b)} \times \frac{\Pr(\theta = a)}{\Pr(\theta = b)},$$

for any two possible values a and b for θ. Succinctly, a ratio of posterior probabilities is the product of the likelihood ratio and the corresponding ratio of prior probabilities.

The specification of prior distributions can be controversial. Sometimes, it is cited as a strength of the Bayesian approach, in that often predata knowledge is available, and should be factored into the analysis. Sometimes, though, the prior specification is seen as more subjective than is desirable for scientific pursuits. In many circumstances, prior distributions are specified to represent a lack of knowledge; for instance, without information on disease prevalence, one might set $q = 0.5$ in the diagnostic testing scenario above. Or, for a continuous parameter (an exposure prevalence, say), an investigator might assign a uniform prior distribution, to avoid favoring any particular prevalence values in advance of observing the data.

Less controversially, the coherent summarization of postdata knowledge via the posterior distribution is generally perceived as a strength of Bayesian analysis. For instance, the best estimate for a parameter might be "read off" the corresponding posterior density curve, as a mean, median, or mode of the curve. Similarly, the width of the curve describes the accuracy of the estimate. The coherent summarization of uncertainty is particularly important in complex modeling situations, where multiple models and data sources feed into one another. The Bayesian approach avoids the pitfall of overconfident inferences arising from taking an estimate from one model and data source and "plugging it in" to another model as if it were a known value.

Since posterior distributions describe postdata knowledge about unobservables, they also describe postdata evidence about hypotheses concerning unobservables. In contrast to a frequentist hypothesis test leading to a p value, the Bayesian approach leads to the posterior probability that a hypothesis is true. Often this posterior probability for a particular null hypothesis is larger than the corresponding p value.

This practical difference, in tandem with the different foundations and interpretations of frequentist and Bayesian hypotheses testing, continues to generate much debate and discussion.

Computational requirements and lack of software have hampered the transfer of Bayesian technology into epidemiologic practice, although there have been improvements over the past 15 years. New algorithms (Markov chain Monte Carlo algorithms) can implement Bayesian analysis in complex problems with many parameters, and software has been developed to implement these algorithms while shielding the user from algorithmic details. These algorithms represent the posterior distribution via a computer-generated sample (of large, user-specified size) from this distribution. This yields a curious duality: "Nature" is assumed to generate the study data via random sampling according to the statistical model, whereas the investigator generates inferences by random sampling from the posterior distribution. It should be mentioned that there are also non-simulation-based computational strategies, and in some problems, Bayesian inference can be implemented with software for standard (non-Bayesian) techniques, via the addition of "pseudo data" that represent the prior knowledge.

Some of the best applications of Bayesian methods involve prior distributions that arise naturally as plausible scientific assumptions. In disease-mapping applications, for instance, the variation in population rates across regions is plausibly thought to be spatially smooth. Correspondingly, a prior distribution can be constructed such that rates for a pair of adjacent regions are likely more similar than for a pair of distant regions. Another good example arises in meta-analysis. A prior distribution can compromise between the implausible extremes of identical effects across studies or totally unrelated effects across studies. Also, Bayesian methods are well-suited for many epidemiological problems that are characterized by multiple sources of uncertainty and/or extreme magnitudes of uncertainty. In the diagnostic testing situation, for example, the test sensitivity and specificity may themselves not be known exactly, in which case prior distributions could be assigned to these quantities as well.

Bayes's Theorem

Bayes's theorem, also known as Bayes's rule, is a theorem of probability theory that originated from the works of the Reverend Thomas Bayes (1783). Bayes's theorem connects the conditional and marginal probability of events or probability distributions of random variables. In interpretations of probability, it can be seen as a way of understanding how a probability is updated or revised in light of a new piece of evidence. Bayesian analysis is built on Bayes's theorem and has been used in a wide variety of contexts, ranging from marine biology to the development of "Bayesian" spam blockers for e-mail systems. In the philosophy of science, it has been used to try to clarify the relationship between theory and evidence. The direct use of Bayes's theorem on epidemiology and health science is closely related to diagnostic and screening testing, while Bayesian analysis is gaining extensive application in estimation and statistical inference in epidemiology.

Statement of Bayes's Theorem

Bayes's theorem is a statement on probability. For any two events A and B, the Bayes's theorem is given by

$$P(A|B) = \frac{P(B|A)P(A)}{P(B)}. \qquad [1]$$

Here, $P(A|B)$ is the conditional probability of A given B, and $P(B|A)$ is the conditional probability of B given A. $P(A)$ and $P(B)$ are the marginal probabilities

of events A and B, respectively. To see this theorem expressing how a probability is updated in the presence of new evidence, $P(A)$ is considered as the *prior* probability of A, that is, the probability of A without taking any other information account. Then given the information on B, the updated probability of A, $P(A|B)$ is calculated. $P(A|B)$ is also called *posterior* probability because it takes information of B into account.

There is an alternative formulation of Bayes's theorem. Note that based on the rule of total probability,

$$P(B) = P(B|A)P(A) + P(B|\bar{A})P(\bar{A}), \qquad [2]$$

where $P(A)$ and $P(\bar{A})$ are the probabilities of event A occurring and *not* occurring, respectively, and $P(B|\bar{A})$ is the conditional probability of B given A *not* occurring. Then by substituting $P(B)$ with Equation 2 in Equation 1, Equation 1 could be rewritten as

$$P(A|B) = \frac{P(B|A)P(A)}{P(B|A)P(A) + P(B|\bar{A})P(\bar{A})}. \qquad [3]$$

The application of Bayes's theorem in diagnostics and screening tests is based on Equation 3.

The above formulations of Bayes's theorem are for discrete events. For continuous distributions, there is a version of Bayes's theorem based on probability densities:

$$f(\theta|x) = \frac{f(x|\theta)f(\theta)}{f(x)} = \frac{f(x|\theta)f(\theta)}{\int_{-\infty}^{+\infty} f(x|\theta)f(\theta)}. \qquad [4]$$

In this formula, $f(\theta)$ is the prior distribution of parameter θ; and $f(\theta|x)$ is the posterior distribution of θ, updated from $f(\theta)$ by incorporating information from x. Parameter θ is often the interest of inference. This formulation for continuous variable is widely used in Bayesian analysis.

Bayes's Theorem and Screening Test

In screening tests, there are several important quantities, including predictive value positive (PV^+), predictive value negative (PV^-), sensitivity, and specificity, that are expressed in terms of probabilities. These quantities are defined as follows:

- PV^+ of a screening test is the probability that a person has a disease given that the test is positive.
- PV^- of a screening test is the probability that a person does *not* have a disease given that the test is negative.
- Sensitivity of a screening test is the probability that the test is positive given the person has a disease.
- Specificity of a screening test is the probability that the test is negative given the person does *not* have a disease.

Let $A =$ disease, $B =$ test positive, $\bar{A} =$ no disease, and $\bar{B} =$ test negative, then predictive value positive $= P(A|B)$, predictive value negative $= P(\bar{A}|\bar{B})$, sensitivity $= P(B|A)$, and specificity $= P(\bar{B}|\bar{A})$. If the proportion of disease in the general population is $P(A)$, the relationship between predictive value positive, predictive value negative, sensitivity, and specificity can be expressed by using Bayes's theorem. With appropriate substitution of terms in Equation 3, PV^+ and PV^- could be given as

$$PV^+ = \frac{\text{sensitivity} \times P(A)}{\text{sensitivity} \times P(A) + (1 - \text{specificity}) \times (1 - P(A))} \qquad [5]$$

and

$$PV^- = \frac{\text{specificity} \times (1 - P(A))}{(1 - \text{sensitivity}) \times P(A) + \text{specificity} \times (1 - P(A))}. \qquad [6]$$

Note that $P(B|\bar{A}) = 1 - P(\bar{B}|\bar{A})$ and $P(\bar{A}) = 1 - P(A)$. In Equation 5, $P(A)$ is the proportion of disease in the general population, and predictive value positive PV^+ could be considered as the updated probability of disease given a positive testing result. Similarly in Equation 6, $1 - P(A)$ is the proportion of *not* having the disease in the general population, and predictive value negative PV^- could be considered as the updated probability of not having the disease given a negative testing result. An example of hypertension will illustrate the general concept of PV^+ and PV^- of a screening test.

Suppose that among people with hypertension, 84% of those are classified as hypertensive by an automated blood pressure machine; whereas among people with normal blood pressure, 23% are classified as hypertensive by the blood pressure machine. In other words, sensitivity $= P(B|A) = 0.84$ and specificity $= P(\bar{B}|\bar{A}) = 1 - 0.23 = 0.77$. Furthermore, suppose some epidemiological study showed that 20% of the general adult population is hypertensive.

Then, PV^+ and PV^- of the blood pressure machine are calculated as

$$PV^+ = \frac{0.84 \times 0.20}{0.84 \times 0.20 + 0.23 \times 0.80} = 0.48$$

and

$$PV^- = \frac{0.77 \times 0.80}{(1 - 0.84) \times 0.20 + 0.77 \times 0.80} = 0.95.$$

Therefore, a negative result from the machine is very predictive and the probability of *not* having hypertension given a negative result is 95%. However, a positive result from the machine is not very predictive with only 48% probability of having hypertension for a positive result.

The above results could also be interpreted in a Bayesian framework. For any person randomly selected from the general adult population, without any other information, the prior probability of having hypertension is 0.20, and equivalently, the prior probability of *not* having hypertension is $1 - 0.20 = 0.80$. With the test result from an automated blood pressure machine, the posterior probability of having hypertension increased to 48% given a positive test and the posterior probability of *not* having hypertension increased to 95% given a negative test. New information from the blood pressure test updates the probability of having hypertension.

As another example, Bayes's theorem is useful in evaluating the result of drug tests. Suppose that a certain drug test will correctly identify a drug user as testing positive 99% of the time, or sensitivity = 99%, and will correctly identify a nonuser as testing negative 99% of the time, or specificity = 99%. This would seem to be a relatively highly accurate test, but Bayes's theorem will reveal a potential flaw. Assume that a corporation decides to test its employees for drug use, and 0.5% of the employees use the drug. It is of interest to know that the probability is that, given a positive drug test, an employee is actually a drug user. It could be shown that

$$PV^+ = \frac{0.99 \times 0.005}{0.99 \times 0.005 + (1 - 0.99) \times 0.995} = 0.3322.$$

Despite the high accuracy of the test, the probability that the employee with a positive test is actually a drug user is only about 33%. The rarer the condition that is being tested, the greater the percentage of positive tests that will be false positives. This illustrates why it is important to do follow-up tests and to consider the issue of false positives when routinely screening for a rare event.

Behavioral Risk Factor Surveillance System

The Behavioral Risk Factor Surveillance System (BRFSS) is a survey conducted annually in the United States by the Centers for Disease Control and Prevention (CDC) in cooperation with state health departments. The BRFSS, whose primary focus is behavioral risks to health, began collecting data in 1984 with 15 states participating; since 1994, all 50 states, the District of Columbia, and the territories of Puerto Rico, Guam, and the U.S. Virgin Islands have been included in the BRFSS.

The BRFSS was the first ongoing national survey to collect data about health and health risk behaviors, and it was designed from the start to provide estimates of these behaviors at both the state and the national levels. Creation of the BRFSS was in large part due to the realization by epidemiologists and public health officials, in the early 1980s, of how much influence individual health and health risk behaviors such as smoking and exercise exerted on morbidity and mortality.

BRFSS data are collected through telephone surveys on a rolling basis throughout the year. The actual data collection is performed either by state health departments or by contractors, using a standardized questionnaire developed by the CDC in cooperation with the state health departments.

Households surveyed are selected through random-digit dialing, and one adult (defined as a person 18 years of age or older) in a selected household is surveyed. Information about health risk behavior of persons younger than 18 years is collected in a separate survey, the Youth Risk Behavior Surveillance System. Persons living in institutions or who do not have a home telephone are automatically excluded from the sample, as are people who are not willing and able to complete a telephone interview in English or Spanish. The states send the collected data to the CDC, who aggregates it, then returns it to the states, and publishes it on the BRFSS Web site.

The BRFSS questionnaire consists of three parts:

1. the *core* component, meaning those questions used by all states and territories; these questions are provided by the CDC and must be administered using exactly the wording and order in the questionnaire;
2. *optional* modules, meaning sets of questions on specific topics such as arthritis or exercise behaviors, which each state may choose to administer or not; these questions are provided by the CDC, and the states are required to use the module exactly as written and in its entirety (although once chosen, the module must be administered exactly as provided in the questionnaire); and
3. *state-added questions*, which are developed or otherwise acquired by an individual state in response to their specific concerns; these questions are not provided by the CDC, and their subject matter, wording, and order are determined entirely by the state using the questions.

The core component is further divided into *fixed* core component questions such as demographics and major risk behaviors such as smoking, which are asked every year; *rotating* core component questions that are included in the core every other year and as optional module questions in the alternate years; and *emerging issues* core questions that typically focus on "late-breaking" health issues. Optional modules are self-contained units that consist of questions focused on a particular topic: For instance, in 2005 there were 26 optional modules whose focus included diabetes, prostate cancer screening, indoor air quality, and intimate partner violence. Up to 10 emerging issues questions may be included in a given year: After that year, they are either discontinued or incorporated into the core or optional modules.

BRFSS data are collected using sampling procedures and weighted so that accurate estimates of risk behaviors may be made at the state and national levels. Some states also stratify their samples to allow them to estimate prevalence for specific metropolitan areas or regions within the state. The different weighting factors are combined into a single variable (*FINALWT* in 2005) that may be used to weight the data to represent the population of noninstitutionalized adults more than 18 years of age. Use of this weighting variable is sufficient to provide accurate point estimates (e.g., means), but complex survey software that can take into account the survey design must be used to account for the sampling procedures and produce accurate estimates of variability (e.g., standard deviations and confidence intervals).

BRFSS data and supporting materials, including the questionnaires used each year, are available for download from the BRFSS Web site. Data from the BRFSS are widely used to evaluate health risks within states and nationally and is extensively used in academic research as well. The BRFSS Web site maintains a searchable bibliography of scientific publications based on BRFSS data, state publications based on BRFSS data (some including the full text of the publication available online), and *Morbidity and Mortality Weekly Report* (MMWR) publications based on BRFSS data (all with full text available online). In addition, a bibliography of methodological papers relating to the BRFSS is available on the BRFSS Web site.

BRFSS data are subject to all the limitations of telephone survey data, including response bias, exclusion of persons without a home telephone, exclusion of people who are unable to conduct a telephone survey and potential for misunderstanding or lack of disclosure by the respondent. Because data are collected by different entities within each state, another potential limitation is that quality of the data may vary from state to state, and information about factors influencing quality may not be available to the individual researcher. However, these limitations are balanced by the fact that the range of data, both in years surveyed and in topics covered, is greater than that available from any similar survey. In addition, the fact that the BRFSS was conducted using scientific sampling procedures makes it possible to use the data to generalize about the prevalence of health risk behaviors at both the state and the national levels.

Bias

Error happens. Scales are set incorrectly. Memories fade. Study participants try to give the ''right'' answer. When these mistakes are systematic, that is, not random, they will likely cause a biased result. The term *bias* can be translated fairly as ''wrong'' with the additional refinement of ''wrong due to systematic error.'' Thus, in the general statistical and scientific languages, a biased estimate is an incorrect estimate. In epidemiology, biased estimates typically refer to the distortion of a measure of association between exposure and outcome. This entry describes these measures, including the rate ratio, relative risk, attributable risk, and odds ratio.

The following examples will help illustrate bias. Underestimation would be caused by a scale that always weighs people 10 lb less than their true weight. A survey with leading questions (e.g., ''Do you believe that smoking is bad?'') may draw the desired answers more frequently than the study population actually believes. Study participants with a condition linked to the research may be more likely to follow study procedures or be available for follow-up than participants without the condition.

Causes of biased estimates in epidemiologic studies are generally categorized as *selection* bias and *information* bias. Selection bias refers to ways an estimate may be incorrect due to how participants were enrolled in a study or dropped out of a study (e.g., lost to follow-up). Information bias refers to ways an estimate may be incorrect due to measures made during the study. More than 100 terms for information bias exist, many with similar or overlapping meaning. This entry describes common forms of bias that affect estimates in epidemiologic studies. Confounding can also bias measures of association and is discussed in a separate entry.

Selection Bias

To put selection bias into context, one must understand the logistical challenges of conducting an epidemiologic study. Most of the time, epidemiologists have the capacity (or funding) to study only a relatively small sample of people. However, their goal is to make inferences about a larger population, called the *target population.*

For instance, consider a study to assess the efficacy of a booster vaccine for mumps among people living in the United States. The target population would include individuals who have not had mumps and have had an initial mumps vaccination. Because the target population is so large, it is not feasible to study all of them, and it may also be difficult to obtain a true random sample of the target population.

The *study population* is defined as the group of individuals in the target population who are eligible to be in the study. In statistical parlance, these eligible people have a nonzero probability to be included in the study. For the vaccine research, a convenient study population may be individuals attending high schools in five selected cities. The study population is selected to provide a representative sample of the target population and is largely determined by logistical factors. For example, the investigators must consider the geographic locations of qualified investigators and school districts willing to participate in the study. The study sample may be a random sample of students in these districts who provide informed consent. A more likely (and logistically convenient) scenario would be a random sample of schools where either the whole school or all students in a specific grade are selected.

Multiple steps are usually required to select a study sample from the study population. Each step between the study population and study sample presents an opportunity for bias to be introduced and create a sample that no longer represents the study population, resulting in a biased measure of association. The following scenarios illustrate the complexity of capturing a sample without introducing selection bias.

Medical records may be incomplete for students who transferred in to the school from another district or state. If medical records are used to determine prior vaccination status, the unavailability of the records might make these students ineligible for the study. If these students are less likely to have been vaccinated, excluding them would overestimate the vaccination coverage of the community.

The community may have a large percentage of home-schooled children. These children would not be eligible for the study but may have a different risk of mumps due to lower opportunity for exposure. The study would underestimate the value of booster vaccination if the selection criteria are predicated on enrollment in public school.

Forms of Selection Bias

For selection bias to distort the measure of association, the probability of selection must be disproportionate across different combinations of exposure and disease. Well-designed studies try to minimize the likelihood that selection of study subjects will distort the exposure-disease relationship. Discussion of selection bias is often specific to study designs. The following are some of the more common forms of selection bias that occur. The focus here is on the core study designs used in epidemiology: cohort, case-control and cross-sectional designs, and randomized trials.

Nonresponse Bias

Almost everyone has contributed to nonresponse bias by declining to participate in a telephone survey. Busy people tend to decline to participate in surveys unless they have an inherent interest in the issue.

Epidemiologic studies are challenged by increasingly low response rates. Fewer and fewer people are willing to participate in research studies, perhaps related to the increased proliferation of telemarketing, privacy protection technologies, and regulations. Most national surveys conducted by randomly calling households (random-digit dialing or RDD) have response rates substantially less than 50% of the eligible study sample selected. Thus, there is a significant likelihood that the participants will differ markedly from the nonparticipants. This, in turn, increases the likelihood that the study sample will not adequately reflect the study population or target population.

Because almost every study population will have nonrespondents, it is important to characterize the degree and direction of bias likely to be introduced. Nonresponse by some eligible subjects, however, does not necessarily mean that the measure of association will be biased. It just means that the opportunity exists for bias to influence the outcome. If the distribution of disease (for cohort studies) or the distribution of exposure (for case-control studies) among participants (volunteers) is different from that of nonparticipants (nonresponders), a biased measure of association could result. Researchers interested in the impact of nonresponse on national health surveys conducted by RDD, such as the Centers for Disease Control and Prevention's (CDC's) Behavioral Risk Factor Surveillance System (BRFSS), have not identified substantial nonresponse bias for similar health outcomes when compared with much more expensive in-person interview studies with higher response proportions.

In case-control studies, nonresponse bias has been identified as an important issue. With this study design, the control group is used to estimate the distribution of exposure in the study population. Those who are cases (and thus have a particular interest in the research) are often more likely to respond than individuals who are randomly selected for the control group. Volunteers who do agree to participate are often healthier than the general population, so the control group may not be representative of the population from which the cases arose. If the exposure of interest is associated with healthy behaviors, for example, then the measure of association (e.g., odds ratio) will likely be biased. The following is an example:

> A case-control study is designed to examine the relationship between smoking and type 2 diabetes. Among cases (new cases of diabetes), smokers and nonsmokers are equally likely to agree to participate. Among controls, however, smokers are less likely to participate. A history of smoking among controls

would therefore be too low, and the effect of smoking on diabetes would be overestimated.

Selective Survival Bias (Neyman Bias)

Selective survival bias occurs in case-control studies when cases are selected from those who have disease, not exclusively from those who are newly diagnosed. The distinction here is between prevalent disease (those with an existing condition) and incident disease (those with a new diagnosis of the condition). Prevalent disease is influenced by factors that cause the disease as well as factors that influence cure or survival. If the study design allows individuals with established disease (prevalent cases) into the study, then the researcher may not be able to distinguish between effects related to cure or survival versus effects related to the likelihood of developing disease. To limit the risk of selective survival bias, most epidemiologists now limit study eligibility to incident cases when possible. For diseases with insidious onset, such as Alzheimer's disease, this may be difficult. The following is an example:

> Researchers enroll clients of a local psychology practice who are being treated for depression as cases in a case-control study designed to examine the effect of diet on the development of depression. If a well-balanced diet decreases the amount of time a client needs treatment for depression, then those with a well-balanced diet will leave the psychology practice sooner than those with poor diets. Using the diets of clients needing ongoing treatment will overestimate the effect of a poor diet because the effect of a poor diet on the development of depression is inadvertently linked to the effect of a poor diet on the need for ongoing treatment.

Berkson's Bias

This bias occurs in case-control studies when the probability of hospitalization for cases differs by whether or not they were exposed. If exposed cases are more likely to be hospitalized than nonexposed cases, then using only hospitalized cases in a case-control study will overestimate the prevalence of exposure among cases. The following is a well-known example of Berkson's bias:

> In hospital-based case-control studies of oral contraceptives and thromboembolism, early research found a strong association. However, because the medical community was aware of the risk of thromboembolism due to oral contraceptives, physicians were more likely to hospitalize women who had symptoms if they were taking oral contraceptives. The differential probability of hospitalization depending on oral contraceptive use resulted in a biased (overestimated) odds ratio.

Inclusion Bias

Inclusion bias occurs when controls selected for a case-control study are more likely to be exposed than the study population from which they arose. The most common examples are from case-control studies that use hospitalized patients as controls. If the exposure is associated with increased risk of diseases other than the one being studied, then the hospital-based controls may have higher history of exposure than the general population. Since this will make the exposure of the controls similar to the exposure of the cases, inclusion bias typically results in a bias toward the null. When hospital-based controls are used, researchers can try to avoid this bias by excluding controls with conditions known to be associated with the exposure of interest.

For example, consider a case-control study of alcohol use and liver cancer. Hospital-based controls may be more likely to drink alcohol than nonhospitalized, healthy people, because alcohol use is associated with many diseases resulting in hospitalization (e.g., cardiovascular disease, injuries).

Exclusion Bias

Case-Control Studies

Exclusion bias is a term used to describe two different forms of bias. For case-control studies, exclusion bias occurs when different exclusion criteria are applied to cases and controls. For example, cases may be eligible even if they have other health conditions (comorbidities), but controls are excluded unless they are healthy. As an example, consider the case-control study of alcohol use and liver cancer described above.

Researchers want to select only hospitalized controls with diseases unrelated to alcohol, so they exclude patients with a history of heart disease, even if the patients are being admitted for other conditions. Some

of the cases, however, will also have a history of heart disease, so the excluded controls do not represent the same underlying population as the cases. To avoid this, the exclusion criteria should have been related to the reason for admission to the hospital rather than prior history of disease.

Randomized Trials

Exclusion bias also describes biased results from randomized trials. The bias arises when intent-to-treat analysis is not used. Intent-to-treat analysis involves analyzing the data based on the original random assignment. Study participants are included in the denominator based on their initial assignment into treatment groups; participants are not pulled out of the denominator due to early departure from the study, noncompliance with the assigned treatment, or loss to follow-up, among other issues. Because early departure and noncompliance may be related to the toxic effects of the treatment under study, lack of good data for these individuals should be considered in the analysis to best describe the effects of the intervention or treatment. For example, consider the following:

> A rare side effect for a new drug is severe headache. In a clinical trial, patients receiving the drug and experiencing the headache are likely to stop taking the drug. Patients receiving the placebo do not experience the headache and do not discontinue participation in the study. Excluding patients who stop taking the drug will make the treatment group less comparable with the placebo group.

Healthy Worker Effect

The healthy worker effect is a bias that occurs in cohort studies and arises from the fact that those who work tend to be healthier than those who do not. Thus, when comparing the mortality of workers in a high-risk industry (e.g., potentially toxic chemicals) with the mortality experience of the general population, the harmful effects of the exposures may be underestimated.

For example, consider a cohort study of exposure to toxic fumes on lung function that compares the lung function among firefighters with that among office workers. Firefighters must be extremely physically fit to perform their jobs; office workers do not. Firefighters who have poor lung function stop being firefighters and get office jobs. The firefighters who remain at their jobs will have better lung function than the office workers, and the effect of the toxic fumes will be underestimated.

Matching

Matching cases and controls in a case-control study can introduce selection bias. Fortunately, problems with the estimation can be corrected by statistical analysis and are thus rarely an issue if the proper techniques are used for adjustment.

Overmatching refers to inappropriate use of matching when it is either not necessary or causes bias. The purpose of matching is to improve statistical efficiency in the control of confounding by assuring that each strata of the confounder has enough controls. Matching on a factor that is not a confounder will introduce confounding by that factor and decrease statistical efficiency, but the bias due to confounding can be accounted for in the analysis. A greater problem with overmatching occurs when cases and controls are matched on factors that are affected by the exposure and disease. If cases and controls are matched on intermediaries between the exposure and disease, the resulting bias cannot be accounted for in the analysis. The following is an example:

> In a study of occupational exposure to radiation and the risk of leukemia, researchers matched cases and controls based on when they started working and length of employment at the nuclear facility. The purpose of matching on these employment-related factors was to control for the effects of differences in safety practice over time. Length of employment is also correlated with radiation dose, however, since longer work history means a higher cumulative dose of radiation. Cases and their matched controls, therefore, had the same radiation doses, and matching on employment date obscured the effect of dose on leukemia risk.

Loss to Follow-Up

Loss to follow-up can cause bias in both clinical trials and cohort studies. If it seems counterintuitive to consider loss to follow-up as a type of selection bias, think of it as differential selection *out* of the study. Typically, participants who leave a study differ from those who remain enrolled in important ways. For

clinical trials, individuals who are not getting "better" on the treatment may disproportionately decide to leave the study. This difference in attrition can bias the study results, as in the following example:

> In a cohort study of breastfeeding and risk of infections in the infant, researchers enroll women giving birth at a local hospital, some who are breastfeeding and some who are not. They count the number of infections the infants have in their first year. Women with less stable economic situations may be less likely to breastfeed and also harder to track if their living situation is not stable. Other factors related to infection risk, such as day care attendance, may also differ.

Missing Information

This type of selection bias occurs at the analysis stage. There are many potential reasons for missing information, such as participants refuse to answer some survey questions or medical records cannot be found. The most common method for dealing with missing data in epidemiology studies is to exclude the individuals with missing information based on key factors. Thus, they are selected out of the study in the analysis phase. Another rarely used technique to deal with missing information is estimation of the values using statistical imputation. The following is an example of missing information bias:

> A study was conducted to assess the racial disparities that exist for hypertension during pregnancy. All hospital records for delivering a baby during a year period in a state were identified in a computerized database. If information on race was missing, the record was excluded. An association between race (black, white) and hypertension during pregnancy was identified. Black women were more likely to be hypertensive during pregnancy than white women in the state. It was then noted that some hospitals did not record race on computerized records so all women who delivered their baby at one of these hospitals were missing. If women served by these hospitals were different on both race and hypertension, then the measure of association computed would be biased due to the deletion of missing data.

Estimating the Effect of Selection Bias

It is rarely possible to estimate the effect of selection bias mathematically. To do so requires the following information: an accurate study participation rate, and knowing the exposure and outcome status for both participants and nonparticipants. When this information is available, the percentages can be used to estimate the amount and direction of bias. Also, the biased measure can be adjusted to provide a more accurate estimate of the true measure of association.

For most studies, the data described above are not available to compute the mathematical adjustments for selection bias. Nevertheless, it is important to contemplate the types of selection bias that can occur with different study designs. The researcher can then choose the study design that best minimizes all forms of bias, including selection bias. With careful consideration, one can often identify the *direction* that selection bias will pull the measure of association, but the *magnitude* of the bias is more difficult to conceptualize. Experience in the topic area and study population improves the ability to predict both the magnitude and the direction of bias.

Understanding selection bias is critical to strategic study design. Experienced epidemiologists usually design studies to keep the magnitude of bias as small as possible and point the direction of bias *toward* the null. This conservative approach means that the measure of association can be interpreted as an underestimate of the true strength of association. If the direction of the bias is *away* from the null, then computing the actual magnitude of the bias becomes essential to the determination of whether an association exists at all.

Reducing the Effect of Selection Bias

Case-control studies are particularly vulnerable to selection bias. Cases are often drawn from hospitals or clinical practices that do not have well-defined populations from which to select controls. Even people hospitalized in the same facility may not be from the same source population because the catchment areas for hospitals often vary by diagnostic group.

Carefully delineating the source population from which the cases arose is imperative to develop a good framework for selecting controls to minimize selection bias. Integrating the suggestions below in the study design phase may help:

- For case-control studies, select controls that best represent the source population for the cases. Controls should come from a population that is similar in every way to the cases, except for the outcome of

interest. In other words, if the control had gotten the disease, they would have been a case in the study.
- Reduce loss to follow-up with regular outreach to study participants. In clinical trials, you can attempt to measure the impact of unavoidable loss to follow-up with a small pilot study among those who dropped out of the study.
- Anticipate which factors may be intermediate between the exposure and disease and avoid matching cases and controls according to these factors. This will reduce the likelihood of overmatching.
- Consider using statistical imputation to minimize the bias introduced by missing information in the analysis stage.

Information Bias

Information bias is caused by errors in the measurement of study factors among participants. Misclassification occurs when study subjects are assigned to the wrong disease or exposure group. In a cohort study or clinical trial, information bias primarily results from misclassification of disease outcome (e.g., disease was not diagnosed or the subject was mistakenly determined to have disease), but misclassification of exposure is also possible. In a case-control study, information bias primarily results from misclassification of exposure, but misclassification of disease status is also possible. Misclassification is directly related to sensitivity and specificity of the measurements. If the sensitivity and specificity are both 100%, then there is perfect measurement and no misclassification will occur. However, if either sensitivity or specificity is lower, misclassification will likely occur. It is inevitable that misclassification will happen in epidemiology research. Even when measures are validated, there will never be perfect measurement.

The type of bias that results from misclassification depends on how the misclassification happened. When mistakes occur on the classification of responses to one factor independent of the other factors, it is called *nondifferential misclassification.* More specifically, nondifferential misclassification of disease occurs when the errors are not linked to exposure status. For instance, if disease status is determined by laboratory tests that have 98% sensitivity and 90% specificity, then all study participants have the same chance of being incorrectly classified. Similarly, nondifferential misclassification of exposure means that mistakes made by categorizing participants by exposure status are not related to their disease status. Nondifferential misclassification usually results in a bias toward the null; that is, the measure of association is underestimated. In very rare situations, the bias results in an overestimate.

Differential misclassification occurs when the error in classification is somehow linked to both the subject's exposure status and the disease status. Differential misclassification can result in an over- or underestimate of the measure of association, so careful understanding of the type of bias and potential effect of the bias is needed to interpret the study findings.

Interviewer Bias

When the interviewer knows the study hypothesis or goals of the study, a conscious or unconscious attempt may be made to elicit responses consistent with the desired information. This potential bias particularly exists if the interviewer knows the study hypothesis and specific exposure, intervention, or disease status of the study participants. Interviewer bias is generated by using intonation (emphasis) or gestures when questions are asked or using prompts to elicit certain responses differentially depending on the subject's status. It is important to note that even if the study design blinded interviewers to participants' exposures and diseases, it is possible that the participants will spontaneously share this information with the interviewer. The following is an example:

> In a case-control study of diet and heart disease, the interviewer asks participants about dietary habits, exercise, and lifestyle choices. The interviewer knows which participants have heart disease and which do not. When the survey turns to questions about diet, the interviewer inadvertently smiles and rushes through the questions about snack foods for controls who are obviously lean and healthy, assuming their diet would not contain snack foods.

Recall Bias

People's ability to remember accurately depends on a number of factors, including the significance of the exposure, the degree of ruminating about the exposure, prompts (e.g., calendars, pictures) to improve memory, and motivation. Recall bias occurs

when groups are different in their ability to recall information. Investigators designing case-control studies must be particularly cognizant of the potential for recall bias to be an issue.

Consider, for example, a case-control study of maternal health behaviors during conception and early first trimester and the risk of birth defects. The recall may be very different for mothers of newborns with a birth defect compared with mothers of healthy newborns. Mothers of newborns with a congenital health condition may ruminate on possible exposures to isolate a cause. In contrast, mothers of healthy newborns are much more focused on adjusting to the current needs of the baby and pondering the future of their new child. Case mothers are likely to be more accurate than control mothers, and control infants would be more likely to be misclassified as unexposed. If the behavior is harmful, the differential misclassification of exposures based on case-control status would result in an overestimate of the odds ratio.

Telescoping

Telescoping occurs when individuals are asked to report exposures or diseases that occurred within a specified time period (e.g., during the past year). It can also occur when participants are asked when symptoms began. In case-control studies, controls are often asked about their exposures at the time the case was diagnosed. Unlike the cases, controls have no inherent meaning assigned to this particular day or month in the past and therefore have difficulty pinpointing it in relation to their own life events. Telescoping typically occurs because the person has difficulty bounding the time period of the inquiry, as in the following example:

> In a cross-sectional study of eye infections among contact lens wearers, the participants are asked about their lens hygiene and previous eye conditions. The participants are asked to report on these factors for the previous 6 months. Some participants have difficulty remembering and report eye infections that occurred more than 6 months previously.

Reporting Bias

Reporting bias occurs when the participant, consciously or unconsciously, provides incorrect information. This can happen when the participant tries to please the investigators by supplying the presumed "correct" answer. If the respondents are aware of the hypothesis being studied, reporting bias is likely to cause differential misclassification resulting in an overestimate or underestimate of the measure of association. In a case-control study, this misclassification occurs because cases will be more likely to report being exposed while the converse will be true for the controls. Another form of reporting bias may be due to underreporting of exposures or experiences. Underreporting is a particular issue when collecting sensitive information (e.g., illegal drug use, high-risk sexual activities). Underreporting may be differential or nondifferential, depending on the study being conducted.

In a cross-sectional study of occupation and sexually transmitted disease (STD), participants in high-status occupations (e.g., executives, physicians) are less likely to honestly report the occurrence of an STD.

Detection Bias

Detection bias occurs primarily in cohort studies where the ability to detect disease is different for the exposed compared with the unexposed. If those with an exposure are more likely to be seen regularly by a clinician, they will also be more likely to be diagnosed. Diseases with an indolent progression are especially vulnerable to this issue. The following is an example of detection bias:

> In studies of high-risk materials (e.g., chemical, radiation), the disease experience of cohorts working with the material is compared with the disease experience of the general population with similar characteristics (e.g., males). These studies are often performed using retrospective cohort designs and the outcome status (e.g., thyroid cancer) is based on medical record reviews. Thyroid cancer is rarely fatal and is often an incidental finding on medical examination. In a study of radiation and thyroid cancer, it is possible that those who work in occupations with exposure to radiation have more frequent and extensive medical examinations and thus are more likely to have a thyroid cancer diagnosis than the general population.

Hawthorne Effect

The Hawthorne effect describes the change in normal behavior typical of individuals who know

they are being observed as part of the research process, as in the following example:

> A field trial is designed to examine the effect of a new hand-washing campaign among hospital workers. The new campaign is introduced among employees of five hospitals. Five other hospitals are used as a comparison (usual hand-washing behavior) group. At the comparison (usual hand washing) hospitals, the staff knows that hand washing is being monitored, and the amount of hand-washing behavior increases and improves. The amount of hand washing at the comparison hospitals does not reflect the norm and the effect of the new campaign is underestimated.

Panel Effect

The panel effect is caused by repeated interviews about exposures and diseases during the study period. Participants tend to report fewer events over time, thus misclassification occurs as a result of lowering sensitivity. Panel effect may produce differential or nondifferential misclassification depending on the study design. An example is the following:

> In a cohort study of the relationship between diet and birthweight, pregnant women are asked to complete a dietary recall at each prenatal visit. As time goes on, participants lose enthusiasm and the completeness and accuracy of the diet recall decreases. The effect causes nutrient intake to appear lower as pregnancy progresses.

Estimating the Effect of Information Bias

Fortunately, it is often possible to estimate the degree of information bias in epidemiologic studies. For example, when nondifferential misclassification occurs due to imperfect sensitivity and specificity, measures of association can be adjusted for the misclassification. When sensitivity and specificity are known, it is possible to estimate the magnitude as well as direction of misclassification bias.

Using a measure with high sensitivity and specificity is ideal, but sometimes not practical for research purposes. To evaluate the potential role of information bias in the study, investigators might design a pilot study to measure the sensitivity and specificity of the questionnaire or measuring instrument. For types of information bias that cannot be so directly evaluated, and thus not amenable to mathematical adjustment, the investigator must carefully consider the magnitude and direction of the information bias. Examples of such deliberation may be found in the discussion sections of published research studies.

Reducing the Effect of Information Bias

Epidemiologists use multiple methods to reduce the opportunity for information bias to occur and reduce the magnitude of the bias. Several suggestions are provided here:

- Interviewers should be blinded to the research question and hypothesis and, if possible, to the exposure or disease status. Train interviewers to conduct structured interviews, test interviewers to establish interrater reliability before the study begins, and provide periodic refresher sessions. Anticipate participant questions and provide structured responses for interviewers.
- Select questionnaires or measurement instruments with established validity and reliability.
- Recall bias is reduced with the use of calendars or temporal landmarks to improve the memory. Pictures and other memory aids may help improve the recall of medications or other exposures. Furthermore, a checklist may elicit a more complete recall of medications taken than would open-ended questions.
- For cohort studies, use similar methods of detecting diseases among exposed and unexposed populations.

Binomial Variable

Binomial variables are frequently encountered in epidemiological data, and the binomial distribution is used to model the prevalence rate and cumulative incidence rate. Binomial variables are created through repeated trials of a Bernoulli process, often called Bernoulli trials. Daniel Bernoulli (1700–1782) was the first mathematician to work out the mathematics for Bernoulli trials. *Bernoulli trials* must satisfy the following three conditions:

1. The experiment has two possible outcomes, labeled *success* (S) and *failure* (F).
2. The trials are independent.
3. The probability of a *success* remains the same from trial to trial; this is called the *success probability* and is denoted with the letter p.

The word *success* as used here is arbitrary and does not necessarily represent something good. Either of the two possible categories may be called the success S as long as the corresponding probability is identified as p.

A random variable for the number of successes in a sequence of Bernoulli trials is called a *binomial variable.* The probability distribution for a binomial variable is called the *binomial distribution.* The binomial probability formula for the number of successes, X, is

$$P(X = k) = \binom{n}{k} p^k (1-p)^{n-k},$$

where the *binomial coefficient* $\binom{n}{k}$ is defined as

$$\binom{n}{k} = \frac{n!}{k!(n-k)!}$$

and $k!$ is the product of the first k positive integers and is called k factorial. In symbols,

$$k! = k \cdot (k-1) \cdot \cdots 2 \cdot 1.$$

Consider the following example. Epidemiological surveys have determined that 9% of men and 0.25% of women cannot distinguish between the colors red and green. This is the type of color blindness that causes problems reading traffic signals. If six men are randomly selected for a study of traffic signal perceptions, the probability that exactly two of them cannot distinguish between red and green can be calculated using the binomial distribution formula as follows.

We must carefully define which outcome we wish to call a success. For convenience, we define a *success* as a randomly selected man who cannot distinguish between the colors red and green, so $p = 0.09$. Let X denote the number of men of the six who cannot distinguish between the colors red and green. The number of trials is the number of men in the study, so that $n = 6$. Using the binomial probability formula for $k = 2$ yields

$$\begin{aligned} P(X = 2) &= \binom{6}{2}(0.09)^2(1-0.09)^{6-2} \\ &= \frac{6!}{2!(6-2)!}(0.09)^2(0.91)^4 \\ &= (15)(0.09)^2(0.91)^4 = 0.0833. \end{aligned}$$

Therefore, the probability that exactly two of the six men cannot distinguish between red and green is 8.33%.

Biomarkers

A biomarker is broadly defined as a substance that can be measured and evaluated as an indicator of normal or pathogenic biologic processes or of a biologic response to a therapy or intervention. In epidemiology, biomarkers are often used to measure internal dose, biologically effective dose, early

biologic response, altered structure or function, and susceptibility. By incorporating biomarkers into epidemiologic assessments, researchers may more precisely measure exposures or outcomes, reduce exposure and/or disease misclassification to produce less biased estimates of association, and elucidate biologic processes underlying exposure-disease relationships. The increasing integration of biomarkers in epidemiologic studies has fostered the creation of a distinct multidisciplinary subspecialty called molecular epidemiology in which molecular, cellular, and other biologic measurements are incorporated into cross-sectional, retrospective, and prospective observational studies and clinical trials.

Types of Biomarkers

Biomarkers may take the form of exogenous compounds (e.g., absorbed chemicals, pesticides, food derivatives, metals), whose presence can be detected and quantified in biologic media, as well as measures of endogenous biologic substances, such as nucleic acids, proteins, and lipids. Biomarkers may be measured from any number of biologic media, including blood, urine, hair, feces, sputum, nails, and other body fluids and tissues. Table 1 lists the types of different biomarkers that have been used in epidemiologic assessments.

Uses of Biomarkers in Epidemiologic Studies

For purposes of epidemiologic research, biomarkers can be broadly grouped into three categories: (1) biomarkers of exposure, (2) biomarkers of effect, and (3) biomarkers of susceptibility. These categories are defined by their position in the spectrum of the exposure-outcome relationship. It is important to note that many biomarkers may play multiple roles, depending on the particular research question being posed. For example, circulating low-density lipoprotein (LDL) may be both a measure of exposure (as a risk factor for coronary heart disease) and a measure of outcome (in a trial of a lipid-lowering therapeutic) within two different studies.

When evaluating exposures, a distinction can be made between the external dose, or the amount that the subject is physically exposed to in their immediate environment, and internal dose, or the total amount of exposure that the subject has absorbed internally over a period of time. Depending on the measure, *biomarkers of exposure* can reflect the internal dose at any stage along its pathway, from the initial unaltered but absorbed exposure to a biologically altered and metabolized form delivered to tissues, and finally to the chemically and/or structurally altered biologic substance as a result of exposure.

Table 1 Types of Biomarkers

Type of Biomarker	*Examples*
Exogenous compounds	
Chemicals (including pesticides)	Polychlorinated biphenyl (PCBs)
Metals	Aluminum, chromium
Food derivatives	Isoflavones (e.g., genistein, daidzein)
Endogenous compounds	
Nucleic acids	DNA, mRNA
Proteins (including antibodies, some growth factors, and hormones)	c-Reactive protein, estrogen receptor
Lipids (such as cholesterol, some steroid hormones, and growth factors)	Triglycerides, estradiol
Molecular characteristics	
DNA sequence variation	Genetic polymorphisms
Cellular characteristics	
Morphologic changes	Sperm motility

Biomarkers identified and measured in body tissues or fluids that are either unchanged or metabolically altered are considered biomarkers of internal dose, while biomarkers of biologically effective dose are markers measured in target or surrogate tissue that reflect the interaction of the absorbed exposure with a subcellular target. Examples of internal and biologically effective dose biomarkers are given in Table 2.

Biomarkers of effect include those that measure biological or biochemical changes in target cells or tissues that occur as result of exposure (Table 3). These may include preclinical biologic effects, such as elevated tumor-specific antigen levels (e.g., prostate-specific antigens or PSA) produced in response to tumor presence, and early-stage disease, such as preneoplastic tissue that may progress to cancer. Molecular markers are also useful in differentiating diseases with the same appearance into different individual, such as estrogen receptor positive (ER+) versus estrogen receptor negative (ER−) breast cancers, thus reducing outcome heterogeneity, improving the precision of effect estimates, and guiding medical treatment.

Biomarkers of susceptibility are similar to effect modifiers in traditional epidemiologic terms. Even when individuals are similar in their environmental exposures, inherent differences in biological responsiveness can produce markedly different doses at the target site and, therefore, different effects. Biomarkers of susceptibility are frequently acquired or genetic factors that influence the response to exposure, yet are preexisting individual characteristics that are independent of exposure. Biomarkers of susceptibility can identify subpopulations of individuals who have a different response to the effects of exposure. Among the more widely studied biomarkers of susceptibility are genetic polymorphisms in enzymes involved in drug and xenobiotic metabolism. Interindividual differences in rates of metabolism will affect the distribution and persistence of different xenobiotic metabolites, which can have downstream implications on biologically effective dose and outcome. For example, individuals with slow *NAT2* acetylator phenotypes have been observed to have higher risk of bladder cancer, relative to fast acetylators, particularly among smokers and those exposed to bladder carcinogens.

Methodologic Considerations in Epidemiologic Studies

Although similar to more traditional measures of exposure, disease, and susceptibility, specific methodologic considerations must be considered when using biomarkers in epidemiologic studies. When selecting an appropriate marker to study, three primary considerations include (1) the feasibility of sample collection, (2) the reduction of systematic error and bias, and (3) ethical issues. Many of these are also applicable to general biomonitoring and exposure assessment studies that use biomarkers.

When selecting a biomarker for incorporation in an epidemiologic study, researchers must consider the feasibility of collecting the type of tissue required (e.g., the invasiveness of the procedure and the availability of the tissue), cost, and ease of assays that will be used for analysis. For example, for measures of certain tumor protein markers, fresh frozen tumor tissue is preferred, yet is procedurally and

Table 2 Examples of Biomarkers of Exposure

Marker	*Exposure*	*Biological Media*
Internal dose		
Cotinine	Nicotine in cigarette smoke	Body fluids
HIV antibodies	HIV virus	Sera or plasma
Asbestos particle	Inhaled asbestos	Lung parenchyma
Biologically effective dose		
DNA adducts	Benozy(a)pyrene	White blood cells
Protein adducts	Ethylene oxide	Red blood cells

Source: Adapted in part from Hulka (1990).

Table 3 Examples of Biomarkers of Effect

Marker	*Disease*
Elevated PSA	Prostate cancer
Dysplastic cervical cells	Cervical cancer
Microsatellite instability (tumor DNA)	MSI + vs. MSS colorectal cancer

logistically difficult to collect. Paraffin-embedded fixed tissue may be more easily obtained from tissue blocks, but some markers may be altered by or degraded prior to the fixative process. In general, it is preferable to collect tissues by the least invasive method possible. Biomarkers that can be measured from tissues such as fingernails, hair, sputum, urine, feces, and expired air are less invasive to the study subject when collecting, while markers requiring the collection of blood, tumor and normal organ tissue, adipose tissue, and bone marrow are considerably more invasive and difficult. Analytic techniques are that automated, nonlabor intensive, and, for large studies, have high throughput can increase the reliability and precision of measures, as well as reduce the study costs.

Measurement error may induce bias in a study involving biomarkers if appropriate measures are not taken to avoid or reduce its effects. The standardization of protocols for biospecimen collection, processing, and storage can help minimize measurement error, as well as procedures to ensure uniformity in the analytic procedures (e.g., using the same assay, technicians). The incorporation of quality assurance and quality control measures into study protocols can also help reduce error. Specific knowledge of the behavior and modifying influences on the biomarker of interest is also important in improving accuracy and validity of measures. Understanding of the normal distribution of a biomarker measure can provide insight into the accuracy of a diagnostic technique (e.g., Are obtained values within the range of expected values?). Knowledge of how biomarker measures might differ if obtained from different tissues (e.g., PCBs measured in serum vs. adipose tissue), using different techniques (e.g., growth factors measured using ELISA vs. IRMA), at different times (diurnal or seasonal variation), under different storage conditions (e.g., -70° C or room temperature, degradation of marker over time), and in relation to subject characteristics, such as disease state, treatment effects, diet, or physical activity.

Finally, as rapid advances in biotechnology increase the accessibility and feasibility of incorporating biological markers into epidemiologic studies, the ethical issues and legal considerations confronting epidemiologists have become particularly relevant. Topics of current interest to policymakers, ethicists, researchers, and clinicians include disclosure of research results (Should researchers inform participants of results, particularly if results have yet to be confirmed or validated?), confidentiality (Who will have access to a subject's biological information? Will information affect a subject's insurability?), banking of samples for future research (Will stored samples be linked by identifying information to subject? Are researchers obligated to recontact subjects to inform them of results of future research?), and the psychological and social risks (Should adjunct services such as genetic counseling referrals be required to communicate results? Is it ethical test for disease, or susceptibility to diseases, for which there is no effective treatment?).

The rapidly evolving technology in cellular and molecular biology and genetic research promises to identify many new biomarkers that will offer both exciting opportunities and technical, ethical, and other challenges in epidemiologic research. This field should lead to improvements in epidemiologic research, better understanding of the natural history of disease, characterization of risk factors for disease, and the development of more effective and targeted medical treatments.

Biomedical Informatics

Biomedical informatics is broadly defined by the American Medical Informatics Association (AMIA) as the study of "effective organization, analysis, management, and use of information in health care" ("About Informatics," AMIA Web site). Although not requiring the inclusion of computers, the field has grown parallel to the explosive growth of the computer industry, and the two are often associated. Biomedical informatics deals with all aspects of information processing and communication toward a common goal of providing better health care. Its foundations stem from the intersection of computer science, clinical medicine, biomedical engineering, mathematics, and cognitive science. Most health care research today touches some aspect of biomedical informatics, typically through the use or creation of electronic databases, searching online resources, or management of electronic monitoring systems. This entry provides an overview of the history and scope of this field, current research techniques, and applications in both clinical medicine and epidemiology.

The Field of Bioinformatics

The field of bioinformatics can be divided into three broad categories: clinical informatics, public health/population informatics, and translational bioinformatics. Within each of these are potential theoretical and applied divisions. The aims of each branch, however, is the same: to find better ways to research, share, and use the fast-growing fund of medical knowledge.

Clinical informatics is the umbrella term surrounding the information needs of clinicians, medical staff, and patients. It is a broad term covering both inpatient and outpatient medicine and has been the subject of recent state and federal legislation. There are several areas of research within clinical informatics. The goals of each of these areas are to improve patient care through better information management.

Public health or population informatics is similar to clinical informatics except in scope. Population informatics encompasses biosurveillence, preventative medicine research, and disease incidence data.

Translational bioinformatics includes research on tools for acquiring, storing, analyzing, and sharing information. Although not limited to genetic information, this area includes technologies behind the Human Genome Project (1991–2003) that have allowed for processing and storage of large quantities of genetic data and has led to an explosion of information on gene expression, protein synthesis, and biomarker determination. Much of the rapid growth in our understanding of genetics stems from the development of microarrays. A single microarray (a silicon wafer on which genes or gene fragments are attached) can yield 4,000 to 50,000 measurements of gene expression, and many studies use multiple microarrays. Although the biology behind these technologies is beyond the scope of this entry, research in this area continues with the creation and analysis of large genetic databases to facilitate discovery of linkages between genetic information and disease processes. Several new prognostic tests and pharmaceutical agents have been developed through analysis of these data that target specific genes or gene products.

History of Informatics

Some of the early notable achievements in informatics occurred in the 1960s. The first version of the National Library of Medicine's MEDLARS/MEDLINE bibliographic database was released in 1963. In 1966, Massachusetts General Hospital Utility Multiprogramming System was created in Octo Barnett's laboratory as one of the first systems designed specifically for hospital staff to interact with a clinical database. Several large companies such as IBM, 3M, and Hewlett-Packard created medical systems in the 1970s to 1990s with variable success. From 1982 to 1985, the Veterans Administration (VA) began a project to create a decentralized computer network throughout its hospital system, which in 1994 was renamed VistA (Veterans Health Information System and Technology Architecture). It is the current system used to integrate and manage all the clinical information systems throughout the VA network.

The World Wide Web began to connect people internationally in the early 1990s, and approximately 50% of the U.S. households had personal computers by the year 2000. A study by the American Medical Association in 2001 showed that 79% of clinical practices used the Internet to research medical information, and 63% used the Internet to search for drug information. Surveys of medical providers during that same year, however, showed that only 31% of emergency rooms, 29% of outpatient departments, and 17% of physician practices used electronic health records. Thus, around the turn of the century, online resources were in use, but personal records and health systems were mostly paper based. In 2004, President Bush issued an executive order creating the Office of the National Coordinator for Health Information Technology with a goal of nationwide implementation of electronic medical records by 2014.

Much of the recent growth of the use of clinical information systems and of legislation surrounding their implementation stems from two reports released by the Institute of Medicine (IOM) from 1999 to 2001. These reports catalyzed change in the medical community and brought clinical informatics to the forefront by identifying areas where modern medicine was failing to provide safe and effective care. The first report, "To Err Is Human," discussed the prevalence of medical errors, and in particular preventable medical errors. Basing their findings on two studies from different parts of the United States, the IOM estimated that 44,000 to 98,000 deaths occurred each year to medical errors alone. Subsequent reports found that more than 50% of these errors took place during clinician ordering and transcription of these orders. Difficulties in interpreting handwriting, acronyms, and time delays were just a few of the underlying reasons outlined by these reports. Another study on the analysis of handwritten prescriptions in 2005 found that 7.6% contained errors and 2% contained potentially life-threatening errors. Difficulty arises, however, in discussing medical errors in that several definitions of errors have been used. In addition, many studies do not establish reliably of their measures of error, and often no efforts are made to determine which errors led to adverse outcomes.

The second report, "Crossing the Quality Chasm," outlined clinical inequities for various populations as well as disparities between medical knowledge and clinical practice. This report and others found an approximate 5-year delay between evidence-based guidelines and their subsequent widespread use in clinical practice. This delay was more striking in smaller and rural practices.

These two reports stressed that safety was a systems problem and helped to spearhead new initiatives in clinical informatics to study and improve health care information use and delivery. Several key research areas of clinical informatics, including computerized physician order entry (CPOE), electronic prescribing, and the use of electronic medical records, have grown in response to theses concerns.

CPOE attempts to reduce errors at the point of ordering. Clinicians type their orders directly into a computer alleviating transcription errors and handwriting issues. The additional advantage to this method is that a sophisticated computer system can also perform checks on the item ordered ensuring completeness, accuracy, and safety. This type of feedback is called clinical decision support and involves anything from checking prescriptions against patient allergies or formularies to providing clinicians with cost estimates of the procedure or medication they are prescribing. Although the exact prevalence of physician order entry in the United States is unknown, one published survey estimated that only 9.6% of hospitals in the United States have fully implemented CPOE as of 2002. Multiple studies of CPOE with clinical decision support have shown significant reductions in targeted medical errors.

Electronic prescribing (e-prescribing), where the prescription is sent from an ordering clinician to the pharmacy electronically, is seen as one method for eliminating errors of prescription interpretation. Current issues surrounding e-prescribing include security, verifiability of the prescriber, and network creation between patients, pharmacists, and physicians.

Patient Records

Several exciting new developments are under way to allow patients greater access to their medical records, increase the accuracy of these records, and maintain an individual's privacy and security of their medical data.

Many hospitals have established "patient portals" where patients can view parts of their medical records, request prescription refills, schedule appointments, and communicate electronically with their health care provider. Several studies have suggested that such portals could increase patient participation in their medical care and ultimately help maintain the accuracy of their medical record.

In 1996, the Health Insurance Portability and Accountability Act, also known as the Kennedy-Kassebaum bill, was passed into law as a measure to increase access, portability, and security of a person's medical records. The law outlined procedures and circumstances where one's medical records could be shared and established a requirement that the amount of information disclosed be the "minimum necessary." Although initially envisioned as a blueprint for facilitating mobility of patient information between providers, the largest effect of the bill has been in establishing security protocols for the storage and dissemination of personal medical data. These safety protocols cover clinical as well as research use of data.

Text Mining and Natural Language Processing

Unfortunately, most of the clinical records in the United States are not computerized. Of the records on computer systems today, much of the information is not stored in a structured, machine-readable way. Lab reports, admission and discharge summaries from hospital stays, and medication lists all contain useful information that could be used by a computer or clinician to make future decisions about a patient's care. However, parts of the report are often not identified specifically; as a result, a large amount of time is required for chart review and data extraction. Text mining is the process of information identification and extraction through pattern recognition. An example might be in searching for patient charts to find all smokers. Charts can be searched to identify phrases about smoking such as "packs per day" or "nicotine," and specific charts can be tagged for further analysis. Natural language processing goes one step further in that it analyzes the meaning of a text using techniques such as identifying contextual cues, isolating parts of speech, and phrase recognition. A very simple example of this is the recognition of negative phrases in a sentence: "Formerly a two-pack per day smoker, Mr. Smith has been controlling his cravings for nicotine successfully for the past 3 months with gum and patches." Searching for "packs per day" alone might suggest that the patient is a current smoker, although phrase analysis would show that the main idea of the sentence is that Mr. Smith has been controlling his smoking habit. Methods such as these are being used to better isolate and tag key medical information for use in clinical systems today.

Biosurveillance

Biosurveillance is the study of disease outbreaks that occur naturally or as part of a bioterrorist attack. In 1998, the Clinton administration authorized a system to provide early warning against bioterrorist attacks. Currently, the government is investing heavily in building the infrastructure necessary to detect outbreaks, share information, and analyze data of this type. Research in this area is focused on interoperability between diverse systems, signals detection of new outbreaks, and measures for hospitals to manage outbreaks.

Syndromic surveillance is the detection of health indicators before official diagnoses are made through pattern recognition and signal variance detection. The process involves mapping of natural fluctuations of disease prevalence and monitoring for changes in these patterns. An example of this might be analysis of respiratory syndromes in emergency rooms. These syndromes typically have a peak in late fall or early winter. By monitoring emergency room visits using patient complaints and symptoms as markers of respiratory illness, comparisons of the current findings can be made with previous years, or between emergency rooms themselves. This type of data has also been used in studies to determine vaccination timing of different age groups.

Informatics and Cognitive and Social Science

Equally as important as the tools we use is how we interact with them. Cognitive studies in informatics are helping us understand how we process information, human-computer interactions, and insights into how clinicians make decisions based on available, and often incomplete, information. Topics within the purview of cognitive science include the study of interface design, such as the best ways to present trends of lab results, or sophisticated analysis of ICU decision making.

There have also been several studies of successful and failed implementations of electronic medical record systems. Implementation within a hospital system is a large financial and operational commitment; yet even after investing millions of dollars in a system, implementations may fail. Two notable failures include the University of Virginia's CPOE system in 1993 and Cedar-Sinai's CPOE system in 2003, both of which

were stopped due to complaints by physicians using the system. Typically, the reason for success or failure is a systems management issue surrounding training on the new system, workflow changes, or participation of various departments in the planning stages. The University of Virginia failed to involve the physicians in the creation and implementation of the system and subsequently mandated its use without adequate understanding of the changes it would require, resulting in an organized physician boycott. At Cedars-Sinai Medical Center, physician buy-in was solicited from only a few users prior to implementation, and the system required significant workflow changes and time for users to perform common tasks. Current implementation efforts, having learned from studies outlining these difficulties, now spend considerable resources to understand how new information systems interact and affect other hospital resources.

Biomedical informatics is a diverse and growing field. It provides tools for patients, nurses, doctors, pharmacists, and researchers to use in order to manage their information needs. It will also help us ask better questions, find better answers, and share what we learn as we continue to build on the information technologies we have today.

Bioterrorism

Bioterrorism can be defined as the deliberate release of biological agents with the intention of infecting civilians for belligerent purposes. These agents are usually naturally occurring microorganisms such as bacteria, viruses, and fungi; however, they can also be engineered to be more deadly, drug resistant, or easier to transmit. Bioterrorists may spread disease through air, water, and food, and from person to person, infecting humans, animals, or plants. Such an attack on humans with an agent causing a disease such as smallpox or botulism could lead to severe illness and possibly death and could result in widespread fear among the public. Furthermore, it could result in significant economic, social, and political damage as critical infrastructures struggle to handle the effects of disease on the population. Experts are concerned about the possibility of bioterrorist agents falling into the hands of groups or individuals who could use them to inflict devastation in the name of political, personal, or religious beliefs.

Development and Use of Bioterrorist Agents

In 1984, members of the Rajneeshees, a religious cult, sprayed *Salmonella typhimurium* on salad bars in The Dalles, Oregon, causing 750 cases of food poisoning, though no deaths occurred. In the 1990s, the Aum Shinrikyō extremist cult in Japan attempted to use bioterrorism agents but were unsuccessful because they could not overcome the technical hurdle of dissemination. They later released sarin gas in the Tokyo subway. During the anthrax attacks of September 2001, *Bacillus anthracis* spores sent through the U.S. Postal Service resulted in 22 cases of the disease and five deaths.

Russia, the United States, and Iraq ran biological weapons programs during the 20th century, but these were dismantled by the end of the century. Before closing, these programs employed thousands of scientists, and concern remains among experts that some of the scientists might have taken their bioweapons knowledge and possibly samples of biological agents to sell to the highest bidder.

Rationale for Using Biological Weapons

While concern over the likelihood of bioterrorist attacks has risen in light of recent attacks that indicate an erosion of taboos against mass killings, there are still some barriers to obtaining and using the necessary agents. For example, bioterrorist agents are difficult to produce in large quantities, and they can be difficult to aerosolize for maximum spread. But while bombs and guns may still be favored by terrorist organizations because of their ease of use and accessibility, advances in biotechnology, access to information on the Internet, and the availability of dual-use equipment and technologies increase the probability that biological weapons will be used in the future.

At present, terrorist organizations can obtain small amounts of biological agents from hundreds of germ banks worldwide and use them to produce large quantities of potential bioweapons. Agents could also be stolen from research laboratories—a possible explanation for the anthrax letters of 2001. They might be purchased from a former bioweapons scientist or a rogue nation. With the proper information, terrorists could isolate and grow agents from natural sources; anthrax can be found in animal hides and soil, while tularemia is found in soil. Of special concern, the developing field of genetic engineering makes it possible to create new or genetically modified biological agents that are more deadly than those presently available, and for which there are no cures. This was the goal of the scientists in the bioweapons program in the former Soviet Union.

Once they are available, these biological agents offer terrorists many advantages. In 1999, the Gilmore Commission identified five possible reasons why terrorists might use weapons of mass destruction, including bioweapons:

1. to kill as many people as possible;
2. to exploit the classic terrorist weapon—fear;
3. to allow terrorist groups to negotiate from a position of strength;
4. to take advantage of the fact that a biological attack could go undetected for some time, allowing terrorists to escape; and
5. to cause economic and social damage by targeting the agricultural sector.

In addition, experts calculate that the cost per life taken is considerably less for biological agents than for standard terrorist weapons, and biological agents are becoming increasingly easy to produce.

Dissemination and Detection of Biological Agents

More than 60 potential biological agents are presently available to bioterrorists. In liquid or powder form, the agents can be dispersed as an aerosol made up of particles small enough to enter the lungs. The North Atlantic Treaty Organization has identified 31 bioterrorist agents they believe are most likely to be used, and the U.S. Army Medical Research Institute of Infectious Diseases has further narrowed this list to 6, based on availability, ease of production, lethality, stability, and infectivity: anthrax, smallpox, plague, tularemia, botulinum toxin, and agents of viral hemorrhagic fever.

Dissemination of biological agents can occur either indoors or outdoors, though an outdoor attack would require a larger quantity of the agent. Terrorists might create an aerosol cloud of dried anthrax spores and spread the disease by equipping low-flying airplanes or trucks with sprayers. The agent could be spread indoors using a small aerosol

canister equipped with a remote device or by a suicide terrorist or someone who has received prophylactic treatment against the agent.

Early detection of bioterrorist attacks requires a universally available surveillance network that can provide the necessary information accurately and in a timely manner. However, of those systems presently available, some use unreliable diagnostic codes that may fail to determine the exact nature of an agent or that may fail to detect it at all when there are too few pathogens. Syndromic surveillance, the most likely to be effective, is so labor intensive that its use remains limited. At present, discovery of a bioterrorist attack is likely to be made by an alert physician who diagnoses a rare disease or identifies a suggestive pattern of disease. However, since most physicians have not seen diseases caused by bioterrorist agents, they will not be able to determine when an attack has occurred.

The federal government uses a surveillance system called BioWatch, a network of detection equipment set up around the country to detect the release of biological agents. However, biological agents must be released in large quantities or in close proximity to the detectors for the system to recognize them. The equipment is also subject to frequent false positives, so it is useful only in certain high-risk areas.

Protection, Prophylaxi, and Treatment

Many countries, including the United States and the United Kingdom, have developed national response plans for dealing with natural disasters and acts of terrorism. These plans will play an important role in the response to bioterrorism and, together with plans for global infectious disease outbreaks, will provide effective response mechanisms that will require only limited adaptations to meet the challenge of bioterrorist attacks. Responders will have to modify existing laws to maximize effectiveness of responses. The Model Emergency Health Powers Act, developed by U.S. lawyers and adopted by some states, can be used to enhance state governments' response capability.

In the event of a bioterrorist attack, the National Bioterrorism Response Plan and planning documents from local and state health departments and emergency management agencies would establish protocols for mass prophylaxis distribution. Hospitals are currently working to increase their surge capacity to meet the challenges of an attack, and the Strategic National Stockpile (SNS) contains vaccines, medications, and equipment for use during a mass casualty event and is making efforts to increase that supply. However, levels of preparedness vary widely across the nation, and the SNS will be inadequate in the event that simultaneous attacks are launched against a number of targets.

Bipolar Disorder

Bipolar disorder is a mental illness characterized by drastic mood swings from very high (manic phase) to very low (depressive phase). The diagnosis of bipolar disorder is usually based on the *Diagnostic and Statistical Manual of Mental Disorders* of the American Psychiatric Association (fourth edition) criteria, a tool developed by the American Psychiatric Association for clinicians.

The *DSM-IV* includes two types of bipolar disorder diagnoses, Bipolar I and Bipolar II. Bipolar I disorder is identified when a person presents with one lifetime occurrence of either a manic episode or a mixed episode. Although bipolar disorder is known for the polarization of moods, a diagnosis of Bipolar I does not require the presence of a depressive state. The manic episode alone can satisfy the criterion for Bipolar I, if the mania is not caused by another mental disorder. A manic person can be described as a normal person in fast-forward. When a patient is experiencing a manic episode, he or she experiences

an elevated, irritable, or expansive mood. To meet the diagnostic criterion specified by the *DSM-IV*, the mood must occur for longer than 1 week and must be accompanied by three or more other symptoms not caused by mood-altering substances, medications, or other medical conditions. Other symptoms may include any of the following: inflated self-esteem or grandiosity, decreased need for sleep, being more talkative than usual or experiencing pressure to keep talking, flight of ideas or subjective experience that one's thoughts are racing, distractibility, increase in goal-directed activity or psychomotor agitation, or excessive involvement in pleasurable activities that have a high potential for painful consequences.

In the other form of Bipolar I disorder, mixed bipolar episodes—the other criterion for Bipolar I—the symptoms of mania and depression occur simultaneously; symptoms include agitation, trouble sleeping, and significant change in appetite, psychosis, and suicidal ideation. A person may feel sad and hopeless, yet extremely energized.

The diagnosis of Bipolar II disorder, according to the *DSM-IV*, is a clinical course characterized by one or more episodes of major depression and at least one hypomanic episode. In contrast to the manic episode, the depressed pole of bipolar disorder is characterized by extreme sadness. A depressive episode (depression) of bipolar disorder is diagnosed with the same criteria as major depressive disorder. The criteria for diagnosis are the presence of five or more symptoms lasting most of the day for 2 weeks or longer. At least one of the symptoms must include depressed mood or loss of pleasure or interest, and symptoms must not be due to other physiological conditions or substances. The symptoms may include any of the following in addition to depressed mood or loss of interest and pleasure in all or almost all activities: decreased or increased appetite/change in weight; insomnia or hypersomnia; psychomotor agitation or retardation; fatigue or loss of energy; feelings of worthlessness, or excessive or inappropriate guilt; diminished ability to think or concentrate, or indecisiveness; or recurrent thoughts of death, suicidal ideation with or without a plan or suicide attempt.

Hypomania, the other element of Bipolar II, is defined as a mild to moderate level of mania. Hypomania may feel good to a person and may be accompanied by good functioning and enhanced productivity, but without treatment it may lead to mania or swing into depression. Also, psychosis or psychotic symptoms may occur in severe cases of mania or depression. Common symptoms include auditory and visual hallucinations and delusions.

Most researchers now agree that there is no single cause for bipolar disorder. Etiology of the disease may be attributed to three factors: genetic vulnerabilities, biological vulnerabilities, and levels or styles of coping with socioenvironmental stress. Also, other factors such as environment, life events, and individual attributes may contribute to the cause.

Throughout history and dating back to ancient Greece, the presence of bipolar disorder, formally known as manic-depressive disorder, has captivated scholars. More than 80 years ago, the course of this illness was described systematically, and the heterogeneity in the types of symptoms, the pattern of episodes, and the level of functioning was noted. Those in literature, the arts, and history have been inspired by the creativity of individuals with bipolar disorder, including Vincent Van Gogh, Martin Luther, Robert Schumann, Pytor Illyich Tchaikovsky, and the Pulitzer Prize winners John Berryman, Amy Lowell, and Anne Sexton.

Two major community surveys in the United States of the lifetime prevalence of bipolar disorder indicate that from 1.0% to 1.6% of adults and 1.2% of children and adolescents (9 to 17 years) are affected by this illness. Misdiagnoses and underdiagnoses of bipolar disorder are ongoing concerns, especially among adolescence and children, and may contribute to incorrect prevalence of the disorder. Community studies of this issue are difficult to conduct, however, as standard epidemiological surveys may fail to reliably diagnose as many as 50% of cases. Researchers have identified several features of bipolar depression that may distinguish it from unipolar depression, including longer episode duration, increased probability of psychotic symptoms, and limited efficacy of antidepressant medications.

With regard to gender and bipolar disorder, Bipolar I affects men and women equally, but Bipolar II disorder is more common in women. Males may also present differently than females with the disorder. Commonly, the first episode in males is a manic. Females are more likely to be depressive.

The onset of bipolar disorder may occur at anytime during the life span, but the median age of onset for the disorder is 18 years of age. The Epidemiologic Catchment Area study reported a mean age of 21 years for bipolar disorder. Although bipolar disorder can be present before the onset of puberty, the

available evidence suggests that full-blown mania in children is relatively rare. At the opposite end of the age spectrum, newly diagnosed mania in patients more than the age of 65 is uncommon. There are no known significant differences among racial groups in prevalence of either Bipolar I or Bipolar II disorder.

Birth Certificate

Birth certificates provide important data about a newborn's status, the child's parents, the mother's use of prenatal care, and complications and events during pregnancy. As such, they are a key resource for maternal and child health epidemiology. They also serve as the basis for legal identity. The history, organization, availability, content, uses, and accuracy of birth certificates are summarized in this entry.

In the United States, the annual collection of birth statistics on a national basis began in 1915, with 10 reporting states and the District of Colombia; by 1933, it included the entire country with at least 90% coverage in each state. The standard certificate of live birth was developed in 1900 and has since undergone 12 revisions, with the 1989 and 2003 revisions expanding the content of medical information. National statistics on fetal deaths have been compiled annually since 1922.

The National Center for Health Statistics (NCHS) collates national and state data on live births, deaths, and fetal deaths based on vital records filed in state registration offices. States generally adhere to the standard certificates developed by the NCHS but can choose to add or delete items. The NCHS regularly publishes reports on birth certificate statistics and prepares public use data sets for further analysis. These include a Linked Birth/Infant Death File (linking live birth and infant death [0 to 365 days] certificates for all infants born during a cohort year) that may be used to help explain trends in infant heath and mortality. Technological advances further allow linkages with data for Medicaid enrollment and other publicly funded health programs to assess quality of perinatal outcomes.

Birth certificates have two parts. The first provides demographic data on the parents and infant; the second, completed from hospital records, gives data on maternal and infant health. Birth certificates offer useful information for researchers, policymakers, and state officials to evaluate trends in maternal and infant health and the quality of care delivered to pregnant women. Birth certificate data allow for the creation of many potential health status outcome and health risk indicators.

The reliability and validity of birth certificate data vary considerably by item, but their quality and completeness are reasonable for population-based analyses. Basic demographic characteristics (e.g., maternal age) and maternal data tend to be more accurately and completely reported than those for fathers or social traits (e.g., education). Medical information about the birth or the newborn is typically least adequately reported. Data are more likely to be missing for very low birthweight infants, teenage and unwed mothers, and those with less than a high school education. Absent accurate data, however, high-risk groups are less likely to be understood or helped, and inaccurate conclusions may be drawn about underlying variables of interest, such as substance abuse during pregnancy.

Birth Cohort Analysis

A birth cohort is a group of individuals born during a given calendar time period within a specified geographical region. For example, the U.S. 1950 annual birth cohort refers to the group of people born in the United States during the calendar year 1950, and the 1950 to 1952 birth cohort identifies those born during the period covering the three consecutive calendar years 1950, 1951, and 1952. Birth cohort analysis is an observational cohort analysis (as opposed to an experimental cohort analysis such as clinical trials) of an entire birth cohort or of a selected sample of the birth cohort.

Data for birth cohort analysis are best depicted by a Lexis diagram with the horizontal axis denoting calendar time and the vertical axis denoting age wherein each individual live birth is represented by a lifeline with 45° inclination from the horizontal axis. Starting at birth on the horizontal axis, each individual is followed continuously as he or she passes through different ages during all or part of the life span, that is, until death or censoring (such as out-migration), whichever occurs first. Events of interest occurring to an individual during his or her lifetime are marked on his or her lifeline. The events of interest typically include exposure to risk factors (such as start of smoking) and occurrence of health outcomes (such as incidence or recurrence of a disease or medical condition) as well as vital events (such as giving birth, change of marital status, and death). Each marked lifeline represents the complete life history of an individual and constitutes a sample path. So the life histories for all individuals (all marked lifelines) in the birth cohort constitute the sample space.

Since we start at the beginning of life at which time one is susceptible to almost all risk factors, events, and health outcomes, almost any of them can be studied by birth cohort analysis. In particular, the recorded birth cohort data as described above allow calculation of both cumulative incidence and incidence density and so can be used to perform the following cohort analyses retrospectively.

Event History Analysis Using Survival Time Data. When sample size is not too large, this can be done by applying likelihood methods and martingale theory to produce statistical inference (maximum likelihood or martingale estimates and hypothesis testing comparing different birth cohorts) of disease incidence rates and of effects of risk factors on disease incidence.

Construction of Cohort Life Tables Using Age Group Data (for Large Populations). Such tables include attrition life tables and the most general increment-decrement life tables to obtain transition probabilities from one state to another and to obtain an estimate of the expected duration of stay in each state. In addition to comparing two different cohort life tables, one can also compare a cohort life table with a period life table, both constructed on the same base period, to see if there exists any period-cohort effect or birth cohort effect.

Comparing the Health Outcome or Vital Event of Interest (Say, Mortality) of the Birth Cohort With That of the Corresponding General Population to See if the Special Life Event Experienced by the Birth Cohort Has Caused a Significant Change in Mortality Level. This may be done by calculating the standardized mortality ratio (SMR) and testing the null hypothesis $SMR = 1$ using the asymptotic unit normal test statistic $Z = \ln SMR/\sqrt{D}$, where $SMR = D/E$ and D and E are the observed deaths and expected deaths (based on the mortality of the corresponding general population), respectively, in the cohort.

Comparing Birth Cohorts of Different Calendar Periods for Period-Cohort Effects, Using Logrank and Related Tests for Survival Time Data and Logistic Regression for Binary Outcome Data. Period-cohort effect arises because different birth cohorts may experience different levels of health outcomes as they grow up exposed to differing environmental and societal changes, which in turn lead to differing behavior changes. For example, age-sex patterns of lung cancer mortality between the 1900 birth cohort and the 1950 birth cohort differ greatly because prevalence of smoking, amount smoked per day, age at initiation, and lifetime smoking duration are all influenced by the calendar year of birth. These covariate data can be used to investigate the effects of different kinds of risk using the extended Cox

regression model, Poisson regression, logistic regression model, or structural equations models.

Analysis of Panel Data and Data on Repeated Measures of an Outcome Variable. Methods for analyzing longitudinal data such as generalized estimating equations and random coefficients analysis may be used to account for intraperson time series correlation due to repeated observations on the same individual as well as missing data.

Finally, when birth cohort data are not available but a series of consecutive cross-sectional data are available, one can still form birth cohorts by concatenating from serial cross-sectional age-specific data. What has often been done in this case is to construct an open birth cohort by concatenating a series of period/age-matched cross-sectional data. For example, Kemm determined for Great Britain the percentage of current smokers and ever smokers by age in successive birth cohorts and the percentage of ever smokers who continue, as well as alcohol consumption, by analysis of data from serial cross-sectional surveys of smoking status.

Birth Defects

Birth defects, also known as congenital malformations or anomalies, are abnormalities in the structure or function of organs that are present at birth. They are the leading cause of infant death and contribute to morbidity and long-term disability in the population. Birth defects are a heterogeneous group of outcomes that are not always apparent at delivery. Major birth defects are structural malformations that are either lethal, require medical or surgical treatment, or are of cosmetic importance.

The frequency of congenital anomalies is highest in pregnancies that result in miscarriages or stillbirths. Major birth defects occur in 2% to 3% of live births in the United States. Some of the most common types of birth defects are heart defects (1 in 100 to 200), neural tube defects (1 in 1,000), orofacial clefts (cleft lip and cleft palate; 1 in 700 to 1,000), and hypospadias (abnormal development of the urethra; 1 in 200 to 300 males). Down syndrome, a chromosomal disorder known as trisomy 21, occurs in about 1 in 800 births.

Risk Factors

While approximately 10% of birth defects are attributed to environmental factors and 20% are attributed to single-gene or chromosomal defects that may be inherited or represent new mutations, the causes of the remaining 70% of birth defects remain unknown. Most birth defects are believed to arise from interactions between genes or interactions between environmental factors and genes.

Teratogens are agents that can cause birth defects. The timing of exposure to a teratogen during pregnancy is important: The greatest risk for structural malformations exists for exposures occurring between the third and eighth week of gestation (the embryonic period), when most organ systems are developing (organogenesis). The period in which an organ or system is at greatest risk of damage from a teratogen is referred to as the critical period: For some organs and systems, this period extends beyond the eighth week into the fetal period. However, structural birth defects are less likely to occur after the eighth week because most organ systems have already been established. Some well-known human teratogens include thalidomide (a sedative), isotretinoin (an antiacne medication sold under the brand name Accutane), valproic acid (an antiseizure medication sold under the brand name Depakote), warfarin (an anticoagulant sold under the brand name Coumadin), and mercury (a heavy metal).

Other factors have been identified as risk factors for birth defects, such as dietary deficiencies (vitamin A), maternal behaviors (smoking and alcohol

consumption), maternal illnesses (diabetes mellitus and rubella infection), and family history of a similar defect (hypospadias). Some defects vary by maternal age (Down syndrome), race (tetralogy of Fallot), ethnicity (spina bifida), or infant sex (anencephaly). Epidemiologic research has demonstrated that taking a multivitamin containing folic acid, a B vitamin, before conception and in early pregnancy lowers the risk of having a baby with a neural tube defect. Other research suggests that folic acid may reduce the risk of other types of birth defects. Since the mandated folic acid fortification of cereal grains and flour in the United States in 1998, the occurrence of neural tube defects has decreased and reductions in other birth defects have been observed.

Methodologic Challenges

Researching the causes of birth defects is challenging because specific birth defects are rare, the developing embryo and fetus are exposed to a variety of genetic and environmental factors during pregnancy, and the biologic mechanisms that cause most birth defects are unknown. Due to pregnancy losses, the defects identified at birth represent only the birth prevalence, not the true incidence of the condition. The retrospective ascertainment of exposure in epidemiologic studies is a concern because mothers of infants with defects may more accurately recall exposures during pregnancy than mothers of healthy infants, a bias known as recall bias. Adding further complexity to the study of birth defects is the interplay between genetic and environmental factors in the etiology of many anomalies.

Ongoing Surveillance and Research

Public health surveillance systems are important in collecting and analyzing data on birth defects in human populations. The systematic and ongoing monitoring of births of malformed infants in the population allows for the description of birth defect patterns that may suggest environmental causes, such as infections, drugs, other chemicals, or physical agents. The Metropolitan Atlanta Congenital Defects Program was created in 1967 in response to the thalidomide tragedy. Surveillance data from the program have been used to describe the epidemiology of birth defects and evaluate possible etiologic factors. The program also served as the source of data for the Atlanta Birth Defects Case-Control Study, which helped increase the understanding of risk factors associated with birth defects. The National Birth Defects Prevention Network was organized in 1997 with the goal of establishing a network of population-based birth defects surveillance and research programs to assess the impact of birth defects, identify risk factors for targetting primary prevention activities, and assist in the prevention of secondary disabilities.

To help reduce the burden of birth defects in the United States, Congress passed the Birth Defects Prevention Act of 1998 (Public Health Law 105–168). The bill authorized the Centers for Disease Control and Prevention to

1. collect, analyze, and make birth defects data available;
2. operate regional centers for applied epidemiologic research on the prevention of birth defects; and
3. educate the public about the prevention of birth defects.

As a result, the Centers for Disease Control and Prevention established the Centers for Birth Defects Research and Prevention, which funded centers around the United States. The main activity of each center is to participate in the National Birth Defects Prevention Study, the largest collaborative birth defect study in the United States. Approximately 35 categories of birth defects are included in this ongoing case-control study. The study seeks to improve the study of birth defects by including a large ethnically and geographically diverse birth population that will provide unprecedented statistical power to evaluate potential risk factors, more etiologically homogeneous case definitions for specific birth defects groups, an interview with questions on a wide array of exposures and potential confounders, and the collection of DNA for the study of genetic susceptibility and interactions between genes and the environment. Cases are identified from population-based birth defect surveillance systems, and controls are randomly selected from birth certificates or birth hospital records. Mothers of infants are interviewed and parents are asked to collect cheek cells from themselves and their infants for DNA testing. Because of the large sample sizes, scientists will be able to study the epidemiology of some rare birth defects for the first time. The combined interview data and banked DNA will enable

future research as new hypotheses and technologies develop.

Bloodborne Diseases

Bloodborne diseases are caused by pathogens such as viruses or bacteria that are carried in the blood. In the United States, the most common bloodborne diseases are hepatitis B, hepatitis C, and HIV/AIDS. Hemorrhagic fevers, including Ebola, are not a health threat in the United States, but sporadic outbreaks have occurred in Africa and other parts of the world since 1976. Common routes of infection with bloodborne diseases include unprotected sexual activity, contact with blood through needles or other sharps, and transmission from mother to child during the birth process.

Common Bloodborne Diseases

Hepatitis B is caused by infection with the hepatitis B virus (HBV). In about 30% of cases, the person experiences no symptoms; others may experience jaundice, fatigue, abdominal pain, loss of appetite, nausea, vomiting, and joint pain. Infection may become chronic, particularly to infants infected at birth, and may lead to death from chronic liver disease (15% to 25% of all cases). A hepatitis B vaccine has been available since 1982 and is recommended for people in high-risk groups, including health workers, household members and sexual partners of persons infected with HBV, injection drug users, and persons traveling to or living in parts of the world where HBV infection is endemic. According to the Centers for Disease Control and Prevention (CDC), about 300,000 cases of HBV occur in the United States annually.

Hepatitis C is caused by infection with the hepatitis C virus (HCV). Persons at highest risk include injection drug users, persons treated for blood-clotting problems before 1987 or who received a blood transfusion before 1992, and hemodialysis patients. Eighty percent of individuals infected with HCV have no symptoms, but hepatitis C causes liver damage and is a leading indicator for liver transplants. About 70% of infected individuals develop chronic liver disease and 5% to 20% will develop cirrhosis. There is no vaccine for hepatitis C but several drug treatments are available. According to the CDC, about 26,000 new cases of HCV were identified in the United States in 2004, and 4.1 million people are living with the disease.

HIV (human immunodeficiency virus) is a virus transmitted primarily through blood; typical routes of infection include unprotected sexual activity and use of unsterilized needles (and outside the industrialized world, use of other unsterilized sharps and transfusion of contaminated blood). Acquired immunodeficiency syndrome (AIDS) is a label given to the advanced stages of HIV infection, when the person's immune system starts failing and he or she is subject to many opportunistic infections as well as

unusual cancers such as Kaposi's sarcoma. There is no vaccine for AIDS but a number of medical treatments are available. The CDC estimates that there are approximately 44,000 new infections annually; approximately 1.1 million people in the United States were living with HIV/AIDS in 2003.

Viral hemorrhagic fevers (VHFs) are a group of illnesses caused by bloodborne viruses, which damage the vascular system and cause hemorrhage (bleeding). Most VHFs are zoonotic, with rodents and arthropods the main reservoirs; however, the hosts of Ebola and Marburg viruses, two of the best-known VHFs, are unknown. Symptoms of infection with a VHF include fever, fatigue, dizziness, muscle aches, loss of strength, exhaustion, and bleeding under the skin, in internal organs, and from body orifices. There are no vaccines for VHFs and treatment is primarily supportive. Prevention of VHF infection is based on preventing contact with host species, for example, controlling rodent populations, keeping them out of homes and workplaces, and cleaning up rodent nests and droppings. VHFs can be spread through physical contact, so isolation of infected individuals is recommended, with Universal Precautions (defined below) observed by health care workers treating VHF patients.

Prevention and Control

The group at greatest risk for bloodborne infection, worldwide, is health workers who are exposed to blood and other body fluids in the course of their work. In the industrialized world, most other cases of bloodborne disease are caused by injection drug use (with unsterile needles) or are sexually transmitted. In the developing world, ordinary medical care such as receiving an injection may carry a high probability of infection due to lack of sterilization. Use of barrier methods (condoms and dental dams) can prevent or reduce the transmission of most sexually transmitted diseases, and sterilization or use of disposable sharps (e.g., needles and scalpels, which are intended to penetrate the skin) can sharply reduce the risk of infection during medical care.

The World Health Organization estimates that 3 million health workers annually experience percutaneous (needle stick or other sharps injury) exposure to bloodborne pathogens, about two thirds of those to hepatitis B. Most of these exposures are preventable, and a set of procedures known as Universal Precautions has been developed to minimize infection. Immunization against hepatitis B and postexposure management such as the provision of prophylactic medication are also recommended for health workers.

Eight types of activities are recommended in the Universal Precautions: hand washing after patient contact; no needle recapping; establishing a system for safe disposal of sharps; use of gloves when contact is anticipated with body fluids, broken skin, or mucous membranes; use of mask, eye protection, and gown if splashing with body fluids is anticipated; covering broken skin; cleaning up spills of body fluids; and establishing a system for disposal of hospital wastes. These are called universal because they should be practiced in all health care circumstances, without making a judgment about whether a particular individual or blood sample might be infected.

Body Mass Index (BMI)

Body mass index (BMI) is a calculated measurement of a person's height and weight for the purpose of classifying individuals as underweight, normal weight, overweight, or obese. BMI is sometimes referred to as the *Quetelet Index*, named after Lambert

Adolphe Jacques Quítelet (1796–1874), the Belgian sociologist and statistician who developed it. Quítelet, who wrote a book about the "average man," was interested in developing a simple method for classifying an individual's weight scaled according to height. His Quetelet Index, which later became the modern BMI measurement, is the most recognized calculation for obesity statistics. The BMI calculation is frequently used by national and international organizations in health policy discussions concerning obesity-related issues.

Reliability

BMI is generally used as an indicator of body adiposity, although it does not measure body fat directly. However, research has demonstrated the BMI to be a reliable indicator of body fatness when correlated with direct measurements such as underwater weighing, skin fold thickness measurements, computed tomography (CT), and dual-energy X-ray absorptiometry (DEXA). The BMI is a simple, inexpensive method for estimating body adiposity and is a more practical method for health care practitioners and the general public to use.

Calculation

BMI can be calculated using metric units or by an adapted version with imperial units. The same formula is used for both adults and children.

BMI Calculated With Metric Units

Formula: weight (kg)/[height (m)]^2

Calculation: [weight (kg)/height (m)/height (m)]

BMI Calculated With Imperial Units

Formula: weight (lb)/[height (in.)]$^2 \times$ 703

Calculation: [weight (lb)/height (in.)/height (in.)] $\times$ 703

Interpretation

Although the BMI calculation for adults and children is the same, the interpretation of the calculation is different for each age group. Adults, 20 years of age or older, use the standard weight categories for all ages and both genders. *Underweight* adults have a BMI of less than 18.5; *healthy weight* adults have a BMI of at least 18.5 but less than 25; *overweight but not obese* adults have a BMI of at least 25 and less than 30; and *obese* adults have a BMI of 30 or more. BMI and weight status categories can vary slightly depending on the reporting agency.

BMI interpretation for children and adolescents are age and gender specific and use the BMI percentile. The calculated BMI for children and adolescents is plotted on the BMI-for-age growth chart to obtain the BMI percentile. Percentiles are commonly used in the United States to assess the growth of an individual child as compared with children of the same gender and age. Gender and age are significant when assessing a child's growth pattern because the amount of body fat changes with age and the amount of body fat differs between genders. Weight status based on the BMI percentile for children and adolescents are as follows: *underweight* children or teens with a BMI-for-age that is less than the 5th percentile; *normal weight* children or teens with a BMI-for-age that is at least the 5th percentile but less than the 85th percentile; *at risk for overweight* children or teens with a BMI-for-age that is at least the 85th percentile but less than the 95th percentile; and *overweight* children or teens with a BMI-for-age greater than the 95th percentile.

Clinical Uses

BMI is used as a screening tool to compare an individual's weight status with that of the general population. It is also used to identify possible weight problems in both adults and children. The BMI ranges for the adult population are based on the relationship between weight and morbidity and mortality. Overweight and obese adults are at an increased risk for a variety of diseases and health conditions such as coronary artery disease, hypertension, type 2 diabetes, dyslipidemia, stroke, gallbladder disease, and osteoarthritis.

The BMI ranges for children aged 2 to 19 are based on the relationship of weight and risk for developing weight-related health problems. Children with a BMI-for-age percentile in the overweight range are at risk for developing hypertension, hyperlipidemia, hyperglycemia, sleep apnea, and other respiratory disorders. More than 50% of all overweight children have at least one cardiac risk factor, and 25% of overweight children have two or more cardiac risk factors.

Other developmental and social problems include low self-esteem, social discrimination, and poor performance in school. Furthermore, overweight adolescents are more likely to become overweight or obese adults with various chronic diseases, including cardiovascular disease and type 2 diabetes.

It is important to remember that the BMI calculation is not a diagnostic tool. A child with a BMI-for-age in the 85th percentile and higher or an adult with a BMI greater than 25 should be assessed further to determine potential health risks. A detailed health history, family history, diet evaluation, and exercise assessment are warranted. A direct method of adiposity measurement, that is, skin fold thickness measurements or underwater weighing, would provide an accurate and reliable indicator of actual body adiposity. Appropriate therapeutic interventions can be made based on the individual's comprehensive assessment.

Limitations

Although the correlation between the adult BMI and estimated body adiposity is relatively strong, there are some variations based on sex and age. For example, older adults tend to have more body fat than younger adults with the same BMI, and women tend to have more body fat than men with the same BMI. Furthermore, highly trained athletes will have a higher BMI that reflects an increase in muscularity and not in true body adiposity. These individuals should be assessed using other direct methods, as previously noted, for measuring their body fatness. The limitations mentioned above should be taken into account when using the BMI calculation under these circumstances.

Box-and-Whisker Plot

The box-and-whisker plot, also called a boxplot, was invented by John Tukey. It is a graph of a data set that consists of a line extending from the minimum value to the maximum value, and a box with lines drawn at the first quartile Q_1; the median, the second quartile; and the third quartile Q_3, with outliers plotted as individual data points. It is useful for revealing the central tendency and variability of a data set, the distribution (particularly symmetry or skewness) of the data, and the presence of outliers. It is also a powerful graphical technique for comparing samples from two or more different treatments or populations.

Although boxplots are usually generated using statistical software, they also may be constructed by hand, using the following steps:

1. Draw a rectangular box whose left edge is at Q_1 and the right edge is at Q_3. The box width is therefore the interquartile range $IQR = Q_3 - Q_1$. Draw a vertical line segment inside the box at the median.
2. Place marks at distances 1.5 times the *IQR* from either end of the box: These are the inner fences. Similarly, place marks for the outer fences at distances 3 times *IQR* from either end.
3. Extend a horizontal line segment (''whiskers'') from each end of the box out to the most extreme observations that are still within the inner fences.
4. Represent values for mild outliers or observations between the inner and outer fences by circles. Represent values for extreme outliers or observations beyond the outer fences by asterisks.

The median is the middle value in the ordered data list. It is the number that divides the bottom 50% of the data from the top 50%. The median is also the second quartile Q_2. Use the following steps to find the median of a data set:

1. Arrange the data from smallest to largest.
2. If the number of observations is odd, then the median is the observation exactly in the middle of the ordered list.
3. If the number of observations is even, then the median is the average of the two middle observations in the ordered list.

The first quartile Q_1 is the median of the lower half of the ordered data, and the third quartile Q_3 is the median of the upper half of the ordered data. If the number of observations is odd, the median of the entire data is included in both halves.

Example

Biological disturbances that are closely associated in adults suffering from endogenous depression (depression with no obvious external cause) are cortisol hypersecretion and shortened rapid eye movement (REM) period latency (the elapsed time from sleep onset to the first REM period). In a paper titled "Plasma cortisol secretion and REM period latency in adult endogenous depression," Gregory Asnis and colleagues reported on a comparison of REM period latency for patients with hypersecretion and patients with normal secretion. The data values are given below.

Hypersecretion Sample (n = 8)

0.5, 1.0, 2.4, 5, 15, 19, 48, 83

minimum = 0.5

maximum = 83

median = 10

$Q_1 = 1.7$

$Q_3 = 33.5$

$IQR = 31.8$

$1.5(IQR) = 47.7$

Normal Secretion Sample (n = 17)

5, 5.5, 6.7, 13.5, 31, 40, 47, 47, 59, 62, 68, 72, 78, 84, 89, 105, 180

minimum = 5

maximum = 180

median = 59

$Q_1 = 31$

$Q_3 = 78$

$IQR = 47$

$1.5(IQR) = 70.5$

Figure 1, the boxplot representing these data, displays several interesting features. Each sample has a mild outlier and an upper tail rather longer than the corresponding lower tail. Normal secretion REM period latency values appear to be substantially higher than those for hypersecretion; this was confirmed by a formal analysis.

Breastfeeding

Human milk is the appropriate nutrition for infants. Exclusive breastfeeding for the first 6 months and continued breastfeeding with appropriate introduction of solids at 6 months reduces the risk of many illnesses and chronic diseases. The *Healthy People 2010* breastfeeding goals are to increase to 75% the proportion of women who initiate breastfeeding, to 50% the proportion of women who are breastfeeding at 6 months, and to 25% the proportion of women who breastfeed for 1 year. The World Health Organization (WHO) recommends 6 months of exclusive breastfeeding, followed by the timely introduction of appropriate complementary foods, and continued breastfeeding for 2 years and beyond.

Despite documentation and public knowledge of the health, social, and economic benefits of breastfeeding and recommendations from numerous organizations, including the American Academy of Pediatrics, the American Public Health Association, and the WHO, breastfeeding incidence, exclusivity, and duration are well below the goals identified in *Healthy People 2010.* National data also reveal disparities in breastfeeding practices, primarily associated with economic and education status. The primary demographic factors associated with not breastfeeding or breastfeeding for a short duration include being nonwhite, poor, unmarried, or younger than 25; completing 12 or less years of education; and living in the southeastern United States. To improve breastfeeding practices and to reduce existing disparities in infant and young child feeding, interventions need to target not only individuals but also organizations and communities.

Defining Breastfeeding

Breastfeeding behaviors are neither clearly defined nor consistently operationalized in much of the literature. Some studies of feeding practices define breastfeeding as exclusive (infants receive only human milk, with no water, other liquids, or solids), others permit water to be included in "exclusive" breastfeeding, and others allow any amount of human milk to constitute the equivalent of "breastfeeding," even if human milk substitutes (HMS, also referred to as "formula") or other liquids and solids are also part of the child's diet. Moreover, some studies define successful initiation of breastfeeding as having "ever breastfed," even just once, while others require that breastfeeding lasts a specific number of days or weeks to meet the criteria for successful initiation, and others fail to define how "breastfeeding" is measured. Another consideration is the way in which the milk is being given, and whether the child is fed directly from the breast or fed human milk from a bottle.

Inconsistent definitions of breastfeeding make it difficult to compare and interpret study findings. If breastfeeding is not clearly defined, breastfeeding once a day could be grouped in the same category as exclusive breastfeeding, despite the very different amounts of human milk and exposure of the infants to other nutrients. Additionally, carefully identifying when and why women discontinue exclusive breastfeeding may permit development of specific interventions to prevent untimely weaning. Women who discontinue exclusive breastfeeding in the first week postpartum may have experienced feeding technique difficulties, whereas women who stop exclusively breastfeeding later may do so because they are returning to work or school and have no place to express their milk. Different strategies are needed to address each of these situations.

Risks and Costs of Not Breastfeeding

Mothers and children who do not breastfeed lose the physiological, immunological, and psychological benefits that breastfeeding confers and face increased risk for a number of acute and chronic diseases. Women who do not breastfeed may experience more postpartum bleeding, increased risk of breast and ovarian cancers, as well as increased risk of osteoporosis and rheumatoid arthritis, short intervals between births, and longer time to return to prepregnancy weight than women who breastfeed. Child

health risks associated with not breastfeeding or not receiving human milk include, but are not limited to, increased morbidity from gastrointestinal, respiratory, and middle-ear infections, more atopic illness and allergic disease, as well as increased risk of childhood obesity and type 1 and type 2 diabetes.

In addition to health benefits, breastfeeding has economic benefits. A 1997 study estimated that HMS provided by the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) cost more than $2.6 million annually. Furthermore, the cost of 1 year of HMS for families not enrolled in WIC is estimated to be as much as $1,500. Apart from savings resulting solely from not purchasing HMS, breastfed infants generally have fewer illnesses and lower health care costs. In a study of medical care costs incurred in the first 12 months of life, expenditures for infants not breastfed were estimated to be $200 higher than for breastfed infants, part of which may be attributable to significantly lower incidence of otitis media (ear infection) among breastfed infants. By increasing U.S. breastfeeding rates to the *Healthy People 2010* goal of 50% breastfeeding at 6 months, estimated national savings of more than $3.6 billion would be realized from reduced costs related to hospital care, parents' lost wages, and premature deaths, just considering otitis media ($3.6 million), gastroenteritis ($9.9 million), and necrotizing enterocolitis ($3.2 *billion*).

Promoting, Protecting, and Supporting Breastfeeding

To effectively promote, protect, and support breastfeeding, action at multiple levels is required at several levels. The WHO developed the International Code of Marketing of Breast-Milk Substitutes (the Code), which prohibits advertising of HMS to the public, and requires that only accurate, scientific information about HMS be given to health care providers. The WHO/UNICEF Ten Steps to Successful Breastfeeding state that all mothers should have access to skilled support to initiate and continue breastfeeding; health care providers must be adequately trained to provide clinical care; and continued health care provider support should be augmented with trained community lay or peer counselors. The Ten Steps, as listed on the UNICEF Web site describing the Baby Friendly Hospital, Initiative include the following:

1. Have a written breastfeeding policy that is regularly communicated to all health care staff.
2. Train all staff in skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breastfeeding.
4. Help mothers initiate breastfeeding within half an hour of birth (in the United States this timeframe is expanded to 1 hr).
5. Show mothers how to breastfeed and how to maintain lactation, even if they should be separated from their infants.
6. Give newborn infants no food or drink other than breast milk, unless medically indicated.
7. Practice rooming-in, which allows mothers and infants to remain together 24 hr a day.
8. Encourage breastfeeding on demand.
9. Give no artificial teats (bottle nipples) or pacifiers (also called dummies or soothers) to breastfeeding infants.
10. Foster the establishment of breastfeeding support groups and refer mothers to them on discharge from the hospital or clinic.

Government can monitor and enforce industry compliance with the Code, mandate paid maternity leave, and protect the breastfeeding rights of working women through legislation or regulation. The media can portray breastfeeding as the norm.

Breastfeeding Practices in the United States

Data from the Ross Laboratories Mothers Survey indicate that the proportion of women who initiate breastfeeding in the United States has increased steadily, from a low of 24.7% in 1971 to 70.1% in 2002. Data from the 2003 National Immunization Survey indicate similar findings (70.3%). The percentage of WIC-eligible women who initiate breastfeeding is substantially lower than that of the general population. In 2002, 58.8% of WIC mothers initiated breastfeeding compared with 79.2% of non-WIC mothers. Disparities are also evident in duration data. Breastfeeding promotion is a mandated part of WIC programming, but researchers suggest that WIC sends mixed messages by providing vouchers for HMS,

thereby appearing to endorse it as an equivalent or acceptable form of infant nutrition.

Influences on Infant and Young Child Feeding Practices

Interactions with health care providers have been identified as an important influence on women's infant feeding decisions and practices. While a variety of personnel can provide effective breastfeeding support, International Board Certified Lactation Consultants have specific education and training to help mothers establish lactation and continue breastfeeding. Mother-to-mother support such as that offered in groups such as La Leche League International, Nursing Mothers Counsels, and lay or peer counselors may help women sustain breastfeeding beyond the early postpartum period.

Hospital policies and procedures developed around an HMS-feeding paradigm can be detrimental to breastfeeding. For example, early separation of mother and newborn, ''test-feeding'' using a bottle of sterile water, and imposing a schedule on the newborn (vs. feeding on cue) are some of the traditional hospital policies that thwart mothers' efforts to initiate and exclusively breastfeed. Not only WIC's distribution of vouchers for HMS but also samples distributed by hospitals and physicians' offices and WIC, as well as use of items such as pens with HMS manufacturers' logos, act as a silent, yet powerful, endorsement of the brand as well as the product.

A mother's childbirth experience can also be potentially harmful to breastfeeding. Some studies have found that women who give birth by cesarean section are less likely to successfully initiate and continue breastfeeding compared with women who have vaginal births, possibly due to surgery-related delays in the time between birth and mother-child skin-to-skin contact and delays in first breastfeeding.

Budd, William
(1811–1880)

Dr. William Budd is considered a pioneer in the development of the germ theory of disease and waterborne transmission. He is best known for identifying water as the source of transmission in typhoid fever.

Budd was born in Devon, England, into a medical family. His father was a physician, and 6 of his 10 brothers studied medicine. After initially completing an apprenticeship with his father, he spent 4 years training in Paris, where he was a student of Pierre Charles Alexandre Louis, who is often referred to as the ''father of epidemiology.'' In 1841, Budd settled in Bristol, England, where he worked as a physician at St. Peter's Hospital and the Bristol Royal Infirmary. It was during his time in Bristol that Budd developed his theory regarding the transmission of typhoid fever.

In 1853, Budd recorded an outbreak of typhoid fever in the Welsh town of Cowbridge. Local celebrations during this time involved two parties on successive nights at a town inn. Eight of those who attended the parties died of typhoid fever. Budd noticed the close proximity of a local well that was located next to the septic tank of the inn. Given this, he suggested that water may have been the source of the infection. This theory was further developed after

noting that a person recovering from typhoid fever had left the inn before the parties began and also that all the eight individuals who became ill had had the same lemonade at the party, made with water from the well.

This theory was later reinforced in 1866 when Budd and a colleague traced a similar outbreak in a group of farm cottages. A father from one of the cottages had become infected with typhoid fever from elsewhere and then returned home to one of the cottages. Several days later, people in the neighboring cottages also became ill with typhoid fever. Budd noted that the drains of the cottages with infected people were linked to the same stream and that those who became infected lived downstream from the original outbreak. Budd concluded that water had been the source of transmission of infection.

In addition to suggesting typhoid was waterborne, Budd also argued that the mode of transmission was fecal-oral. Given this, Budd suggested that poor hygiene and living conditions contributed to its spread and recommended improved sanitary measures, including hand washing and boiling water, to slow and prevent transmission. It was thought that this application of preventive measures helped reduce the spread of cholera in Bristol during this time. In this way, Budd was a great contributor to the public health sanitation movement.

In 1873, Budd's classic paper on typhoid fever, "Typhoid Fever: Its Nature, Mode of Spreading, and Prevention," was published. Although his primary research focused on typhoid fever, he also suggested, along with Dr. John Snow, that cholera was a waterborne disease. He died in 1880, the same year that the typhoid bacillus, *Salmonella typhi*, was isolated.

C

Cancer

Cancer occurs when abnormal cells grow out of control. Normal cells in the body grow, divide, and die, and as we become older, our cells divide at a decreasing rate. Cancer cells, however, continue to grow and divide unchecked by the body, and they outlive normal cells. Cancers are capable of both invasion, or spreading into adjacent tissue, and metastasis, or traveling and settling into new, noncontiguous parts of the body. Cancer cells commonly form a tumor, or mass of cells, but they may also circulate in the bloodstream. *Carcinogenesis* describes the transformation of normal cells to neoplastic cells or abnormal cells that grow uncontrollably. *Neoplasia* is the process by which neoplasms develop from normal tissue. Cancers generally develop from a single neoplastic cell, commonly referred to as clonal expansion. *Dysplasia* refers to the early stages of neoplasia in which clonal expansion of abnormal cells occur.

Cancers are usually named for the site in which the neoplastic cells originated, even in cases of metastasis to other organs. Cancers are also usually named for their histology or morphologic features. *Carcinomas* are cancers of the epithelium and consist of cells found on external surfaces, internal cavity linings, and glandular linings, with cancers named *squamous cell carcinoma, transitional cell carcinoma*, and *adenocarcinoma*, respectively. *Sarcomas* are cancers of the mesenchyme, from which supporting tissue, including connective tissue, bone, cartilage, and muscle, is derived, and are often used with a prefix denoting the tissue of origin. Some cancers are given eponymous names, including Hodgkin lymphoma and Burkitt lymphoma.

Multistage Process of Carcinogenesis

Carcinogenesis involves two major phases, initiation and promotion. Initiation is the first stage and usually involves the interaction between a carcinogen (cancer-causing agent) and DNA that is permanent and irreversible. The promotion phase, on the other hand, is generally reversible and instable; it progresses when the abnormal cell is stimulated to grow and divide. Initiation and promotion generally occur as a multistage process that involves a series of genetic and molecular alterations and events.

Cancers arise as a result of damage to the DNA—mutations of critical genes involved in the regulation of cell growth and division. Often, the body has the capability of repairing DNA; the process of carcinogenesis begins when the body is unable to repair the damage. Two major classes of genes involved in carcinogenesis are oncogenes and tumor suppressor genes. Oncogenes generally have important roles in cell growth and differentiation. When a single copy of an oncogene is altered, leading to inappropriate or overexpression, neoplasia may result. The function of tumor suppressor genes is to prevent the development of cancers, generally by maintaining the integrity of the genome through cell cycle control and apoptosis, or signaled cell death; carcinogenesis, however, may occur on the loss or damage of both copies of the genes. A cancer develops generally when several mutations have occurred in the same

cell. In addition to being caused by exposure to carcinogens, some critical mutations may be inherited, giving the individual a genetic predisposition for cancer.

Staging Classification

Tumors are classified by stage, which defines the extent to which a particular cancer has grown and spread. Staging is useful in indicating the potential prognosis of an individual case of cancer and helps in the selection of the most appropriate treatment methods. Many different staging methods are in use to describe tumors, but the one most commonly used is the TNM system. This system assesses tumor size (T), involvement of lymph nodes (N), and distant metastasis (M). Tumors are then classified into Stage I (early-stage tumor), II, III, or IV (advanced tumor) based on the TNM description. Tumors may also be described as in situ (no invasion), localized, invasive, or distant (distant metastasis present).

Survival

Survival is the time between cancer diagnosis and death. It is commonly expressed as a 5-year survival, which is the percentage of patients alive after 5 years of follow-up from the diagnosis date. Relative survival takes into account the background risk of dying among those without cancer given the same age, sex, and race. Survival varies greatly depending on the type of cancer and the stage of the cancer at diagnosis. Survival has been generally increasing in the United States. Increases in survival reflect detection and diagnosis of cancers at earlier stages and improvements in treatment methods.

Treatments

Different ways in which cancer may be treated include surgery, radiation, chemotherapy, and biological therapies. Generally, surgery and radiation are used for localized cancers, whereas chemotherapy and biological therapy are used for metastatic cancers. Chemotherapy involves anticancer drugs that are intended to target cancer cells. Biological therapy, also known as immunotherapy or biotherapy, is based on the idea of using the immune system to control cancer cells. Often, combinations of these methods are used to treat cancer. For example, some chemotherapies or radiation may also damage normal cells, and biological therapies may be used in conjunction to help repair normal cells damaged by these other methods.

Current Cancer Burden

The Global Impact

As the control of infectious diseases in the world improves, the burden, or impact, of chronic diseases, such as cancer, is expected to rise. According to GLOBOCAN 2002, a global cancer database produced by the International Agency for Research on Cancer (IARC), an estimated 11 million new cancers and 7 million cancer deaths occurred in the world in 2002. The most common new cancers for both sexes combined were of the lung (12% of all cancers), breast (11%), colon/rectum (9%), and stomach (9%), and the most common cause of death from cancer were of the lung (18%), stomach (10%), liver (9%), and colon/rectum (8%). Among males, the most new cases of cancer were of the lung (17%), prostate (12%), stomach (10%), and colon/rectum (9%) in terms of new cases; the top cancers in terms of new deaths among males were lung (22%), stomach (12%), liver (11%), and colon/rectum (7%). Among females, the most common new cancers were breast (23%), cervix (10%), colon/rectum (9%), and lung (8%); the most common causes of new deaths among women were breast (14%), lung (11%), cervix (9%), and stomach (9%) cancers.

Cancer in the United States

According to the American Cancer Society (ACS) *Cancer Facts & Figures 2002* report, the United States was estimated to have nearly 1.3 million new cancer cases and more than 555,000 deaths from cancer in 2002. Cancer risk is strongly associated with age; 77% of cases were diagnosed among people aged 55 years or older. The lifetime risk of developing cancer among men and women was 1 in 2 and 1 in 3, respectively. Cancer was the second leading cause of deaths after heart disease. Based on the ACS report, the most commonly occurring new cancers in the United States were breast (16%), prostate (15%), lung (13%), and colon/rectum (12%). The top cancer killers included lung (28%), colon/rectum (10%), breast (7%), and prostate (5%). As expected, rankings of the cancers in males were

different from the rankings in females. The most common new cancers among men were prostate (30%), lung (14%), colon/rectum (11%), and urinary bladder (7%), whereas among women, the top new cancers were breast (31%), lung (12%), colon/rectum (12%), and uterine corpus (6%). The most common causes of deaths from cancer among men were lung (31%), prostate (11%), colon/rectum (10%), and pancreas (5%) and among women were lung (25%), breast (15%), colon/rectum (11%), and pancreas (6%).

Specific Cancers

Worldwide data on the following cancers are based on the most recent information available from GLOBOCAN 2002. Current trends may differ from these 2002 estimates by varying degrees depending on changes in risk or prevention strategies (incidence) and improvements in cancer detection or treatment (mortality). Incidence and mortality statistics of the United States are also based on 2002 estimates to allow for comparability with the worldwide data from GLOBOCAN 2002. More recent estimates for the United States are available at the ACS Web site. Survival estimates for the United States are based on data from the ACS *Cancer Facts & Figures 2006* report.

Breast Cancer

Worldwide, 1.15 million females were estimated to be newly diagnosed in 2002 with invasive and in situ breast cancer, and more than 411,000 females were expected to die annually from breast cancer, making it the cancer with the most new cases and deaths among females. The age-standardized incidence and mortality rates of invasive and in situ breast cancer among females were 37.5 and 13.2 per 100,000 females, respectively. The high ratio of incidence to mortality indicates an overall good prognosis throughout the world. Areas of high risk are usually the more developed parts of the world, including the United States, Canada, parts of Europe, and Australia and New Zealand.

In the United States, 203,500 females were diagnosed with invasive breast cancer and an additional 54,300 were diagnosed with in situ breast cancer in 2002. The age-standardized incidence rate of invasive and in situ breast cancer in the United States was 101.1 per 100,000 females, more than 2.7 times that of the world. Forty thousand women were estimated to die from breast cancer annually, with an age-standardized mortality rate of 19.0 per 100,000. In the United States, the average 5-year survival for breast cancer is roughly 88%. Survival, however, is very much dependent on tumor stage. Localized cancers are associated with a 98% survival, whereas cancers with distant metastasis are associated with a 26% survival.

Risk Factors

The most important risk factors for breast cancer are those that affect reproductive and hormonal patterns. For example, factors associated with increased levels of endogenous estrogens, such as early menarche, late age at first birth, low parity, and late menopause, increase risk for breast cancer. Obesity and alcohol consumption also increase risk. Genetic or familial factors also affect risk: Women with a family history of breast cancer have an increased risk, and when mutations to the *BRCA1* gene are involved, risk is very high and the cancers occur early in life.

Prospects for Prevention

At present, the most practical approach to improving the burden of breast cancer is by decreasing the mortality rate through early detection by screening. The ACS recommends regular annual mammographic screening and clinical breast examinations (CBE), as well as monthly breast self-examinations (SBE), for women aged 40 years and older. Women aged 20 to 39 years are recommended to have a CBE every 3 years and monthly SBE. Although recent evidence indicates that magnetic resonance imaging (MRI) may be more sensitive than mammography in detecting tumors in women with an inherited breast cancer susceptibility, mammography, CBE, and SBE are still part of the standard recommended screening guidelines according to the ACS, especially for women of the general population.

Prostate Cancer

Worldwide in 2002, 679,000 males were estimated to be newly diagnosed with prostate cancer, and 221,000 were estimated to die from the cancer. The age-standardized incidence and mortality rates were 25.3 and 8.2 per 100,000 males, respectively. Areas of high incidence include North and South

America, most of Europe, Australia, and New Zealand, whereas areas of low incidence include Asia and North Africa.

In the United States, 189,000 males were estimated to be newly diagnosed with prostate cancer in 2002. The age-standardized incidence rate of prostate cancer in the United States was 124.8 per 100,000 males, nearly five times the world average. This difference has been in large part attributed to the use of prostate-specific antigen (PSA) blood testing, which is more common in the United States than in other countries in the world; PSA blood testing is effective in detecting latent cancers, and most prostate cancers in the United States are detected at that stage—the great majority of which would never progress to invasive cancer. The age-standardized mortality rate was 15.8 per 100,000 with 30,200 estimated annual deaths from prostate cancer. The incidence among white, African American, and Asian males was 169.0, 272.0, and 101.4, respectively, demonstrating a racial component in conferring risk. In the United States, the survival rate for all prostate cancers is nearly 100%. Separating by stage, localized cancers are associated with a 100% survival, whereas cancers with distant metastasis are associated with a 34% survival.

Risk Factors

Age, ethnicity, and family history are the most established risk factors. In 2002, more than 70% of all prostate cancers in the world were estimated to have been diagnosed in men aged 65 and older. As previously mentioned, African American men have the highest incidence in the United States. Five percent to 10% percent of prostate cancers may be attributed a strong family history of the cancer. Although prostate cancer has been extensively studied, the environmental risk factors for it remain unclear. Thus far, diets high in fat, meat, and dairy products have been associated with increased risk.

Prospects for Prevention

Regular exercise; a high-vegetable diet that is low in fat, red meat, and dairy products; and avoidance of obesity are recommended. Additionally, the ACS recommends that the PSA blood test, as well as the digital rectal examination, should at least be offered annually to men aged 50 or older. High-risk males, including African Americans and those with strong family histories of prostate cancer, should be offered the tests annually at age 45 and older. Men being tested, however, should be informed of the benefits as well as the limitations, with overtreatment or unnecessary treatment a likely consequence of a positive PSA test result.

Lung Cancer

The world was estimated to have more than 1.35 million new cases (965,400 males, 386,800 females) and 1.18 million deaths (848,300 males, 330,700 females) annually from lung cancer in 2002. Lung cancer was the top-ranked cancer in both new cases and deaths among males. The age-standardized incidence rates among males and females were 35.5 and 12.1 per 100,000, respectively, and the age-standardized mortality rates among males and females were 31.2 and 10.3 per 100,000, respectively. A ratio of incidence to mortality close to 1 indicates an overall poor prognosis throughout the world. Areas of high risk among males include the United States, Canada, most of Europe, and parts of East Asia. High-risk areas for females include the United States, Canada, parts of Europe, Australia, New Zealand, and China.

In the United States, 169,400 new cases (90,200 males, 79,200 females) and 154,900 deaths (89,200 males, 65,700 females) from lung cancer were estimated to have occurred in 2002. The age-standardized incidence rates of lung cancer among males and females in the United States were 61.9 and 36.1 per 100,000, respectively, and the mortality rates were 48.7 and 26.8, respectively. Survival of lung cancer is among the lowest of all types of cancers. In the United States, the survival rate of all lung cancers is nearly 15%. Separating by stage, localized cancers are associated with a 50% survival, whereas cancers with distant metastasis are associated with a 2% survival.

Risk Factors

The most important risk factor for lung cancer is clearly tobacco smoking. Passive exposure to environmental tobacco smoke (ETS) is believed to increase risk among nonsmokers. Other risk factors include occupational exposure to harmful materials, such as asbestos and rubber exposure, and air pollution. Diets high in vegetables, especially green vegetables and carrots, and fruits may decrease risk.

Prospects for Prevention

The promotion of smoking cessation and programs oriented to persuade adolescents not to start smoking are the most cost-effective campaign against lung and other smoking-related cancers and diseases. Social pressure to make smoking socially unappealing and legislation to make smoking financially less accessible are important measures for prevention. These preventive measures have had great success in the United States.

Early detection using sputum cytology and chest radiographs have shown no favorable impact on mortality and, therefore, are not recommended for screening of lung cancer. Spiral computerized topography and detection of molecular markers, such as p53 mutations, in sputum, however, have received increasing interest and are being evaluated as possible screening methods.

Cancer of the Colon or Rectum

More than 1.02 million new cases of colorectal cancer (550,500 males, 472,700 females) and 529,000 deaths (278,400 males, 250,500 females) were estimated to have occurred worldwide in 2002. The age-standardized mortality rates (10.2 and 7.6 per 100,000 for males and females, respectively) were nearly half the incidence rates (20.1 and 14.6 per 100,000 for males and females, respectively), indicating a relatively good prognosis throughout the world. Areas of high risk for both males and females include the United States, Canada, most of Europe, Australia, New Zealand, and Japan.

In the United States, 148,300 new cases (72,600 males, 75,700 females) and 56,600 deaths (27,800 males, 28,800 females) from colorectal cancer were estimated to have occurred in 2002. The age-standardized incidence rates of colorectal cancer among males and females in the United States were 44.6 and 33.1 per 100,000, respectively, and the mortality rates were 15.2 and 11.6, respectively. In the United States, the average survival for colorectal cancers is 64%. Localized colorectal cancers are associated with a 90% survival, whereas cancers with distant metastasis are associated with a 10% survival.

Risk Factors

Diets rich in vegetables and unrefined plant foods, such as cereals and legumes, protect against colorectal cancer, whereas diets rich in red meat increase risk. The mechanism by which these foods confer risk, however, remains unclear. Alcohol also increases risk for colorectal cancer. Regular physical exercise may decrease risk, and obesity may increase risk.

Prospects for Prevention

Given the dietary and behavioral risk factors for colorectal cancer, improvements in diet and frequency of exercise are a prospect for prevention. Diets rich in vegetables and unrefined plant foods and moderate in red and processed meat, as well as regular exercise and weight control, should be promoted. Another potential prevention route is screening. Colorectal cancer can be detected early, by screening using tests for occult blood in stool, sigmoidoscopy, or colonoscopy. Any of these methods can be used for early detection of colorectal adenomatous polyps, which are precursors of colorectal cancer and localized cancers.

Cancer Registries

A cancer registry, also referred to as a tumor registry, is a cancer surveillance system that provides continued follow-up care on all cancer patients in a given location, hospital, or state. It is the chief method in the United States by which information is systematically collected about people diagnosed with cancer. Cancer registries document and store all significant elements of a patient's history and treatment. Depending on the resources available, the information may include basic demographic data such as age, sex, ethnicity, race, residence, and place of birth; date of diagnosis; date and cause of death; the type of cancer and its anatomical location; the extent of disease at the time of diagnosis; the types of treatment received; and the outcomes of treatment and clinical management. The information collected is then used to monitor cancer trends over time; to determine cancer patterns in various populations; to guide the planning and evaluation of cancer-control programs; to help set priorities for allocating health resources; to advance clinical, epidemiological, and health services research; and to provide information for a national database for cancer incidence.

The first modern registries for epidemiological purposes were created in the state of Connecticut in 1936. In Europe, registries were started in Denmark (1942), Belgium (1943), and the United Kingdom (1945). In 1940, New York passed the first law that required reporting of cancer cases diagnosed in the state and outside New York City to the state health department; the law was amended in 1973 to include all cancer cases in the state. Currently, most state-based cancer registries require reporting of cancer cases by state law. At present, population-based cancer registries exist in 45 states, the District of Columbia, and three U.S. territories (Puerto Rico, the Republic of Palau, and the Virgin Islands). All information reported to cancer registries is considered confidential, with strict procedures in place to protect the privacy of cancer patients.

Each time a patient is diagnosed with a new tumor, a report is sent to the state health department. When a person is diagnosed with more than one type of cancer, information is obtained for each separate tumor in a case report. Most registries include reports of all malignant cancers. Some types of cancers, including all skin cancers, and certain other types of basal cell and squamous cell carcinomas may not be reported because they are rarely fatal and usually do not require hospitalization. These data are reported to a central statewide registry from various medical facilities, including hospitals, physicians' offices, therapeutic radiation facilities, freestanding surgical centers, and pathology laboratories.

Because cancer surveillance is legally required and considered a major public health priority, cancer registry data are generally of high quality, relatively complete, and representative of the state's population. Some registries, especially in states that lack the resources to maintain them, are not timely in releasing information and may be incomplete. Most registries do not track clinical outcomes in reported cases.

Within the United States, there are multiple national organizations and programs actively collecting and reporting cancer data. These include the Centers for Disease Control's (CDC's) National Program of Cancer Registries (NPCR); the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) program; the Commission on Cancer of the American College of Surgeons' National Cancer Database; the Central Brain Tumor Registry of the United States; and the CDC's National Center for Health Statistics' Vital Statistics Monthly Reports and data tapes. In addition, the American Cancer Society and two professional organizations, the National Cancer Registrars Association and the North American Association of Central Cancer Registries (NAACCR), disseminate cancer-related information to the public and to professional communities.

Many cancer registries are supported through the NPCR, which was created in 1992 when Congress passed the Cancer Registries Amendment Act. NPCR has established a standard for data collection that guides reporting in states. In addition, all cancer registries are represented in the NAACCR, which also sets standards and goals for the member registries to meet and to promote the use of cancer registry data in studies of defined populations and in cancer-control programs. To facilitate the implementation of a national standard, NAACCR instituted a program in 1997 that annually reviews member registries' abilities to produce complete, accurate, and timely data. Registries that meet the highest standards receive NAACCR certification.

One of the most heavily used cancer registries is the SEER registry, which was established in 1971.

Its goals include assembling and reporting estimates of cancer incidence and mortality in the United States, monitoring annual cancer incidence trends to identify unusual changes in specific forms of cancer occurring in population subgroups, providing recent information on changes over time in diseases, and promoting studies designed to identify factors susceptible to cancer-control interventions.

SEER collects cancer data on a routine basis from designated population-based cancer registries in 11 geographic areas of the United States, including 6 states, 1 territory, and 4 metropolitan areas. The geographic areas represent an estimated 14% of the U.S. population. Trends in cancer incidence, mortality, and patient survival as well as many other studies are derived from the SEER database. The database contains information on approximately 2.3 million in situ cancer and invasive cancers diagnosed between 1973 and 1996, with approximately 125,000 new cases added each year.

Cancer registries such as SEER are used to conduct either retrospective or cross-sectional epidemiological studies. Cancer registries have been used to assess cancer trends, to monitor the impact of cancer on the general population or a subpopulation, to identify environmental carcinogens, to monitor cancer-related effects of tobacco, to identify geographic areas with higher than average cancer rates, to study patterns and outcomes of cancer care, and to identify risk groups for research and public health interventions.

Capture-Recapture Method

The capture-recapture method is a technique for estimating the size of a population that cannot be directly measured in its entirety. It is derived from ecological research methods. To take a census of a group of animals (e.g., the population of fish in a pond), researchers capture a subset of animals, mark or tag them in some way, release them, then capture another sample (recapture). Some of the animals from the first sample will reappear in the second sample as well; some animals will appear only in one of the two captures. From this information, the size of the whole population can be estimated.

Capture-recapture methods have been adapted by epidemiologists for use in the surveillance of and identification of human illnesses. Routine surveillance methods are likely to fail to identify every affected person. Capture-recapture methods can be used to more completely identify the size of a given population. In epidemiology, the ‘‘capture’’ involves identifying affected persons from lists, registers, or other sources of information about diagnosed cases of a given condition. The presence of an individual on one of these various sources is similar to the capture of an animal by an ecologist. Use of two or more overlapping but incomplete lists of cases, multiple ‘‘captures,’’ allows for estimation of the number of cases missing from all lists, and from that an estimation of the total population size.

With two different sources, each person will appear on one, both, or neither list. The status of all cases on the lists can be summarized in a 2×2 table, where cell a represents presence on both lists, cell b represents presence on List 1 but not on List 2, cell c represents presence on List 2 but not on List 1, and cell d represents absence from both lists.

Table 1 Representation in a 2 × 2 Table of the Status of All Cases Identified From Two Independent Sources

		On List 2?	
		Yes	*No*
On List 1?	*Yes*	*a*	*b*
	No	*c*	*d*

Note: The number of cases not found on either list (cell *d*) may then be estimated from this table using the property that the cross-products (*ad* and *bc*) will be the total estimated population size.

From this, we can use the property that the product of cells *a* and *d* will equal the product of cells *b* and *c* to solve for the unknown quantity in cell *d*. Specifically, $d = bc/a$. After estimating the frequency of cell *d*, the size of the entire population of interest may be estimated by summing all four cells $a + b + c + d = \textit{total estimated population size}$. However, this method assumes that Lists 1 and 2 are independent, that is, that the presence of a case on List 1 does not influence whether or not a case is on List 2. Using only two sources, this assumption cannot be tested and estimates cannot be adjusted for possible dependency between sources.

More than two sources may be used as well. With three sources, eight estimates can be produced, accounting for all possible interactions between and dependencies among sources. Methods exist for then selecting the best single estimate from the eight possible estimates. As the number of sources increases beyond three, however, the number of possible estimates quickly becomes unwieldy, though it is possible that some smaller sources could be combined to reduce the overall number of sources used in the estimation.

Capture-recapture methods, as with other methods of estimation, are subject to uncertainty and potential bias. The single most likely source of uncertainty with this method lies in the accuracy with which records for an individual can be matched across sources. In addition, a lack of complete independence between sources may create a directional bias that will affect estimates.

Stroup (Eds.), *Monitoring the health of populations: Statistical principles and methods for public health surveillance* (pp. 341–359). New York: Oxford University Press.

Carcinogen

A carcinogen is an agent, mixture, or exposure that increases the occurrence of cancer. Carcinogen identification is an activity based on the evaluation of the results of scientific research. Pertinent data for carcinogen identification include human epidemiologic studies, long-term bioassays in experimental animals, and other relevant data on toxicokinetics and cancer mechanisms. Several classification systems exist to identify the degree of carcinogenicity of agents. The most widely used system is developed by the International Agency for Research on Cancer (IARC), which is part of the World Health Organization.

Most of the existing data about whether an agent might cause cancer originate from laboratory (cell culture and animal) studies. Although it is not possible to predict with certainty which substances will cause cancer in humans based on animal studies alone, virtually all known human carcinogens that have been adequately tested have been found to produce cancer in lab animals. In many cases, carcinogens are first found to cause cancer in lab animals and are later found to cause cancer in humans. For most carcinogens, it is assumed that those that cause cancer at larger doses in animals will also cause cancer in humans.

Another source of data about carcinogens comes from epidemiologic studies, which provide evidence of a carcinogenic hazard but often are not sufficiently sensitive to identify a carcinogenic hazard except when the risk is high or when it involves an unusual form of cancer. In addition, it is difficult to single out any particular exposure as having a definite link to cancer. For these reasons, laboratory studies generally provide the best means of assessing potential risks to humans.

The IARC Classification System for Carcinogens

The most widely used system for classifying carcinogens originates from IARC. This agency releases the

IARC Monographs on the Evaluation of Carcinogenic Risks to Humans, which are scientific evaluations developed by international working groups of expert scientists. Agents are selected for evaluation on the basis of evidence of human exposure and some evidence or suspicion of carcinogenicity. The *IARC Monographs* include a critical review of the pertinent peer-reviewed scientific literature as the basis for an evaluation of the weight of the evidence that an agent may be carcinogenic to humans. Published continuously since 1972, the scope of the *IARC Monographs* has expanded beyond chemicals to include complex mixtures, occupational exposures, lifestyle factors, physical and biologic agents, and other potentially carcinogenic exposures. In the past 30 years, IARC has evaluated the cancer-causing potential of about 900 likely candidates. These evaluations provide the scientific support for public health measures implemented by many national and international health agencies around the world. IARC categorizes agents into the following five potential categories.

Group 1: Carcinogenic to Humans

If a substance is classified as belonging to Group 1, it is labeled "carcinogenic to humans." This category is used when there is sufficient evidence of carcinogenicity in humans. An agent may be placed in this category when evidence of carcinogenicity in humans is less than sufficient but there is sufficient evidence of carcinogenicity in experimental animals and strong evidence in exposed humans that the agent acts through a relevant mechanism of carcinogenicity. Only 91 agents have been characterized as "carcinogenic to humans."

Group 2A: Probably Carcinogenic to Humans

This category is used when there is limited evidence of carcinogenicity in humans but sufficient evidence of carcinogenicity in experimental animals. In some cases, an agent may be classified in this category when there is inadequate evidence of carcinogenicity in humans, sufficient evidence of carcinogenicity in experimental animals, and strong evidence that the carcinogenesis is mediated by a mechanism that also operates in humans. An agent, mixture, or exposure may be classified in this category solely on the basis of limited evidence of carcinogenicity in humans. Sixty-seven agents have been classified as "probably carcinogenic to humans."

Group 2B: Possibly Carcinogenic to Humans

This category is used for agents, mixtures, and exposures for which there is limited evidence of carcinogenicity in humans and less than sufficient evidence of carcinogenicity in experimental animals. It may also be used when there is inadequate evidence of carcinogenicity in humans but there is sufficient evidence of carcinogenicity in experimental animals. In some instances, an agent, mixture, or exposure for which there is inadequate evidence of carcinogenicity in humans but limited evidence of carcinogenicity in experimental animals together with supporting evidence from other relevant data may be placed in this group. Two hundred and forty agents have been categorized as "possibly carcinogenic to humans."

Group 3: Unclassifiable as to Carcinogenicity in Humans

This category is used most commonly for agents, mixtures, and exposures for which the evidence of carcinogenicity is inadequate in humans and inadequate or limited in experimental animals. Agents for which the evidence of carcinogenicity is inadequate in humans but sufficient in experimental animals may be placed in this category when there is strong evidence that the mechanism of carcinogenicity in experimental animals does not operate in humans.

Group 4: Probably Not Carcinogenic to Humans

This category is used for agents or mixtures for which there is evidence suggesting a lack of carcinogenicity in humans and in experimental animals. In some instances, agents or mixtures for which there is inadequate evidence of carcinogenicity in humans but evidence suggesting a lack of carcinogenicity in experimental animals, consistently and strongly supported by a broad range of other relevant data, may be categorized into this group.

Other Carcinogen Classification Systems

In addition to the IARC, other programs and agencies have implemented systems for labeling the carcinogenicity of substances. For example, the National Toxicology Program, mandated in 1978 by an act of the U.S. Congress, releases its *Report of Carcinogens* approximately every 2 years and lists agents as either

"known to be a human carcinogen" or "reasonably anticipated to be a human carcinogen."

The U.S. Environmental Protection Agency (EPA) assesses the health hazards of chemical contaminants present in the environment. These assessments cover cancer and other adverse effects. The hazard assessments are coupled with dose-response assessments that the EPA uses in its regulatory and informational programs.

The California EPA maintains a list of "chemicals known to the state to cause cancer" under the mandate created by Proposition 65, a 1986 ballot initiative enacted to protect citizens from chemicals known to cause cancer, birth defects, or other reproductive harm and to inform citizens about exposures to such chemicals. A chemical is listed if an independent committee of scientists and health professionals finds that the chemical has been clearly shown to cause cancer, if an authoritative body has identified it as causing cancer, or if a California or U.S. government agency requires that it be labeled or identified as causing cancer.

Cardiovascular Disease

Cardiovascular disease (CVD) ranks as the leading cause of morbidity and mortality among developed countries and is rapidly emerging as the predominant cause of death in many developing countries. There are numerous differences in incidence across ethnic groups and geographic regions within countries. Coronary heart disease (CHD) is the predominant manifestation of CVD and responsible for the majority of cases of CVD in developed countries. Numerous longitudinal epidemiological studies conducted in the past 60 years have provided valuable insight into the natural history and risk factors associated with the development of and prognosis associated with CVD. Randomized clinical trials have demonstrated the value of treatment of several key risk factors, most notably hypertension and hypercholesterolemia, for both the primary and the secondary prevention of CVD. This entry reviews the descriptive epidemiology of CVD, its associated risk factors, assessment of CVD risk, and the evidence behind the control of CVD risk factors for the prevention of CVD.

Definitions, Incidence, and Distribution

CVD comprises many conditions, including CHD, heart failure, rheumatic fever or rheumatic heart disease, stroke, and congenital heart disease. Of these, 7 in 10 deaths from CVD are due to CHD (53%) and stroke (17%) (Figure 1). CHD, the most common CVD condition, increases in prevalence directly with age in both men and women (Figure 2).

Myocardial infarction, angina pectoris (especially if requiring hospitalization), and sudden coronary death are the major clinical manifestations of CHD. CHD initially presents as sudden coronary death in approximately one third of the cases. Other forms of documented CHD include procedures done as a result of documented significant atherosclerosis, such as coronary artery bypass grafting (CABG) or percutaneous coronary interventions (PCI), including angioplasty and stenting. Persons with documented significant disease from a coronary angiogram, echocardiogram, nuclear myocardial perfusion, magnetic resonance imaging, or computed tomography angiographic or coronary calcium scan can also confirm the presence and extent of coronary artery disease; however, because the definitions used to define significant disease vary and/or such results do not typically result in hospitalization, these cases are not normally counted as incident or prevalent CHD, nor are they considered "hard" (usually death or hospitalized diagnosed

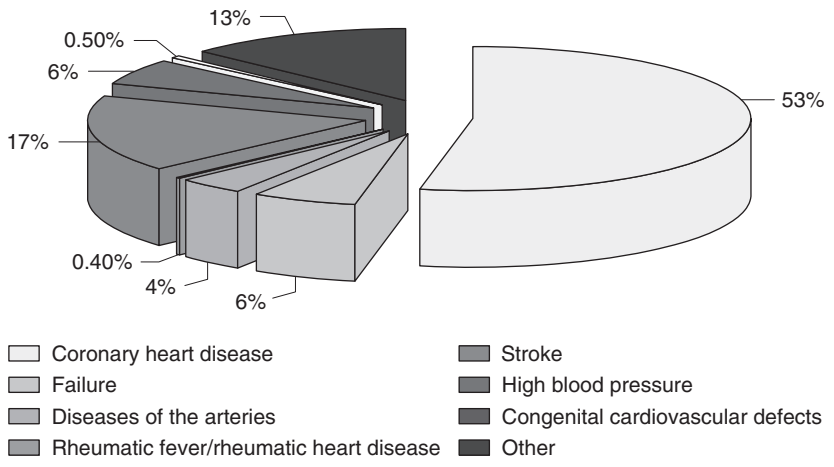

Figure 1 Percentage Breakdown of Deaths From Cardiovascular Disease

Source: Thom et al. (2006).

conditions) cardiovascular endpoints for the purposes of clinical trials. Nonfatal or fatal myocardial infarction and sudden coronary death are most typically included as "hard" CHD endpoints.

Mortality rates from CVD and CHD vary widely across different countries. From the most recent data available, among men, CVD death rates per 100,000 range from 170 in Japan to 1,167 in the Russian Federation, with the United States at 307. Corresponding CHD death rates were 53, 639, and 187, respectively. Among women, these rates were lowest in France but highest in the Russian Federation, with intermediate rates in the United States. These rates were 69, 540, and 158 for CVD, respectively, and 18, 230, and 77 for CHD, respectively. Next to the Russian Federation, Romania, Bulgaria, and Hungary had the next highest rates both for CVD and CHD. Spain, Australia, Switzerland, and France (or Japan) were the other countries with the lowest rates.

Significant variation in CVD and CHD rates also exists within the United States, with total CVD mortality highest in Mississippi at 421/100,000 and lowest in Puerto Rico at 234/100,000. CHD mortality was highest in Oklahoma at 227/100,000 and lowest in Utah at 100/100,000.

CVD and CHD prevalence rates vary dramatically by age, gender, and race. Overall CVD prevalence (including hypertension) from ages 20 to 34 to 75+ ranges from 11.2% to 77.8% in men and 6.2% to 86.4% in women, with the corresponding prevalences of CHD ranging from 0% to 16.6% in men and 0.3% to 10.3% in women. Most recent statistics show that the prevalence of CHD also varies widely by race and gender within the United States—males 8.4% overall, 8.8% in non-Hispanic white males,

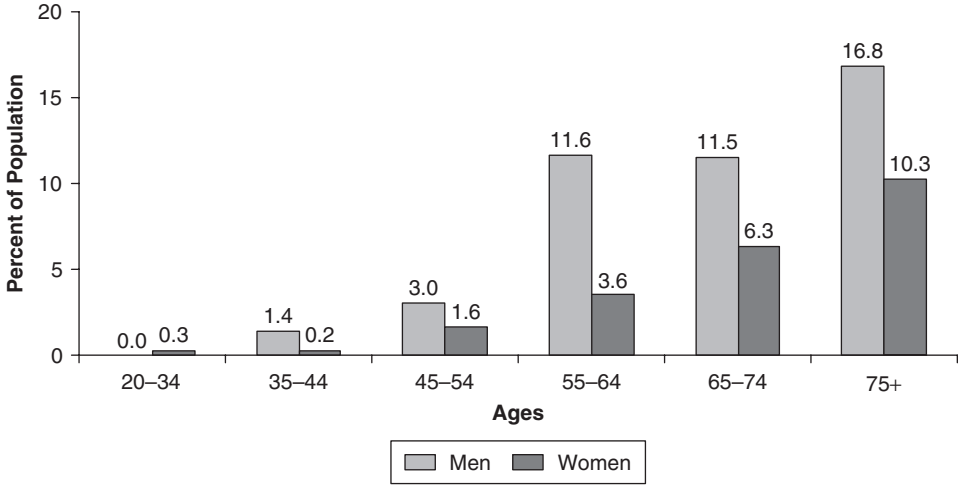

Figure 2 Prevalence of Coronary Heart Disease by Age and Sex, NHANES 1999 to 2002

Source: Thom et al. (2006).

7.4% in black males, 5.6% in Mexican American males; females 5.6% overall, 5.4% in non-Hispanic white females, 7.5% in black females, and 4.3% in Mexican American females. Prevalence rates were also noted to be 3.8% in Asians and 8.2% in American Indian and Alaska Natives. Stroke prevalence in 1999 to 2003 among U.S. adults was 3.6% in American Indians or Alaska Natives, 3.3% in blacks, 2.2% in whites, and 2.0% in Asians. For heart failure, the overall U.S. adult prevalence was 2.3% in 2003 and ranged from 1.6% in Mexican American females to 3.5% in non-Hispanic black females.

Risk Factors for Cardiovascular Disease

The Framingham Heart Study, a large longitudinal investigation of the natural history of CVD begun in 1948, originally identified many of the factors that are associated with an increased risk of CVD and originally coined the term *risk factors*. Increased awareness of major risk factors for CVD initially identified by the Framingham Heart Study and by other researchers helped lead to important public health initiatives against smoking in the 1960s, hypertension in the 1970s, and hypercholesterolemia in the 1980s. More recently, obesity and physical inactivity have also been recognized as key risk factors for CVD. Diabetes is also now widely regarded as a CHD risk equivalent, and the importance of a clustering of major cardiometabolic risk factors, commonly referred to as the metabolic syndrome, has received significant attention in the research and clinical community. Of interest is that over recent decades, while certain risk factors such as elevated cholesterol, blood pressure, and smoking have decreased in prevalence, others such as diabetes have increased (Figure 3). Risk factors often cluster together, and their co-occurrence and number of risk factors present is directly related to the incidence of CHD (Figure 4). A brief discussion of the key, traditional risk factors for CVD is provided below.

Family History

A premature family history of CHD is a well-established but unmodifiable risk factor for future CHD and can sometimes be the crucial and single most important risk factor in predisposing an individual to early CHD. A large proportion of heart attacks or strokes occurring at a young age are felt to be attributed to inherited or familial predisposition or susceptibility, and knowledge of an individual's family history can help guide preventive efforts. A premature family history is generally defined as

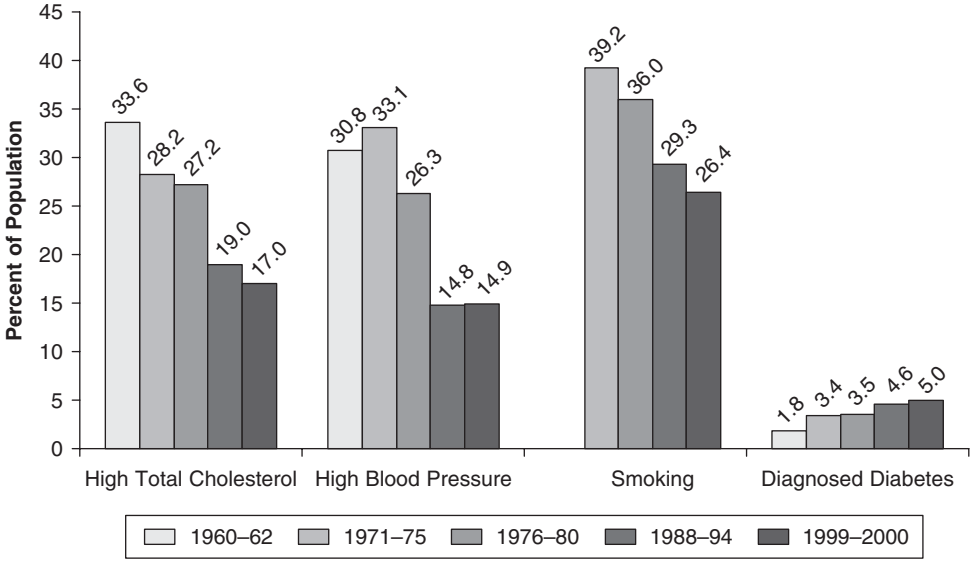

Figure 3 Trends in Cardiovascular Risk Factors in the U.S. Population, Ages 20 to 74

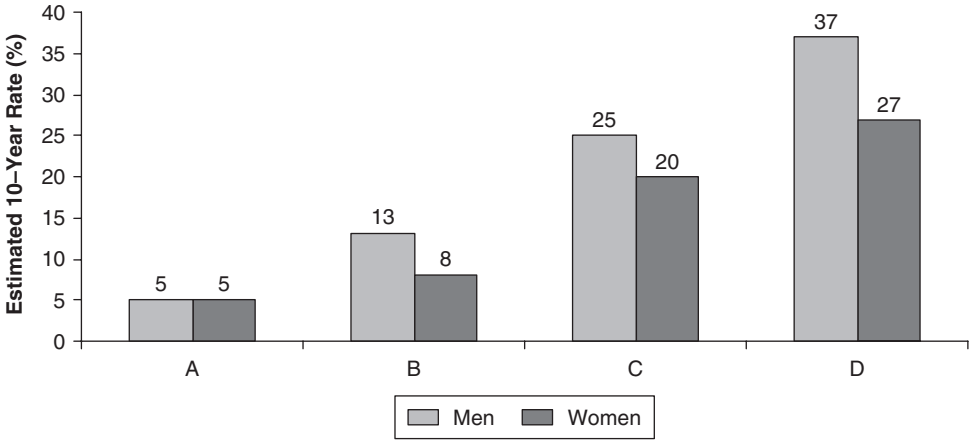
Source: Gregg et al. (2005).



Blood pressure (mmHg)	120/80	140/90	140/90	140/90
Total cholesterol (mg/dl)	200	240	240	240
HDL cholesterol (mg/dl)	50	50	40	40
Diabetes	No	No	Yes	Yes
Cigarettes	No	No	No	Yes

Figure 4 Estimated 10-Year CHD Risk in 55-Year-Old Adults According to Levels of Various Risk Factors: Framingham Heart Study

Source: Wilson et al. (1998).

having a male first-degree relative experiencing a first manifestation of CHD below the age of 45 or a female first-degree relative experiencing CHD below the age of 55. The number of affected relatives with premature CHD is also felt to be an important factor, whereas those with one affected relative can be shown to have a fourfold greater risk of CHD and those with two or more affected relatives may have more than a 12-fold greater risk of CHD compared with those without any affected relatives. Moreover, it has been shown that 35% of all early CHD occurs in just 3.2% of families, all of whom have a strong positive family history of CHD. Familial hypercholesterolemia, where cholesterol levels exceeding 1,000 have been commonly reported and where individuals homozygous for the defective LDL-cholesterol receptor gene have been known to have heart attacks and die by age 20, is among the most widely studied genetic conditions responsible for CHD. Other genetic defects responsible for hypertension, obesity, diabetes, and other major cardiovascular risk factors have also been identified and are the subject of major investigations.

Diabetes and Metabolic Syndrome

Diabetes mellitus is a major risk factor for CVD and is associated with a greater risk for CHD, stroke, and peripheral vascular disease. Most recent U.S. data show prevalences of approximately 10% in black and Mexican American men and as high as 12% in black women (Figure 5). More than three fourths of those with diabetes die of cardiovascular complications, most notably myocardial infarction and stroke. In appreciation of this, diabetes has been designated as a CHD risk equivalent, because the risk of CHD in those with diabetes without known heart disease has been shown to be similar to recurrent CHD events in those with CHD (but without known diabetes). Most population-based studies have shown about a twofold greater risk of CHD in men with versus without diabetes, but a three- to sevenfold greater risk of CHD in women. Diabetes is typically diagnosed by a fasting glucose > 126 mg/dl or casual glucose level of > 200 mg/dl. An abnormal glucose challenge test is also used to establish diagnosis. Clinical trial evidence to show whether controlling

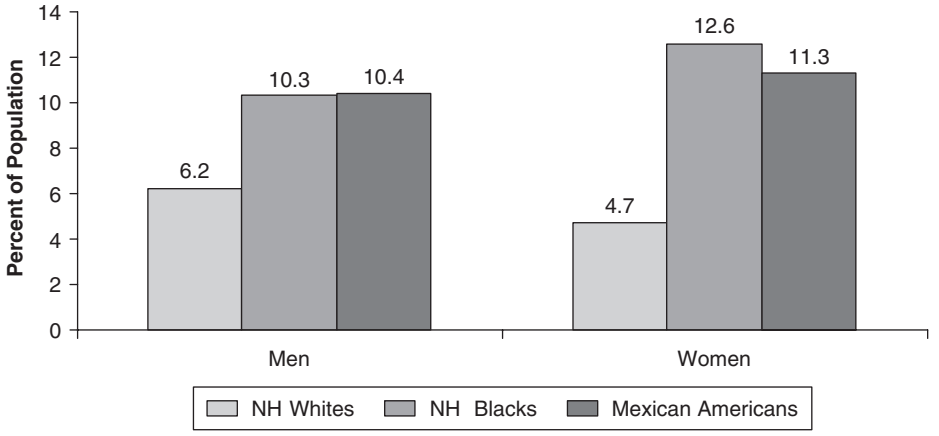


Figure 5 Age-Adjusted Prevalence of Physician-Diagnosed Diabetes in Americans Aged 20 and Older by Race/Ethnicity and Sex, NHANES: 1999 to 2002

Source: Thom et al. (2006).

diabetes lowers cardiovascular event rates is lacking. Ongoing large-scale multicenter trials are now underway to show whether aggressive glycemic control can reduce cardiovascular event risk. Most persons with diabetes have hypertension and dyslipidemia (particularly low HDL-cholesterol and elevated triglycerides). The majority of persons with diabetes are inadequately controlled for hypertension and dyslipidemia. Control of diabetes focuses on lifestyle (diet and exercise) and pharmacologic management to reduce the hemoglobin A1C levels to below 7%, blood pressure to < 130/80 mmHg, and LDL-cholesterol levels to < 100 mg/dl, which are all important to reducing the future risk of CVD events.

Of particular interest recently is the designation of metabolic syndrome, referring to a constellation of cardiometabolic risk factors that are associated with a greater risk of developing future diabetes and CVD. Certain definitions place insulin resistance or abdominal obesity as the necessary condition, for which additional conditions, including elevated blood pressure, low HDL-cholesterol, elevated triglycerides, and impaired fasting glucose, form the definition. The most recent National Cholesterol Education Program definition requires the presence of at least three of the following five criteria: abdominal obesity defined by a waist circumference > 35 in. in women or > 45 in. in men, high-density lipoprotein (HDL)-cholesterol < 40 mg/dl in men or < 50 mg/dl in women, fasting triglycerides > 150 mg/dl, elevated blood pressure > 130 mmHg systolic or > 85 mmHg diastolic or on hypertensive therapy, or impaired fasting glucose defined as > 100 mg/dl or on hypoglycemic therapy. Numerous studies have shown an increased risk of future CVD events in persons with the metabolic syndrome. Among U.S. adults, a stepwise increase in risk for CHD, CVD, and total mortality has been shown from having neither condition to metabolic syndrome without diabetes, diabetes, preexisting CVD, and CVD plus diabetes (Figure 6).

Hypertension

Blood pressure, and particularly systolic blood pressure, is strongly and positively related to the risk of future CHD and stroke. Hypertension is currently defined as a systolic blood pressure of 140 mmHg or higher, diastolic blood pressure of 90 mmHg or higher, or if the person is taking antihypertensive medication. Recent data show approximately 29% of U.S. adults to have hypertension, with a prevalence that rises dramatically with age to nearly 70% of men and more than 80% of women aged 75 years or above (Figure 7). The Seventh Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure also defines those with a level of blood pressure of 120 to 139 mmHg systolic or 80 to 89 mmHg diastolic as "prehypertensive" because of the greater future risk for these persons to develop hypertension. Among U.S. adults, approximately 29%

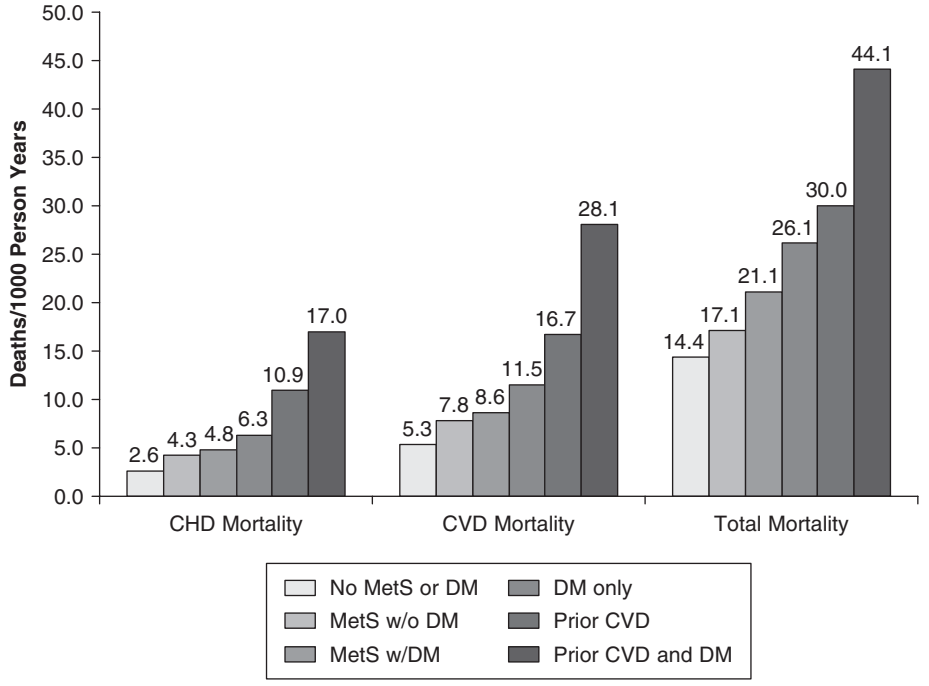

Figure 6 Mortality Rates in U.S. Adults, Ages 30 to 75, With Metabolic Syndrome (MetS), With and Without Diabetes Mellitus (DM) and Preexisting CVD NHANES II: 1976 to 1980 Follow-Up Study (Mean 13 Years Follow-Up)

Source: Malik, Wong, and Franklin (2004).

Note: Estimates are age-adjusted.

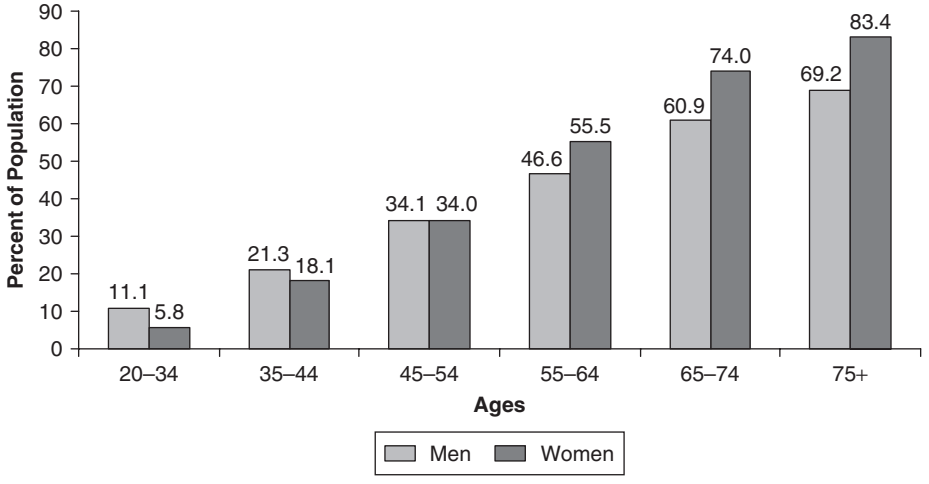

Figure 7 Prevalence of High Blood Pressure in Americans by Age and Sex, NHANES 1999 to 2002

are prehypertensive. Blood pressure is not considered normal unless < 120 mmHg systolic and < 80 mmHg diastolic.

Numerous clinical trials have shown that lowering blood pressure substantially decreases the risk of future cardiovascular events, stroke, and end-stage

renal disease. In hypertensive persons, it is recommended to achieve a blood pressure goal of < 140/90 mmHg, or < 130/80 mmHg for those with diabetes or chronic kidney disease. While there have been major improvements in the treatment of hypertension, only about one third of adult patients with hypertension are adequately controlled. This varies substantially by ethnicity (in 1999–2000, rates of control were lowest in Mexican Americans [18%], followed by non-Hispanic blacks [28%], and non-Hispanic whites [33%]).

Dyslipidemia

Increased levels of total and low-density lipoprotein (LDL)-cholesterol have long been recognized as major risk factors for CHD. A direct curvilinear relation exists between total and LDL-cholesterol with the risk of CHD; compared with those with total cholesterol levels of 200 mg/dl, those with levels of 240 mg/dl are at approximately a twofold greater risk, and those with levels of 300 mg/dl a fourfold risk. However, there is significant overlap in total cholesterol levels between those who experience CHD events versus those who do not, and approximately one third of heart attacks occur in persons with "normal" levels of total cholesterol below 200 mg/dl. Importantly, a low level of HDL-cholesterol, regardless of level of total cholesterol, is strongly associated with an increased risk of CHD (Figure 8). Other lipid abnormalities include elevated serum triglyceride levels, small particle size LDL-cholesterol (known as small dense LDL-cholesterol), and elevated lipoprotein (a) levels. While an elevated LDL-cholesterol level is the most common lipid abnormality in U.S. adults, those with diabetes often have elevated triglycerides and low HDL-cholesterol. In 2003, 40% of U.S. adults had an LDL-cholesterol > 130 mg/dl, and 23% had a low HDL-cholesterol of < 40 mg/dl.

Current National Cholesterol Education Program (NCEP) guidelines focus on treatment of LDL-cholesterol in persons with dyslipidemia. Numerous primary and secondary prevention clinical trials have documented the efficacy of lowering LDL-cholesterol, particularly by the HMG-CoA reductase inhibitor drugs ("statins"), where approximately 25% to 35% reductions in CHD and CVD incidence and, in some studies, significant reductions in mortality have been demonstrated. Furthermore, recent clinical trials also show an effect on reducing incidence of first stroke from LDL-cholesterol reduction.

Trials done specifically in those with diabetes or CHD, regardless of baseline LDL-cholesterol level and in patients with CHD who have fairly normal LDL-cholesterol levels, also show significant reductions in first or recurrent CHD events, which has led to emerging recommendations to treat all patients with CHD or diabetes with statins, even if their baseline LDL-cholesterol is < 130 mg/dl. Standard NCEP goals for

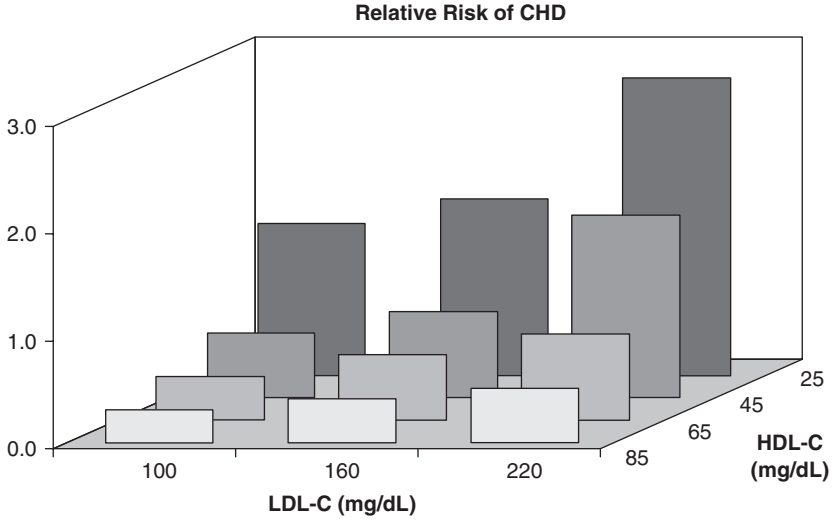

Figure 8 Low HDL-Cholesterol Is an Independent Predictor of CHD Risk Even When LDL-Cholesterol Is Low

Source: Gordon, Castelli, Hjortland, Kannel, and Dawbaer (1977).

treatment of LDL-cholesterol include achieving levels of < 100 mg/dl in those with preexisting CHD or other CHD risk equivalents such as those with diabetes or other atherosclerotic disease or a calculated global risk of > 20% for CHD in 10 years, < 130 mg/dl in those with two or more risk factors, and < 160 mg/dl in those with less than two risk factors (see the section below on risk assessment). Optional goals for lowering LDL-cholesterol to < 70 mg/dl have been recommended for those at the very highest risk (e.g., preexisting CVD plus diabetes or other uncontrolled risk factors, or with acute coronary syndromes).

Cigarette Smoking

Tobacco smoking is among the leading preventable causes of death. Numerous studies have linked tobacco use to the incidence of and mortality from CVD, with approximately a half million deaths annually in the United States being attributed to tobacco use. Furthermore, environmental tobacco smoke ("secondhand smoke") is responsible for approximately 40,000 deaths from heart disease annually in the United States. Cigarette smokers are two to four times more likely to develop CHD than nonsmokers. Also, their risk of stroke is doubled and risk for peripheral vascular disease is more than 10 times as likely as that of nonsmokers. The most recent data among U.S. adults in 2004 show an overall prevalence of smoking of 20%, with a wide variation by ethnic/gender groups, ranging from 5% in Asian females to 37% in American Indian/Alaska Native men. Among adolescents (aged 12 to 17), recent prevalence estimates also show great variation, from 9% in Asians to 30% in American Indians/Alaska Natives.

Interventions for smoking are varied. For youth, school- and community-based prevention programs, state and federal initiatives, and cessation assistance are available. For adults, behavioral treatment, self-help approaches, and pharmacologic therapy are used, with varying levels of success.

Obesity and Physical Inactivity

Recent estimates show that two thirds of U.S. adults are overweight or obese (body mass index of 25 kg/m^2 or higher), with 30% being obese (body mass index of 30 kg/m^2 or higher). Since the 1960s, there has been a dramatic, nearly threefold increase in obesity prevalence among men and more than a twofold increase in women (Figure 9).

Furthermore, recent data show one third of children and adolescents are overweight, based on being at or above the 95th percentile for sex-specific body

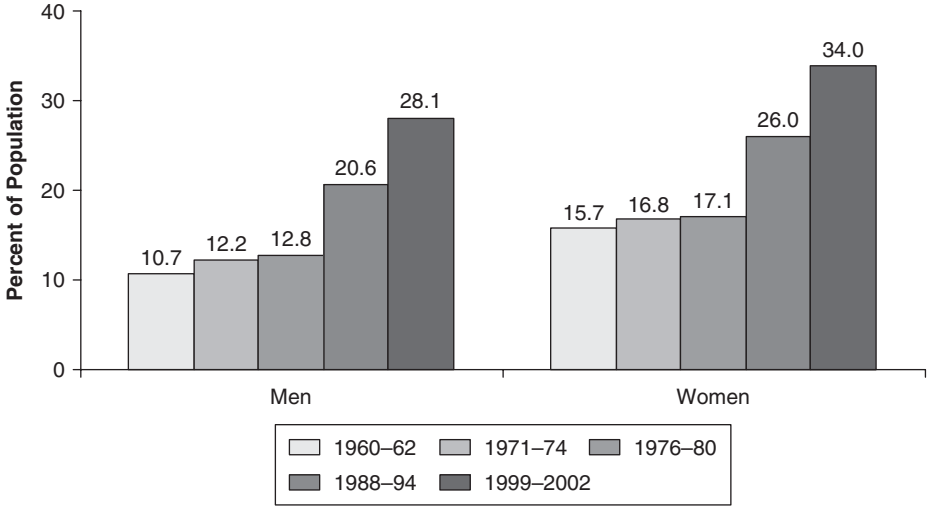

Figure 9 Age-Adjusted Prevalence of Obesity in Americans Ages 20 to 74 by Sex and Survey: NHES, 1960 to 1962; NHANES, 1971 to 1974, 1976 to 1980, 1988 to 1994, and 1999 to 2002

Source: Thom et al. (2006).

Note: Obesity is defined as a body mass index of 30 kg/m^2 or higher.

mass index for age. Further recent estimates show that only 30% of the U.S. adult population is physically active (light or moderate activity at least five times per week for 30 min or vigorous activity at least three times per week for 20 min).

Obesity has been shown by numerous studies to be associated with an approximately 1.5- to 2-fold increase in risk of death from CHD, with the increase in risk beginning below the 25 kg/m^2 cut point for overweight. Numerous studies also show approximately 20% to 40% lower risks of mortality and cardiovascular events associated with increased levels of physical activity or measured fitness. Cardiovascular risk factors are linked to obesity, including hypertension, dyslipidemia (including low HDL-cholesterol levels), type 2 diabetes, obstructive sleep apnea, and hyperinsulinemia. Increases in physical fitness have also been shown to be linked to increases in HDL-cholesterol levels and reductions in systolic and diastolic blood pressure, insulin resistance, and glucose intolerance. Abdominal obesity, most commonly indicated by a waist circumference of > 40 in. in men or > 35 in. in women, is a major component of the metabolic syndrome. Studies demonstrate that weight loss can substantially improve many cardiometabolic risk factors.

The National Institutes of Health Obesity Educational Initiative provides guidelines on the identification, evaluation, and treatment of overweight and obese adults. Assessment includes measurement of body mass index, waist circumference, as well as accompanying other risk factors. Moderate hypocaloric diets of 1,000 to 1,200 kcal per day are generally recommended to provide moderate, sustained weight loss. Incorporating diet and exercise together has been shown to result in longer-term success in weight control.

Cardiovascular Disease Risk Assessment

To understand an individual's risk of CVD or CHD, it is important to understand an individual's "global risk" of developing the condition. Most typically, this involves determination of the future risk of developing CHD in the next 10 years. This can be done by various "risk assessment" algorithms. Most commonly used for this purpose are the Framingham Risk Algorithms that are recommended to assess an individual's 10-year risk of CHD for the purposes of appropriate stratification for risk-factor management, especially lipid management. From knowing an individual's age, gender, systolic blood pressure (and treatment status), current smoking status, total cholesterol, and HDL-cholesterol, for which each factor is assigned a certain number of points according to its presence (and degree) or absence, a total score is obtained (Tables 1 and 2), which corresponds to the probability of suffering a hard CHD event in the next 10 years based on Framingham follow-up data. If the projected 10-year risk of CHD is $< 10\%$, the individual is generally considered to be at low risk of CHD, 10% to 20% intermediate risk, and if $> 20\%$ is judged to be at high risk and, in fact, a CHD risk equivalent (a condition or combination of risk factors conferring a future risk or prognosis similar to that of diagnosed CHD). Besides known CHD, other CHD risk equivalents include diabetes and other forms of atherosclerotic disease such as peripheral arterial disease, significant carotid artery disease, or abdominal aortic aneurysm. Use of these algorithms have been recommended for those with at least two major risk factors out of the following: premature family history of CHD ($<$ 45 in male or $<$ 55 in female first-degree relative), low HDL-C, hypertension, cigarette smoking, and advanced age (male $\geq$ 55 years old or female $\geq$ 65 years old). Those with fewer than two risk factors are felt to be generally at lower risk, and those with diabetes, CHD, or other atherosclerotic disease would also be designated at high risk for aggressive treatment, so such a calculation would not be warranted in these individuals.

In those where a global risk estimate is obtained, depending on the risk status, the appropriate intensity of treatment for given risk factors is considered. For instance, if an individual is a high risk or a CHD risk equivalent, treatment for dyslipidemia would be recommended to reduce the LDL-cholesterol level to < 100 mg/dl. If at intermediate risk or low risk, however, these goals would be < 130 and < 160 mg/dl, respectively.

While estimation of global risk as described above is recommended, it may be best considered a starting point in risk assessment. The presence of other risk factors not included in the risk algorithms, such as abdominal obesity, elevated triglycerides (if severe enough), impaired fasting glucose, or a strong positive premature family history, if present, however, could be used by the clinician to stratify an individual's risk or intensity of treatment upward. Others have also recommended novel risk-factor

measures, such as C-reactive protein, a measure of systemic inflammation, or the presence of subclinical atherosclerosis, such as coronary artery calcium or carotid intimal media thicknesses, to aid in risk stratification, where if present in significant amounts, could be rationale for stratifying an individual's intensity for treatment upward. High levels of high-sensitivity C-reactive protein have been shown in numerous studies to be independently related to the risk of future cardiovascular events, although controversy remains as to whether it provides incremental prediction of risk over global risk assessment. Both carotid intimal medial thickness and coronary calcium measures have been shown in numerous studies to be associated with the future risk of cardiovascular events, independent of standard risk factors. Coronary calcium measures also provide incremental predictive value over global risk assessment for the prediction of cardiovascular events.

Cardiovascular Disease Prevention

Cardiovascular epidemiology and prevention encompasses an extensive field investigating the distribution and variation of CVD conditions, most notably CHD and stroke, their risk-factor determinants, and strategies at the population and individual levels aimed to prevent the development or recurrence of CVD. Epidemiologic approaches to studying CVD provide us with the tools for preventive efforts at the individual and population levels. *Primordial prevention* is aimed at prevention of the risk factor for CVD, such as efforts aimed to prevent hypertension, obesity, or dyslipidemia. *Primary prevention* focuses on the modification

of these and other known risk factors aimed to prevent the clinical manifestations of CVD, such as myocardial infarction and stroke. *Secondary prevention* focuses on those who already have manifestations of disease, but where aggressive control of risk factors can have a major impact in preventing recurrences of disease. Concerted efforts between governmental agencies, the community, and the private sector are required to best address our continuing epidemic of CVD.

Case-Cohort Studies

The case-cohort design was proposed by Ross Prentice as an alternative design in epidemiologic follow-up studies that is less expensive than a full-scale cohort study. The case-cohort design involves collecting covariate data only for cases, that is, subjects who experience the event of interest in a cohort, and for members of a relatively small randomly selected subcohort. The subcohort may serve as a comparison group for several different types of disease outcomes.

The case-cohort design can substantially reduce cost and effort of exposure assessment by limiting exposure to a small fraction of the cohort with only a small loss of efficiency compared with a full cohort design. The case-cohort design is most beneficial when the most expensive part of the study is not in ascertaining subjects but in measuring their exposures. If the main cost is in ascertainment, a full cohort analysis might be a more sensible approach to analysis.

The design is particularly suited to settings such as molecular epidemiologic studies, where raw materials for covariate information, for example, biospecimens, can be collected and stored. For the cases, these specimens can then be analyzed after the failure, that is, event of interest, has occurred, to determine what an

individual's levels of exposure were at the times before failure. The case-cohort design has been applied in cancer research, cardiovascular disease, and HIV research and has become increasingly popular in genetic epidemiologic studies.

Most methods used to study relative risks in failure time models are based on the Cox proportional hazards model, which assumes a multiplicative form for the model of disease occurrence

$$\lambda(t,x(t),\beta) = \lambda_0(t)rr(x(t),\beta),$$

where $x(t)$ denotes covariates at time t, $\lambda_0(t)$ stands for the baseline hazard rate for subjects with $x = 0$, and rr denotes the relative risk part, with $rr(x(t),\ 0) = 1$. Under the case-cohort design, most existing relative risk estimators are based on modifications of the full cohort partial likelihood score functions, by weighing the contributions from cases and subcohort members by the inverse of their true or estimated sampling probabilities. In the pseudo-likelihood approach proposed by Ross Prentice, for each failure, a sampled risk set is formed by the case and the controls who are in the subcohort. Subcohort members contribute to the analysis over the entire time on study, but the failures outside the subcohort contribute only at their failure times. The pseudo-likelihood contribution is based on the conditional probability that the case fails given that someone fails among those sampled into the risk set. The pseudo likelihood is then the product of the conditional probabilities over failure times. Letting Y_i denote the "at-risk" indicator of the ith subject at the failure time and rr the relative risk part, the pseudo likelihood is given by

$$\prod_{\text{failure times}} \frac{rr_{\text{case}}(x(t),\beta)}{\sum_{\text{case and subcohort}} Y_i rr_i(x(t),\beta)}$$

This pseudo likelihood differs from the partial likelihood for a full cohort study in that the denominator is summing over subjects at risk in the subcohort rather than subjects at risk in the entire cohort. In addition, as cases are added at the time of event, the risk sets are not nested.

The score of the pseudo likelihood has expected value of 0 at the true value of β, but the inverse information does not estimate the variance of the estimator due to sampling-induced covariances between the score terms. The estimator has an asymptotic normal distribution and several approaches to variance estimation are available. Standard Cox regression software can be used to estimate parameters for case-cohort samples; however, variance computations need to be adapted to accommodate the design, which can be done using the *delta beta* option available in many statistics software packages.

When a correlate of the exposure is available for all cohort members, an exposure-stratified subcohort may substantially improve efficiency over a randomly chosen subcohort.

Absolute risk can be estimated from the subcohort using, for example, the Nelson-Aalen estimator for the cumulative baseline hazard, $\int_0^t \lambda_0(u)du$, by summing up the contributions for failure times up to time t:

$$\frac{1}{1/f \sum_{\text{subcohort}} rr_i(x(t),\hat{\beta})},$$

where f denotes the proportion of the cohort sampled into the subcohort.

A second approach to sampling from assembled cohort studies is the nested case-control design. In the nested case-control design, cases of a disease that occur in a cohort are identified, and for each a specified number of matched controls is selected from among those cohort members who have not developed the disease by the time of disease occurrence in the case. Efficiency comparisons between the nested case-control design and the case-cohort design indicate that the former can be somewhat more efficient, due to the sampling-induced positive correlation in score terms in the case-cohort design.

An attractive feature and an advantage of the case-cohort design over the nested case-control design is that the subcohort may serve as the comparison group for multiple disease outcomes. Methods for variance adjustments and hypothesis testing when using a common control group for a range of disease outcomes in case-cohort studies have been proposed, and cause-specific baseline hazard estimates to obtain cause specific absolute risk estimates are available.

Case Definition

A case definition is a set of criteria used in making a decision as to whether an individual has a disease or health event of interest. Given that one of the goals of epidemiology is to quantify the magnitude of disease in a population, a case definition is an imperative step in this process because it establishes what criteria constitute a case of the disease. Case definitions are used both in ongoing public health surveillance and during outbreak investigations in field epidemiology.

A case definition should include several key characteristics. It should be clear, simple, and concise so that it can be easily applied to the population of interest. A case definition should be applied equally to all individuals being investigated. By applying the case definition in such a standardized way, the possibility of misclassification bias is minimized. Typically, a case definition includes both clinical and laboratory characteristics. These are ascertained by one or many methods that might include diagnosis by a physician, completion of a survey, and/or routine population screening methods. Individuals meeting a case definition can be categorized as ''confirmed,'' ''probable,'' or ''suspected.''

Case definitions are used in ongoing public health surveillance to track the occurrence and distribution of disease within a given jurisdiction. In the United States, the Centers for Disease Control and Prevention have published a list of uniform case definitions for the mandatory reporting of several diseases called ''Case Definitions for Infectious Conditions Under Public Health Surveillance.'' This list provides explicit case definitions for diseases of interest so that they can be reported by clinicians to public health authorities in a standard and uniform way across geographic locations. This is particularly useful for studies that compare the prevalence of disease across regions as they can use the same case definitions and, therefore, obtain a more accurate picture of disease.

The establishment and application of case definitions are also critical components of outbreak investigations in field epidemiology. A case definition is developed at an early stage of the outbreak investigation so that individual cases can then be identified. While the same criteria apply for developing a case definition in routine public health surveillance, in an outbreak investigation a case definition may also include information regarding person, place, and time, in addition to clinical and laboratory characteristics. For example, a case definition developed for a foodborne outbreak may include only those individuals who ate at a certain restaurant during a specified period of time. Furthermore, a case definition may initially be more broadly defined in an outbreak investigation scenario. This is done to increase sensitivity and therefore capture as many true cases as possible and minimize missing true cases. As the investigation continues and more knowledge is gained about the nature of the cases, the definition may be narrowed and therefore more specific. This is particularly important for a newly emerging disease where a standard case definition does not yet exist. An example of this was the outbreak of Severe Acute Respiratory Syndrome in Toronto in 2003 where a new case definition had to be developed as this was a new disease.

Case-Fatality Rate

Case-fatality rate (CFR) is a clinical measure that describes a person's likelihood of dying from a disease

once he or she is diagnosed with it. It is calculated by dividing the number of deaths from a specified disease during a specified time by the number of individuals who have that disease during that time and multiplying this ratio by 100. It is a measure of disease severity and is often used for prognosis. It can also be used to evaluate the effect of new treatments—with improved treatments, the CFR is expected to decrease. The CFR is not a constant; it can vary between populations and over time depending on the interplay between agent, host, and environment, as well as available treatments and quality of care. The higher the CFR, the higher the likelihood of dying from the disease.

Although CFR has a simple formula, getting an accurate estimate of CFR is not simple. One of the difficulties in estimating CFR is ensuring the accuracy of the numerator. This becomes harder as duration of the disease of interest lengthens because a person becomes more likely to die of another cause prior to death from the disease itself. As a result, the CFR may be underestimated because people who die from another cause will not be counted in the numerator although they may have died from the disease at a later date had they not succumbed to something else first. For an accurate estimate of CFR, one also must be certain that those included in the numerator actually died from the disease in question. If this number includes people who died from other causes, the CFR will be overestimated. These difficulties explain why CFR tends to be a measure used for acute infectious diseases or diseases with short duration rather than for chronic diseases or diseases with long duration.

The denominator used to calculate CFR can also pose a challenge for an accurate estimate. If less severe cases are missed, and therefore not included in the denominator, CFR will be overestimated. For example, underestimating CFR may occur because of an inaccurate denominator that is determined during the early stages of an investigation when people who have the disease in question are missed because they died of the disease prior to the investigation starting.

It is important to point out the difference between CFR and mortality rate. Although number of deaths is the numerator for both, mortality rate is calculated by dividing the number of deaths by the population at risk during a certain time frame, and as a true rate, it estimates the risk of dying of a certain disease. As an example, let us consider two populations. One of them has 1,000 people; of these, 300 people have the disease and 100 people die of it. In this case, the mortality rate for the disease is $100/1{,}000 = 0.1$, or 10%, and the CFR is $100/300 = 0.33$, or 33%. The other population also has 1,000 people but 50 people have the disease and 40 die from it. Here, the mortality rate is $40/1{,}000 = 0.04$, or 4%, and the CFR is $40/50 = 0.8$, or 80%. The incidence of death from the disease is higher in the first population, but the severity is greater in the second. This points to the fact that the two measures provide us with different information.

In summary, the CFR is a proportion that depicts the percentage of people diagnosed with a certain disease who die from the disease within a certain period of time after diagnosis and provides us with information about disease severity.

Case Reports and Case Series

Case reports and case series in epidemiology and medicine are a type of descriptive study based on singular or grouped uncontrolled observations of patients. Case reports are defined here as singular reports on one individual patient, while case series are collections of information on more than one patient. The subjects in a series usually share one or more common characteristics, such as disease, treatment, or side effect. Usually subjects are followed for a period of time to observe a particular outcome; however, for reasons often to do with convenience or practicability, series may be retrospective collections of patient histories. A series may also be purely descriptive of a point in time—for example, describing variations of clinical presentations. While some series are purely observational, case series can also be uncontrolled clinical trials of interventions, the most sophisticated of which are Phase I or II studies conducted by the pharmaceutical industry. Case

reports and series are an important part of medical publishing due to their perceived methodological ease and observational character.

The number of patients in series is not limited, and large observational studies may be considered case series. This definition by logical extension would also include any series of clinical or physiological experiments in healthy or diseased subjects provided it is uncontrolled; however, in practice these investigations are usually not considered case reports or series.

While case series have no explicit comparison group, most have implicit comparisons, namely, a "normal" clinical course or population. This comparison group may be mentioned or even quantified based on available clinical data.

The most undisputed and common usage of case reports is in clinical education. There they are used as a practical and easily available method to illustrate typical or unusual presentations or clinical courses. Most clinical teaching in medicine relies on cases discussed either informally during ward rounds, during more formalized conferences, or in publications.

Case reports and series are particularly valuable for the reporting of adverse events, where they are used to quickly alert the public to potential side effects of new interventions. Due to the limited number of patients exposed during the development of any clinical interventions, rare side effects usually cannot be detected; thus case reporting is essential in this area. Numerous guidelines have been developed to establish causal relationships in adverse event reporting. However, due to their anecdotal character, case reports and series of adverse events can lead to false-positive reporting. One example is Debendox (Bendectin), a drug that was licensed for pregnancy-related morning sickness. After unsubstantiated reports of fetal malformations, the drug failed on the market, even though large studies refused a causal relationship between the drug and the birth defects.

Case series have been and are extensively used to inform the practitioner about the clinical presentations of diseases or syndromes. They inform about the frequency of signs and symptoms and are thus indispensable for clinical science. Case series may also be used to identify a new set of signs, symptoms, or clinical course as a new pathological entity or separate a clinical entity as a different disease or syndrome. The latter may be comparative and then does not fulfill our criteria. Exceptional case reports may also illuminate the pathophysiology of a particular condition and may overlap with basic science reporting.

A particular strength of case reports is their use in genetics. A well-documented family history can identify a hereditary trait as well as its mode of inheritance and thus document genetic origin; however, it cannot illustrate the relevance of spontaneous mutations in clinical practice.

Case reports and case series have a long history of being used to establish therapeutic effect and to promote treatments that were later discarded because their beneficial effect could not be confirmed by more stringent research such as controlled clinical trials. Therefore, case reports and case series are now considered to be unsuitable for establishing the superiority of one treatment over another, and they have been shown to be particularly prone to reporting bias. However, case reports and series do influence clinical practice, and they remain the only source of information about new therapies under circumstances in which clinical trials are not feasible. To ensure that the information provided by case reports or series is optimized, reporting needs to be complete and transparent for the reader. The authors should give information about diagnosis and diagnostic criteria and outcome measurement, describe the treatment in detail, and use consecutive patients to avoid selection bias as much as possible. Exclusion and inclusion criteria should be explained, the patients must give informed consent, and reporting should be of intention to treat; that is, all patients who start a treatment must be followed and reported whether they finish the treatment or give it up. All issues pertinent to patient safety must be reported. Finally, the authors should describe the expected outcome under standard therapy or the natural course of the disease to give an indication of the comparative advantage or disadvantage of their therapy, although case series can never quantify this difference due to lack of controls. To improve the inference from case reports, the *n* of 1 randomized trial has been suggested, which is a crossover design used mainly to inform individual treatment decisions. In situations where the general outcome of a disease is death and patients on a new treatment survive, case reports and case series can reach the highest grade of evidence, and controlled trials are not needed to establish causal relation. Effects such as these are rare in medicine; an example is insulin treatment of type 1 diabetes mellitus. In observational case reports or

series, the distinction between innovative, often compassionate treatment and experimental clinical trials may be blurry. Phase I and II trials, however, are sophisticated clinical studies and cornerstones of drug development. Most of them are essentially case series, although some studies use placebo controls in Phase I to evaluate side effects, and in the later phases of Phase II drug development controls may be used; these trials may also be randomized.

Categorical Data, Analysis of

While many health-related outcomes are measured on a continuous basis (age, blood pressure, virus particles per milliliter of blood), many common types of epidemiologic data analysis are performed using categorical data. Categorical data are data that exist in discrete groupings. Categories may be predefined, such as gender (male or female), while others may be defined by cutpoints in the data, such as hypertensive (blood pressure greater than or equal to 120/80) or normotensive (blood pressure lower than 120/80). This type of classification results in having only two categories, as opposed to the full range of blood pressure measurements possible. Because these types of data are so common, a specialized field of statistical techniques has been developed. This section documents the key approaches for categorical data analysis used in epidemiology.

Simple Analysis

The 2×2 (“two-by-two”) table is frequently analyzed in very basic epidemiologic studies. This approach is suitable for a study with two levels of exposure (e.g., exposed, not exposed), two categories of outcome (e.g., disease, no disease), and no other factors that might influence the association between exposure and outcome (i.e., no confounding or effect modification). Table 1 displays the common layout of a 2×2 table for an epidemiologic study.

The type of study design will determine the methods used to compute measures of interest, such as the frequency of the outcome for each exposure group, or an estimate of the association between exposure and outcome. This entry will first focus on the simple 2×2 table, and then cover stratified analysis of 2×2 tables to assess the influence of confounding and effect modification.

Simple (Crude) Analysis of Cohort Studies and Randomized Trials

In cohort studies, the investigator wants to determine if an exposure causes new cases of disease (or other outcome). While no single cohort study can definitively prove such a relationship, determining causation is the underlying goal of the research. Cohort studies provide at least two pieces of information

Table 1 Classic 2×2 Table for Epidemiologic Study Data Analysis

	Outcome	No Outcome	Total
Exposed	a	b	$a+b$
Not exposed	c	d	$c+d$
Total	$a+c$	$b+d$	$T=a+b+c+d$

that are useful in understanding causal relationships: (1) determining if an association between exposure and outcome exists (including strength of association) and (2) temporal association. At the beginning of the study period, individuals are classified as exposed or not exposed, and no participants have the outcome of interest. Participants are followed forward to determine who develops the outcome.

From a study design perspective, prospective cohort studies and randomized trials are very similar, primarily differing in how exposure status is assigned. In randomized trials, exposure is assigned by the researchers based on a random assignment protocol, while in cohort studies, exposure is not under the control of the experimenter. The same analytic methods are appropriate for both cohort studies and randomized trials.

A Simple Example With Equal Follow-Up Time

A classic example of a retrospective cohort study is a food poisoning outbreak at a wedding reception. The day after attending an outdoor reception catered by a local company, 65 of 130 guests had symptoms of gastroenteritis (i.e., vomiting, diarrhea, stomach cramps) that resulted in an emergency department visit for medical care. The epidemiologist interviewed all 130 individuals who attended the reception and determined what they ate, if they had symptoms of gastroenteritis, and when those symptoms began. All individuals were asked about symptoms on the wedding day and for the week after the wedding. The investigation identified another 7 individuals with symptoms meeting the case definition for the disease, bringing the total to 72 cases. Of these, 4 people had these symptoms the morning of the wedding. Because of the warm afternoon sun at the reception, consumption of potato salad was suspected as the source of infection (the exposure). Table 2 was designed for the data analysis:

Table 2 Example: Hypothetical Outbreak of Gastroenteritis Among Wedding Guests

	Disease	*No Disease*	*Total*
Potato salad	66	34	100
No potato salad	2	24	26
Total			126

Note that the total for the analysis is 126, not 130. This is because in cohort studies, all individuals must be outcome-free at the beginning of the study. Since 4 people reported symptoms starting before the wedding, this illness could not have been caused by food consumed at the reception. Incidence of disease, meaning the amount of new disease, for exposed and nonexposed individuals is computed using *incidence proportions* (also called *cumulative frequencies*).

$$\begin{aligned}&\text{Incidence proportion (ate potato salad)}\\&= a/(a+b)\\&= 66/100\\&= 0.660\\&= 66\%.\end{aligned}$$

$$\begin{aligned}&\text{Incidence proportion (did not eat potato salad)}\\&= c/(c+d)\\&= 2/26\\&= 0.077\\&= 7.7.\end{aligned}$$

Thus, 66% of individuals who ate potato salad at the wedding developed gastroenteritis during the following week; 7.7% of those who did not eat potato salad became ill with gastroenteritis. Two measures help clarify the association between exposure and disease; that is, are people at more risk of developing gastroenteritis if they ate potato salad than if they did not? The *relative risk* is the ratio of the two incidence proportions:

$$\text{Relative risk} = 0.660/0.077 = 8.6.$$

Those who ate potato salad were about eight times more likely to develop gastroenteritis in the following week compared with those who did not. This is far in excess of a relative risk of one, which would indicate no association between exposure and outcome; that is, the frequency of disease is the same regardless of exposure.

The *risk difference* is the difference of the two incidence proportions.

$$\text{Risk difference} = 0.660 - 0.077 = 0.583 = 58.3/100.$$

The risk difference is helpful to understand how many people developed the outcome because they

were exposed (if the exposure was causal). Another term for risk difference is *attributable risk*, because if the exposure is causal, this provides an estimate of the number of people who developed disease attributable to the exposure. In this case, the risk difference is 0.583, or 58.3/100. That is, of the 100 people exposed to potato salad, it is estimated that 58 people developed gastroenteritis because they ate it. What about the other 8 people who ate potato salad and developed gastroenteritis? Based on the proportion of people who developed gastroenteritis in the nonexposed group, there is at least a potential that about 8 people in the exposed (potato salad) group developed gastroenteritis from other causes. There are several possible explanations, including a different source of gastroenteritis causing disease in the community.

In this example, everyone was followed for 1 week (or until they became ill). So everyone had an equal chance to be discovered ill by the epidemiologist conducting the investigation. The measures of incidence and related measures of association described in this section are appropriate only if everyone in the study is followed for the same length of time or until developing the outcome.

For *cross-sectional* studies, the analysis methods are the same as presented in this section for cohort studies; however, the difference in interpretation is critical. In cross-sectional studies, prevalence is measured, not incidence. Thus, the measure of association focuses on factors associated with existing disease, not new disease or outcome.

Unequal Follow-Up Time for Cohort Studies and Randomized Trials

When a study is conducted over a longer period of time, it is unlikely that everyone will be followed for the entire study period. In a hypothetical 20-year follow-up study, if one person is followed for 1 year and another individual is followed for 15 years, there is more opportunity to identify disease (or another outcome) in the second person compared with the first. Thus, when unequal lengths of follow-up in cohort studies or randomized trials occur, incidence is measured as a rate and risk can be estimated from the rate if desired.

Consider a hypothetical study of a toxic exposure in a small community of 2,000 people. Public health epidemiologists registered people in the community and determined their exposure based on laboratory tests and the person's location during the brief exposure period. Then, the individuals in the registry were monitored to determine what health effects, if any, were related to exposure. The exposures were grouped into three categories: (1) low ($n = 1{,}200$), (2) moderate ($n = 500$), and (3) high ($n = 300$). Over time, some people were lost to follow-up. Every 5 years, the epidemiologists analyzed the data to determine if there was any identifiable disease related to exposure. Because the toxins were known to cause respiratory tract diseases, the focus of investigation was specific to lung diseases. After 10 years of follow-up, the incidence rates were as calculated as shown in Table 3:

Incidence rate (low exposure)
$= 7/10{,}987$ person-years at risk
$= 6.4$ per 10,000 person-years at risk.
Incidence rate (moderate exposure)
$= 15/4837$ person-years at risk
$= 31.0$ per 10,000 person-years at risk.
Incidence rate (high exposure)
$= 12/2878$ person-years at risk
$= 41.7$ per 10,000 person-years at risk.

The reason that the person-years at risk do not add up to 12,000, 5,000, and 3,000, respectively, is because each person was not followed disease-free for 10 years. A contribution of less than 10 years occurs if (1) a person develops lung disease (no longer at

Table 3 Example: Toxic Exposure in Small Community

	Low Exposure	*Moderate Exposure*	*High Exposure*	*Total*
Number of cases of lung disease	7	15	12	34
Person-years of risk (py)	10,987	4,837	2,878	18,702
Rates per 10,000 py	6.4	31.0	41.7	18.2

risk) or (2) a person is lost to follow-up and the outcome of interest (lung disease) is unknown.

$$\begin{aligned}&\text{Rate ratio (comparing moderate with low exposure)}\\&\quad = 31/10{,}000 \text{ person-years}\\&\quad = 4.84 = 6.4/10{,}000 \text{ person-years.}\\&\text{Rate ratio (comparing high with low exposure)}\\&\quad = (41.7/10{,}000 \text{ person-years})/\\&\qquad (6.4/10{,}000 \text{ person-years}) = 6.52.\\&\text{Rate difference (comparing moderate with}\\&\quad \text{low exposure}) = (31/10{,}000 \text{ person-years})\\&\qquad\qquad - (6.4/10{,}000 \text{ person-years})\\&\qquad\qquad = 24.6/10{,}000 \text{ person-years.}\\&\text{Rate difference (comparing high}\\&\quad \text{with low exposure}) = (41.7/10{,}000 \text{ person-years})\\&\qquad\qquad - (6.4/10{,}000 \text{ person-years})\\&\qquad\qquad = 35.3/10{,}000 \text{ person-years.}\end{aligned}$$

Thus, the rate at which the groups develop disease increases as the level of exposure increases. For those with low exposure, about 6 persons develop disease for each 10,000 person-years of risk that occurs. The rate of disease is about 4.8 and 6.5 times faster for those who had a moderate or high exposure compared with low exposure.

The rate difference provides insight into the estimated number of people who may have become sick due to the exposure, if it was truly responsible for the disease differentials. Using these calculations, for every 10,000 person-years of moderate exposure, about 24 cases of lung disease potentially could be attributed to exposure. Given that there were about 5,000 person-years at risk that experienced moderate levels of toxic exposure in the 10-year period of the study, there may be about 12 cases of lung disease that occurred related to moderate exposure. It is important to emphasize that this example proposes a situation where the "toxic exposure" is causing the increased risk of disease seen.

Case-Control Study and Odds Ratio

In contrast to the cohort studies discussed above, the analysis of case-control studies is not straightforward because of the way study participants are selected. In a case-control study, participants are selected on outcome status and then their exposure is determined.

Table 4 Example: Consumption of Tea and Oral Cancer

	Oral Cancer	*No Oral Cancer*
At least 1 cup of tea/day	46	199
Less than 1 cup of tea/day	28	205
Total	74	404

This presents the problem of not being able to look at incidence proportions for the different exposure groups, as was done for the wedding outbreak above. The basic statistic of interest in a case-control study is the relative odds (also called the odds ratio [*OR*]) of exposure between the cases and controls.

Consider a hypothetical study designed to assess if there was a difference in development in oral cancer based on tea consumption. Cases were identified as patients in a specific region with newly diagnosed oral cancer, and controls were people randomly selected from the same region. Note that in modern epidemiology, controls are selected to represent the population from which the cases arose. Thus, it is possible that a person with oral cancer can be in the control group; however, this is very unlikely due to the rarity of oral cancer. In this example, no one in the control group has oral cancer. Epidemiologists interviewed the cases and controls to determine if they drank an average of at least one cup of tea per day or if they drank less than one cup of tea per day, on average. The results are shown in Table 4.

Odds are calculated as the number of exposed cases (or controls) divided by the number of unexposed cases (or controls).

$$\begin{aligned}&\text{Odds of exposure among cases}\\&\quad = a/c = 46/28 = 1.64.\\&\text{Odds of exposure among controls}\\&\quad = b/d = 199/205 = 0.97.\end{aligned}$$

The relative odds or odds ratio is calculated by dividing the odds of exposure among cases by the odds of exposure among controls.

$$\begin{aligned}\text{Odds ratio} &= \text{Relative odds of exposure}\\&\qquad (\text{cases compared with controls})\\&= (a/c)/(b/d) = (ad)/(bc) = 1.69.\end{aligned}$$

Note that the relative odds of exposure are mathematically equivalent to the relative odds of having the disease for exposed compared with nonexposed.

$$\text{Relative odds of disease (exposed compared with nonexposed)} = (a/b)/(c/d) = (ad)/(bc).$$

Thus, in this hypothetical example, the odds of drinking at least one cup of tea per day are about 1.7 times as high in individuals with oral cancer compared with individuals without oral cancer. Because of the study design, no direct estimates of risk can be calculated for the given exposures, and therefore, relative risk and risk difference measures cannot be calculated from the analysis of a case-control study. However, if the disease being studied is rare, commonly defined as less than 10% in all exposure categories, then the odds ratio estimates the relative risk. Thus, the interpretation of this study is that the risk of developing oral cancer among daily tea drinkers is about 1.7 times that of those who drink less or no tea. In epidemiology, if the odds ratio does not estimate the relative risk, it is rarely of interest.

Confidence Intervals and Test Statistics

When reporting estimates, whether incidence, prevalence, proportion exposed, or measures of association, it is important to provide some estimate of precision. The most common form is the confidence interval. Confidence intervals are based on classical statistics theory that requires some form of random selection or random assignment (conditions rarely met in epidemiologic studies). However, confidence intervals are often used for epidemiologic studies that do not involve randomization and are more loosely interpreted as information on precision of the estimate. Confidence intervals for ratio measures (e.g., relative risk, odds ratio) are highly skewed, and thus their confidence intervals are not symmetrical. Fortunately, as long as the sample size of the study is reasonably large, the natural logarithm of the ratio measure (e.g., relative risk, odds ratio, rate ratio) has an approximately normal distribution. Thus, to compute a confidence interval for ratio measures, we first take the logarithm of the measure, compute the confidence interval for the logarithm of the measure (e.g., ln(odds ratio)), then transform the confidence interval by exponentiating each value to obtain the confidence interval in the original units.

For example, using the data from the case-control study, the $OR = 1.69$. Thus,

$$\ln(OR) = 0.52.$$

The variance of the $\ln(OR) = 1/a + 1/b + 1/c + 1/d$.

$$\text{Variance}[\ln(OR)] = 1/46 + 1/199 + 1/28 + 1/205 = 0.067$$

$$95\%\text{confidence interval for } \ln(OR): \ln(OR) + z_{1-\alpha/2} \times \sqrt{\text{variance}[\ln(OR)]}$$

$$0.52 + 1.96 \times (0.259).$$

Exponentiating, the 95% confidence interval for *OR* is (1.01, 2.80).

The Chi-Square Test

The presence of an association between two categorical variables, such as exposure and outcome, can also be tested using the chi-square (χ^2) test statistic. The χ^2 test is used to determine if the observed data in a 2×2 table are statistically significantly different from what would be expected, given the row and column totals for the table. Chi-square testing can be performed for a single 2×2 table, or it can be used to test for overall association when performing stratified analysis, which is discussed in detail below. Chi-square testing is not recommended when the cell counts are low, often defined as having one or more cells with expected value below five, or when there are empty cells in the table.

For a simple table, the χ^2 test statistic is calculated as

$$\chi^2 = \Sigma[(\text{observed data} - \text{expected data})^2/(\text{expected data})],$$

where observed data are the frequencies for the individual cells in the table as observed in the study, and expected data are the frequencies that would be expected, given the distribution of the data in the margins, if there was no association between exposure and outcome. Critical values for the χ^2 distribution are found using a standard χ^2 table, with knowledge of the significance level (α) and the degrees of

freedom. Degrees of freedom for a table are calculated as follows:

$$\text{Degrees of freedom} = (\text{No. of rows} - 1) \times (\text{No. of columns} - 1).$$

Thus, for a 2×2 table, there will be 1 *df*.

The calculation of the χ^2 test statistic will be illustrated using the case-control study example from above. Observed and expected data are shown in Table 5.

Based on these data,

$$\chi^2 = (46-38)^2/38 + (199-207)^2/207 + (28-36)^2/36 + (205-197)^2/197 = 4.10.$$

The critical value for the χ^2 distribution for significance at the $\alpha = .05$ level with 1 *df* is 3.84. Since the computed χ^2 test statistic is greater than the critical value, the null hypothesis of no association between exposure and outcome can be rejected, indicating that there is a statistically significant association. This corresponds to what was found in the calculation of the confidence interval for the odds ratio, where the null value (i.e., 1) was not contained in the calculated confidence interval. The χ^2 test statistic is based on classical statistical theory that requires random sampling, a requirement seldom met in epidemiology studies. In general, epidemiologists focus primarily on estimates and compute a confidence interval to provide some indication of precision rather than relying on test statistics and *p* values because the latter provide limited information given that assumptions for the test typically are not met.

Stratified Analysis: Considering Potential Confounders and Effect Modifiers

Rarely is the association between exposure and outcome unaffected by other factors. Issues of confounding, effect modification, and mediation are particularly important considerations in epidemiologic studies.

Effect Modification

Effect modifiers are factors that modify the relationship between exposures and outcomes. For example, boys have three times the asthma incidence as girls until puberty; after puberty, the asthma incidence is about the same for both boys and girls. For example, analyzing the association between gender and asthma, without considering age, using a simple 2×2 table would not reveal this complexity because all ages would be combined in the table. Stratified analysis is a simple approach that provides an opportunity to examine the potential role of effect modifiers.

In its simplest form, stratified analysis uses 2×2 table data analysis techniques, creating a separate table for each subgroup. For the example of gender and asthma incidence, age is an effect modifier, thus a separate table needs to be made for each age group, as shown in Table 6.

Because the association between gender and asthma incidence is different according to age group, there is no value in combining the information.

Table 5 Observed Data and Expected Data

	Oral Cancer	*No Oral Cancer*	*Total*
Observed data			
≥ 1 cup of tea/day	46	199	245
< 1 cup of tea/day	28	205	233
Total	74 (15.5%)	404 (84.5%)	
Expected data			
≥ 1 cup of tea/day	$245 \times 0.155 = 38$	$245 \times 0.845 = 207$	245
< 1 cup of tea/day	$233 \times 0.155 = 36$	$233 \times 0.845 = 197$	233
Total	74 (15.5% = 0.155)	404 (84.5% = 0.845)	

Table 6 Example: Stratified Analysis of Gender and Asthma

Age: 13 Years or Older		
	Asthma	*No Asthma*
Boys	**Relative Risk = 1**	
Girls		

Age: Less Than 13 Years		
	Asthma	*No Asthma*
Boys	**Relative Risk = 3**	
Girls		

Rather, the answer to the question "What is the association between gender and asthma incidence among children?" must be "It depends on the age of the children." When effect modification occurs, an overall estimate of the association might be misleading. In fact, an overall relative risk that combines all ages likely would partially hide the strong association between gender and asthma among young children and erroneously suggest that there is an association between gender and asthma among older children.

Clinical medicine incorporates effect modifiers frequently for medication decisions. For example, it is known that oral contraceptives are associated with an increased risk of stroke. However, clinical researchers found that the association between oral contraceptives and stroke varies based on a woman's age, smoking status, and presence of hypertension. The risk of stroke is low for young, nonsmoking women without hypertension but increases for older women, smokers, and those with hypertension. These relationships were identified, in part, through a stratified analysis where the association between oral contraceptives and stroke was studied for each combination of age, smoking, and hypertension.

Confounding

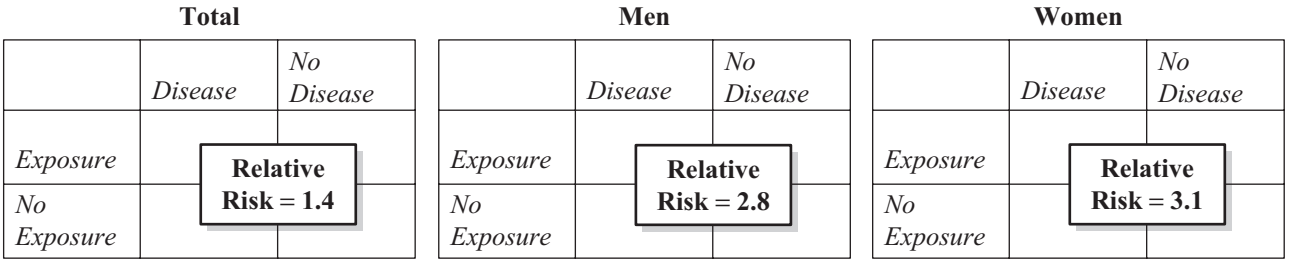
Three key criteria define a confounder: (1) risk factor for the outcome being studied, (2) associated with the exposure being studied independent of the outcome, and (3) not in the causal pathway between the exposure and outcome. Confounders are nuisance factors for the research at hand; if ignored, they can distort the true association between exposure and outcome, resulting in incorrect (biased) estimates. However, if information on confounders is collected, they can be neutralized in the study design or statistical analysis. That is, their effect can be controlled in the analysis so that these factors do not bias the measure of association between exposure and outcome. We focus on confounding in the absence of effect modification. If effect modification by a factor exists, whether the factor is also a confounder is not important from a decision-making perspective in the analysis process.

Confounding can be assessed using stratified analysis. When the data are stratified on a potential confounder, confounding exists if the stratum-specific estimates are (1) approximately the same and (2) different from the overall (also called simple or crude) analysis. Consider the example of a 2-year study between an exposure and disease where gender is thought to be a potential confounder. The stratified analysis results are in Table 7.

For men, exposure is associated with about three times more disease than nonexposure. The same is true for women. However, when all data are combined, the relative risk is 1.4—very different from the stratified results. The difference in overall relative risk is due to confounding. Simply put, the overall estimate of the relative risk is *wrong*. The best estimate of the association between exposure and disease is about 3.

When confounding occurs, the stratum-specific estimates tend to be similar but not exactly the same. Unlike effect modification, where the stratum-specific rates enhance the explanation of the relationship between exposure and outcome, confounding simply distorts the estimate of association between exposure and outcome. Thus, it makes sense to combine the strata into one estimate, as described in the next section.

Table 7 Example of Confounding



Adjusted Estimates of Measures of Association

Epidemiologists have several techniques to remove the confounding effect in an estimate of the association between an exposure and outcome. This process is known as adjusting for confounders. Two methods of estimation that are particularly popular use a stratified analysis approach; both take weighted averages of the stratum-specific estimates.

Mantel-Haenszel Stratified Analysis

The Mantel-Haenszel method is the best-known method for estimating an adjusted measure of association to control for confounding. This method takes a weighted average of the stratum-specific estimates making two key assumptions: (1) The sample size overall is large (note that the sample sizes in the strata may be small but the total sample size must be large), and (2) there is no association between the exposure and outcome. This last assumption appears to be unreasonable for most studies; however, if an association exists and the ratio measure is between 0.4 and 2.5, then the assumption of no association produces only a minor bias toward the null value (i.e., the estimate is slightly biased underestimating the strength of association). Most studies of risk factors for chronic diseases meet this strength criterion. The first assumption is not needed to compute an adjusted estimate but is important to compute confidence intervals or test statistics.

The Mantel-Haenszel method was developed in 1959 when computers were not commonly available. From a computational perspective, its attraction was substantially due to its simplicity. Because of the assumption of no association, the formula for a weighted average of stratum-specific estimates becomes very easy to compute by hand. This particular advantage is no longer important given the availability of computers.

Mantel-Haenszel estimates have another important advantage when dealing with data that include empty cells. When taking weighted averages of strata-specific estimates, in most situations, if a zero occurs in a stratum, even if there are 100 people in the stratum, no data from that stratum will be incorporated into the overall adjusted estimate of the measure of association. The reason is because the measure of association (e.g., relative risk, odds ratio) would be either zero or not defined for the stratum. However, the Mantel-Haenszel method will typically incorporate about half of the information from that stratum into the overall adjusted estimate. Thus, if a zero cell exists, more information will be used by the Mantel-Haenszel method than by other methods also designed to calculate a weighted average of the strata-specific estimates.

The confidence interval for a Mantel-Haenszel adjusted estimate is called a *test-based confidence interval.* The reason it is called test-based is because it is developed from the Mantel-Haenszel test statistic, based on the assumption that no association between exposure and outcome exists.

Precision-Based (Taylor Series) Stratified Analysis

The precision-based, or Taylor series, approach to stratified analysis also takes a weighted average of the stratum-specific estimates (e.g., relative risks). The weight for each stratum is the inverse of the variance

for that stratum. This selection of weights is very common in statistics. The estimate from the stratum with the most data, and thus the most information, typically has the largest weight; similarly, the estimate from the stratum with the least data typically has the smallest weight. Therefore, the overall estimate of association, controlling for the confounder (or confounders), is pulled toward the stratum with the most information. The main disadvantage of this method is that if a stratum has a zero cell, then none of the data in that stratum may be included in the analysis. If no zero cells exist, then this approach is mathematically stronger than the Mantel-Haenszel method because no assumption about the strength of association is needed.

Formulas for computing Mantel-Haenszel and precision-based point estimates, confidence intervals, and overall tests of association are displayed in Table 8.

Stratified Analysis Problem

Most real studies provide data that are not straightforward as in the examples above. The purpose of presenting this problem is to provide an example of stratified analysis using real data and provide some insight into how decisions are made by epidemiologists during the analytic process. This study concerns the number of cesarean sections performed in two regions of a state. The researchers took a quick look at the association between region (exposure) and type of delivery (outcome) for women hospitalized in these regions with their first singleton delivery. This simple analysis is presented in Table 9.

$$\text{Relative risk} = \frac{28.1\%}{17.1\%} = 1.64.$$

Before concluding that the proportion of cesarean sections is higher in Region A due to physician practice (the leading hypothesis), it is important to consider potential confounders and effect modifiers. For instance, the reason for the difference could be due to differences in age or comorbidities (i.e., differences in guideline-appropriate cesarean sections are due to underlying patient characteristics among women giving birth in the two regions). There are several methods to evaluate if ''other factors'' are the reason for an association.

Table 10 presents the data stratified in three ways: on age, receipt of Medicaid benefits (a proxy measure for poverty), and comorbidities. Looking at the age stratification, for girls 16 to 17 years of age, Region A is associated with about 2.2 times the number of cesarean sections compared with Region B. However, for women 18 to 49 years, Region A is associated with about 1.5 times the cesarean sections compared with Region B. There are relatively fewer girls delivering their first baby compared with women 18 years and older, so the confidence interval is larger for the stratum of girls than the stratum of women. Also, while there are fairly large differences in percentages of cesarean sections for women 18 to 34 years and 35 to 49 years within each region, the relative risks for each age group are only moderately different. This distinction is important: Careful analysis requires looking at both the percentages and the measures of association.

Examination of the other stratification variables indicates that women with comorbidities were more likely to have a cesarean section and those with Medicaid were slightly less likely to have a cesarean section. These results are expected, but it is always good to assess if the study's data are consistent with the literature.

Stratification allows for the evaluation of confounding and effect modification simultaneously, using the general criteria for confounders and effect modifiers discussed above. Considering the association between

Table 8 Formulas for Precision-Based and Mantel-Haenszel Point Estimates and Confidence Intervals for Cumulative Incidence Ratio, Incidence Density Ratio, and Odds Ratio

Based on a series of stratified tables laid out as

	Outcome	*No Outcome*	
Exposure	a_i	b_i	N_{1i}
No exposure	c_i	d_i	N_{01}
	M_{1i}	M_{0i}	T_i

The following formulas can be used:

	Cumulative Incidence Ratio	*Incidence Density Ratio*
Precision-based point estimate	$aCIR = \hat{e}\left[\dfrac{\sum_{i=1}^{I}\left(\dfrac{a_i c_i N_{1i} N_{0i}}{a_i d_i N_{1i} + b_i c_i N_{0i}}\right)\left(\ln \hat{CIR}_i\right)}{\sum_{i=1}^{I}\left(\dfrac{a_i c_i N_{1i} N_{0i}}{a_i d_i N_{1i} + b_i c_i N_{0i}}\right)}\right]$	$aIDR = \hat{e}\left[\dfrac{\sum_{i-1}^{I}\left(\dfrac{a_i b_i}{a_i + b_i}\right)\left(\ln \hat{IDR}_i\right)}{\sum_{i-1}^{I}\left(\dfrac{a_i b_i}{a_i + b_i}\right)}\right]$
Precision-based confidence interval	$\hat{e}\left[\ln\left(\hat{aCIR}\right) \pm z_{1-\alpha/2}\left(\dfrac{1}{\sqrt{\sum_{i=1}^{I}\left(\dfrac{a_i c_i N_{1i} N_{0i}}{a_i c_i N_{1i} + b_i c_i N_{0i}}\right)}}\right)\right]$	$\hat{e}\left[\ln\left(\hat{aIDR}\right) \pm z_{1-\alpha/2}\left(\dfrac{1}{\sqrt{\sum_{i=1}^{I}\left(\dfrac{a_i b_i}{a_i + b_i}\right)}}\right)\right]$
Mantel-Haenszel point estimate	$mCIR = \dfrac{\sum_{i=1}^{I}\dfrac{a_i N_{0i}}{T_i}}{\sum_{i=1}^{I}\dfrac{c_i N_{1i}}{T_i}}$	$mIDR = \dfrac{\sum_{i=1}^{I}\dfrac{a_i N_{0i}}{T_i}}{\sum_{i=1}^{I}\dfrac{b_i N_{1i}}{T_i}}$
Mantel-Haenszel confidence interval	$\hat{e}\left[\ln \hat{mCIR} \pm z_{1-\alpha/2}\sqrt{\dfrac{\sum_{i=1}^{I}\dfrac{(M_{1i}N_{1i}N_{0i} - a_i c_i T_i)}{T_i^2}}{\left(\sum_{i=1}^{I}\dfrac{a_i N_{0i}}{T_i}\right)\left(\sum_{i=1}^{I}\dfrac{c_i N_{1i}}{T_i}\right)}}\right]$	$\hat{e}\left[\ln \hat{mIDR} \pm z_{1-\alpha/2}\sqrt{\dfrac{\sum_{i=1}^{I}\dfrac{(M_{1i}N_{1i}N_{0i})}{T_i^2}}{\left(\sum_{i=1}^{I}\dfrac{a_i N_{0i}}{T_i}\right)\left(\sum_{i=1}^{I}\dfrac{b_i N_{1i}}{T_i}\right)}}\right]$
Mantel-Haenszel test statistic for overall association	$\chi^2_{MH} = \dfrac{\left(\sum_{i=1}^{I}\left(\dfrac{a_i d_i - b_i c_i}{T_i}\right)\right)^2}{\sum_{i=1}^{I}\dfrac{N_{1i}N_{0i}M_{1i}M_{0i}}{T_i^2(T_i - 1)}}$	$\chi^2_{MH} = \dfrac{\left(\sum_{i=1}^{I} a_i - \sum_{i=1}^{I}\dfrac{M_{1i}N_{1i}}{T_i}\right)^2}{\sum_{i=1}^{I}\left(\dfrac{M_{1i}N_{1i}N_{0i}}{T_i^2}\right)}$

(Continued)

(Continued)	*Odds Ratio*
Precision-based point estimate	$aOR = \hat{e}\left[\dfrac{\sum_{i=1}^{I}\left(\frac{1}{\frac{1}{a_i}+\frac{1}{b_i}+\frac{1}{c_i}+\frac{1}{d_i}}\right)\left(\ln\ \hat{OR}_i\right)}{\sum_{i=1}^{I}\left(\frac{1}{\frac{1}{a_i}+\frac{1}{b_i}+\frac{1}{c_i}+\frac{1}{d_i}}\right)}\right]$
Precision-based confidence interval	$\mathrm{e}\left[\ln\left(a\hat{CIR}\right) \pm z_{1-\alpha/2}\left(\dfrac{1}{\sqrt{\sum_{i=1}^{I}\left(\frac{1}{\frac{1}{a_i}+\frac{1}{b_i}+\frac{1}{c_i}+\frac{1}{d_i}}\right)}}\right)\right]$
Mantel-Haenszel point estimate	$mOR = \dfrac{\sum_{i=1}^{I}\frac{a_i d_i}{T_i}}{\sum_{i=1}^{I}\frac{b_i c_i}{T_i}}$
Mantel-Haenszel confidence interval	$\hat{e}\left[\ln\ \hat{MOR} \pm z_{1-\alpha/2}\sqrt{\dfrac{\sum_{i=1}^{I}\left(\frac{a_i+d_i}{T_i}\right)\left(\frac{a_i d_i}{T_i}\right)}{2\left(\sum_{i=1}^{I}\frac{a_i d_i}{T_i}\right)^2} + \dfrac{\sum_{i=1}^{I}\left[\left(\frac{a_i+d_i}{T_i}\right)\left(\frac{b_i c_i}{T_i}\right)+\left(\frac{b_i+c_i}{T_i}\right)\left(\frac{a_i d_i}{T_i}\right)\right]}{2\sum_{i=1}^{I}\left(\frac{a_i d_i}{T_i}\right)\sum\left(\frac{b_i c_i}{T_i}\right)} + \dfrac{\sum_{i=1}^{I}\left(\frac{b_i+c_i}{T_i}\right)\left(\frac{b_i c_i}{T_i}\right)}{2\left(\sum_{i=1}^{I}\frac{b_i c_i}{T_i}\right)^2}}\right]$
Mantel-Haenszel test statistic for overall association	$\chi^2_{\mathrm{MH}} = \dfrac{\left(\sum_{i=1}^{I}\left(\frac{a_i d_i - b_i c_i}{T_i}\right)\right)^2}{\sum_{i=1}^{I}\frac{N_{1i}N_{0i}M_{1i}M_{0i}}{T_i^2(T_i-1)}}$

region and delivery type, stratified separately by each factor, it appears that

- Age is an effect modifier.
- Medicaid benefits is a confounder (both strata estimates are lower than the crude, thus the crude overall estimate would overestimate the true association).
- Comorbidity is an effect modifier.

The following thought process will help develop our conclusions. The first question to consider is, ''Does the crude result portray the overall association between the exposure and outcome?''

- If the answer is ''*yes*,'' then no adjusted or stratified estimates are needed. The analysis is done and the crude table with its estimates can be used to present the information.
- If the answer is ''*no*,'' then the next question is, ''Do we need to provide each stratum-specific estimate individually or can we summarize some or all of the estimates into one?'' The key point is to focus on what is the best way to explain the association between exposure (region) and outcome (type of delivery). In this example, $RR = 1.64$ does not provide a good estimate overall.

The literature also indicates that the more risk factors pointing to the benefit of cesarean sections, the more likely they will be done regardless of where a woman lives. This is called the *ceiling effect.* In this case, both older age and multiple comorbidities are

	18–49	1,956	27.7	5,104	72.3	986	19.8	3,990	80.2	1.23 (1.13, 1.33)

Note: Adjusted estimates for 18- to 49-year-olds are adjusted for age groups. All estimates adjusted for use of Medicaid insurance.

factors that increase the likelihood that a cesarean section would be beneficial, so it is likely that these factors would increase the proportion of cesarean sections being done anywhere. Thus, note that women 35 to 49 years with two comorbidities had the largest proportion of cesarean sections, but the relative risk portraying the association between regions and delivery type were some of the smallest in magnitude (i.e., 1.09 and 1.21), indicating a large proportion of births by cesarean section in this group, regardless of region.

Also note on the other extreme that for girls 16 to 17 who are healthy and unlikely to have a cesarean

section, a regional difference in practice patterns in this group will be most noticeable. In this example, it is clear that such an effect is evident. For the study at hand, there is no "correct" choice. It may be a study where Table 11 is provided. A smaller summary may be prepared as in Table 12. With only one anomaly in combining ages 18 to 49 years within the other two factors, the overall story appears reasonable to combine these ages. Collapsing the estimate by insurance type may also be useful.

To summarize, many decisions need to be made during the statistical analysis of epidemiologic data. Maintaining a focus on the research question of interest is important and more difficult for those with little experience. Understanding the nature of the association, including how the exposure may be related to the outcome, even if only theoretically, can aid the decision-making process.

Causal Diagrams

From their inception in the early 20th century, causal systems models (more commonly known as structural-equations models) were accompanied by graphical representations or path diagrams that provided compact summaries of qualitative assumptions made by the models. Figure 1 provides a graph that would correspond to any system of five equations encoding these assumptions:

1. Independence of *A* and *B*
2. Direct dependence of *C* on *A* and *B*
3. Direct dependence of *E* on *A* and *C*
4. Direct dependence of *F* on *C*
5. Direct dependence of *D* on *B*, *C*, and *E*

The interpretation of "direct dependence" was kept rather informal and usually conveyed by causal intuition, for example, that the entire influence of *A* on *F* is "mediated" by *C*.

By the 1980s, it was recognized that these diagrams could be reinterpreted formally as probability models, which opened the visual power of graph theory for use in probabilistic inference and allowed easy deduction of other independence conditions implied by the assumptions. By the 1990s, it was further recognized that these diagrams could also be

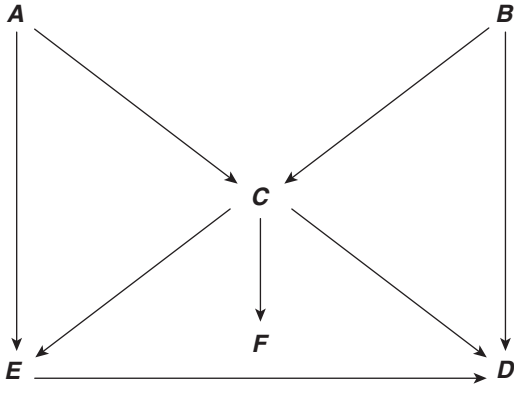

Figure 1 Example of a Directed Acrylic Graph

used as a formal tool for causal inference, such as predicting the effects of external interventions. Given that the graph is correct, one can see whether the causal effects of interest (target effects, or causal estimands) can be estimated from available data, or what additional observations are needed to validly estimate those effects. One can also see how to represent the effects as familiar standardized effect measures.

This entry gives an overview of (1) components of causal graph theory, (2) probability interpretations of graphical models, and (3) the methodological implications of the causal and probability structures encoded in the graph.

Basics of Graph Theory

As befitting a well-developed mathematical topic, graph theory has an extensive terminology that, once mastered, provides access to a number of elegant results that may be used to model any system of relations. The term *dependence* in a graph, usually represented by connectivity, may refer to mathematical, causal, or statistical dependencies. The connectives joining variables in the graph are called *arcs*, *edge*, or *links*, and the variables are also called *nodes* or *vertices.* Two variables connected by an arc are *adjacent* or *neighbors,* and arcs that meet at a variable are also adjacent. If the arc is an arrow, the tail (starting) variable is the *parent* and the head (ending) variable is the *child.* In causal diagrams, an arrow represents a "direct effect" of the parent on the child, although this effect is direct only relative to a certain level of abstraction, in that the graph omits any variables that might mediate the effect.

A variable that has no parent (such as A and B in Figure 1) is *exogenous* or *external*, or a *root* or *source* node, and is determined only by forces outside the graph; otherwise it is *endogenous* or *internal.* A variable with no children (such as D in Figure 1) is a *sink* or *terminal node.* The set of all parents of a variable X (all variables at the tail of an arrow pointing into X) is denoted by $\text{pa}[X]$; in Figure 1, $\text{pa}[D] = \{B, C, E\}$.

A *path* or *chain* is a sequence of adjacent arcs. A *directed path* is a path traced out entirely along arrows tail-to-head. If there is a directed path from X to Y, X is an *ancestor* of Y and Y is a *descendant* of X. In causal diagrams, directed paths represent causal pathways from the starting variable to the ending variable; a variable is thus often called a cause of its descendants and an effect of its ancestors. In a *directed* graph, the only arcs are arrows, and in an *acyclic* graph there is no feedback loop (directed path from a variable back to itself). Therefore, a directed acyclic graph (DAG) is a graph with only arrows for edges and no feedback loops (i.e., no variable is its own ancestor or its own descendant). A causal DAG represents a complete causal structure in that all sources of dependence are explained by causal links; in particular, all common (shared) causes of variables in the graph are also in the graph.

A variable *intercepts* or *mediates* a path if it is in the path (but not at the ends); similarly, a set of variables S intercepts a path if it contains any variable intercepting the path. Variables that intercept directed paths are *intermediates* on the pathway. A variable is a *collider* on the path if the path enters and leaves the variable via arrowheads (a term suggested by the collision of causal forces at the variable). Note that being a collider is relative to a path; for example, in Figure 1, C is a collider on the path $A \rightarrow C \leftarrow B \rightarrow D$ and a noncollider on the path $A \rightarrow C \rightarrow D$. Nonetheless, it is common to refer to a variable as a collider if it is a collider along any path (i.e., if it has more than one parent). A path is *open* or *unblocked* at noncolliders and *closed* or *blocked* at colliders; hence, a path with no collider (such as $E \leftarrow C \leftarrow B \leftarrow D$) is *open* or *active*, while a path with a collider (such as $E \leftarrow A \leftarrow B \rightarrow D$) is *closed* or *inactive.*

Two variables (or sets of variables) in the graph are *d-separated* (or just separated) if there is no open path between them. Some of the most important constraints imposed by a graphical model correspond to independencies arising from separation; for example, absence of an open path from A to B in Figure 1 constrains A and B to be marginally independent (i.e., independent if no stratification is done). Nonetheless, the converse does not hold; that is, presence of an open path allows but does not imply dependency. Independence may arise through cancellation of dependencies; as a consequence, even adjacent variables may be marginally independent; for example, in Figure 1, A and E could be marginally independent if the dependencies through paths $A \rightarrow E$ and $A \rightarrow C \rightarrow E$ canceled each other. The assumption of faithfulness, discussed below, is designed to exclude such possibilities.

Some authors use a bidirectional arc (two-headed arrow, $\leftrightarrow$) to represent the assumption that two

variables share ancestors that are not shown in the graph; $A \leftrightarrow B$ then means that there is an unspecified variable U with directed paths to both A and B (e.g., $A \leftarrow U \rightarrow B$).

Control: Manipulation Versus Conditioning

The word "control" is used throughout science, but with a variety of meanings that are important to distinguish. In experimental research, to control a variable C usually means to manipulate or set its value. In observational studies, however, to control C (or more precisely, to control for C) more often means to condition on C, usually by stratifying on C or by entering C in a regression model. The two processes are very different physically and have very different representations and implications.

If a variable X is influenced by a researcher, the DAG would need an ancestor R of X to represent this influence. In the classical experimental case in which the researcher alone determines X, R and X would be identical. In human trials, however, R more often represents just an *intention* to treat (with the assigned level of X), leaving X to be influenced by other factors that affect compliance with the assigned treatment R. In either case, R might be affected by other variables in the graph. For example, if the researcher uses age to determine assignments (an age-biased allocation), age would be a parent of R. Ordinarily, however, R would be exogenous, as when R represents a randomized allocation.

In contrast, by definition, in an observational study there is no such variable R representing the researcher influence on X, and conditioning is substituted for experimental control. Conditioning on a variable C in a DAG can be represented by creating a new graph from the original graph to represent constraints on relations within levels (strata) of C implied by the constraints imposed by the original graph. This conditional graph can be found by the following sequence of operations:

1. If C is a collider, join ("marry") all pairs of parents of C by undirected arcs; here dashed lines without arrowheads will be used (some authors use solid lines without arrowheads).
2. Similarly, if A is an ancestor of C and a collider, join all pairs of parents of A by undirected arcs.
3. Erase C and all arcs connecting C to other variables.

Figure 2 shows the graph derived from conditioning on C in Figure 1: The parents A and B of C are joined by an undirected arc, while C and all its arcs are gone. Figure 3 shows the result of conditioning on F: C is an ancestral collider of F and so again its parents A and B are joined, but only F and its single arc are erased. Note that, because of the undirected arcs, neither figure is a DAG.

Operations 1 and 2 reflect that if C depends on A and B through distinct pathways, the marginal dependence of A on B will *not* equal the dependence of A on B stratified on C (apart from special cases). To illustrate, suppose A and B are binary indicators (i.e., equal to 1 or 0), marginally independent, and $C = A + B$. Then among persons with $C = 1$, some will have $A = 1$, $B = 0$ and some will have $A = 0$, $B = 1$ (because other combinations produce $C \neq 1$). Thus, when $C = 1$, A and B will exhibit perfect negative dependence: $A = 1 - B$ for all persons with $C = 1$.

Conditioning on a variable C reverses the status of C on paths that pass through it: Paths that were open at C are closed by conditioning on C, while paths that were closed at C become open at C (although they may remain closed elsewhere). Similarly, conditioning on a descendant of C partially reverses the status of C: Typically, paths that were open at C remain open, but with attenuated association across the path; while paths that were closed at C become open at C, although not as open as when conditioning on C itself. In other words, conditioning on a variable tends to partially reverse the status of ancestors on paths passing through the ancestors. In particular, conditioning on a variable may open a path even if it is not on the path, as with F in Figure 1.

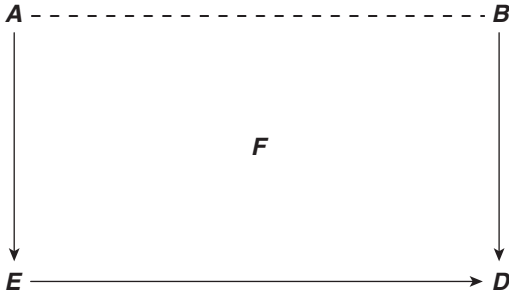

Figure 2 Graph Resulting From Figure 1 After Conditioning on C

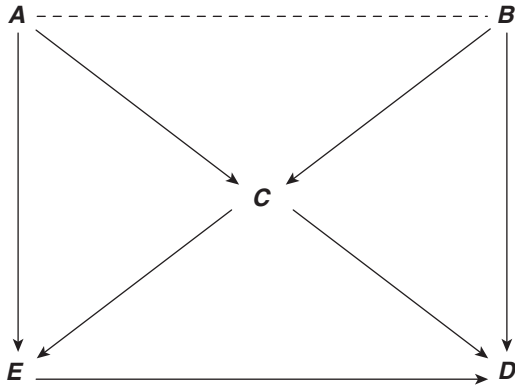

Figure 3 Graph Resulting From Figure 1 After Conditioning on F

A path is closed after conditioning on a set of variables S if S contains a noncollider along the path, or if the conditioning leaves the path closed at a collider; in either case, S is said to block the path. Thus, conditioning on S closes an open path if and only if S intercepts path and opens a closed path if S contains no noncolliders on the path and every collider on the path is either in S or has a descendant in S. In Figure 1, the closed path $E \leftarrow A \rightarrow C \leftarrow B \rightarrow D$ will remain closed after conditioning on S if S contains A or B or if S does not contain C, but will be opened if S contains only C, F, or both.

Two variables (or sets of variables) in the graph are *d-separated* (or just separated) by a set S if, after conditioning on S, there is no open path between them. Thus, in Figure 1, $\{A, C\}$ separates E from B, but $\{C\}$ does not (because conditioning on C alone results in Figure 2, in which E and B are connected via the open path A). In a DAG, pa[X] separates X from every variable that is not affected by X (i.e., not a descendant of X). This feature of DAGs is sometimes called the "Markov condition," expressed by saying the parents of a variable "screen off" the variable from everything but its effects. Thus, in Figure 1, pa[E] = $\{A, C\}$, which separates E from B but not from D.

Dependencies induced by conditioning on a set S can be read directly from the original graph using the criterion of *d-separation*, by tracing the original paths in the graph while testing whether colliders are, or have, descendants in S. The conditional dependencies are then illustrated in the original graph by drawing a circle around each C in S to denote the conditioning, then defining a path blocked by S if C is a noncollider on the path, or by a circle-free collider that does not have a circled descendant. Thus, if we circle C in Figure 1, it will completely block the $E - D$ paths $E \leftarrow C \leftarrow B \rightarrow D$ and $E \leftarrow A \rightarrow D$ but unblock the path $E \leftarrow A \rightarrow C \leftarrow B \rightarrow D$ via the circled collider C, which is equivalent to having a dashed arc as in Figure 2. Were we to circle F but not C, no open path would be completely blocked, but the collider C would again be opened by virtue of its circled descendant F, which is equivalent to having a dashed arc as in Figure 3.

Selection Bias and Confounding

There is considerable variation in the literature in the usage of terms such as *bias*, *confounding*, and related concepts that refer to dependencies that reflect more than just the effect under study. To capture these notions in a causal graph, we say that an open path between X and Y is a *biasing path* if it is not a directed path. The association of X with Y is then *unbiased* for the effect of X on Y if the only open paths from X to Y are the directed paths. Next, consider a set of variables S that contains no effect (descendant) of X (including those descended through Y). The dependence of Y on X is *unbiased given* S if, after conditioning on S, the open paths between X and Y are exactly (only and all) the directed paths in the starting graph. In such a case, we say S is *sufficient* to block bias in the $X - Y$ dependence and is *minimally sufficient* if no proper subset of S is sufficient.

The exclusion from S of descendants of X in these definitions arises first, because conditioning on X-descendants Z can partially block directed (causal) paths that are part of the effect of interest (if those descendants are intermediates or descendants of intermediates); and second, because conditioning on X descendants can unblock or create paths that are not part of the $X - Y$ effect, and thus create new bias. For example, biasing paths can be created when one conditions on a descendant Z of both X and Y. The resulting bias is called *Berksonian bias*, after its discoverer, Joseph Berkson.

Informally, confounding is a source of bias arising from causes of Y that are associated with but not affected by X. Thus, we say an open nondirected path from X to Y is a *confounding path* if it ends with an arrow into Y. Variables that intercept confounding paths between X and Y are *confounders.* If a confounding path is present, we say *confounding* is present and

that the dependence of Y on X is *confounded*. If no confounding path is present, we say the dependence is *unconfounded*, in which case the only open paths from X to Y through a parent of Y are directed paths. Note that an unconfounded dependency may still be biased due to nondirected open paths that do not end in an arrow into Y (e.g., if Berksonian bias is present).

The dependence of Y on X is *unconfounded given* S if, after conditioning on S, the only open paths between X and Y through a parent of Y are the directed paths. Consider again a set of variables S that contains no descendant of X. S is *sufficient* to block confounding if the dependence of Y on X is unconfounded given S. "No confounding" thus corresponds to sufficiency of the empty set. A sufficient S is called *minimally sufficient* to block confounding if no proper subset of S is sufficient.

A *backdoor path* from X to Y is a path that begins with a parent of X (i.e., leaves X from a "backdoor") and ends at Y. A set S then satisfies the *backdoor criterion* with respect to X and Y if S contains no descendant of X and there are no open backdoor paths from X to Y after conditioning on S. In a DAG, the following simplifications occur:

1. All biasing paths are backdoor paths; hence, the dependence of Y on X is unbiased whenever there is no open backdoor path from X to Y.
2. If X is exogenous, the dependence of any Y on X is unbiased.
3. All confounders are ancestors of either X or of Y.
4. A backdoor path is open if and only if it contains a common ancestor of X and Y.
5. If S satisfies the backdoor criterion, then S is sufficient to block $X - Y$ confounding.

These conditions do not extend to non-DAGs such as Figure 2. Also, although pa[X] always satisfies the backdoor criterion and hence is sufficient in a DAG, it may be far from minimal sufficient. For example, in a DAG there is no confounding and hence no need for conditioning whenever X separates pa[X] from Y (i.e., whenever the only open paths from pa[X] to Y are through X).

The terms *confounding* and *selection bias* have somewhat varying and overlapping usage. Epidemiologists typically refer to Berksonian bias as selection bias, and some call any bias created by conditioning selection bias. Nonetheless, some writers (especially in econometrics) use selection bias to refer to what epidemiologists call confounding. Indeed, Figures 1 and 3 show how selection on a nonconfounder (F) can generate confounding. As a final caution, we note that the biases dealt with by the above concepts are only confounding and selection biases. Biases due to measurement error and model-form misspecification require further structure to describe.

Statistical Interpretations

A joint probability distribution for the variables in a graph is *compatible* with the graph if two sets of variables are independent given S whenever S separates them. For such distributions, two sets of variables will be statistically unassociated if there is no open path between them. Many special results follow for distributions compatible with a DAG. For example, if in a DAG, X is not an ancestor of any variable in a set T, then T and X will be independent given pa[X]. A distribution compatible with a DAG thus can be reduced to a product of factors $Pr(x|\text{pa}[X])$ with one factor for each variable X in the DAG; this is sometimes called the "Markov factorization" for the DAG. When X is a treatment, this condition implies the probability of treatment is fully determined by the parents of X, pa[X].

Suppose now we are interested in the effect of X on Y in a DAG, and we assume a probability model compatible with the DAG. Then, given a sufficient conditioning set S, the only source of association between X and Y within strata of S will be the directed paths from X to Y. Hence the *net effect* of $X = x_1$ versus $X = x_0$ on Y when $S = s$ is defined as $Pr(y|x_1, s) - Pr(y|x_0, s)$, the difference in risks of $Y = y$ at $X = x_1$ and $X = x_0$. Alternatively, one may use another effect measure such as the risk ratio $Pr(y|x_1, s)/Pr(y|x_0, s)$. A *standardized effect* is a difference or ratio of weighted averages of these stratum-specific $Pr(y|x, s)$ over S, using a common weighting distribution. The latter definition can be generalized to include intermediate variables in S by allowing the weighting distribution to causally depend on X. Furthermore, given a set Z of intermediates along all directed paths from X to Y with $X - Z$ and $Z - Y$ unbiased, one can produce formulas for the $X - Y$ effect as a function of the $X - Z$ and $Z - Y$ effects ("front-door adjustment").

The above form of standardized effect is identical to the forms derived under other causal models.

When S is sufficient, some authors go so far as to identify the $Pr(y|x, s)$ with the distribution of potential outcomes given S. There have been objections to this identification on the grounds that not all variables in the graph can be manipulated and that potential-outcome models do not apply to nonmanipulable variables. The objection loses force when X is an intervention variable, however. In that case, sufficiency of a set S implies that the potential-outcome distribution equals $\sum_s Pr(y|x, s)Pr(s)$, the risk of $Y = y$ given $X = x$ standardized to the S distribution.

Some Epidemiologic Applications

To check sufficiency and identify minimally sufficient sets of variables given a graph of the causal structure, one need to only see whether the open paths from X to Y after conditioning are exactly the directed paths from X to Y in the starting graph. Mental effort may then be shifted to evaluating the reasonableness of the causal independencies encoded by the graph, some of which are reflected in conditional independence relations. This property of graphical analysis facilitates the articulation of necessary background knowledge and eases teaching nonstatisticians algebraically difficult concepts.

As an example, spurious sample associations may arise if each variable affects selection into the study, even if those selection effects are independent. This phenomenon is a special case of the collider-stratification effect illustrated earlier. Its presence is easily seen by starting with a DAG that includes a selection indicator $F = 1$ for those selected, 0 otherwise, as well as the study variables, then noting that we are always forced to examine associations within the $F = 1$ stratum (i.e., by definition, our observations stratify on selection). Thus, if selection (F) is affected by multiple causal pathways, we should expect selection to create or alter associations among the variables.

Figure 4 displays a situation common in randomized trials, in which the net effect of E on D is unconfounded, despite the presence of an unmeasured cause U of D. Unfortunately, a common practice in health and social sciences is to stratify on (or otherwise adjust for) an intermediate variable F between a cause E and an effect D, and then claim that the estimated (F residual) association represents that portion of the effect of E on D not mediated through F. In Figure 4, this would be a claim that on

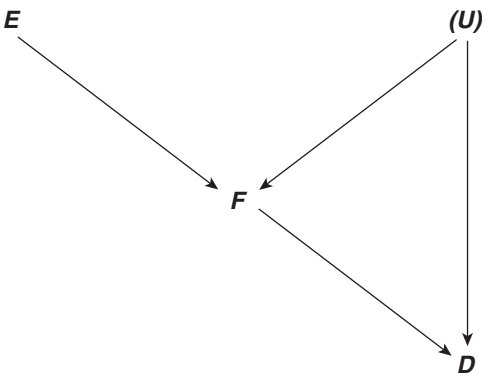

Figure 4 Graph in Which Net (Total) Effect of E on D Is Unconfounded but the Direct Effect Is Confounded by U

stratifying on F, the $E - D$ association represents the direct effect of E on D. Figure 5, however, shows the graph conditional on F, in which we see that there is now an open path from E to D through U, and hence the residual $E - D$ association is confounded for the direct effect of E on D.

The $E - D$ confounding by U in Figure 5 can be seen as arising from the confounding of the $F - D$ association by U in Figure 4. In a similar fashion, conditioning on C in Figure 1 opens the confounding path through A and B in Figure 2; this path can be seen as arising from the confounding of the $C - E$ association by A and the $C - D$ association by B in Figure 1. In both examples, further stratification on either A or B blocks the created path and thus removes the new confounding.

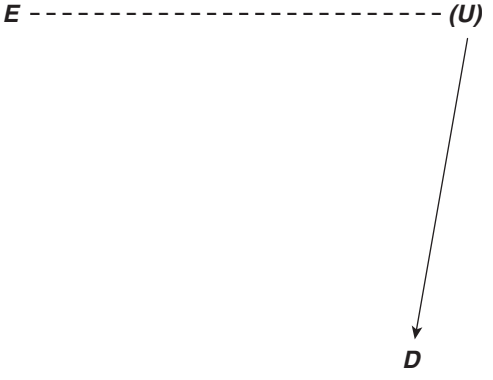

Figure 5 Graph Resulting From Figure 2 After Conditioning on F

The generation of biasing paths by conditioning on a collider or its descendant has been called ''collider bias.'' Starting from a DAG, there are two distinct forms of this bias: confounding induced in the conditional graph (Figures 2, 3, and 5) and Berksonian bias from conditioning on an effect of X and Y. Both biases can in principle be removed by further conditioning on variables along the biasing paths from X to Y in the conditional graph. Nonetheless, the starting DAG will always display ancestors of X or Y that, if known, could be used remove confounding; in contrast, no variable need appear that could be used to remove Berksonian bias.

Figure 4 also provides a schematic for estimating the $F - D$ effect, as in randomized trials in which E represents assignment to or encouragement toward treatment F. Subject to additional assumptions, one can put bounds on confounding of the $F - D$ association (and with more assumptions remove it entirely) through use of E as an *instrumental variable* (a variable associated with X and separated from Y by X).

Questions of Discovery

While deriving statistical implications of graphical models is uncontroversial, algorithms that claim to discover causal (graphical) structures from observational data have been subject to strong criticism. A key assumption in certain ''discovery'' algorithms is a converse of compatibility called *faithfulness.*

A compatible distribution is *faithful to* or *perfectly compatible with* a given graph if for all X, Y, and S, X and Y are independent given S only when S separates X and Y (i.e., the distribution contains no independencies other than those implied by graphical separation). A distribution is *stable* if there is a DAG to which it is faithful. Methods exist for constructing a distribution that is faithful to a given DAG. Methods also exist for constructing a minimal DAG compatible with a given distribution (minimal in that no arrow can be removed from the DAG without violating compatibility). Faithfulness implies that minimal sufficient sets in the graph will also be minimal for consistent estimation of effects. Nonetheless, there are real examples of near cancellation (e.g., when confounding obscures a real effect), which make faithfulness questionable as a routine assumption. Fortunately, faithfulness is not needed for the uses of graphical models discussed here.

Whether or not one assumes faithfulness, the generality of graphical models is purchased with limitations on their informativeness. The nonparametric nature of the graphs implies that parametric concepts such as effect modification cannot be displayed by the graphs (although the graphs still show whether the effects and hence their modification can be estimated from the given information). Similarly, the graphs may imply that several distinct conditionings are minimal sufficient (e.g., both $\{A, C\}$ and $\{B, C\}$ are sufficient for the $E - D$ effect in Figure 1), but offer no further guidance on which to use. Open paths may suggest the presence of an association, but that association may be negligible even if nonzero. For example, bounds on the size of direct effects imply more severe bounds on the size of effects mediated in multiple steps (indirect effects), with the bounds becoming more severe with each step. As a consequence, there is often good reason to expect certain phenomena (such as the conditional $E - D$ confounding shown in Figures 2, 3, and 5) to be small in epidemiologic examples. Thus, when quantitative information is used, graphical modeling becomes more a schematic adjunct than an alternative to causal modeling.

Causation and Causal Inference

In the health sciences, definitions of cause and effect have not been tightly bound with methods for studying causation. Indeed, many approaches to causal inference provide no definition, leaving users to imagine causality however they prefer. Without a formal definition of causation, an association is distinguished as causal only by having been identified as such based on external and largely contextual considerations. Because they have historical precedence and are still widely used, this entry first reviews such methods. It then discusses definitions and methods based on formal models of causation, especially those based on counterfactuals or potential outcomes.

Canonical Inference

The oldest and most common systematic approach to causal inference in epidemiology was the comparison of observations to characteristics expected of causal relations. The characteristics might derive from subject-matter judgments or from consideration of causal models, and the comparisons might employ formal statistical methods to estimate and test those characteristics. Perhaps the most widely cited of such an approach is based on the considerations of Sir Austin Bradford Hill, which are discussed critically in numerous sources as well as by Hill himself.

The canonical approach usually leaves terms such as *cause* and *effect* as undefined concepts around which the self-evident canons are built, much like axioms are built around concepts such as *set* and *is an element of* in mathematics. In his famous 1965 article on association and causation, Hill noted that he did not want to undertake a philosophical discussion of causation. Only proper temporal sequence (cause must precede effect) is a necessary condition for a cause-effect relation to hold. The remaining considerations are more akin to diagnostic symptoms or signs of causation—that is, they are properties an association is assumed more likely to exhibit if it is causal than if it is not. Furthermore, some of these properties (such as specificity and dose response) apply only under specific causal models. Thus, the canonical approach makes causal inference most closely resemble clinical judgment than experimental science, although experimental evidence is listed among the considerations. Some of the considerations (such as temporal sequence, association, dose-response or predicted gradient, and specificity) are empirical signs and thus subject to conventional statistical analysis. Others (such as plausibility) refer to prior belief, and thus (as with disease symptoms) require elicitation from experts, the same process used to construct prior distributions for Bayesian analysis.

The canonical approach is widely accepted in epidemiology, subject to many variations in detail. Nonetheless, it has been criticized for its incompleteness and informality, and the consequent poor fit it affords to the deductive or mathematical approaches familiar to classic science and statistics.

Although there have been some interesting attempts to reinforce or reinterpret certain canons as empirical predictions of causal hypotheses, there is no generally accepted mapping of the entire canonical approach into a single analytic methodology. One simply uses standard statistical techniques to test whether empirical canons are violated. For example, if the causal hypothesis linking X to Y predicts a strictly increasing trend in Y with X, a test of this statistical prediction may serve as a statistical criterion for determining whether the hypothesis fails the dose-response canon. Such usage falls squarely in the falsificationist/frequentist tradition of 20th-century statistics, but it leaves unanswered most of the policy questions that drive causal research; this gap led to the development of methodologic modeling.

Methodologic Modeling

In the second half of the 20th century, a more rigorous approach to observational studies emerged in the wake of major policy controversies, such as those concerning cigarette smoking and lung cancer. This approach begins with the idea that within strata of some sufficient set of confounders Z, there is a population association or relation between X and Y that is the target of inference. In other words, the Z-stratified associations are presumed to accurately reflect the effect of X on Y in that population stratum, however effect may be defined. Estimates of this presumably causal association are then the effect estimates.

Observational and analytic shortcomings bias or distort these estimates. Units may be selected for observation in a nonrandom fashion; stratifying on additional unmeasured covariates U may be essential for the $X-Y$ association to approximate a causal effect; inappropriate covariates may be entered into the analysis; components of X, Y, or Z may not be adequately measured; and so on. In methodologic or bias modeling, one models these shortcomings. In effect, one attempts to model the design and execution of the study, including features (such as selection biases and measurement errors) beyond investigator control. The process is thus a natural extension to observational studies of the design-based paradigm in experimental and survey statistics.

Nonetheless, many of the parameters in realistic bias models will not be estimable from the data, necessitating inferential approaches well beyond those of conventional statistics. The simplest approach is to fix these parameters at specific values, estimate effects assuming these values are correct, and see how effect estimates change as these values are varied. This process is called sensitivity analysis. One can also assign the parameters prior probability distributions based on background information and summarize the effect estimates over these distributions or over the resulting posterior distribution.

These ideas are well established in engineering and policy research, albeit in a wide variety of forms and specialized applications. Models for specific biases have a long if scattered history in epidemiology; nonetheless, methods for statistical inference from bias models have only recently begun to appear in epidemiologic research.

Statistical Formulation

Consider the problem of estimating the effect of X on Y, given a collection of antecedent covariates Z. Standard approaches estimate the regression of Y on X and Z, $E(Y|x, z)$, and then taking the fitted (partial) regression of Y on X given Z as the effect of X on Y. Usually, a parametric model $r(x, z; \beta)$ for $E(Y|x, z)$ is fit and the coefficient for X is taken as the effect (this approach is reflected in common terminology that refers to such coefficients as ''main effects''); the logistic model for a binary Y is the most common epidemiologic example. Model fitting is almost always done as if

1. within levels of X and Z, the data are a simple random sample and any missingness is completely random;
2. the causal effect of X on Y is accurately reflected by the association of X and Y given Z (i.e., there is no residual confounding—as might be reasonable to assume if X were randomized within levels of Z), and
3. X, Y, and Z are measured without error.

In reality, it is more frequently the case that (1) sampling and missing-data probabilities may jointly depend on X, Y, and Z in an unknown fashion; (2) stratifying or adjusting for certain unmeasured (and possibly unknown) covariates U might be essential for the association of X and Y to correspond to a causal effect of X on Y; and (3) some of the X, Y, and Z components are mismeasured. Several approaches have been developed to deal with these problems.

Selection Biases

Let $V = (X, Y, Z)$. One approach to sampling (selection) biases posits a model $s(v; \sigma)$ for the probability of selection given v, then uses this model in the analysis along with $r(x, z; \beta)$, for example, by incorporating $s(v; \sigma)$ into the likelihood function or by using $1/s(v; \sigma)$ as a weighting factor. The parameters β and σ usually cannot be completely estimated from the data under analysis, so one must either posit various fixed values for σ and estimate β for each chosen σ (sensitivity analysis), or else give β and σ a prior distribution and conduct a Bayesian analysis. A third approach, Monte Carlo risk analysis or Monte Carlo sensitivity analysis (MCSA), repeatedly samples σ from its prior distribution, resamples (bootstraps) the data, and re-estimates β using the sampled σ and data; it then outputs the distribution of results obtained from this repeated sampling-estimation cycle. MCSA can closely approximate Bayesian results under certain (though not all) conditions. These selection-modeling methods can be generalized (with many technical considerations) to handle arbitrary missing data.

Unmeasured Confounders

Suppose U is a collection of unmeasured (latent) covariates required for identification of the effect of X on Y. One approach to problem (2) is to model the distribution of U and V with a probability model $p(u, v; \beta, \gamma) = p(y|u, x, z; \beta)p(u, x, z; \gamma)$. Again, one can estimate β by likelihood-based or by weighting methods, but because U is unmeasured, the parameter (β, γ) will not be fully estimable from the data and so some sort of sensitivity analysis or prior distribution will be needed. Results will depend heavily on the prior specification given U. For example, U may be a specific unmeasured covariate (e.g., smoking status) with well-studied relations to X, Y, and Z, which affords straightforward Bayesian and MCSA analyses. On the other hand, U may represent an unspecified aggregation of latent confounders, in which case the priors and hence inferences are more uncertain.

Measurement Error and Misclassification

Suppose that the collection of "true" values $V = (X, Y, Z)$ has a corresponding collection of measurements or surrogates W (which might include multiple surrogates for X, Y, or Z). The measurement-error problem (Problem 3) can then be expressed as follows: For some or all units, at least one of the V components is missing, but the measurements in W that correspond to the missing V components are present. If enough units are observed with both V and W complete, the problem can be handled by standard missing-data methods. For example, given a model for the distribution of V and W, one can use likelihood-based methods, or impute V components where absent and then fit the model $r(x, z; \beta)$ for $E(Y|x, z)$ to the completed data or fit the model to the complete records using weights derived from all records using a model for missing-data patterns. Many direct Bayesian approaches to measurement error are also available.

Alternatively, there are many measurement-error correction procedures that adjust the "naïve" β estimates obtained by fitting the regression using W as if it were V. This adjustment is usually accomplished with a model relating V to W fitted to the complete records, as in instrumental-variable (regression calibration) corrections and their extensions. Many recent methods based on assuming various subsamples with information on multiple surrogates are available (so W may be of much higher dimension than V and may have complex missing-data patterns).

All methods assume that missingness in V and W components is random, which is often quite implausible because noncooperation increases with demands on subjects, collection of some components may be demanding (e.g., as when W includes diet diaries or biomarkers), and cooperation may be related to unobserved true values or confounders. Thus, selection modeling will be needed along with measurement modeling to account for this nonrandom ("nonignorable") missingness. Further nonidentified modeling becomes a necessity if a component of V is never observed on any unit (or, more practically, if there are too few complete records to support large-sample missing-data or measurement-error procedures). Latent-variable methods are natural for this situation. For example, one could model the distribution of (V, W) or a sufficient factor from that distribution by a parametric model; the unobserved components of V are then the latent variables in the model. As before, the parameters will not be fully identified, making Bayesian methods a natural choice for summary inferences.

Realistic specification for nonidentified measurement-error models can become quite complex, with inferences

displaying extreme sensitivity to parameter constraints or prior distributions. Nonetheless, methodologic modeling helps provide an honest accounting for the large uncertainty that can be generated by even modest measurement error.

Counterfactuals and Potential Outcomes

Skeptical that induction in general and causal inference in particular could be given a sound logical basis, the 18th-century Scottish philosopher David Hume nonetheless captured the foundation of the potential-outcome approach when, in his *Enquiry Concerning Human Understanding*, he defined "a cause to be an object, followed by another, ... where, if the first object had not been, the second had never existed." A key aspect of this view of causation is its *counterfactual* element: It refers to how a certain outcome event (the "second object," or effect) would not have occurred if, *contrary to fact*, an earlier event (the "first object," or cause) had not occurred. In the 20th century, this counterfactual view of causation was adopted by numerous philosophers and scientists. In parallel, there appeared statistical theories of causal inference that incorporated this view into their foundation, which is today widely recognized under the heading of *potential-outcome models* of causation.

To describe these models, suppose we wish to study the effect of an intervention variable X on a subsequent outcome variable Y defined on an observational unit or a population; for example, X could be the daily dose regimen for a drug in a clinical trial, and Y could be survival time. Given X has potential values $x_1, \ldots, x_J$ (e.g., drug doses), we suppose that there is a list of *potential outcomes* $\boldsymbol{y} = (y(x_1), \ldots, y(x_J))'$, such that if $X = x_j$, then $Y = y(x_j)$. The list $\boldsymbol{y}$ thus exhibits the correspondence between treatments, interventions, or actions (the X values) and outcomes or responses (the Y values) for the unit, and so is sometimes called a *response schedule*.

Under this model, assignment of a unit to a treatment level x_j is a choice of which potential outcome $y(x_j)$ from the list $\boldsymbol{y}$ attempts to observe. It is ordinarily assumed that the assignments made for other units do not affect the outcomes of another unit, although there are extensions of the model to include between-unit interactions, as in contagious outcomes. Regardless of the X assignment, the remaining potential outcomes are treated as existing pretreatment covariates on which data are missing. Because at most one of the J potential outcomes is observed per unit, the remaining potential outcomes can be viewed as missing data, and causal inference can thus be seen as a special case of inference with missing data.

To say that intervention x_i causally affects Y relative to intervention x_j means that $y(x_i) \neq y(x_j)$, that is, X "matters" for Y for the unit. The *sharp* (or strong) null hypothesis is that $y(x)$ is constant over x within units; this means that changing X would not affect the Y of any unit, that is, $y(x_i) = y(x_j)$ for every unit and every x_i and x_j; this hypothesis forms the basis of exact permutation tests such as Fisher's exact test. The effect of intervention x_i relative to x_j on a unit may be measured by the difference in potential outcomes $y(x_i) - y(x_j)$. If the outcome is strictly positive (such as life expectancy or mortality risk), it could instead be measured by the ratio $y(x_i)/y(x_j)$.

Because we never observe two potential outcomes on a unit, we can only estimate population averages of the potential outcomes. We do this by observing average outcomes in differently exposed groups and substituting these observations for the average potential outcomes—a perilous process whenever the observed exposure groups are atypical of the population of interest with respect to other risk factors for the outcome. A more subtle problem is that only for difference measures will the population effect (the difference of average potential outcomes) equal the population average effect (the average difference of potential outcomes). Hence, the average of the differences $y(x_i) - y(x_j)$ in the population is often called the *average causal effect*. For some popular measures of effect, such as rate ratios and odds ratios, the population effect may not even equal any average of individual effects.

The theory extends to probabilistic outcomes by replacing the $y(x_j)$ by probability functions $p_j(y)$. The theory also extends to continuous X by allowing the potential-outcome list $\boldsymbol{y}$ to contain the potential outcome $y(x)$ or $p_x(y)$ for every possible value x of X. Both extensions are embodied in graphical probability models for intervention effects. Finally, the theory extends to complex longitudinal data structures by allowing the treatments to be different event histories or processes.

From Randomized to Observational Inference

Potential outcomes were developed as part of a design-based strategy for causal inference in which randomization provided the foundation for inference. Indeed, before the 1980s, the model was often referred to as "the randomization model," although the causal concepts within it do not hinge on randomization. It thus seems that the early strong linkage of potential outcomes to randomized designs deflected consideration of the model for observational research. By the 1970s, however, their extension to observational studies was well under way. In this context, the models made clear the distinction between causal and statistical relations: Causal relations refer to relations of treatments to potential outcomes *within* treated units, whereas statistical relations refer to associations of treatments with actual outcomes *across* units. Consequently, the models have aided in distinguishing confounding from collapsibility, synergy from statistical interaction, and causation probabilities from attributable fractions.

The conceptual clarification also stimulated development of statistical methods for observational studies, leading, for example, to propensity-scoring and inverse-probability-of-treatment methods for confounder adjustment, as well as new insights into analysis of trials with noncompliance. In many cases, such insights have led to methodologic refinements and better-informed choices among existing methods. In the longitudinal data setting, however, potential-outcome modeling has led to entirely new methodologies for analysis of time-varying covariates and outcomes, including *g*-estimation and marginal structural modeling.

A serious caution arises, however, when it is not clear that the counterfactual values for X (treatments other than the actual one) represent physical possibilities or even unambiguous states of nature. A classic example is gender (biological sex). Although people speak freely of gender (male vs. female) as cause of heart disease, given a particular man it is not clear what it would mean for that man to have been a woman instead. Do we mean that the man cross-dressed and lived with a female identity his entire life? Or that he received a sex-change operation after birth? Or that the zygote from which he developed had its male chromosome replaced by a female chromosome?

Potential-outcome models bring to light such ambiguities in everyday causal language, but do not resolve them. Some authors appear to insist that use of the models be restricted to situations in which ambiguities are resolved, so that X must represent an intervention variable, that is, a precise choice among treatment actions or decisions. Many applications do not meet this restriction, however, and some go so far as to confuse outcomes (Y) with treatments (X), which can lead to nonsensical results. Examples include estimates of mortality after "cause removal," for example, removal of all lung cancer deaths. Sensible interpretation of any effect estimate requires asking what intervention a unit could have given the unit a value of X (here, lung cancer death) other than the one that was observed, and what side effects that intervention would have. One cannot remove all lung cancer deaths by smoking cessation. A treatment with a 100% cure rate might do so, but need not guarantee the same subsequent life span as if the cancer never occurred. If such questions cannot be given at least a speculative answer, the estimates of the impact of cause removal cannot be expected to provide valid information for intervention and policy purposes.

Structural Equations and Causal Diagrams

Paralleling the development of potential-outcome models in the 20th century, an entirely different approach to causal analysis arose in observational research in economics and related fields. Like methodologic modeling, this *structural-equations* approach does not begin with a formal definition of cause and effect, but instead develops models to reflect assumed causal associations, from which empirical (and hence testable) associations may be derived. These models may, however, be given a potential-outcomes formulation.

Like most of statistics, before the 1980s, structural-equations methods were largely limited to normal linear models to derive statistical inferences. Because these models bear no resemblance to typical epidemiologic data, this limitation may in part explain the near absence of structural equations from epidemiology, despite their ubiquity in social science methodology. From their inception, however, the models have been accompanied by graphical representations or path diagrams that provide compact summaries of qualitative assumptions made by the structural model.

Such diagrams also provide visual explanations of insights and problems difficult to see with other methods, and so provide an invaluable teaching tool.

Conclusion

Different approaches to causal inference represent separate historical streams rather than distinct methodologies and can be blended in various ways. The result of any modeling exercise is simply one more input to informal judgments about causal relations, which may be guided by canonical considerations. Insights and innovations in any approach can thus benefit the entire process of causal inference, especially when that process is seen as part of a larger context. Other traditions or approaches (some perhaps yet to be imagined) may contribute to the process. It thus seems safe to say that no one approach or blend is a complete solution to the problem of causal inference, and that the topic remains one rich with open problems and opportunities for innovation.

Censored Data

Samples are often collected in such a way that the exact value of one or more cases is unknown. Such missing information is referred to as *censored data.* In one source of such censored data, values are known to exceed or fall below some limit. Often, for example, in a study based on the survival times of laboratory animals, a protocol requires that all data be collected within a specified period of time. For an appreciably sized subset of subjects, an exact survival time may not be known, simply because the study ends before the event of interest (such as the animal's death) could be observed. Because the exact survival times for those who lived longer than the length of the study are not known, this illustrates the generation of right-censored data. Another common example occurs when the age of study participants is recorded in exact years for most subjects, but the ages of those younger than 18 are all recorded as less than 18 years. Because the exact ages of persons younger than 18 years are not known, this is an example of left-censored data. In general, when some, but not all, values are recorded on a continuous scale of measurement, special techniques are required that differ from the many of the common procedures based on what is called *maximum likelihood* (ML) estimation.

Work with censored data is facilitated by a notational convention for observed values called *order statistics.* The sample median is an example of an order statistic. Unlike the mean of a size n sample, which is represented by placing a bar above a letter, as in $\overline{X}$, the subscripted symbol $X_{([n+1]/2)}$, when n is an odd number, or $[X_{(n/2)} + X_{([n/2]+1)}]/2$, when n is an even number, designates the median. More generally, by calling on parenthesized subscripts to denote ascending variate value magnitudes, the order of variate values can be designated. For example, the smallest and largest values are denoted respectively as $X_{(1)}$ and $X_{(n)}$. (In case of a tied value, the counterpart of a coin toss distinguishes between variate designations, say, between $X_{(i)}$ and $X_{(i+1)}$.)

Censored and Incomplete Ordered Measurements

The value placed within some ith order statistic's parenthesized subscript denotes a quantity called a *rank.* Nonparametric inferential methods that are based on ranks often help trade off statistical power and/or efficiency, on the one hand, to gain robustness, in other words, insensitivity to departures from assumptions, on the other. In the context of the many applications that make use of censored samples, order statistic-based methods have been developed that are both robust and efficient. This is accomplished by statistical approaches that differ from ML procedures, such as the well-known Kaplan-Meier (KM) estimator.

The title of Kaplan and Meier's classic paper, "Nonparametric Estimation From Incomplete Observations," refers to incomplete observations, not censored observations. This distinction is central to an understanding of the epidemiological roles that order statistics often play and can be illustrated by a common laboratory experiment. In toxicological studies, measurements are often entered in a three-column spreadsheet as shown in Figure 1. All but the last entry (across from Day 734 in Column A) record the dates when one or more animals die. The last entries record when animals are sacrificed to determine if the targeted tumor is present at the end of the study's data-gathering stage, X_s. In Column B, across from days-survived column entries, the daily number of natural or sacrifice deaths where, at autopsy, the targeted tumor is found is recorded, here as 7. Column C records the number of deaths that day deemed to be non-toxic-substance attributable (because at autopsy there is no trace left of the targeted tumor), here as 14.

Suppose, on the one hand, an animal dies prior to X_s and, at autopsy, no tumor is found. Then, because some nontargeted factor has limited this animal's period of observation, information concerning this animal is said to be *incomplete.* On the other hand, when at or soon after sacrifice it is detected that had the experiment been continued beyond X_s, an animal would have had a good chance of dying due to the targeted tumor, this animal contributes a *censored* measurement.

For example, were all measurements complete and the experiment long enough to assure that more than $n/2$ animals die, then a sample median can provide an estimate of expected survival time. Yet even if all animals die prior to X_s, were there even one

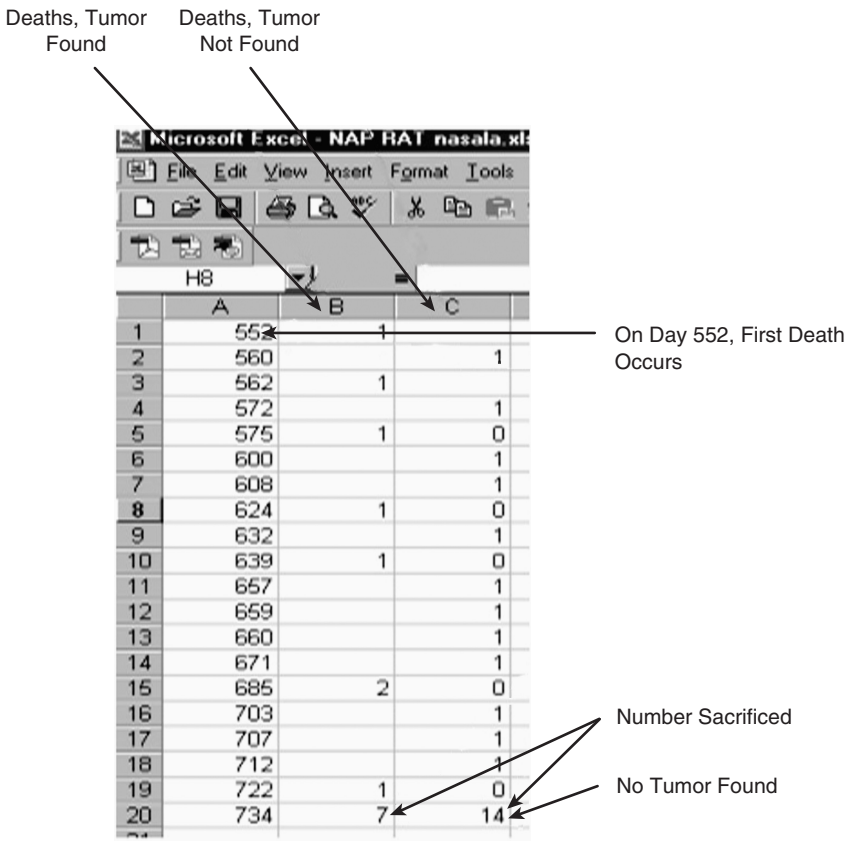

Figure 1 Example of Survival Spreadsheet That Illustrates the Distinction Between Censored and Incomplete Measurements

incomplete measurement, it would follow that KM, life-table, or other specialized methods, not order statistics-based approaches such as the sample median, must be used. Among these approaches, one general class of method has been found to be both computationally simple and, given several reasonable assumptions, efficient in the sense of making optimal use of available data.

Computational and Data Usage Efficiency

Although it plays many other important statistical roles, the median itself is rarely used today to study censored data from animal experiments and other investigations. Unlike the median as a way of working with censored measurements, among their many advantages best linear unbiased (BLU) techniques can help study data from a wide range of experiments and observational investigations. They can be used in any study based on six or more subjects among which, prior to date X_s, a death or some other targeted outcome occurs on 2 or more days. Besides being applicable to a wide range of problems, once one of the many published BLU tables is located, computational procedures require little more than hand calculation.

For statistical models such as the normal, logistic, and exponential, simplicity is attributable to the *L*, linear, part of the BLU designation. Tables are readily available that can be used to calculate BLU estimates. For a user-specified n and a specified degree of censoring, these tables list linear model weights. For example, the sample mean $\overline{X}$ of an uncensored independent and identically distributed normal sample serves a dual role as an ML and a BLU estimator. Since $\overline{X}$ can be computed by multiplying each respective order statistic by the same weight, $1/n$, when $n = 5$, the first tabled sequence of weights lists the value 0.2000 five times.

Any second set of weights listed in a BLU estimator table defines the BLU generalization of an *s* or weighted sample range estimator of the scale parameter σ. In the $n = 5$ example, the weights -0.3724, -0.1352, 0.0000, 0.1352, and 0.3724 are listed below each 0.2000 entry. Correspondingly, for $n = 5$, the estimator $-0.3724\, X_{(1)} - 0.1352\, X_{(2)} + 0.1352\, X_{(4)} + 0.3724\, X_{(5)}$ is the BLU counterpart of the sample standard deviation *s*. Below these uncensored-case BLU estimator weights, censored sample counterpart weights are listed.

Tables are provided by Dixon and Massey that correct for *s*'s bias when the sample standard deviation is calculated from normal data. The *B* of BLU stands for *best* among all linear *unbiased* (LU) estimators. In other words, whether or not it is based on censored data, among LU estimators it makes the best use of data, as judged by the usual mean squared error, efficiency, criterion. The sample standard deviation, *s*, although a biased estimator of the

normal model's scale parameter σ, is slightly more efficient than its BLU counterpart.

Since its computation requires root finding, s is not a linear estimator. Even when it is calculated using uncensored data, any BLU-based estimator of σ is almost as efficient in the normal case as either s, or s's ML counterpart $\sqrt{[(n-1)/n]}s$. The determination of BLU-based estimators of μ and σ that are based on censored data requires even fewer calculations than are required to compute their size n sample uncensored counterparts. Hence, it is surprising that no ML or other statistical technique provides much competition for BLU approaches as a way to study censored samples.

Centers for Disease Control and Prevention

The Centers for Disease Control and Prevention (CDC), a component of the U.S. Department of Health and Human Services, has two primary purposes: to improve people's health in their daily lives and to respond to health emergencies. CDC is the principal agency responsible for improving public health in the United States, and it conducts research and public health interventions both in the United States and globally. CDC headquarters are located in Atlanta, Georgia, with a workforce of more than 8,000 employees in various locations throughout the world. As the name suggests, CDC consists of a number of centers that focus on particular aspects of public health. These include the National Center for Environmental Health/Agency for Toxic Substances and Disease Registry, the National Center for Injury Prevention and Control, the National Center for Health Statistics, the National Immunization Program, and the National Institute for Occupational Safety and Health.

The roots of the CDC lie in the Malaria Control in War Areas (MCWA) program, whose mission was to control or prevent malaria and murine typhus fever in the southern United States during World War II. The Communicable Disease Center, the direct descendant of the MCWA, was organized in Atlanta, Georgia, on July 1, 1946. The role of the new Communicable Disease Center was much expanded from that of the MCWA; it was responsible for researching and controlling all communicable diseases except tuberculosis and venereal disease, which at that time were handled through separate offices located in Washington, D.C. Over the years, CDC has expanded to include many agencies addressing specific diseases and health issues, including venereal disease (1957), tuberculosis (1960), immunization (1960), quarantines (1967), and smoking (1986). CDC's purview has expanded to include all diseases and conditions that affect human health, including chronic diseases and related risk factors such as obesity, tobacco use, and exposure to environmental toxins. The name *Center for Disease Control* was adopted in 1970; in 1981, this became *Centers for Disease Control* and in 1992, *Centers for Disease Control and Prevention*; however, the acronym CDC is still used for the organization.

CDC has played an important role in several of the major infectious disease issues of the 20th century. For instance, when some children inoculated with the Salk vaccine were infected with polio, the national inoculation program was halted; however, CDC was able to trace the cases to contaminated vaccine from a laboratory in California, and the inoculation program was resumed. Guidelines for national influenza vaccination were developed after CDC used surveillance procedures to trace the course of the 1957 influenza

epidemic. CDC established a smallpox surveillance unit in 1962, developed improved vaccine and vaccination techniques, and established surveillance procedures adopted by the World Health Organization in its campaign for the global eradication of smallpox. The first diagnosis of AIDS was described in the June 15 issue of *Morbidity and Mortality Weekly Report* (*MMWR*), published by CDC. CDC investigators traced toxic shock syndrome to a particular brand of tampon, which was subsequently removed from the marketplace.

The Epidemic Intelligence Service (EIS), headquartered at the CDC Atlanta offices, consists of physicians, scientists, and other public health professionals who have been trained at the CDC in applied epidemiology. EIS was founded in 1951 after the outbreak of the Korean War, in response to a perceived threat of biological warfare; its role today is to provide experts in surveillance and response to epidemics, and its purview includes chronic diseases and injuries as well as infectious diseases. Today, EIS officers serve in a variety of locations, including CDC offices and state and local health departments, and are available to respond to requests for epidemiological assistance, including investigation of disease outbreaks, all over the world.

MMWR, established in 1961, is a weekly online and print journal published by the CDC, which contains primarily current reports of disease occurrence and risk factors. Each week includes a section of notifiable diseases, and the remainder of the articles are on various topics, including reports of disease outbreaks and focused analyses of publicly available data sets such as the National Health Interview Survey (NHIS). Electronic copies of *MMWR* dating back to 1982 are available through the CDC Web site or by e-mail subscription without charge, and paper copies may be purchased through the same Web site.

Central Limit Theorem

A series of theorems in mathematical statistics called the central limit theorems provide theoretical justification for approximating the true sampling distribution of many sample statistics with the normal distribution. This entry discusses one such theorem for the sample mean. Similar theorems exist for sample median, sample standard deviation, and sample proportion. The word *central* in the name of the theorem means ''fundamental.'' The central limit theorem for the sample mean states that for a large sample size, the sampling distribution of the sample mean $\overline{X}$ is approximately normal, no matter what the population distribution looks like. The approximation becomes better with increasing sample size. This surprising fact was proved in fairly general form in 1810 by Pierre-Simon Laplace.

The graphs in Figures 1 through 5 show the idea of the Central Limit Theorem.

Figure 1 is a histogram of a random sample data from a normally distributed population with a mean 50 and a standard deviation 2; Figure 2 is a histogram for a sampling mean $\overline{X}$ with a sample size $n = 2$ from a normal distribution with a mean 50 and a standard deviation 2. Even the sample size is small; in this case, $\overline{X}$ is still normal with a mean 50 and a standard deviation $2/\sqrt{2} = 1.4142$. In fact, when the population is normal, the sampling distribution of $\overline{X}$ is exactly normal for any sample size.

Figure 3 is a histogram of a random sample data from a chi-square distribution with 1 *df*. This is a right-skewed distribution; Figure 4 is a histogram for a sampling mean $\overline{X}$ for a sample size 2 from a chi-square distribution with 1 *df*. When sample size is small, the sampling distribution of $\overline{X}$ is still right-skewed; Figure 5 is a histogram for a sampling mean

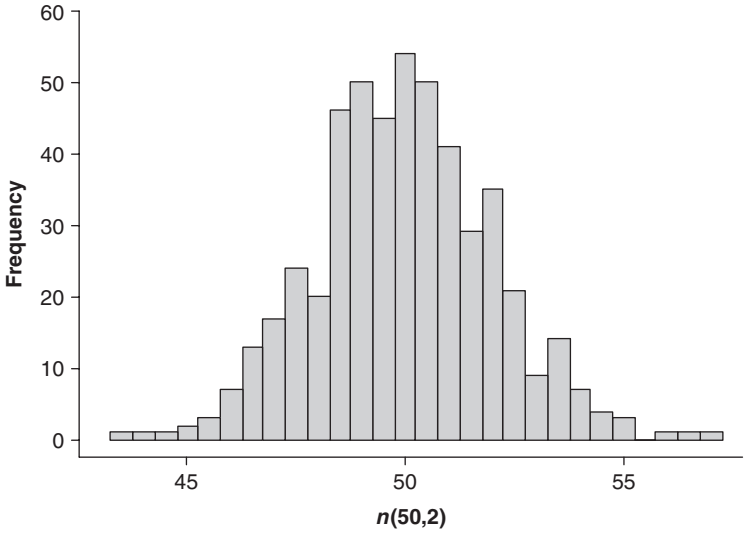

Figure 1 A Histogram of a Random Sample Data From a Normally Distributed Population With a Mean 50 and a Standard Deviation of 2

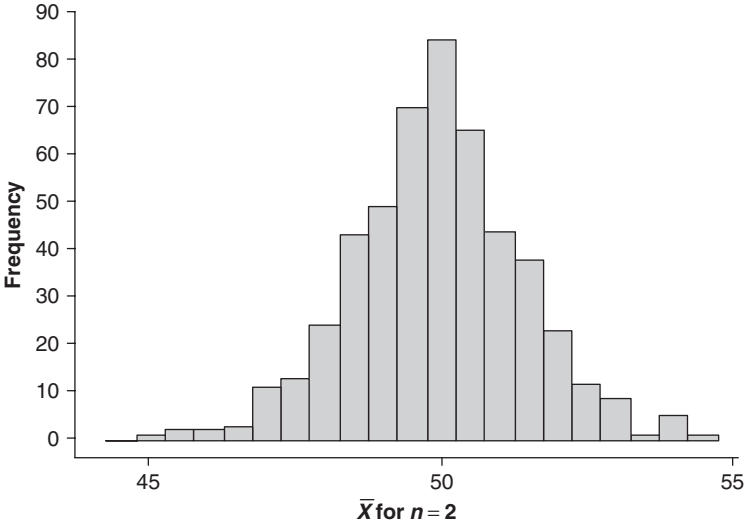

Figure 2 A Histogram for a Sampling Mean $\overline{X}$ With a Sample Size $n = 2$ From the Same Normal Distribution With a Mean 50 and a Standard Deviation 2

$\overline{X}$ for a sample size 30 from the same chi-square distribution with 1 *df*. In this case, the sampling distribution of $\overline{X}$ is approximately normal.

In symbol, let X be a random variable with mean μ and standard deviation σ, and $\overline{X}$ be the sample mean; when the sample size n is large, the standardized variable Z is approximately the standard normal variable:

$$Z = \frac{\overline{X} - \mu}{\sigma/\sqrt{n}} \approx N(0, 1).$$

This result has enabled statisticians to develop some large-sample procedures for making inferences about a population mean μ even when the shape of the population distribution is unknown. Application of the

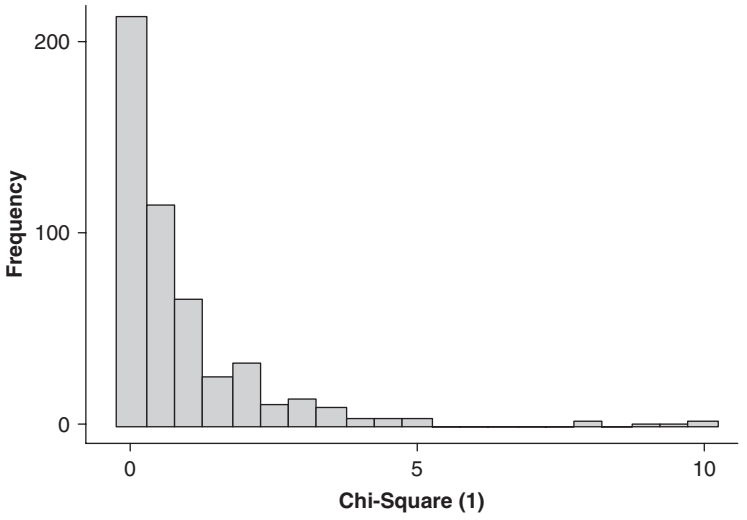

Figure 3 A Histogram for a Random Sample Data From a Chi-Square Distribution With 1 *df*

Note: This is a right-skewed distribution, that is, values near 0 are most common, and the probability of a given value decreases as the value increases.

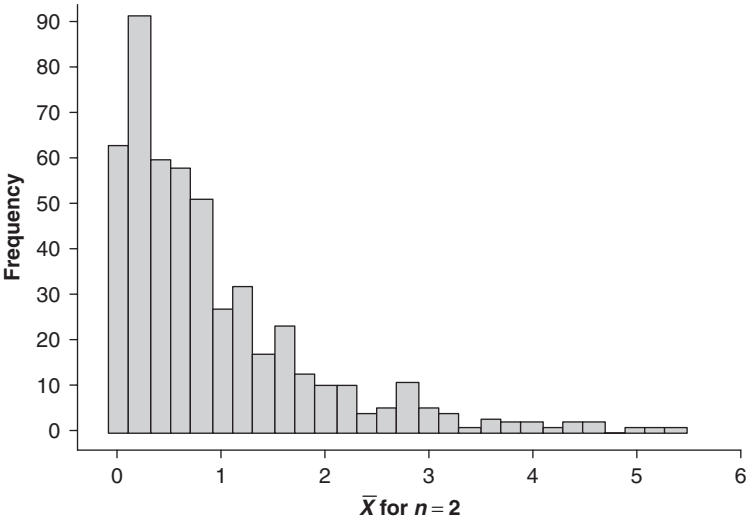

Figure 4 A Histogram for a Sampling Mean $\overline{X}$ With a Sample Size 2 From a Chi-Square Distribution With 1 *df*

central limit theorem requires a rule of thumb for deciding whether n is indeed sufficiently large. When the population distribution is quite skewed, only the ones for $n = 30$, 40, or more, the sampling distribution of $\overline{X}$ may have reasonably normal shapes. If the population distribution is somewhat skewed, then $n = 10$ or 15, and the sampling distribution of $\overline{X}$ may have reasonably normal shapes. The rule that many statisticians recommend is $n \geq 30$.

Example

Suppose that a random sample of size 64 is to be selected from a population with mean 40 and standard

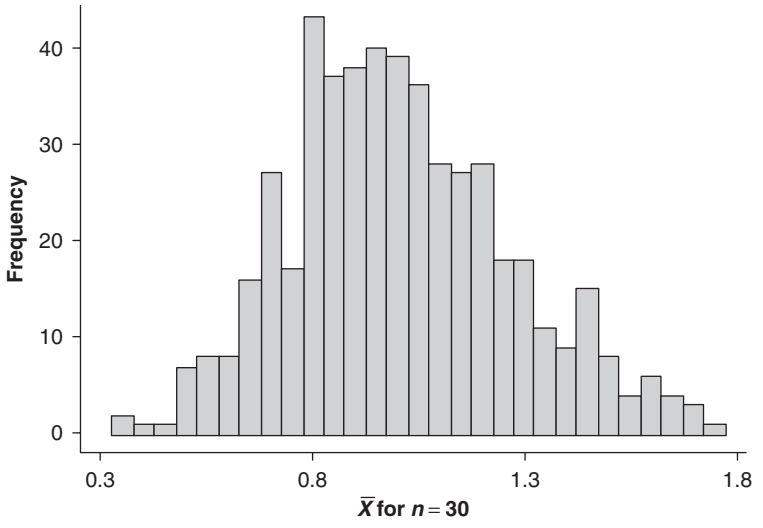

Figure 5 A Histogram for a Sampling Mean $\overline{X}$ With a Sample Size 30 From a Chi-Square Distribution With 1 *df*

deviation 5. What is the approximate probability that $\overline{X}$ will be within 0.5 of the population mean μ?

Solution: Since $\mu = 40$, and $\sigma = 5$, so that

$$\frac{\sigma}{\sqrt{n}} = \frac{5}{\sqrt{64}} = 0.625$$

$$\begin{aligned} &P(-0.5 < \bar{x} - \mu < 0.5) \\ &= p\left(\frac{-0.5}{0.625} < \frac{\bar{x} - \mu}{0.625} < \frac{0.5}{0.625}\right) \\ &\approx p(-0.8 < z < 0.8) \\ &= 0.7881 - 0.2119 = 0.5762. \end{aligned}$$

The approximate probability that the sample mean $\overline{X}$ will be within 0.5 of the population mean μ is about 57.62%.

Child Abuse

Child abuse and neglect remains a significant public health and social problem in the United States. Epidemiologic methods provide a systematic approach for surveillance, determination of risk factors, and estimates of service delivery needs on the basis of prevalence and incidence estimates. During the past decade, the information provided by many multidisciplinary studies has increased awareness about child maltreatment, improved the treatment of families and offenders, and promoted stricter law enforcement. This work is at the base of the current trend that shows a decline in child abuse and neglect, with 38,000 less children abused in 2004 compared with the previous year, according to "Child Maltreatment 2004," a report from the Children's Bureau, U.S. Department of Health and Human Services (2006). This entry reviews the definitions of physical abuse, sexual abuse, and neglect; discusses prevalence (number of victims in a population at any point in time with a maltreatment experience that occurred recently or a long time ago) and incidence data (number of new cases occurring in the population during a given

period of time) for child abuse in the United States; and identifies risk factors for child abuse.

Definitions of Child Abuse

In the United States, federal legislation establishes the minimum standards for the definition of child abuse and neglect that states must incorporate as part of their definitions. The Federal Child Abuse Prevention and Treatment Act (CAPTA) (42 U.S.C.A. §5106g) defines child abuse and neglect as

> a recent act or failure to act on the part of a parent or caretaker which results in death, serious physical or emotional harm, sexual abuse or exploitation; or an act or failure to act which presents an imminent risk of serious harm. (Child Welfare Information Gateway, 2005, p. 1)

Some states define child abuse and neglect as a single concept, while other states include definitions for several categories of abuse and neglect. Physical abuse, sexual abuse, and neglect are included in definitions of child abuse in all states. Physical abuse is generally defined as a nonaccidental physical injury to the child or any action that results in a physical impairment. Sexual abuse includes

> the employment, use, persuasion, inducement, enticement, or coercion of any child to engage in, or assist any other person to engage in, any sexually explicit conduct or simulation of such conduct for the purpose of producing a visual depiction of such conduct; or the rape, and in cases of caretaker or interfamilial relationships, statutory rape, molestation, prostitution, or other form of sexual exploitation of children, or incest with children. (Child Welfare Information Gateway, 2005, p. 1)

Neglect generally encompasses failure to provide for no apparent financial reason (deprivation of adequate food, clothing, shelter, medical care) and lack of supervision. The majority of states (except Georgia and Washington) include emotional abuse in their definitions, generally defined as damage to the psychological capacity or emotional stability of the child (evidenced by symptoms such as anxiety, depression, aggressive behavior, withdrawal, and other substantial changes in behavior, cognition, or emotional response). Abandonment is included by many states either as part of their definition of neglect (18 states) or as a separate definition (13 states), and it includes situations

> when the parent's identity or whereabouts are unknown, the child has been left by the parent in circumstances where the child suffers serious harm, or the parent has failed to maintain contact with the child or to provide reasonable support for a specified period of time. (Child Welfare Information Gateway, 2005, p. 2)

Some states include in their definition of child abuse or neglect the abuse of substances by a parent, generally defined as the manufacturing of drugs in the presence of a child; using drugs in the presence of a child; selling, distributing, or giving drugs or alcohol to a child; and use of drugs that impairs the caregiver's ability to adequately care for the child (Child Welfare Information Gateway, 2005).

In the definition of child abuse and neglect, a "child" means a person less than 18 years old. The persons responsible for the child and reportable under the civil child abuse reporting laws to child protective services (CPS) include parents, guardians, foster parents, relatives, or other caretakers responsible for the child.

Prevalence

According to "Child Maltreatment 2004," a national report based on data submitted annually by the states to the federal government, an estimated 872,000 children in the United States were determined to be victims of child abuse or neglect in 2004, with a rate of victimization of 11.9 per 1,000 children. Girls were slightly more likely to be abused, while children below 3 years old had the highest rate of victimization (16.1 per 1,000 children of the same age group). The majority of children were victims of neglect (more than 60%), almost 18% suffered physical abuse, 10% were sexually abused, and 7% were emotionally abused. An estimated 1,490 children died in 2004 due to abuse or neglect, and more than 80% of them were younger than 4 years old. Approximately 80% of the persons responsible for the abuse or neglect were parents; of those, almost 60% were female (mostly the mother) (Children's Bureau, 2006).

A new source of prevalence data is the National Survey of Child and Adolescent Well-Being (NSCAW), the first national probability study of children investigated

for child abuse and neglect, which included a sample of 5,501 children (ages 0 to 14) who were randomly selected from the families who entered the U.S. child welfare system between October 1999 and December 2000. NSCAW baseline's report showed a higher prevalence of physical abuse (27%) than the prevalence reported in "Child Maltreatment 2004" for the same period (for the year 2000 the prevalence was 19%, almost the same as 2004). NSCAW reported that for almost 47% of children, the most serious type of abuse was neglect (27% failure to supervise, 20% failure to provide), 11% were victims of sexual abuse, 7% of emotional maltreatment, and 1.6% of abandonment (NSCAW, 2005).

Incidence

The National Incidence Study (NIS) of child maltreatment is a national survey of sentinel reporters from randomly selected counties across the nation. These sentinels are professionals from different fields, including education, health, social work and law, who submit data forms on any children who were maltreated during the study period, regardless of whether the case has been reported to CPS. NIS includes more than 5,600 professionals serving 42 counties. The last NIS (NIS-3) reported that in 1993, birth parents accounted for 78% of the maltreatment under the NIS-3 harm standard (that requires that an act or omission results in demonstrable harm to be classified as abuse or neglect). Of the children maltreated by birth parents, 75% were maltreated by their mothers and 46% by their fathers. The pattern of abuse differs by the gender of the alleged perpetrator; in general, children tended to suffer more neglect from women and more abuse from men. Mothers were responsible for 60% of the cases of physical abuse, 28% of the cases of sexual abuse, 55% of the cases of emotional abuse, 93% of the cases of physical neglect, 78% of the cases of emotional neglect, and 86% of the cases of educational neglect (Sedlack & Broadhurst, 1996).

A second source of child maltreatment incidence data is the Gallup nationwide survey of parents conducted in 1995. In this survey, 1,000 parents self-reported discipline methods used with their children during the past 12 months using the Parent-Child Conflict Tactic Scales (CTSPC). The CTSPC measures whether a parent has carried out specific acts of physical and psychological aggression regardless of whether the child was injured. Approximately half of the parents reported using corporal punishment including spanking on bottoms with bare hands (47%) and slapping on the hand, arms, or leg (37%). A smaller proportion reported severe physical assault such as shaking a child below 2 years (4%), beating them up (0.2%), and throwing or knocking them down (0.2%). Neglect was more prevalent than severe physical assault. Parents reported that they left the child alone even when an adult should be with him or her (20%), were not able to make sure that the child received the food he or she needed (11%), and were so drunk that they had problems taking care of the child (2.3%). The Gallup survey found that mothers have a higher rate of corporal punishment when children are younger. The rate of severe physical assault for mothers was more than double that of fathers (mothers 5.91 per 1,000, fathers 2.58 per 1,000), but the difference was not statistically significant (Straus, Hamby, Finkelhor, Moore, & Runyan, 1998).

Risk Factors

A number of risk factors have been associated with child maltreatment and its recurrence. In terms of the family characteristics, risk factors include family composition (single parents are more likely to abuse or neglect their child), caregiver substance abuse, domestic violence, mental health problems of caregivers, young maternal age, and maternal history of abuse. In terms of the maltreatment characteristics, cases involving neglect are most likely to recur, followed by cases involving physical abuse; cases of sexual maltreatment are the least likely to recur. Regarding children's ages, general reports of child abuse and neglect recurrence have shown that younger children are more likely to experience recurrence compared with older children. One hypothesis for this difference is that older children (12 to 17 years old) are more likely to age out of the system before a subsequent event of maltreatment. Children's health status has also been associated with the risk of abuse and neglect. High-risk infants, children with developmental delays, and children with handicaps who may be frequently irritable, difficult to soothe, unresponsive, or who reject holding are at higher risk of victimization (Appel & Holden, 1998; Barnett, Miller-Perrin, & Perrin, 1997; Edleson, 2001).

Child and Adolescent Health

The 20th century saw important and dramatic progress in child and adolescent health. With the recognition of child health as a distinct field and the development of pediatrics as a specialty of medicine, infections have been successfully treated and prevented, congenital anomalies have been classified and ameliorated, and newborn care has markedly increased the number of successful outcomes for premature or ill infants. Child development and behavioral studies have allowed for innovations in injury prevention, more effective parenting, and therapy of mental health issues for the young. This entry reviews assessment of child and adolescent health with special emphasis on prevention and discusses the roles of developmental disabilities, injury, and chronic diseases in child health.

Child Health

Routine, periodic health supervision visits are the cornerstone of preventive care for infants and children among pediatric health care workers worldwide.

Newborn Screening

In the past 50 years, developed nations have successfully implemented population-wide newborn laboratory screening programs that detect conditions such as phenylketonuria, sickle cell disease, and hypothyroidism early enough that treatment can prevent or ameliorate many of the consequences of the disease. Dozens of conditions can now be identified within days of birth using a few drops of blood; the large scale of the programs allows ultimate savings of money and human life for recognition of even very rare metabolic, hormonal, and other disorders.

Growth Surveillance

Monitoring child growth parameters of height, weight, and head circumference allows early warning and intervention in problems such as malnutrition, congenital malformations, chronic infection, and other chronic diseases. Such monitoring can be done easily and with minimal cost; it provides invaluable information to guide further care. Optimal maternal nutrition and prenatal care are foundations for infant growth; prevention of premature birth is one of the most important challenges in health care today. Human milk is the optimal food for newborns.

Poor growth is evaluated based on deviations from the expected growth curve or trajectory. For example, infants with poor weight gain, but normal height and head circumference growth, may not be receiving adequate caloric intake. They may suffer starvation in cases of dire poverty or maternal neglect, or they may not absorb the nutrition that is provided (infectious diarrhea)—this is often called "failure to thrive." Children with suboptimal weight and height, but relatively normal head circumference, may have had

prolonged protein calorie deprivation or a chronic medical condition such as chronic renal failure. In the United States, the incidence of overweight and obesity now exceeds failure to thrive and undernutrition.

Immunizations

Prevention of infectious disease by childhood immunization is one of the triumphs of medical science. Smallpox has been eradicated. Poliomyelitis may be near worldwide eradication. At present, effective immunization against tetanus, diphtheria, pertussis, hepatitis A and B, influenza, measles, mumps, rubella, varicella, hemophilus influenza B, and pneumococcus have reduced or nearly eliminated these conditions in many geographic areas. Newer immunizations against rotavirus, meningococcus, and human papillomavirus have recently begun widespread use. In the near future, other infections will also be targeted. Unfortunately, vaccination programs worldwide are often hindered by political, economic, and cultural barriers as well as practical issues such as requirements for vaccine refrigeration during storage.

Developmental Assessment

Developmental assessment ensures that children are progressing on appropriate developmental trajectories or that they receive appropriate support if there are areas of concern. Many tools can be used to assess developmental progress. One of the most important roles of the care provider is to listen to parents and address their concerns with appropriate screening tools, evaluation, and referrals to the appropriate subspecialists for further evaluation.

Developmental assessment should consist of a review of the child's progress in motor, cognitive, and social/emotional streams of development. Screening tools can be helpful to assure that all areas of development are addressed. Patterns of developmental delay are helpful both to clarify areas of concern and to assist with diagnosis.

Social Assessment

Safety/Abuse

Child abuse and neglect are worldwide, transcultural phenomena that can be recognized by perceptive and well-trained health care workers, treated with medical and psychological methods, and effectively prevented with parental education and support from home health visitors. Physical abuse often results when isolated, poorly prepared caretakers face predictable developmental crises such as crying and toilet training. Neglect of basic needs may indicate emotional or intellectual problems in the family. Both physical abuse and neglect more often occur in the settings of poverty, substance abuse, domestic violence, and other stressors. Sexual abuse of children may be incestuous, may involve family acquaintances, or may be related to pedophilia and child prostitution; a myriad societal and legal strategies will be needed to prevent these incidents.

Parenting

Child development and discipline issues are common. As fewer extended families live together, the common intergenerational knowledge base of normal development and effective child-raising techniques is replaced by media information, professional opinion, and information gained in schools. Scientific attention to parenting greatly increased over a century ago with psychoanalytic investigations by Sigmund Freud and Carl Jung and, later, the behavioral modification theories of B. F. Skinner and others. At mid-century and beyond, popularizers of parenting advice such as Benjamin Spock and Berry Brazelton advised a child-centered, relaxed parenting style. Currently, cognitive science and genetic ideas influence popular understanding of parenting practice and effects.

Adolescent Health

Growth/Puberty

Adolescence is marked by the rapid growth to adult height, development of secondary sexual characteristics and ability to reproduce, and psychological and cognitive changes leading to maturity. As developed societies require longer years of education before economic independence from parents, behavioral adolescence is extended to the 20s while, in a not fully understood trend, the onset of puberty (pubarche) has seemed to begin earlier.

Social Assessment

Adolescent health assessment importantly includes the adolescent's friends, social milieu, risky behaviors and habits, psychological state, academic and vocational progress, and family setting. Such a global view reflects

the reality that in the United States, adolescent mortality and serious morbidity are most often due to consequences of unintentional injury, homicide, suicide, sexual behaviors, and drug and alcohol abuse. Furthermore, many of these behaviors, once established in adolescence, are the basis for later problems in adult life. Teenage pregnancy, more common in underprivileged populations, makes continued educational and vocational successes less probable.

Developmental Disabilities

Developmental disabilities are a diverse group of severe chronic conditions that are associated with cognitive and/or physical impairments. People with developmental disabilities may have difficulty with communication, mobility, learning, self-care, and independent living. Developmental disabilities begin anytime from birth through adolescence and usually last throughout a person's lifetime.

Cognitive Developmental Disabilities

Important cognitive developmental disabilities include mental retardation and autism. Mental retardation is characterized both by a significantly below-average score on a test of mental ability or intelligence and by limitations in the ability to function in areas of daily life, such as communication, self-care, and getting along in social situations and school activities. Children with mental retardation can and do learn new skills, but they develop more slowly than children with average intelligence and adaptive skills. There are different degrees of mental retardation, ranging from mild to profound. A person's level of mental retardation can be defined by their intelligence quotient (IQ) and by the types and amount of support they need.

Children with autism spectrum disorders (ASDs) have significant impairments in social interaction and communication and exhibit unusual behaviors and interests. Many people with ASDs also have unusual ways of learning, paying attention, or reacting to different sensations. The cognitive abilities of people with ASDs can vary from profoundly mentally retarded to gifted ability levels.

Motor Developmental Disabilities

Motor developmental disabilities include cerebral palsy and neuromuscular disorders. *Cerebral palsy* is an umbrella term covering a group of nonprogressive, but often changing, motor impairment syndromes secondary to lesions or anomalies of the brain arising in the early stages of its development. Children and adolescents with cerebral palsy have alterations in muscle tone that make it difficult to maintain posture or be independently mobile.

Neuromuscular disorders can be caused by alterations in the function anywhere in the neuromuscular system from the brain, spinal cord, anterior horn cells, nerves, neuromuscular junction, and muscles. Prognosis and treatment depend on the cause and location of the abnormality. Examples of neuromuscular disorders include muscular dystrophy, Guillain-Barré syndrome, myasthenia gravis, and peripheral neuropathies.

Injury

As medical advances have decreased the effects of many diseases, the recognition of injuries as a major cause of child and adolescent morbidity and mortality has engendered injury control and prevention efforts. As one example, child car seats have saved many children from avoidable death or injury. Awareness of unintentional injury allows the possibility of even more prevention, while trauma care centers have improved survival among the injury victims. Intentional injury, including homicide and suicide, continues to be a major source of trauma; prevention efforts may involve better screening for depression, alcohol and drug treatment programs, and community education efforts.

Brain Injury

Brain injury is the most common cause of acquired disability in childhood, and most primary care physicians will encounter a child who has experienced brain injury. It is difficult to know the exact numbers of children with brain injury because children with milder injuries may not present for evaluation. However, almost all children with severe brain injury are seen in emergency departments prior to referral for further care. Between 100,000 and 200,000 children are hospitalized with brain injury every year in the United States. Of the children hospitalized with brain injury, many will have long-term disability.

Traumatic brain injury is most commonly caused by motor vehicle collisions in teenagers and by falls and physical abuse in younger children. Nontraumatic brain injury is caused by metabolic disorders (organic

acidemias, fatty acid oxidation defects), cerebral vascular accidents (stroke), anoxic injury (cardiac or respiratory arrest, near drowning, near hanging), central nervous system tumors, and hypoxic seizures.

Many of the causes of brain injury are preventable, and improvements in car safety have already made great improvements in decreasing the morbidity and mortality of brain injury. Increased awareness of the dangers of all-terrain vehicles and the risks associated with impaired driving will continue to decrease the incidence of new injury.

Spinal Cord Injury

Spinal cord injury (SCI) is due to a trauma causing a contusion or a partial or complete transaction of the spinal cord. SCI is a common cause of permanent disability and death in children. About 11,000 people a year sustain a SCI, and more than half of SCIs occur among young people between the ages of 16 and 30 years. The majority of SCI victims are boys and young men.

Like brain injury, many incidents of SCI are preventable with improved car safety and the use of appropriate protective gear during sports activities. Gunshot wounds and stab wounds are also both common and preventable causes of spinal cord injury.

Chronic Diseases

During the epidemiologic transition of the last century, major causes of mortality in the developed world shifted from infectious diseases to degenerative processes such as cancer and heart disease. In the childhood and adolescent years, a similar shift occurred away from now preventable or treatable infections to prematurity or congenital conditions. Children with special health care needs, including cancer, asthma, and consequences of prematurity, are the focus of much tertiary pediatric care and require substantial support services, including in-home therapies and hospice care.

Obesity/Diabetes Mellitus

The epidemic of obesity and its complications (including type 2 diabetes mellitus) reflect nutritional abundance and a mismatch between energy intake and expenditure. Medical and surgical approaches to this problem are inadequate; societal changes will be necessary for its solution. All organ systems are adversely affected, and early onset of obesity portends a more problematic course in later life.

Asthma

An improved armamentarium of pharmacologic treatments has made control of asthma possible for the great majority of affected children. Still, many children have restricted lifestyles with this illness for a variety of reasons: Adherence to suggested treatments is often incomplete due to inadequate patient or parent education, availability of care is limited by lack of health insurance, environmental factors are incompletely controlled (pollution, plant allergens, home dust, and animal danders). The roles of heredity, early antigen exposures, and infant nutrition in the genesis of asthma are currently undergoing intensive study.

Cancer

Although an uncommon childhood disease, cancer is a major cause of childhood mortality and morbidity. Leukemia is the most common childhood malignancy and, in the case of acute lymphoblastic leukemia, the most dramatic success story, with cure attained in more than 70% of children. Other cancers have proved less susceptible to the chemotherapy, radiation, and surgery forms of therapy being continually studied and improved.

Infections

Successful treatment and, even more significantly, prevention of childhood infections has been the most dramatic success story in child and adolescent health. Smallpox has been eradicated from the world; polio transmission occurs only in isolated pockets in the world. Diphtheria, tetanus, pneumococcal, hemophilus influenzae, measles, and chickenpox (varicella) vaccines have drastically reduced the incidence of these illnesses in the developed world; efforts in less developed areas have the potential for similar lifesaving results. Efforts to better control and prevent malaria through insect control, medicated sleep netting, medication, and development of a vaccine could result in substantially bettered childhood morbidity and mortality. Control and treatment of other parasitic diseases, tuberculosis, and human immunodeficiency virus are also acute needs.

Mental Illness

As life-threatening infections and other illnesses threatening children have diminished, more attention has been given toward child mental health and what Robert Haggerty (1998) called "the new morbidity" of developmental and psychosocial concerns (p. 1327). Attention deficit hyperactivity disorder is the most common early childhood diagnosis; psychostimulant medication and counseling help significantly. Depression affects children and adolescents as well as adults; suicide remains a leading cause of death in developed countries among teenagers, and prevention efforts are not yet systematized to acceptable levels of effectiveness. Eating disorders such as anorexia nervosa and bulimia are uncommon but serious problems in teenagers.

Chi-Square Test

The chi-square test is used for categorical data. There are three situations in which one can use the chi-square test: to test for independence, for equality of proportions, and for goodness of fit. The test statistic and the expected values for the first two cases are identical, but the hypotheses and sampling situations are distinctly different. For the goodness-of-fit situation, the test statistic and expected values are similar but not identical, and the hypotheses and sampling situation are also different from the other cases. The first two cases are presented first. All data tables were created by the author for this entry.

Test for Independence

Situation. One has a single random sample, and this sample is cross-categorized by two variables each with 2 or more categories. The null hypothesis is that there is no relationship between Variable 1 and Variable 2, that is, the two variables are independent of each other. The alternative hypothesis is that there is a relationship between the two variables, that is, the two variables are dependent.

For example, one has a random sample of people who are cross-categorized by race and blood type. The null hypothesis is that there is no relationship between race and blood type, and the alternative hypothesis is that there is a relationship between race and blood type.

Test for Equality of Proportions

Situation. One has a single variable of interest with 2 or more categories and multiple independent random samples. The null hypothesis is that there is no difference in the proportion of each category across the different populations. The alternative hypothesis is that there is at least one difference in a proportion across the different populations.

For example, one has four treatment groups. These treatment groups are the multiple independent random samples. The variable of interest has two categories *survived* or *died.* The null hypothesis is that the proportions that survived are the same for each treatment group and the proportion that died are the same for each treatment group. The alternative hypothesis is

that at least one proportion is different between the treatment groups. The test for equality of proportions is analogous to the one-way analysis of variance test for equality of means for quantitative data.

Expected Values and Tests Statistic: Independence and Equality of Proportions

With the tests for independence and equality of proportions, the data should be given in table form where i represents the ith row and j represents the jth column of the table. One finds the expected value (E_{ij}) for each ijth cell. The expected value for the ijth cell is the value that one would *expect* if the null hypothesis is true.

$$E_{ij} = \frac{i\text{th row total} \times j\text{th column total}}{\text{grand total}}.$$

Reasoning Behind the Expected Value for Test for Independence

For the test for independence, the null hypothesis states that Variable 1 and Variable 2 are independent. By independence,

$$\begin{aligned} &P[i\text{th row category}] \cdot P[j\text{th column category}] \\ &\quad = P[i\text{th row category} \cap j\text{th column category}] \\ &\quad = P[ij\text{th cell}]. \end{aligned}$$

So the best estimate of the $P[ij$th cell] is the estimate of the proportion of the ith row multiplied proportion of the jth column, that is,

$$\frac{i\text{th row total}}{\text{grand total}} \times \frac{j\text{th column total}}{\text{grand total}}.$$

To find the expected *count*, one would multiply by the grand total, which gives the above formula for E_{ij}.

Reasoning Behind the Expected Value for Test for Equality of Proportions

For the test for equality of proportions, the null hypothesis states that the proportion of each category is the same across the different populations. Let the columns represent the different samples representing the populations and the rows represent the categories of the variable of interest. Consider the ith category. The best estimate of the probability of the ith category is ith row total/grand total. To find the expected *count* for the jth column, one would multiply by the jth column total, which gives the above formula for E_{ij}.

Test Statistic

The observed value (O_{ij}) denotes the observed count in the ijth cell. The test statistic for both cases is $\chi^2 = \sum_i \sum_j \left(O_{ij} - E_{ij}\right)^2 / E_{ij}$ and degrees of freedom, $df = (r-1)(c-1)$ where r is the number of rows and c the number of columns. One rejects the null hypothesis if the $\chi^2 >$ critical value from the chi-square distribution with $df = (r-1)(c-1)$ and desired significance level (usually, $\alpha = 0.05$).

The chi-square test should not be used if any cell has an expected value less than 1. Also, when one has expected values less than 5, the results may be incorrect. Then the use of a nonparametric test such as Fisher's exact test should be considered.

Example 1

If one's situation was the test for independence, then one would have a random sample of 330 items

Table 1 Example 1: Table of Observed Values

	Column 1	*Column 2*	*Column 3*	*Column Total*
Row 1	28	45	27	100
Row 2	25	32	33	90
Row 3	17	33	30	80
Row 4	30	10	20	60
Row total	100	120	110	330

Table 2 Example 1: Table With Observed Values, Expected Values, and Contribution to the Test Statistic

Observed Count Expected Value Contribution	*Column 1*	*Column 2*	*Column 3*	*Column Total*
Row 1	28	45	27	100
	30.30	36.36	33.33	
	0.175	2.051	1.203	
Row 2	25	32	33	90
	27.27	32.73	30.00	
	0.189	0.16	0.300	
Row 3	17	33	30	80
	24.24	29.09	26.67	
	2.164	0.525	0.417	
Row 4	30	10	20	60
	18.18	21.82	20.00	
	7.682	6.402	0.000	
Row total	100	120	110	330

that are cross-classified by two variables, Variable 1 (row) and Variable 2 (column). The null hypothesis is that Variable 1 and Variable 2 are independent of each other.

If one's situation was the test for equality of proportions, then one would have three independent samples (columns) that are classified by a variable (row) that has four categories. The null hypothesis is that the probability of Row 1 category is the same for all three populations (represented by the columns), the probability of Row 2 category is the same for all three populations, the probability of Row 3 category is the same for all three populations, and the probability of Row 4 category is the same for all three populations.

The expected cell count for the first row and the first column is

$$E_{11} = \frac{100 \cdot 100}{330} = 30.30.$$

and its part of the test statistic is

$$\chi^2 = \frac{(O_{11} - E_{11})^2}{E_{11}} = \frac{(28 - 30.30)^2}{30.30} = 0.175.$$

The following table gives the expected cell counts and the cells contribution to the test statistic.

The test statistic $\chi^2 = 0.175 + 2.051 + \ldots + 6.402 + 0.000 = 21.124$.

For this example, $df = (4-1)(3-1) = (3)(2) = 6$. If $\alpha = 0.05$, the critical value from a chi-square distribution is 12.59. Therefore, one would reject the null hypothesis.

After one has rejected the null hypothesis, one should investigate which cells contributed the most to the test statistic. In the above table, cells (4, 1) and (4, 2) contributed 7.682 and 6.402 to the test statistic, that is, the observed count for (4, 1) was much greater than the expected count, and for (4, 2) the observed count was much smaller than what would have been expected. One may also wish to observe the cells that had little contribution to the test statistic.

Goodness of Fit

Situation. One has *A* single random sample and *A* single variable of interest with 2 or more categories. The null hypothesis is that the population proportions follow a specific distribution, and the alternative hypothesis is that the population proportions do not follow the specific distribution.

Table 3 Example 2: Table of Observed Values

Category 1	*Category 2*	*Category 3*	*Category 4*	*Total*
12	25	50	13	100

Table 4 Example 2: Table With Observed Values, Expected Values, and Contribution to the Test Statistic

Category 1	*Category 2*	*Category 3*	*Category 4*	*Total*
12	25	50	13	100
10	30	40	20	
0.4	0.83	2.50	2.45	

Table 5 Chi-Square: Summary

	Test for Independence	*Test for Equality of Proportions*	*Goodness of Fit*
Sample	A single sample	Multiple samples	A single sample
Variable(s)	Two variables of interest	A single variable of interest	A single variable of interest
Null hypothesis	Variable 1 and Variable 2 are independent of each other.	For each category, the proportion is equal across the different populations.	The proportion of each category is given.
Expected value	$\frac{i\text{th row total} \times j\text{th column total}}{\text{grand total}}$	$\frac{i\text{th row total} \times j\text{th column total}}{\text{grand total}}$	Proportion given in the null sample size
Test statistic	$\sum_i \sum_j \frac{(O_{ij}-E_{ij})^2}{E_{ij}}$	$\sum_i \sum_j \frac{(O_{ij}-E_{ij})^2}{E_{ij}}$	$\sum_i \frac{(O_i-E_i)^2}{E_i}$
df	$(r-1)(c-1)$	$(r-1)(c-1)$	No. of categories -1

Note: In all the three cases, the chi-square test is suspect if expected values are below 5 and should not be performed if you have expected values below 1.

For example, one believes that the distribution of certain traits in offsprings will follow a specific pattern. One has a random sample of offsprings and classifies the offsprings according to the traits. The null hypothesis is that the traits follow a specific distributional pattern, and the alternative is that the traits do not follow the pattern.

The expected value for a category is equal to the proportion given in the null hypothesis for the category multiplied by the sample size. The test statistic is $\chi^2 = \sum_i (O_i - E_i)^2/E_i$ and $df =$ No. of categories -1. One rejects the null hypothesis if the $\chi^2 >$ critical value from the chi-square distribution with df and desired significance level (usually, $\alpha = 0.05$).

One should not use the goodness-of-fit test if one does not have a large enough sample size to ensure that the expected values are 5 or above.

Example 2

The null hypothesis is $p_1 = 0.10$, $p_2 = 0.30$, $p_3 = 0.40$, and $p_4 = 0.20$ versus the alternative that at least one probability is not equal.

The expected value for category 1 is $0.10 \times 100 = 10$, and the contribution to the test statistic is $(12-10)^2/10 = 0.40$. The following table contains the observed count, expected values, and contribution to the test statistic.

The test statistic is $\chi^2 = 0.4 + 0.83 + 2.50 + 2.45 = 6.18$. The critical value from the chi-square distribution with $df = 4 - 1 = 3$ and $\alpha = 0.05$ is 7.81, so one would not reject the null hypothesis and conclude that the data do not give enough evidence to say that the distribution is different from $p_1 = 0.10$, $p_2 = 0.30$, $p_3 = 0.40$, and $p_4 = 0.20$.

Table 5 summarizes the three cases of the chi-square test.

Cholesterol

Cholesterol was first described near the end of the 18th century by a French chemist, Antoine Francois de Fourcroy, and then named "cholesteroline" by Michel Eugene Chevreul in 1815. Cholesterol is an insoluble constituent of animal fats found among the lipids in the bloodstream and in all cells of the human body. As an essential component of cell membranes and serum lipoproteins, cholesterol enables transmembrane transport and the transport of triglycerides. As a precursor of bile acids, cholesterol aids in the absorption of fat in the intestine. And as a precursor to adrenal steroids and sex hormones, cholesterol aids in endocrine regulation. When regulated properly by the body, cholesterol ensures survival. When regulated improperly, cholesterol threatens good health. Elevated serum cholesterol levels often lead to the buildup of arterial plaques, heart attack, and even death.

Cholesterol originates in one of two ways: either in the bile or through the diet. The intake of biliary cholesterol is typically 600 to 1,000 mg per day, while the intake of dietary cholesterol is only 250 to 500 mg per day. Biliary cholesterol is primarily synthesized from acetyl CoA through the HMG-CoA reductase pathway in many cells and tissues.

Since it is insoluble, cholesterol cannot travel freely through the blood. Cholesterol transport in the body is achieved through the use of lipoproteins. Lipoproteins consist of a core of neutral lipids surrounded by a polar surface coat that allows for the transport of cholesterol and other insoluble triglycerides. There are five major classes of lipoproteins: chylomicrons, very-low-density lipoproteins (VLDL), intermediate-density lipoproteins (IDL), low-density lipoproteins (LDL), and high-density lipoproteins (HDL). LDL carry triglycerides and cholesterol on to other body cells, while HDL transport cholesterol back to the liver for excretion.

Of the lipoprotein fractions, LDL, IDL, and VLDL are considered atherogenic. Conversely, increased concentrations of HDL correlate with lower rates of atherosclerosis. LDL pass through the arterial walls and become modified to form fatty streaks that in turn become fibrous plaques and finally lesions. These lesions often bring about calcification, hemorrhage, and ulceration. Atherosclerosis usually remains asymptomatic until an atheroma obstructs the bloodstream in the artery, and angina or myocardial infarction may subsequently develop.

Physiological and behavioral risk factors for atherosclerosis and coronary heart disease include age, heredity, diabetes, obesity, high blood pressure, and smoking, among others. In 1986, the statins, a class of pharmaceuticals that disrupt cholesterol biosynthesis by inhibiting HMG-CoA reductase, first became commercially available. Since then, the statins have emerged as the most effective therapeutic regimen for controlling a patient's blood cholesterol level, and clinical trials have repeatedly confirmed that altering lipoprotein transport significantly lowers a patient's risk for and incidence of cardiovascular disease.

Chromosome

A chromosome is a large macromolecule that functions as the structural unit of the genetic material. In eukaryotes, chromosomes are molecules consisting of linear, double-stranded deoxyribonucleic acid (DNA) and associated proteins. In prokaryotes, chromosomes are typically single-stranded, circular molecules. In epidemiology, knowledge of chromosomes is essential because chromosomal abnormalities are a leading cause of human genetic diseases. These abnormalities can include deletions (where part or all of a chromosome is missing), duplications (part or all of a chromosome is duplicated, resulting in excess genetic material), translocations (part of a chromosome is transferred to another chromosome), or inversions (part of the chromosome has detached, ''flipped over,'' and reattached, resulting in the genetic material being in the wrong order).

The totality of all the chromosomes in an individual is referred to as its genome. Each chromosome consists of genes (functional regions of the DNA that encode proteins), noncoding DNA, and associated structural proteins and ribonucleic acid (RNA). The sum of the material that makes up the chromosome is called chromatin. The number of chromosomes present varies greatly between species, ranging from a single chromosome (in the case of many bacteria) to more than 50 chromosomes in many animals. Humans have 46 paired chromosomes, receiving 23 from each parent. These include 22 pairs of autosomal chromosomes and one pair of sex chromosomes, which determine the gender of the individual: Females receive an X chromosome from each parent (giving them an XX genotype), while males receive an X chromosome from their mother and a Y chromosome from their father (resulting in an XY genotype).

One of the most important genetic diseases is Down's syndrome, which is the result of a trisomy (a duplication, leading to three copies) of chromosome 21. Individuals with Down's syndrome typically have mild to moderate mental retardation, decreased muscle tone, and shortened limbs. The incidence of Down's syndrome is approximately 1 in 800 births in the United States, and is most common in mothers who are above the age of 40 at birth. However, genetic testing can be carried out during pregnancy to inform parents if their fetus is positive for this chromosomal abnormality.

While Down's syndrome results from an extra autosomal chromosome, other genetic conditions can result from duplication or deletion of all or portions of the sex chromosomes (X and Y). Men with Klinefelter's syndrome possess an extra X chromosome, leading to an XXY genotype. Physically, they tend to be sterile, and tall with long arms and legs. Females with Turner syndrome, on the other hand, lack a second sex chromosome, and genetically are X0. Female sex characteristics may be present but are underdeveloped.

Chromosomal abnormalities also play a role in some cancers. Tumor cells frequently are aneuploid, meaning they have an abnormal number of chromosomes. They may also contain translocations or portions of chromosomes that have been copied not just once but dozens or hundreds of times.

Chronic Disease Epidemiology

With important advances in medicine and public health and overall increases in average life expectancy in the developed and developing world in the 20th century, chronic diseases have now reached epidemic proportions globally. This entry provides an overview of factors that have contributed to the worldwide emergence of chronic diseases; describes the epidemiology of the major chronic diseases of

cardiovascular disease, cancer, and diabetes; and highlights some of the core epidemiologic and statistical methods for studying chronic diseases.

Global Emergence of Chronic Diseases

In industrialized countries, the latter half of the 20th century bore witness to the emergence of chronic diseases as major contributors to morbidity and mortality. In recent years, similar patterns have been taking place in the developing world. These trends are largely due to significant advancements in medicine and public health—including improvements in sanitation, nutrition, and the discovery of antibiotics such as penicillin—that led to overall reductions in perinatal and childhood mortality, declines in the incidence of infectious diseases, and rises in life expectancy. Together, these changes caused a shift in the incidence of infectious diseases to chronic, noncommunicable diseases, particularly because many chronic diseases are highly age dependent. This shift has been labeled the "epidemiologic transition." Simultaneous increases in economic development and urbanization have also spurred changes in lifestyle factors, including diet, physical activity, and stress, and compounded the burden of morbidity and mortality from chronic diseases. Globally, approximately 58 million deaths are estimated to have taken place in 2005, with 60% (35 million deaths) attributed to chronic diseases. The leading causes of death from chronic diseases are cardiovascular diseases (primarily heart disease and stroke), cancer, chronic respiratory diseases, and diabetes. With the large populations and the epidemiologic transition in the developing world, chronic diseases have become a global epidemic. In 2005, 80% of all deaths from chronic diseases had occurred in low- and middle-income countries. Some of these countries, such as India, face "double burdens" of acute infectious diseases (e.g., malaria) and chronic diseases.

Major Chronic Diseases

Cardiovascular Disease

Cardiovascular disease (comprised mainly of heart disease and stroke) accounted for 30% (17 million) of all deaths, and 10% of disability-adjusted life-years worldwide in 2005, and thus represents the leading cause of mortality and morbidity globally. It is anticipated that the developing world will experience the greatest increases in the burden of cardiovascular disease in the decades to come. Between 1990 and 2020, the developing world is projected to have 137% and 120% increases in the number of deaths from coronary heart disease among men and women, respectively. In contrast, these increases are estimated to be 29% and 48% in developed countries. Likewise, 124% and 107% increases of stroke deaths among men and women in developing countries are expected over the same time period, with lesser respective increases of 78% and 56% in developed countries.

In Western developed nations, including the United States, Canada, and Australia, mortality rates from coronary heart disease rose until the late 1960s, after which there was a secular decline in mortality rates. A similar pattern was observed for stroke mortality rates, although the decline began as much as two decades earlier and was more pronounced than for heart disease. Presently in these countries, coronary heart disease mortality rates exceed stroke mortality rates. Despite the declines in annual rates of death for both coronary heart disease and stroke, the absolute number of deaths from each outcome has substantially increased over the past decade. This is mainly due to population aging, with mortality rates increasing successively with age. Notably, disparities in these outcomes, particularly along racial/ethnic lines, are well established. For example, in the United States, compared with whites, in both men and women, heart disease and stroke death rates are higher among blacks, yet lower among Asians/Pacific Islanders and Hispanics.

Established risk factors for coronary heart disease and stroke include age, male gender, smoking, elevated low-density lipoproteins, low high-density lipoproteins, hypertension, diabetes, physical inactivity, obesity, and low socioeconomic status. Risk factors for which consensus is less established include novel inflammatory markers, elevated homocysteine and elevated lipoprotein(a) levels, psychological factors such as depression and hostility, and physical and social environmental factors such as residence in a low-income neighborhood. Strokes are classified as ischemic (occurring mainly as a result of atherosclerosis) or hemorrhagic (for which the most important risk factor is hypertension), with approximately 80% of strokes in Western developed countries being ischemic. In countries in sub-Saharan Africa and Asia (such as China and Japan), hemorrhagic strokes are relatively more common than ischemic strokes. Unlike Western developed nations, these regions are

also characterized by higher mortality rates from strokes than from coronary heart disease.

Cancer

Cancer accounted for 13% (7.6 million) of all deaths, and 5% of disability-adjusted life-years worldwide in 2005, and is the second leading cause of mortality and morbidity internationally. In 2000, among men, the leading causes of cancer deaths were lung, stomach, liver, and colon and rectal cancer. Among women, the main contributors were breast cancer, followed by lung, stomach, and colon and rectal cancer. For both sexes combined, lung cancer accounted for the greatest proportion (17%) of cancer deaths. The number of new cases of cancer is estimated to escalate by 50% to 50 million in 2020. This dramatic increase is largely driven by population aging globally and the epidemiologic transition in countries in the developing world.

In the United States, among men, lung, prostate, and colon and rectal cancer were the top three contributors to cancer death in 2001, with liver and stomach cancer ranking fifth and sixth, respectively. Among women, lung, breast, and colon and rectal cancer were the leading causes of cancer death, with stomach cancer ranking fifth. Death rates for the top three contributors to cancer death for men and women have been on the decline (for lung and prostate cancer, since the early 1990s, and for colon and rectal cancer, since around 1980). These trends for lung cancer and colon and rectal cancer in part reflect similar falls in incidence rates. In contrast, breast cancer and prostate cancer incidence rates have continued to rise steadily; declines in mortality rates from these cancers may be the result of earlier screening detection and improved medical treatments. Like cardiovascular disease, racial/ethnic disparities also exist for cancer outcomes. Mortality rates are higher among blacks than whites for cancers of the colon and rectum, lung (men only), breast, and prostate, and incidence rates are higher among blacks for all these cancers except breast cancer. Some of these disparities may be due to lower socioeconomic status, with 24% of blacks living below the poverty line (vs. 8% in whites). Socioeconomic status likely influences the adoption of risk factors for cancer, as well as access to cancer screening and high-quality medical treatment.

Approximately 35% of deaths from cancer globally have been attributed to nine potentially modifiable risk factors. Both worldwide and in low- and middle-income countries, the leading risk factors for death from cancer in 2001 were smoking, alcohol consumption, and low fruit and vegetable intakes. In high-income countries, smoking, alcohol consumption, and overweight and obesity were the main contributors to cancer mortality. These modifiable risk factors offer a vast opportunity for preventing substantial morbidity and mortality globally.

Diabetes

Diabetes comprised 2% (1 million) of all deaths, and 1% of disability-adjusted life-years worldwide in the year 2005. It is projected that the total number of adults with diabetes will more than double from 171 million in the year 2000 to 366 million in 2030. This rapid increase can be attributed to aging of the population globally, the epidemiologic transition in the developing world, and the increasing prevalence of poor diets, sedentary behaviors, and obesity in developed nations. India, China, and then the United States are estimated to have the highest numbers of diabetes cases in both 2000 and 2030.

In the United States, nearly 1 in 10 Americans above the age of 20 had diabetes in 2005, with a slightly lower prevalence among women (8.8%) than men (10.5%). Based on death certificate records, diabetes ranked as the sixth leading cause of death in 2002. However, diabetes is most likely underreported as an underlying cause of death on death certificates.

Diabetes is associated with both macrovascular complications (heart disease and stroke) and microvascular complications (including blindness and kidney disease). Established risk factors for diabetes include age, obesity, physical inactivity, and a family history of diabetes. Furthermore, in the United States, blacks and Hispanics are 1.5 to 2 times more likely to develop diabetes than whites.

Epidemiologic and Statistical Methods

The investigation of potential risk factors for chronic diseases, including estimates of the strength of the associations of these factors with diseases, is based on epidemiologic studies that range in design from ecologic studies (in which only data at a group level and not individual level are compared), to case-control studies (in which cases of disease are compared with respect to the potential risk factor to individuals from

the same source population), prospective cohort studies (in which data on the risk factor are measured at one point in time and the individuals are then followed over time through regular examinations, tests, or surveys), and randomized clinical trials (in which individuals are randomly assigned to a treatment or placebo group and followed over time). The occurrence of chronic disease can be identified through surveys (i.e., with self-report) or through medical records or disease registries (for cancer diagnoses), while reports of deaths from chronic diseases are often requested from the next of kin and then confirmed through medical records or national death registries.

In these studies, statistical methods are applied to estimate the associations between the risk factor under study and the chronic disease outcome, controlling for age and other factors that predict the outcome and that may also be associated with the risk factor under study (i.e., potential confounders). The analyses hence typically use multivariable regression models to derive estimates. These models often take the specific form of logistic regression models, or Poisson or Cox regression models, which differ according to how the model structure is specified. In instances where a physical or social environmental characteristic is being examined as a main predictor or is included as a confounder, applying multilevel models (such as two-level models in which similarities on the outcome in individuals within the same spatial area are taken into account) is appropriate to obtain more valid estimates of the statistical significance of associations.

Moreover, when different populations are being compared (such as across countries) for a chronic disease, it is important to calculate and compare age-standardized disease rates, so that different age structures between populations do not bias the comparisons. This is achieved through a standardization procedure, whereby age-specific disease rates are weighted according to a standard population, such as the World Health Organization World Standard population, to produce a summary of age-standardized incidence or mortality rate from the disease.

Apart from mortality figures, disability-adjusted life-years (DALYs) provide summary measures of disease burden in terms of both mortality and morbidity to allow for comparisons across countries or regions. DALYs combine years of life lost due to premature mortality (YLL) with years of life lived with disability (YLD) for a given disease or group of diseases. Like mortality, to permit more valid comparisons across countries or regions, it is appropriate to age-standardize DALYs using a standard population to produce summary measures.

Finally, epidemiologic studies that examine the risk factors for chronic diseases, or the determinants of trends in chronic disease incidence or mortality rates, are more likely to be valid when they consider that a true risk factor typically does not immediately cause the outcome, but rather precedes the outcome by a certain number of years. For example, based on biological mechanisms, a prospective cohort study on smoking and heart disease incidence with 10 to 15 years of follow-up is more likely to be valid and to find a stronger association than a study that measures both smoking exposure and heart disease status at the same point in time. Similarly, studies that explore the possible effects of economic growth on trends in stroke mortality rates years later are more likely to be valid and sensitive than those that model economic growth and stroke mortality for the same time period.

Future Patterns of Chronic Disease

Chronic diseases have become the major contributor to mortality and morbidity globally. Over the next few decades, the burden of chronic diseases will grow fastest in countries in the developing world, largely due to the epidemiologic transition, economic development, and urbanization. Because the major chronic diseases worldwide—cardiovascular disease, cancer, and diabetes—share several modifiable risk factors, there exist tremendous opportunities to prevent these diseases. Epidemiologic studies have played an important role in identifying such risk factors, and in investigating other factors that may determine patterns of chronic disease within countries and around the world.

Circumcision, Male

Male circumcision is a practice that has been carried out across societies of the world for thousands of years. Recent scientific and epidemiological research provides evidence of protective effects against penile foreskin-related disorders, urinary tract and sexually transmitted infections, penile and cervical cancer, and HIV. This entry provides a comprehensive overview of male circumcision's prophylactic role as a low-risk, low-cost procedure with significant potentially long-term benefits to the individual and society.

Male circumcision is the removal of the foreskin (prepuce) from around the head (glans) of the penis. The amount of skin removed varies drastically by individual due to different foreskin sizes. A short prepuce does not completely cover the glans and exposes the tip of the head even when flaccid, whereas a long prepuce is loose and droops down from the end of an unerect penis. Many of these differences are genetic, so there are generalized trends among like populations. When erect, the glans emerges from the foreskin sleeve. Circumcision removes the foreskin, thus always exposing the head of the penis.

Who Gets Circumcised and Why?

Male circumcision dates back several thousand years. The earliest documentation comes from Egyptian tomb artwork dated to the Sixth Dynasty (2345–2181 BCE). The book of Genesis (17:11) speaks of circumcision as a rite of passage for Jews during the age of Abraham, who lived around 2000 BCE. Although its origin is unknown, male circumcision practice is widespread today, extending from Africa to the Middle East, the islands of the Pacific to the West.

Male circumcision practices differ greatly by culture. Its practice is often associated with rites of passage into adulthood, religious sacrifice, and hygiene promotion. Approximately 25% of males are circumcised globally. The age at time of circumcision also varies with culture, extending from infancy through puberty and into adulthood. Jews and Muslims mandate circumcision as a part of their religious practice and account for 100,000 and 10 million annual circumcisions, respectively. Pacific Islanders are traditionally circumcised as a rite of initiation, as are Australian aboriginals. In Africa, circumcision practice is disparate, dictated largely by influences ranging from colonization to tribal rituals.

In the United States, 65% to 90% of males are circumcised. This wide range is attributed to differences between the statistical reporting of birthing centers and the observed rate of practice that includes adult circumcision. From 1988 to 2000, the U.S. newborn circumcision rate increased by 12.8%. This increase is most prominent in states where immigration is low, because most immigrants to the United States, particularly Hispanics, are traditionally not circumcised.

Outside religious or medical influences, circumcision decisions are based most heavily on parental preference. For mothers, there is a strong correlation between their son's circumcision status and the woman's ideal male partner's circumcision status. Likewise, fathers make the decision based on personal experience.

Histological and Biological Effects of Male Circumcision

To fully comprehend the protective effects of male circumcision, one needs to have a general understanding of the histological and biological differences between a circumcised and uncircumcised penis.

Keratin is a protein found in skin cells that acts as a primary line of immunological defense against infection. According to a histological study conducted

in 2006 by McCoombe and Short, different regions of the penis are keratinized to varying degrees. In an uncircumcised male, the outer surface of the foreskin is heavily keratinized while the inner surface is not and closely resembles the mucosal epithelia of the cervix and nasal passageways. When the penis is erect, this weak inner prepuce is exposed and stretched, thus putting it in direct contact with potentially infectious agents during unprotected sex.

Furthermore, the warm mucosal environment under the foreskin favors growth of microorganisms. The preputial sac must be properly and frequently cleaned to prevent infection. Multiple studies show lower levels of penile hygiene in uncircumcised men, as compared with those who are circumcised. This poor genital cleanliness contributes to higher incidence of penile discomfort and infection.

Circumcision removes the weakly keratinized inner prepuce and cesspool-like preputial sac. The basis for male circumcision's prophylaxis is believed to be in the keratinization of the penis and the reduction of bacterial growth.

Health Benefits of Male Circumcision

Substantial observational, epidemiological, and biological research points to the prophylactic role of male circumcision. These benefits include a reduced incidence of

1. Foreskin-related disorders
2. Urinary tract infections
3. Sexually transmitted infections
4. Human papillomavirus
5. Penile cancer
6. Cervical cancer
7. HIV

Foreskin-Related Disorders

The following three foreskin-related disorders are common among uncircumcised men.

- *Phimosis* is a condition in which the foreskin of the penis becomes constricted and difficult to retract. Although congenital phimosis is common in young boys while the epithelial layers between the glans and foreskin keratinize and separate, 90% are no longer affected by age 3. After age 6, phimosis is considered problematic and is most commonly owed to poor hygiene. Repetitive forceful retraction of a congenital phimosis by parents in an attempt to clean under their child's foreskin may also contribute to the onset of acquired phimosis. At least 10% of uncircumcised adult males are afflicted by acquired phimosis.

- *Paraphimosis* is a condition where the retracted foreskin cannot be brought back again over the glans of the penis to its naturally occurring position. Paraphimosis is a true urologic emergency and is most often relieved by circumcision or foreskin slitting. Frequent bladder catheterizations in adults, without replacing the foreskin in its resting position, is a common cause of adult paraphimosis.

- *Balanoposthititis* is an inflammation of the foreskin and glans, most often caused by acute infection underneath the foreskin of an unhygienic penis. It is also common among uncircumcised, diabetic men owing to a weakened, shrunken penis.

Urinary Tract Infections

Infections of the urinary tract are regarded as common among the pediatric population with the highest prevalence and greatest severity in boys prior to 6 months of age. A study at Kaiser Permanente hospitals in northern California revealed that 86% of the urinary tract infections (UTIs) among boys occurred in those who were uncircumcised. A meta-analysis of nine studies found an average 12-fold increase of UTI incidence in uncircumcised boys. The pathophysiological basis for this high incidence is the ease in which uropathic bacteria cling to the mucosal lining underneath the foreskin and travel up the urethra, thereby infecting the urinary tract. With long-term morbidity and potential mortality associated with untreated UTIs, preventive measures are highly desirable.

Sexually Transmitted Infections

The association between circumcision status and sexually transmitted infection (STI) is not yet entirely conclusive. A range of studies conducted in recent years show differential patterns of association. In a 2006 meta-analysis, Weiss, Thomas, Munabi, and Hayes reviewed 26 studies and found a strong

association for syphilis and chancroid infection but no association with genital herpes (HSV-2) in men. Another study showed women with uncircumcised male partners to be 2.2 times more likely to contract HSV-2 and 5.6 times more likely for chlamydia infection.

The proposed biological rationale for increased STI incidence in uncircumcised men and their partners is multifold. The area underneath the prepuce is susceptible to microabrasions during intercourse and is a moist breeding ground for pathogens. Incidence appears to be influenced by genital hygiene, availability of running water, sexual practices, and socioeconomic status. As a result, developed countries are less likely to see male circumcision's impact on STI incidence. In poorer settings, where penile hygiene suffers, incidence is much higher for uncircumcised males and their partners.

Human Papillomavirus

Incidence and Prevalence

Human papillomavirus (HPV) is a sexually transmitted virus that affects both men and women. It spreads primarily through genital contact and can remain undetected for years. Approximately 20 million people are currently infected with HPV. More than 50% of sexually active men and women acquire genital HPV infection at some point in their lives, and, by age 50, at least 80% of women will have had HPV. Nearly 6.2 million Americans get a new HPV infection each year.

Link to Penile and Cervical Cancers

High-risk types of HPV (namely, Types 16 and 18) are associated with the incidence of penile cancer in men and cervical cancer in women. Nearly 50% of penile cancer cases are coupled with HPV infection, and the relationship between HPV-positivity and cervical cancer is almost 100% in women.

Prophylactic Benefits of Male Circumcision

Recent studies point to a link between circumcision status and HPV infection, the most convincing of which was led by Castellsague in 2002. It shows HPV detection in 19.6% of uncircumcised men but in only 5.5% of circumcised men. After adjusting for potential confounding factors, such as sexual behavior, circumcised men are only one third as likely to have HPV infection.

Penile Cancer

Incidence and Prevalence

In the United States, the total annual incidence of penile cancer is approximately 1 per 100,000. Incidence is even lower in Israel—0.1 per 100,000—where almost all men are circumcised. The prevalence is much higher in poor countries, especially African countries where male circumcision is not routinely practiced. Here, penile cancer rates can be 10 times more common than in developed countries, representing 10% to 22% of all male cancers.

Etiology

The majority of penile malignancies are cancers of the skin and can be found anywhere along the shaft of the penis although they are most often found on the foreskin and glans. It is treatable if detected early. The relationship between male circumcision and penile cancer is believed to be attributed to poor hygiene. The decaying cells on the undersurface of the foreskin (smegma) produce irritation and lead to cancer development. The presence of venereal warts and HPV has also been implicated in the etiology of penile cancers.

Prophylactic Benefits of Male Circumcision

The evidence pointing to male circumcision's benefit in penile cancer prevention is astounding. Males who are circumcised at birth almost never get penile cancer. In fact, of the approximately 50,000 reported cases of penile cancer in the United States since the 1930s (10,000 of which resulted in death), only 10 cases were reported in circumcised men. Those who are circumcised within the first few years of life have a decreased incidence, and adult circumcision confers almost no protective effect.

Cervical Cancer

Incidence and Prevalence

Cancer of the cervix is the second most prevalent cancer in women worldwide with 450,000 new diagnoses per year. With more than 80% occurring in less

developed countries, it is the leading cause of cancer-related death for these women. In the United States, an estimated 10,000 women will be diagnosed with cervical cancer in 2006 and nearly 4,000 will die from it.

Prophylactic Role of Male Circumcision

A number of studies have documented higher rates of cervical cancer in women who have had one or more uncircumcised male sexual partners. Castellsague et al.'s multinational study revealed that women are 5.6 times more likely to have cervical cancer if their partner is uncircumcised and at high risk for HPV exposure. Penile HPV infection is associated with a fourfold increase in the risk of cervical HPV infection in the female partner, which then has a 77-fold increase in the risk of cervical cancer. Thus, the cervical cancer epidemic worldwide appears to be contributed, at least in part, to the uncircumcised male.

Human Immunodeficiency Virus

Incidence and Prevalence

More than 25 million people have died from AIDS. To date, 60 million have been infected and 40 million are currently living with HIV. The overwhelming majority of these individuals—98% of women and 94% of men—live in developing countries. More than 80% of these infections arise from vaginal intercourse. An extrapolation model estimates 1 billion to be HIV-positive by 2050 with an exponential increase in HIV-orphaned children.

Prophylactic Role of Male Circumcision

As previously discussed, histological analysis of an uncircumcised penis shows the inner prepuce to be weakly keratinized and more susceptible to minor trauma during intercourse. The distribution of HIV-susceptible Langerhans's cells is greatest on the outer surface of the foreskin, with high levels also at the inner foreskin layer. The weakly keratinized inner prepuce with frequent microabrasions, coupled with high-density Langerhans's cells and their HIV-1 receptors, substantially increases susceptibility to infection. Moreover, selective entry of HIV at the inner prepuce has been shown by direct experimentation using punch biopsies. Live uptake was observed at the inner preputial Langerhans's cells and none on the keratinized tissue of the outer foreskin, histologically similar to the shaft of the circumcised penis.

To further compound the risk, the preputial sac underneath the foreskin is speculated to act as a storage site for HIV after intercourse, therefore prolonging time of exposure and allowing for greater infection. Ultimately, the weakest point (inner prepuce) of an uncircumcised penis is exposed to potentially infected vaginal secretions during and after vaginal intercourse.

Epidemiological Studies

Since the 1980s, more than 40 studies have been conducted to understand the role of male circumcision in HIV incidence. Observational studies have consistently shown a considerably lower incidence of HIV in localities where male circumcision is practiced. Weiss's large systematic meta-analysis of 27 of these studies showed the HIV incidence to be 2.4-fold higher in uncircumcised men when adjusted for confounding factors. A study in Dar es Salaam, Tanzania, analyzed the differential risk to women due to their partner's circumcision status. It was found that married women with one sex partner were at a four times higher risk of HIV infection if their husband was uncircumcised.

To study the absolute protective effect of male circumcision, a prospective study followed heterosexual couples in which one partner was HIV-positive. The incidence of seroconversion was 17 per 100 person-years among the 137 uncircumcised males, whereas none of the 50 circumcised men seroconverted. The effect was equally apparent in Muslim (who wash after intercourse) and non-Muslim men, suggesting religious and cultural behaviors were not involved in transmission rates.

In 2005, the results of the first randomized controlled trial (RCT) in Orange Farm, South Africa, were published. The protective benefit of circumcision was so great that the Data and Safety Monitoring Board halted the trial 6 months early so that the control group could immediately be offered circumcision. Male circumcision prevented more than 60% of HIV infections, an efficacy rate similar to that of a vaccine. Moreover, 99% of men were "very satisfied" with their new circumcision status. The two other RCTs—Kenya and Uganda—are still in progress with projected completion dates for 2007 and 2008, respectively.

In response to Auvert et al.'s (2005) Orange Farm results, a study estimated the potential impact of male circumcision in sub-Saharan Africa. Assuming

full coverage of male circumcision and a 60% protective effect, Williams et al. (2006) predicts male circumcision could avert 2 million new HIV infections and 0.3 million deaths over the next 10 years, with even greater effects in the 10 years to follow.

Implementation of Male Circumcision as a Public Health Measure

In response to these studies, some countries are promoting male circumcision as a means of protection. In these locations, circumcision clinics are overwhelmed with huge demand from young men. In Swaziland, for example, there is an 8-month waiting list for adult male circumcision. Not only does the implementation of male circumcision yield protection from HIV, it also provides a means for accessing males in reproductive health issues.

Many public health officials share a valid concern that male circumcision interventions may be misinterpreted as a guarantee against HIV infection, thus encouraging risky behavior in newly circumcised men. This circumstance can be avoided if male circumcision implementation and integration is carried out carefully. It must be promoted as part of an educational package reiterating that it reduces, but does not eliminate, the risk of HIV infection.

Sociosexual Perspectives

Socially, preference for male circumcision differs by culture. A survey of women in the United States indicates preference for male circumcision because of cleanliness, visual appearance, and benefits to intercourse. In Korea, male circumcision is viewed as necessary for penile hygiene measures. African women often prefer male circumcision because of its known reduced STI risk.

Functional differences due to circumcision status are difficult to quantify. Somatosensory tests yield no differences in penile sensitivity, and histological research reveals similar keratin levels for uncircumcised and neonatally circumcised penises. A national study among 1,400 men in the United States found that uncircumcised men are more likely to experience sexual dysfunctions later in life, including a two times greater difficultly in maintaining an erection.

Whether or not sexual pleasure is enhanced or diminished via circumcision is subjective, differing by individual, partner, and sexual behaviors. However, an English study of 150 adult-circumcised men revealed that 38% claimed an enhanced sensation in vaginal intercourse, 18% reported a decreased sensation, and 44% said it was unchanged. Of these men, 61% were pleased with their new circumcision status and 17% were not.

A Note on Female Genital Mutilation

There is an important distinction to be made between male circumcision and female genital mutilation (FGM), sometimes under the misnomer "female circumcision." The most widely practiced form of FGM entails removal of the clitoris and labia for traditional or religious practices. This genital scarring results in dyspareunia and life-threatening complications during labor and delivery. Male circumcision, in contrast, has major health benefits.

Risks of Male Circumcision

As with any surgical procedure, there are inherent risks with circumcision. Clinical studies performed over the past decades have provided overwhelming evidence that when performed by an experienced operator, circumcision is a very safe surgical procedure. Surgical complications range from 0.2% to 0.6% and include excessive bleeding (1 per 1,000 cases) and local infections (1 to 10 per 1,000). Both complications can be easily addressed and solved. Greater concerns exist in poor countries where access to clean surgical tools and running water is difficult. Overall, male circumcision is one of the top 40 most frequently performed surgical procedures with thousands of years of practice.

Classification and Regression Tree Models

Classification and regression tree models, also known as recursive partitioning or CART™, are a class of nonparametric regression models becoming increasingly popular in epidemiology and biomedical data analysis, as well as in the computer science and data-mining fields. These models became popular when this methodology was formalized by Leo Breiman and colleagues in their book *Classification and Regression Trees*. Subsequent availability of commercial software (e.g., Salford Systems, Inc.) and academic freeware (R ''tree'' and ''rpart'' functions) for fitting these models helped make this approach practical to data analysis. One of the most common uses of classification and regression tree models in epidemiology is to develop predictive rules for diagnosis; other uses include developing screening guidelines and creating prognostic models.

The goal of regression and classification is to fit a mathematical model that takes categorical or continuous input (independent or predictor variables) and returns a predicted value for an output (dependent or outcome variable). To take a simple example, the analyst may want to predict a person's weight as a function of their height using a simple linear regression model where height is the input and weight is the output. In collecting data, the analyst will have measured height and weight on numerous people and are likely to have several individuals with nearly or exactly the same height. For this subset, the weights will follow a distribution with some people being heavier or lighter than others. A simple linear regression of weight on height gives a formula that for a particular height, the model returns the ''expected'' or ''mean'' weight for individuals at that height. The concept of the ''expected'' or ''mean'' weight for individuals at a particular height is essential for understanding regression. In statistics, a simple linear regression gives the conditional mean of Height for a given value of Weight $= w$, which we write as $E(\text{Weight}|\text{Height} = h) = \beta_0 + \beta_1 \times \text{Height}$, where $E(\text{Weight}|\text{Height} = h)$ is the expected value of weight for a person with height h, and β_0 and β_1 are the parameters of the equation used to make this prediction.

A similar concept applies to the classification problem where the input variables are used to predict which group an individual or some other object belongs to. The proper statistical approach for this type of analysis includes discriminant analysis, though often logistic regression is used by many applied data analysts. In classification, the idea of conditional expectation, that is, $E(\text{Weight}|\text{Height} = h)$, is replaced with a statement of probability of belonging to one of the classes. The simplest problem considers two classes, say, patients who either responded to treatment or did not. In a treatment study comparing response rates for patients receiving drugs versus patients receiving a placebo, the analyst would fit models to obtain estimates of conditional probabilities of response, for example, Prob(Patient responded|Patient received drug) versus the Prob(Patient responded|Patient received placebo).

Nonparametric recursive partitioning has the same goals as regression and classification, as above, but does not assume a particular parametric model. Using a nonparametric approach allows more flexibility in the model fitting adjusting for fluctuations in the data, however, at giving up computational simplicity and formal tests of hypothesis (e.g., testing for significance of a coefficient). In the case above, where weight was regressed on height, a linear relationship might be

reasonable for a homogeneous population, for instance, within a particular age range and gender group. It might become less reasonable if all ages from infants to the elderly were included, or if outliers such as weight lifters and marathon runners were included. (While a more complex parametric model with more terms and interactions might fit the data well, confirming that the parametric model is correct cannot always be done easily, especially as the number of input variables increase.)

Example: Kyphosis Following Spinal Surgery

To illustrate recursive partitioning we will consider a simple two-class classification problem and then the regression problem. These techniques will be illustrated using the kyphosis data set available through the R software package (www.r-project.org), which represents data on children who have had corrective spinal surgery. The outcome variable `Kyphosis` is a binary variable with levels `absent` or `present` indicating if a kyphosis (a type of deformation) was present after the operation. The input variables include `the age` in months of the child, the number of vertebrae involved, and the number of the first (topmost) vertebra operated on, that is, the starting vertebra. The first 10 rows of data are presented in Table 1.

Recursive partitioning methods attempt to find ranges over the input variables where the value of the outcome variable is more likely to be one class rather than the other. In the entire data set, 17 of the 81 rows had an outcome of Kyphosis "present," so the proportion of Kyphosis was 21% overall. By finding the appropriate ranges, or partitions of the covariate space, we can see if the proportion of present and absent outcomes increases or decreases over different values and combinations of values of these variables. Figure 1 presents a partition using the variables age and starting vertebrae.

In this figure, each case is plotted at their age and start value and labeled as kyphosis absent (A) or present (P). The covariate space is partitioned into five regions and the proportion of outcomes indicated. The top region consists of 27 cases all with kyphosis absent. This region is defined by the starting vertebrae above number 14, while the bottom region defined by the starting vertebrae less than 9 is more likely to have kyphosis present (11 of 19, or 58%).

In brief, recursive partitioning finds subregions such that the class membership within that region is more homogeneous than in the data set overall.

Calculating a recursive partitioning model is computationally intensive but conceptually easy. The algorithm takes each input variable and goes through each possible cut point that splits the data into two groups. The cut points are determined from the data and are the midpoints between the ordered values (e.g., for age these cut points might be 10.5 months,

Table 1 First 10 Rows of Kyphosis Data Set

Row	*Kyphosis*	*Age*	*Number*	*Start*
1	Absent	71	3	5
2	Absent	158	3	14
3	Present	128	4	5
4	Absent	2	5	1
5	Absent	1	4	15
6	Absent	1	2	16
7	Absent	61	2	17
8	Absent	37	3	16
9	Absent	113	2	16
10	Present	59	6	12

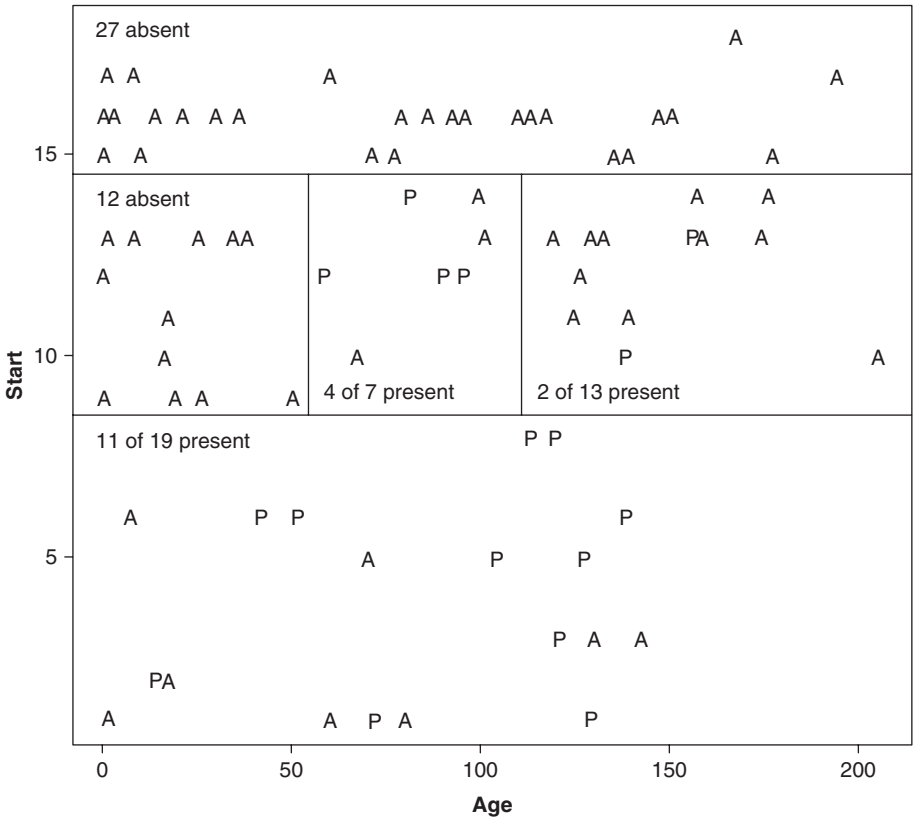

Figure 1 Partition of Kyphosis Data Set by Age and Starting Vertebrae

11.5 months, 12.5 months). For each split examined, the outcome variable is compared across the two sides—the side with cases where the age is greater than the cut point and the side where the age is less than the cut point. In the kyphosis data, 21% of the cases have kyphosis present. If a split of a variable resulted in one side having only kyphosis present (100%) and the other side having only kyphosis absent (0%), then this would be considered a perfect split and the algorithm would stop. This result would suggest that the most accurate prediction of kyphosis would be based entirely on the age of the child.

In practice, perfect splits are rarely found in data. However, criteria for deciding on the best split are available. One, the Gini diversity index, is a popular algorithm that is maximized for perfect splits and minimized for cases where half the cases in a partition are in one class and half are in the other. Any criteria used to determine the best split has the qualities that it can be quickly calculated and can be used to rank how well the split performed in classifying the outcome variable.

To recap, at the start of the algorithm recursive partitioning goes through every cut point for every input variable and records which variable by cut point combination produced the best split of the data into more homogeneous classes. This variable by cut point combination is selected as the first or initial split dividing the data into two partitions. In recursive partitioning, the algorithm is then repeated on both partitions independently to find the best variable by cut point combination that produces the best split for each side. One of the great strengths of the recursive partitioning approach is that this process proceeds independently on either side of a split, so that subsequent splits can be made on the same or different variables.

Recursive partitioning models produce a clear data representation in the form of a tree that details the partitioning process and data. For the kyphosis data, the recursive partitioning algorithm produces the tree presented in Figure 2.

At the top of the tree, all 81 cases are present and initially split into two subgroups based on the starting

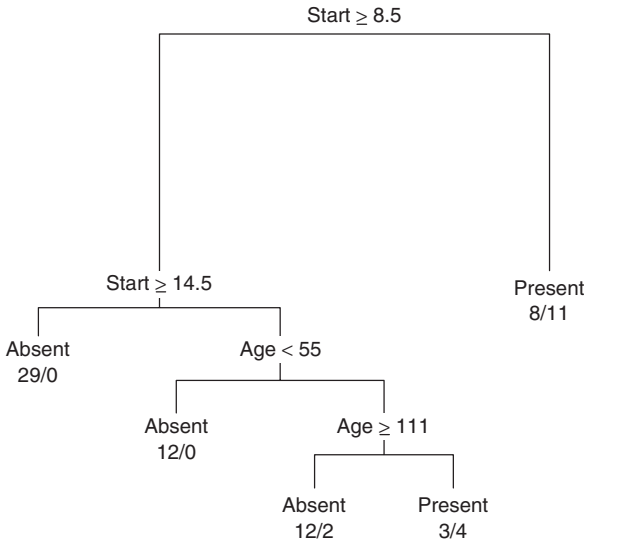

Figure 2 Classification Tree for Kyphosis Data

number of the vertebrae operated on. Cases whose starting number is greater than 8.5 (i.e., the ninth vertebrae or further) are classified into the left branch of the tree and those cases whose starting number is less than 8.5 (i.e., the eighth or lower vertebrae) are classified into the right branch. There were 19 cases classified into the right branch—8 with kyphosis absent and 11 with kyphosis present. These are not further partitioned, because no further splits significantly increased the proportion of cases with kyphosis present. This group is labeled kyphosis present because that diagnosis applies to the majority of its cases. If this model were used for prediction, future cases whose starting vertebrae number is less than 8.5 would be predicted to be kyphosis present. Cases classified into the left branch (starting number is greater than 8.5) were subsequently split on starting number greater than or less than 14.5. In the far left terminal node, which consists of cases whose starting number is greater than 14.5, all cases are always kyphosis absent (29 out of 29) indicating that this deformity is possibly limited to cases where the starting vertebrae is a low number. The other splits are followed as described above and result in all 81 cases being assigned to a single partition.

Regression trees, used when the outcome variable is continuous, are fit and interpreted in a similar manner. In this case, however, the criteria for making a split is calculated by some measure in the reduction in variance (e.g., reduction in mean squared error) and the terminal nodes are labeled by the mean of the observations for that partition. In terms of a conditional mean, as in parametric regression, the splits along a branch define the conditions.

Clinical Epidemiology

Clinical epidemiology is the application of the methods and principles of epidemiology, which is focused on population health, to the practice of clinical medicine, which is focused on the health of particular individuals. Modern medical practice should at all times be predicated on the best available scientific evidence. But at no time is there, in fact, any scientific evidence that pertains directly and reliably to a particular, individual patient. Rather, scientific evidence is derived from the past experience of other patients, or of subjects in clinical trials of various design. The relative correspondence between the one patient now receiving care and the many patients or subjects from whom scientific evidence has been derived is therefore an assessment prerequisite to clinical decisions, and an interface where science in medicine must inescapably collide with judgment. Clinical epidemiology is both a philosophical approach to medical decision making and a collection of tools and techniques that may inform the practice of medicine. This entry reviews the principles of clinical epidemiology, describes the relationship between this field and clinical practice, and discusses the use of clinical epidemiology in determining what diagnostic tests to perform. It also

explores fundamental principles of statistics and probability, such as Bayes's theorem, that inescapably underlie medical decisions and can and should be used to inform and fortify them.

Evidence has securely claimed its place among the dominant concepts in modern medical practice. To the extent possible, clinicians are expected to base their decisions (or recommendations) on the best available evidence. The consistent application of evidence to clinical decision making rests on the traditional fault line separating clinical practice from public health. Despite efforts to bridge that gap, the philosophical divide between a discipline devoted to the concerns of populations and another devoted to the advocacy of an individual can seem impassable. But evidence is, in fact, the bridge, because evidence-based practice is population-based practice.

Evidence applied clinically derives from the medical literature, where the standards of evidence, and therefore practice, continuously evolve. But apart from case reports, what is reported in the literature is not the experience of *an* individual patient and certainly not the experience of *the* individual patient, but rather the experience of a population of other patients. Therefore, the practice of evidence-based medicine requires the application of population-based data to the care of an individual patient, different in ways both discernible and not, from the subjects whose experience is reported. All decisions made on behalf of (or, preferably, with) individual patients are extrapolation or interpolation from the prior experience of other patients. Clinical medicine is evidence based only if it is population based.

To base clinical decisions for an individual on the individual alone, the outcome of an intervention would need to be known in advance. In other words, medicine would need to borrow from astrology, or some alternative system of predicting future events. The choice of an initial antihypertensive drug for a hypertensive patient cannot be based, before the drug is prescribed, on the response of the patient in question. Nor can the benefits to the patient be known in advance. The drug is chosen based on the published results of antihypertensive therapy in other patients. The particular drug is selected based on the characteristics of the patient, and how closely they approximate those of others who have benefited from specific therapies. Once the drug is selected, while the therapeutic effect on the surrogate measure (e.g., blood pressure) is detectable, most outcome benefits to the patient (e.g., stroke prevention) remain unknowable. The physician can never identify the stroke that was prevented in an individual but can only surmise that the risk of stroke has been reduced for that individual.

Implicit in the concept of evidence being the derivative of population experience is the need to relate that experience back to the individual patient. The inapplicability of some evidence to some patients is self-evident. Studies of prostate cancer are irrelevant to female patients; studies of cervical cancer are irrelevant to male patients. Yet beyond the obvious is a vast sea of gray. If a patient is older than, younger than, sicker than, healthier than, taller, shorter, simply different from the subjects of a study, do the results pertain? Because an individual patient will never be entirely like the subjects in a study (unless they were, in fact, a subject, and even then their individual experience might or might not reflect the collective experience), will the results, the evidence, ever be truly pertinent? No degree of evidence will fully chart the expanse of idiosyncrasy in human health and disease, and to work skillfully with evidence is to acknowledge its limits.

Principles of Clinical Epidemiology

Every clinical decision derives in whole or in part from the tacit comparison of a patient to a population of patients, and the skill with which that comparison is made becomes a fundamental element in the skill with which medicine is practiced. Integral to that comparison is the capacity to recognize the defining characteristics of both patients and populations as the basis for defining the bounds of similarity and dissimilarity. Equally important is the capacity to evaluate the context in which evidence was gathered, to determine its applicability to a given clinical decision. An ability to evaluate the quality as well as the pertinence of evidence is essential. And of course, an ability to find reliably the best available evidence when one is uncertain about a clinical decision is prerequisite to its interpretation.

While clinical choices (for both testing and treatment) are predicated on, at a minimum, the knowledge, judgment, values, preconceived notions, experiences, preferences, and fears of both clinician and patient, clinical decision making is greatly influenced by three discrete considerations: probability, risk, and alternative. Probability is fundamental to such decisions, as patients are evaluated and treated only for a specific

condition or conditions it seems they might have. The physician will recommend a particular test or treatment when the patient seems likely enough to need it.

Some low-probability diagnoses are pursued because they pose such high risk. Physicians admit some patients to the hospital to evaluate for myocardial infarction (MI or heart attack) although they believe the probability of MI to be low, because the risk associated with undetected MI is high. Similarly, physicians are taught to do a lumbar puncture (LP, also known as a spinal tap) whenever they wonder, "Should I do an LP?" because of the devastating consequences of failing to identify a case of meningitis.

Finally, alternatives need to be factored in. When chest pain seems atypical for angina, but no alternative explanation is at hand, the physician is more apt to treat the pain as angina. When pneumonia is present to explain shortness of breath, the physician will be less inclined to work up pulmonary embolism (PE), despite pleuritic chest pain and tachycardia. By a process to which physicians are, for the most part, comfortably incognizant, they make every decision factoring in considerations of probability, risk, and alternatives.

But a process to which one is more or less inattentive is a process that cannot be optimally regulated. Because the physician's decisions rely on their evaluation of probability, risk, and alternatives, these parameters should become of sufficient interest to warrant conscious oversight. And each of these parameters is population based. There is no probability of genuine relevance to an individual; there is the rate of occurrence in populations and the degree of concordance between individual and population characteristics. There is no true individual risk; for an individual, an event occurs (100% risk) or does not (0% risk). There is, however, the comparability of the patient to groups in whom the event rate in question is higher or lower. And the alternatives available for an individual patient are those options and interventions applied under similar circumstances to other patients, with varying degrees of success.

Clinical Epidemiology and Clinician Performance

Consider that a patient presents to a medical office. How likely is it that the patient has coronary disease? Naturally, at this point, the clinician can't answer the question. There is as yet virtually no information about the patient. Yet the clinician would have probably already begun the process of generating an estimate. If the provider were a pediatrician, patients in his or her practice are unlikely to have coronary disease. Therefore, this patient presenting to you is unlikely to have coronary disease. A similar situation occurs if the provider is a specialist (other than a cardiologist) to whom patients are referred after passing through the filter of primary care. But even if the clinician in this case were an internist or family practitioner, he or she would have already started to consider the probability of coronary disease. For practitioners in the United States, many of their adult patients will have coronary disease; so, too, might the patient in question. In certain other countries, the probability of coronary disease may be so low that practitioners there seldom need to consider it and, thus, would not consider it in this patient.

Of note, even at this very preliminary stage of evaluation, is the role of bias, or, more bluntly, prejudice in clinical decision making. Clinicians reach decisions based on experience—either their own or that of others. Making inferences about an individual based on the prior experience one has had with others in the same population as that patient is the essence of prejudice, or prejudging. But this is not meant to have negative connotations in clinical practice. Prejudice—or rather a tendency to judge the probability of a diagnosis in an individual based on the probability of that condition in the population the patient comes from—is appropriate and essential. It would be foolish to consider coronary disease routinely in individual patients from a population in which coronary disease almost never occurred. The prejudice born of experience, and familiarity with the population in question, would influence clinical judgment, and decisions, in an appropriate way.

So one immediately begins to formulate an impression of probability based on the characteristics of other patients one has seen. But we want more information. In this case, we would like to know whether or not the patient has chest pain suggestive of angina. We would like to know the patient's age and gender; whether or not the patient is hypertensive or diabetic; whether the patient smokes, is sedentary, has hyperlipidemia; whether the patient has a family history of heart disease or is obese. In attempting to determine how probable coronary disease is in the patient in question, we ask questions that sequentially allow us to place the patient in the context of

populations in which coronary disease is more or less probable. If the patient has chest pain typical of angina pectoris and happens to be a 70-year-old male smoker with diabetes, hypertension, hyperlipidemia, and a family history of heart disease, we can now answer the question with considerable confidence: The probability of coronary disease is high. Our inferences about an individual patient are derived from the historical experience of other patients whom we believe to be much like our own.

The history and physical examination can be considered a process of sequential hypothesis testing. Each question asked tests hypotheses about the population from which the patient might come. Once this is acknowledged, there comes a point in the history when additional questions (and answers) cannot dissuade the physician from a particular conclusion. In the case under consideration, a point in the history would be reached when coronary disease would seem sufficiently probable to warrant further investigation. Even if the answers to subsequent questions were negative, lowering the probability of coronary disease, a suspicion—based on both probability and risk—might be great enough to warrant commitment to investigating the possibility of that condition. Recognizing this semi-quantitative element in decision making is essential to manage the result. For example, if the patient seemed very likely to have coronary disease, would the physician abandon that belief if the ECG were normal? Probably not. The answer would depend on how robust the clinical suspicion of coronary disease were, compared with the negative results of any testing done.

In the process of sequentially testing hypotheses about the patient, health care providers are in essence endeavoring to define as narrowly as possible the population of which the patient is representative. Once that goal is achieved, epidemiology can offer a fairly stable estimate of the probability of the particular condition under consideration. That estimate is the *prevalence* of the condition in the population on which we've settled. Prevalence, the proportion of a specified population with a particular condition at a particular point in time, is related to the probability of disease in an individual member of that population. *Incidence*, the number of new cases of a particular condition in a defined population during a given period of time (typically a year), is related to the risk of that condition in an individual member of that population.

Clinical epidemiology allows the physician to convert the population data of the epidemiologist into a concept of practical utility to patient care. The analogue of prevalence for the individual patient is the *prior probability*, the probability of the condition in question *prior to* any subsequent assessments that might be indicated to further test our hypothesis(es). In essence, there is a discrete probability of a condition prior to every question posed during the history that is modified by each answer to become an estimate of the *posterior probability*, the probability resulting from, or following, a test. Each such posterior probability becomes the prior probability estimate in advance of the next question. The questions should be tailored to the continuously revised probability estimate, so that the pertinent hypotheses are tested. The process of questioning, physical examination and laboratory testing, sequential hypothesis testing, and sequential conversion of prior probability, to posterior probability, back to prior probability, is in advance of the next maneuver.

This process of reasoning is guided both by knowledge of the reliability of particular medical tests and by knowledge of the prior probability of a particular result. If the prior probability of a particular condition is very close to 0, a much higher standard of technological evidence should be required to conclude with confidence that a condition has been *ruled in.* If a prior probability is very close to 1, a high standard of evidence should also be required to support the conclusion that disease can be *ruled out.* A test not reliable enough to alter a very high or low prior probability estimate is of little clinical utility. But worse, if the principles of clinical epidemiology are overlooked, the test is potentially harmful. A positive test, if interpreted identically in patients in whom probability of disease is high or low, will provide misinformation as often as information. Dissociated from the principles of clinical epidemiology, medical technology, whether invasive or noninvasive, poses very real threats to patient care.

Clinical Epidemiolgy and Test Performance

The performance of tests used to refine the probability of any particular diagnosis can be cast in terms of sensitivity and specificity. *Sensitivity* is the ability of a test to detect disease when it is present. *Specificity* is the ability of a test to exclude disease when it is absent.

The denominator for sensitivity is the presence of the condition in question (e.g., disease); sensitivity can tell us nothing about the test's performance in patients who are condition (disease) free. In terms of a population, the denominator for sensitivity is the prevalence, the proportion of the population with the condition. Of those with the condition, some will test positive (true positives), and some will test negative (false negatives). Sensitivity is the proportion of disease positives in whom the test is positive. If a test is negative in a patient with disease, it is a false negative result.

Specificity pertains to the proportion of the population that is free of disease. In comparable terms, the denominator for specificity, all disease-free individuals, is 1 − prevalence. A test is specific when it reacts only to the singular condition under investigation. The proportion of those free of disease identified as disease free is the specificity; those who are disease free but have a positive test result are false positives. Note, then, that among those with disease there are true positives and false negatives; sensitivity defines the rate at which true positives are identified. Among those free of disease, there are true negatives and false positives.

Test characteristics are an important element in medical screening programs, defined as efforts to assess for early disease in a population with no outward signs of pathology. While intuition might suggest otherwise, highly sensitive tests are useful for ruling out pathology, and highly specific tests for ruling it in. The logic is as follows. A highly sensitive test reliably detects disease when present. A highly sensitive test is thus almost always positive when disease is present, and hardly ever negative when disease is present. Therefore, if a highly sensitive test is negative, it is almost certainly because disease is truly absent. A positive result of a highly specific test reliably rules in disease for precisely the same reasons.

Most diagnostic studies are subject to interpretation in light of a cutoff point. Virtually any laboratory test result is more suggestive of disease when it is well outside the normal range than when it is just outside the normal range. Does the abnormal test result warrant treatment or further workup? If the result is just outside the normal range, perhaps not. Why? Because at such a level, many disease-free individuals might also have a "positive" test. In other words, a cutoff point that makes it easy to detect disease when it is present makes it comparably easy to detect disease mistakenly when it is absent.

Conversely, what happens when the apparently healthy ("normal") patient has an extreme result on a routine laboratory test? Because a cutoff far outside the normal range makes it likely that some true cases of disease will be missed, but unlikely that disease-negative individuals will test positive, a positive result almost certainly indicates disease (or laboratory error). Further investigation is clearly warranted. While such interpretations are second nature to any experienced clinician, knowing the statistical properties that underlie such decision making fortifies the process. When a test result is sufficiently outside the normal range to warrant careful evaluation, but not so clearly abnormal as to provide definitive evidence of disease, an understanding of the variation in sensitivity and specificity with variation in the cutoff point can help determine when to test further, when to treat, and when to observe expectantly.

Generally, when a disease is serious, when detection is important, and when false positives can be distinguished from true positives with follow-up testing that is readily available, a relatively low cutoff point is desirable. When a disease is less serious or indolent, when detection of disease is not urgent, and/or when distinguishing false from true positives is difficult without costly or invasive procedures, a relatively high cutoff point is desirable.

Quantifying Clinical Uncertainty

Clinical medicine remains challenging, and always will, because no two patients are just alike, and an exact match between any patient and a population is unachievable. Nonetheless, the ability to diagnose at all relies on approximating a match. How does a clinician know that someone with rhinorrhea (a runny nose) has a viral upper respiratory infection rather than a cerebrospinal fluid (CSF) leak? In fact, they do not actually *know*; they *infer* that because colds are common, CSF leaks are rare, and patients with colds share characteristics with all the other patients treated for colds, that this particular patient with rhinorrhea has a cold. Clinicians rarely can or do apply pathognomonic tests (i.e., tests that render a diagnosis with complete accuracy). Rather, providers overcome the discomfort of residual uncertainty with estimates of probability. And these estimates are population derived; all clinical decisions involve the application of what is known about populations to what is suspected about an individual.

Bayes's Theorem

This concept is rendered statistically useful by Bayes's theorem, developed in the 18th century by Thomas Bayes. In principle, the theorem asserts that the probability of any condition in an individual is related to the probability of that condition in the population of which the individual is a member (the underlying population prevalence of the condition). The theorem has been modified to indicate that the result of any diagnostic test alters the probability of disease in the individual patient, effectively because each successive result reclassifies the population from which the individual comes (i.e., a patient with chest pain and a negative cardiogram versus a patient with chest pain and an ischemic cardiogram). In its basic form, the theorem is expressed as a series of conditional probabilities:

$$PD+ = [(pT+|D+)pD+]/\{[(pT+|D+)pD+] + [(pT+|D-)pD-)]\}$$

where

$PD+$: the posterior probability of disease (aka posttest probability)
$|$: given that; a symbol of conditional probability
$pT+$: the probability of a positive test
$D+$: disease is present
$pD+$: the prior probability of disease (aka pretest probability or prevalence)
$D-$: disease is absent
$pD-$: the probability of nondisease; $1 -$ prevalence

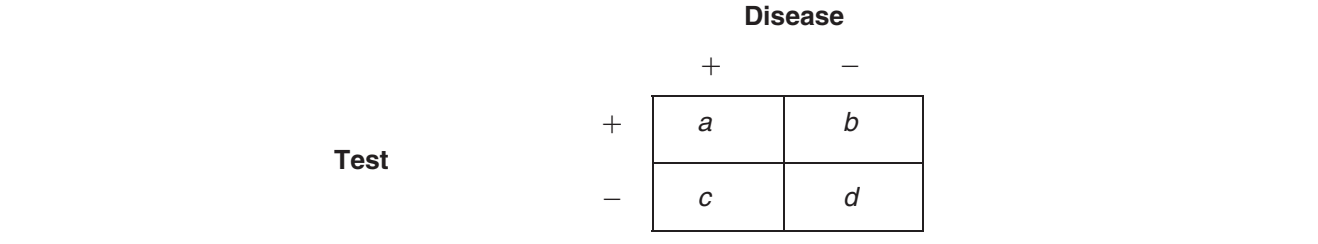
Deconstructed, Bayes's theorem becomes less intimidating. Consider the numerator $[(pT+|D+)\ pD+]$. The probability of a test being positive *given that* (conditional probability) the disease is present is the test sensitivity. Expressed in a 2×2 contingency table (Figure 1), the probability of a positive test in those who have disease is simply cell a, the true positives. Bayes's theorem is now

$$PD+ = \text{true positives}/\{\text{true positives} + [(pT+|D-)pD-]\}$$

or

$$PD+ = a/\{a + [(pT+|D-)pD-]\}$$

We've made good progress because the first term in the denominator of the theorem is the same as the numerator term. What of the second term in the denominator $[(pT+|D-)pD-)]$? As shown in Figure 1, this is the probability of a positive test result among those without disease. This term reduces to cell b of the table shown in Figure 1, the



$D+$:	$a+c$
$D-$:	$b+d$
$_PT+\|D+$:	a
$_PT+\|D-$:	B
$_PD+$:	$(a+c)/N$
$_PD-$:	$(b+d)/N$

Figure 1 The 2×2 Contingency Table and Bayes's Theorem

term representing the false positives. The theorem can now be expressed as

$$PD+ = \text{true positives}/(\text{true positives} + \text{false positives})$$

or

$$PD+ = a/(a+b)$$

Thus, Bayes's theorem asserts the following: The probability that an individual with a positive test result truly has disease is the proportion of all positive test results (true and false) that are true positives. This is the same formula as the positive predictive value, the probability that a positive test result truly indicates the presence of disease.

There is one other useful way of expressing the theorem. The probability of a positive test in those with the disease is the sensitivity, while the probability of disease is the prevalence. Thus, the formula can be expressed as

$$PD+ = [\text{sensitivity} \times \text{prevalence}/[\text{sensitivity} \times \text{prevalence} + [(pT+|D-)pD-)].$$

The probability of a positive test result among those truly free of disease is the false positive error rate, or 1 − specificity, and the probability of disease absence is 1 − prevalence. The formula can now be converted to

$$PD+ = [\text{sensitivity} \times \text{prevalence}/\{[\text{sensitivity} \times \text{prevalence}] + [(1-\text{specificity})(1-\text{prevalence})]\}.$$

In this form, Bayes's theorem permits calculation of the posterior probability of disease, the probability of disease after testing, provided one knows the prior probability, and the sensitivity and specificity of the diagnostic test. Working with Bayes's theorem rather than just the positive predictive value offers both conceptual and logistical advantages. Conceptually, Bayes's theorem emphasizes the importance of prior probability to the probability of disease after testing. Logistically, Bayes's theorem allows us to determine the posterior probability of disease without resorting to a 2 × 2 table.

Application

Consider three patients suspected of having deep venous thrombosis (DVT) on the basis of history and physical examination. Patient 1 has risk factors for DVT, such as a long period of immobility or a known hypercoagulable state. Patient 2 has no obvious risk factors for DVT. Patient 3 is therapeutically anticoagulated on warfarin for a prosthetic heart valve.

If each of these three patients presented with identical signs and symptoms of DVT in the left lower extremity, our estimates of the probability of DVT would likely vary. The first patient seems very likely to have DVT, because the patient comes from a population of patients in which the occurrence of DVT is known to be high. The second patient has a moderate or intermediate probability of DVT. The third patient, other things being equal, should be at low risk for DVT given that the INR (the International Normalized Ratio, a standard measure of how much blood has been "thinned" by warfarin) level is therapeutic.

Assume that the first patient is estimated to have an 80% probability of DVT. Further assume that the venous Doppler ultrasound is ordered and that it has a sensitivity of 80% and a specificity of 75% for clot above the knee. The test is positive. How does this affect our diagnosis?

Bayes's theorem provides an answer, while forcing us to consider that the test result must modify, rather than replace, our prior probability estimate. The posterior probability of disease is

$$PD+ = \frac{[\text{sensitivity} \times \text{prevalence}]}{\left[\begin{array}{l}\text{sensitivity} \times \text{prevalence}] \\ +[(1-\text{specificity})(1-\text{prevalence})\end{array}\right]}.$$

In this scenario, the sensitivity is 80%, the prevalence is 80%, and the specificity is 75%. The formula then becomes

$$PD+ = (0.8 \times 0.8)/\{(0.8 \times 0.8) + (0.25 \times 0.20)\}$$
$$PD+ = 93\%.$$

Thus, after a positive Doppler ultrasound test, the probability of DVT is 93%.

What if the same test, with the same operating characteristics, were applied to the second patient, who appears to be at intermediate risk for DVT? We can use a prior probability of 50% to convey our substantial uncertainty. In this case,

$$PD+ = (0.8 \times 0.5)/\{(0.8 \times 0.5) + (0.25 \times 0.5)\}$$
$$PD+ = 76\%.$$

Note that the posterior probability of DVT in this patient, that is, the probability after a positive diagnostic study, is lower than the prior probability in the patient in the first scenario. Also of note is the much greater change between prior and posterior probability estimates than in the first scenario. When our prior probability estimate was 80%, a fairly reliable diagnostic test increased our posterior probability by 13%. Using the same test, but with a prior probability estimate of 50%, the posterior probability increased 26%, or twice as much. In general, the greater the degree of diagnostic uncertainty (i.e., the closer the prior probability estimate is to 50%), the more helpful the diagnostic testing becomes, and the more test results will modify the posterior relative to the prior probability.

The patient who is therapeutic on warfarin but with a presentation suggestive of DVT has a low prior probability of the condition; we can estimate it at 10%. The same venous Doppler testing is applied, with the same operating characteristics. For this patient, the posterior probability is

$$PD+ = (0.8 \times 0.1)/\{(0.8 \times 0.1) + (0.25 \times 0.9)\}$$
$$PD+ = 26\%.$$

This demonstrates the hazard of simply replacing our clinical estimates with the results of diagnostic testing. Despite a positive Doppler ultrasound (given the operating characteristics provided), the patient in question is far more likely *not* to have DVT, than to have DVT. In fact, three out of four similar patients will be free of DVT.

Confronted with such a scenario, one is generally tempted to reconsider the prior probability estimate. If the test is positive, then the patient seems to have the disease in question, and therefore must have been more likely to have the disease in question than I originally thought.

This kind of rethinking is both important and dangerous. It is important because the prior probability estimate is just that, an estimate, and one we tend not to like making in a strictly quantitative manner in the first place. Reconsideration of the prior probability estimate is appropriate. But if the prior probability estimate is, in fact, reasonable, it should not be discarded or replaced based on the results of diagnostic testing. This is an inappropriate use of test results and gives them influence over the diagnostic process they should not have. Test results influence the probability of disease by converting the prior probability to a posterior probability; if the same test is used also to recalibrate the prior probability estimate, the same test result is effectively being used twice. Test results should be interpreted in light of the prior probability of disease, not used to replace that estimate. That estimate may be revisited but on the basis of clinical judgment, rather than a test result.

Implications of Bayes's Theorem for Diagnostic Testing

Does judicious application of Bayes's theorem to the process of workup and diagnosis require that we include a calculator in our black bags? The answer is a resounding *no* (although there are times it can come in handy) because there is generally substantial uncertainty about the prior probability estimate. Therefore, the use of the theorem to generate a very accurate posterior probability of disease is unreliable. What is reliable is the theorem's capacity to demonstrate the interaction of prior probability estimate and test result. If one is very confident that disease is present, only a truly exceptional test result can make one substantially more certain. Similarly, if the test is negative, it can refute that impression reliably. Bayes's theorem provides mathematical evidence to support the concept that the value of diagnostic testing depends both on the performance characteristics of the test and the clinical scenario in which the test is ordered.

Astute use of the Bayes's theorem, or at least the concepts behind it, should at times result in more diagnostic testing, and at times less. When one might be inclined to order a test despite considerable confidence that the disease is present or absent, the theorem should highlight the extent to which test results will modify that level of confidence. When the test result is unlikely to change the clinical impression, the test may well be unnecessary. Alternatively, when a needed test yields a surprise result, the theorem would argue against abandoning the prior probability and replacing it with the test result. In this situation, further, confirmatory testing is likely to be required.

Finally, how reliably can the theorem, and its application, be when the whole process begins with a prior

probability estimate that is seldom more than an educated guess? This seeming weakness is a strength in the application of Bayes's theorem, because it forces clinicians to confront the issue of uncertainty rather than ignore it. That the estimates among a group of clinicians vary is in a way reassuring; no matter how statistics and evidence are applied, much of clinical practice will be shaped by judgment. Application of Bayes's theorem is not intended to eliminate uncertainty in the diagnostic process, but rather to disclose it, so we can wrestle with it more effectively.

One way to "wrestle" directly with the uncertainty in the prior probability estimate is to conduct a sensitivity analysis. This term refers to any situation in which the a priori assumptions are modified across some range of plausible values to determine whether conclusions are altered. In the case of Bayes's theorem, one can vary the prior probability estimate over a range of reasonable values. What is reasonable is the product, again, of judgment, but is bounded by 0 and 1 (100%).

While one might be ill at ease in any given clinical situation to say, for example, that the prior probability of disease was 22%, one might be quite secure that it was between 5% and 50%. By interpreting the test result over the range of prior probability estimates, one can determine if the conclusion remains the same or changes.

Consider a test with 95% sensitivity and specificity, which is used to diagnose a condition for which treatment is absolutely necessary, but invasive and painful. If the test, for example, an MRI, is positive and the prior probability is set at 5%, the positive test results in a posterior probability of 0.5, or 50%. While this is a substantial increase, it hardly is adequate to justify invasive therapy. If the prior probability is set at 50%, the posterior probability is 0.95, or 95%. We might establish a "rule of thumb": If the prior probability estimate is reliably greater than 50%, and the MRI is positive, the disease is almost certainly present, and treatment is indicated. If the prior probability is substantially lower than 50%, a positive MRI will suggest a need for further, confirmatory testing, before invasive therapy is initiated.

Conceptual Factors Influencing Probability Estimates

Bayes's theorem is concerned with probability. But as noted earlier, probability is just one of the three concepts that should share comparable prominence in the diagnostic process. The other two are risk and alternatives. When a disease is very serious and can be modified with treatment (e.g., meningitis), the need to pursue a workup cannot be discounted just because the condition is relatively improbable. However, if a condition is truly trivial, then no matter how probable, diagnostic testing is unlikely to be valuable. And if a condition is extremely improbable, then no matter how serious, it should probably not be pursued. That we conduct our workups this way is clear; not every patient with fever or headache has a lumbar puncture.

And this is where the third concept comes in: alternatives. When an alternative diagnosis is very probable, then the diagnosis under consideration becomes less so. If the patient with fever and a headache appears to have a viral upper respiratory illness (i.e., a cold), then the probability that the symptoms are due to meningitis is that much less. Once a "cold" is diagnosed with confidence, the consideration of meningitis is resolved. But what of situations in which no good alternative suggests itself? For example, what of the patient with chest pain atypical for angina, but at least equally atypical for a gastrointestinal or musculoskeletal source? The lack of alternatives makes the principal diagnosis(es) in question more probable. Thus, the building blocks of a solid diagnosis are considerations of probability, alternatives, and risk.

The practice of clinical medicine, dedicated as it is to the care of individuals, cannot avoid population-based principles. Physicians cannot practice clinical medicine and avoid the practice of clinical epidemiology. But the discipline of evidence-based practice or clinical epidemiology (the terms might reasonably be used interchangeably) is not one in which most clinicians have had the necessary initiation. The art of clinical decision making is judgment, an even more difficult concept to grapple with than evidence. As the quality and scope of evidence to support clinical interventions is, and will likely always remain, limited in comparison to the demands of clinical practice, the practice of evidence-based medicine requires an appreciation for the limits of evidence, and the arbiters of practice at and beyond its perimeters. Judgment fortified by the highest standards of decision-making science is a force to be reckoned with, enabling clinicians to achieve the best possible results. And ultimately, that is the validation of evidence-based

practice, or population-based practice, or clinical epidemiology: the outcomes to which such concepts contribute. Rigorous reasoning is the means, desirable outcomes the ends.

Clinical Trials

Clinical trials are experimental studies performed mainly on humans, but sometimes on animals, tissues, and cultures as well, to assess the effectiveness and safety of an intervention under investigation such as a new drug, diagnostic procedure, surgical procedure, prophylactic procedure, or screening program. There are many types of clinical trials. This entry focuses on randomized controlled clinical trials and randomized crossover designs for studying treatment effects. Rigorously designed clinical trials such as randomized concurrently controlled clinical trials conducted with human subjects, usually patients, have become well established as the scientific method based on empirical evidence that investigators must use to assess new treatments if their claims are to find widespread acceptance. Clinical trials have become indispensable in discovering new techniques to prevent and treat diseases, and their applications have been largely responsible for the compression of morbidity and decline in mortality rates at advanced ages in recent years.

Types of Trials

In *experimental studies*, the investigator manipulates the study factor (exposure groups) and randomly allocates experimental units to different exposure groups. An experimental study is also called a trial. A trial must progress longitudinally in time from exposure to outcome. This together with the ability to manipulate the study factor and to randomize the experimental units makes a stronger causal inference using experimental studies than using *quasi-experimental studies*,

which involve manipulation of the study factor but not random allocation of experimental units, or using *observational studies*, which involve neither manipulation of the study factor nor randomization of experimental units. Experimental studies without control or comparison groups (e.g., Phase I/II clinical trials) are called *uncontrolled trials*, while experimental studies with control or comparison groups are called *controlled trials.* A controlled trial in which the allocation of experimental units to different exposure groups is done randomly so that all experimental units have an equal chance of being allocated to each of the exposure groups is known as a *randomized controlled trial* (RCT), which can be a randomized controlled clinical trial (when the unit of randomization is a patient such as the Phase III clinical trial); a randomized controlled field trial (when the unit of randomization is a normal individual, rather than a patient, such as the vitamin C trial of Karlowski et al., 1975); or a randomized controlled community (cluster—a group of people in a community) trial (when the unit of randomization is a community or cluster such as Project Burn Prevention trial of Mackay and Rothman and water fluoridation trial of Ast and Schlesinger (1956). The less common field trials and community (cluster) trials are aimed at the evaluation of primary preventives, while the more common clinical trials are used to evaluate treatment effectiveness of a disease or to find a preventive of disease recurrence or death. All randomized trials are controlled. In nonrandomized controlled trials, the groups may not be comparable due to selection and confounding biases and so estimates of effects of the intervention may not be valid without further statistical adjustments.

Clinical Trial Protocols

Researchers for each clinical trial follow a protocol reviewed and approved by an institutional review board (IRB), a separate board of scientists, statisticians, physicians, and nurses who are not associated with the clinical trial. A Clinical Trial Protocol contains a study plan that describes the organization of a clinical trial, the background, rationale, objectives, and hypotheses; how the subjects are to be selected and how data are to be collected; primary exposures and methods of their measurements (an exposure is a factor that either causes, prevents, or treats an outcome), outcomes of interest and methods of their measurements; as well as intervening variables and methods of their measurements, type of study design, method of randomization, methods to control confounding bias prior to data analysis if randomization is not used, measures of association to be used, statistical methodology and analysis, including methods to control confounding bias during data analysis, and power calculations. It may also address issues of noncompliance, dropout as well as selection and information biases, and how nondifferential misclassification may affect the interpretation of results. The protocol also states the number of participants, eligibility requirements, agents that will be used, dosages, schedule of tests, the length of the study, and the larger population to which the results can be generalized. Note that both issues of internal validity and external validity have been covered in the description of clinical trial protocol given above. This protocol will also serve as the basis for writing the final report.

Randomized Controlled Clinical Trials

Essentially, a randomized controlled clinical trial is conducted by recruiting a group of patients from a target population. With adequate allocation concealment to protect against selection bias, the consenting eligible patients from the group of recruited patients are then randomly allocated to the treatment and control arms, which are then followed to the end of the trial with outcomes between the different arms compared. The patients recruited from the target population must meet the required eligibility criteria (inclusion and exclusion criteria) and, for ethical reasons, must give their informed consent before their randomization into different treatment groups to avoid selection and confounding biases. This ensures that the difference in treatment groups is caused by the difference in treatments alone. A concurrent control arm is needed so that outcomes with and without treatment(s) can be compared.

The choice of the control group will have an impact on research question and sample size. Use of a placebo in the control arm would help achieve blind treatment allocation and exclude placebo or Hawthorne effects, but ethical considerations demand that the control group should be the established treatment for the disease under study provided that its therapeutic effects have been well documented. Blinding is also used to exclude detection and performance biases, which occur when the investigator/patients know the treatment being given and which could

affect assignment, assessment, or compliance. These biases occur particularly when a subjective outcome variable such as pain or quality of life is measured.

Noncompliance—the failure to follow protocol requirements—can (1) result in a smaller difference between the treatment and control arms than truly exists, thereby diluting the real impact of a treatment, and (2) reduce study power, making it harder to detect an effect when it exists. Compliance measures can be used to improve estimates of treatment effects. The real strength of a randomized controlled clinical trial lies in the randomization. With sufficient sample size, randomization in which each treatment group is equally likely to be allocated to each patient would produce close similarity across the groups in all respects other than the intervention, including the unmeasured and unknown factors. That is to say, by randomization, both known and unknown confounders are controlled at the outset. This strengthens the validity of the causal inference. To preserve the baseline comparability, to maintain the statistical power of the original study population, and to ensure unbiasedness against noncompliance, intent-to-treat analysis should be conducted. Such analysis, also known as treatment assignment analysis, gives information on the effectiveness of the treatment under real-life conditions, unlike efficacy analysis, which determines the treatment effects under ideal conditions. In an intent-to-treat analysis, all participants who are randomized to a treatment are analyzed, regardless of whether they complete or even receive the treatment. Given the covariate measures at baseline and during follow-up monitoring, the statistical methods for analyzing the treatment effects of randomized controlled clinical trials depend on what endpoints are chosen to measure outcomes. For example, if disease incidence or death or occurrence of some event is the endpoint, logistic or Poisson regression models may be used to analyze the data; such analysis would also serve to control the residual confounding during the analysis. If survival time is the endpoint, then the Cox regression models as well as counting processes martingale methods may be used. If the endpoint consists of continuous response measures, then simple two-sample t tests or, when several treatments are involved, analysis of factorial experiments may be used. If repeated measures are involved, then methods for longitudinal data analysis such as random coefficient analysis may be used.

Parallel Group Designs

Most clinical trials belong to the so-called parallel group designs in which subjects in different arms are followed in parallel. Parallel group designs have four phases. Phase I tests a new drug or treatment in a small group of people (usually less than 10 normal volunteers), using an uncontrolled trial, the purpose being to learn how to administer a treatment safely and to determine optimal dosage or the so-called maximally tolerated dose (MTD) based on dose escalation investigations. Phase II expands the study to a larger group of people (often 30 to 40 patients or normal volunteers), the purpose being to test patient responses, to monitor side effects, and to determine the minimum effective dose (MED). These may be either uncontrolled trials or RCTs with patients who are expected to benefit from the treatment as experimental units. Phase III expands the study to an even larger group of people (usually running from hundreds to thousands of patients) for a full-scale evaluation of treatment using a randomized controlled clinical trial, as described above, with control group being either placebo or standard treatment. Patients are also closely monitored for severe adverse side effects for possible cancellation of the trial. Phase IV takes place after the drug or treatment has been licensed and marketed—postmarketing surveillance. It typically compares two treatments that are approved for similar uses to determine which one is more effective. It may also be conducted to study long-term safety and efficacy and to study new uses or cost-effectiveness of FDA-approved treatment.

Crossover Designs

In the design of RCTs, the opposite of parallel group designs are the crossover designs, which involve a switch of study treatments for each participant in a clinical trial. Thus, the participants serve as their own controls, which allow more precise estimates of treatment effects by making comparison within subjects rather than between subjects. Most crossover studies are *planned* crossover studies in which the predetermined period of treatment before switching to another treatment is specified in advance in the protocol. Noncurable medical conditions such as asthma and diabetes are suitable candidates for planned crossover studies as they present the possibility of giving more than one treatment to each patient. Other crossovers

are *unplanned* such as when patients in medical care are switched to surgical treatment because of deterioration in their condition. In planned crossover studies, there are as many groups as there are permutations of treatment sequences so that each group is uniquely determined by its first treatment. Each participant is randomized to receive his or her first treatment so as to produce roughly equal numbers of participants in each group. They are then followed for a predetermined period of time and then switched to a different treatment for another predetermined period of time and so on. Each period is of the same length for all participants, with the crossover point being blinded where possible. At the end of the study, outcomes are compared across treatments by combining the responses to each treatment from different groups. Thus, in parallel group designs, each group receives just one treatment and the treatments are administered concurrently, while in crossover designs, each group receives all treatments one after another and the treatment order differs across the groups. To avoid the so-called carryover effects in planned crossover studies, a washout period may intervene between treatments to allow the human body time to metabolize and excrete the previous treatment. The double-blind, two-treatment, two-period crossover designs are particularly popular in clinical pharmacology. These can be analyzed as special cases of repeated measure analysis of variance. The hypothesis of no treatment difference is tested simply by using a two-sample t test to compare the two sets of within-patient difference summed over all individuals. The main advantage of this design is the gain in statistical power, namely, that it can achieve statistically significant results with fewer subjects than would be required with a parallel design because the sample size required for this design depends on the variability within subjects, not between subjects as in the case of parallel design. (For most response variables, the within-subject variance is smaller than the between-subject variance.) Note that in the statistical analysis of treatment differences of crossover studies we assume no treatment-period interaction (which implies no carryover effects).

Sequential Trials

Clinical trials are costly and time-consuming. The idea of stopping such trials early when the treatments are being found to be unsafe or ineffective has been pursued on ethical and economic grounds. Wald's sequential procedure has been used to achieve this aim. Sequential trials in which the data are analyzed after each patient's results become available, and the trial continues until a clear benefit is seen in one of the comparison groups, or it becomes clear that no significant difference between the groups will emerge serve to achieve this aim. Thus, unlike parallel group and crossover designs, the number of subjects studied is not fixed in advance in sequential trials. Flexible sequential trials based on the discretization of Wiener processes and the group sequential designs implemented with a boundary for the null hypothesis (futility boundary) and a boundary for the alternative hypothesis (efficacy boundary) allow early stopping favor in either of the null or of the alternative as soon as conclusive interim evidence of being efficacious or not became available. Sequential trials and development of monitoring strategy that allows for interim looks at the accumulating data so as to shorten the average length of the trial are discussed in the articles by Jennison and Turnbull, Lan and DeMets, Pampallona and Tsiatis, Pocock, O'Brien and Fleming, and Whitehead listed in the further readings below.

Cluster Analysis

Cluster analysis (CA) is an exploratory data analysis set of tools and algorithms that aims at classifying different objects into groups in a way that the similarity between two objects is maximal if they belong to the same group and minimal otherwise. In biology, CA is an essential tool for taxonomy of plants, animals, or other specimens. In clinical medicine, it can be used to identify patients who have diseases with a common cause, or patients who should receive the same treatment or who should have the same level of response to treatment. In epidemiology, CA has many uses, such as finding meaningful conglomerates of regions, communities, or neighborhoods with similar epidemiological profiles, when many variables are involved and natural groupings do not exist. In general, whenever one needs to classify large amounts of information into a small number of meaningful categories, CA may be useful.

Researchers are often confronted with the task of sorting observed data into meaningful structures. CA is an inductive exploratory technique in the sense that it uncovers structures without explaining the reasons for their existence. It is a hypothesis-generating rather than a hypothesis-testing technique. Unlike discriminant analysis where objects are assigned to preexisting groups on the basis of statistical rules of allocation, CA generates the groups, or "discovers" a hidden structure of groups within the data.

Classification of Methods

In a first broad approach, CA techniques may be classified as *hierarchical*, if the resultant grouping has an increasing number of nested classes, which resemble a phylogenetic classification, or *nonhierarchical*, if the results are expressed as a unique partition of the whole set of objects.

Hierarchical algorithms can be divisive or agglomerative. A divisive method begins with all cases in one cluster. This cluster is gradually broken down into smaller and smaller clusters. Agglomerative techniques usually start with single-member clusters that are successively fused until one large cluster is formed. In the initial step, the two objects with the lowest distance or highest similarity are combined into a cluster. In the next step, the object with the lowest distance (or highest similarity) to either of the first two is identified and studied. If it is closer to a fourth object than to either of the first two, the third and fourth objects become the second two-case cluster; otherwise, the third object is included in the first cluster. The process is repeated, adding cases to existing clusters, creating new clusters, or combining those that have emerged until each object has been examined and allocated to one cluster, or stands as one separate cluster by itself. It should be noted that at each step of this process, a different partition is formed that is nested in the partition generated in the following step. Usually, the researcher chooses the partition that turns out to be the most meaningful for a particular application.

Distance and similarity are key concepts in the context of CA. Most algorithms, particularly those yielding hierarchical partitions, start with a distance or similarity matrix. The cell entries of this matrix are distances or similarities between pairs of objects. There are many types of distances of which the most common is the *Euclidean distance.*

The Euclidean distance between any two objects is the square root of the sum of the squares of the differences between all the coordinates of the vectors that define each object. It can be used for variables measured at an interval scale. Euclidean distance is calculated as

$$d(x,y) = \left\{ \sum_i (x_i - y_i)^2 \right\}^{1/2}.$$

When two or more variables are used to calculate the distance, the variable with the larger magnitude

will dominate. To avoid this, it is common practice to first standardize all variables. The choice of a distance type is crucial for all hierarchical clustering algorithms and depends on the nature of the variables and the expected form of the clusters. For example, the Euclidean distance tends to yield spherical clusters.

Other commonly used distances include the following:

- *The Manhattan distance.* It is defined as the average distance across variables. In most cases, it yields results similar to the simple Euclidean distance. However, the effect of single large differences (outliers) is dampened (since they are not squared). It is computed as

$$d(x, y) = \sum_i |x_i - y_i|.$$

- *The Chebichev distance.* It may be appropriate when objects that differ in just one of the variables should be considered different. It is calculated as

$$d(x, y) = \max_i |x_i - y_i|.$$

- *The power distance.* It is used when it is important to increase or decrease the progressive weight that is assigned to variables on which the respective objects are very different. The power distance is controlled by two parameters r and p as shown by the following expression:

$$d(x, y) = \sum_i \left(|x_i - y_i|^p\right)^{1/r}$$

  where r and p are user-defined parameters. Parameter p controls the progressive weight that is placed on differences on individual variables, while parameter r controls the progressive weight that is placed on larger differences between objects. If r and p are equal to 2, then this distance is equal to the Euclidean distance.
- *The percent disagreement.* It may be used when the data consist of categorical variables. It is computed as

$$d(x, y) = \text{number of } x_i \neq y_i / i.$$

Linkage Rules

When clusters are composed of a single object, the distance between them can be calculated with any of the distances shown above. However, when clusters are formed by two or more objects, rules have to be defined to calculate those distances.

The distance between two clusters may be defined as the distance between the two closest objects in the two clusters. This linkage rule is known as *the nearest neighbor rule* and it will string objects together and tend to form chain-like clusters.

Other popular linkage rules are the pair-group average and the pair-group centroid. The first of these rules is defined as the average distance between all pairs of objects in the two different clusters. This method tends to form natural distinct clumps of objects. The pair-group centroid is the distance between the centroids or centers of gravity of the clusters.

The most frequently used nonhierarchical clustering technique is the *k-means algorithm*, which is inspired by the principles of analysis of variance. In fact, it may be thought of as an analysis of variance "in reverse." If the number of clusters is fixed as k, the algorithm will start with k random clusters and then move objects between them with the goals of minimizing variability within clusters and maximizing variability between clusters.

Coefficient of Determination

The coefficient of determination, R^2, is a useful measure of the overall value of the predictor variable(s) in predicting the outcome variable in the linear regression setting. R^2 indicates the proportion of the overall sample variance of the outcome that is predicted or explained by the variation of the predictor

variable, or in the case of multiple linear regression, by the set of predictors.

For example, an R^2 of 0.35 indicates that 35% of the variation in the outcome has been explained just by predicting the outcome using the covariates included in the model. Thirty-five percent might be a very high portion of variation to predict in a field such as the social sciences; in other fields such as rocket science, one would expect the R^2 to be much closer to 100%. The theoretical minimum R^2 is 0; however, since linear regression is based on the best possible fit, R^2 will always be greater than zero, even when the predictor and outcome variables bear no relationship to one another.

Just as R^2 will virtually always be greater than zero, R^2 will also always increase when a new predictor variable is added to the model, even if the new predictor is not associated with the outcome. To combat this effect, the adjusted R^2 incorporates the same information as the usual R^2 but then also penalizes for the number of predictor variables included in the model. As a result, as new predictors are added to a multiple linear regression model, R^2 will always increase, but the adjusted R^2 will increase only if the increase in R^2 is greater than one would expect from chance alone. In such a model, the adjusted R^2 is the most realistic estimate of the proportion of the variation in Y that is predicted by the covariates included in the model.

When only one predictor is included in the model, the coefficient of determination is mathematically related to the Pearson's correlation coefficient, r. Just as one would expect, squaring the correlation coefficient results in the value of the coefficient of determination. The coefficient of determination can also be found with the following formula: $R^2 = MSS/TSS = (TSS - RSS)/TSS$, where MSS is the model sum of squares, TSS is the total sum of squares associated with the outcome variable, and RSS is the residual sum of squares. Note that R^2 is actually the fraction of the proportion of variability explained by the model out of the total variability in Y.

The coefficient of determination shows only association. As with linear regression, it is impossible to use R^2 to determine whether one variable causes the other. In addition, the coefficient of determination shows only the magnitude of the association, not whether that association is statistically significant.

In summary, the coefficient of determination provides an excellent one-number summary of how clinically relevant the predictor variable is in a given linear regression model; the adjusted R^2 provides the same one-number summary when more than one predictor is included in the model.

Cohort Effects

Cohort effects are variations in factors such as health status or mortality that are attributed to the unique physical and social environment to which a cohort is exposed during its lifetime. A commonly used synonym is *generation effects.*

A cohort is defined as an aggregate of individuals within a specified population who experience the same event (e.g., birth) at the same time or within the same time interval, and who are observed over time. A cohort is usually identified by the event itself and by the time period during which the event occurs, and also, at least implicitly, by geographic location, that is, the physical environment. For example, the U.S. birth cohort of 2000 includes all persons born in the United States in the calendar year 2000. The time period that defines a cohort can be very short, or it can extend over several years; a decade is commonly used to identify a cohort.

The importance of taking cohort membership into consideration was first noted by demographers, and subsequently by other social and behavioral sciences, including epidemiologists. Cohort studies (and cohort analysis) are conducted to separate the effects due to cohort membership from those due to age or period. However, there is an inherent problem since cohort, age, and period are all related to time, and the interpretation of findings is subject to confounding. Since each of these time-related variables is dependent on the other two, attributing an observed

effect to any one of them usually requires knowledge of biological, historical, or behavioral factors that might produce age, period, or cohort effects. Multiple regression techniques can help disentangle age, period, and cohort effects. However, the question remains whether cohort membership has any effect apart from age and period, since cohorts are defined by the sharing of age and period.

A classic example of the attempt to separate age, period, and cohort effects is Wade Hampton Frost's examination of tuberculosis mortality rates in Massachusetts between 1880 and 1930, which showed that apparent changes in the age distribution of tuberculosis mortality could be better interpreted as a decline in mortality over cohorts, rather than as changes in age-specific mortality over time. In a graph of mortality rates, with age along one axis and year of death along the other, the cohort effect can be seen by tracing the diagonal axis of the graph, which plots the mortality of each cohort as it ages over time.

A cohort effect was discerned in the pattern of deafness in New South Wales, Australia; prevalence was especially high in 1911 among those who were 10 to 14 years old, in 1921 among 20- to 24-year-olds, and in 1931 among 30- to 34-year-olds. The most likely explanation for this prevalence pattern was the 1899 measles epidemic in New South Wales, which resulted in congenital deafness among a large proportion of those born to women exposed to measles during pregnancy.

Collinearity

Collinearity is a concern when two regression covariates are associated with one another. In essence, because the covariates are correlated, their prediction of the outcome is no longer independent. As a result, when both covariates are included in the same regression model, each one becomes less statistically significant because they are explaining some of the same variance in the dependent variable. Cues that collinearity may be a concern are (1) high correlation or association between two potential covariates, (2) a dramatic increase in the p value (i.e., reduction in the significance level) of one covariate when another covariate is included in the regression model, or (3) high variance inflation factors. The variance inflation factor for each covariate is $1/(1 - R^{2}*)$, where $R^{2}*$ is the coefficient of determination for the model excluding only that covariate. Variance inflation factors of 1 or 2 show essentially no collinearity; 5 represents moderate collinearity. Variance inflation factors greater than 10 suggest that collinearity is such a concern that one might consider removing one of the collinear covariates. Variance inflation factors of 20 and higher show extreme collinearity.

In the schematic on the left in Figure 1, X_1 and X_2 are nearly unassociated with one another, so the overlapping gray area is quite small. In the schematic on the right, the overlapping area is larger; in this gray area, the two covariates are battling to predict the same variance in the outcome, so that each prediction has lower statistical significance. If the outcome were income level, one might expect covariates such as education and previously winning the lottery to be similar to the schematic on the left. Alternatively, covariates such as education and parental income level would likely be more similar to the schematic on the right.

Multicollinearity describes a situation in which more than two covariates are associated, so that when all are included in the model, one observes a decrease in statistical significance (increased p values). Like the diagnosis for collinearity, one can assess multicollinearity using variance inflation factors with the same guide that values greater than 10 suggest a high degree of multicollinearity. Unlike the diagnosis for collinearity, however, one may not be able to predict multicollinearity before observing its effects on the multiple regression model, because

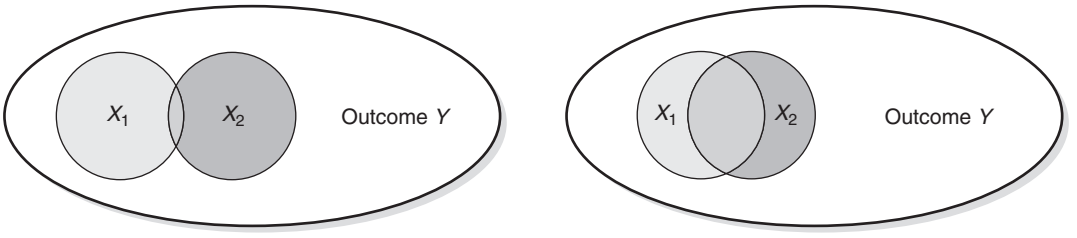

Figure 1 Collinearity Schematic

Note: Low collinearity is shown on the left, while moderate to high collinearity is represented on the right.

any two of the covariates may have only a low degree of correlation or association.

Sometimes the goal of a multiple regression model is to provide the best possible prediction of the outcome. In this situation, even with high variance inflation factors, one might choose to include several somewhat collinear covariates; the result will likely be that one or more fails to achieve statistical significance. However, care should be taken in this situation. A high degree of multicollinearity goes hand in hand with instability in the regression coefficients themselves. If the goal is simply to predict the outcome, then this instability need not be a major concern since the predicted value of Y would be unlikely to change much with a slightly different model. However, if one also cares about the regression equation used to make the prediction, multicollinearity can become a grave concern.

Community-Based Participatory Research

Community-based participatory research (CBPR) in public health is a collaborative approach to research that equitably involves diverse partners, including community members, organizational representatives, and academic researchers, in all aspects of the research process. All partners contribute their expertise and share responsibility and ownership to enhance understanding of a topic of importance to the community, and to translate the knowledge gained into action to improve community health and well-being. Through research findings that can guide interventions and policy change, CBPR can contribute substantially to epidemiology's key functions of identifying and understanding the distribution and determinants of health and disease, and applying this knowledge to improve the public's health.

CBPR is an established approach to inquiry rooted in several research traditions across multiple disciplines, including participatory research and participatory action research. Common to these approaches is an emphasis on engaging community and academic partners in understanding and improving community well-being. CBPR is increasingly applied in epidemiological research and is well suited for investigating complex relationships between the social, economic, physical, and biological environments, and how they interact to influence health across multiple levels. Because CBPR is grounded in equitable collaboration between community members and academic researchers, CBPR is particularly relevant to the investigation of health disparities rooted in racial, economic, and social inequality.

As an approach to research rather than a particular research design or method, CBPR can be applied to a wide range of research efforts, including observational research, exposure assessment, risk assessment, intervention research and evaluation, and as a guide to policy development. CBPR draws on the full range of study designs, including cross-sectional, longitudinal,

experimental, and quasi-experimental, and may include both quantitative and qualitative methods of data collection and analysis.

CBPR can also form the foundation for comprehensive etiologic research and intervention research investigation of a particular health issue over time. For example, an ongoing community-academic partnership effort to examine and address exposure to environmental triggers of childhood asthma in Detroit, Michigan, as described by Parker et al. (2003), included prioritizing the health issue, successful competition for multiyear federal funding, a laboratory study of allergens and asthma, an epidemiological study of air quality and health indicators, and an intervention to reduce environmental triggers for childhood asthma at the household, neighborhood, and policy levels.

What distinguishes CBPR methodologically from other approaches to research is the engagement of the community as coinvestigator in determining what is being studied, how, by whom, and for what purpose. CBPR provides a framework for applying traditional and innovative research methods in ways that involve partners equitably, address power and cultural differences, maximize strengths and resources of partners, and build individual, organizational, and community capacity. Participatory approaches can enhance research quality and applicability and contribute to innovation in research methods. See Viswanathan et al. (2004) for a systematic review of existing evidence on the conduct and evaluation of CBPR, commissioned by the Agency for Healthcare Research and Quality.

Principles of Community-Based Participatory Research

CBPR entails a shared commitment to conducting research based on a set of principles and procedures developed by each specific partnership and intended to promote equitable engagement of all partners. The process of developing shared guidelines for practice forms the foundation of a particular CBPR partnership and guides the design, conduct, and application of the research. While no one strategy is applicable to all CBPR endeavors, there are core underlying principles derived from theory and practice that inform the conduct of CBPR. The following principles or key elements synthesized by Israel and colleagues together comprise a set of goals toward which research partnerships may strive within a CBPR orientation, with the potential for enhancing the quality and application of the research.

- *CBPR recognizes community as a unit of identity.* Understanding complex public health issues requires examining the interaction between people and their social, economic, and physical environments. CBPR processes contextualize investigation and action within specific communities, which may be defined geographically (e.g., neighborhood), sociopolitically (e.g., ethnic group), or based on some other aspect of shared identity. With an emphasis on engaging community members in identifying issues of local concern, CBPR can be an effective means for epidemiologists to conduct studies that matter to the health of the public.

- *CBPR builds on existing knowledge, strengths, and resources within the community.* By drawing on community assets, CBPR challenges a deficit model that emphasizes community problems and identifies strengths and resources that can enhance the design and implementation of research and facilitate its translation into interventions or policy change.

- *CBPR facilitates a collaborative, equitable partnership that engages community members and researchers in all phases of research.* This partnership involves an empowering and power-sharing process that addresses social inequalities, particularly those based on race, class, and gender. CBPR can link communities that have historically been marginalized or excluded from research with researchers committed to eliminating social inequalities and is particularly relevant to understanding and addressing health disparities. Engaging in equitable relationships recognizes the importance of local knowledge, helps build a more complex understanding of the phenomenon of interest, and shifts power from outside researchers toward the community as experts in their own experience of the determinants of health.

- *CBPR promotes colearning and capacity building among all partners.* CBPR brings together individuals and organizations with diverse knowledge, skills, and resources with the intent of reciprocal exchange of these capacities. For example, community members have knowledge and insights about dynamics that influence health in their communities of which outside researchers may not be aware. Researchers from outside the community can strengthen community capabilities as researchers and agents of change.

By partnering, community members and researchers can develop research that is relevant to the local community within historical and cultural contexts and that also addresses important public health questions; combine knowledge and perspectives to strengthen the quality of the data; pool their expertise to strengthen the effectiveness of interventions; and bring additional resources and employment opportunities for marginalized communities. This colearning process helps build the capacity of all partners to address public health concerns.

- *CBPR achieves a balance between knowledge generation and action for the mutual benefit of all partners.* CBPR aims to both generate knowledge and translate research findings into actions that benefit the community. CBPR may include development of interventions or policies that direct resources and influence determinants of health.

- *CBPR focuses on the local relevance of public health problems within a broader ecological framework that recognizes multiple determinants of health.* CBPR can strengthen epidemiology's goal of understanding the distribution and determinants of disease or health in populations and applying this knowledge to controlling health problems, particularly those associated with racial and socioeconomic disparities in health. CBPR is particularly relevant for examining interactions among determinants of health and identifying mechanisms for change across downstream, midstream, and upstream levels.

- *CBPR involves all partners in interpreting and disseminating results within the community and to wider audiences.* The partnership process enables collective interpretation of results, facilitates framing of findings in ways that are respectful of the community, and emphasizes communication of findings to multiple audiences, including community residents, scientists, funders, and policymakers. By engaging all partners in planning for dissemination and including both community and academic partners as coauthors and copresenters, CBPR recognizes community members for their ownership and role in knowledge production and provides expanded opportunities for dissemination.

CBPR is a long-term process that involves systems development within the partnership and between partner organizations, as well as a commitment to sustainability. CBPR relationships extend beyond a single research project and promote continued engagement in efforts to improve community well-being over time.

Recent edited volumes that detail principles and practice of CBPR and describe specific applications in public health include *Community-Based Participatory Research for Health* (Minkler & Wallerstein, 2003) and *Methods in Community-Based Participatory Research for Health* (Israel, Eng, Schulz, & Parker, 2005). In addition, several review articles (Israel, Schulz, Parker, & Becker, 1998; Viswanathan et al., 2004), as well as special journal issues, such as *Health Education and Behavior* (Volume 29, Issue 3, 2002) and *Environmental Health Perspectives* (Volume 110, Supplement 2, 2002), describe specific applications of CBPR for public health research and practice.

Community Health

The term *community health* refers to the health status of a community and to the public and private activities undertaken to protect or improve the health of its members. The public and private activities are divided into three domains: health promotion, health protection, and health services. Each of these is discussed in greater detail below. *Health* can be defined as the physical, mental, emotional, and social resources for a productive and satisfying life. A *community* can be defined as a group of people who live under the same regulations, social norms, values, and organizational structure. Community members share a sense of identity and belonging, a common system of symbols, language, rituals, and ceremonies. They also share common needs and a commitment to meeting them. Communities can be based on geography, such as neighborhoods and towns, or they can be based on some other unifying factor, such as religion, ethnicity, or ancestry.

Population health differs from *community health* in that it describes the health of groups of people who do not represent a community. That is, they do not share a geographical identity, values, or any of the unifying factors mentioned above. Yet these populations as a group share similar health characteristics and concerns. The following are examples of such non-community-based populations that share common health characteristics and concerns: adolescents, adults 25 to 44 years of age, women 50 years of age or older, seniors living in public housing, prisoners, and blue-collar workers. Thus, a population can be based on age, gender, occupation, or any other characteristic. The health status of these groups and the public and private activities undertaken to protect and improve their health constitute population health.

Community and population health are affected by four factors: physical factors (e.g., community size and industrial development), social and cultural factors (e.g., politics and religion), individual behavior (e.g., getting immunized and willingness to recycle), and community organization (i.e., can a community come together to solve a problem).

History of Community Health Practice

Early History

Community health and the practice of community health have a long history. In all likelihood, the earliest community health practices went unrecorded. While there is archeological evidence of human concern about health dating as early as 25,000 BCE, the first inscribed health-related laws can be traced to Hammurabi, the king of Babylon, who in 1900 BCE issued a code of conduct that included laws pertaining to physicians and health practices.

During the years of the classical cultures (500 BCE to AD 500), the Greeks promoted men's physical strength and skill and made advances in community sanitation. The Romans built on the Greeks' engineering, practiced street cleaning and refuse removal, and built aqueducts that transported water from distant places. Although the Romans did little to advance medical thinking, they were the first to build hospitals.

The Medieval and Renaissance Periods

In the Middle Ages (AD 500–1500), when formal learning in Western Europe was largely restricted to monasteries, most believed that diseases and other health problems arose from spiritual causes and required spiritual solutions. Little progress was made in community health. Leprosy, plague, and other communicable diseases were epidemic. The plague epidemic of the 14th century, also known as the Black Death, was the worst of these, killing an estimated 25 million people in Europe alone.

Epidemics continued during the Renaissance period (AD 1500–1700), but there was a growing recognition of the relationship between the physical environment and diseases. More accurate descriptions of the courses of diseases led to better identification of specific diseases.

The 18th and 19th Centuries

The 18th century brought industrial growth to England and Western Europe. Generally, however, living conditions remained unhealthy, and many workplaces were unsafe. Toward the end of the century, in 1796, the English physician Edward Jenner successfully

demonstrated the process of vaccination for smallpox. Meanwhile, in the United States, in 1798, a young government established the Marine Hospital Service to meet the need for hospital services for merchant marines. The Marine Hospital Service eventually became the U.S. Public Health Service.

During the first half of the 19th century, there were few advances in community health practice in the United States. Unsanitary living conditions and epidemics were still concerns, but improvements in farming practices resulted in a better food supply and improved nutrition. Except for major epidemics, community health problems were not addressed by governmental agencies at any level. This began to change in 1850, when Lemuel Shattuck drew up a health report for the Commonwealth of Massachusetts. The Shattuck Report outlined the public health needs of the state and marks the beginning of the modern era of public health in the United States.

The second half of the 19th century was highlighted by the remarkable works of Louis Pasteur of France (the germ theory of disease) and Robert Koch of Germany (demonstrated that a particular microbe, and no other, causes a particular disease). Because of the works of Pasteur, Koch, and many others, the period from 1875 to 1900 has become known as the bacteriological period of public health. As monumental as these scientific achievements were, at the beginning of the 20th century, communicable diseases remained the leading causes of death in the world.

Health Resources Development in the United States

In the United States, the period 1900 to 1960 was known as the health resources development period. During this period, the number of medical and nursing schools increased significantly, new hospitals were built, and the number of health care professionals grew rapidly. This period also saw a rapid growth in the number of voluntary health agencies. The National Association for the Study and Prevention of Tuberculosis (now the American Lung Association) was founded in 1904 and the American Cancer Society in 1913. The federal government finally became involved in health and safety regulation when it passed the Pure Food and Drugs Act of 1906. Twenty-nine years later, the passage of the Social Security Act of 1935 signaled the federal government's first major involvement in social issues. World Wars I and II accelerated the rate of medical discoveries, including the development of new drugs (i.e., penicillin) and new medical procedures. In 1946, Congress passed the National Hospital Survey and Construction Act (Hill-Burton Act) to improve the distribution and enhance the quality of American hospitals.

Social Engineering and Health Promotion in the United States

The realization that many Americans were still not benefiting from the medical progress made during the first half of the 20th century led to a period of social engineering (1960–1973) during which the government tried to assure that more Americans would receive health care. Passage of amendments to the Social Security Act that established Medicare (payment of medical bills for the elderly and certain people with disabilities) and Medicaid (payment of medical bills for the poor) highlighted this period. The health promotion period (1974 to the present) began when it was recognized that the greatest potential for improving the health of communities and populations was not through health care but through improving lifestyle behaviors that are best addressed by health promotion and disease prevention programs.

In 1980, the U.S. Department of Health Education and Welfare released *Promoting Health/Preventing Disease: Objectives for the Nation*, its first comprehensive, 10-year health plan for the nation. This "blueprint for health" set forth health goals and objectives to improve the health of all Americans. Progress toward achieving the plan's objectives was measured, and new goals and objectives were developed and announced for each succeeding decade: *Healthy People 2000* and *Healthy People 2010.* Similar plans have now been developed by the governments of other countries, states, provinces, and even local communities.

Essential Disciplines

Those who practice community health must also have some level of expertise in three other disciplines: epidemiology, community organizing, and health education. John Last has defined *epidemiology* as the study of the distribution and determinants of health-related states or events in specified populations, and the application of this study to control health problems. The

practice of epidemiology involves the collection of data about cases of disease or other health-related events and the calculation of rates and other forms of measurement. Herbert and Irene Rubin define *community organizing* as the bringing together of people to combat shared problems and increase their say about decisions that affect their lives. For example, communities may organize to help control violence in a neighborhood. *Health education* is the process of providing individuals, groups, or communities with learning experiences to help them make decisions that improve their health. A stress management class for church members is an example of health education. Health education is a basic component of health promotion programming that is discussed in more detail below.

Community and Population Health Through the Life Span

Most communities include people at all stages of their lives from the youngest members (infants) to the oldest members (elders). A closer look at each age segment of the community reveals that each of these groups has characteristic health problems. The most frequently used groupings are mothers, infants (ages < 1), and children (ages 1 to 14); adolescents and young adults (ages 15 to 24); adults (ages 25 to 64); and elders (65 years of age and older).

Maternal, infant, and child health encompasses the health of women of childbearing age from prepregnancy through pregnancy, labor, delivery, and the postpartum period, and the health of a child prior to birth through adolescence. Health statistics for this group reveal much about access to health care and the community's commitment to its most vulnerable members. High rates of maternal, infant, and childhood morbidity and mortality indicate inadequate access to health care, too many unplanned pregnancies, insufficient prenatal care, inadequate nutrition, substance abuse problems, and inadequate levels of immunization.

Community health programs that address these problems include those offered by state and local health departments and other agencies. Early intervention with educational programs and preventive medical services for women, infants, and children can lower morbidity and mortality rates, reduce the necessity of costly medical and/or social assistance, and optimize health in later years.

Family planning is defined as the process of determining and achieving a preferred number and spacing of children. A major concern in many communities is teenage pregnancies. Nearly 1 million U.S. teenagers become pregnant each year and most ($\sim 85\%$) of these pregnancies are unintended. Family planning services such as those offered by Planned Parenthood and other agencies can reduce the number of unwanted pregnancies and the number of low-birthweight (LBW) infants. These services include health education, risk assessment, and medical services that begin before the pregnancy and continue through birth. Prenatal care that begins before or very early in pregnancy reduces the chances of an LBW infant and the poor health outcomes that are associated with it. A controversial way of dealing with unintended or unwanted pregnancies is with abortion. Abortion has been legal in the United States since 1973 when the Supreme Court ruled in *Roe v. Wade* that women have a constitutionally protected right to have an abortion in the early stages of pregnancy. According to the Centers for Disease Control and Prevention, approximately 850,000 legal abortions are performed each year in the United States.

Infant and child health are the result of parent health behavior during pregnancy, prenatal care, and the care provided after birth. Critical health concerns for infants and children include immunizations; protection from injuries, both unintentional and intentional; and proper nutrition. One of the most successful programs in the latter regard is the Special Supplemental Food Program for Women, Infants, and Children, known as the WIC program. This program, sponsored by the U.S. Department of Agriculture, provides food, nutritional counseling, and access to health services for low-income women, infants, and children. The WIC program serves more than 8 million mothers and children per month and has been shown to save approximately 3 dollars for each dollar spent.

During the adolescent and young adult years, people complete their physical growth, marry and start families, begin a career, and enjoy increased freedom and decision making. They also adopt beliefs, attitudes, and behaviors about health and make lifestyle choices that will either promote or hamper their health in later years. For many, this is a time for risk-taking behavior (e.g., use and abuse of drugs, risky sexual behavior, and sedentary lifestyle) that can result in unintended injuries and even permanent disabilities. Communities that establish sensible guidelines for numbers of bars and liquor stores,

provide and promote the use of parks and recreation facilities, and plan neighborhoods with safety in mind can foster better health choices for all. In communities where interventions have been successful, these interventions have been comprehensive and community-wide in scope and sustained over time.

The adult population (ages 25 to 64) represents about half of the U.S. population and can be subdivided into those who are 25 to 44 and those 45 to 64 years of age. For the younger of these two subgroups, the leading cause of death is unintentional injuries, followed by cancer and heart disease. For the older group, the leading cause of death is cancer, followed by heart disease; these two causes account for nearly two thirds of all deaths. For most individuals, however, these years of life are the healthiest. Community health interventions for this population are aimed at improving the quality of life rather than extending life.

Members of the community who have reached their 65th birthday are referred to here as elders. This is the fastest-growing segment of the population. By 2030, one in five is expected to be 65 years and older. In 2011, the first baby boomers (those born between 1946 and 1964) will turn 65. From a community and population health perspective, greater attention will need to be placed on the increased demands for affordable housing, accessible transportation, personal care created by functional limitations, and all segments of health care, including adult day care and respite care. Signs of preparation for the growing population of elders are evident in many communities (i.e., senior centers and Meals-on-Wheels), but the increase in demand is expected to accelerate. As this happens, it will be important for communities not to lose focus on the health of its most vulnerable members, its mothers, infants, and children.

The Domains of Community and Population Health

The public and private activities of community and population health practice are divided into three domains: *health promotion*, *health protection*, and *health services.*

Health Promotion

Health promotion comprises the educational, political, environmental, regulatory, and organizational efforts designed to motivate and empower individuals, groups, and communities to take action to improve or protect their health. Health promotion programs encourage people and communities to adopt healthy behaviors and lifestyles and participate in community or political actions that influence health. Formal health promotion programs involve assessing community needs, setting goals and objectives, planning an intervention, implementing the plan, and evaluating the results. Health education is an important part of most health promotion interventions.

An area of community health that is usually amenable to health promotion programming efforts is recreation and fitness. A needs assessment might suggest that a community enhance its quality of life by building or improving sidewalks, bike paths, and hiking trails and by providing and promoting organized recreational programs that meet the social, creative, aesthetic, communicative, learning, and physical needs of its members. Such programs would contribute to the mental, social, and physical health of community members and provide healthy alternatives to the use of tobacco, alcohol, and other drugs as leisure pursuits. At a prescribed time following implementation of the program, its goals and objectives should be evaluated and compared with baseline data collected during the assessment stage. The plan or its implementation should then be adjusted to maximize health outcomes.

Health Protection

Health protection comprises all the efforts and actions undertaken to maintain the health and safety of a community, including the enactment, implementation, and enforcement of ordinances, laws, rules, and policies that protect community members from injuries and diseases. Such protective measures might include efforts to reduce the number and seriousness of injuries; control disease vectors, such as mosquitoes; assure that the air is clean, and that food and water are safe to consume; dispose of wastes properly; and assure that public transportation and housing and occupational and recreational environments are safe and healthy. The development and implementation of such protective measures often require citizen involvement, community organization, and effective government. Examples of successful public health protection policy include the Clean Air Act, implementation of safety belt laws, and the lowering of the blood alcohol concentration limit for impaired driving to 0.08% from 0.10%. Although these examples represent either federal laws or federal

mandates, it is important to recognize that the impetus for them may have begun with local, community-based action.

Health Services and Other Resources

The organization and deployment of the services and resources necessary to plan, implement, and evaluate community and population health strategies constitute the third domain in community health practice, health services. Today's communities are much more complex that those of the past, so high levels of organization are required to respond effectively to community health challenges. The types of agencies that might respond to a community health challenge include both governmental and nongovernmental agencies. These may be local, statewide, national, or even international agencies.

Governmental health agencies are funded primarily by tax dollars, are managed by government officials, and have specific responsibilities that are outlined by the governmental bodies that oversee them. Governmental health agencies include the World Health Organization, the U.S. Department of Health and Human Services, state and territorial health departments, and local health departments.

Nongovernmental health agencies are funded primarily by private donations or, in some cases, by membership dues. Voluntary health agencies such as the American Cancer Society and the American Heart Association are funded primarily by private donations. Professional organizations such as the American Public Health Association, the British Medical Association, the Canadian Nurses Association, and the Society for Public Health Education are funded by membership dues.

Philanthropic foundations are privately endowed organizations, many of which provide funds for worthwhile health programs or services. Examples of such foundations are the Robert Wood Johnson Foundation, the Henry J. Kaiser Family Foundation, the Bill and Melinda Gates Foundation, and the W. K. Kellogg Foundation.

Service, social, and religious organizations also contribute to community and population health by raising money and funding health-related programs. For example, the Lions Club works to help prevent blindness, and a countless number of religious organizations feed, clothe, and provide shelter for those in need.

Finally, there is another type of agency, the quasi-governmental agency. Quasi-governmental health organizations have some official responsibilities, but they also operate, in part, like voluntary health organizations. An example of this type of community health organization is the American Red Cross (ARC). Its official duties include acting as a representative of the U.S. government during natural disasters and serving as the liaison between members of the armed forces and their families during emergencies. In addition to these official responsibilities, the ARC engages in many nongovernmental services such as blood drives and safety services classes such as first-aid and water safety instructions. Most of its funding comes through private donations.

Community Trial

Community trials, also called community intervention studies, are (mostly preventive) experimental studies with whole communities (such as cities or states) as experimental units; that is, interventions are assigned to all members in each of a number of communities. These are to be distinguished from field trials where interventions are assigned to healthy individuals in a community and from clinical trials in which interventions are assigned to patients in a clinical setting. Except for the experimental unit, the conduct of controlled community trials follow the same procedures as controlled clinical trials, including the requirement of informed consent of the communities meeting the eligibility criteria (e.g., consent being given by city mayors or state governors), randomization to treatment and control groups, and follow-up and measurement of endpoints. In contrast to clinical trials, blinding and double blinding are not generally used in community trials. Community trials are needed to evaluate directly the potential efficacy of large-scale public health interventions, and they are indispensable for the evaluation of interventions that cannot be allocated to individuals as experimental units. For example, in studying the effects on dental caries of adding fluoride to the water supply (see Example 2 below), Ast and colleagues found it impossible to add fluoride to drinking water for selected individuals; instead, a controlled community trial was conducted in which whole towns were allocated to receive fluoride in their water or not. Just as with other randomized controlled clinical trials, a randomized controlled community trial requires a sufficient number of communities to involve in the experiment for the randomization to achieve its purpose of reducing confounding bias. In reality, considerably fewer study units are capable of being randomized in community trials than in clinical trials, simply because the study units for the former are considerably larger than those for the latter. For this reason, community trials are often quasi-experimental studies rather than experimental studies and so are considered to have lower validity than clinical trials. However, community trials still have higher validity than all observational analytic and descriptive studies. After enough information has been accumulated from descriptive or observational studies about the risk factors and their potential for modification, community trials may then be conducted to assess the benefit of new public health programs. Below are two real examples of community trials, only the first example being a bona fide community trial.

Example 1: The Indonesian Vitamin A Study

This was a randomized controlled community trial conducted to determine if vitamin A supplementation is effective in reducing childhood mortality in Indonesia. The experimental units were villages and the intervention (vitamin A supplements) was given to whole villages. The study was for 1 year during which time 200,000 IU vitamin A were given twice to children aged 12 to 71 months in 229 randomly allocated treatment villages, while children in 221 control villages were not given vitamin A until after the study. Mortality among children in the control villages was 49% higher than that in the villages given vitamin A (mortality risk ratio $RR = .0073/.0049 = 1.49$, $p < .05$). Many more vitamin A randomized controlled community trials have been carried out worldwide in addition to the Indonesian study. Most of them yielded significant mortality risk ratios, indicating that supplements given to vitamin A–deficient populations would increase survival.

Example 2: The Newburgh-Kingston Caries Fluoride Study

This was a controlled community trial conducted to determine if increasing fluoride levels in drinking water would reduce children's dental caries. Two experimental units, the towns of Newburgh and Kingston in New York State, were assigned to a treatment (fluoridation) arm and a control (unfluoridation) arm, respectively. Starting from 1945 fluoride was added to Newburgh's water supply but not Kingston's. After 10 years of fluoridation, the prevalence rates of decayed, missing, or filled teeth (DMF) for fluoridated Newburgh children from age 6 to 16 years were found to be from 57.9% to 40.9% (the percentage decreases as age increases) lower than those for the corresponding unfluoridated children of Kingston (the DMF rates were similar between the two towns in 1945). However, with only two experimental units, randomization cannot achieve the intended purpose of reducing confounding bias. Hence, this study is only

a quasi-experimental study. Appropriate statistical adjustment of potential confounding variables would have to be made at the analysis stage before valid conclusions can be reached.

Comorbidity

In medicine and in psychiatry, comorbidity is defined as a preexisting concomitant but unrelated disease or diseases, in addition to a primary disease, disorder, initial diagnosis, or index condition. The term *comorbidity* is also used to describe the effect of all other disorders or diseases an individual patient might have other than the primary diagnosis or disease of interest. Results from the first National Comorbidity Survey, released in 1994, revealed that 79% of all seriously ill people (inclusive of all diseases) were comorbid. Comorbidity has serious implications for the diagnosis, treatment, rehabilitation, and outcome of affected individuals. Comorbidity may also affect the ability of affected individuals to function and may be used as a prognostic indicator for length of hospital stay, cost, and mortality.

According to the *Diagnostic and Statistical Manual* (*DSM*) published by the American Psychiatric Association, anxiety and major depressive disorders commonly occur together or are common comorbid disorders. Such comorbidity is found among about half of all the individuals with these disorders. Comorbidity is also common among substance users, both physiologically and psychologically (e.g., substance use/misuse and bipolar disorder). The presence of mental disorders associated with substance use and dependence—the dually diagnosed—among those attending substance use treatment services has been reported to be between 30% and 90%. A survey in 1994 found that 65% of those attending mental health services reported alcohol use disorders. Moreover, alcohol use–related disorders are also common among persons diagnosed with schizophrenia.

There are currently no standardized means of quantifying or classifying prognostic comorbidity. Many tests attempt to standardize the "weight" or predictive value of specific complications or comorbid conditions, based on the presence of secondary or tertiary diagnoses. The Charlson Co-Morbidity Index attempts to consolidate each individual comorbid condition into a single, adjusted variable that measures or predicts the 1-year mortality or other outcomes for a patient who presents with a range of comorbid conditions. The Charlson Co-Morbidity Index has demonstrated excellent predictive validation and contains 19 categories of comorbid conditions, primarily defined using the *International Statistical Classification of Diseases and Related Health Problems*, *Version 9, Clinical Modification* (ICD-9-CM) diagnoses codes. The comorbidity score reflects the cumulative increase in likelihood of 1-year mortality due to the severity of the effect of comorbidities; the higher the score, the more severe the burden of comorbidity.

Social scientists, health care scholars, and policymakers advised caution in the use and reliance on the Charlson Index because the ICD-9-CM codes used in the indexes or composite variables often lead to difficulties in distinguishing between complications and comorbidities. A complication is usually defined as a medical condition that is acquired during a hospital stay and could have been prevented. If these disease categories cannot be reliably differentiated, it is possible that the burden of comorbid conditions might be overestimated. Those urging caution in using the Charlson Index coding schema have also noted that the comorbidity and complication codes often fall in the same disease category resulting in a lack of distinction between principal diagnoses present at admission versus those that developed or occurred during the hospital stay.

Roos augmented the Charlson Index by developing a comorbidity algorithm that does not use individual diagnoses directly in calculating the comorbidity score, thereby limiting the effect of complications in risk adjustment. In addition, Quan modified and updated the Charlson Index ICD-9-CM coding indices to ICD-10, thus reducing the inability to distinguish between related comorbidities and complications.

Competencies in Applied Epidemiology for Public Health Agencies

The Centers for Disease Control and Prevention (CDC) and the Council of State and Territorial Epidemiologists (CSTE) developed the *Competencies for Applied Epidemiologists in Governmental Public Health Agencies* (applied epidemiology competencies or AECs for short) to improve the practice of epidemiology within the public health system. The document defines the discipline of applied epidemiology and describes expected competencies for different levels of practicing epidemiologists working in government public health agencies. This document describes the rationale for developing the AECs and provides an overview of the participants, the development process, the AECs, their target audience, and the intended uses by those audiences.

CDC, the lead federal governmental agency on this project, is part of the U.S. Department of Health and Human Services and has responsibility for prevention and control of disease and other health-related conditions. As the professional organization representing epidemiologists at the state and recently at the large-city and county levels, CSTE is a key partner for CDC, particularly regarding applied epidemiology and workforce development. In January 2004, CDC and CSTE hosted a workforce summit to address concerns affecting public health epidemiologists. Leaders in applied epidemiology were invited to discuss key workforce issues. Participants strongly supported the need to establish core competencies for applied epidemiologists. Subsequent to the summit, CDC and CSTE identified competency development as a priority.

The reasons for pursuing this competency-development process were myriad. Multiple studies have demonstrated a substantial shortage of epidemiologists needed by local and state public health agencies. In addition, epidemiologists practicing in public health agencies often do not have sufficient training to accomplish their responsibilities. Promotion and retention of trained epidemiologists is often hindered by a lack of clear career ladders for epidemiologists. Previous, smaller-scale efforts to define the field have been independent and uncoordinated. The only national efforts, spearheaded by organizations such as the American College of Epidemiology (ACE) and the Association of Schools of Public Health (ASPH), focused on academic or doctoral epidemiologists. The ACE and ASPH efforts underemphasize critical applied epidemiology competencies in the areas of public health surveillance and field or outbreak investigation.

Competencies are observable and are identified in action-oriented statements that delineate the essential knowledge, skills, and abilities required for the performance of work responsibilities. Defining competencies for applied epidemiologists provides

- a roadmap for training the existing workforce;
- guidelines for academia to use in training the future workforce;
- definition of the skills needed for hiring epidemiologists;
- a basis for evaluating, rewarding, and promoting epidemiologists;

- improved ability to define the discipline; and
- a tool useful for any potential certification process.

In October 2004, CDC and CSTE convened an expert panel to define AECs for local, state, and federal public health epidemiologists. This panel comprised representatives from state and local health agencies, schools of public health, and private industry and from throughout CDC. To facilitate rigorous integration of both epidemiologic and workforce development perspectives in the process, two cochairs were recruited: Guthrie Birkhead, MD, MPH, New York State Department of Health, Albany, New York, a highly acclaimed leader in applied epidemiology; and Kathleen Miner, PhD, MPH, CHES, Rollins School of Public Health, Emory University, Atlanta, Georgia, also an equally acclaimed leader in workforce development. Additional academic epidemiologists and public health workforce development specialists also played key roles as reviewers on this panel. Other specific organizational partners included the ASPH, the Association of State and Territorial Health Officials, the American Public Health Association, and the National Association of County and City Health Officials.

The panel used a structured process to define the AECs during multiple face-to-face meetings and teleconferences that were interspersed with input from surveys of other practicing and academic epidemiologists. Jac Davies, MS, MPH, CSTE consultant, captured and synthesized all the comments for expert panel discussion and prepared the final documents, with oversight from the leadership group that consisted of the cochairs and the CDC convener (Denise Koo, MD, MPH). CSTE employees Jennifer Lemmings, MPH, LaKesha Robinson, MPH, and Executive Director Patrick McConnon, MPH, provided critical staffing for the effort, organizing the meetings and conference calls, coordinating the surveys and collating their results, and posting preliminary and final versions of the competencies on the CSTE Web site.

The AECs were built on the framework of the Core Competencies for Public Health Professionals—a product of the Council on Linkages (COL) Between Academia and Public Health Practice—and thus are consistent with the larger field of public health practice. They include not only epidemiologic or analytic competencies and competencies in other basic public health sciences but also competencies in the other COL domains of policy development and program planning, communication, cultural competency, community dimensions of public health practice, financial planning and management, and leadership and systems thinking. The AECs resulted from 2 years of highly collaborative work by the expert panel. Epidemiologists at all levels of public health practice from throughout the country and from academia provided substantial input into the AECs.

The document defines competencies for four tiers of practicing epidemiologists, categorized on the basis of level of responsibility, experience, and education: entry-level or basic, midlevel, supervisory, and senior scientist/researcher. The expert panel intended that all persons practicing applied epidemiology gain minimal competency in all the defined skill domains within the tier that most closely matches their level of responsibility. However, it is not expected that every applied epidemiologist will be equally competent in all areas. Different public health programs might emphasize different competency areas, and a government agency's responsibilities, needs, and resources might require epidemiologists in individual positions to focus on particular competencies.

The target audience and intended uses of the AECs include the following:

- practitioners, using the AECs for assessing current skills, creating career development plans, and planning specific training to meet educational needs;
- employers, using AECs for creating career ladders for employees, developing position descriptions and job qualifications, developing training plans for employees, and assessing epidemiologic capacity of the organization; and
- educators, using AECs for designing education programs that meet the needs of public health agencies and incorporating critical elements of epidemiologic practice into existing coursework.

It is expected that the AECs will be used as the basis for instructional competencies for training government epidemiologists and as the framework for developing position descriptions, work expectations, and job announcements for epidemiologists practicing in public health agencies. CDC plans to use the competencies as the basis for its Epidemic Intelligence Service and other epidemiology training activities. These competencies should also provide impetus for additional partnerships between academia and public health practice and might also prove useful for the training of other health professionals in quantitative or

population health skills. After public health agencies have used them for a period of time, CDC and CSTE will evaluate their utility and effectiveness as part of an ongoing process to update and improve them.

Complementary and Alternative Medicine

Complementary and alternative medicine (CAM) is a group of diverse medical and health care systems, practices, and products that are not presently considered a part of conventional medicine. There are three general types of CAM: (1) Western alternative medical therapies, (2) traditional medical systems, and (3) complementary approaches. Researchers estimate that 68% of U.S. adults will use at least one form of CAM in their lifetime. Research and policy initiatives in CAM are growing in response to the widespread use. This entry discusses definitions and utilization of CAM, public policy with regard to CAM, and the relationship between CAM and public health. It also examines challenges for research on CAM; concerns related to reimbursement, credentialing, and education; legal and ethical issues; and the need for an integrative approach to CAM.

Defining CAM

Although the terms *complementary medicine* and *alternative medicine* are often used interchangeably, they have unique meanings. Alternative medicine suggests methods used in place of conventional Western medicine, while complementary medicine implies methods used in combination with conventional health care. As the field of unconventional medicine has grown, the combined term (*complementary and alternative medicine* or CAM) has become the acceptable nomenclature to depict the field. The National Institutes of Health Center for Complementary and Alternative Medicine (NCCAM) defines CAM as a group of diverse medical and health care systems, practices, and products that are not presently considered a part of conventional medicine. It includes medical or preventive practices that are not routinely taught in medical schools nor underwritten by third-party payers. These definitions, however, are exclusionary. More inclusive definitions suggest that CAM is a heterogeneous set of health systems and practices from cultures around the world that share characteristics differentiating them from conventional medicine. Most share a holistic approach that emphasizes wellness and health maintenance; acknowledges and integrates body, mind, and energy/spirit as the core and coequal elements of the human system; appreciates the role of environmental factors in health; and affirms the centrality of personal attitudes and choices in the creation of health and illness. According to the Cochrane Collaboration, an international nonprofit group that maintains a database of health care information, CAM is defined as a broad domain of healing resources that encompasses all health systems,

modalities, and practices and their accompanying theories and beliefs, other than those intrinsic to the dominant health system of a particular society or culture in a given historical period. For example, Western medicine (also referred to as allopathic or conventional medicine), which is practiced by medical doctors (MDs) and is dominant in the United States, understands and treats illness from a biologic perspective. Acupuncture, which is neither taught in medical school nor has a recognized biologic basis for its effects, is therefore considered CAM.

CAM can be classified into three broad types: (1) Western alternative medical therapies, for example, homeopathy, naturopathy, herbal medicine, aromatherapy; (2) traditional medical systems, for example, Chinese medicine, Indian Ayurveda, Tibetan medicine, Native American healing, Latin American curanderismo; and (3) complementary approaches, for example, mind-body interventions, psychoneuroimmunology (the study of the relationship between social and psychological factors and biologic processes), energetic healing. Western alternative medical therapies are relatively newer systems of health and healing developed in Europe or America. Some stem from or are related to conventional Western medicine, while others are unique. Traditional medical systems stem from cultural perspectives and form a complete approach to health care. Complementary approaches rely on the mind-body connection or energy as the primary mode of cure and may be used in conjunction with biomedical approaches.

Use of CAM

David Eisenberg and his colleagues conducted random-digit-dial cross-sectional studies in 1990 and 1997 that assessed the use of CAM in the United States. They found that the proportion of U.S. adults using CAM practices increased from 34% in 1990 to 42% in 1997. A trend analysis of these data suggests that 68% of U.S. adults will use at least one form of CAM in their lifetime. The Eisenberg studies also found that the most commonly used forms of CAM are relaxation therapies (16.5%), herbal medicine (12.1%), massage (11.1%), and chiropractic (11%); other studies added lifestyle/diet and exercise/movement to the list.

CAM is used most frequently to treat chronic conditions such as musculoskeletal problems, anxiety, depression, and headaches that have not been successfully treated with conventional medicine. In general, individuals are more likely to use CAM if they are more educated, have experienced a transformational event that changed their life, are in poorer overall health, and believe in a holistic philosophy. The appeal of CAM may be due to its perception of being natural and less artificial. In addition, its connection to cosmic forces (vitalism) and spiritual roots may drive its use.

In the Eisenberg studies, only about 40% of respondents informed their primary health care provider (PCP) about their use of CAM. Reasons for the lack of disclosure include the belief that it is not important or relevant to PCPs to know about their use; the belief that PCPs would not understand; the belief that PCPs would disapprove of CAM use; and the fact that PCPs do not ask about CAM use. A review by Astin and colleagues found that physicians refer clients for CAM when (1) the patient is not responding to conventional treatment, (2) it is requested by the patient, and (3) the physician believes in its effectiveness and safety.

Public Policy and CAM

In 1993, the National Institutes of Health established the Office of Alternative Medicine with a budget of $20 million to fund projects that explored the impact of CAM approaches on a number of health conditions. Since its inception, the Office has become a Center (1999), allowing expanded support of research. The NCCAM continues to grow, with a current budget in excess of $110 million.

A number of national and international activities have been conducted that explore and respond to CAM use and safety. In 2002, the World Health Organization published its *Global Statement on Traditional or Complementary and Alternative Health* (T/CAM). This document reports on the worldwide use of T/CAM and delineates steps to increase the quality, efficacy, and accessibility of these approaches.

Also in 2002, the White House Commission on CAM published a policy statement that provides recommendations on (1) the coordination of research, (2) education and training of practitioners, (3) information dissemination to health care providers, and (4) strategies for increasing access to CAM. A set of 10 principles (including wholeness orientation in health care delivery, evidence of safety and efficacy, emphasis on health promotion) guided the development of the recommendations.

Finally, the Institute of Medicine released its report on complementary and alternative medicine in the United States in 2005. The report explains the use, users, and types of CAM in the United States. The report provides several recommendations regarding research, training, and translation and dissemination of accurate information. The core recommendation is that all health-related treatments, conventional or CAM, should use the same standards and principles to determine treatment effectiveness.

CAM and Public Health

Traditionally, the public health sector has not embraced CAM. In part, this may be due to the fact that CAM is "complementary" and "alternative" to conventional medicine and that its relationship to public health has been unclear. The field of public health emphasizes the health of the entire community through an emphasis on prevention and by linking interventions to multiple social and environmental determinants of disease. This approach includes a focus on disease prevention and health maintenance, a holistic focus on the person in the context of the natural and human-created environment, and attention to personal choices and health behaviors. Public health is therefore grounded in principles consonant with those of the CAM practices. It is incumbent on the public health community to recognize the similarities between public health and CAM and to increase its cultural competency through increased understanding and acceptance of the diverse beliefs and practices of community members.

Challenges for Research on CAM

The quantity and quality of scientific research on CAM have increased, particularly since the advent of funding through the NCCAM. The PubMed search engine contains 420,000 references to CAM-related articles in medical and scientific journals. The NCCAM currently funds several Centers of Excellence for Research on CAM in the areas of acupuncture, antioxidants, energy medicine, herbal therapy, mindfulness-based stress reduction, and traditional Chinese medicine; six Centers for Dietary Supplements Research; and nine Developmental Centers for Research on CAM that support developmental research on CAM through collaborations between CAM schools and conventional biomedical research institutions. Current funding priorities of the NCCAM include research on mechanisms of action, active ingredients, pharmacology, bioavailability, and optimal dosing, safety, and efficacy. Areas of special interest include anxiety and depression, cardiovascular diseases, ethnomedicine, immune modulation/enhancement, inflammatory bowel disease and irritable bowel syndrome, insomnia, liver, obesity/metabolic syndrome, and respiratory diseases.

There are several barriers to the use of conventional scientific approaches for evaluating CAM therapies. Since Western culture and mainstream biomedical practice rely on principles of scientific evidence, CAM practices are currently judged within the scientific community on the basis of evidence from controlled research studies. The "gold standard" for medical research is the double-blind randomized controlled trial, in which the treatment and a control (placebo) are administered randomly to patients; neither the patient nor the health care provider knows who is getting the real treatment. Since CAM refers to a large and heterogeneous grouping of health interventions, the nature of many modalities in CAM can make comparison to conventional practice difficult. There is diversity even within some therapies (e.g., acupuncture, which may use either a 5-element or an 8-principle model); others are designed to be tailored to an individual patient on the basis of nonmedical considerations, making them difficult to standardize (e.g., homeopathy). A common research concern is distinguishing the effects of treatment from the placebo effect; because some CAM interventions are intended to stimulate the body's self-healing potential, this may become a meaningless distinction in CAM. Identifying appropriate controls can be challenging, and the design of double-blind trials is often impossible when practitioner knowledge is required to administer a CAM intervention appropriately.

The Cochrane Collaboration has also found evidence of publication bias resulting in the exclusion of research on some CAM topics from scientific publications, as well as a pattern of some CAM topics being published exclusively in languages other than English. The Collaboration is standardizing the assessment of research quality, which will provide more comparability of results across biomedical and complementary health research.

Reimbursement for CAM Care

Pelletier and associates estimate that total expenditures for CAM in 1997 were $27 billion, of which $21.2

billion was paid to practitioners for their professional services; this was a 45% increase over what was reported in 1990 data. Most of those expenses are paid by consumers out of pocket. Insurers decide whether to cover CAM treatment based on evidence regarding the clinical efficacy, safety, and cost-effectiveness of the treatment; consumer demand in their service area; state mandates; and standards of practice and practitioner licensure. Reimbursement rates depend on the local market, procedure code, and practitioner education and licensure; in most instances, a procedure is covered only if it is determined to be medically necessary (rather than important for general wellness).

As of 1999, Medicaid coverage is provided for CAM treatment in 36 states; chiropractic care is the most common treatment covered. States paying for services other than chiropractic are concentrated in the Northeast, Mid-Atlantic, and Pacific regions of the United States. In a few states, naturopaths or chiropractors are reimbursed as primary care providers under Medicaid.

Credentialing and Education

Licensure of both conventional and CAM health care practitioners is under the purview of each state legislature, and state policies on professional licensure and scope of practice vary. Chiropractic is licensed in every state, and acupuncture in 42 states; other practices (such as naturopathy and massage) are licensed in some states, whereas still others are rarely licensed (homeopathy is licensed in only 3 states, and practice is restricted to licensed medical doctors). Unlicensed CAM practitioners are liable to prosecution for the unlicensed practice of medicine. Nonlicensing professional credentialing in CAM modalities is provided by professional associations and educational institutions, and so credentialing is not widely standardized or legally recognized.

A 1997 survey by Wetzel and colleagues indicated that 64% of medical schools offered elective courses in CAM or included some CAM information in required courses. The focus and content of the training received by medical practitioners in CAM vary widely and are not universally included in the core curriculum.

Ethical and Legal Issues

Ethical and legal issues in CAM include the practice of CAM modalities by untrained providers (either conventional or CAM providers), client safety, and the interface between CAM and conventional medical practice. Ethical practice requires training and some form of licensure or credentialing. If practitioners do not have a working knowledge and experience in the use of CAM modalities, they cannot obtain informed consent from patients, and therefore client safety cannot be guaranteed. A large proportion of individuals who use CAM do not inform their biomedical practitioners; therefore, physicians have a responsibility to support and protect their patients by inquiring about their use of CAM practices, educating patients about the questions to ask of CAM practitioners, and providing information about known interactions among therapeutic interventions. Although referral to licensed and accredited CAM practitioners is not likely to create liability for malpractice claims, biomedical physicians using CAM interventions themselves may incur legal or insurance repercussions for deviation from standard practice. All CAM providers are, however, ethically bound to practice within their scope of training and to obtain informed consent for treatments.

Toward an Integrative Approach

As the U.S. population continues to change, Americans become increasingly dissatisfied with conventional health care alone, and the cost of health care continues to skyrocket, a model that integrates CAM, and conventional medicine should be considered. An integrative model of health care suggests an evolving population-based approach, with conventional medicine as one approach to health care. Integration is occurring at a number of levels and to various degrees. The consumer level is driving the demand for CAM, followed by practitioners who are responding to the demand. Health care institutions are responding to practitioners' use of CAM, although to a lesser degree. For example, some integrative medicine clinics are being implemented and evaluated, while a significant number of schools of medicine are beginning to offer courses and content in CAM. Regulatory bodies are only beginning to explore the role of CAM in credentialing. Finally, there is little or no integration at the policy level.

Although an integrative approach may be ideal, there continue to be barriers, including lack of research and information about the efficacy and cost-effectiveness of CAM treatments. A truly integrated

system would be holistic in its treatment approach, blend conventional health and CAM into a seamless continuum, employ a collaborative team, and result in effective and cost-efficient care.

Confidence Interval

Most statistical analysis is conducted to reach some conclusion or decision about one or more parameters associated with a population of interest (statistical inference). There are two types of estimators used to assist in reaching a conclusion: point estimators and interval estimators. If the sampling distribution of the point estimator is known, then a likely range of values can be computed for the parameter being estimated. This range is called an interval estimator or confidence interval.

Before proceeding to more detail, here are some terms specific to confidence intervals. *Confidence limits* or *confidence bounds* are the upper and lower values of the range for the parameter given by the confidence interval. These limits are obtained from a sample and are random variables. The *pivotal quantity* is the point estimate used to estimate the population parameter and is the center of the confidence interval. The *half-width* of the confidence interval is the distance from the pivotal quantity to one of the limits and is a positive value. The desired significance level for the confidence interval is denoted by α (alpha), and is given by a number between 0 and 1. Typical values for α are between 0.01 and 0.05. The *confidence coefficient* is calculated as $(1 - \alpha)$, and is sometimes called the *coverage probability* or *inclusion probability* (although these terms are misleading, as explained later). Typical values for the confidence coefficient are between 0.95 and 0.99. The *confidence level* or *degree of confidence* is the confidence coefficient expressed as a percentage, $100(1 - \alpha)\%$. Typical values for the confidence level are between 95% and 99%. The *standard error* or *standard deviation* of the sampling distribution is used in calculating the confidence interval and depends on the particular point estimator used as well as the sampling method used.

Since point estimates do not provide a means for assessing the reliability or confidence placed on them, confidence intervals are preferred. They require no

additional information about reliability since it is provided by the degree of confidence and the half-width of the interval. The goodness of an interval estimation procedure can be determined by examining the fraction of times in repeated sampling that interval estimates would contain the parameter to be estimated. This fraction is called the confidence coefficient. The confidence coefficient is specified by the researcher, and it expresses how much assurance he or she wishes to have concerning whether the interval estimate encompasses or "covers" the parameter of interest. If 0.95 is the confidence coefficient associated with using a particular confidence interval formula, 95% of the time in repeated sampling, confidence intervals calculated using that formula will contain the true value of the population parameter. The flexibility to change confidence coefficients is another benefit of interval estimation compared with point estimation. Increasing the degree of confidence will widen a confidence interval; decreasing the degree of confidence will narrow a confidence interval.

There are three very common erroneous statements concerning confidence intervals. Here are these misstatements within the realm of using a sample mean, $\overline{X}$, to estimate a population mean, μ, with 95% confidence.

1. *There is a 95% chance that the confidence interval contains* μ. The parameter value is a fixed quantity, although it is unknown. Once a confidence interval is computed, the population value is either in it or not; there is no probabilistic statement to be made. For this reason, the terms *inclusion probability* and *coverage probability* are misleading when referring to the confidence coefficient.
2. *There is a 95% chance that the confidence interval contains* $\overline{X}$. Since the sample mean is the pivotal quantity that is the center of the confidence interval, there better be 100% certainty that the confidence interval contains $\overline{X}$.
3. *Ninety-five percent of the data are contained in the interval.* Regardless of whether the statement is referring to the sample data or the population data, the actual amount of data contained in the interval for the mean is irrelevant. However, the half-width of the 95% interval for individual values of x is approximately $\sqrt{n}$ times larger than the half-width of the 95% interval for the mean, where n is the sample size.

To help avoid misconceptions about confidence coefficients, some statisticians have suggested thinking of the sample value as fixed (the pivotal quantity) and then asking what parameter values (the confidence interval) make that sample value the most plausible. The chances are in the sampling procedure, not in the parameter. The confidence coefficient refers to the long-run proportion of intervals that include the population parameter based on using the same sampling procedure and the same sample size and the same interval estimator. In this sense, a researcher is $100(1-\alpha)\%$ confident that a computed confidence interval covers the true value of the parameter.

Cautious researchers will state their confidence levels as approximate levels. There are two reasons for this caveat being used: (1) The standard errors have been estimated from the data; (2) often an assumption of normality has been made about the population of data values. A confidence interval may be expressed in several different forms. Commonly used and equivalent expressions of a 95% confidence interval for a population mean are given by, "With approximately 95% confidence,"... (1) $3 < \mu < 10$; (2) μ lies between 3 and 10 units; (3) μ lies within 6.5 ± 3.5 units; and (4) μ is contained in the interval [3, 10].

Formulas for Calculations

The general form of a confidence interval is: $\hat{\theta} \pm cv_{\alpha/2}\sigma_{\hat{\theta}}$, where $\hat{\theta}$ is the pivotal quantity, $cv_{\alpha/2}$ is a critical value from an appropriate distribution (also called the $\alpha/2$ quantile of the distribution), and $\sigma_{\hat{\theta}}$ is the standard deviation of the sampling distribution of $\hat{\theta}$. Each different estimator $\hat{\theta}$ will have a different standard error formula, which depends on the sampling method used as well as the sample size. The formulas given here assume that a simple random sample was taken from the target population. If a different type of sample was used, then these formulas may not apply. Other formulas and additional information about confidence interval computation may be found in most elementary statistics texts.

- *Mean.* $100(1-\alpha)\%$ confidence interval for μ, where data are normally distributed and σ^2 is known: $\overline{X} \pm z_{\alpha/2}(\sigma/\sqrt{n})$. The z values come from the standard normal distribution.
- *Mean.* $100(1-\alpha)\%$ confidence interval for μ, where σ^2 is unknown and either n is large or data are normally distributed: $\overline{X} \pm t_{\alpha/2,\nu}(s/\sqrt{n})$. The t values come from the Student's t distribution with $\nu = n - 1$ *df*.

- *Mean difference, paired data.* $100(1-\alpha)\%$ confidence interval for $d=\mu_1-\mu_2$, where n is large and σ_d^2 is unknown: $\bar{d}\pm t_{\alpha/2,\nu}(s_d/\sqrt{n})$. The t values come from the Student's t distribution with $\nu=n-1$ *df*.
- *Proportion.* $100(1-\alpha)\%$ confidence interval for p or π, where n is large enough to have at least five in each category: $\hat{p}\pm z_{\alpha/2}\sqrt{[\hat{p}(1-\hat{p})]/n}$. The z value comes from the standard normal distribution.
- *Variance.* $100(1-\alpha)\%$ confidence interval for σ^2, where n is large:

$$\frac{(n-1)s^2}{\chi^2_{\alpha/2,\nu}}\le\sigma^2\le\frac{(n-1)s^2}{\chi^2_{(1-\alpha/2),\nu}}.$$

  The χ^2 values come from the χ^2 distribution (chi-square).
- *Odds Ratio (OR).* $100(1-\alpha)\%$ confidence interval for *OR*, where n is large,

$$\widehat{OR}=\frac{ad}{bc}\text{ and }\sigma_{\ln(\widehat{OR})}=\sqrt{\frac{1}{a}+\frac{1}{b}+\frac{1}{c}+\frac{1}{d}},$$

  where the standard 2×2 table presentation is

$$\begin{bmatrix}a & b\\ c & d\end{bmatrix},$$

  which is

$$e^{\left[\ln(\widehat{OR})\pm z_{\alpha/2}\hat{\sigma}_{\ln(\widehat{OR})}\right]}\le OR\le e^{\left[\ln(\widehat{OR})\pm z_{\alpha/2}\hat{\sigma}_{\ln(\widehat{OR})}\right]}.$$

  The z value comes from the standard normal distribution.

Confounding

The word *confounding* has been used to refer to at least three distinct concepts. In the oldest and most widespread usage, confounding is a source of bias in estimating causal effects. This bias is sometimes informally described as a mixing of effects of extraneous factors (called confounders) with the effect of interest. This usage predominates in nonexperimental research, especially in epidemiology and sociology. In a second and more recent usage originating in statistics, confounding is a synonym for a change in an effect measure on stratification or adjustment for extraneous factors (a phenomenon called *noncollapsibility* or *Simpson's paradox*). In a third usage, originating in the experimental-design literature, confounding refers to inseparability of main effects and interactions under a particular design. The three concepts are closely related and are not always distinguished from one another. In particular, the concepts of confounding as a bias in effect estimation and as noncollapsibility are often treated as equivalent, even though they are not.

Confounding as a Bias in Effect Estimation

A classic discussion of confounding in which explicit reference was made to "confounded effects" is in Chapter 10 of John Stuart Mill's 1843 edition of *A System of Logic, Ratiocinative and Inductive.* In Chapter 3, Mill lays out the primary issues and acknowledges Francis Bacon as a forerunner in dealing with them. In Chapter 10, Mill lists a requirement for an experiment intended to determine causal relations: "None of the circumstances [of the experiment] that we do know shall have effects susceptible of being *confounded* [italics added] with those of the agents whose properties we wish to study."

In Mill's time, the word "experiment" referred to an observation in which some circumstances were under the control of the observer, as it still is used in ordinary English, rather than to the notion of a comparative trial. Nonetheless, Mill's requirement suggests that a comparison is to be made between the outcome of our "experiment" (which is, essentially, an uncontrolled trial) and what we would expect the outcome to be if the agents we wish to study had been absent. If the outcome is not as one would expect in the absence of the study agents, then Mill's requirement ensures that the unexpected outcome was not brought about by extraneous "circumstances" (factors). If, however, these circumstances do bring about the unexpected outcome and that outcome is mistakenly attributed to effects of the study agents, then the

mistake is one of confounding (or confusion) of the extraneous effects with the agent effects.

Much of the modern literature follows the same informal conceptualization given by Mill. Terminology is now more specific, with "treatment" used to refer to an agent administered by the investigator and "exposure" often used to denote an unmanipulated agent. The chief development beyond Mill is that the expectation for the outcome in the absence of the study exposure is now almost always explicitly derived from observation of a control group that is untreated or unexposed. Confounding typically occurs when natural or social forces or personal preferences affect whether a person ends up in the treated or control group, and these forces or preferences also affect the outcome variable. While such confounding is common in observational studies, it can also occur in randomized experiments when there are systematic improprieties in treatment allocation, administration, and compliance. A further and somewhat controversial point is that confounding (as per Mill's original definition) can also occur in perfectly randomized trials due to *random* differences between comparison groups; this problem will be discussed further below.

The Potential-Outcome Model of Confounding

Various models of confounding have been proposed for use in statistical analyses. Perhaps the one closest to Mill's concept is based on the *potential-outcome* or counterfactual model for causal effects. Suppose we wish to consider how a health-status (outcome) measure of a population would change in response to an intervention (population treatment). More precisely, suppose our objective is to determine the effect that applying a treatment x_1 had or would have on an outcome measure μ relative to applying treatment x_0 to a specific target population A. For example, cohort A could be a cohort of breast cancer patients, treatment x_1 could be a new hormone therapy, x_0 could be a placebo therapy, and the measure μ could be the 5-year survival probability. The treatment x_1 is sometimes called the *index* treatment and x_0 is sometimes called the *control* or *reference* treatment (which is often a standard or placebo treatment).

The potential-outcome model posits that in population A, μ will equal μ_{A1}if x_1 is applied, μ_{A0} if x_0 is applied; the causal effect of x_1 relative to x_0 is defined as the change from μ_{A0} to μ_{A1}, which might be measured as $\mu_{A1} - \mu_{A0}$ or μ_{A1}/μ_{A0}. If A is given treatment x_1, then μ will equal μ_{A1} and μ_{A1} will be observable, but μ_{A0} will be unobserved. Suppose, however, we expect μ_{A0} to equal μ_{B0}, where μ_{B0} is the value of the outcome μ observed or estimated for a population B that was administered treatment x_0. The latter population is sometimes called the control or reference population. *Confounding* is said to be present if $\mu_{A0} \neq \mu_{B0}$, for then there must be some difference between populations A and B (other than treatment) that affects μ.

If confounding is present, a naive (crude) association measure obtained by substituting μ_{B0} for μ_{A0} in an effect measure will not equal the effect measure, and the association measure is said to be *confounded.* For example, if $\mu_{A0} \neq \mu_{B0}$, then $\mu_{A1} - \mu_{B0}$, which measures the association of treatments with outcomes *across* the populations, is confounded for $\mu_{A1} - \mu_{A0}$, which measures the effect of treatment x_1 on population A. Thus, to say an association measure $\mu_{A1} - \mu_{B0}$ is confounded for an effect measure $\mu_{A1} - \mu_{A0}$ is to say these two measures are not equal. A noteworthy aspect of this view is that confounding depends on the outcome measure. For example, suppose populations A and B have a different 5-year survival probability μ under placebo treatment x_0; that is, suppose $\mu_{B0} \neq \mu_{A0}$, so that $\mu_{A1} - \mu_{B0}$ is confounded for the actual effect $\mu_{A1} - \mu_{A0}$ of treatment on 5-year survival. It is then still possible that 10-year survival, υ, under the placebo would be identical in both populations; that is, υ_{A0} could still equal υ_{B0}, so that $\upsilon_{A1} - \upsilon_{B0}$ is not confounded for the actual effect of treatment on 10-year survival. (We should generally expect no confounding for 200-year survival, since no treatment is likely to raise the 200-year survival probability of human patients above zero.)

A second noteworthy point is that confounding depends on the target population of inference. The preceding example, with A as the target, had different 5-year survivals μ_{A0} and μ_{B0} for A and B under placebo therapy, and hence $\mu_{A1} - \mu_{B0}$ was confounded for the effect $\mu_{A1} - \mu_{A0}$ of treatment on population A. A lawyer or ethicist may also be interested in what effect the hormone treatment would have had on population B. Writing μ_{B1} for the (unobserved) outcome under treatment, this effect on B may be measured by $\mu_{B1} - \mu_{B0}$. Substituting μ_{A1} for the unobserved μ_{B1} yields $\mu_{A1} - \mu_{B0}$. This measure of association is confounded for $\mu_{B1} - \mu_{B0}$ (the effect of treatment x_1 on 5-year survival in population B) if

and only if $\mu_{A1} \neq \mu_{B1}$. Thus, the same measure of association, $\mu_{A1} - \mu_{B0}$, may be confounded for the effect of treatment on neither, one, or both of populations A and B, and may or may not be confounded for the effect of treatment on other targets.

Confounders (Confounding Factors)

A third noteworthy aspect of the potential-outcome model is that it invokes no explicit differences (imbalances) between populations A and B with respect to circumstances or covariates that might influence μ. Clearly, if μ_{A0} and μ_{B0} differ, then A and B must differ with respect to factors that influence μ. This observation has led some authors to define confounding as the presence of such covariate differences between the compared populations. Nonetheless, confounding is only a consequence of these covariate differences. In fact, A and B may differ profoundly with respect to covariates that influence μ, and yet confounding may be absent. In other words, a covariate difference between A and B is a necessary but not sufficient condition for confounding, as can be seen when the impact of covariate differences may balance each other out, leaving no confounding.

Suppose now that populations A and B differ with respect to certain covariates and that these differences have led to confounding of an association measure for the effect measure of interest. The responsible covariates are then termed *confounders* of the association measure. In the above example, with $\mu_{A1} - \mu_{B0}$ confounded for the effect $\mu_{A1} - \mu_{A0}$, the factors responsible for the confounding (i.e., the factors that led to $\mu_{A0} \neq \mu_{B0}$) are the confounders. It can be deduced that a variable cannot be a confounder unless it can affect the outcome parameter μ within treatment groups and it is distributed differently among the compared populations. These two necessary conditions are sometimes offered together as a definition of a confounder. Nonetheless, counterexamples show that the two conditions are not sufficient for a variable with more than two levels to be a confounder. Note that the condition of affecting the outcome parameter is a causal assertion and thus relies on background knowledge for justification.

Prevention of Confounding

An obvious way to avoid confounding is estimating $\mu_{A1} - \mu_{A0}$ to obtain a reference population B for which μ_{B0} is known to equal μ_{A0}. Such a population is sometimes said to be *comparable* to or *exchangeable* with A with respect to the outcome under the reference treatment. In practice, such a population may be difficult or impossible to find. Thus, an investigator may attempt to construct such a population, or to construct exchangeable index and reference populations. These constructions may be viewed as design-based methods for the control of confounding.

Perhaps no approach is more effective for preventing confounding by a known factor than *restriction.* For example, gender imbalances cannot confound a study restricted to women. However, there are several drawbacks: Restriction on enough factors can reduce the number of available subjects to unacceptably low levels and may greatly reduce the generalizability of results as well. Matching the treatment populations on confounders overcomes these drawbacks and, if successful, can be as effective as restriction. For example, gender imbalances cannot confound a study in which the compared groups have identical proportions of women.

Unfortunately, differential losses to observation may undo the initial covariate balances produced by matching. Neither restriction nor matching prevents (although it may diminish) imbalances on unrestricted, unmatched, or unmeasured covariates. In contrast, *randomization* offers a means of dealing with confounding by covariates not accounted for by the design. It must be emphasized, however, that this solution is only probabilistic and subject to severe constraints in practice.

Randomization is not always feasible or ethical, and many practical problems, such as differential loss (dropout) and noncompliance, can lead to confounding in comparisons of the groups actually receiving treatments x_1 and x_0. One somewhat controversial solution to dropout and noncompliance problems is *intent-to-treat analysis*, which defines the comparison groups A and B by treatment assigned rather than treatment received. Confounding may, however, affect even intent-to-treat analyses, and (contrary to widespread misperceptions) the bias in those analyses can exaggerate the apparent treatment effect. For example, the assignments may not always be random, as when blinding is insufficient to prevent the treatment providers from protocol violations. And, purely by bad luck, randomization may itself produce allocations with severe covariate imbalances between the groups (and consequent confounding), especially if

the study size is small. *Blocked* (matched) randomization can help ensure that random imbalances on the blocking factors will not occur, but it does not guarantee balance of unblocked factors.

Adjustment for Confounding

Design-based methods are often infeasible or insufficient to prevent confounding. Thus, there has been an enormous amount of work devoted to analytic adjustments for confounding. With a few exceptions, these methods are based on observed covariate distributions in the compared populations. Such methods can successfully control confounding only to the extent that enough confounders are adequately measured. Then, too, many methods employ parametric models at some stage, and their success may thus depend on the faithfulness of the model to reality.

The simplest and most widely trusted methods of adjustment begin with *stratification* on confounders. A covariate cannot be responsible for confounding within internally homogeneous strata of the covariate. For example, gender imbalances cannot confound observations within a stratum composed solely of women. More generally, comparisons within strata cannot be confounded by a covariate that is unassociated with treatment within strata. This is so, whether the covariate was used to define the strata or not. Thus, one need not stratify on all confounders to control confounding. Furthermore, if one has accurate background information on relations among the confounders, one may use this information to identify sets of covariates statistically sufficient for adjustment. Nonetheless, if the stratification on the confounders is too coarse (e.g., because categories are too broadly defined), stratification may fail to adjust for much of the confounding by the adjustment variables.

One of the most common adjustment approaches today is to enter suspected confounders into a model for the outcome parameter μ. For example, let μ be the mean (expectation) of an outcome variable of interest Y, let X be the treatment variable of interest, and let Z be a suspected confounder of the $X - Y$ relation. Adjustment for Z is often made by fitting a generalized-linear model $g(\mu) = g(\alpha + \beta x + \gamma z)$ or some variant, where $g(\mu)$ is a strictly increasing function such as the natural logarithm $\ln(\mu)$, as in log-linear modeling, or the logit function $\ln\{\mu/(1-\mu)\}$, as in logistic regression. The estimate of the exposure coefficient β that results is then taken as the Z-adjusted estimate of the X effect on $g(\mu)$.

An oft-cited advantage of model-based adjustment methods is that they allow adjustment for more variables and in finer detail than stratification. If, however, the form of the fitted model cannot adapt well to the true dependence of Y on X and Z, such model-based adjustments may fail to adjust for confounding by Z. For example, suppose Z is symmetrically distributed around zero within X levels, and the true dependence is $g(\mu) = g(\alpha + \beta x + \gamma z^2)$; then using the model $g(\mu) = g(\alpha + \beta x + \gamma z)$ will produce little or no adjustment for Z. Similar failures can arise in adjustments based on models for treatment probability (often called "propensity scores"). Such failures can be minimized or avoided by using reasonably flexible models, by carefully checking each fitted model against the data, and by combining treatment-probability and outcome models to produce more robust effect estimators.

Finally, if (as is often done) a variable used for adjustment is not a confounder, bias may be introduced by the adjustment. The form of this bias often parallels *selection bias* familiar to epidemiologists and tends to be especially severe if the variable is affected by both the treatment and the outcome under study, as in classic *Berksonian bias* (e.g., in the use of hospital-based controls when hospitalization is related to exposure). In some cases, the resulting bias is a form of confounding within strata of the covariate; adjustment for covariates affected by treatment can produce such confounding, even in randomized trials.

Confounded Mechanisms Versus Confounded Assignments

If the mechanism by which the observational units come to have a particular treatment is independent of the potential outcomes of the units, the mechanism is sometimes described as *unconfounded* or *unbiased* for μ; otherwise, the mechanism is confounded or biased. Randomization is the main practical example of such a mechanism. Graphical models provide an elegant algorithm for checking whether the graphed mechanism is unconfounded within strata of covariates. Note, however, that in typical epidemiologic usage, the term *confounded* refers to the result of a single assignment (the study group actually observed), and not the behavior of the mechanism. Thus, an unconfounded mechanism can by chance produce confounded assignments.

The latter fact resolves a controversy about adjustment for baseline (pretreatment) covariates in randomized trials. Although some assert that randomized comparisons are ''unbiased'' without adjustment, this unbiasedness is actually a property of the mechanism. Particular assignments can be confounded in the single-trial sense used in epidemiology. Once the trial is under way and the actual treatment allocation is completed, the unadjusted treatment-effect estimate will be biased conditional on the observed allocation if the baseline covariate is associated with treatment in the allocation, and the covariate affects the outcome; this bias can be removed by adjustment for the covariate.

Confounder Selection

An essential first step in the control of confounding is to identify which variables among those measured satisfied the minimal necessary conditions to be a confounder. This implies among other things that the variables cannot be affected by exposure or outcome; it thus excludes intermediate variables and effects of exposure and disease, whose control could introduce Berksonian bias. This initial screening is primarily a subject-matter decision that requires consideration of the causal ordering of the variables. Relatively safe candidate confounders will be ''pretreatment'' covariates (those occurring before treatment or exposure), which at the very least have the advantage that they cannot be intermediates or effects of exposure and outcome. Exceptions occur in which control of certain pretreatment variables introduce bias, although the bias so introduced may be much less than the confounding removed.

Variables that pass the initial causal screening are sometimes called ''potential confounders.'' Once these are identified, the question arises as to which must be used for adjustment. A common but unjustified strategy is to select confounders to control based on a test (usually a significance test) of each confounder's association with the treatment X (a test of imbalance) or with the outcome Y, for example, using stepwise regression. Suppose Z is a pretreatment covariate (potential confounder). The strategy of testing the Z association with X arises from a confusion of two distinct inferential problems:

1. Do the treated ($X = 1$) evince larger differences from the untreated ($X = 0$) with respect to Z than one should expect from a random (or unconfounded) assignment mechanism?
2. Should we control for Z?

A test of the $X - Z$ association addresses the first question, but not the second. For Question 2, the ''large sample'' answer is that control is advisable, regardless of whether the $X - Z$ association is random. This is because an imbalance produces bias conditional on the observed imbalance, even if the imbalance is random. The mistake of significance testing lies in thinking that one can ignore an imbalance if it is random, which is not so. Random assignment guarantees only valid performance of statistics unconditionally, averaged over all possible treatment assignments. It does not, however, guarantee validity conditional on the observed Z imbalance, even though any such imbalance must be random in a randomized trial. Thus, the $X - Z$ test addresses a real question (one relevant to studying determinants of response/treatment), but is irrelevant to the second question.

The case of testing the Z association with Y devolves in part to whether one trusts prior (subject-matter) knowledge that Z affects Y (or is a proxy for a cause of Y) more than the results of a significance test in one's own limited data. There are many examples in which a well-known risk factor exhibits the expected association with Y in the data, but for no more than chance reasons or sample-size limitations that association fails to reach conventional levels of ''significance.'' In such cases, there is a demonstrable statistical advantage to controlling Z, thus allowing subject-matter knowledge to override nonsignificance.

Another problematic strategy is to select a potential confounder Z for control based on how much the effect estimate changes when Z is controlled. Like the testing methods described above, it also lacks formal justification and can exhibit poor performance in practice. The strategy can also mislead if the treatment affects a high proportion of subjects and one uses a ''noncollapsible'' effect measure (one that changes on stratification even if no confounding is present), such as an odds ratio or rate ratio.

In practice, there may be too many variables to control using conventional methods, so the issue of confounder selection may seem pressing. Nonetheless, hierarchical-Bayesian or other ''shrinkage'' methods may be applied instead. These methods adjust for all the measured confounders by estimating the confounder effects using a prior distribution for those effects. Some of these methods (e.g., the

"Lasso") may drop certain variables entirely, and thus in effect result in confounder selection; unlike significance-testing-based selection, however, this selection has a justification in statistical theory.

Control Group

Many experiments are designed to include a control group and one or more experimental groups; in fact, some scholars reserve the term *experiment* for study designs that include a control group. Ideally, the control group and the experimental groups are identical in every way except that the experimental groups are subjected to treatments or interventions believed to have an effect on the outcome of interest, while the control group is not. The control group is the standard to which comparisons are made in an experiment, and inclusion of a control group greatly strengthens the study's ability to draw conclusions.

A typical use of a control group is in an experiment in which the effect of a treatment is unknown, and comparisons between the control group and the experimental group are used to measure the effect of the treatment. For instance, in a pharmaceutical study to determine the effectiveness of a new drug on the treatment of migraines, the experimental group will be administered the new drug and the control group will be administered a placebo (a drug that is inert, or at least that is assumed to have no effect on migraines). Each group is then given the same questionnaire and asked to rate the effectiveness of the drug in relieving symptoms. If the new drug is effective, the experimental group is expected to have a significantly better response to it than the control group. Another possible design is to include several experimental groups, each of which is given a different dosage of the new drug, plus one control group. In this design, the analyst will compare results from each of the experimental groups to the control group. This type of experiment allows the researcher to determine not only if the drug is effective but also the effectiveness of different dosages. In the absence of a control group, the researcher's ability to draw conclusions about the new drug is greatly weakened, due to the placebo effect and other threats to validity. Comparisons between the experimental groups with different dosages can be made without including a control group, but there is no way to know if any of the dosages of the new drug are more or less effective than the placebo.

It is important that every aspect of the experimental environment be as alike as possible for all subjects in the experiment. If conditions are different for the experimental and control groups, it is impossible to know whether differences between groups are actually due to the difference in treatments or to the difference in environment. For example, in the new migraine drug study, it would be a poor study design to administer the questionnaire to the experimental

group in a hospital setting while asking the control group to complete it at home. Such a study could lead to a misleading conclusion, because differences in responses between the experimental and control groups could have been due to the effect of the drug, or could have been due to the conditions under which the data were collected. For instance, perhaps the experimental group got better instructions or it was more motivated by being in the hospital setting to give accurate responses than was the control group.

A control group study can be managed in two different ways. In a single-blind study, the researcher will know whether a particular subject is in the control group, but the subject will not know. In a double-blind study, neither the subject nor the researcher will know which treatment the subject is receiving. In many cases, a double-blind study is preferable to a single-blind study, since the researcher cannot inadvertently affect the results or their interpretation by treating a control subject differently from an experimental subject.

Only in the presence of a control group can a researcher determine whether a treatment under investigation truly has a significant effect on an experimental group and the possibility of making an erroneous conclusion is reduced.

Control Variable

In research design, a control variable is defined as a variable that is known to or expected to influence the dependent variable and might also affect the explanatory or independent variable in an analysis, but is not the focus of interest for the researcher. The influence of a control variable may interfere with the main analysis, for instance, by obscuring between-treatment or between-group differences, or creating apparent relationships between variables of interest. Often variables of this type are used to create blocks in an experimental design or stratify a sample. Occasionally, the examination of the influence of control variables is called "elaboration of the analysis" because they are not the variables of main interest in the analysis.

Within the realm of designed experiments, a control variable may be kept constant or controlled for each test or replication of the experiment. In observational studies, control variables are often used in analysis to divide the study population into smaller, more homogeneous groups, to test for the influence of potentially confounding factors. For example, if a researcher wanted to compare death rates between smokers and nonsmokers, he or she would also need to control for gender (males are the largest proportion of smokers, and males also have higher incidences of heart disease). Therefore, death rate differences between smokers and nonsmokers may actually be due to differences between genders. This could be examined by performing a stratified analysis in which data from males and females were analyzed separately. Control variables may also be included in the analysis; for instance, a continuous control variable may be included in a generalized linear model before the independent variables of interest, to separate the amount of variance accounted for by each.

Control variables have many other names within the literature (see Table 1). Some of the names may

Test variables	Figures 1a to d

[a]Usually refers to dependent variables, but sometimes used for control variables.

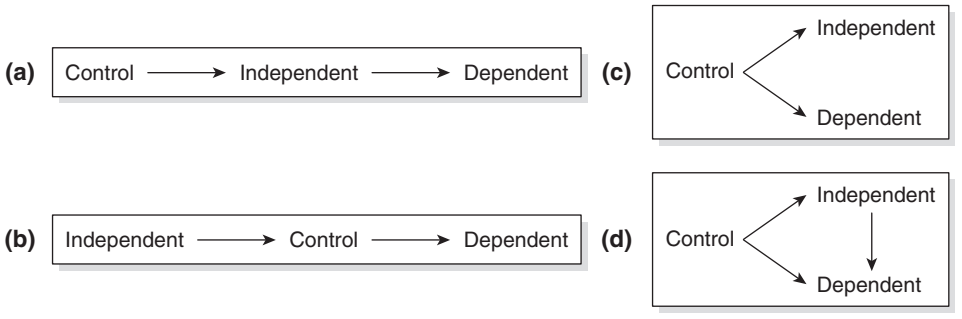

Figure 1 Various Relationships Between Control, Independent, and Dependent Variables

be used interchangeably with "control variable"; while other names indicate the specific relationship between the control variable and the independent and dependent variables. Figures 1a through d illustrate the various types of relationships that may be present between control, independent, and dependent variables.

Antecedent or indirect control variables influence the independent variables within an analysis, as illustrated in Figure 1a, which in turn influence the dependent variable(s).

Intervening, mediating, or subordinate control variables are in the causal chain between the independent and dependent variables, as illustrated in Figure 1b. In this case, the independent variable influences the control variable, which in turn influences the dependent variable, so that the effects of the independent variable on the dependent variable are seen only through the influence of the control variable.

If two statistically related variables become statistically independent when a third variable is included in the analysis, then the control variable may be called an incidental variable, as illustrated in Figure 1c. Usually, this type of relationship between the two variables of interest is referred to as spurious because it is due to the influence of the control variable rather than due to any inherent relationship between the variables of interest. A classic example of a spurious relationship is the relationship between ice cream sales and murder rates. These two variables are significantly positively correlated over the calendar year: When ice cream sales increase, so does the murder rate. However, taking into account the third variable of temperature as a control variable, we find the relationship between sales and murder rates is spurious, because both ice cream sales and murders tend to increase when the temperature increases, as in the hottest days of summer.

Sometimes, introducing a control variable reduces, but does not eliminate, the association between independent and dependent variables. This is illustrated in Figure 1d when the control variable influences both the independent and the dependent variables, but they also have a relationship independent of the control variable. The inclusion of a control variable in an analysis may also reverse the nature of the relationship between the independent and dependent variables.

If a variable may potentially be a confounding factor, it is best to include it as a control variable within the analysis. Potential control variables may be identified from the researcher's experience, from a literature review, from a conceptual model that guides research, or from the researcher's hypothesis. For example, if two blood pressure medications are being compared for their abilities to reduce systolic blood pressure, potential confounding factors include, but are not limited to, starting systolic blood pressure, age of patients, and activity level. By using starting systolic blood pressure and age as continuous covariates and an ordinal (categorical) covariate of activity level within the analysis, these factors become control variables.

In the previously referenced analysis of death rates between smokers and nonsmokers, age would be a confounding factor in addition to gender. Older people tend to smoke more heavily and are, therefore, more at risk for lung cancer. Hence, a comparison of death rates between smokers and nonsmokers should be done separately by gender as well as age. For example, male smokers below the age of 25 would be compared with male nonsmokers below

the age of 25; while female smokers above the age of 65 would be compared with female nonsmokers above the age of 65. These rates could also be compared through standardization of the rates.

Convenience Sample

Nonprobability sampling is used by researchers to find members of a population pool when this population cannot be enumerated to allow for a probability sample to be constructed. There are four general categories of nonprobability sampling: convenience, quota, purposive, and snowball sampling.

A convenience sample is a selected group from a particular population that is chosen based on their accessibility to the researcher. Examples of convenience samples include selecting neighborhood residents by inviting participants from those entering a supermarket, selecting grade school students from the local elementary school, and selecting undergraduate students from a freshman-level class.

A quota sample is a convenience sample in which the researcher seeks to control some variability in his or her sample. As in a probability sampling—stratified sampling method—a researcher may preselect the proportions of certain strata that he or she desires in the final sample. For example, a researcher who desires that 50% of the final sample of 100 students be male may recruit subjects from a freshman-level class of undergraduates with a different proportion of male students but restrict participation among males once 50 agree to participate, focusing solely on the inclusion of females until 50 are included in the sample.

A purposive sample is a convenience sample whose population parameters are defined by the purpose of the research. For example, a researcher may want to understand more about undergraduate students who work full-time. To obtain potential participants, the researcher may place fliers throughout the school asking specifically for undergraduates who are currently holding a full-time job.

A snowball sample is a convenience sample in which the researcher identifies a smaller pool of accessible members of the particular population and requests that those members identify other appropriate potential members. This method is similar to a purposive sample selection but is useful if access to the population pool is particularly challenging for the researcher but less so for members of that population. For example, a researcher interested in organ donation may use a known organ donor who is associated with donor support groups to facilitate access to the members of these groups.

Although it is impossible to determine the probability of selection in a nonprobability sample, and thus a researcher cannot statistically measure the representation of the selected population, this does not necessarily mean that the sample is not representative. Whereas nonprobability samples cannot be assessed quantitatively, they can and should be assessed qualitatively with regard to the true sampling frame of the participants in the study. Often, a researcher can use the demographic characteristics of his or her sample to explore how well they compare with the population of interest. Additionally, a researcher should be thoughtful as to why the particular group was accessible and if this in any way may influence the findings of the study.

Council of State and Territorial Epidemiologists

The Council of State and Territorial Epidemiologists (CSTE) is a professional organization whose mission is to advance health and guide public health procedures through the appropriate use of epidemiologic data. The organization's activities include the identification of nationally notifiable diseases, development of standardized case definitions and operating procedures, epidemiologic capacity building, and advocacy for the use of epidemiologic information in policy development and decision making.

History

In the United States, during the late 19th century, to prevent the introduction and spread of cholera, smallpox, plague, and yellow fever, Congress charged the U.S. Marine Hospital Service, now the Public Health Service, with the first official collection information from individuals afflicted with disease. For the next 60 years, state and territorial health authorities worked with the Public Health Service to designate additional diseases to be reported. Then, in 1951, under the direction of Alexander Langmuir, the Centers for Disease Control and Prevention's (CDC's) first Epidemiology Division Director, the Association of State and Territorial Health Officers convened the first national meeting of state and territorial epidemiologists. At this meeting, CSTE, initially the Conference of State and Territorial Epidemiologists, was established and, with input from the CDC, given the authority to identify and recommend nationally notifiable diseases for inclusion in the National Public Health Surveillance System list.

Purpose and Select Activities

CSTE aims to improve health and affect public health practice through the appropriate use of epidemiology. To accomplish this, CSTE works with the CDC on a number of projects.

Standardized Definitions and Procedures. To assure that the quality of data being reported by each state and territory is adequate, CSTE and the CDC collaborate to create standardized case definitions and surveillance procedures for notifiable diseases. In addition to communicable diseases, which are typically notifiable, CSTE works with both the National Institute of Occupational Safety and Health and the National Center for Chronic Disease Prevention and Health Promotion to prioritize conditions and risks for national surveillance.

Assessment. CSTE actively seeks to assess and enhance the epidemiologic capabilities of the states and territories. In 2001 and 2004, CSTE surveyed health departments to assess their core epidemiologic capacity and future training needs.

Advice and Expertise. CSTE provides advice and technical support to epidemiologists and also designates surveillance consultants to the CDC and other federal and international agencies.

Membership and Organization

CSTE members include epidemiologists representing 50 states, 8 territories, and Puerto Rico. The organization hosts two types of members. Active members include epidemiologists who currently work for a state, territorial, or a local health department. Associate members include epidemiologists who work in federal health agencies or academia.

Counterfactual Models

See Attributable Fractions

Cox Model

The Cox proportional hazards model is a regression technique that allows modeling of survival times (or hazard functions) as a function of a set of covariates. The model was first introduced by D. R. Cox in 1972. The Cox model makes it possible to estimate the survival distribution while accounting for a number of covariates simultaneously or to compare the hazard functions of two or more groups while adjusting for discrete or continuous covariates. It is widely used in medical research to investigate the association between survival and a set of possible risk factors. In randomized clinical trials, the Cox model is used to determine the efficacy of new treatments or therapies on survival or on the occurrence of an event of interest (e.g., disease remission or recurrence).

The Cox proportional hazards model can be considered a generalization of the Kaplan-Meier (or product limit) estimator of a survival curve that accounts for both discrete and continuous risk factors. A great advantage of the Cox model compared with other regression approaches for survival data is its simplicity and the interpretability of its parameter estimates.

Form of the Model

Let $\mathbf{z} = z_1, z_2, \ldots, z_p$ be a $p \times 1$ vector of covariates or risk factors and let $h(t|\mathbf{z})$ be the hazard function, which depends on the covariates $\mathbf{z}$. The general form of the proportional hazard model is

$$h(t|\mathbf{z}) = \psi(\mathbf{z})h_0(t)$$

where $\psi(\mathbf{z})$ is a function of the covariates, and $h_0(t)$ is the underlying baseline hazard. $h_0(t)$ can be interpreted as the hazard of death in the absence of an effect of the covariates or when the covariates assume a reference value (e.g., absence of an exposure factor or membership to a placebo or a standard therapy group).

The most common form of the function $\psi(\mathbf{z})$ is

$$\psi(\mathbf{z}) = \mathrm{e}^{\beta'\mathbf{z}},$$

so that the hazard, given the covariates, can be expressed as

$$h(t|\mathbf{z}) = h_0(t) \exp\left(z_1\boldsymbol{\beta}_1 + z_2\boldsymbol{\beta}_2 + \cdots + z_p\boldsymbol{\beta}_p\right).$$

In this model, the predictors $(z_1, z_2, \ldots, z_p)$ are assumed to act additively on $\ln h(t|\mathbf{z})$. $\boldsymbol{\beta} = \boldsymbol{\beta}_1, \boldsymbol{\beta}_2, \ldots, \boldsymbol{\beta}_p$ is a $p \times 1$ vector of unknown parameters that relate the covariates $\mathbf{z}$ to the hazard.

While in parametric survival models we make an assumption about the distribution of the baseline hazard $h_0(t)$, in the Cox proportional hazard model we make no assumption about the shape of the underlying hazard. The only parametric part of the model is the one that contains information about the predictors, $\psi(\mathbf{z})$. For this reason, the Cox model is called a semi-parametric model. Since in most applications we are interested more in the relationship between the predictors and the survival, rather than the shape of the hazard, the Cox proportional hazard model is suitable for most applied problems. Note that the model does not have an intercept as the baseline hazard $h_0(t)$ accounts for that. The Cox model can be used to estimate the survival function $s(t)$ for fixed values of the covariates.

The Partial Likelihood and Parameter Estimation

As with other regression models, estimation of the regression parameters for the Cox model proceed by maximizing the likelihood function.

Although the full likelihood for the survival data with covariates can be expressed as the product of two terms,

$$L(\boldsymbol{\beta}, h_{0(t)}) = L_1(\boldsymbol{\beta}) + L_2(\boldsymbol{\beta}, h_{0(t)}),$$

the first one involving the model parameters $\boldsymbol{\beta}$, and the second one involving both $\boldsymbol{\beta}$ and the baseline hazard $h_0(t)$, valid inference about the regression parameters can be derived by using $L_1(\boldsymbol{\beta})$ only. The function $L_1(\boldsymbol{\beta})$ is called a partial likelihood and was first introduced by Cox in 1975. The rationale for using the partial likelihood rather than the full likelihood is that it is our interest to make inference about the regression parameters, while we are not concerned about the form of the baseline hazard. Since the partial likelihood $L_1(\boldsymbol{\beta})$ contains most of the information about $\boldsymbol{\beta}$, it is sufficient for estimating the model parameters. In fact, it has been shown that the partial likelihood approach is almost as efficient as the full likelihood approach albeit much simpler.

To see how the partial likelihood is constructed, consider a sample of N individuals who are followed up in time prospectively. During the observation period, suppose that K of these individuals die. Also assume that $N - K$ individuals are right-censored,

that is, do not die during the observation period. Let $t_1 \leq t_2 \leq \cdots t_K$ be the ordered failure times for the K individuals who die during the observation period.

For the generic individual $j(j = 1, 2, \ldots, N)$, let

t_j = observed follow-up time
z_j = vector of predictors
$R(t_j)$ = the risk set at time t_j, that is, the number of individuals who are alive and at risk of death at time t_j.

The probability that a generic individual $j(j = 1, K)$ with covariates z_j dies at time t_j, given that $R(t_j)$ individuals are at risk and only one individual dies at t_j, is given by

$$L_j = \frac{e^{\beta z_{(j)}}}{\left(\sum_{l \in R(t_j)} e^{\beta z_{(l)}} \right)}.$$

The partial likelihood is then obtaining as the product of all these probabilities across all failing individuals in the sample.

$$L_p(\beta) = \prod_{j=1}^{k} \frac{e^{\beta z_{(j)}}}{\left(\sum_{l \in R(t_j)} e^{\beta z_{(l)}} \right)}.$$

Thus, the partial likelihood is obtained by comparing the risk for the failing individual at a specific time with the risk of all other individuals at the same time.

It should be noted that censored observations contribute information only in the denominator of the partial likelihood, not the numerator. Since the partial likelihood is the product of terms each contributing a small amount of information about the parameters $\boldsymbol{\beta}$, the goodness of the partial likelihood does not depend on the sample size but on the number of censored observations. The larger the number of censored observations, the less informative the partial likelihood.

The partial likelihood is valid when there are no ties in the data set, that is, there are no two observations with the same survival time. In cases of ties, the Breslow approximation to the partial likelihood should be used.

Estimates of the regression parameters $\boldsymbol{\beta}$ are obtained as the values that maximize the partial likelihood.

Interpretation of the Regression Parameters

From the model

$$h(t|\mathbf{z}) = h_0(t)e^{\boldsymbol{\beta}'\mathbf{z}}$$

we can derive

$$\frac{h(t|\mathbf{z})}{h_0(t)} = e^{\boldsymbol{\beta}'\mathbf{z}},$$

so that

$$\ln\, h(t|\mathbf{z}) - \ln\, h_0(t) = \boldsymbol{\beta}' z.$$

Thus, $\boldsymbol{\beta}$ is the log-relative risk of a subject with covariates vector z compared with a subject with covariate vector $z = 0$.

Consider the following simple example with one discrete covariate. Let z indicate whether or not individuals are exposed to a risk factor (e.g., smoking), so that

$$z = \begin{cases} 0 & \text{if the exposure is absent} \\ 1 & \text{if the exposure is present,} \end{cases}$$

and suppose we are interested in the effect of this exposure on survival.

The Cox model for this simple case is

$$h(t|\mathbf{z}) = h_0(t)e^{\beta z}.$$

From the model above we derive that the hazard for an unexposed individual is

$$h(t|\mathbf{z} = 0) = h_0(t)e^{\beta(0)} = h_0(t),$$

while the hazard for an exposed individual is

$$h(t|\mathbf{z} = 1) = h_0(t)e^{\beta(1)} = h_0(t)e^{\beta}.$$

The ratio of these two quantities is called the hazard ratio, or risk ratio or relative risk, and is expressed as

$$RR(t) = \frac{h(t|z = 1)}{h(t|z = 0)} = \frac{h_0 e^{\beta}}{h_0} = e^{\beta}.$$

Thus, the parameter β indicates the amount (on an exponential scale) by which the risk of death increases or decreases depending on the exposure. The Cox model can be modified to account for time-varying covariates (in this case, the model is called a hazard model, rather than a proportional hazards model).

Note that $RR(t) = e^{\beta}$ is independent of time. Thus, the model states that the relative risk is constant over time, that is, the effect of the predictors is the same at all times. This characteristic of the Cox model is called proportional hazards property.

Hypothesis Testing About the Regression Parameters

Given two samples of exposed and unexposed individuals, testing the null hypothesis

$$H_0 : \beta = 0$$

that the exposure has no effect on survival is equivalent to testing the hypothesis

$$H_0 : S_E = S_U$$

that the survival distribution of the unexposed sample is identical to the survival distribution of the exposed sample. When the covariate of interest is discrete, testing the hypothesis that $\beta = 0$ is equivalent to performing a log-rank test.

The test statistic for the null hypothesis $H_0 : \beta = 0$ takes the form

$$Z = \frac{\hat{\beta}}{se_{\hat{\beta}}}.$$

This test follows a standard normal distribution with mean 0 and variance 1 under the null hypothesis. Thus, values of this test that exceed the critical value for a prespecified Type I error would lead to rejecting the null hypothesis of no effect of the predictor.

Critical Value

Critical values are used in hypothesis testing to delimitate two regions: one in which the analyst rejects the null hypothesis and another in which the hypothesis cannot be rejected. Therefore, critical values are closely linked to the concept of hypothesis testing. For instance, in a two-sided t test to compare two sample means, if the sample sizes are 21 and 21, so that we have 40 *df*, the critical value for a 0.05 level of significance (i.e., a 95% level of confidence) is 2.01 (this value can be found in tables for the Student's t test). If the computed t statistic is, say, 2.32, we reject the null hypothesis—that the two samples correspond to two populations with the same population mean—at the 0.05 level of significance, because the computed t value exceeds the critical value (and that implies that if the null hypothesis were true, the probability of values like those observed or more extreme is below 0.05). However, we cannot reject the null hypothesis at the 0.01 level of significance because for that level of significance the critical value is 2.42, which is above the computed $t = 2.32$.

This example shows that critical values are arbitrary. They are just values corresponding to particular probabilities arbitrarily chosen (usually 0.05 or 0.01) in theoretical statistical distributions. The presentation of confidence intervals is usually preferred to the indication of the fact that the null hypothesis has or has not been rejected because the test statistics was above or below the critical value.

Since hypothesis testing is usually ignored in the Bayesian approach to statistics, the concept of critical value is irrelevant in that theoretical framework.

Cultural Sensitivity

Cultural sensitivity refers to the process by which health research and intervention respond to the cultural belief systems, behaviors, experiences, and social context of populations. Culturally sensitive approaches acknowledge that conceptualizing determinants of health behaviors and outcomes, conducting research, and creating interventions to reduce disease risks may not rely on universally applied predictors, methods, or settings. In addition, certain constructs may not have the same meaning or may be experienced differently in diverse groups. In epidemiology, cultural sensitivity has relevance to both study design and health promotion.

When conducting research, a culturally sensitive approach is necessary from the beginning of the study design. To appropriately consider the role culture plays in health, local experience and cultural norms must be built into the study methodology. That is, the research question being asked and the extent to which it is appropriately informed by sociocultural factors are critical in conceptualizing the study. For example, if a researcher seeks to investigate the risk factors for experiencing depression and operationalizes depression as a psychological state involving feelings of sadness or being "down," this very definition will artificially restrict the research findings if the study is conducted in a population that expresses depressive symptomatology primarily in physical terms or through other psychological symptoms, such as boredom.

The measures that are used to assess both health outcomes and risk factors must be carefully considered. This can be particularly true for studies in psychiatric epidemiology, where measurement of mental, as opposed to physical, illness presents unique challenges. For example, conditions such as "dependent personality disorder" are themselves strongly imbued with cultural notions of abnormality and adaptive functioning, and these are likely to be built into the tools that researchers use to assess outcomes. Moreover, many standardized scales with established reliability and validity were initially developed with European American populations, and their validity with culturally diverse groups has not been empirically tested.

However, cultural sensitivity also applies to physical outcomes such as heart disease or other conditions that were once thought to be relatively "culture-free." In this regard, researchers must attend closely to the ways in which risk factors are defined and assessed. For example, food frequency questionnaires are often used to measure dietary intake. If the measure is not culturally sensitive, it may not include a variety of foods that are commonly consumed in the target population. If this is the case, the researcher may need to modify the instrument by providing additional spaces to report commonly eaten foods. Ideally, however, the measure would already have been validated in the relevant population and would include any foods typically consumed by the population being studied. Examining associations between stress and illness is another relevant example. When assessing stress, researchers must ensure that the measures are not based on sources of stress that are likely to be irrelevant to the population in question, and they may need to include culturally specific sources of stress, such as racism, discrimination, acculturative stress, or language barriers.

In the research setting, a culturally sensitive approach would also attend to the interaction between researchers and participants. For example, racial/ethnic matching may be necessary, meaning that researchers who interact with participants would be of the same race or ethnic group. This is particularly true for certain topics such as worldview, stigma, identity, and experiences with racism. In these and other contexts, participants' responses can be significantly affected by the interviewer. Informed consent procedures can also be made more culturally sensitive by paying particular attention to participants' level of familiarity with the research enterprise and exploring possible feelings of mistrust. Additionally, research has shown that most consent forms are written at literacy levels that are too high for many participants and contain many technical terms and jargon. Poor readability of consent forms is compounded for those with limited English proficiency.

With regard to interventions, some researchers have conceived of culturally sensitive health promotion programs as informed by surface structure and deep structure. Surface structure refers to matching interventions to certain characteristics of a population. This might include using printed materials that depict individuals from the same population, delivering messages through particular channels (e.g., a local Spanish newspaper) or in particular settings. For example, to reach African American populations, some researchers have implemented nutrition interventions in churches, and others have created printed health materials that draw on spiritual themes and imagery relevant to African Americans. Deep structure refers to the sociohistorical, cultural, and psychological factors that shape health beliefs and behaviors. For example, health promotion programs often strongly emphasize individual choices and behaviors. If such a program is implemented with a population for whom an orientation toward kinship and communal bonds is salient, it will be discordant with the deep structure of the culture and less likely to succeed.

Infusing epidemiologic research and health interventions with culturally sensitive methodologies is best completed in collaboration with community partners and may require an iterative process whereby study goals and methods are refined over time. It is also critical for researchers to carefully think through how culture may apply to particular health considerations in particular populations, rather than relying on stereotypes or broad generalizations. Similarly, particular behaviors that are significantly determined by social and economic conditions should not be interpreted as uniquely representing culture. For example, frequent consumption of high-calorie foods may simply reflect local food resources, rather than cultural preferences. Finally, ''culture'' does not consist of static patterns of behavior, core values, or worldviews. Sociogeographic and historical context influences the ways in which cultural thought and behavior are expressed.

Cumulative Incidence

Cumulative incidence provides an estimate of the risk that a person will experience an event or develop a disease during a specified period of time. It is calculated as the number of new events or cases of disease that develop in a population at risk during a specific time interval. Cumulative incidence (also referred to as cumulative incidence or incidence proportion) allows researchers to predict risk of a disease or event over a year, 10 years, or even a lifetime; this time period must always be specified when the cumulative incidence is reported.

One example of cumulative incidence is the risk of developing flu among seniors vaccinated against influenza. Another would be the proportion of passengers who develop gastroenteritis while vacationing on a commercial cruise ship for a week. A third example would be the proportion of patients who develop postoperative complications within 1 month of surgery. Individuals in each of these examples meet both the following criteria: (1) They are free of the outcome (influenza, gastroenteritis, or postoperative complications) at the beginning of the study period, and (2) they have the potential to develop the outcome of interest during the study time period.

In the influenza example above, seniors in a study are vaccinated at the beginning of flu season, before any influenza cases arise in the region. There are two ways for the investigators to define the flu season: as a time period (e.g., November to April) or by a combination of a time period and observed events. For instance, in the United States, the flu season is the time period between the first influenza case in the area and the last influenza case in the area during one continuous period of time between September and June. However, the study period is defined; it is the same for all participants in the study, and they all have the same opportunity to be identified as

infected with influenza if they should contract the disease.

Cumulative incidence is a useful tool to provide information about the risk of an outcome during a prescribed period of time. In studies where a group is followed for a short period of time, it is possible to compute cumulative incidence directly. For studies where longer follow-up periods are needed, such as in cohort studies of diet and the risk of diabetes, it is not usually possible to estimate cumulative incidence directly. Rather, this question is addressed through the computation of incidence rates. However, rates characterize disease incidence for a group, whereas cumulative incidence characterizes the accumulated risk over time.

From a clinical perspective, cumulative incidence is helpful to public health professionals and clinicians because it can personalize the risk of developing a disease or condition over a period of time that is meaningful to the patient. For instance, a pediatrician might describe an overweight child's likelihood of developing type 2 diabetes in the context of the next 10 years, or by adolescence. While cumulative incidence cannot be computed directly in studies with long follow-up periods due to loss to follow-up, it can be estimated in such studies by first calculating the incidence rate and then estimating the cumulative incidence from the rate. In this case, rates should be constant throughout the course of the study, and if they are not, distinct rates must be calculated for discrete time periods and then aggregated to obtain the best estimate of the cumulative incidence.

If the incidence rate *does not vary* over the time period, cumulative incidence can be estimated as follows:

$$\text{Cumulative incidence} = 1 - \hat{e}\{-(\text{incidence rate}) \times (\text{time})\}.$$

If the incidence rate *does vary* during the study period, and incidence rates for discrete time periods are known, cumulative incidence can be estimated as follows:

$$\text{Cumulative incidence} = 1 - \hat{e}\{-\Sigma(\text{incidence rate})_i \times (\text{time})_i\}.$$

Data Management

Data analysts often say that they spend 80% of their time getting the data ready to analyze, and 20%, or less, actually analyzing them. As this emphasis usually is not reflected in courses in epidemiology and public health that include data analysis, an obvious gap is created that tends to be filled only through practical experience. Yet data are an omnipresent part of life in the 21st century. Electronic data are in our pockets, in small databases residing on our memory sticks, and in cell phones and personal data assistants. They are on our desktops, residing in our computers' personal information managers. They are in spreadsheets and relational databases on our desktops or on a computer server.

Though the specifics of the data manager's task vary depending on the software we use, a handful of basic principles are common to all systems. This entry looks at issues regarding existing data, designing new databases, and formulating questions about data. It also discusses object-oriented database structures, database utilization with Web-enabled remote servers, and data security.

Studying Existing Data

Often, we work with data we did not collect ourselves. Even if we were involved in the data collection process, many other people may have had input into both the design and the content of those files. When we receive data files from other hands, we first need to inspect each file carefully with two principal concerns in mind: Are these data correct and undamaged? And what issues exist within these files?

Years of experience have taught the lesson that nothing can be assumed, not even that the correct data file has been provided. We should determine the dates of both file creation and most recent update, plus the numbers of cases and numbers of variables included in the files, and compare these item for item with the specifications (contained in the Manual of Procedures—the "MOP") provided by the persons who provided the data sets. The absence of a codebook should be taken as a warning to inspect the file with particular care. We can learn a great deal by running boxplots, violin plots, and panel plots to rapidly obtain a visual depiction of how each variable is distributed, plus basic descriptive statistics or frequencies for every variable in the entire set of files, and perhaps cross-tabulations for selected variable pairs. All these approaches help locate file transfer problems (e.g., if a variable was imported in the wrong format or is entirely missing); peculiarities within the data, especially those values that are out of the expected range; and entries that are apparently meaningless (e.g., a code for a categorical variable that doesn't translate correctly).

Strategies for uncovering hidden issues about the data set will vary with each situation. However, the following procedures are nearly always appropriate: checking for duplicate cases, locating extreme or out-of-range data, and studying the amount and patterns of missing data. Very few data sets are entirely complete.

Therefore, to best analyze a data file, we need to determine how many data are missing and why they are missing, and identify the patterns of missing data among variables. For purposes of analysis, we are obliged to think carefully about how we treat missing data, because such decisions can substantially affect our results. Cross-tabulations can reveal patterns of missing data involving pairs of variables, and we can write code that reveals the patterns among larger groups of variables. Knowing the amount and pattern of missing data within a file allows us to decide if we should consider some kind of interpolation or other substitution for missing data values. Note, however, that newer statistical modeling procedures often have vastly improved ways of handling missing values, so the consequences of varying missing value substitution algorithms are best addressed with the aid of a knowledgeable statistician.

This is also the time to closely study those variables constructed with all the characters on the keyboard, letters only, or some combination of letters and numbers, to see how many variants occur within each such variable, and to design methods to parse the alphanumeric strings into meaningful blocks or subgroups if necessary. The task of analyzing text statistically has quite different requirements from analyzing data statistically.

Existing data sets may contain millions of cases, and each case may contain thousands of possible pieces of information. Regardless of the dimensions, these files must be opened by software that recognizes the same electronic format (a fact we need to know unambiguously), or they may be distributed in legacy formats (including ASCII, one of the most basic of electronic renderings of characters from the keyboard) and must be imported into our software to be useful. Even when the process is a simple push of a button, we always need to check on elementary concerns, such as the new files equaling the source files in both numbers of cases and names and numbers of variables (truncations can quietly occur for numerous reasons). Some legacy formats do not support the variable-naming conventions that are regularly employed in other formats. Imports from ASCII, in particular, need to be rigorously reviewed to ensure that every variable is extracted from the correct position within the source file.

All these concerns fall under the rubric of "achieving veridicality"—essentially, ensuring that our version of the data set faithfully and completely represents the original information. The next step is to determine the meaning of each variable and its categories, information that should be included in the codebook. The analyst should not have to guess at the meaning of variables from their names, particularly when the prior users relied on acronyms for variable naming, based on what might be usual parlance in one or another professional environment but is not in everyday public language.

When there are repeated measures for the same respondent, as is exceedingly common in medical data bases, the complexity of the data's underlying structure is correspondingly increased. It is not unusual to find, for example, that the database's designers elected to capture a given measure at a fixed frequency (heartbeats per minute), which was then aggregated (average heartbeats per minute per 5-min interval), then repeated across one fixed interval (average heartbeats per minute per 5-min interval for each of 288 such intervals per day), then repeated again across another fixed interval (average heartbeats per minute per 5-min interval per day for each of several days of intensive-care treatment). Increasingly, data are collected with repeats occurring not at regular intervals but instead as a function of trigger events (such as the onset of seizure activity or specific treatment intervention); as a result, any single case may differ substantially from the next case in the frequency of such repeats. Because statistical analysis packages expect data files to be structured in very specific ways, the analyst must understand the meaning of each variable and the structure of the data file they receive, and be able to restructure the file if necessary to make it compatible with the program's expectations.

Designing a Well-Functioning Database

In many circumstances, we can reduce the number of key considerations regarding building a database to just three: how complex our data will be, how we want to get data into the database repository, and how we want to ask questions about those data. It is becoming common, however, to also incorporate further mission-critical elements needed to meet the inherent goals of particular studies, elements that are discussed later in this entry.

Complexity of Data

How complex are our data? The anticipated data for our study may be conceptually simple—only a small number of distinct variables are gathered from

a modest number of respondents. We use the term *respondent* here synonymously with *case, patient, study participant, monitoring location*, or other such source of information. Any one respondent is a single instance of the target sample. The term *variable* is a placeholder for a test item, a physiological signal, a status indicator, an outcome assessment, and any of numerous other markers associated with the respondent. Any one variable is a single instance of such a marker with a capture process that generally applies to every respondent (though it might not).

This data may be arranged in a rectangular database, in which by convention each respondent is assigned a row, and each variable—plus one—gets a column. This assignment is literal when we use flat-field software like a spreadsheet or a two-dimensional database software product, though it may be merely figurative when we use one of the more advanced database software approaches discussed later. We use the extra column to identify the respondent with a unique name or identification number or code. If the initial assumption of design simplicity is indeed appropriate, this rectilinear framework has an intuitive appeal harking back to making lists with paper and pencil. The simple framework has advantages over other, more complex database structures: It can be brought to reality with a minimum of time and personnel resources. Its computing demands can be met at virtually no cost using even old equipment and inexpensive software. Its result is a single file that most likely can be saved electronically in a legacy format that is widely recognized by other software. Everyone wins because costs and complexities are reduced to a minimum at all turns.

However, this is not always the simplest arrangement in practice. Every research study has a context in which to place each respondent—a specific set of information that identifies who or what the respondent is, where the data were gathered, and associated factors (many of which may be risk factors essential for one's planned analyses). A time stamp marking the moment the piece of data was collected is but one of many additional variables that can be critical to the analyst in sorting out possible relationships across variables. An instrument calibration table for each case, likely a table off on its own, can be essential to ensuring comparability across cases. So, even in the most simple appearing of circumstances, our data set will likely have to grow to accommodate entries in additional variables.

Another challenge to our admirable but potentially troubling simplicity is that, as noted earlier, the data to be collected may be multiple instances of the same measurement for each respondent. For example, there might be multiple instances of the same test items, multiple physiological signals of the same type, or multiple types of such signals, all of which might be acquired over several repeated occasions, which might or might not be the same occasions for each variable cluster. As noted earlier, rectilinear solutions do not readily accommodate such multiplicities without some care.

Yet another challenge is that often the data we seek are not instantly translatable from reality to a single numeric or alphabetic entry. An example of this phenomenon is medications taken by a patient at a particular time; such a list may have no entries for one individual but dozens for another. Our rectilinear framework mandates that each instance of a medication be allotted a column. Though we could enter all possible medications in one continuous entry, this will raise serious issues for later querying and analyzing. So in our simple solution, the number of columns must grow to accommodate the individual with the longest list of medications, whoever that person might be; this solution means that for many individuals, most of those fields will be empty. We can pick a "good enough" number and live with it even if respondents show up with longer lists, or we live instead with the fact that the design of the database will need to be modified while in use. Neither option is especially palatable. Other forms of data that translate poorly from reality to discrete numeric or alphabetic entries are narrative material, such as physicians' or nurses' notes; decision trees or routing information, such as schedules; and photographic evidence, such as medical imaging. Fortunately, useful database solutions exist for these situations, discussed later in this entry.

Relational databases can accommodate complexity by using more than one single data frame—for example, discrete sets of information (often called "tables") may be stored for each patient, one containing demographic information, a second set containing diagnoses and procedures, a medication set, a physiology set, an imaging set, a calibration set, and a physicians' and nurses' note set. Each of these may have very different dimensions and may be populated at different times by input from different individuals. Not every patient is likely to be represented in every data set, since not

every data set may apply to every patient (e.g., some patients need no special procedures and are discharged quickly, while others are extensively medicated and stay a long time). Keeping these variable sets distinct is a major step toward management efficiency and significantly improves the task of quality assurance.

Getting Data Into the Database

How do we best get data into our database? In retrospective studies, we need to identify the existing sources of information, find and gain approvals and passwords from the correct persons or corporate and government entities controlling access to those sources, ensure that all human subjects' requirements are met, and identify the combination of personnel who have suitable data transfer or data entry skills along with the place and time where they will be able to accomplish their work. Even if data are already computerized, there is no guarantee whatsoever that files are accessible or, once accessed, are transferable. Many computer systems with fine warehouses of potentially useful data are nearly impenetrable except by in-house systems staff who invariably are shorthanded and overworked. Over the years, archives of valuable data were often stored on media, such as computer tape, which are now unreadable because the necessary tape drives have long been obsolete, or because the media have physically decayed—oxide particles resting in the bottom of a tape canister are an inelegant clue. And retrospective studies, except for those using publicly available data sets without case identifiers, need appropriate institutional approval.

In prospective studies, the tasks differ but their number is equally large, and they must include approvals ensuring that all federal, state, and institutional safeguards are met for human (or animal) subject participation. The studies must also include unambiguous plans for exactly how participants are to be identified, recruited, and enrolled; how and when such enrolled participants will be measured and by exactly what measurement instruments; and how such measures will be captured over time into a working database. Although these issues are subject to wide variation, there are certain consistencies. When designing the database for a study, we usually include tables within the data set that will allow participant tracking from the moment of first contact, even before data are formally obtained. Second, at the moment the first subject is enrolled, there must be a systematic way to capture data into a secure archive—that is, a database of records with dimensions large enough to support the complete study. Database design should not be postponed under any circumstances because doing so might compromise the study's fundamental integrity. Third, as subjects start becoming enrolled, there must be a plan for immediate data quality assurance, since there will be no opportunity to redo the enrollment process. This means that our data collection instruments must be fully up and running: Paper-and-pencil testing must be valid and reliable, electronic instrumentation must be plugged in and delivering quality signals that are of the correct electronic format, and plans about what is to happen if a glitch occurs (a systems fault, a participant refusal, an unplanned or adverse event) must be clear in advance, not invented on the fly if the need arises. Fourth, we need a regular mechanism for verifying and backing up the data that have been captured to date, for there is truly very little merit in conducting a study only to discover afterward that the data sets are unreadable or lost.

Some studies, either retrospective or prospective, can gain immeasurably by advance attention to the database's front-end appearance, its "look and feel." With modern database software, there is no reason not to have a visually appealing form for each conceptually discrete section of the data set. Data entry can be simplified and can also be made more accurate by good screen design. Among the options available in modern database software are radio buttons for binary data, drop-down menus for discrete-choice variables, and cascading sheets for data that are to be entered only contingent on the values of other data (alternate branching). Data that are conceptually clustered together (e.g., all diagnoses, all imaging results, all monitors of a certain type) should be visually clustered as well. Throughout the data entry form, each data item can be accompanied by a floating explanation (a "text balloon") that appears on-screen when our mouse pauses for a predetermined time over the item. On-screen help files can be generated even for small studies, and they are often invaluable in large efforts. Additionally, each data item can be quality controlled so the program will accept data only within certain ranges. What all this costs in setup time is amply rewarded at the time of data entry and data quality review. The ultimate aim is to ensure that mistakes in the data can be easily and rapidly found and corrected if they occur at all.

Though once common due to extreme limits on computer memory and storage, it is now seen as essential to avoid unneeded translation codes in the data entry process (e.g., "1" for male, "2" for female). The reason is that such codes rarely, if ever, add any inherent value, while they certainly obscure the actual meaning of the entry and make it harder to conduct complete and thorough reviews for quality assurance. It is also essential to avoid missing-value indicators that could be genuine values in their own right (e.g., "99" for age). Some missing-value codes can be generated automatically by database software, for instance, to differentiate between data missing because they are not present for that respondent (and will not be forthcoming at any future time); missing because they are contingent on an earlier data element and thus not logically appropriate to complete; or missing because they have yet to be identified, although they are expected to be forthcoming as the respondent completes participation in the study.

Asking Questions

Whether we have acquired an existing database of information or have designed and populated a database of our own, we can think about how best to ask questions of it. Conceptually, querying is the way the data in hand are culled into cohesive and manageable chunks suitable for statistical analyses. It is also a way to readily explore relations across discrete tables within the data set. It becomes a powerful tool, driven by the linking of tables using the respondent identifier as the term in common—a single value that allows a subset of data in one table to be joined with a subset of data from another table within the data set. Properly thought out, the linking of subsets in such queries can be one of the handiest ways to assess well-constructed research hypotheses.

Often, a set of conventions known as SQL (Structured Query Language) is used to query databases; variants of the SQL code are included with many types of software, including relational databases, such as Access, and statistical analysis packages, such as SAS (Statistical Analysis Systems). The elemental query statement in SQL is built from a statement containing three clauses:

SELECT < using a list of attributes >

FROM < a data table or list of tables >

WHERE < one or more conditions must be satisfied > .

The results of a query will be anything inside the data set that satisfies every facet of that query statement. Boolean logic applies to these queries, so AND and OR often are used in specifying the WHERE conditions. Queries can be used to answer questions, such as "how many female subjects have been recruited to date?" and "what were our total lab expenses last month?"

One good way to work with large data sets, especially those that are works in progress, with more respondents or patients or study participants still to supply their data, is to set aside a copy of the data set from some start date to some intermediate checkpoint and to explore it in its own "sandbox"—that is, where we can try testing and querying based on the knowledge we have right now and experiment without interfering with the original data even if we make mistakes. A little time devoted to identifying data patterns in this subset and working out the forms of various queries can pay off handsomely when the full data set is available.

Object-Oriented Databases

Not every data set can be readily envisioned as a series of tables. One illustration often cited is the task of understanding educational systems. Each student will appear in a variety of classes, and each class will have a number of different students. Each teacher will have numerous students and each student will have several teachers, but not every teacher is solely responsible for one class. Each group of students belongs to both a grade and a school, though grades occur across schools and different schools may contain only some of the grades. Another illustration is found in "whole-part" relationships, where we need a database to track parts that used to create end products, where a given product can be made up of many different parts and subassemblies, and where the same part or subassembly can be used in the making of many products. In both instances, many of our measures will have more than one attribute, a situation that is not at all easy to convey inside a simple rectilinear table structure. The relationships between various "respondents" who have complex class affiliations are generally captured poorly, the resulting tables are likely to store data quite inefficiently, and querying them successfully may be difficult.

An object data model allows multivalued attributes to be incorporated into the data structure. Though they

do not lend themselves well to conventional querying, some query languages are built to handle situations that involve such complex and irregular data. If we find ourselves with a data design in mind that relies on complicated data structures, we first investigate how we would try to handle the incoming data using traditional relational methods and then explore the many possible programming and performance solutions that can be achieved by object-oriented (OO) technologies.

The hospital patient record is an example of a data design for which OO technologies might be well suited because of their flexibility and possible ease of use. Seldom, if ever, is the patient record a simple information structure, because an enormous variety of patients, diagnoses, specialists, treatments, and so forth must be accounted for. The OO approach, under the right circumstances, can handle these data in ways that support both data acquisition and querying that are optimized for the task. However, this step should be taken only by those who are well versed in data management with conventional tabular data and who have a distinct need for high performance when faced with complex data. These sentiments apply as well to the set of techniques called data mining, based on technology from advanced statistics, artificial intelligence, and machine learning. Data mining focuses on isolating and confirming relationships deep inside the data set that might not have been the principal focus of the original data design team. While these techniques can be practically applied across a range of data management software settings, they should be approached with caution.

Remote Servers

Highly versatile data management solutions can be developed using the World Wide Web for an interface, adding a level of computing power that would have been unthinkable only a few years ago. With careful design, large databases can be assembled that are responsive to any Web-enabled source (with appropriate security precautions), whether the source is an investigator sitting at his or her desk or someone standing anywhere in the world with a Web-enabled cell phone or wireless handheld device.

What is gained is a uniform look-and-feel for accessing data, making inputs and changes, and developing queries. Whether the data are numeric, alphabetic, or images makes no real conceptual difference, only practical differences in how the screens are best displayed. Also gained from such an implementation is the ability to have multiple research teams that are widely separated from one another be able to use and also update the same data sets in an identical manner. Since all data are stored on one main server, it becomes a central source for data checking and for resolving quality concerns wherever they arise.

Implementations of this concept have been resounding successes. One powerful hospital-based solution uses a single integrated data system, to which its designers simply add various functionalities by adding modules. In many hospital-based studies, the required modules are available off the shelf. In addition, wireless devices can be used to gather data from patients and deliver it to the server in real time. A physician at an international conference can call up an entire set of both records and current monitoring for patients on another continent; examine the most immediate physiological signals, medications, scans, and other professionals' notes as if they were at the bedside; and deliver orders to the hospital staff. In the research context, these capabilities mean that multisite studies can be linked together seamlessly even if separated by long distances.

Security

Good data security is predicated on two different principles that should be followed simultaneously. First, data should be kept in locations that cannot ever be accessed by unauthorized people; and second, if security is breached, it should be impossible to derive any personal information of any kind from the data set. This means it is a bad idea to include personal names or government-issued identification numbers (Social Security numbers, driver's license numbers) within a data set. Indeed, it is difficult to see how Social Security numbers can play an appropriate role in research under any reasonable circumstances. In some studies, medical record numbers may be internally essential for purposes of ongoing data acquisition, but the following three precautions should be implemented at the earliest possible time: a plan for data encryption should be enforced; some other identifier, such as an arbitrary study identification number, should replace the medical record number for purposes of linking; and a thorough expunging of any data values on the formal list of protected health information (PHI) should be conducted before the data are archived and released.

PHI is formally defined as any individually identifiable health information in any form, including verbal communications that is collected or created as a consequence of the provision of health care by a covered entity (e.g., a practitioner, clinic, hospital, health system). All researchers whose studies require one or more pieces of such information from study participants must obtain approval by the appropriate institutional review board, even for retrospective studies. Except for purposes of treatment, investigators are restricted to the minimum PHI considered reasonably necessary to conduct the research. In addition to names and Social Security numbers, the identifiers at issue include dates of birth, death, admission, and discharge (except year); postal addresses, including city, state, and zip code; telephone and fax numbers; medical record numbers; health plan ID numbers; account numbers; certificate or license numbers; vehicle identifiers; device identifiers and serial numbers; URLs, e-mail addresses, and IP addresses; biometric identifiers, including fingerprints; full-face photos and other comparable images; and any other unique identifying number, characteristic, or code.

Additional security burdens are increasingly being placed by funding agencies on data managers to ensure "data set durability." That is, once a transaction has been committed to the database, a complete record of its action, including what it replaced, must be fully preserved even if software or hardware fails partway through the transaction. For instance, if a transaction is interrupted by a system crash, then when the system is restarted, the database will both recover itself in its entirety and conclude the incomplete transaction. A complete transaction history, including who made any given change to the database, is stored in a separate file. Data management and information technology specialists are essential when these requirements are in place.

Databases constructed to be Web accessible must use both closely controlled passwords to allow access and high-level signal encryption to ensure security when data are transmitted from one node to another. The fact that a wireless handheld is capable of linking to enormous quantities of clinical or research-related data does not mean this should ever occur without appropriate security measures. In addition, increasingly portable forms of electronic storage require extra vigilance, because there have been many cases of confidentiality being breached, for instance, because data were taken home and placed on an unsecured computer or stored on a memory stick, which was later stolen or misplaced. It has recently become all too easy to put highly inappropriate information in exceedingly vulnerable places. The woeful plight of individuals who have taken data sets home or committed them to memory sticks for portability and then lost these items to thievery is an urgent reminder of the constant need to consider data security at all levels.

Data Transformations

Data transformations modify measured values systematically. Epidemiologists often transform measured values so that they conform more closely to a distribution germane to a statistical method that the epidemiologist would like to apply. For instance, many common statistical techniques assume that a data set consists of approximately normally distributed values, and if this is not the case, a transformation may be applied to the data before analysis. For example, measured data might be used to calculate the heart rate (HR) ratio variate, $HRR = (\text{HR work} - \text{HR rest})/(\text{HR predicted maximum} - \text{HR rest})$, then this data transformed to the new variate $\arcsin(\sqrt{HRR})$. In terms of the matchup between, on the one hand, the statistical methodology applied to study $\arcsin(\sqrt{HRR})$ and, on the other, the assumptions that underlie this methodology, a variate such as $\arcsin(\sqrt{HRR})$ is often a preferred transform of a variate such as *HRR*.

In modern statistical usage, transformations help preprocess raw data prior to the implementation of a general-purpose software package. Were the steps from data input to some display or printing device's output compared with a journey by car through a city, a transformation such as $\arcsin(\sqrt{HRR})$ would play the role of an access road to the software package's freeway on-ramp. Software validity, or, loosely speaking, journey safety, depends on underlying assumptions. Hence, data transformations are usually classified on the basis of types of assumptions. These include a measured variate's *standard* normality, its *general* normality, model linearity, and/or variate homoscedasticity—that is, standard deviation equality regardless of a change of explanatory variates' values. In addition, some useful transformations are not designed to preprocess measurements individually. Instead, once an estimator, such as the sample correlation r, or a test statistic has been computed using raw measurements, these transformations can help enhance the normality of the estimator or test statistic.

Transformations and Simulated Data

Besides the transformation of measured values, transformations are often used in the process of simulating artificial data values. Such procedures make use of notation that is informative when transformation preliminaries to data analyses are illustrated. Of particular importance, by using a pair of uniformly distributed random numbers as input, a Box-Muller Transformation (BMT) generates a pair of independent, *standard* normal variates, in other words, a pair of normal variates with a mean of zero and variance of one. To answer the two questions "Why does the BMT have so many applications?" and "How are transformation components assembled?" it is helpful to call on the following notational conventions. The two Greek letters ϕ and Φ (lower- and uppercase phi, respectively) represent the standard normal density function (i.e., bell curve) and standard normal cumulative distribution function (cdf), respectively. In the same way that $\sin^{-1}$ often designates the arcsine function, Φ^{-1} designates the inverse of Φ.

The function denoted as Phi inverse (Φ^{-1}) (which in older statistical and epidemiological texts is often called the *probit function*) provides a useful notational device. One reason for the inverse of Phi's utility stems from the tendency for transformation and other data analysis steps to be taken in the reverse of the order in which data simulation process components are implemented. For instance, no data analysis text discusses a scale parameter σ (standard deviation) before discussing a location parameter μ (mean). Yet to generate artificial variates, a standard variate—say, for example, Z—is always multiplied by σ first, before μ is added to the resulting product.

Similarly, when a transformation such as $\ln(HRR - \tau)$ is computed, an important type of parameter, a *threshold parameter* τ, is subtracted from *HRR* as a *first* step before computing the logarithm of $(HRR - \tau)$ as a *second* step. However, when such an *HRR* is simulated, the value assigned to τ is added as the *last* step that is needed to create this artificial variate. To create the artificial *HRR* variate's value, a function such as Φ^{-1} is often approximated as a second step. This function is evaluated at the value that the program provides for the random and uniformly distributed, newly conceived, variate Z.

Besides its connection to the log-odds-ratio, the logit function, $\Lambda^{-1}(z) = \ln[z/(1-z)]$, plays an important role in many transformation applications. For example, to transform some newly conceived Z to obtain a logistically distributed variate, all that is needed is to compute $\Lambda^{-1}(Z)$, that is, plug in the program-supplied value of Z for the z of $\ln[z/(1-z)]$. The BMT's unique role stems from the mathematical quirk that, according to the Rosenlicht-Ritt Theorem, unlike the logit function Λ^{-1}, it is impossible to calculate Φ^{-1} as a finite composite of elementary functions, such as x^k, $\exp(x)$, $\sin(x)$, and/or their inverses $\sqrt[k]{y}$, $\ln(y)$, and $\arcsin(y)$. It has therefore been proven that finding some nonapproximate way of obtaining an artificial normal $\Phi^{-1}(Z)$ is, even in our computer-rich era, as futile a quest as trying to square a circle was to an early Greek mathematician whose tools consisted of a straightedge and compass.

While a data analyst has the luxury of working with the well-known elementary function relationship for the standard normal density, $\phi(z) = (1/\sqrt{2\pi})\exp(-z^2/2)$, health data simulation procedures must either make do with approximations of Φ^{-1} or, alternatively, if exact values are preferred, call on the BMT. Nature has placed a stumbling block on what can be thought of as the most straightforward way of obtaining simulated normal variates, the computation of one normal by transforming one Z. However, thanks to the cleverness of the BMT, a pair of normal variates can be obtained by using the pair of elementary functions that were discovered by Box and Muller.

Transformations to Standard Normality

Also based on some approximation of the function Φ^{-1}, in epidemiological studies a transformed *measured* variate's standard normality is often enhanced by the same steps psychologists and educators take to construct a normalized score. A simple example is the rank-based algorithm that underlies Van der Waerden's test. This procedure is implemented by certain packaged computer programs, such as SPSS, and is described in their HELP sections.

To understand how this can provide a transformation of any variate that has a continuous cdf, first consider a curve called the sample cdf $F*$, where this curve is constructed using a size n sample. To the left of all ordered data values $F*$ is zero. Then, at each ordered data value, it raises one step of height $1/(n+1)$ from its previous value. Then, $\Phi^{-1}F*$ (i.e., Φ^{-1} of F^*) is an often-used transformation to standard normality. Specifically, to transform any one of n measurement values, say, x_i, the computer program that implements the transformation first computes $\tilde{z}_i = F*(x_i)$. Then, it evaluates $\Phi^{-1}(\tilde{z}_i)$.

Measurement Transformation to General Normality

Unlike the $\Phi^{-1}F*$ transformation to standard normality, a transformation to general normality is implemented with the help of some choice from among ln, arcsin, square root, or other elementary function, as are other types of transform, such as those of Fisher, Box, and Cox described below. Why the roles of transformations to general normality, on the one hand, and to standard normality, on the other, differ is explained by the conceptualization *marginal*.

Suppose a joint density function $f_1(y, x)$ describes the frequency with which variate Y's value, y, and variate X's value, x, occur together, and conditional density function $f_2(y|x)$ describes the frequency that variate Y's value, y, occurs when X equals x. Then, for $Y =$ HR Work, and $X =$ HR Rest, within the identity $f_1(y,x) = f_2(y|x)f_3(x)$, in other words, the frequency that $Y = y$ (i.e., the variate Y assumes the value y) and $X = x$ occur together, equals the frequency that $Y = y$, given that $X = x$, times the frequency that $X = x$. The function $f_3(x)$ is called the marginal density of X. Similarly, within the identity $f_1(y,x) = f_5(x|y)f_4(y)$, the representation $f_4(y)$ denotes the marginal density of Y.

Many investigations, such as those conducted with the help of analysis of variance (ANOVA), concern the parameters μ and σ within the model of a *marginal* density like the general normal $(1/\sqrt{2\pi}\sigma)\exp(-[(y-\mu)/\sigma]^2/2)$. Other investigations including most, but not all, multivariate analyses target the correlation parameter ρ, or in some other way are concerned with a joint distribution. Transforming to *standard* normality paves over marginal density features characterized by μ and σ that procedures such as ANOVA are designed to study.

The representation F designates a measured variate's cdf and $F(y|x)$ designates the cdf of Y, given that $X = x$. Also used to check putative elementary-function-based transformations, the composite curve $\Phi^{-1}F$ can be estimated by either a $Q-Q$ plot or, alternatively, by a graph of either a sample cdf $F*$ or its cumulative polygon counterpart when graphed on normal probability paper. Given normality, the curve estimated by this graph is a diagonal line, the derivative of which is the horizontal line $y = (1/\sigma)$.

Regression and Multivariate Transformations

Epidemiologists and other scientists often wish to check homoscedasticity, in other words, whether the variability of Y changes as x changes. Homoscedasticity is assumed in common statistical analyses, such as linear regression, based on unweighted least-squares methodology; so if the data do not meet this requirement, it may be transformed as described below. The curve $[\phi\{\Phi^{-1}F(y|x)\}]/f(y|x)$ can help check whether or not homoscedasticity and/or linearity will be better ensured by either use of some log-based transformation or, alternatively, by some other elementary-function-based transformation. It can also help assess whether or not a log or other transformation should be implemented or, alternatively, if no transformation is needed. Specifically, if x_0 and y_0 designate fixed values, that is, constants, when, for any given x_0, the function of y, $[\phi\{\Phi^{-1}F(y|x_0)\}]/\ f(y|x_0)$, is constant valued for all y, it follows that $f(y|x_0)$ must be normal. Given normality, it has also been shown that $[\phi\{\Phi^{-1}F(y_0|x)\}]/f(y_0|x)$'s being constant valued for any y_0 is both a necessary and a sufficient condition for homoscedasticity.

Besides elementary-function-choice correctness, such as between the transformation alternatives log(*HRR*)

and $\arcsin\sqrt{HRR}$, a transformation's value often depends on a less obvious choice. This can be explained by again considering the access road leading to a smooth trip made with the help of a packaged program. An often-encountered pothole is the assumption that the threshold parameter τ within $\ln(HRR - \tau)$ is zero valued. When this assumption is incorrect, a transformed data set will often de-emphasize large values and overemphasize small values. Since small values often are unreliable, this can have disastrous consequences for epidemiological investigations.

Figures 1, 2, and 3 illustrate the consequences of a simplistic assumption that τ is zero valued. Data cases reported to the California Department of Health Services through mid-January 1992 were reviewed. Special attention was paid to transfusion-associated cases for whom, in terms of the 1993 expanded case definition of the acquired immunodeficiency syndrome (AIDS), the date when seroconversion occurred could be determined (Singleton, Tabnak, Kuan, & Rutherford, 1996). A total of 648 men and women who were White, African American, Hispanic, and Asian, all with transfusion-associated AIDS, met the criteria for inclusion in the study. Based on the 293 white males found among the 648 cases, a best-fitting lognormal model is shown in Figure 1, as is a model-free (generalized histogram) frequency curve estimator based on the observed values of the variate, time in days between AIDS-contaminated transfusion and AIDS diagnosis.

By using procedures described in detail by Tarter and Lock (1993, chaps. 6 and 7) and elaborated on by Tarter and Hill (1997), it was estimated that an appropriate value to be added to variate values prior to log transformation was 3,352 days. Figure 2 illustrates use of this value. Only in the right tail is there any appreciable difference between a fitted normal and the generalized histogram. However, Figure 3 illustrates the consequences of failing to add this value prior to log transformation, that is, the curve based on the variate ln(Progression), with τ assumed to equal zero, produces an unwanted bubble over the fitted normal's left tail due to the overly spread short progression time.

In HIV/AIDS research, cancer epidemiology, and many other types of studies, lag-time considerations—such as incubation period, study start-up, and end-phase issues—tend to reduce the validity of small observed values. This sort of background noise contamination, and the way that it can distort log-observed and log-expected frequencies seriously, is illustrated in Tarter (2000, sec. 12.1). For example, data obtained from large census tracts are, overall, more informative than its small census tract counterparts. Suppose a graph of points, each corresponding to an individual census tract, describes log-observed and log-expected cancer frequencies. Then, it would be unfortunate if a transformation procedure tends to increase the deviations from a fitted regression curve over small expected values. This would have the effect of emphasizing tracts that, possibly due to the small size of their at-risk populations, have few expected cases.

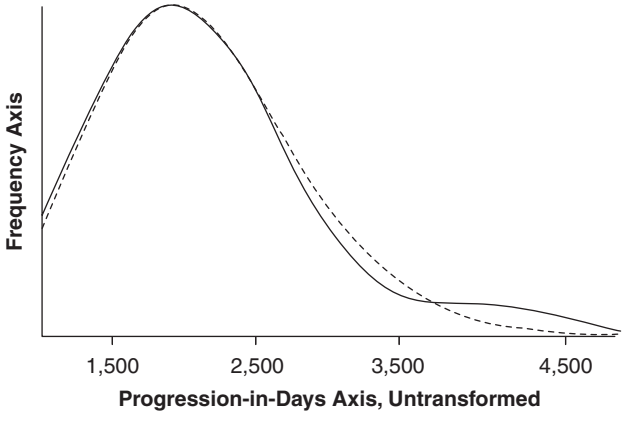

Figure 1 Model-Free Frequency Curve Estimator Based on Pretransformed Progression to AIDS Data Together With Best-Fitting Lognormal Model

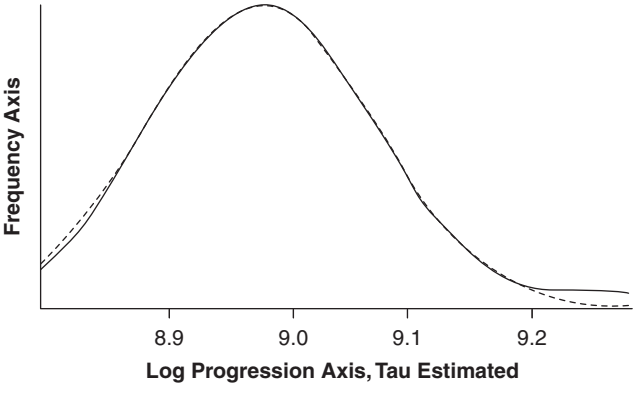

Figure 2 Model-Free Frequency Curve Estimator Based on Transformed Progression to AIDS Data (Based on Appropriate Estimated τ) Together With Best-Fitting Normal Model

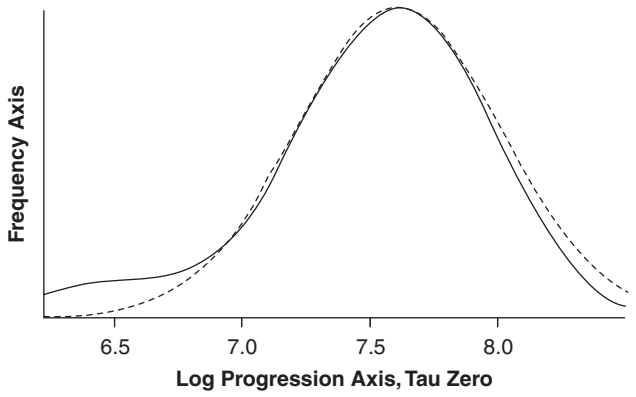

Figure 3 Model-Free Frequency Curve Estimator Based on Transformed Progression to AIDS Data (Based $\tau = 0$) Together With Best-Fitting Normal Model

Background noise versus relevant information limitations are often encountered in animal experiments. In many such studies, early deaths are due to extraneous, nonintervention-related factors. In other environmental as well as in many epidemiological investigations based on observational data, large observed values also tend to contain a noise component. This tends to either be, in effect, a call for attention (such as the need to consider the possibility that outliers are present within a data set) or, alternatively, of little importance in comparison with relevant information. Consequently, because it emphasizes small, not large, observed values, the bubble shown in Figure 3 overwhelms the scientifically informative portion of the observed sample values and has the effect of enhancing the background noise's contribution to any message that Mother Nature has seen fit to send us.

Given that the value assumed by τ is appropriate, the Box-Cox transformation is often useful. It can be applied in parametric regression applications where Y is an observed response variate, such as *HRR*, and the expected value of transformed variate $Y^{(\lambda)}$ is modeled as a linear combination of explanatory variables. For τ less than the smallest observed Y, when $\lambda \neq 0$, the function of Y, $Y^{(\lambda,\tau)}$, is defined to equal $[(Y-\tau)^{\lambda}-1]/\lambda$ and, when $\lambda = 0, t = \ln(Y-\tau)^{\lambda}$.

Fisher's Transformation

For a sample of observed binomial proportions of X outcomes out of N possible outcomes, instead of the variate X/N, a common data transformation is $\arcsin\sqrt{X/(N+1)} + \arcsin\sqrt{(X+1)/(N+1)}$. Correspondingly, for a Poisson variate X whose mean exceeds 0.8, $\sqrt{X} + \sqrt{(X+1)}$ is usually recommended. In more complex applications, such as those involving the sample correlation coefficient r, *Fisher's transformation* is often used. For example, suppose that a Pearson correlation r is computed from $\arcsin(\sqrt{HRR})$ transformed explanatory measurements and corresponding worker productivity measurements. Although it is hoped that both the composite, Fisher's z, as well as its n $\arcsin(\sqrt{HRR})$ components can all be validly assumed to have normal distributions, unlike each of the n $\arcsin(\sqrt{HRR})$ transformed *measurements*, z is called a *transformed estimator* or *transformed test statistic*. Note that a lowercase nonitalicized letter is used here to distinguish *Fisher's* z from a *Z score* such as that provided by the transformation $\Phi^{-1}F*$, or an argument such as Z substituted for the z of $\ln[z/(1-z)]$ to transform Z to a standard logistic variate.

Death Certificate

Most industrialized countries have required certification of deaths for years, and death certificates are a primary source of mortality data in many countries. In such countries, death certificates are the official source of information about deceased persons, the date and location of their death, and the causes of their death. In the United States, mortality data are collected in local jurisdictions and reported using a Standard Certificate of Death and model procedures developed cooperatively by the National Center for Health Statistics (NCHS) and local jurisdictions, the latter being the 50 states, two cities (New York City and Washington, D.C.), and five territories (Puerto Rico, the U.S. Virgin Islands, Guam, American Samoa, and the Commonwealth of the Northern Mariana Islands). The NCHS compiles and releases aggregated data drawn from death certificates, but requests for a copy of the death certificate for an individual must be directed to the local jurisdiction. Release of death certificate information for an individual may be restricted to relatives and persons with a documented medical need or lawful right to the data.

The Standard Certificate of Death for the United States was most recently revised in 2003. Death certificate information customarily supplied by the medical certifier (typically a physician, medical examiner, or coroner) includes the date and time the person was pronounced dead; the immediate cause of death and up to three conditions leading to the immediate cause; other conditions contributing significantly to death; whether an autopsy was performed and whether the autopsy findings were available to complete the death certificate; if tobacco use contributed to the death; if the manner of death was natural; an accident, a suicide, a homicide, pending investigation or could not be determined, and if accidental, more details about the nature of the accident.

Information on the Standard Certificate of Death typically completed or confirmed by the funeral director includes decedent's name, sex, Social Security number, age, birthplace, residence, marital status, military services, name and address of parents and spouse, place of death, method and place of disposition (burial, cremation, donation, etc.), education, race, ethnicity, usual occupation, and kind of business or industry in which they were employed.

Information from death certificates is widely used in public health reporting, surveillance, and epidemiological research because the data are collected in a standard format and are available, at least theoretically, for every person who dies in the United States. However, death certificate information must be interpreted with care. Some researchers, such as Michael S. Lauer and colleagues, have strongly criticized the usefulness of cause-of-death information drawn from death certificates: They point out that even under ideal conditions, it is often difficult to determine the cause of death in the presence of comorbid illnesses and without information drawn from an autopsy and that the death certificate is often completed by a physician who is unfamiliar with the deceased person's medical history. A more moderate view regards cause-of-death information drawn from death certificates to be accurate for some diseases such as specific cancers but questionable in other cases, so the usefulness of this type of information depends on the particular disease or risk factor being studied. The intended use of the information should also be considered: For instance, death certificate information may be adequate for routine surveillance on many causes of death but completely inadequate for research on many specific causes.

Decision Analysis

Decision analysis is the art and science of informing difficult decisions. It has a long and varied history, with roots in economics, business, psychology, engineering, and other fields. It is inherently multidisciplinary, especially with regard to analyses that involve the health of individuals or populations. Decision analysis can be used to inform clinical, health funding, or policy decisions.

The basic steps in decision analysis are universal to most rational and systematic decision-making processes. Briefly, a problem is defined, including the decision situation and context. Objectives, based on what the different stakeholders (participants in the decision) value or deem important, are defined and quantitative measures or scales (i.e., ''attributes'') are determined. Alternative choices are defined. The problem is then modeled, using ''expected value'' methods (described later), and the alternatives are ranked in terms of how well they satisfy the objectives. Sensitivity analyses are performed to examine the impact of uncertainties, and the need for further analysis or refinement is determined. A framework that is often cited is Hammond, Keeney, and Raiffa's (1998) PrOACT, which stands for problems, objectives, alternatives, consequences, and trade-offs. An important aspect of decision analysis frameworks is that they are iterative in nature and function as decision support tools rather than the ''final answer.''

In health care and public health, most decisions revolve around improving survival, health state, and/or quality of life. Thus, in decision analyses involving health outcomes, an important consequence measure is typically some measure of health status, such as mortality, morbidity, or a combined measure, such as quality-adjusted life years (QALYs). These measures are assumed to represent utilities or measures of preference; that is, an alternative that improves, say, survival over another alternative (all other things being equal) will be preferred. There is an extensive literature on this subject, including pros and cons of different measures. Good summaries are provided by Brent (2003) and Drummond and McGuire (2001). As health interventions or policies nearly always involve resource limitations, cost per unit utility gained or ''cost-effectiveness'' is often used as a decision criterion. Less common are cost-benefit analyses, in which all consequences, including health status or survival, are measured in monetary terms. Health decision analyses are sometimes incorrectly viewed as synonymous with economic evaluations. Indeed, it is informative to address multiple objectives important to multiple stakeholders in what is termed *a multi-attribute decision analysis*, but to date these applications have been limited in the health care field, although multi-attribute analyses have been applied in the public health field.

The analytical aspects of decision analysis center on estimation of the ''expected value'' of different alternatives. The expected value of an alternative is a function of the probability-weighted consequence(s). This is typically estimated using a decision tree or influence diagram. As an example, a decision may be whether one should choose intervention or Treatment *a*, *b*, or *c* to reduce mortality from disease *X*.

Say that Treatment *a* represents ''watchful waiting'' or even doing nothing. Each ''branch'' of the tree represents the probability that the patient will live or die, given a particular treatment. In the case of the present example, say that a utility of 1 is assigned to life, and a utility of 0 is assigned to death. If Treatment *b* increases the probability of survival by a greater degree than *a* or *c*, then its probability-weighted consequence will be larger, and thus it will be the preferred alternative under the axioms of utility theory.

Whether a decision analysis is performed using single utility measures or a multi-attribute summary function, the result is a set of expected-value estimates for all alternatives evaluated, which allows a ranking; that is, the higher the expected value, the more preferred the alternative. If a ratio measure such as cost-effectiveness is used, the interpretation of a decision analysis is more complex. The concept of ''dominance'' is used in economics to account for the bivariate nature of cost-effectiveness. In the previous example, if Alternatives *a* and *b* are both more effective and less costly than *c*, then *c* would never be preferred; thus, Alternative *c* is dominated by *a* and *b*.

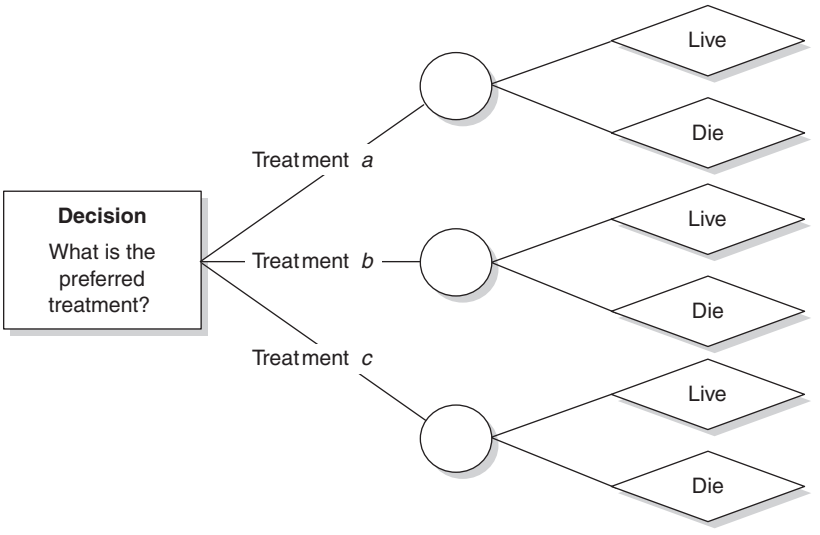

Figure 1 Example of a Simple Decision Tree

Note: In typical representation, a rectangle represents a decision, a circle a probability, and a diamond a consequence.

The appropriate comparator in this case is the marginal or incremental cost-effectiveness of, say, a new drug or procedure compared with others, as cost-effectiveness is a ratio and the absolute value is of little interest.

Most decision analyses are complex, and there are many methodological refinements. In the health field, accounting for variability across individuals in a population, uncertainty in parameter estimates, and temporal changes over time are often important. As in epidemiology, population heterogeneity can be influential on the results of analyses, thus stratification and modeling at an individual level (microsimulation) have proven informative. Health state probabilities change over time (an example is the probability, say, more than 30 years, of developing cancer), thus modeling methods that allow for this, such as Markov methods, are now routinely applied in health decision analysis. Hunink et al. (2001) provide a good summary of these methods.

Although decision analyses in themselves account for uncertainty with regard to expected consequences, they do not address uncertainties in the probability estimates or other inputs themselves. An important adjunct to decision analysis is the ability, known as sensitivity analysis, to examine the impact of parameter uncertainty on decisions. The simplest way to evaluate uncertainty associated with the information used in a decision analysis is to adjust the input values one at a time or simultaneously to examine how the results change. A more powerful way to do this is to use methods such as Monte Carlo simulation to adjust the inputs over ranges or distributions of values and then to use a statistical means, such as rank correlation, to determine the most influential variables. When uncertain variables, such as the predictive value of diagnostic tests, are of interest, a measure known as the expected value of imperfect information is highly informative, because it allows the decision maker to evaluate the impact of using tests to refine judgments. In these analyses, a test that has a higher positive predictive value, for example, will have more "value" in terms of making an informed decision than a test with a lower positive predictive value. Influence diagrams, which are a more efficient way of performing decision analyses than decision trees, are particularly useful in estimating the expected value of information. Clemen and Reilly (2001) provide further explanations of these methods.

Decision analysis intersects with epidemiology in several different ways. In a broad sense, epidemiological studies (both controlled and observational) provide useful information for evaluating the benefits and risks of a drug, device, procedure, or program. One of the more obvious is in the context of randomized clinical trials (RCTs) for drugs, devices, procedures, and

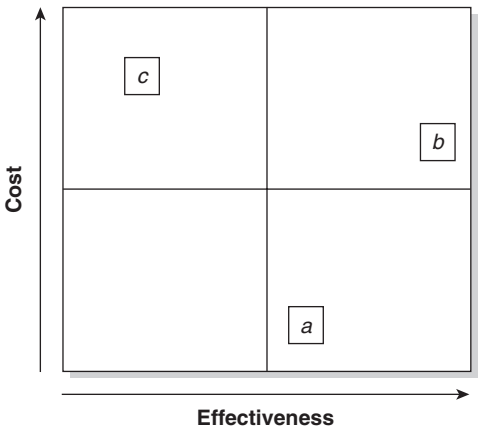

Figure 2 The Results of a Cost-Effectiveness Analysis

Note: Treatment *c* is dominated by Treatments *a* and *b*, and thus *c* would not be a preferred choice. The decision as to whether *a* or *b* is preferred may depend on available resources or other factors not accounted for in this particular analysis.

the like. As many regulatory approval agencies use cost-effectiveness as a decision criterion, a natural extension of an RCT is a decision analysis, in which the new drug or technology is compared with others on the market. Epidemiological studies can also provide useful natural history information for diseases, which can inform detailed decision analyses. For example, Markov decision analyses use transition probabilities between disease states to examine changing health outcomes and costs associated with the disease over time and how these can change with different treatments. This is particularly important in diseases such as cancer, which can last many years.

Decision analysis has many of the same strengths and weaknesses as epidemiology. The strengths relate to robust methodologies that when applied to good information give informative results. Conversely, if the decision analysis is poorly framed and conducted, and applied to biased data, then the results may be worse than meaningless. Decision analysis is fundamentally different from epidemiology because it not only is descriptive but also can be normative; that is, it can tell us both what is and what we should do. A poorly conducted epidemiological study may simply create controversy, but a poorly conducted decision analysis can affect policy on a national scale and indeed affect the lives of the public. For this reason, several organizations publish guidelines for health decision analyses; for example, see Canadian Agency for Drugs and Technologies in Health (2006) and Weinstein et al. (2003).

Degrees of Freedom

A good understanding of degrees of freedom (*df*) is important in statistics, but most statistics textbooks do not really explain what it means. In most cases, degrees of freedom are thought of as a parameter used to define statistical distributions and conduct

hypothesis tests. For instance, the sampling distribution for the t statistic is a continuous distribution called the t distribution. The shape of the t distribution depends on one parameter, the degrees of freedom. In a sample of size n, the t distribution has $n-1$ *df*.

Degrees of freedom can be thought of in other ways also. The degrees of freedom indicate the number of independent pieces of information that are allowed to vary in a system. A simple example is given by imagining a four-legged table. When three of the legs are free to be any length, the fourth leg must be a specified length if the table is to stand steadily on the floor. Thus, the degrees of freedom for the table legs are three. Another example involves dividing a sample of n observations into k groups. When $k-1$ cell counts are generated, the kth cell count is determined by the total number of observations. Therefore, there are $k-1$ *df* in this design.

Generally, every time a statistic is estimated, 1 *df* is lost. A sample of n observations has n *df*. A statistic calculated from that sample, such as the mean, also has n *df*. The sample variance is given by the following equation:

$$\sum_{i=1}^{n}(x_i-\bar{x})^2,$$

where $\bar{x}$ is the sample mean. The degrees of freedom for the sample variance are $n-1$, because the number of independent pieces of information in the system that are allowed to vary is restricted. Since the sample mean is a fixed value—it cannot vary—1 *df* is lost. Another reason there are $n-1$ degrees of freedom is that the sample variance is restricted by the condition that the sum of errors $(\sum_{i=1}^{n}(x_i-\bar{x}))$ is zero. When m linear functions of the sample data are held constant, there are $n-m$ *df*.

We can look at degrees of freedom another way by referring to simple regression for an example. Often, we want to compare results from a regression model (the full model) with another model that includes fewer parameters and, therefore, has fewer degrees of freedom (the reduced model). The difference in degrees of freedom between the full and reduced models is the number of estimated parameters in the full model, $p(f)$, minus the number of estimated parameters in the reduced model, $p(r)$. The full regression model is

$$Y_i=\beta_0+\beta_1X_i+e_i.$$

There are two parameters to be estimated in this model, $p(f)=2$. The reduced model is constructed based on the null hypothesis that β_1 is equal to zero. Therefore, the reduced model is

$$Y_i=\beta_0+e_i.$$

There is only one parameter to be estimated in this model, $p(r)=1$. This means that there is $p(f)-p(r)=1$ piece of information that can be used for estimating the value of the full model over the reduced model. A test statistic used to compare the two models (the F-change statistic, for instance) will have 1 *df*.

Of course, these are very simple illustrations. In some cases, the degrees of freedom must take into account sample size and number of parameters together. For example, in simple regression there are $n-p(f)-1$ *df* for estimating error.

Demography

Demography is the study of how populations are structured and change due to the interplay of births, deaths, and migration. In narrow terms, "formal demography" refers to the scientific study of human populations with a focus on their size, structure, distribution, and development. Defined more broadly as "population studies," demography also studies the causes and consequences of population compositions and changes, and draws on neighboring disciplines, such as sociology, economics, anthropology, and epidemiology. Scholars working in this tradition can be designated as social, economic, cultural, or health

demographers, underscoring the field's multidisciplinary nature. There is increasing overlap between the concepts and methodologies of demography and epidemiology. However, separate histories, missions, professional discourses, and cultures have hindered dialogue between the two fields.

Just as epidemiology can be traced to John Snow's account of cholera in 19th-century London, so the origin of formal demography lies in John Graunt's pioneering 1662 analysis of London's "Bills of Mortality." This yielded a crude life table, revealed much about demographic changes occurring within British society, and drew attention to the need for population statistics in public administration. The origins of population studies can be traced to Thomas Malthus, who published his first essay on the "principle of population" in 1798. His thesis, that population growth threatened prosperity because it ultimately outran increases in food supplies, stimulated interest in the relationships between population and resources.

Demography has since built a rich empirical research tradition and a substantial body of conceptual knowledge. In the 20th century, its dominant theoretical preoccupation has been with demographic transition theory. This refers to the movement of death and birth rates in a society from a pretransitional stage, where both are high, to a posttransitional stage, where both are low. In between is the demographic transition itself, a period of rapid and substantial population growth due to births exceeding deaths, as characterized by most developing countries in the latter half of the 20th century. Birth and death rates eventually converge as the transition nears an end, resulting in little growth through natural increase (the excess of births over deaths). Although largely a set of generalizations from observed trends with limited explanatory and predictive power, demographic transition theory has proved a useful framework for describing and comparing population change over time and space. It also gave rise to both epidemiologic and health transition theory.

In the late 1960s, the problem of world population growth dominated demographic thought. The world's population growth rate peaked at 2% in the late 1960s, equivalent to a doubling time of 34 years (i.e., at a 2% rate of growth, the population would double in 34 years). Birth rates have since fallen nearly everywhere, but there remains a clear distinction in both population growth rate and age structure between the industrialized and affluent countries of Europe, North America, Australia, New Zealand, and Japan, and many nonindustrialized countries in Central and South America, Africa, and Asia. The latter continue to exhibit relatively high population growth rates and youthful age structures, meaning a high proportion of their population is less than 18 years of age. In contrast, many industrialized countries have a stable or negative growth rate and aging populations. The United States has a positive growth rate due mostly to its sustained high rates of immigration, with immigrants primarily younger than the native born and more likely to have children. Successive cohorts of small family size eventually lead to population decline because to maintain a stable population size, an appreciable proportion of couples must have families larger than two children to counterbalance those unmarried, married but sterile, voluntarily childless, and one-child families. This is the situation facing much of Europe and East Asia today. In 2005, fertility had reached below the replacement level of 2.1 children per woman in 44 developed countries. In 15 countries fertility had fallen to below 1.3, levels unprecedented in human history.

Demographic analysis is used in both the public and private sectors to help solve planning and management problems. Examples include projecting and analyzing future population composition, delineating legislative districts, marketing new products, and planning new services. Formal demography provides a set of techniques for describing, summarizing, and manipulating data collected in censuses, surveys, and vital registration systems. Techniques such as indirect estimation, intercensal cohort comparisons, and model life tables are applied alongside an array of statistical methods and, increasingly, qualitative methods. Demographers have provided and analyzed much of the factual information about American and other societies, showing how life changes vary by gender, age, socioeconomic status, ethnicity, race, geographic, and family origin. The release of findings from the 2000 U.S. Census through the Internet made demographic information more accessible to the public and policymakers alike.

The main substantive focus of academic demography has shifted, as the dominating concern is no longer world population growth. The toll of the HIV/AIDS pandemic, especially in sub-Saharan Africa and parts of Asia, has reinvigorated interest in studying mortality and morbidity. Demographers study a diverse set of topics, using surveys, such as the U.S. National Survey of Family Growth, to evaluate reproductive

patterns, fertility-regulation trends, or changing family structures. Issues of immigration and aging have assumed a larger role in the discipline.

Health demography has become an important subfield due to the importance of health as both cause and consequence of demographic and socioeconomic changes. More health surveys are being conducted, and more researchers are interested in the close relationship between health and changes in mortality. Increases in the number and proportion of elderly persons, and in per capita spending on their behalf, also receive much attention due to their influence on rising health care costs. Health demographers have extended the concept of conventional life tables to include measures of "active" or "healthy" life expectancy.

Demographers have become increasingly interested in health transitions and trajectories, while epidemiologists have become more concerned with population-level disease dynamics. This is evident in research on aging, health disparities, poverty and health, reproductive epidemiology, sexual risk behavior, sexually transmitted diseases, and other topics. Demography and epidemiology have converged in many ways even if practitioners in the two fields may not be aware of this development.

Dependent and Independent Variables

One of the fundamental distinctions in medical and epidemiological research is that between *independent* and *dependent* variables. In the simplest sense, the *dependent* variable is the result or outcome being studied and the *independent* variables are factors that are assumed to exert an influence on it. These basic concepts are very simple but can become confusing in practice, particularly since different researchers use different terms for the same concept. In addition, because some researchers believe that the terms *independent* and *dependent* variable imply a causal relationship, they prefer to use one set of terms for experimental research (where it is possible to hypothesize causality) and another for observational research (where due to the number of uncontrolled influences on the outcome, some researchers prefer to speak of correlations or other observed relationships without labeling them as causal).

In experimental research, if a variable under investigation is to be described in terms of other variables, then this variable is called a *dependent variable* (or *response variable* or *outcome variable*). A variable that is believed to influence a dependent variable is called an *independent variable* (or *explanatory variable*, or *causal variable*, or *input variable*). When data are displayed graphically, the dependent variable is generally represented on the *y*-axis and the independent variable(s) on the *x*-axis.

In a standard regression equation of the form

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \cdots,$$

the Y-variable is the *dependent variable* and the X-variables are the *independent variables.* Studies often include numerous independent variables and may also include multiple dependent variables.

To take an experimental example, a researcher randomly assigns subjects to receive one of five different oral contraceptives to study their effect on high-density lipocholesterol (HDLC), a substance found in blood serum. It is believed that high levels of this substance help delay the onset of certain heart diseases. In this case, the five oral contraceptives are independent variables, and the HDLC is the dependent variable. Other independent variables might be included in the study, including the participants' age, weight, and previous medical history.

The very language of independent and dependent variables implies causality (the value of the dependent variables is assumed to *depend* in some way on the value of the independent variables), and researchers do sometimes refer to independent variables as *causes* of change in the value of the dependent variable and

changes in the dependent variable as *effects* caused by the independent variables. However, particularly in observational studies, causality cannot be assumed simply because a relationship exists between two variables, and for this reason, some researchers prefer to use the terms *predictor* variable for independent variable and *criterion* variable for dependent or outcome variable in nonexperimental research. The reason is that one variable can *predict* the value of another in the sense that there is an observable relationship or association between the two, without implying the *causal* relationship that exists between them. For instance, in the United States, race is *associated* with poorer outcomes on a number of health measurements, but that fact is not taken as proof that race is the *cause* of the poorer outcomes.

Descriptive and Analytic Epidemiology

Descriptive and analytic studies are the two main types of research design used in epidemiology for describing the distribution of disease incidence and prevalence, for studying exposure-disease association, and for identifying disease prevention strategies. Generally speaking, descriptive studies deal with the "*what*" questions, for example, describing "what happened" in terms of disease occurrence, while analytic studies ask the "*why*" questions, for example, why some people develop disease and others don't.

Descriptive Studies

Descriptive studies are designed to describe data on health outcomes, such as disease incidence, prevalence, and mortality according to three variables: person, place, and time. *Person* variables describe the people who develop disease in terms of their personal characteristics, such as age, gender, race, marital status, blood type, immune status, occupation, socioeconomic status, and so on, and where and when they were exposed to the agent causing the disease. *Place* variables may include any or all three sites: where the individual was when disease occurred; where the individual was when he or she became infected from the source; and where the source became infected with the etiologic agent. *Time* variables may refer to duration, age, calendar time, birth cohort, or time trend (secular trend, period trend, and seasonal trend). All these belong to *what* questions, because they tell us what happened. Graphical methods and descriptive statistics are commonly employed in descriptive studies.

Descriptive studies can be used to generate hypotheses about the causal association between exposure and outcome. For example, for a given disease, detailed plotting of the duration from exposure to death (time variable) against age and sex (person variable) may prompt generation of the hypothesis of higher mortality being associated with older males. The putative association or causal relationship may then be confirmed or refuted by testing this hypothesis using an analytic study design such as a prospective cohort study. A well-known historical example of a hypothesis-generating descriptive study is the exploratory analysis of the mortality rates from stomach cancer and from colon cancer of ethnic Japanese living in Japan and California. A comparison of cancer mortality rates of Japanese living in these two localities and between first- and second-generation Japanese immigrants in California and Hawaii suggested the hypothesis that diet and lifestyle (environmental factors) were more important risk factors than heredity (genetic factors) for this type of cancer.

Besides the main purpose of generating hypotheses, descriptive studies can also be used to assess the health status of a population and to plan public health programs. Descriptive studies include the following types:

1. *Prevalence surveys* are sample surveys conducted for the purpose of estimating the prevalence of a health condition or outcome or exposure to risk factors in a population, at a particular point in time.

2. In a *cross-sectional study*, both the health condition (or outcome) and exposure to risk factors are

measured on the same subjects at the same time, so that the joint distribution is also available. Cross-sectional studies can be used to calculate the prevalence ratio (referring to the proportion of existing cases), but not the incidence ratio (referring to the rate of occurrences of new cases), and can generate causal hypotheses but not to draw causal inferences.

3. A *case report* describes a single case and often focuses on unusual aspects of a patient's disease/condition or unusual association between the diseases and exposures, while a *case series* is a study of a series of case reports with a common health outcome of interest.

4. *Surveillance studies* refer to the ongoing systematic collection, analysis, and interpretation of outcome-specific data: These studies can be very useful, for instance, in alerting public health officials if many cases of a previously rare disease are occurring in a particular area, which would suggest the need for further investigation.

5. *Analysis of secondary administrative data* is not a true study design but refers to analysis of routinely collected data, such as those from population census, vital registrations, and tumor registries with the usual demographic characteristics of age, sex, race, and so on, and region. The above example of cancer study on Japanese migrants using mortality rates pertains to this type.

Analytic Studies

Analytic studies are the other main type of research design in epidemiology. They are designed to make comparisons and to test statistically hypothesized causal relationships. Ecological (group-level) data may be used for descriptive studies for the purpose of generating hypotheses, but for testing hypotheses, analytic studies are generally employed that require individual-level data. Analytic studies consist of experimental (intervention) studies, quasi-experimental studies, and nonexperimental (observational) studies.

1. In *experimental (intervention) studies*, the investigator manipulates the study factor (exposure variable) and randomly allocates experimental units to different exposure groups so as to reduce bias and increase validity.

2. In *quasi-experimental studies*, the investigator manipulates the study factor only but not randomization of study subjects. Both experimental and quasi-experimental studies must progress longitudinally in time from exposure to outcome. This clear temporal relationship strengthens the researcher's ability to make causal inferences. In addition, random assignment of experimental units to exposure groups in experimental studies improves the researcher's ability to make causal inferences.

3. In *nonexperimental (observational) studies*, the investigator does not randomize the study subjects and also has no control on the study factor (exposure status) that is determined by the experimental units themselves and can only observe, record, and analyze results. An observational study may be either longitudinal or cross-sectional, and when longitudinal, it may be either prospective or retrospective. There are many observational study designs: We mention six of the most common below.

   a. In *prospective cohort studies*, the investigator begins by selecting two groups from the target population to whom the outcome event(s) of interest has not occurred, one exposed and the other not exposed to some risk factor of interest. Both groups are then followed longitudinally to observe the incidence of the outcome event(s) for a fixed period of time, and the investigator notes differences in the incidence of the outcome between the groups at the end of the follow-up.
   b. In *retrospective (historical) cohort studies*, the event of interest has already occurred, and the investigator uses a complete record of secondary data to define which subjects were exposed to which risk factors and traces the subjects from some past time point to the present using the historical record rather than following the participants prospectively over time.
   c. In *case-control studies*, the researcher begins by selecting for study individuals who either have experienced the outcome event (called the *cases)* or have not experienced it (called the *controls*). These two groups are then traced back in time to determine their exposure status. Case-control study design provides weaker causal inference than cohort studies, due mainly to the existence of confounding factors as well as selection and recall biases. However, case-control studies are more efficient for studying rare diseases.
   d. In *ecological studies*, both exposure status and outcome status are measured on groups of people rather than on individuals. Examples of groups as units of observation include classes in school, counties, nations, occupational groups, and socioeconomic groups. Outcome event rates and exposures are

measured in each of a series of groups of people, and their relation is examined to generate hypothesis (descriptive study) or to test etiologic hypothesis at a population level (analytic study). For example, one may plot standardized death rates versus smoking rates for each of many (say, 30) counties to examine the relationship between tobacco smoking and mortality at the county level. Ecological studies are prone to ecological bias when cause-effect relationships at individual level are being inferred from observations at a population level.

e. *A nested case-control study* is a case-control study nested within a cohort study in which only one group without reference to the exposure status is followed for incidence of the outcome event. The incidences that emerge during the study period are entered into the case-control study as cases, with controls sampled from those without outcome event in the cohort during the study period and matched, taking the time of occurrence of the outcome event as the matching variable. Finally, the exposure frequencies are compared between cases and controls as in the classical case-control study to see if there is an association between exposure and outcome. The nested case-control study design is less subject to recall bias than the classical case-control study, and it is more efficient than the classical cohort study.

f. A *case-cohort study* is an unmatched nested case-control study with controls sampled from those without outcome event in the cohort at the beginning of the study period, that is, prior to any occurrence of incidence case, rather than during the study period. Exposure information needs to be ascertained on only those sampled as controls at the beginning of the study period and subsequent cases occurring during the study period. The main advantage of case-cohort study over the nested case-control study is that the same subset of cohorts can be used as a control group for studies of multiple outcomes for the former, while the latter requires different risk sets for each outcome studied. Consequently, nested case-control studies have gradually been replaced by case-cohort studies, particularly in investigation of biomarkers as risk factors for chronic diseases.

Determinants of Health Model

The determinants of health model is a hypothetical construct for understanding population health and the multiple range of factors that determine its level. In a broad sense, the determinants of health model is the most recent and comprehensive explanatory attempt to understand causality in epidemiology and its translation into policy intervention, from both the population and societal perspectives; therefore, the model is particularly relevant to public health research and practice. The current determinants of health model is firmly rooted in the eco-epidemiology paradigm, insofar as it recognizes causes of health—and "causes-of-causes," that is, their determinants—at multiple levels of organization and within the historical context of both societies and individuals. Those levels of organization span from the microlevel, downstream, or proximate causes to the macrolevel, upstream, or distal causes of population health and have, as a chief model feature, the multilevel interaction among causes.

Determinants of health are all those factors, whether events, characteristics, or other definable entities that, directly or indirectly, exert an influence on the health of individuals and, by means of their action and interactions among different levels of organization, *determine* the given status of the health of the population. The understanding of the determinants of the population's health and their complex causal patterns has been originally shaped, and continue to be shaped, by contemporary debates—as well as their historical

circumstances—about medical care or curative medicine and health policy, and then by the unremitting need to reexamine and reorient the social debate to better define and put in place the type and scope of reforms that would help improve the health of the population.

Over the course of the second half of the past century, there have been several significant shifts in perspective, each of them associated with correspondingly different *models* of health determinants. A major motivation for this search for a better health determinants model has been the growing need to define a population health approach, vis-à-vis the emergent understanding that the determinants of health are much broader than the medical care system itself. This evolving thinking can be regarded as a consequence of the recognition of, on the one hand, the unsuitability of the dominant biomedical perspective to guide health policy toward the equitable improvement of a democratic nation's health status and, on the other hand, that approaching health from a population perspective commits a nation to understanding and acting on the full array of factors that determine health.

Marc Lalonde's 1974 report on a new perspective on the health of the population in Canada signaled the emergence of the modern era of health promotion by advancing a more comprehensive conceptual framework for health situation analysis and advocating the role of preventive approaches in national health policy. Under this model, health determinants were deemed as pertaining to four dimensions, or so-called health fields: human biology, environment, lifestyle, and health care organization. The report expressed a widely shared view that health determinants go beyond the individual level and, more specifically, that health was not attainable for the majority of the population through a concentration of public health funds on personal services. Fueled by the prominent risk-factor epidemiology paradigm, however, the emphasis was rapidly placed on the role of personal behavioral choices or individual lifestyles in determining health status.

A subsequent shift in perspective took place with the 1986 Ottawa Charter and the expansion of the health promotion movement, calling attention to the role of factors outside the health care sector and, in particular, the social and economic factors as determinants of population health status. Simultaneously, the emergence of ecological activism gave prominence to environmental determinants of health advocating, especially healthy behaviors in the workforce and safety rules in the workplace. Since the early 1990s, evidence has been growing worldwide in support of the contention that society's capacity to generate, accumulate, and/or fairly distribute wealth and prosperity is also of paramount importance to determine the health of its population.

The current and preferred model of determinants of population health was originally proposed by Göran Dahlgren and Margaret Whitehead to guide WHO strategy to promote health equity in Europe and has also guided the Independent Inquiry into Inequalities in Health in the United Kingdom and the Committee on Assuring the Health of the Public in the 21st Century of the Institute of Medicine of the National Academies in the United States. This multilevel model embodies the emergent eco-epidemiology paradigm that postulates an integrated approach to investigating disease in the population and its prevention by subsuming levels of causation, life course trajectories, kinds of causes, and types of diseases, that is, disease causation, pathogenesis, and population health as processes taking place at multiple levels of organization and within the historical context of both societies and individuals.

In addition to the more "downstream" biological and behavioral bases for disease, that is, the proximate health determinants, the Dahlgren and Whitehead model identifies four layers of main influences on health, toward the most "upstream" bases for population health or distal health determinants:

1. the level of individual lifestyles factors and attitudes, such as eating, sleeping, drinking and smoking habits, exercise, sex, consumption patterns, etc.;
2. the level of social, family, and community networks, including social relations, social support, neighborhood contextual influences, social membership, significant others, etc.;
3. the level of material and social conditions in which people live and work, such as housing, water and sanitation, social security, education, employment, work environment, food production and availability, health care services, transportation and other urban-planning determinants, etc.; and
4. the level of broad social, economic, cultural, and environmental conditions, which includes political determinants, socioeconomic inequalities, economic, societal and health systems, environmental

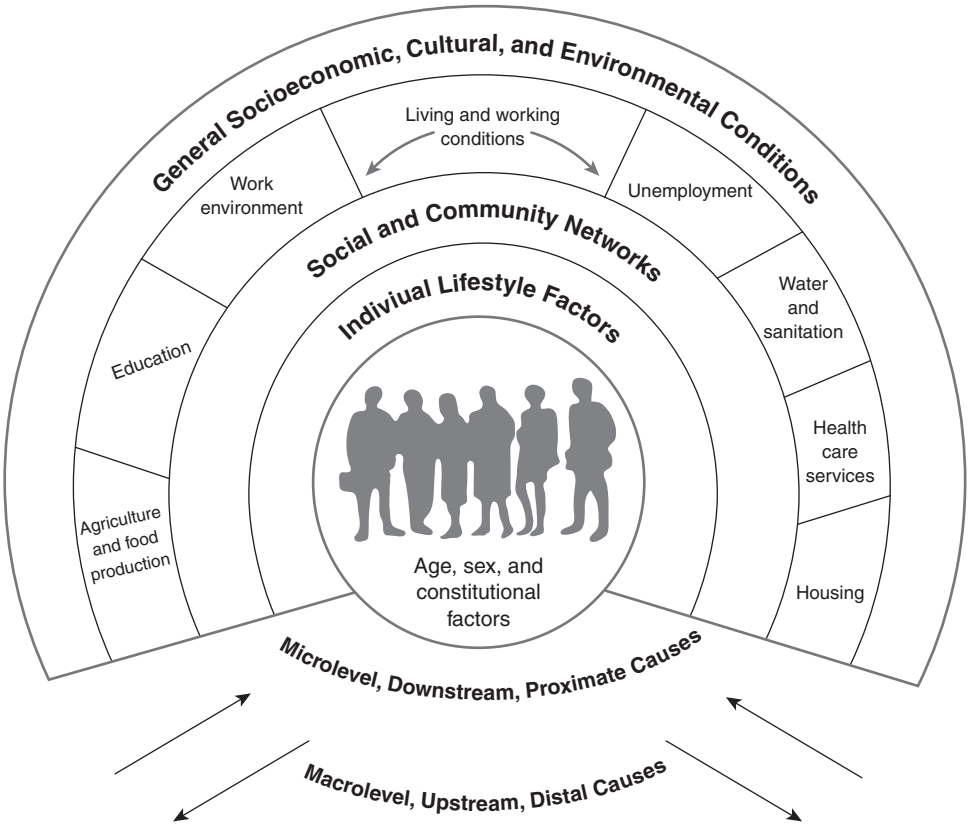

Figure 1 The Dahlgren and Whitehead Model of Health Determinants

preservation, cultural values such as tolerance to diversity, and policies and societal norms at the global, international, national, regional, and local levels.

Figure 1 helps illustrate the multilevel nature of the multiple determinants of population health and the interaction between and among the various levels of health determinants. It may help to see the powerful influences of income maintenance and fairness, educational attainment, public health services, social security and/or air quality, for instance, on a population's health. More important, it may illustrate how macro-, mid-, and microlevel determinants interact along complex and dynamic pathways to produce health at the population level, as well as to realize how historical context changes over time as, for instance, life course changes at the individual level, demographic change at the societal level, and disease itself also changes as agents evolve, adapt, and modify their pathogenicity. The figure may also help show how the health sector must work with other sectors, and how community networks must be taken into account, to generate health policies that improve a population's health. In fact, these levels of hierarchical organization of the population health determinants in the Dahlgren and Whitehead model translate, conversely, into four levels for policy intervention, aimed at (1) influencing individual lifestyles and attitudes, (2) strengthening social and community support, (3) improving living and working conditions, and (4) bringing about long-term structural changes, respectively.

Epidemiology at both edges of the Dahlgren and Whitehead determinants of health model is in frank expansion: Molecular and genetic epidemiology from the side of proximate determinants and social epidemiology from the side of distal determinants are increasing the knowledge base on population health and the potential to create healthy public policy. The development and repercussions of the Human Genome

Project, on the one hand, and the works and efforts of the WHO Commission on Social Determinants of Health, on the other hand, are just two outstanding examples of the burgeoning intellectual activity in which epidemiology is currently engaged to further progress the appropriate conceptualization of the determinants of population health and advance the appropriate public health practice to truly achieve health for all.

Diabetes

Diabetes mellitus is a chronic condition in which the pancreas, a gland near the stomach, fails to make insulin or does not make enough insulin, or in which the body becomes insensitive to insulin. Insulin is a hormone that works to convert what we eat to glucose or sugar. Insulin supplies muscles and other tissues with glucose for growth and energy. Without insulin, the body's blood sugar cannot be regulated, leading to a buildup of sugar in the blood (hyperglycemia) and loss of fuel for the body. Symptoms of diabetes include excessive thirst, frequent urination, unexplained weight loss, extreme hunger, vision changes, tingling in the hands or feet, dry skin, and sores that are slow to heal.

Diabetes is a major public health problem. In 2005, approximately 1.1 million people worldwide died from diabetes. Diabetes is the sixth leading cause of death in the United States. The consequences of diabetes are severe. Diabetes is associated with heart disease, stroke, kidney failure, blindness, nontraumatic amputations, and nerve damage.

History

The earliest written record of diabetes dates back to 1552 BCE in Egypt when a physician, Hesy-Ra, described one of the symptoms of diabetes as frequent urination. It was not until the late 19th century that scientists began to understand the disease. In 1869, a German medical student, Paul Langerhans, described islands of cells in the pancreas. Later, these cells were discovered to be the source of insulin and were named ''Islets of Langerhans.'' In 1889, two European scientists, Oskar Minkowski and Joseph von Mering, discovered that removing the pancreas from dogs resulted in diabetes and therefore recognized that diabetes is a disease of the pancreas. In 1921, Canadian scientists Frederick Banting and Charles Best extended the work of Minkowski and von Mering by giving dogs without a pancreas extracts from the Islets of Langerhans from healthy dogs. Consequently, Banting and Best were able to isolate insulin and to inject insulin from bovine pancreases into humans. Their first patient was an 11-year-old boy, Leonard Thompson, who was suffering from diabetes, at that time an invariably fatal disease. After Banting and Best injected the boy with insulin, his blood sugar levels decreased, and he thrived.

Types of Diabetes

There are three main types of diabetes: type 1, type 2, and gestational diabetes.

Type 1 Diabetes

Type 1 diabetes occurs when the pancreas produces little or no insulin and it is necessary to take insulin daily by injection. Type 1 diabetes is thought to be an autoimmune disease in which the immune system attacks the insulin-producing cells of the pancreas. Approximately 10% of persons with diabetes are type 1 and most new cases occur in children; in fact, diabetes is one of the more common chronic diseases among children. Around 40% of type 1 cases are found in

persons less than 20 years of age at the onset, and the incidence peaks at ages 2, 2 to 6, and 10 to 14.

It is unclear what causes type 1 diabetes, because the exact mechanism for developing the disease is unknown. However, many scientists believe that development of type 1 diabetes follows exposure to an "environmental trigger" that results in an attack against the beta cells of the pancreas in some genetically predisposed people. Risk factors for type 1 diabetes are not well understood, but autoimmune, genetic, and environmental factors are involved in developing this type of diabetes. There has been some implication of a viral connection but that has yet to be proven. Relatives of type 1 diabetics have a 10% to 15% greater risk of developing the disease than those without any family history of the disease. Males and females are at similar risk for type 1 diabetes.

Type 2 Diabetes

Type 2 diabetes occurs when the pancreas produces insulin but either the pancreas produces too little for the body (insulin deficiency) or the body does not respond effectively to the insulin (insulin resistance). Type 2 usually develops in persons over the age of 40, although recently cases have been increasing among children. Many type 2 diabetics go undiagnosed for many years, and therefore it is difficult to determine true incidence and prevalence in the population, but it is estimated that about 90% of persons with diabetes are type 2. About 80% of persons with type 2 diabetes are overweight. Increasingly, young children are being diagnosed with type 2 diabetes, and this increase has been associated with consumption of a high-calorie diet and insufficient exercise. Between 45% and 80% of children diagnosed with type 2 diabetes have at least one parent with diabetes. The risk factors include older age, obesity, family history of diabetes, prior history of gestational diabetes, impaired glucose tolerance, physical inactivity, and race/ethnicity. African Americans, Hispanic/Latino Americans, American Indians, and some Asian Americans and Pacific Islanders are at higher risk for this type of diabetes. Native Americans have the highest prevalence of type 2 diabetes: Prevalence among the Pima Indians of the American Southwest is more than 50% among adults. Unlike type 1 diabetes, type 2 diabetes can be prevented through a number of ways such as maintaining a healthy body weight and increasing the amount of physical activity: For instance, a number of studies have shown that regular physical activity can significantly reduce the risk of developing type 2 diabetes.

Gestational Diabetes

Gestational diabetes is the third type of diabetes. Gestational diabetes occurs when women develop diabetes during pregnancy and usually lasts only during the pregnancy. Gestational diabetes occurs in 2% to 5% of all pregnancies. Offspring of mothers who have had gestational diabetes are at higher risk of developing diabetes during their lifetime. Gestational diabetes occurs more frequently in African Americans, Hispanic/Latino Americans, American Indians, and people with a family history of diabetes. Obesity is also associated with higher risk. Women who have had gestational diabetes are at increased risk of later developing type 2 diabetes. Some studies have found that nearly 40% of women with a history of gestational diabetes developed type 2 diabetes in the future.

Prevalence and Incidence

According to the Centers for Disease Control and Prevention, more than 14 million Americans have diagnosed diabetes and approximately 6 million are undiagnosed. The number of Americans with diabetes is expected to increase to 29 million by 2050.

There are 1.4 million Americans with type 1 diabetes and 10 to 20 million people worldwide. The incidence of type 1 diabetes is increasing each year, by approximately 3% to 5%, and about 50,000 new cases are diagnosed each year worldwide. The highest rates of type 1 can be found in Scandinavia and Sardinia, while Asia has the lowest rates in the world.

The prevalence of type 2 diabetes is expected to double in the next 25 years; in 2000, there were 150 million type 2 diabetics worldwide; in 2025, it is estimated that there will be 300 million.

Treatment

Persons with diabetes need to eat nutritious foods, exercise, and self-monitor blood glucose levels to maintain good control of their diabetes. Some type 2 diabetics need to take oral medication or insulin to regulate their blood glucose levels, and all type 1 diabetics must use insulin to control their blood glucose levels. The HbA1c (glycosylated hemoglobin) is a lab test that is conducted every 3 months to

determine average blood glucose level over the past 3 months. The 10-year Diabetes Control and Complications Trial found that persons with diabetes who had very good blood glucose control (as measured by lower HbA1c) reduced their risk of complications of eyes, kidneys, and nervous systems.

Research

Current research is examining ways to cure diabetes. Transplantation of human islets into patients with type 1 diabetes and pancreas transplantation are approaches that may be more common in the future. However, there is a shortage of donor pancreases, and persons who receive a pancreatic transplantation must remain on immunosuppressant drugs. Other research is being conducted in the use of stem cell therapies to cure diabetes. Medical devices, such as insulin pumps, have not been a cure for diabetes but have enabled patients to significantly improve blood glucose control.

Diffusion of Innovations

The *diffusion of innovations* model describes how change takes place within a social system and provides a schema for the systematic study of the adoption of a product, a practice, or an idea by members of a social system. The most commonly used definition of diffusion of innovations is that articulated by Everett Rogers (1995): "Diffusion is the process by which an innovation is communicated through certain channels over time among members of a social system" (p. 5).

The model offers a logical fit with the traditional task of epidemiology—to systematically study changes in the health of populations with a focus on the patterns of disease occurrence and the factors that influence these patterns. The diffusion model offers opportunities to study and analyze changes in products and exposures as well as in behaviors and policies related to health. The diffusion model and the discipline of epidemiology are both concerned with incidence, prevalence, and change as well as with time, place, and persons. The diffusion model offers a valuable framework to guide epidemiologists in the formulation of research questions to study a wide range of health-related exposures, behaviors, as well as policies and their effects on the health of populations.

The diffusion model is based on two underlying premises: (1) that communication is essential for the diffusion and subsequent acceptance or rejection of an innovation and (2) that new products, practices, and ideas can alter the structure and function of a social system. Change is measured by the numbers of people, groups, or institutions adopting the innovation over time. Consequently, the key variables of interest are time (earliness of knowing about innovation), rate (adoption of different innovations in a social system and/or within and among different social groups), and innovativeness (the degree to which groups or organizations adopt new ideas). Analyses can establish the flow of influence, offer charts of the diffusion curve, develop mathematical models of the diffusion process, and test out contributions of key elements and characteristics.

Lessons learned from diffusion studies in anthropology, sociology, education, folklore, communication, marketing, economics, and public health have helped contemporary scholars and practitioners transform the diffusion of innovation model from a descriptive model into a proscriptive one. Diffusion theory is currently used as an analytic framework for understanding and measuring social change and, in practical application, to guide the design and evaluation of products, programs, and communication strategies in public health and health communication.

History

The diffusion model developed through an interest in social transformation and explorations of the

consequences of the development, spread, and adoption or rejection of new products, activities, and ideas. For example, anthropologists studied the introduction of the horse within and among indigenous population groups of North America, the spread and modification of dance ceremonies among Native American groups, and the spread of corn cultivation from America to Europe. Early sociological studies included the examination of social and legal trends, such as the influence of a city on surrounding areas, the diffusion of governing practices, and the use and consequences of technology. Rural sociologists focused on the spread of new ideas among farmers and the subsequent change in agricultural practices. Thousands of studies in myriad fields have added to the diffusion literature over time.

Constructs

Key constructs include the innovation, the communication processes and channels as well as the agents of change, the potential adopters, and the social system. The innovation (the product, practice, or idea) need not be a new invention but must be perceived as new by individuals or other units of adoption. Its characteristics influence the likelihood that it will be adopted. These include relative advantage, compatibility, malleability, and complexity.

Innovations that are perceived to be of lower social or economic costs, that provide a good fit with values and current practices, and that are of low complexity are more likely to be adopted than those carrying high costs, representing a variance with common values, and appearing to be difficult to understand, to communicate, or to use. Those innovations flexible enough to withstand some change to provide a better fit with prevailing practices and cultures hold more appeal. This flexibility, sometimes labeled a reinvention, involves change in some of the characteristics of the innovation to increase compatibility of the innovation with the existing social system. It is also of importance whether or not potential users can observe as well as try the innovation without undue sacrifice or commitment.

Communication channels and the agents of change affect the diffusion process as well. Face-to-face communication, for example, is generally considered stronger than is mass communication. Radio has greater reach than does television in preindustrialized societies. Furthermore, agents of change—those bringing innovations to members of a social system—often have a stronger effect if they are members of or like members of the community rather than if they are perceived as being marginal to or outsiders of the social structure of the community. Overall, the diffusion analysis must consider who talks to whom, who is considered influential and trustworthy, and who has easy access to or is barred from various communication channels. Characteristics of the potential adopters are of critical concern. Overall, factors such as socioeconomic status, culture, gender, race, age, cultural norms, religion, education, social support, and family ties all influence access to and perceptions of the innovation.

A vital aspect of the diffusion model, and one closely linked to an analysis of adopters, is the consideration of time. The population is often divided into groups based on the time it takes for people to adopt the innovation. The groups are innovators, early adopters, early majority, late majority, and late adopters. Innovators, for example, are often viewed as creative but marginal individuals. Early adopters, close to sources of communication, are often highly integrated into the social system. They often carry a high degree of opinion leadership, are respected by their peers, and serve as role models for others. It is only when these respected members of a community consider, discuss, and adopt the innovation that wide diffusion takes place. Those in the early majority generally interact frequently with peers and are exposed to various sources of information. Those in the late majority are people who are further removed from key communication channels or who remain skeptical and adopt only after pressure from their peers or out of economic necessity.

In older articulations of the model, those who are introduced to the innovation late and who adopt late were called laggards. Often, people who fall into the laggard category are distant, disadvantaged, or marginalized. These members of the population were often further removed from key channels of communication than were those who were able to learn about and adopt the innovation early. They are also more likely to lack resources, including time and money, to take chances. Often, they are socially isolated. It is precisely this part of the population, often considered "at risk," that is of greatest concern to public health policymakers and practitioners. Thus, public health program strategies often include a purposive targeted dissemination to those who are further removed from traditional communication sources and who live in relative disadvantage.

Diffusion occurs within a social system. The analysis of the diffusion process considers the members or units of a social system, including individuals, groups, organizations, or subsystems. The social system includes structural, political, economic, as well as geographic characteristics. The structure may be considered the patterned arrangements of the various units, such as the formal hierarchical structure of a bureaucratic organization with formal laws and rules. Norms may be just as powerful in other, less formal groups. Social factors also consider how decisions are made and whether or not people have an array of options or, at minimum, the freedom to adopt or reject the proposed innovation. Decisions may be individually based, be communal (arrived at through consensus), or be mandated (made through the imposition of authority). Those designing public health safety programs, for example, see initial strong adoption of practices such as seat belt use with the passage of laws (an authority-based decision) but diminished use when consensus was not considered and if enforcement is lacking. In general, the structure of a social system can facilitate or impede diffusion of innovations and thereby influence the rate of adoption of the innovation over time.

Finally, consequences of innovations are documented and analyzed. Three classifications of consequences are often considered: direct or indirect consequences, anticipated versus unanticipated consequences, and desirable or undesirable consequences.

Direct Standardization

Direct standardization is a method of comparing population disease or death experiences, removing the effects of differences in population characteristics. Direct standardization is an important tool used in comparing the health of populations. Additionally, it can be used to monitor the health of the nation as is done with the Healthy People 2010 objectives. This entry uses an example of deaths from heart disease in the state of New York to illustrate the use of direct standardization.

Do men really have more heart disease deaths than women in the state of New York? In this case, two populations are compared, New York men and New York women. The heart disease death rate for New York men is 144.1 per 100,000 in 2000, and for New York women it is 160.5 per 100,000. Thus, the rate of death due to heart disease for women is higher than that for men. This finding is surprising but true, and is due largely to the fact that women tend to live longer than men, and thus live to an age where heart disease is a very common cause of death. In the terminology of epidemiology, the comparison of heart disease death rates is confounded by age. The death rates for men and women are really composed of two components: different heart disease death rates for each age group and different age distributions.

In this study, age is a confounder, a nuisance variable that affects our ability to clearly understand how gender affects the death rate for heart disease. Both the age distributions of men and women in the United States and the fact that heart disease deaths are more common as people get older are well known, but we need an analytical technique that incorporates these facts into our comparison of heart disease death rates by gender. Direct standardization provides that technique and allows us to calculate age-specific death rates, which compare heart disease death experiences by gender while controlling for age. Table 1 shows that for each age group, men have a higher heart disease mortality rate compared with women. The reason the overall, or crude, mortality rate is higher for women compared with men is because of the older age distribution for women in New York.

Both the crude mortality rates and the standardized mortality rates can be viewed as weighted averages of the age-specific mortality rates. In the crude mortality rate, the weighting reflects the number of men and women in each age category in New York State, while in the standardized rate, a reference or standard population is chosen. In Table 1, the crude rate for men is rewritten as weighted average.

Table 1 Crude Rates

	Men			*Women*		
	Number of Cases	*Number Population*	*Age Specific Rate***	*Number of Cases*	*Number Population*	*Age-Specific Rate***
< 45 years	774	15,304,246	5.1	336	15,959,393	2.1
45–54	1,684	1,226,925	137.3	613	1,326,011	46.2

65–74	5,540	561,262	987.1	3,772	714,784	527.7
Total	26,357	18,293,496	144.1	31,562	19,659,418	160.5

Note: **Per 100,000 in 2000.

Men

$$\text{Overall rate (crude)} = \frac{(\text{Total cases})}{(\text{Total population})} = \frac{(26,357)}{(18,293,496)} = 144.1 \text{ per } 100,000$$

$$= \frac{\left(\text{Pop}_{<45} \times \frac{(\text{Cases}_{<45})}{(\text{Pop}_{<45})}\right) + \left(\text{Pop}_{45-54} \times \frac{(\text{Cases}_{45-54})}{(\text{Pop}_{45-54})}\right) + \left(\text{Pop}_{55-64} \times \frac{(\text{Cases}_{55-64})}{(\text{Pop}_{55-64})}\right) + \left(\text{Pop}_{65-74} \times \frac{(\text{Cases}_{65-74})}{(\text{Pop}_{65-74})}\right) + \left(\text{Pop}_{65-74} \times \frac{(\text{Cases}_{75+})}{(\text{Pop}_{75+})}\right)}{\text{Pop}_{<45} + \text{Pop}_{45-54} < \text{Pop}_{55-64} + \text{Pop}_{65-74} + \text{Pop}_{75+}}$$

$$= \frac{\left(15,304,246 \times \frac{(774)}{(15,304,246)}\right) + \left(1,226,925 \times \frac{(1684)}{(1,226,925)}\right) + \left(786,187 \times \frac{(2,977)}{(786,187)}\right) + \left(561,262 \times \frac{(5,540)}{(561,262)}\right) + \left(414,876 \times \frac{(15,382)}{(4,414,876)}\right)}{15,304,246 + 1,226,925 + 786,187 + 561,262 + 414,876} = 144.1$$

$$= \frac{(\text{Pop}_{<45} \times \text{Age-specific rate}_{<45}) + (\text{Pop}_{45-54} \times \text{Age-specific rate}_{45-54}) + (\text{Pop}_{55-64} \times \text{Age-specific rate}_{55-64}) + (\text{Pop}_{65-74} \times \text{Age-specific rate}_{65-74}) + (\text{Pop}_{65-74} \times \text{Age-specific rate}_{75+})}{\text{Pop}_{<45} + \text{Pop}_{45-54} + \text{Pop}_{55-64} + \text{Pop}_{65-74} + \text{Pop}_{65-74}}$$

$$= \frac{(15,304,246 \times 5.1) + (1,226,925 \times 137.3) + (786,187 \times 378.7) + (561,262 \times 987.1) + (414,876 \times 3,707.6)}{15,304,246 + 1,226,925 + 786,187 + 561,262 + 414,876} = 144.1$$

$$= \frac{\sum \text{Age-specific pop}_i \times \text{Age-specific rate}_i}{\sum \text{Age-specific pop}_i.}$$

Women

$$\text{Overall rate (crude)} = \frac{(\text{Total cases})}{(\text{Total population})} = \frac{(31,562)}{(19,659,418)} = 160.5 \text{ per } 100,000.$$

Source: New York State Vital Statistics (2000).

In theory, any population can be used as a standard population, even a fictional population. However, a directly standardized rate can be compared only with another directly standardized rate, so if directly standardized rates from this study are to be compared with other studies, then the standard population needs to be the same for both. In the United States, the 2000 census is the standard population used by most

Table 2 Direct Standardization

Men

$$= \frac{\begin{array}{l}(\text{Standard pop}_{<45} \times \text{Age-specific rate}_{<45}) + (\text{Standard pop}_{45-54} \times \text{Age-specific rate}_{45-54}) \\ \quad + (\text{Standard pop}_{55-64} \times \text{Age-specific rate}_{55-64}) + (\text{Standard pop}_{65-74} \times \text{Age-specific rate}_{65-74}) \\ \quad + (\text{Pop}_{65-74} \times \text{Age-specific rate}_{75+})\end{array}}{\text{Pop}_{<45} + \text{Pop}_{45-54} + \text{Pop}_{55-64} + \text{Pop}_{65-74} + \text{Pop}_{75+}}$$

$$= \frac{\begin{array}{l}[(178,932,504 \times 5.1) + (37,030,152 \times 137.3) + (23,961,506 \times 378.7) \\ \quad + (18,135,514 \times 987.1) + (16,573,966 \times 3707.6)]\end{array}}{[178,932,504 + 37,030,152 + 23,961,506 + 18,135,514 + 16,573,966]} = 243.9.$$

Women

$$= \frac{\begin{array}{l}[(178,932,504 \times 2.1) + (37,030,152 \times 46.2) + (23,961,506 \times 165.4) \\ \quad + (18,135,514 \times 527.7) + (16,573,966 \times 3,346.7)]\end{array}}{[178,932,504 + 37,030,152 + 23,961,506 + 18,135,514 + 16,573,966]} = 209.7$$

Source: National Center for Health Statistics (2006).

researchers and the federal government (e.g., Healthy People 2010 goals). Thus, if the 2000 U.S. Census is used in this study, then not only can the standardized rates be compared within this study, but they can also be compared with national directly standardized rates.

Table 2 shows the equations for direct standardization. The formula is the same weighted average formula used for crude rates, but the weights are those taken from the standard population. Thus, the only difference between the formula for men and women now are the age-specific heart disease death rates, and the directly standardized rates are no longer confounded by age. The results show that men have a higher heart disease death rate than women, when directly standardized to the U.S. 2000 population. Note that the raw numbers calculated in direct standardization are meaningless except for purposes of comparison.

The target for heart disease mortality rate is 166 per 100,000, directly standardized to the 2000 U.S. Census, by 2010. Because the rates in this example involving New York are standardized to the same population, comparisons can be made. Clearly, death rates in New York State are much higher than the 2010 target for the nation, and in fact, New York State has one of the highest heart disease mortality rates in the United States.

Disability Epidemiology

Disability epidemiology constitutes a subdiscipline within epidemiology, similar to areas such as maternal and health epidemiology or nutritional epidemiology, which focus on a particular area and augment the approach and methodology common to many epidemiological endeavors with specific concerns and techniques relevant to the subject matter. This entry describes several key aspects of the definition of

disability epidemiology, provides an overview of disability surveillance, and examines methodological issues in the field.

Definitions

The practice of disability epidemiology includes consideration of the basic elements of descriptive epidemiology (who, what, where), etiological determinants of impairments, and the frequency and predictors of different outcomes of disability. All these questions incorporate the common epidemiology study designs and methods. Adapting from John Last's classic definition of epidemiology, disability epidemiology is, then, the study of the distribution, determinants, correlates, and outcomes of disability and application of this study to maximizing the health and quality of life of people and populations with disability (PWD).

The concepts and content of disability epidemiology derive naturally from a number of other epidemiology disciplines, such as injury, neurological diseases, maternal and child health, aging, and outcomes research. Despite some differences in methods and focus, epidemiology principles do not alter remarkably as one moves from one content area to another.

However, unlike specific disease areas (e.g., neurological diseases), the focus of disability epidemiology is less concerned with diagnoses and specific impairments than with broad functional levels, such as mental, sensory, and mobility. This focus is derived from the definition of disability found in the World Health Organization (WHO) International Classification of Functioning, Health and Disability (ICF), which is based on a social versus a traditional medical model of disability. This paradigm moves from a diagnosis and treatment model of disability to one where people are defined in the broader context of social roles and participation—so that consideration of disability is essentially removed from the constraints of medical care and definitions. In this paradigm, *disability* is an umbrella term, where participation (the key outcome) is a function of aspects of environment, intrinsic personal factors, body function and structure, and activities. The ICF has been proposed as the unifying framework for disability measurement in public health.

In the ICF paradigm, disability must be defined as a state that is largely independent of health and health status. The distinction between the two is difficult to incorporate into traditional epidemiology, however. While epidemiologists are comfortable with the notion of prevention occurring at primary, secondary, and tertiary levels, in disability research, prevention includes both prevention of new primary disabilities or impairments and prevention of the adverse outcomes of disability. This separation of health and disability is accomplished in the Healthy People 2010 chapter on disability. Prominent in this document is the following basic assumption about disability:

> Disability is a demographic descriptor rather than a health outcome. It should be used to monitor disparities in health outcomes and social participation. The Americans with Disabilities Act (ADA) provides an important rationale for universal collection of disability status [in data collection]. (Objectives Report: Disability and Secondary Conditions; Centers for Disease Control and Prevention [CDC], 2001)

The field of disability epidemiology has a small group of professionals who concentrate primarily on disability epidemiology and a number of others whose work touches on that subject matter and approach.

Descriptive Epidemiology: Disability Surveillance

On the basis of the UN disability statistics, the WHO estimates that about 600 million people worldwide live with disability (global statistics and data collection efforts are available on the United Nations Web site listed at the end of this entry). The United States and other Western nations answer public health questions and program plans regarding disability based on ongoing surveillance systems. As a nation, we need to know various characteristics of our population to monitor our progress and allocate resources. We may have a relatively simple question, "How many people are there in the United States with disabilities?" but the answer depends on (1) our definition of disability and (2) the mechanism we choose for collecting the information. Several sources of information about disability prevalence are available from the federal government, the most important of which are the Behavioral Risk Factor Surveillance System (BRFSS) operated jointly by the CDC and state health departments and the U.S. Census Bureau.

The Behavioral Risk Factor Surveillance System

In a report issued in conjunction with the development of Healthy People 2010, the CDC specifically

recommended consistent definitions, universal collection of disability status, and methodological studies to help provide more accurate and useful data. The CDC generated the very broad definition of disability based on the standardized questions below. Two disability-related questions are now a regular feature of the CDC-supported annual core questions that are used by all states (BRFSS, 2001 Survey Questions, p. 21):

1. Are you limited in any way in any activities because of physical, mental, or emotional problems? Yes/No/Don't know/Not sure/Refused
2. Do you now have any health problem that requires you to use special equipment, such as a cane, a wheelchair, a special bed, or a special telephone? Yes/No/Don't know/Not sure/Refused

Additional questions that collect more detailed information about disability and caregiving are offered in some years as optional modules (used by individual states or not, at their discretion).

Publicly available BRFSS data are weighted to be representative of the entire U.S. population and the population of individual states; analysis based on smaller geographic areas is sometimes possible by special arrangement with the CDC or states.

In the 2001 BRFSS, a total of 41,262 respondents said they were either limited, used equipment, or both (19.8%)—people who met definitions based on both questions, however, comprised only 4.8% of the population.

The Census Bureau Resources

The U.S. Bureau of the Census provides data on disability drawn from three primary sources: the decennial census of population, the Survey of Income and Program Participation, and the Current Population Survey. Although the U.S. Census, conducted at 10-year intervals, is not primarily a health surveillance tool, it does provide denominator data for use in population research, policy and political analysis, and resource allocations. In 1990 and 2000, the long form of the census (administered to about one sixth of the U.S. population and weighted to be representative of the entire population) included questions on functional status and disability, permitting better estimation of disability prevalence. The Census 2000 questions addressed instrumental and basic activities of daily living (i.e., self-care, mobility), activity limitations, working, and sensory impairments. These data, available in summary form on the U.S. Census Bureau Web site, show, for example, that 19.3% or 49,746,248 Americans aged 5 years and above were classified as having a disability in 2000, and 56.6% of people aged 21 to 64 years with a disability were employed compared with 77.2% of other Americans. Census data have the advantages of representing the entire U.S. population (as opposed to the BRFSS, which considers only community-dwelling adults above the age of 18 years and has other limitations because it is conducted by telephone) and being representative of and applicable to small geographic areas—as small as neighborhoods. In fact, studies focusing on small local area comparisons may need to rely on census data because of the difficulty of using state (BRFSS) and national data at smaller geographic regions. For example, see the U.S. Census Bureau's county-level report on disability for Florida.

Methodological Issues in Disability Epidemiology

Measurement Issues (Classification and Bias)

One of the benefits of using an ICF classification system is that it allows combining diagnostic groups, which may overcome the problem of small sample size. For example, we might combine specific diagnoses into functional categories, such as mobility, communication, or learning/cognition impairments. This has the advantage of combining conditions that are related in their consequences to the individual as well as increasing the number of cases available in each category and thus the power of the analysis. However, the disadvantage of combining diagnoses in this manner is that heterogeneity of exposures and outcomes bias relationships toward the null, that is, to a finding of no effect. For a study on etiology, combining people with different impairments may obscure the cause of the impairment. For instance, Parkinson's disease, multiple sclerosis, HIV/AIDS, and spinal cord injury all lead to mobility impairments but entail very different etiology. Grouping people with mobility impairments in a study of etiology fails to take into account the very different causal pathways that can produce this outcome. However, for a study on secondary conditions, or outcomes research, this grouping of impairments might be fine as long as proper consideration was paid to other characteristics and risk factors, such as severity of disability.

Ecological Perspectives

Epidemiologists tend to eschew research where associations are made between variables based on grouped data, that is, those that are "ecological" in design. In a purely ecological study, we compare people at an ecological level in terms of exposure and outcome. The problem of inferences about cause-and-effect relationships from grouped data is called the ecological fallacy: Often, conclusions drawn from the analysis of grouped data do not hold when considered at the individual level.

However, some exposures really do operate at an ecological level, including many that have a potential impact on PWD, such as disability awareness media campaigns, laws, severity of winter weather, and wheelchair-accessible public transportation. In cases such as these, there is strong justification for applying a combined ecological and individual-level study design. The Institute of Medicine recommended combined (personal and environmental) models of public health training and thinking as a high priority. Apart from a need for more complex statistical analysis (i.e., mixed variance estimates), there are relatively few barriers to multilevel studies in disability epidemiology. This type of analysis is facilitated by the fact that the ICF includes codes for specific aspects of environment as experienced by individuals. Measures and models that are truly multilevel can provide a very rich area of research to understanding variations in levels of participation of PWD. However, at present, this kind of work is in its infancy, and few disability-relevant ecological-level measures have been defined.

Disaster Epidemiology

The epidemiologic study of disasters is a relatively new area of research and practice in public health settings. The epidemiologic investigation of disaster events focuses on two approaches. The first is the study of the underlying causes of the disaster. This may focus on the event itself or the mortality and morbidity associated with the event. Learning as much as possible about the reasons for disasters is

important for developing population-based prevention activities in the future. The second approach is to use epidemiologic methods to investigate mechanisms for alleviating the burden of a disaster once it occurs. The most direct applications of epidemiology in this situation are the establishment of surveillance systems to identify injuries and the possible emergence of communicable and mental health diseases, the deployment of rapid needs assessment to identify and prioritize solutions to existing problems, and analytical studies of risk factors and the natural history of health events.

Defining Disasters

What is a disaster? One of the most difficult concepts in the discipline is to arrive at a definition of a disaster. The answer to this question is shaped by many factors. Historically, in many areas, disasters have been viewed from a fatalistic perspective. Disasters were or are accepted as a feature of life. In the opinion of many individuals, there is little that one can do to prevent a disaster—it is an "act of God." In recent years, though, there has been a paradigm shift with the perspective in public health and other settings that disasters are something that one should prepare for to mitigate the circumstances arising from a disaster.

The frequency of an event and the level of magnitude of its impact can also influence whether an event is regarded as a disaster or not. Events with a low frequency in occurrence and a high magnitude of impact (in terms of large economic and human losses) are usually declared disasters by government authorities. Events with a high frequency of occurrence and a low magnitude of impact might be regarded as normal or routine events. The determination of what levels are high and what levels are low, though, can be subjective and may vary by culture, prior history with the event, and the ability to respond to the event. Thus, a disaster of similar characteristics might be viewed differently in different settings. Recent efforts have taken place to begin to standardize our view of disasters. The Center for Research on the Epidemiology of Disasters (CRED) in Brussels, Belgium, and other international agencies now typically use the United Nations Department of Humanitarian Affairs definition of disasters as a situation or event that "overwhelms local capacity, necessitating a request to a national or international level for external assistance" (EM-DAT glossary, unpaginated).

Classifying Disasters

Many different types of events can lead to situations that overwhelm local institutions and require external assistance. As one result, crude classification schemes have evolved in the discipline to classify disasters. Most commonly, disasters are classified as either natural disaster events or man-made disaster events. Natural disasters include situations brought about from extreme climatological, geological, or ecological events. Drought, flood, windstorms, extreme temperature, or extreme rain are the most common climate issues that have led to disasters in the past. Earthquakes, tsunamis, and volcanoes are frequency geological-related disasters. Man-made disasters include industrial accidents and acts of terrorism from nuclear, biological, chemical, or explosive materials. Recent episodes of large population displacement related to war have also been identified as a form of a disaster, largely a man-made disaster.

The Impact of Disasters

Much attention has focused on recent high-magnitude disaster events around the world. A proper assessment of the impact of disasters requires a comprehensive look at the totality of disaster events. The best resource to obtain this comprehensive look is through the databases maintained at the CRED. The main database includes disaster events from 1900 to the present, identified primarily from the information of relief and assistance groups, including the Red Cross/Red Crescent Agency. The data in this resource indicate that there are more than 100,000 deaths each year globally from disasters and about 70,000 to 80,000 injuries. The largest disasters from a human suffering viewpoint are droughts/famines. Significant numbers of deaths and injuries are also attributed to earthquakes, floods, cyclones, hurricanes, and tornadoes.

One recent debate has centered on the question of whether disasters are increasing in frequency compared with earlier years. Comparing data over time can be difficult, as the definition of disasters have varied over time. Generally, though, there is a trend indicating a higher frequency of disasters in these recent years. This trend is primarily due to the influence of several factors that affect the development of a disaster. The risk for disaster occurrence and/or the risk for heightened mortality in the event of disaster are

shaped by population growth, population density, environmental degradation, poor or unplanned urbanization, and poverty. Data indicate that the greatest degree of mortality and morbidity from disasters occur in low- and middle-income countries. The degree of calamity associated with a disaster will also be associated with the population density of the area affected and the level of vulnerability in that area. Events occurring in areas with dense population will result in greater harm (by absolute numbers) than events in less dense areas. Similarly, hazards occurring in areas made vulnerable by poor economic development, environmental degradation, or urban planning will result in greater harm than those occurring in stable areas. Vulnerable areas include river watersheds, undefended coastal plains, and hillsides prone to landslides. Many low-income countries have large populations living on vulnerable ground. The intersection of a hazard, high population, and high vulnerability results in a major catastrophe.

Health and Disasters

Disasters can influence human health in many ways. The largest impact of most disasters on human health lies in the injuries that occur from the event itself. In general, disaster events that involve water (such as floods, storm surges, and tsunamis) are the most significant in terms of mortality. The frequency of mortality in these events exceeds the frequency of nonfatal injury. In contrast, earthquakes and events associated with high winds tend to exhibit more injuries than deaths. Injury patterns related to man-made disasters are much more variable in the ratio of deaths to nonfatal injuries.

Health concerns also lie in the circumstances related to the aftermath of a disaster. In most disaster situations, outbreaks of communicable disease are not the primary concern in the short term. It is the view of many disaster professionals that the risk for outbreaks will not lie immediately after an event, but rather 1 to 2 weeks later and only if substantial population displacement and the disruption of health services occur. What is often the primary concern in the aftermath of a disaster is the impact of population displacement. Natural and man-made disasters will often destroy sizeable amounts of property, including houses and farms. From a health perspective, one is concerned with the effect of having little or no shelter (environmental exposure) foremost and overcrowding in available shelters. In the long term, there may also be a health concern over the ability to feed the population affected adequately. Mental health consequences of a disaster are another important health issue that carries both short-term and long-term implications. Several studies demonstrate higher frequencies of depression and posttraumatic stress disorder following major disasters.

Epidemiologic Response to Disasters

Epidemiology and the related methods of epidemiological practice are increasingly being recognized as valuable components to disaster response and disaster planning. The main goal of epidemiology in a disaster situation is to measure and describe the frequency of health events related to the disaster, to identify the factors contributing to these effects, and to identify potential interventions to alleviate the impact of these issues. Rapid needs assessments and surveillance activities are common practices undertaken in the aftermath of a disaster to address this broad goal. Further epidemiological studies may be conducted to identify risk factors, prioritize health interventions, match resources to needs, or to evaluate an intervention's effectiveness.

Epidemiology can contribute toward the understanding of the management and preparedness for disasters. This contribution can be directed at identifying and assessing factors related to the development of disasters, the public health response to disasters, an examination of the health effects of disasters, and the identification of groups in the population at particular risk for adverse health effects. Disasters are complex events, and practitioners in disaster epidemiology activities face many challenges, including establishing communications with professionals from several disciplines, a changing social environment in the face of destruction, a changing political environment, and constraints on the collection and analysis of data.

The analysis of past disasters provides several clues to the reduction of mortality and morbidity in future events. Unique patterns of death and injury have been noted among different classifications of disasters. Future research in the epidemiology of disasters will likely focus on improving the surveillance of mortality and injuries related to disasters, enhancing our understanding of the long-term chronic health effects of disasters, and approaches to integrating epidemiological information into contingency and mitigation planning.

Discriminant Analysis

Discriminant analysis (DA) is a multivariate statistical method used for two purposes: separation of observations into two or more distinct groups and classification of new observations into known groups. In DA, the categorical variables or groups are the dependent variables and the responses are the independent variables, so it is the reverse of a multivariate analysis of variance (MANOVA). Since the two procedures are computationally similar, the same assumptions that apply to MANOVA also apply to DA. Briefly, the assumptions are that the data are normally distributed and the variance/covariance matrices are homogenous across groups. DA is also sensitive to the presence of outliers and multicollinearity among the independent variables.

Separation

DA is used as an exploratory procedure in research to gain a better understanding of reasons for observed differences between groups. For instance, a researcher may be interested in determining which body types are at greater risk for heart disease. The researcher records several measurements (such as height, weight, and cholesterol levels) or response variables on patients who have heart disease and those who do not. The researcher wants to determine how much each measurement contributes to the separation of or discrimination between the groups. The researcher may also wish to classify new patients into risk-level groups given their body measurements.

When DA is used for separation, new variables called canonical discriminant functions (CDF) are created that combine the existing response variables in such a way as to maximize the variation between groups. A CDF is a linear combination of the response variables of the form

$$S_i = l_{i1}x_1 + l_{i2}x_2 + \cdots + l_{ip}x_p,$$

where S_i is the score for ith function, l_{in} is the standardized coefficient for x_n, $n = 1, \ldots, p$. There is one CDF for each independent variable or one for the number of groups minus one, whichever number is the smaller of the two. For example, if there are three groups and five variables, two CDFs are generated. The first CDF explains the greatest percentage of variation between groups. Each successive CDF is independent of the previous function and explains less variance. The characteristic root or *eigenvalue* associated, with the CDF indicates the amount of variance explained by the function.

The magnitude of the CDF coefficients indicates how important each variable is to group discrimination relative to the other variables. However, these coefficients may be misleading in the presence of correlation between the responses, that is, if there is a high degree of collinearity. Just as in regression analysis, addition or deletion of a variable can have a large effect on the magnitude of the other coefficients. Furthermore, when two variables are correlated, their contribution may be split between them or one may have a large weight and the other a small weight.

The canonical structure matrix can also be interpreted. This matrix contains the correlations between the CDF scores and each individual variable. The larger the correlation, the more important the variable is to discrimination.

Classification

There are several ways to use DA for classification. One way is to use Fisher's linear classification functions (LCF) of the form

$$G_j = c_{j0} + c_{j1}x_1 + c_{j2}x_2 + \cdots + c_{jp}x_p,$$

where j indicates the group, c_{jn} is the unstandardized coefficient for the jth group and the nth variable, $n = 1, 2, \ldots, p$, and c_{j0} is the constant for the jth group. There is one LCF for each group, and subjects are classified into the group with the highest discriminant score, G_j.

It is also possible to take a Bayesian approach to DA. This differs from Fisher's method, because it takes into account a priori or prior probabilities of group classification and seeks to minimize the probability of misclassification. Equal prior probability is usually specified when there is no prior knowledge about group proportions. It means that a subject has an equal chance of being assigned to one group or another. For example, without knowing anything about the sample, it may be assumed that a subject has the same chance of having heart disease as he has of not having it. When it is known that the prior probabilities are not equal, they should be specified in the analysis. For instance, it may be known that the probability of a subject having heart disease is 0.4 and the probability that subject does not is 0.6. The classification functions will be more accurate if prior probabilities are proportional to the group sample size.

Subjects are classified into groups using posterior probabilities. Posterior probability is the probability that a particular subject belongs to a certain group given knowledge of the values of the other variables for that subject. It is calculated using the discriminant scores and prior probabilities. A subject is assigned to the group that has highest posterior probability. The maximum likelihood rule for classification is a special case of Bayes's rule where prior probabilities are equal, and therefore, only posterior probabilities are considered when classifying observations.

Classification can also be thought of in terms of decision theory. Suppose that the cost of misclassifying some observations is greater than the cost of misclassifying others. Such a classification rule, therefore, minimizes the expected cost of misclassification. The obvious advantage of such a rule is that varying degrees of error can be taken into account. For example, when classifying individuals as diseased or healthy, it is generally considered more important to correctly classify the diseased individuals than it is to correctly classify the healthy individuals; that is, a greater cost is associated with failing to identify a case of disease where it exists than with incorrectly identifying a healthy person as having a disease.

Once classification functions have been estimated, their performance is assessed by applying the functions to a new set of data, that is, using them to classify different data than was used to estimate the functions in the first place. This is referred to as cross-validation. The accuracy of the classification functions is evaluated by the number of correctly classified subjects. It is not recommended to validate the functions by classifying the same data that were used to estimate the functions for obvious reasons: Doing so capitalizes on chance elements of the original sample that are unlikely to be present in any subsequent samples, thus producing an inflated predicted performance. Classifying the original data can, however, be used to look for outliers and to examine areas where the classification functions do not work well.

Disease Eradication

Disease eradication is defined as the permanent reduction of disease incidence to zero, globally, through deliberate efforts. On eradication of a disease, no disease-related morbidity or mortality can ever occur again. Disease eradication and disease elimination are not synonymous. In disease elimination, incidence of a disease is reduced to zero within a specific geographic area. Continued preventive measures are required in a state of disease elimination since the disease may still arise (i.e., importation of a communicable

disease across country borders), whereas intervention is no longer required on eradication. Eradication is different from extinction, which occurs when the etiologic agent no longer exists in nature or in a laboratory. Smallpox is the only disease to date that has been eradicated.

Epidemiological Criteria to Achieve Eradication

The biological and technical feasibility of eradication of a particular disease depends on the natural history of the etiologic agent and the disease, population characteristics affecting transmission potential, and the availability of diagnostic and intervention measures. Epidemiological criteria that favor disease eradication include the following.

Lack of Nonhuman Reservoir

The presence of a pathogen in nonhuman reservoirs, such as soil or animals, reduces the likelihood of eradication. For instance, while the rabies virus in humans can be contained through either a preventive vaccine or postexposure treatment, wild animals such as bats or raccoons can introduce the virus into human populations. Mass vaccination of animals and other attempts at controlling all natural reservoirs of rabies are not globally feasible, ensuring that rabies is not a viable candidate for eradication.

Sensitive Surveillance

Effective surveillance to detect the circulation of disease in a population is crucial to eradication efforts. Although largely dependent on the existence of well-functioning health systems infrastructures, surveillance in an eradication context is also promoted by favorable disease characteristics (such as a predictable seasonality of incidence, visible symptoms, or short incubation period) and available technologies (inexpensive, rapid, and accurate serological tests). The World Health Organization (WHO) campaign to eradicate yaws in the 1950s failed in part due to the inability to identify infected persons. Because yaws can exist asymptomatically in a latent state, case finding was hampered and many such carriers relapsed to infectious states even after treatment teams had visited a community. Surveillance can also serve as an indicator of progress in eradication efforts. The first 10 years of the yaws campaign had little, if any, screening, and when serological surveys were finally conducted, the discovery of high prevalence of subclinical infections rendered the eradication campaign essentially futile.

Effective Interventions

Interventions for preventive or curative treatment are necessary to remove potential susceptible or infected persons from a population. In addition, disease-specific means of eliminating vectors are crucial. The WHO malaria eradication campaign from 1955 onward was an uphill battle due to chloroquine resistance by parasites, fostered in part by inconsistent prophylactic treatment at subtherapeutic levels that promoted selection of resistant strains over time. A main component of the eradication strategy targeted the mosquito vector through use of insecticides, relying heavily on DDT. However, growing vector resistance to insecticides reduced the effectiveness of insecticide-based preventive measures and ultimately was a factor in the WHO decision in 1969 to revise the goal of malaria eradication to simply control.

A Safe, Highly Effective Vaccine for Vaccine-Preventable Diseases

Constraints prevent administration of a vaccine to all of the world's population, but principles of herd immunity indicate that for infectious diseases, the entire population does not need to be immune for a disease to be eliminated. The degree of herd immunity required to eliminate a disease depends on both disease and population characteristics and thus will differ between world regions. An effective vaccine exists for measles, but to overcome the high degree of contagion, countries need to achieve correspondingly high vaccination coverage levels to provide sufficient herd immunity. Vaccine characteristics, such as ease of administration, length of protection, side effects, and storage requirements, can determine the candidacy of a disease for eradication. The smallpox vaccination efforts were successful in part because the vaccine was inexpensive, safe even in newborns, heat stable, and required only a single dose. Moreover, smallpox vaccination conferred lifelong immunity and persons who were vaccinated had a recognizable scar.

Candidate Diseases for Eradication

The International Task Force for Disease Eradication (ITFDE), which convened from 1989 to 1992,

considered more than 90 diseases for eradication. After weighing epidemiological vulnerability as well as sociopolitical feasibility, the ITFDE concluded that six diseases were potentially eradicable: dracunculiasis (Guinea worm disease), poliomyelitis, lymphatic filariasis, mumps, rubella, and cysticercosis.

Doll, Richard
(1912–2005)

Richard Doll qualified in medicine in 1937, graduating from St. Thomas Hospital in London, but his main epidemiological work began when he joined the staff of the Medical Research Council in London following service in World War II. More than any other person, he was responsible for establishing smoking as the main cause of lung cancer. His early case-control study of the question with Austin Bradford Hill was not the first such study, but he and Hill followed up some 40,000 British doctors after collecting details of their smoking habits, a cohort study that was unique in its regular updating of the subjects' smoking habits. The strong dose-response relation between lung cancer and smoking, together with the high standard and careful assessment of the study's findings, played a major part in convincing people of a causal relation, and in turn helped to change smoking habits. Thus, in 1950, 80% of the men in Britain smoked, but by 2000, this had declined to less than 30%.

Doll was one of the first epidemiologists to investigate the health effects of irradiation. His follow-up with Court Brown in 1957 of 14,000 ankylosing spondylitis patients treated with radiation brought the first independent confirmation, after the report on atomic bomb survivors, that radiation could cause leukemia. The study has since been a major source of data on the dose-response relation of radiation and cancer. In 1954, long before the relevant advances in molecular biology, Doll and Peter Armitage adduced evidence for the multistage nature of carcinogenesis.

He was also responsible for classic studies of asbestos and of nickel refining, being the first to show a significant excess of lung cancer among asbestos workers. He also collaborated with others on the side effects of oral contraceptives.

In 1969, he was appointed to Britain's premier medical chair, the Regius Professorship of Medicine at Oxford, which brought new attention to the subject of epidemiology. He had a wide influence on the progress of the science and was extensively consulted, for example, in the setting up of the International Agency for Research on Cancer (IARC). He was an early promoter of clinical trials and of cancer registries and was an author of the first compendia of worldwide cancer incidence data, *Cancer Incidence in Five Continents*.

Apart from his contributions to science and health, Richard Doll is commemorated in Oxford by Green College, where he was the first warden, and by the two flourishing units that he helped found at Oxford University, the Cancer Research UK Epidemiology Unit and the Clinical Trial Service Unit.

Dose-Response Relationship

Dose-response is a term that describes a relationship between an exposure and the risk of an outcome. A dose-response relationship is one in which increasing levels of exposure are associated with either increasing or decreasing risk of the outcome. Demonstration of a dose-response relationship is considered strong evidence for a causal relationship between the exposure and the outcome, although the absence of a dose-response relationship does not eliminate the possibility of a causal relationship.

The increase in the exposure can be in its intensity or its duration. Exposure can be characterized in different ways such as the peak exposure; the duration of exposure at or above a set level; average exposure, which is a time-weighted average of exposure; or cumulative exposure, which is the sum of time-weighted exposures.

The time to response must be considered when examining the relationship of the exposure to the outcome as there may be a latent period between exposure and the outcome. If the effects of exposure are measured too soon after the exposure, no effect will be seen even in the case where the exposure causes the outcome. One example of this is the increased risk of leukemia after exposure to radiation.

Odds ratios or relative risks can be calculated for categories of increasing exposure each compared with a baseline exposure level, as shown in Table 1. The mathematical relationship of exposure to outcome may be linear, log linear, or follow some other pattern. There may be some level of risk even in the absence of exposure, or there may be a threshold dose below which no affect of exposure on risk is seen (Figure 1).

In some cases, the relationship between exposure and outcome may be U-shaped with high risk at both extremes of exposure, but lower with intermediate exposure (see Figure 2). One example of this is the relationship of vitamin A with birth defects. Increased risk of birth defects is seen not only with deficiency in vitamin A but also with excessive doses.

Table 1 Dose–Response Relationship of Increasing Exposure and Increasing Risk of Disease

Exposure Score	*Disease (+)*	*Disease (−)*	*Odds Ratio*
0	5	95	1.0 (Reference category)
1	10	90	2.11
2	7	43	3.09
3	5	20	4.75

A statistical test for trend can be performed to verify that any apparent trend in the data is statistically significant. The Cochran-Armitage Test is one test for a trend in a binary outcome (ill or not ill) and applies to a linear relationship between exposure and outcome. Another is the Mantel-Haenszel Test, an extension of the chi-square test for trend (see Schlesselman, 1982, pp. 203–206, for details).

Inclusion of small numbers in the groups at the extreme ends of the exposure distribution may lead to statistically unstable rates in these groups. This may affect the validity of an apparent trend. Also, these end categories sometimes include extreme values, and the results can be sensitive to these extreme values.

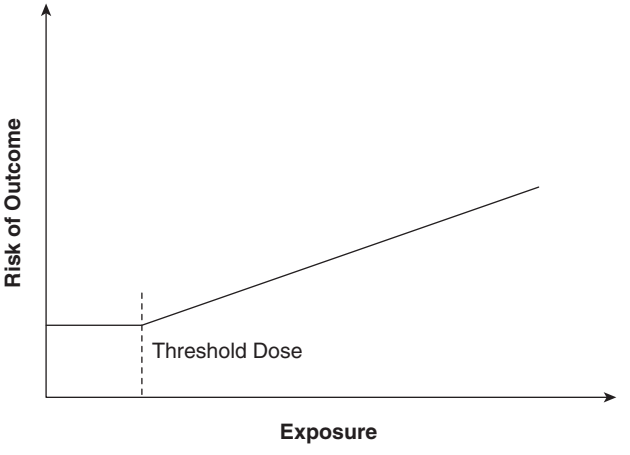

Figure 1 Threshold Dose

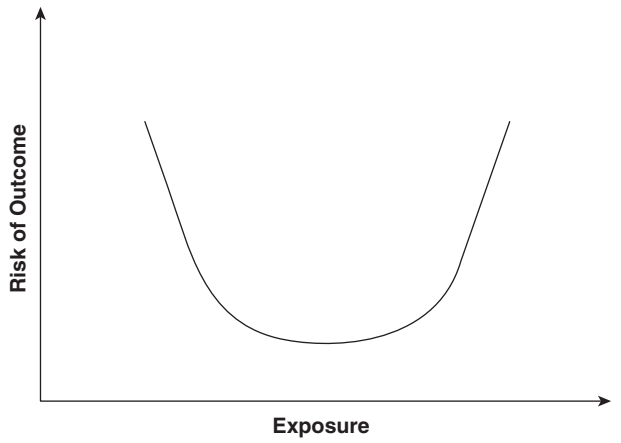

Figure 2 U-Shaped Relationship

For example, very few subjects may be included in the smoking exposure category "More than two packs per day," and this category may include a subject with exposures far in excess of anyone else in the study. For this reason, it is important to examine the effect of extreme values on the results.

Doubling Time

Doubling time is an important concept in many life sciences and in epidemiology, in particular: It refers to the length of time required for some quantity to double in size. It is commonly used to refer to human population size, but it is also used to describe, for instance, growth of viral counts or antigens, tumors, and the number of cases of a particular disease. Suppose we have a quantity $Q(t)$ growing in time t. The function $Q(t)$ may stand for the population size or the amount of a substance at time t. Doubling time is the time it takes for $Q(t)$ to double in size and is uniquely determined by the growth rate $r(t)$. If $Q(t)$ has an exponential growth, then the doubling time can be exactly calculated from the constant growth rate $r(t) = r$. However, without the assumption of exponential growth or knowledge of the growth rate, one still can closely estimate the doubling time using two data values of $Q(t)$ at two time points. The estimation formulas are derived below:

The growth rate for $Q(t)$, assumed to be a continuous function of t, is defined as the relative change of $Q(t)$ with respect to t:

$$r(t) = \frac{1}{Q(t)}\frac{dQ(t)}{dt} = \frac{d \ln Q(t)}{dt}, \qquad [1]$$

where ln stands for natural logarithm ($\log_e$). Equation 1 indicates that the growth rate $r(t)$ has dimension "per unit time." Equation 1 is a simple linear first-order differential equation, which can be easily integrated to yield

$$Q(t) = Q(0)\exp\left(\int_0^t r(u)du\right) = Q(0)\exp(\bar{r}_t t), \qquad [2]$$

where $Q(0)$ is the quantity at time $t = 0$ and $\bar{r}_t = \int_0^t r(u)du/t$ is the average growth rate over the time interval $[0, t]$. Solving Equation 2 for t we obtain

$$t = \frac{\ln[Q(t)/Q(0)]}{\bar{r}_t}. \qquad [3]$$

The doubling time is the value of t, say, τ, such that $Q(\tau)/Q(0) = 2$, which when substituted into Equation 3 yields the following relation between doubling time and average growth rate:

$$\tau = \ln 2/\bar{r}_\tau = .693147/\bar{r}_\tau, \qquad [4]$$

which is approximately equal to 70% divided by the average growth rate, the so-called rule of seventy. Equation 4 says that the doubling time τ is inversely proportional to the average growth rate. The larger the growth rate, the smaller the doubling time. Doubling the growth rate is equivalent to halving the doubling time. For example, a short tumor-doubling time implies that the tumor is growing rapidly in size (measured either in terms of tumor volume or diameter). In fact, tumor-doubling times are considerably shorter in cancer patients who developed metastases than in those who did not develop metastatic disease.

In real applications, the average growth rate $\bar{r}_\tau$ in Equation 4 is unknown and has to be estimated from data in some time interval [0, T], where $Q(0)$ and $Q(T)$ are both known. From Equation 3, we have

$$\bar{r}_\tau \approx \frac{\ln[Q(T)/Q(0)]}{T}. \quad [5]$$

The closer T is to τ, the better the approximation in Equation 5. When $T = \tau$, the approximation becomes an equality. Substituting Equation 5 into Equation 4 yields an estimate of the doubling time as

$$\tau \approx .693147T/\ln[Q(T)/Q(0)]. \quad [6]$$

If the growth rate $r(t) = r > 0$ is a positive constant, then $\bar{r}_t = r$ and $Q(t)$ has an exponential growth. In this case, strict equality instead of approximation holds in Equations 5 and 6, as stated in the first paragraph. We now illustrate an application of formula (Equation 6) to estimate a doubling time in infectious disease epidemiology. During the outbreak of severe acute respiratory syndrome (SARS) epidemic in the early months of 2003, the health authority in Hong Kong had reported 300 SARS cases as of March 30 and reported 1,425 cases up to April 28. So we take the time interval [0, T] as [3/30/2003, 4/28/2003] so that $T = 29$ days, $Q(0) = 300$, and $Q(T) = 1{,}425$, which when substituted into Equation 6 yields 12.9 days as the doubling time—the period of time required for the number of cases in the epidemic to double—during the early stage of the SARS epidemic. If $Q(t)$ data are available for more than two time points, then the doubling time may be estimated using least-squares regression analysis.

Sometimes the components of the growth rate are available and so the growth rate may be calculated directly by subtracting the decrement rate from the increment rate. For example, in demographic applications, global crude birth and death rates are available, which according to the United Nations estimates are .022 per year and .09 per year, respectively. For the year 2000, yielding a growth rate of .013 per year, which when substituted into Equation 4 yields 53 years or approximately 54 (= 70%/.013) years, according to the *rule of seventy*, as the doubling time—the period of time required for the global population to double its size from 6.1 billion in 2000 to 12.2 billion in 2053—if the growth rate in 2000 were to continue.

Drug Abuse and Dependence, Epidemiology of

Drug dependence is a disorder with neurobiological, social, and psychological influences. It is characterized by a pattern of maladaptive behaviors that develop as a consequence of the reinforcing effects of a drug that promotes continued use. Drug abuse and dependence have both direct and indirect impacts on individual health and also lead to social costs including those associated with drug-related crime. Although dependence is often a chronic, relapsing condition that accounts for a large public health burden, a large proportion of those with drug dependence remit even without treatment. This entry reviews the diagnoses of drug abuse and dependence, examines individual and environmental risk factors, discusses the individual and social costs of abuse and dependence, and considers options for the prevention and treatment of drug abuse and dependence.

Diagnoses of Drug Abuse and Dependence

Objective criteria to diagnose dependence can be found in the *Diagnostic and Statistical Manual of Mental Disorders*, published by the American Psychiatric Association, and the *International Statistical*

Classification of Diseases and Related Health Problems, published by the World Health Organization.

Dependence is diagnosed if at least three of the following problems are present: the user is tolerant to the substance (needs to use more to achieve the same effect or the same amount of substance leads to diminishing effect), experiences withdrawal (exhibits withdrawal symptoms or uses the substance to relieve those symptoms), needs to take larger amounts or for a longer time, wants or unsuccessfully tries to control his or her use, spends most of his or her time getting or using the substance or recovering from its use, gives up important activities to use the substance, or continues to use even with the knowledge that he or she has health problems related to substance use. Maladaptive use that does not meet the criteria for dependence is called abuse. Diagnostic criteria for abuse include failing to fulfill obligations at work, school, or home; recurrent use in physically hazardous situations; recurrent legal problems; or continued use despite serious social or interpersonal problems.

Although abuse and dependence are considered as distinct diagnostic entities, there is considerable overlap between these disorders; abuse of drugs usually involves using a large quantity of one or more substances, and regular use often, though not always, leads to dependence. On the other hand, a minority of those who are dependent do not show symptoms of abuse. In addition, it is more difficult to treat the abuse of those people who are highly dependent than those who are not as dependent. Research suggests that drug dependence changes not only the brain chemicals but also the brain structures, and the more dependent a person is, the more difficult it is to reverse the brain into a nondependent stage.

Distribution of Drug Dependence in the Population

Drug dependence is not distributed randomly in the population. Prevalence of dependence is highest among people aged 18 to 54 years, especially among young adults. The extent to which minorities are affected by dependence varies by drugs, region, and age. For example, in the United States, cocaine dependence is more common among whites who are below 30 years of age and among nonwhites who are above 30 years of age. People in geographic areas with economic deprivation and neighborhood disorganization are also more likely to develop dependence than people in more affluent areas. While treatment is available for drug dependence, only about one in five people with dependence gets treated.

Individual and Environmental Risk Factors

Individual Risk Factors

Many factors contribute to the vulnerability of developing substance abuse or dependence, and these factors stem from three general areas: (1) genetic predisposition, (2) nongenetic individual characteristics (psychological traits and demographics), and (3) environmental factors. The mechanisms through which addiction develops in these areas are (1) neurobiological (i.e., drug dependence is a brain disease), (2) disinhibition and reinforcement, and (3) barriers and protective factors. Results from studies among twins who have similar genetic risk factors but different environmental experiences suggest a genetic liability for dependence, similar to the role of genes in other chronic illnesses. There is likely no single gene responsible, but possibly several genes play a role in the neurobiological pathway to drug use disorders. A history of use of multiple drug types and low educational achievement may put one at risk for drug abuse and dependence. Individual choice, sensation seeking, and strategies of coping with stress may also play a role in drug use and abuse, which ultimately may lead to dependence.

Environmental Risk Factors

Although individual risk factors are important, it is also important to consider the effect of societal, social, and structural conditions, which can play both reinforcing and protective roles. For example, the number of family members, loved ones, and influential peers—an individual's social network members—who use or abuse substances may also influence whether or not an individual will use or abuse substances. Not living alone (e.g., living with parents or a spouse), high taxes on legal substances, and, in some cultures, religion have been found to be protective factors for drug dependence.

In addition, different drugs may be available in different countries, cities, or even neighborhoods within one city, and within these large and small geographic areas, social norms related to use and abuse also

influence an individual's chances and choices. Laws that determine which drugs are legally available and which are illegal are an important environmental factor. For example, alcohol is legal in most countries but is illegal in some, for example, Saudi Arabia and Kuwait; and marijuana is illegal in most countries but is legal in a few, for example, Holland. Furthermore, even within a country, legislation may have changed over the course of history to make certain drugs legal or illegal. For example, alcohol was illegal from 1920 to 1933 in the United States. In the 19th century, opiates were legally and freely available for purchase without a prescription in the United States. In the first decade of the 20th century, however, the production, sale, possession, and use of narcotics became illegal in the United States. In addition, again within a single country and within the same time period, certain drugs may be legal for one segment of the population, while they are illegal for another segment, as it is in the case of underage drinking and smoking. Structural conditions, such as these laws about underage drinking and smoking, are meant to protect a section of the society that is especially vulnerable to drug dependence; those who start using or abusing at an earlier age are more likely to develop dependence than those who start their substance use career at a later age due to their greater vulnerability to the neurobiological effects of substance use.

The proportion of people who use different drugs (the prevalence of drug use) and the prevalence of dependence among those who use these drugs vary by country and by drug. As a result, the potential of different drugs to cause dependence varies not only by drug but also by country or culture. For example, alcohol is readily available in most Western countries, but it is restricted in many Muslim countries. Cannabis is very common all over the world. Opiates, such as opium, heroin, or homemade liquid opiates, are available in most countries of the world, but they are rare in South America. On the other hand, cocaine and other coca derivatives are commonly used in South America and North America, but they are rarely used in Central and Eastern Europe or Africa. The reason for this may be that the world's top producer of heroin is Afghanistan and the leading cocaine producer is Colombia, although there is a growing production of heroin in Latin America. As both heroin and cocaine are illegal all over the world and are trafficked illegally, the availability of these drugs will be limited by geography and by local distribution networks.

Impact of Drug Characteristics and the Effect of Methods of Ingestion

Drugs differ in their potential to make people dependent. Tobacco has the highest likelihood of leading to dependence, followed by heroin, cocaine, and alcohol. Research among drug users in the United States has found that nicotine dependence develops in about one of every three people who smoke tobacco, compared with about one quarter of those who ever tried heroin and about 15% of those who ever tried cocaine or alcohol. Prescription medications, such as pain killers and sleeping pills, that are used initially for therapeutic reasons may also lead to dependence and abuse. The nonmedical use of prescription medications is an increasing public health concern in Western countries. It is estimated that about one in five people in the United States has misused prescription medications in his or her lifetime.

Pharmacokinetic properties of specific drugs and how they are used often affect how quickly one may become dependent. Users may orally ingest drugs in several ways—for example, by swallowing (e.g., pills), drinking (e.g., poppy tea), or chewing (e.g., coca leaves). However, oral ingestion is slow, and the speed with which a drug is metabolized and absorbed varies. Intranasal consumption, when drugs are absorbed through the mucous membranes of the nose, is also common because it provides a more rapid effect; drugs can be vaporized and inhaled in vapor form (e.g., "chasing the dragon"), dissolved and sprayed in the nose (e.g., "shebanging," or using cocaine mixed with water), or snorted in powder form (e.g., cocaine, heroin, and amphetamines). During smoking (e.g., marijuana), the drugs are absorbed into the lungs. Drugs can also be injected into the veins, under the skin, or into the muscle by means of hypodermic syringes and needles. The effect of the drug varies depending on the type of administration. For example, after snorting heroin, the users "get high" in about 10 to 15 min, whereas the effect of heroin can be felt about 7 s after smoking it or injecting it into the vein.

Access to and the cost of drugs may also influence what drugs people use and become dependent on. For example, the type of heroin powder available on the streets on the East Coast of the United States is white, while in Central Europe it is brown heroin. White powder heroin can be used several ways: It can easily be snorted up the nose in powder form, and it can also be dissolved in cold water and injected. Brown

heroin, on the other hand, cannot be snorted, but it can be dissolved in hot water and injected. As a result, there is a large portion of heroin users on the East Coast of the United States who use heroin via noninjecting ways, while almost all heroin users in Central Europe inject heroin. People in certain geographic areas or different socioeconomic groups may have easier access to certain drugs. Prevalence of a less expensive form of cocaine, crack, increased dramatically during the mid-1980s, particularly among urban African Americans in the United States. Although outbreaks of methamphetamine use in the form of "ice smoking" have been occurring in East Asia for several decades, the rapid spread in recent years of use and related dependence among "ice" users in the United States can be partly attributed to the ease in which the drug can be manufactured in local clandestine methamphetamine labs.

The Costs of Drug Dependence

It is estimated that drug abuse and dependence cost about $150 billion alone in the United States. The highest cost of drugs is mortality: The use of tobacco, alcohol, or illicit drugs contributes to one in four deaths in the United States, including deaths resulting from lung cancer and liver cirrhosis, with tobacco smoking being the leading preventable cause of death. In addition, much of the cost results from increased criminal activities committed as part of the lifestyle resulting from drug abuse or the nature of illegal drugs. These costs include, but are not limited to, those associated with law enforcement and incarceration of drug offenders. Low educational levels and unemployment are associated with substance dependence, but this is a two-way relationship. Not only are those with less education and no employment more likely to abuse substances, but substance abuse at an early age may also lead to failure to finish school and obtain a higher education, which in turn contributes to unemployment. Also, substance abuse itself can result in both unemployment and underemployment. In addition, among the employed, substance abuse and dependence, like any other chronic illness, can cause loss of work time and productivity.

Some substances have both direct health effects, such as liver cirrhosis resulting from alcohol dependence, and an indirect impact on health (e.g., "meth mouth," the premature and rapid decay and loss of teeth among methamphetamine smokers), mediated through high-risk behaviors associated with drug use. Drug abuse also speeds up the aging process, so aging-related illnesses are more common among those who abuse drugs. Among childbearing women, drug dependence can result in the birth of underweight, premature babies, who may already be physically dependent on the substance, or whose health is permanently damaged (e.g., fetal alcohol syndrome). Some drug users, both males and females, support their habit by engaging in prostitution, thereby increasing their risk of acquiring and/or transmitting sexually transmitted infections. Injecting drug users are at high risk for bloodborne infections, with HIV (the virus that causes AIDS) being one that is transmitted both sexually and through equipment contaminated with blood. The more dependent substance users are, the more likely they are to forego safe injecting or sex practices, since the severity of their dependence shifts their main focus from safer sex or injecting practices to obtaining and using substances. People who belong to more than one at-risk group are especially vulnerable. For example, males who inject drugs and have sex with other men, particularly those who sell sex to other men and thus have a large number of sex partners, are at the highest risk of getting infected or infecting others with HIV.

Mental illness is also correlated with drug dependence. Over one third of those who abuse alcohol and over half of those who abuse illicit drugs suffer from at least one mental illness, and about a third of those who have a mental illness also abuse alcohol or other drugs. Outcomes among people with dual diagnosis, that is, people who are both dependent on one or more substances and have a mental illness, are more severe than if only one disorder was present. Mental disorders often develop before the onset of drug dependence, but substance use itself can also lead to mental illness. To be able to treat people with dual diagnosis effectively, both psychiatric conditions need to be addressed simultaneously.

Prevention and Treatment of Drug Dependence

Prevention programs target the reduction of onset of drug use and also strive to stop the progression of use before it turns into dependence. Programs often target individual or group characteristics believed to have a causal influence on drug involvement (e.g., aggressive behavior, risk taking) but can also include environmental components (e.g., location of alcohol

outlets) and policies (e.g., taxes) targeting availability. Good prevention programs are research based; they are tested and evaluated similarly to how therapeutic drugs are tested and evaluated in clinical trials for efficiency and effectiveness.

Several treatment alternatives are available to those who want to abstain from drug use. Many dependent individuals can quit on their own; however, depending on the circumstances, professional help is recommended for detoxification, and residential programs can lead to favorable treatment outcomes. Counseling and support groups (e.g., 12-step programs) are widely used forms of treatment for dependence, and behavioral therapies, such as contingency management, have also shown great promise. Medications are also available for some drugs, for example, nicotine patches or chewing gums for tobacco dependence and methadone and buprenorphine for opiate dependence. A combination of behavioral therapy and medication, when available, is the most effective. The more treatment a person receives, the more likely he or she will be to recover. Harm reduction, such as needle-exchange programs to prevent bloodborne infections, and overdose prevention to prevent drug-related deaths are aimed at reducing the harm of substance abuse among those who are still active users. The support and encouragement of family and friends is an invaluable addition to any prevention, treatment, or harm-reduction program.

Drug Use, Illicit

See Illicit Drug Use, Acquiring Information On

Dummy Coding

Dummy coding, also known as indicator coding, provides a means for researchers to represent a categorical variable as a set of independent quantitative variables. The resulting dummy variables take on values of 0 and 1 and can be used as predictors in regression analysis. Given a categorical variable that can take on k values, it is possible to create $k - 1$ dummy variables without any loss of information. Dummy variables are often included in regression models to estimate the effects of categorical variables such as race, marital status, diagnostic group, and treatment setting.

When constructing a set of dummy variables, one level of the original categorical variable is selected as a reference category and is excluded from analysis. Each remaining level becomes a single dummy variable on which observations receive a value of 1 if

they fall into the category and 0 if they do not. For example, given a four-level psychiatric diagnosis variable (bipolar disorder, major depressive disorder, other mood disorder, no mood disorder), the "no mood disorder" group might be selected as the reference category. Three dummy variables would then be constructed: "BIPOLAR" would be scored 1 for persons with this diagnosis and 0 for those in the other three diagnostic groups; similarly, "MDD" would be scored 1 for persons with a diagnosis of major depressive disorder and 0 for those with another diagnosis; and "OTHMOOD" would be scored 1 for persons with a diagnosis of an "other mood disorder" and 0 for those diagnosed with bipolar disorder, major depressive disorder, or no mood disorder. Each dummy variable would have 1 *df*.

In regression analyses, the coefficients for each of the $k-1$ dummy variables quantify the estimated effect on the outcome variable of membership in the group in question versus membership in the reference group. For example, in a logistic regression analysis predicting diagnosis of bloodborne infection, a coefficient (β) for the "BIPOLAR" variable of 1.12 would represent the difference in the log-odds of infection between persons with bipolar disorder and those with no mood disorder. Expressed in terms of an odds ratio ($e^{\beta} = 3.06$), persons with bipolar disorder would have slightly more than three times the odds of infection compared with persons in the reference group. Dummy variables are used in a wide variety of regression analyses, including, but not limited to, ordinary least-squares, logistic, Cox, and Poisson regression.

The choice of reference category should be made based on substantive scientific considerations, and the category should be selected to support meaningful contrasts. In the case of race, this often results in the selection of "White" as the reference category. In experimental studies, the control group is often an appropriate choice. Miscellaneous or "other" categories containing a heterogeneous mix of observations (e.g.,"other race") usually do not provide researchers with the ability to make useful inferences and are therefore rarely suitable as reference categories. To ensure stable estimates, the number of observations in the reference category should not be too small relative to the size of the other categories.

Further Readings

Hardy, M. A. (1993). *Regression with dummy variables*. Newbury Park, CA: Sage.

Dummy Variable

A dummy, or indicator, variable is any variable in a regression equation that takes on a finite number of values so that different categories of a nominal variable can be identified.

The term *dummy* simply relates to the fact that the values taken on by such variables (usually values such as 0 and 1) indicate no meaningful measurement but rather the categories of interest.

For example,

$$X_1 = \begin{cases} 1 & \text{if Treatment A is used} \\ 0 & \text{otherwise} \end{cases}$$

and

$$X_2 = \begin{cases} 1 & \text{if female} \\ 0 & \text{otherwise} \end{cases}.$$

The variable X_1 indicates a nominal variable describing "treatment group" (either Treatment A or not Treatment A) and X_2 indicates a nominal variable describing "sex."

The following simple rule always is applied to avoid collinearity and the imposition of a monotonic dose-response in the regression model: For an exposure with K distinct levels, one level is first chosen as the baseline or reference group. Refer to that level as Level 0, with other $K-1$ levels referred to as Level 1, Level 2, and so on up to Level $K-1$. Then, define $K-1$ binary exposure variables as follows:

$$X_1 = \begin{cases} 1 & \text{if an individual's exposure is at Level 1} \\ 0 & \text{otherwise} \end{cases},$$

$$X_2 = \begin{cases} 1 & \text{if an individual's exposure is at Level 2} \\ 0 & \text{otherwise} \end{cases},$$

$$\ldots$$

$$X_{K-1} = \begin{cases} 1 & \text{if an individual's} \\ & \quad \text{exposure is at Level } K-1 \\ 0 & \text{otherwise} \end{cases}.$$

For example, in his book *Statistics for Epidemiology*, Nicholas Jewell notes that dummy variables are used for a variety of measures of variables in the Western Collaborative Group Study of risk factors for coronary heart disease in men:

$$X = \begin{cases} 1 & \text{Type A behavior pattern} \\ 0 & \text{Type B behavior pattern} \end{cases}.$$

Let $W_t =$ Body weight (1b), on continuous scale, and choose the baseline for weight $W_t \leq 150$. Then, define the following dummy variables:

$$Z_1 = \begin{cases} 1 & 150 < w_t \leq 160 \\ 0 & \text{otherwise} \end{cases},$$

$$Z_2 = \begin{cases} 1 & 160 < w_t \leq 170 \\ 0 & \text{otherwise} \end{cases},$$

$$Z_3 = \begin{cases} 1 & 170 < w_t \leq 180 \\ 0 & \text{otherwise} \end{cases},$$

and

$$Z_4 = \begin{cases} 1 & 180 < w_t \\ 0 & \text{otherwise} \end{cases}.$$

Another example shows how to use dummy variables to compare two straight-line regression equations: 40 males and 30 females are randomly selected to study the association of systolic blood pressure and age. The data set is presented in Table 1.

Source: Adapted from Kleinbaum, Kupper, and Muller (1988).

A first-order regression model with an added interaction term for this example is

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_1 X_2 + E,$$

where

$Y = \text{SBP},$

$X_1 = \text{Age}, \text{and}$

$X_2 = \begin{cases} 1 & \text{Female} \\ 0 & \text{Male} \end{cases}.$

This single multiple regression model yields the following two models for the two values of X_2:

$$\begin{cases} X_2 = 0 : Y_M = \beta_0 + \beta_1 X_1 + E \\ X_2 = 1 : Y_F = (\beta_0 + \beta_2) + (\beta_1 + \beta_3) X_1 + E \end{cases}.$$

For the data set, the least-squares regression equation is

$$\widehat{\text{SBP}} = 110.039 + 0.961\,\text{Age} - 12.961\,\text{Sex} - 0.012\,\text{Age} * \text{Sex}.$$

For males, the least-squares regression equation is

$$\widehat{\text{SBP}} = 110.039 + 0.961 X_1.$$

For females, the least-squares regression equation is

$$\widehat{\text{SBP}} = (110.039 - 12.961) + (0.961 - 0.012) X_1 = 97.078 + 0.949 X_1.$$

Further statistical hypotheses may be generated from this model. For instance, we may like to test the null hypothesis that the two regression lines are parallel, which is equivalent to $H_0 : \beta_3 = 0$. If $\beta_3 = 0$, the slope for females equals to the slope for males. The decision from an F test is that there is no statistical basis for believing that two lines are not parallel.

Eating Disorders

Eating disorders comprise a complex, multidimensional group of increasingly common yet poorly understood illnesses. These conditions are characterized by serious and possibly life-threatening disturbances in eating patterns, including both significant levels of food restriction and intense overeating that often involve food bingeing and purging. In addition to a set of extreme, ritualized eating behaviors, sufferers commonly exhibit depression, anxiety disorders such as obsessive-compulsiveness and body dysmorphic disorder, perfectionism, distorted body image, body-checking behavior, and constant weighing. In addition, drug abuse has been found to be prevalent among people with eating disorders. Denial of illness is also characteristic of sufferers as is the valuing of symptoms. Disruption in eating patterns may begin with casual dieting, which, when successful, causes the sufferer to fixate on powerful feelings of accomplishment and personal control leading eventually to an unhealthy relationship with food and one's body.

Typology of Eating Disorders

Three primary types of eating disorders have been described: anorexia nervosa, bulimia nervosa, and binge eating disorder.

Anorexia nervosa is defined by significant weight loss, refusal to maintain a healthy weight for one's height, an obsession with food, acute anxiety about gaining weight, irregular or absent menstrual periods in females, and a distorted body image. In addition to restricting consumption, anorexics often focus their diets on a few food items that they eat in limited quantities. Sufferers report self-medicating their anxiety and relishing the feeling of control that accompanies food restriction.

Anorexia is one of the most deadly mental illnesses, with a morbidity rate as high as 10% of sufferers. It is estimated that 2.5 million Americans experience anorexia, including 0.5% to 3.7% of girls and women. Onset is most frequent during the early or middle years of adolescence, a period of rapid physical and emotional change. While anorexics restrict food intake, they report being preoccupied with it, frequently thinking, dreaming, and talking about it, while obsessively watching others eat or preparing food that they themselves avoid.

Bulimia nervosa is estimated to affect 1.1% to 4.2% of females in the United States. The disease is defined by episodes of binge eating followed by purging. Binges are characterized by the consumption of double or triple the amount of daily needed calories but can involve consuming as many as 20,000 calories at a time. Purging usually involves regurgitation but can include excessive exercise, enemas, and laxative and diuretic abuse. It is used by sufferers as a symbolic emotional cleansing or outpouring of feelings that otherwise remain silenced. While some sufferers purge to rid themselves of excess calories, the cycle is almost always triggered by emotional stress. The binge-purge cycle becomes fixed as an emotional coping method, albeit an unhealthy one, to which most of a bulimic's day is devoted.

Binge eating disorder, although not a psychiatrically affirmed illness, has been widely described and is characterized by a continued pattern of intensive eating episodes over which the sufferer experiences little control. Eating during a binge tends to be rapid, occurs when the sufferer is not physically hungry, and leads to feeling painfully full. Sufferers, who commonly feel self-distain for their behavior, often hide obsessive eating patterns, but unlike bulimics do not engage in purging. Studies have shown that 2% to 5% of the U.S. population suffers from this condition.

The term *bulimarexia* is used to denote a mixed type of eating disorder characterized by the binge-and-purge cycle of bulimia and the serious weight loss typical of anorexia. Rather than reflecting a set of fixed categories that differentiate sufferers, the eating disorder typology represents areas of symptom concentration in what is actually a more dynamic and varied reality. In addition to symptom mixing, anorexia can develop into bulimia because of an inability of anorexics to hide their restrictive tendencies in front of friends and family.

Causes of Eating Disorders

Eating disorders are the product of multiple-interacting factors, including cultural, family, psychological, and genetic factors.

Cultural Factors

Middle-class American society is characterized by a culture of abundance in which food is readily available and the ability to wield control over intake is deemed an admirable quality. As contrasted with societies characterized by food scarcity, in which a plump figure is a sign of beauty, in America, a slender, androgynous body has become a valued female physique. Expectations of thinness are reinforced by the advertisement industry. Studies of magazine content show high numbers of ads and articles about food, including recipes and accounts of the newest chic dishes. At the same time, magazines frequently give voice to social angst about obesity while exhibiting images of perfectly sculpted bodies attained through the use of exercise machines, workout routines, and an endless array of miracle diets. The cultural celebration of thinness and stigmatization of obesity are critical factors in the emergence of epidemic levels of food-related disorders in the U.S. society.

Within the United States, eating disorders traditionally have been most concentrated among upper- to middle-class, white, teenage girls. Having first come to medical attention as a disease of this social group, eating disorders have been called the modern cultural equivalent of 19th-century hysteria, as well as a type of symbolic bodily corseting that parallels the mechanical corseting of an earlier era.

Family Factors

Changing family patterns, including the loss of extended family support, and increasingly blurry family role expectations are thought to contribute to the emergence of eating disorders. Issues of control in parent-child relations are also common contributing factors. Thus, it has been argued that middle-class girls use food restriction as a means of gaining control over lives on which others, especially parents, have had a dominating influence.

Psychological Factors

Sufferers of food disorders are often described as lacking a fully developed sense of self, as self-blaming, and as people inclined toward pleasing others more than themselves. Moreover, because society has not fully accepted eating disorders as bona fide mental illnesses, sufferers are often stigmatized and become objects of derision, further amplifying self-deprecation and denial of symptoms.

Genetic Factors

Research on anorexia among female twins suggests the importance of genetic factors in eating disorders. Anorexia has been found, for example, to be twice as common among both members of identical twin sets compared with fraternal twins.

Globalization and Eating Disorders

Although eating pathologies have been a peculiarly Western and middle-class phenomenon, in recent years, they have begun appearing in non-Western countries, as well as across socioeconomic classes, ethnicities, age groups (including among the elderly), and even genders. Recent analysis has focused on the role of globalization and the diffusion of American or other Western images of the "ideal" body type as

critical elements in the changing international face of eating disorders.

In recent U.S. research, the frequency of a range of eating pathology, including binge eating, restrictive eating, vomiting, and amenorrhea, has not been found to differ by ethnicity, although some symptoms, such as eating until uncomfortably full, is more common among whites and African Americas than among Latinas and Asian Americans. In addition to changes in the ethnic expression of eating disorders, the age of first symptom expression is declining rapidly. While the first appearance of anorexia in the past did not occur before age 13, today it is not uncommon among 9-year-olds.

Health Implications

There are multiple physical effects of eating disorders. Sufferers are often lightheaded and dizzy and can black out. They are commonly sad, irritable, moody, and experience memory loss and fainting. The heart of an eating disorder patient, which is starving along with the rest of the body, may have trouble pumping. This leaves the patient feeling weak and deathly cold. Their limbs often fall asleep due to poor circulation. Electrolyte shortages can cause heart palpitations and the patient may suffer from low blood pressure and a low heart rate. Losing drastic amounts of weight, especially in young people, slows the sex-hormone production rate, delaying puberty. Females who suffer from a food-related disease for prolonged periods of time can become infertile. Similarly, the muscles of food disorder sufferers in time begin to atrophy. Moreover, the bones of sufferers lack nutrients and calcium, leaving anorexics at a high risk for fracture.

Lack of fluids or dehydration can lead to organ failure, while death by starvation or related causes occurs in 10% to 15% of cases.

Treatment and Prognosis

Despite having a poor prognosis, eating disorders are treatable. Treatment includes a combination of methods to address the diverse aspects of the disease. Treatment usually involves a two-pronged approach that focuses both on weight restoration through adherence to a prescribed (and monitored) meal plan as well as on the patient's emotional turmoil with psychotherapy. Depending on the severity of the eating disorder, the patient can be treated in an inpatient clinic or through outpatient therapy. An extensive variety of therapeutic techniques and methods are employed in the treatment of individuals with eating disorders although best practices are in debate. The time period between the initiation of treatment and a return to ideal body weight and healthier eating patterns is approximately 1 year.

Eco-Epidemiology

Eco-epidemiology is an emergent area in the evolution of modern epidemiology, rooted in a new public health scientific paradigm that postulates an integrated approach to investigating disease and its prevention by subsuming levels of causation, life course trajectories, kinds of causes, and types of diseases. By incorporating this way of thinking about causes at multiple levels of organization and within the historical context of both societies and individuals, eco-epidemiology advances the adoption of a unified framework to the different domains of the discipline, emphasizing the ties that bind epidemiology to public health and implying a major shift in what qualifies as rational public health practice.

The emergent era of eco-epidemiology arises from the escalating recognition of constraints and prevailing

criticisms of the current era of chronic disease epidemiology, with its dominant risk-factor paradigm. It also emerges from the growing strength of molecular epidemiology on the one side and of social epidemiology on the other side of the determinants of health model. A fundamental charge against the current paradigm of the present era is its general neglect of the social environment in which disease occurs: It conceives risk for disease as residing largely within individuals and their personal behavior. Under the single-level, risk-factor paradigm, questions about macrolevel social and physical environments or microlevel mediators and antecedents are difficult to frame: Inattention to context leads to a limited and precarious knowledge base for public health action. In addition, description of risk-factor/disease associations—increasingly related to small effects detection, particularly vulnerable to indeterminacy from confounding and bias—are afforded priority over the explanation of causal processes and linkages between them; hence the black box analogy.

Molecular epidemiology focuses on biological mechanisms of disease and social epidemiology on societal determinants of disease. Caught between biology and society, risk-factor epidemiology deals with the middle ground of behaviors and exposures. Eco-epidemiology, also known as *multilevel epidemiology*, recognizes these three levels of organization—the micro, the macro, and the individual—as equally fundamental to the purview of public health epidemiology. In other words, eco-epidemiology explicitly reminds that molecular, lifestyle, and societal explanations of disease are interconnected and reciprocally reinforcing, not mutually exclusive, competing alternatives to understand disease causation and to advance the cause of public health. More specifically, eco-epidemiology not only advocates this paradigm in the interpretation of findings from epidemiological research, but also by including into epidemiological study designs direct measures representing the disease process at each level.

Eco-epidemiology contends that fruitful theories of disease causation and pathogenesis can, in principle, be conceptualized at all levels of organization. Since detectable causes differ across levels, theories at different levels may each point to distinct understandings of disease and prevention. Eco-epidemiological study designs that incorporate individual-level exposures, group-level exposures, individual-level health outcomes, and group-level health outcomes that are explicitly defined and related to each other are notoriously complex—a reflection of a relentlessly multilevel, multicausal, multivariable world. It has been argued that this likely complexity may go against the epidemiologist's justified desire for parsimony. Conversely, in its unifying effort, it adds to the coherence of epidemiology. It also calls for a broader multidisciplinary thought collective and a greater methodological pluralism.

The paradigm shift that is shaping the emergent eco-epidemiology era has four basic premises:

1. Causes of disease occur at all levels of organization.
2. Causes of disease can be distinct at different levels of organization.
3. Different levels interrelate among each other in ways that can mutually influence the play of causes of diseases at each level.
4. At any given time, patterns of disease and health states are the result of dynamic antecedent processes; that is, causes of disease are historically contingent.

Consistent with the concept of emergent group properties, at each ascending level of organization, distinctive characteristics confined to that level emerge. The prevalence of an infectious disease in the population and the magnitude of income inequality are two classical examples of unique group-level attributes from the fields of infectious disease epidemiology and social epidemiology, respectively. Both prevalence of infection and income inequality are inherently unique group attributes and can be studied only at the group level, using individual-level characteristics to control for the effect of other influences. If these group-level variables are not included in the model, it will be impossible to estimate the contextual effects of infectious disease or social determinants of health in a valid way.

Proponents of eco-epidemiology, thus, recognize that epidemiology is in transition from a science that identifies risk factors for disease to one that analyzes the systems that generate patterns of disease in populations, by considering multiple levels of causation, investigating the interplay between genetic and environmental factors, examining the trajectory of health and illness over the life course, and proposing a broader and more unified framework to understand

health production. Eco-epidemiology addresses the interdependence of individuals and their connection with the biological, physical, social, and historical contexts in which they live. To do so, it encompasses the changeable contributions and effects on the individual level of both macrolevels (i.e., societal) and microlevels (i.e., molecular) of organization. Firmly rooted in the concerns of public health, the aim is to study multiple relationships across levels that would contribute to the expansion of the understanding of disease processes. It is expected that under this emergent paradigm shift, epidemiology will be rooted in the investigation of the pathways by which biological and social experiences generate health and disease, and will be equipped to identify the impact of biological and social changes on the health of the populations.

Ecological Fallacy

Relationships observed for groups do not necessarily hold for individuals, and vice versa. The *ecological fallacy* is a fallacy in ecological studies that may arise when an investigator makes an inference about an individual based on aggregate data for a group. In ecological studies, we assess the relation between exposure rates and event rates at group level because we know only marginal distributions of exposure (risk factor) and outcome event and not their joint distributions. Researchers have made unwarranted inferences from the association between exposure to risk factor and outcome event among groups (ecological data) to association among individuals within each group without accounting for the possible ecological bias. Aggregating data loses information. The ecological fallacy may arise because the process of aggregating data may conceal the variations that are not visible at the larger aggregate level (see explanation in Example 2 below). Statistically, a correlation tends to be larger when an association is assessed at the group level than when it is assessed at the individual level.

Example 1: Nativity and Literacy

Robinson calculated the correlation coefficient between nativity (represented by the percentage of the population who are foreign-born) and literacy (represented by the percentage of the population who are literate) for the 48 states in the United States of 1930 to be .53, a positive correlation. This is an ecological correlation because the unit of observation and analysis is the state. But when computed at the individual level, the correlation coefficient turns out to be −.11, a negative coefficient! The fallacy arises because the foreign-born tend to live in states where the native-born are more literate.

Example 2: Blood Pressure and Stroke Mortality

In the Seven Countries Study, Menotti et al. (1997) found that the mean entry-level blood pressures and stroke mortality rates were highly inversely correlated for 16 cohorts of men aged 45 to 59 with 25-year follow-up. This is contrary to the expectation. So the analyses were repeated at the individual level within cohorts, the association between blood pressure and stroke mortality was then found to be strongly positive among most of the cohorts, and hence the correlation for all individuals should have been positive. The explanation of this paradox is that within each cohort, individuals who had had and had died from stroke tend to have had high blood pressure, but when the individual values in each cohort were averaged and the 16 pairs of average values were used to calculate the correlation, the cohorts with higher average blood pressures may have turned out to have smaller mortality rates simply because of the heterogeneity of correlations among the cohorts.

Example 3: Breast Cancer and Fat Consumption

Carroll found that death rates from breast cancer were significantly higher in countries in which fat consumption was high than in those in which fat consumption was low. This is an association for aggregate data, for the unit of observation is country. When inference is made to individual-level association, saying that if countries with more fat in the diet have higher rates of breast cancer, then women who eat fatty foods must be more likely to get breast cancer, an ecological fallacy may be committed because one cannot be certain that the breast cancer cases had high fat intakes. In fact, the problem of ecological fallacy on the link between breast cancer and fat intake was raised by Holmes et al. (1999) when they examined the individual-level data.

The ecological fallacies in the three examples above arise from assuming that all individuals in each ecological group have the same summary measure (the mean value) of the group without accounting for possible confounding by other variables and for the unobserved heterogeneity of individuals in each group. In view of this, when statistically significant association is found between exposure and health outcome at group level (usually aggregate data are easily assessable as they already exist, having been previously collected for other purposes), then individual-level data should be collected to obtain the joint distributions of exposures and outcomes. This would make it possible to test the ecological hypothesis thus generated so as to corroborate or refute the putative ecological association at the individual level. This is because for causal inference, individual data are required to account for population heterogeneity and confounding bias.

More generally, the ecological fallacy may be defined as the fallacy of drawing inferences regarding relationship for units defined at a lower level (such as individuals) based on data collected for units at a higher level (such as groups). In contrast to the ecological fallacy is the less well-known counterpart, the *atomistic fallacy*, which refers to the influence that associations found at the individual level that will necessarily hold at the group level or, more generally, the fallacy of drawing inferences regarding relationship for units defined at a higher level (such as groups) based on data collected for units at a lower level (such as individuals). The atomistic fallacy occurs when characteristics of higher levels are distributed to all lower-level units without taking into account the dependency of the observations among the lower units within each higher-level unit, so that factors that explain variability among lower-level units within higher-level units may differ from those explaining variability across higher-level units.

To avoid both ecological and atomistic fallacies, use may be made of multilevel analysis to separate the total variation in the outcome variable into that part due to variability among lower-level units and that due to variability among higher-level units so as to uncover the true relationship between exposure and outcome.

Economic Evaluation

Economic evaluations involve the quantification of changes in health resource utilization due to the introduction of new courses of action. Policymakers are increasingly turning to such analyses to acquire information before making decisions about alternatives in health care. Such analyses are used by insurers to determine which services to pay for, and government policy analysts use technology assessments to shed light on the economics of new interventions and courses of action. Economic evaluations are used by policymakers and analysts to make systematic decisions concerning the allocation of resources in the market.

There is a growing literature on economic evaluation in health care. Although the studies vary in quality, several good introductions such as the ones by Drummond (1981) provide a basic interpretation of the nature of economic evaluation and an appreciation of the decision making required at all levels.

The Purpose of Economic Evaluations

Economic evaluations answer the following questions to provide an objective set of criteria for making choices among alternatives given scarce resources:

1. Are health services, and the like, worth doing given limited resources?
2. Are we satisfied with the way health resources are used among the different courses of action chosen?

The purpose of an economic evaluation is to compare alternative courses of action that are solutions to the same problem. Without systematic analysis, it is difficult to clearly identify the alternative uses for resources and the opportunity cost of employing one alternative over another in solving a problem. For example, Messonnier, Corso, Teutsch, Haddix, and Harris (1999) suggest that a health department may need to evaluate the efficiency of a diabetes prevention program or a bicycle helmet initiative in reducing the number of disability days in a population.

Cost

Costs are the value of the resources used for any particular course of action. The type and scope of costs depend on the analysis viewpoint (i.e., society, government, patient, employer, program agency). When in doubt, it is best to go to the broadest or societal viewpoint. The real cost of any alternative is measured not by the budgetary allocations but by the health output that could have been achieved through some other alternative that has been foregone because of the commitment of resources or inputs to the alternative in question. This cost is the opportunity cost of the alternative considered and is compared with the alternative's benefits.

Direct costs are the actual expenses incurred by participating in the alternative. This includes the medical expenses, transportation costs, and other training costs that can be part of implementing the alternative. Indirect costs are the productivity losses associated with the course of action, which reflect the opportunity costs of using one alternative and foregoing another. For example, this could include the waiting time for appointments and the transportation time as part of the participation in a course of action. In the private perspective, transfer costs are also included since they reflect changes in payments for individuals, providers, or organizations. From the societal view, direct and indirect costs are included but not transfer costs, since these are not resources used. Overall, economic costs go beyond simply listing expenditures, since opportunity costs need to be reflected.

Private Versus Societal Viewpoints

There are two general viewpoints to an economic evaluation: private and societal. The private perspective is focused on the individual, an organization, or a set of organizations. A health care organization may be interested in the cost benefit of a palliative care program versus traditional medical protocols. In this case, the firm is not interested in the transfer payments that may result by participation, since these are not paying for resources being used. Instead, the firm is concerned with its own direct and indirect costs of the courses of action and their associated outputs. The societal view includes all persons so that the

opportunity cost of the various courses of action can be taken into account. In terms of a palliative care intervention, this would include all direct and indirect costs of the courses of action and the transfer payments that may be involved as well, since they reflect the opportunity costs of pursuing one course of action versus another for the population as a whole. Economic evaluations link the alternative courses of actions' inputs and outputs and provide a comparative analysis of alternative courses of action in terms of both the value of their inputs and outputs. Without such an analysis, it is difficult to objectively justify the value for the money invested in an alternative.

Types of Economic Analyses

The type of output from the alternative courses of action can vary significantly across the methodologies.

Cost Minimization Analysis

In this case, outputs of the courses of action are assumed to be identical, and costs only are considered. For example, Evans and Robinson (1980) did a comparison of the common output of interest in the number of successful procedures at a day surgery center versus performing the procedures at an outpatient center of a hospital. Here, one may find an identical number of procedures performed but possibly different costs. The principal decision rule is focused on the costs per procedure successfully performed, where the least cost course of action is determined to be the efficient choice.

Cost-Effectiveness Analysis

In this case, the output of the courses of action is common across alternatives, but the alternatives have varying degrees of success in achieving the output. Examples by Gray and Elixhauser are the comparisons of different diabetes prevention programs. The decision rule is based on the cost per unit of output or output per unit of costs. The decision maker selects the course of action that yields the most output per dollar spent or the least cost per output. The latter decision is used when the decision maker is working within a given budget. This implies that there is a single, common affect that is constrained, and the alternatives are within the same range of scale. This analysis can be done considering any courses of action with a common output. The worth of the courses of action is assumed to be positive.

The outputs can be health effects directly or measures that show improvements in health status. For instance, one can compare a prevention program versus a chronic care program in terms of disability days saved per dollar invested in each program, as seen in the work of Hatziandreu, Koplan, Weinstein, Casperson, and Warner (1988), and Tengs, Adams, Pliskin, Safran, Siegel, and Weinstein (1995), and others. In cost-effectiveness analysis, there is a dominant dimension of success that is considered. It is important to be open to the possibility of using more sophisticated analyses, such as cost-benefit analysis, if there is more than one dimension of effectiveness.

In conducting a cost-effectiveness analysis, Drummond, O'Brien, Stoddart, and Torrance (1997) noted that several data issues should be addressed. First, the analyst must assure that there is a random allocation of patients to groups. Second, if the investigation is looking at existing literature, it is important to see how studies relate to provider expertise and patient caseload in question. Third, a sensitivity analysis, discussed later, can eliminate the need for clinical trials (especially in extreme effectiveness issues). However, if a clinical trial is used, the investigator must assure that the analysis of the clinical trial doesn't cause any deviation of normal working practices. Laupacis also notes that it is more meaningful if the results of the cost-effectiveness analysis are compared with some standard for the problem being investigated.

Cost-Utility Analysis

This is often considered a special case of cost-effectiveness analysis, where the output of the courses of action is valued commonly across alternatives, but the alternatives have varying degrees of success in achieving the value of the improvement in the output. In this case, both the output and the worth of the courses of action are measured. An example of such an analysis is the improvement in the quality-adjusted life years (QALYs) due to a diabetes intervention versus usual care. As Torrance and Feeney (1989) noted, this technique is preferred by many economists, since it incorporates the utility of the output, or in other words, the preferences of the patients or the population considered.

Utility is the value or worth of a specific health state and can be measured by the preferences of persons for any set of health states. Utility of the health output is different from the health output itself. It brings in quality-of-life adjustments for treatment output, while providing a common denominator for comparing the costs and outputs of different alternatives. The measure for utility is seen in the measures of healthy days or QALYs. Here, Sintonen (1981) and Williams (1981) note that the length of time of the health state is adjusted through a utility scale (0 to 1, with 0 = *death* and 1 = *perfect health*). The decision rule is to choose the alternative with the lowest cost per healthy year equivalent or QALY. Olsen (1994), O'Brien (1995), and Hirth, Chernew, Miller, Fendrick, and Weissert (2000) noted that willingness to pay for an additional QALY can be determined from community-based surveys. However, these surveys need to follow procedures similar to those for contingent valuation studies.

Cost-Benefit Analysis

In this case, the output of the courses of action may not be a single common effect but may be multiple effects that may or may not be common to the alternatives. For example, one could compare a health promotion program for youths with a chronic care intervention with the elderly on a variety of output dimensions. One could perform a cost-effectiveness analysis on multiple effects to determine a decision rule where an alternative is superior on all or a majority of dimensions or choose a primary effect to base the comparison.

Alternatively, one could develop a method to combine multiple effects into one common valuation. Here, the measure of value is the dollar, translating effects into the dollar value of benefits of life years gained, improved productivity, more convenience, and so on. This comparison of dollar costs to dollar benefits is cost-benefit analysis. This results in a ratio of dollar costs to dollar benefits or the sum of net social benefits, where net social benefits = social benefits − social costs. As Drummond (1981) noted, the decision rule is to choose the course of action that has the greatest net social benefits. Benefits will be large enough so that those who gain could theoretically compensate the losers, and everyone is made better off (i.e., the Pareto Principle). The preferred method is to maximize net benefits rather than benefit/cost ratio, since the ratio can be misleading depending on how benefits and costs are categorized.

The implicit assumption is that the courses of action are compared with a do-nothing alternative. However, in health care, since there are usually costs involved in do-nothing states, this is not usually done in practice. The valuation of the benefits can be done through the human capital method or the contingent valuation framework. The instrument depends on the purpose of the evaluation.

Viscusi's (1995) human capital method places a value on the opportunity cost of lost time, such as lost wages or the value of replacement workers for duties without a wage. For example, if a person is in the labor force and needs to take time off from work due to disability, then the value of the loss of work would be measured in the wage rate. If the person is out of the labor force and has a disability that reduces the level of productivity, then the value of the loss is the cost of the replacement worker who has to complete the tasks no longer completed by the person in question. In many ways, this approach is debatable among economists, since wages underestimate the total loss of time, particularly leisure time. Also, the approach favors the employed rather than those out of the labor market, which leads to inequities in compensation. Contingent valuation is what one would hypothetically pay if one could achieve the benefits from specific interventions.

Since the Pareto Principle is satisfied hypothetically, cost-benefit analysis traditionally doesn't account for income redistribution. Redistribution takes the form of taxes and transfers and can be criticized as inefficient. In practice, such as welfare reform plans, redistributional effects have been explicit, where the most general procedure is to classify the benefits and costs on a person-by-person or group-by-group basis.

EFFECTIVENESS

Effectiveness is the extent to which a particular health technology (medical device, drug, procedure, health program, or health service, including interventions) does what it is intended to do (i.e., leads to a beneficial health outcome or result) when it is provided under clinical practice conditions or in the field.

The basic conceptual difference between effectiveness and efficacy of a given medical technology lies in the conditions under which it is provided and estimated. Efficacy refers to its benefits when it is deployed under ideal conditions (under the highest possible control of variables) and effectiveness when it is provided under realistic conditions, such as those encountered in clinical practice.

The effectiveness of a particular health technology can be established or estimated by means of different quasi-experimental and observational study designs. The selection of a study type to estimate the effectiveness of a given health technology depends, among other factors, on the objectives of the study, the conditions under which it has to be carried out, and the availability and the type of data that must be observed.

It is important to clearly distinguish among effectiveness, efficacy, and efficiency (the relationship between the cost or the resources used to provide a specific treatment, intervention, program, or procedure and the results obtained), since they are often confused.

In practice, efficacy and effectiveness of the same medical technology differ, and the former should not be necessarily considered an accurate estimate of the latter. For example, the efficacy of a vaccine or a drug, estimated in a randomized controlled trial, tends to be higher than its effectiveness. The degree of control of variables that is usually attained during the administration of a vaccine or a drug in a randomized trial can almost never be reached during their administration in clinics, primary health care centers, or hospitals. Reasons why the health benefits expressed by efficacy are greater than those referred by effectiveness often include the following:

- The cold chain can fail (i.e., the drug may not be stored at the proper temperature).
- Doses of the active principle of the drug contained in the tablets may vary.

- The clinical characteristics of patients may differ from those of the individuals who participated in the randomized trial, or the spectrum of the disease covered can be different.
- Patient compliance to the prescribed treatment regime is difficult to control, and the degree of adherence often changes according to different factors related to the patient's psychological profile or educational level, the mechanisms for providing health care, accessibility of health services, or, in general, the way in which health services are delivered.

Examples of endpoints (primary or secondary events observed in a patient during the course of a treatment or in a health program during its implementation) usually used to estimate effectiveness are as follows: the 1-year survival rate of patients with a particular type of neoplasm treated with chemotherapy in an outpatient service at a university hospital, the percentage of hypertensive patients with systolic and diastolic pressure adequately controlled after 1 year of treatment in a primary health care center, the 5-year death rate of women enrolled in a breast cancer early detection program, and the postoperative infection rate in surgical patients enrolled in an antibiotic prophylaxis for surgical infections program.

Effect Modification and Interaction

The term *effect modification* has been applied to two distinct phenomena. For the first phenomenon, effect modification simply means that some chosen measure of effect varies across levels of background variables. This phenomenon is thus more precisely termed *effect-measure modification*, and in the statistics literature it is more often termed *heterogeneity* or *interaction*. Referring to the second phenomenon, effect modification means that the mechanism of effect differs with background variables, which is known in the biomedical literature as *dependent action* or (again) "interaction." The two phenomena are often confused, as reflected by the use of the same terms (effect modification and interaction) for both. In fact, they have only limited points of contact.

Effect-Measure Modification (Heterogeneity)

To make the concepts and distinctions precise, suppose we are studying the effects that changes in a variable X will have on a subsequent variable Y, in the presence of a background variable Z that precedes X and Y. For example, X might be treatment level such as dose or treatment arm, Y might be a health outcome variable such as life expectancy following treatment, and Z might be sex ($1 = female$, $0 = male$). To measure effects, write Y_x for the outcome one would have if administered treatment level x of X; for example, if $X = 1$ for active treatment, $X = 0$ for placebo, then Y_1 is the outcome a subject will have if $X = 1$ is administered, and Y_0 is the outcome a subject will have if $X = 0$ is administered. The Y_x are often called *potential outcomes*.

One measure of the effect of changing X from 0 to 1 on the outcome is the difference $Y_1 - Y_0$; for example, if Y were life expectancy, $Y_1 - Y_0$ would be the change in life expectancy. If this difference varied with sex in a systematic fashion, one could say that the difference was modified by sex, or that there was heterogeneity of the difference across sex. Another common measure of effect is the ratio Y_1/Y_0; if this ratio varied with sex in a systematic fashion, one could say that the ratio was modified by sex.

For purely algebraic reasons, two measures may be modified in very different ways by the same variable. Furthermore, if both X and Z affect Y, absence of modification of the difference implies modification of the ratio, and vice versa. As a simple example, suppose for the subjects under study $Y_1 = 20$ and $Y_0 = 10$ for all the males, but $Y_1 = 30$ and $Y_0 = 15$ for all the females. Then $Y_1 - Y_0 = 10$ for males but $Y_1 - Y_0 = 15$ for females, so there is a 5-year modification of the

difference measure by sex. But suppose we measured the effects by expectancy ratios Y_1/Y_0, instead of differences. Then $Y_1/Y_0 = 20/10 = 2$ for males and $Y_1/Y_0 = 30/15 = 2$ for females as well, so there is no modification of the ratio measure by sex.

Consider next an example in which $Y_1 = 20$ and $Y_0 = 10$ for all the males, and $Y_1 = 30$ and $Y_0 = 20$ for all the females. Then $Y_1 - Y_0 = 10$ for both males and females, so there is no modification of the difference by sex. But $Y_1/Y_0 = 20/10 = 2$ for males and $Y_1/Y_0 = 30/20 = 1.5$ for females, so there is modification of the ratio by sex.

Biologic Interaction

The preceding examples show that one should not in general equate the presence or absence of effect-measure modification to the presence or absence of interactions in the biologic (mechanistic) sense, because effect-measure modification entirely depends on what measure one chooses to examine, whereas the mechanism is the same regardless of that choice. Nonetheless, it is possible to formulate mechanisms of action that imply homogeneity (no modification) of a particular measure. For such a mechanism, the observation of heterogeneity in that measure can be taken as evidence against the mechanism (assuming, of course, that the observations are valid). It would be fallacious, however, to infer that the mechanism is correct if homogeneity was observed, for the usual reason that many other mechanisms (some unimagined) would imply the observation.

A classic example is the simple "independent action" model for the effect of X and Z on Y, in which subjects affected by changes in X are disjoint from subjects affected by changes in Z. This model implies homogeneity (*absence* of modification by Z) of the average X effect on Y when that effect is measured by the difference in Y (if Y is a disease indicator, the average of Y is the risk, and the average Y difference is the risk difference). If X and Z both have effects, this homogeneity of the difference forces ratio measures of the effect of X on Y to be heterogeneous across Z. When additional factors are present in the model (such as confounders), homogeneity of the risk differences can also lead to heterogeneity of the excess risk ratios.

Biologic models for the mechanism of X and Z interactions can lead to other patterns; for example, certain multistage models in which X and Z act at completely separate stages of a multistage mechanism can lead to homogeneity of ratios rather than differences, as well as particular dose-response patterns. Special caution is needed in interpreting observed patterns, however, because converse relations do not hold: Many different plausible biologic models will imply identical patterns in the effect measures.

Taking the independent-action model as a baseline, one may offer the following *dependent-action* definitions for an outcome indicator Y as a function of the causal antecedents X and Z. *Synergism* of $X = 1$ and $Z = 1$ in causing $Y = 1$ is defined as necessity and sufficiency of $X = 1$ and $Z = 1$ for causing $Y = 1$; that is, $Y = 1$ if and only if $X = 1$ and $Z = 1$. We also may say that $Y = 1$ in a given individual would be a synergistic response to $X = 1$ and $Z = 1$ if $Y = 0$ would have occurred instead if either $X = 0$ or $Z = 0$. In potential-outcome notation where Y_{xz} is the outcome when $X = x$ and $Z = z$, this definition says synergistic responders have $Y_{11} = 1$ and $Y_{10} = Y_{01} = Y_{00} = 0$. *Antagonism* of $X = 1$ by $Z = 1$ in causing $Y = 1$ is defined as necessity and sufficiency of $Z = 0$ for $X = 1$ to cause $Y = 1$. This definition says synergistic responders have $Y_{10} = 1$ or $Y_{01} = 1$ or both, and $Y_{11} = Y_{00} = 0$.

With these definitions, synergism and antagonism are not logically distinct concepts, but depend on the coding of X and Z. For example, switching the labels of "exposed" and "unexposed" for one factor can change apparent synergy to apparent antagonism, and vice versa. The only label-invariant property is whether the effect of X on a given person is altered by the level of Z (action of X depends on Z); if so, by definition we have biologic interaction. Absence of any synergistic or antagonistic interaction among levels of X and Z implies homogeneity (*absence* of modification by Z) of the average X effect across levels of Z when the X effect is measured by the differences in Y across levels of X. The converse is, however, false: Homogeneity of the difference measures (e.g., lack of modification of the risk difference) does not imply absence of synergy or antagonism, because such homogeneity can arise through other means (e.g., averaging out of the synergistic and antagonistic effects across the population being examined).

A more restrictive set of definitions of interactions is based on the sufficient-component cause model of causation. Here, *synergism* of the indicators X and Z is defined as the presence of $X = 1$ and $Z = 1$ in the

same sufficient cause of $Y = 1$, that is, the sufficient cause cannot act without both $X = 1$ and $Z = 1$. Similarly, *antagonism* of $X = 1$ by $Z = 1$ is defined as the presence of $X = 1$ and $Z = 0$ in the same sufficient cause of $Y = 1$. These definitions are also coding dependent.

The use of indicators in the above definitions may appear restrictive but is not. For example, to subsume a continuous outcome T such as death time, we may define Y_t as the indicator for $T \leq t$ and apply the above definitions to each Y_t. Similar devices can be applied to incorporate continuous exposure variables. The resulting set of indicators is, of course, unwieldy and in application has to be simplified by modeling constraints (e.g., proportional hazards for T).

Noncausal (Statistical) "Interaction"

Both the preceding usages of "effect modification" and "interaction" refer to causal phenomena. In the statistics literature, "interaction" is often used without explicit reference to causality. For example, in the context of regression modeling, an "interaction term" is usually nothing more than a term involving the product of two or more variables. Consider a logistic regression to predict a man's actual sexual preference A ($A = 1$ for men, 0 for women) from his self-reported preference R and the interviewer's gender G ($G = 1$ for male, 0 for female),

$$Pr(A = 1|R,G) = \text{expit}(\alpha + \beta R + \gamma I + \delta RI),$$

where $\text{expit}(x) = e^x/(1 + e^x)$ is the logistic function. Such a model can be useful in correcting for misreporting. The term δRI (or sometimes just RI or just δ) is often called an *interaction term*. It is, however, more accurately called a *product term*, for presumably neither self-report nor interviewer status has any causal effect on actual preference and, thus, cannot interact causally or modify each other's effect (since there is no effect to modify).

If $\delta \neq 0$, the product term implies that the regression of A on R depends on I: For male interviewers the regression of A on R is

$$\begin{aligned} Pr(A = 1|R,G = 1) &= \text{expit}(\alpha + \beta R + \gamma 1 + \delta R1) \\ &= \text{expit}(\alpha + \gamma + (\beta + \delta)R), \end{aligned}$$

whereas for female interviewers the regression of A on R is

$$\begin{aligned} Pr(A = 1(|R,G = 0) &= \text{expit}(\alpha + \beta R + \gamma 0 + \delta R0) \\ &= \text{expit}(\alpha + \beta R). \end{aligned}$$

Thus, we can say that the gender of the interviewer affects or modifies the logistic regression of actual preference on self-report. Nonetheless, since neither interviewer gender nor self-report has an effect on actual preference (biologically or otherwise), they have no biologic interaction.

When both the factors in the regression do causally affect the outcome, it is common to take the presence of a product term in a model as implying biologic interaction and, conversely, to take absence of a product term as implying no biologic interaction. Neither inference is correct: The size and even direction of the product term can change with choice regression model (e.g., linear vs. logistic), whereas biologic interaction is a natural phenomenon oblivious to our choice of model for analysis. Assuming no bias is present, however, a product term in a linear statistical model for a causal dependency can arise only from the presence of biologic interaction in the dependent-action sense.

Efficacy

Efficacy is the extent to which a particular health technology (medical device, drug, procedure, health program, or health service, including interventions) does what it is intended to do (i.e., a beneficial health outcome or result) under ideal conditions. For instance, clinical trials, which are conducted with a selected population and during which subjects may be monitored more closely than they would be in a clinical practice, can establish the efficacy of a health technology.

In fact, these ideal conditions are similar to those sought in conducting experimental research. Therefore, efficacy can be determined or estimated on the basis of the design, the analysis, the conduct, and the results of randomized controlled trials. The characteristics of properly designed and conducted randomized controlled trials make it possible to attain the highest possible control of variables, and to minimize biases as well as other threads to their internal validity. For these reasons, this type of study design can reproduce the closest conditions to the ideal. Of course, the results obtained under the artificial conditions of a clinical trial may not be replicated in ordinary clinical practice, which explains why the efficacy of a treatment is often higher than its efficiency.

Efficacy is calculated using defined endpoints that are primary or secondary events observed in a patient during the course of a treatment or in a health program during its implementation. Examples of endpoints used to estimate efficacy in randomized trials include 1-, 3-, or 5-year survival after the administration of chemotherapy; the number of people immunized after the administration of a vaccine to a group of individuals at risk of becoming infected; the death rate at the end of a randomized trial in patients receiving a drug for lowering hypertension (compared with the death rate of those receiving placebo or other drugs in the control arm of the trial); reduction of the mortality rate from myocardial infarction at the end of the Multiple Risk Factor Intervention Trial; the viral load and the adherence rate among nonadherent HIV-infected patient groups receiving different prescribed regimes of antiretrovirals; and the 24-hr pain relief response to sumatriptan and naproxen in a double-blind, two-arm controlled trial to determine the efficacy of sumatriptan for the acute treatment of migraine.

It is important to clearly distinguish among efficacy, effectiveness (results obtained under realistic conditions, such as in regular medical practice), and efficiency (the relationship between the cost or the resources used to provide a specific treatment, intervention, program, or procedure and the end results obtained), since they are often confused. The basic difference between efficacy and effectiveness of a given medical technology lies in the conditions under which it is provided and estimated: Efficacy refers to benefits when it is deployed under ideal conditions and effectiveness when it is provided under field conditions—that is, those encountered in clinical practice.

Ehrlich, Paul (1854–1915)

Paul Ehrlich was immensely important in the fields of chemistry, immunology, and histology. Perhaps his greatest contribution to public health was his discovery of Salvarsan, also known as 606, the first organic antisyphilitic. Martha Marquardt, his secretary for 13 years, describes his life as "one long fight for the promotion of medical science in the service of mankind" (Marquardt, 1951, p. vi).

Born on March 14, 1854, in Strehlen, Germany, to prosperous innkeepers Ismar and Rosa, Ehrlich's fascination with science was fostered from an early age by his grandfather, a natural scientist, and his cousin, Karl Weigert, a bacteriologist. Ehrlich excelled in

Latin and the sciences throughout school, earning a Doctor of Medicine degree at Leipzig in 1878.

A fervent researcher, nearly all Ehrlich's waking hours were consumed with planning, executing, or contemplating his latest experiment. Though he spent time—at least early in his career—treating patients, it was always the histology and inquiry into the staining of tissues with aniline dyes (to differentiate cell types) that intrigued him most. His methods led to the development of the Gram stain many years later.

After Robert Koch's discovery of the tuberculosis bacillus in 1882, Ehrlich set out to stain the organism and succeeded quickly. Thus began a partnership between Ehrlich and Koch, as well as the capability for rapid diagnosis of tuberculosis, even in the absence of symptoms. Ehrlich contracted the disease during his research and spent 2 years recovering in Egypt. In 1889, Ehrlich returned to science and began working in Koch's newly established Institute for Infectious Disease in Berlin. It was there in 1892 that colleague Emil von Behring discovered the diphtheria antitoxin. It was Ehrlich, however, who optimized the practical use of the serum when he quantified dosage in terms of a standardized measurement obtained through animal studies. This procedure became standard protocol in vaccine development.

Ehrlich's work led him to the formulation of the side-chain theory, his explanation of antibody production. Ehrlich postulated the existence of cellular receptors that attract foreign chemicals and bind them specifically. Once bound, if the chemical did not kill the cell, Ehrlich believed the cell would produce many more receptors, some of which would separate and float through the bloodstream to become antibodies. Ehrlich also worked to find compounds he termed *magic bullets*, which could target pathogenic organisms and destroy them without harming the surrounding host tissues. Ehrlich recognized antibodies as a natural magic bullet and sought to synthesize similar agents to kill trypanosomes and spirochetes. He called this field "chemotherapy" to distinguish it from the prevailing drug research of the day in which investigators sought to remedy symptoms rather than destroy the causative agent. In 1908, Ehrlich was awarded the Nobel Prize in Medicine for his work in immunity.

It was at the Institute for Experimental Therapy in Frankfurt, of which Ehrlich was director from 1899 to 1915, where he made his most famous discovery, Salvarsan. Ehrlich worked to create derivatives of Atoxyl (arsanilic acid), an effective but toxic drug. He produced and tested hundreds of compounds, including 606, which was initially deemed ineffective by an assistant. Two years later, a Japanese apprentice, Sahachiro Hata, used 606 to treat *syphilis-infected rabbits* and found it to be highly efficacious. After repeated tests in a variety of animal models, Ehrlich and Hata announced the finding to the world, and soon after, they were inundated with requests from physicians to begin clinical testing. The drug proved much safer and more successful than mercury or other common treatments available at that time and was given the name Salvarsan. Though supplanted by penicillin in the 1940s, Ehrlich's discovery greatly reduced the prevalence and negative sequelae of syphilis and yaws worldwide and paved the way for chemotherapeutic investigation as we know it today.

In 1914 as World War I began, Ehrlich's health began to falter and he suffered a minor stroke in December. He died on August 20, 1915, after a second stroke.

Marquardt, M. (1951). *Paul Ehrlich.* New York: Henry Schuman.

Emerging Infections

Although emerging infections is a relatively new field of study, many of the diseases it researches have beset mankind for centuries and, along with new emerging infections, are the direct causes of more than 15 million deaths worldwide each year. Millions more die as a result of prior infections such as streptococcal rheumatic heart disease or because of the complications associated with chronic infections.

Among the "plagues" or "pestilences" familiar to students of history are the Black Death, which is believed to have killed up to half the population of medieval Europe, and smallpox and measles, which

are known to have decimated indigenous populations of North and South America when imported by European conquerors, causing millions of deaths and destroying entire civilizations. More recently, the Spanish influenza of 1918 to 1919 was responsible for more than 50 million deaths worldwide. Indeed, a soldier fighting in the trenches of World War I was more likely to be killed by influenza than by a bullet. Emerging infections that are presently at the forefront of medical and epidemiological research include severe acute respiratory syndrome (SARS), HIV/AIDS, West Nile virus, and avian (bird) influenza.

Definitions

Emerging infections can be defined as infections that have recently appeared within a population or that may have existed before but are rapidly increasing their geographic range and prevalence. They may be further classified as newly emerging infections, reemerging infections, or deliberately emerging infections.

Newly Emerging Infections

Newly emerging infections are diseases that have not previously appeared in humans. One such disease is HIV/AIDS, which is believed to have made the leap from animals to humans between 60 and 70 years ago, possibly as a result of contact with infected chimpanzees. To date, human immunodeficiency virus (HIV), the virus that causes AIDS, has infected more than 60 million people worldwide, most living in developing countries, and 70% living in sub-Saharan Africa. With as much as 25% to 30% of the adult population infected, life expectancies have fallen dramatically in many of these countries. Since the appearance of the first recognized case in December 1981, more than 25 million have died of the disease, causing socioeconomic devastation in many populations. While antiretroviral drugs have been developed, there is no cure for the disease, and most of its victims have no access to the treatment.

Reemerging Infections

Reemerging infections are ones that have existed in the past but are undergoing a rapid resurgence in incidence or geographical and host range. Among the most deadly is the tuberculosis (TB). Recognized among humans as far back as 4000 BCE, it was an incurable disease that, in the 19th and early 20th centuries, struck especially hard at the urban poor population. It was not until 1906 that an immunizing agent was developed, and only in 1921 was it used successfully in humans. The development of the antibiotic streptomycin in 1946 provided a treatment for those already suffering from the disease, replacing sanatoria and often draconian surgical interventions.

With the availability of vaccine and treatment, many hoped that tuberculosis could finally be eradicated. However, in the 1980s, drug-resistant strains began to appear, aided in part by failure of patients to complete the full course of drugs. The resulting reemergence of the disease has led to the infection of as many as one third of the world's population. Factors such as the prevalence of HIV/AIDS make entire populations more susceptible to infection with TB. Of special concern is the emergence of multiple drug-resistant strains of TB.

Deliberately Emerging Infections

These infections are caused by microbes that have been developed or adapted by man, generally for belligerent uses. Their intentional spread is considered to be bioterrorism. And while terrorists have historically relied primarily on more accessible and conventional weapons such as guns and explosives to further their objectives, biological weapons are becoming increasingly available. They allow terrorists to move from low-casualty, high-visibility attacks to mass-casualty attacks for which biological weapons are especially suited. Bioterrorist agents may include naturally occurring microbes, or bioengineered organisms deliberately designed to cause the greatest possible harm. Only two bioterrorist events have occurred in the United States. The first was on September 9, 1984, when a religious cult, the Rajneeshees, sprayed *Salmonella typhimurium* on salad bars in The Dalles, Oregon, causing 751 cases of food poisoning but no deaths. The second attack occurred in September 2001, when *Bacillus anthracis* spores were distributed through the U.S. Postal Service, leading to 22 cases of anthrax infection and 5 deaths. Whereas they used a chemical agent in their 1995 subway attack in Tokyo, the religious extremist group Aum Shinrikyō had earlier attempted to use anthrax and botulinum toxin.

Evidence of Al Qaeda's interest in bioterrorism raises the specter of uncontrollable global pandemic.

Moreover, because the bioengineering of microbes makes it possible to significantly increase the deadliness of a disease and the efficiency of its delivery, even diseases that previously occurred naturally, such as smallpox, could become untreatable.

Emergence and Transmission

Many factors influence patterns of emergence and transmission in emerging infections. Most pathogens have been present in the environment without causing serious illness until an opportunity arose for them to infect new populations. Thus, a pathogen in animals (a zoonosis) may become transmittable to humans. Such pathogens include West Nile virus and the avian H5N1 influenza virus. Most mutations in virus strains are minor, resulting in "antigenic drift" over an extended time period. Occasionally, however, strains will mutate significantly, resulting in "antigenic shift" that creates a disease to which humans are susceptible.

The likelihood of transmission to a human host is increased by close proximity between infected animals and humans. Thus, recent human cases of avian influenza are believed to have been a result of human contact with chicken feces and secretions among people who live with or handle affected poultry.

Additional factors in the emergence and transmission of infectious diseases include many in which humans are implicated. Sudden changes in the environment caused by agricultural development, deforestation, and overgrazing can tip the balance in favor of diseases such as Rift Valley fever and schistosomiasis, which are caused by damming rivers, or pulmonary hantavirus syndrome, which struck in the southwestern United States in 1993 as a result of drought and human activities.

Human demographic factors are another source of infection emergence and transmission. The dramatic rise of global travel and commerce was instrumental in introducing the SARS virus to Canada in 2003 when people who had been to China and become infected flew into airports carrying the disease. Smuggling of infected birds and poultry between countries has spread avian influenza among birds, while their natural migrations have led to additional spread of the disease. Population upheavals caused by mass migration or war are further contributors to disease emergence and spread.

Behavior that encourages the emergence and spread of infectious diseases among humans includes intravenous drug use, behaviors that cause the spread of sexually transmitted disease, and drug resistance frequently caused by noncompliant patients. This drug resistance can, as in the case of tuberculosis, turn a formerly curable disease into a pandemic. Such resistance can also lead to reemerging infection when the transmitting hosts develop resistance to the treatment or prevention, as in the case of malaria, which had been held in check by the extensive spraying of pesticides to kill mosquitoes that transmit the disease.

Other factors, including high-density urban living, food mass production, and failures of public health measures and infrastructures, play an important part in the emergence and transmission of infectious disease. Frequently, a number of these factors combine to create a situation like the resurgence of cholera in South America and Africa, possibly as a result of water treatment failure, drought, and civil tensions. And, as we noted above, intentional release of disease into populations, such as in the anthrax cases of 2001 in the United States, are causing increasing concern.

Responses to Emerging Infections

Any treatment of emerging infections must depend on comprehensive surveillance, rapid diagnosis of disease, and implementation of containment strategies. Concern over emerging infections such as avian influenza and hepatitis C has led to concerted efforts to develop appropriate response systems. The continuing efforts at developing effective retroviral therapy for emerging infections have resulted in multiple treatments for HIV/AIDS patients, as well as a number of drugs that may be useful in response to pandemic influenza.

Vaccines are the most effective method of preventing disease when they are available. However, millions who have no access to preventive treatment still die of vaccine-preventable diseases every year. Because emerging infections are, by their very nature, new and/or constantly evolving and developing resistance to treatment, ongoing research and development of new vaccines are crucial to the health of the public. Vaccine development and production technologies must keep pace with emerging infections and the needs of the populations that suffer from them.

Environmental and Occupational Epidemiology

Environmental and occupational epidemiology are subdisciplines of epidemiology and use the same standard epidemiologic research approaches, study designs, and analytical methods in estimating disease occurrence, relative risk, and statistical variability. These two disciplines focus on studying the effects on human health attributable to chemical, particulate, metallic, physical, infectious, and psychosocial agents in the workplace and general environment. Occupational and environmental epidemiology involves a wide variety of methodological techniques that are used to evaluate associations between workplace or community exposures and health outcomes. This entry reviews the study designs used in occupational and environmental research and also examines sources of bias in such studies.

Occupational and environmental epidemiology are closely linked by the nature of the many common exposures of concern. Epidemiologic studies in these fields often consider other factors such as genetics, nutrition, and behavioral patterns, although in the context of their confounding influence on the workplace or environmental-exposure/outcome relationship rather than as primary exposure factors. For example, in a study of radiation exposure and risk of lung cancer, smoking in this context would be considered as a confounder (not a primary risk factor), whereas in a study of health risks due to secondhand smoke, smoking by family, friends, or coworkers would be considered as an environmental or occupational exposure. Several important causal relationships have been identified through occupational and environmental research, such as benzene exposure and acute myeloid leukemia, vinyl chloride and angiosarcoma of the liver, and ultraviolet radiation and melanoma.

Diseases of concern in occupational and environmental epidemiology include virtually the entire spectrum of health events, including cancer and cardiovascular, neurological, respiratory, immunological, and dermal diseases, as well as injuries, reproductive health, and mental health. Infectious disease and nutritional disorders are typically the domain of other epidemiologic subdisciplines, but they are also studied in occupational or environmental epidemiologic research (e.g., the evaluation of health care of food-processing workers, or the evaluation of health impacts of environmental disasters [weather, earthquakes] or sociopolitical conditions [war, political unrest]). The well-known John Snow natural experiment study is a classic example of an environmental epidemiologic study, in which mortality rates of cholera were found to be attributable to different sources of residential water.

The occupational setting offers several advantages for conducting epidemiologic research. Often occupational epidemiologic study results can provide a ''sentinel'' for the potential health effects for a particular agent because exposures are often higher in the workplace and frequently are better characterized there than in the general environment. Also, because the population at risk (a workforce) can be more accurately enumerated, occupational studies may be less vulnerable to potential biases. However, because these studies examine adult working populations, certain limitations exist. Typically, only adult health issues are assessed, and since working populations generally present with a better health profile than the general public, the likelihood for detecting certain health risks may be lower than if the study were conducted in a general population. Environmental epidemiologic studies often examine involuntary exposures and can be useful in providing guidance for public health policy. Epidemiologic methods applied to occupational and environmental settings, particularly in the area of exposure assessment, will continually evolve to keep pace with rapidly changing and more complex environmental exposures.

Study Design and Analysis Issues

Most epidemiologic studies are observational; that is, researchers observe events over time or events that have already happened. Characterizing the distribution of disease is the primary focus of descriptive epidemiology, while analytic epidemiology examines the determinants—that is, potential causes and risk factors of disease. Descriptive studies provide information on patterns of disease by factors such as time, age, and gender and may provide hypotheses for testing possible explanations for the patterns observed. The two primary objectives of analytic epidemiology are to (1) identify associations of disease with possible etiological factors (e.g., occupational, environmental, or lifestyle) and (2) test hypotheses regarding etiology (causation). Analytic studies include a comparison population, thereby enabling the researcher to examine causal relationships between exposure and disease. The two most commonly used types of analytic studies used in occupational epidemiology are cohort studies and case-control studies. These designs are also used in environmental epidemiology, although because of resource limitations and other feasibility considerations, other study designs are often used in environmental epidemiology as well, including cross-sectional and ecological studies. The proportionate mortality ratio or *PMR* study design is a preliminary exploratory design that, historically, was often used in occupational epidemiology but is less relied on in current occupational research.

Cohort Studies

In cohort studies, the investigator selects exposed and nonexposed individuals and follows both groups to compare disease incidence or disease-specific mortality. In a prospective cohort study, the study population is defined contemporaneously and then followed into the future to determine disease occurrence. In a retrospective cohort study, the study population is defined to start at some point in the past and the disease occurrence is determined to the present time. The relative risk is based on a comparison of groups selected within the worker population (known as internal comparison) or by comparison of disease rates from an external population, such as the general population of a country, state, or county. The rates of disease mortality or incidence in the general population or in the internal comparison population are used to calculate a standardized mortality ratio (*SMR*) or standardized incidence ratio (*SIR*). The *SMR* or *SIR* calculated using an external population is a common measure in occupational cohort studies, and it is defined as the number of observed deaths or cases that occur in an exposed population divided by the number of deaths or cases that are *expected* to occur based on the mortality or incidence rates in the general population.

$$SMR = \frac{\text{Observed deaths in exposed group}}{\text{Expected deaths}}.$$

For the *SIR*, observed cases and expected cases are substituted for observed deaths and expected deaths. In calculating an *SMR* or *SIR*, the denominator reflects what the expected number of deaths or cases would be if the group under study had the same age, sex, and race-specific rates as the general population. Because calculations of the *SMR* or *SIR* typically rely on the distribution of age, sex, and race for the specific cohort under study, comparisons of *SMR*s or *SIR*s across different studies and cohorts should be evaluated cautiously given that the distribution of these weighting factors can vary across cohorts, resulting in an alteration of the standardized calculation.

Proportionate Mortality Ratio (PMR) or Proportionate Incidence Ratio (PIR) Studies

Another study design used in occupational epidemiology is the *PMR* study. The PMR is the ratio of the proportion of deaths due to a specific cause in an exposed group to the proportion of deaths due to the same specific cause in an unexposed group (usually state or national mortality data). The advantages of *PMR* studies relate to the relatively low cost, easy access to data, and quick availability of study results. Methodological limitations include the following: (1) exposure information that is restricted to occupation and industry as recorded on the death certificate, (2) the potential for misleading conclusions if populations with different distributions of causes of death unrelated to the exposure under study are compared, and (3) potential biases resulting from the healthy worker effect (see below). Since the direction of bias resulting from these limitations is not usually known, *PMR* studies are difficult to interpret and considered exploratory studies that are generally not relied on for causal inference.

Proportional incidence studies, which are based on disease incidence registries rather than mortality records, have similar characteristics as *PMR* studies.

A less biased approach that is recommended when only numerator data (cases only) are available is a case-control study where controls are selected from other cases of disease not thought to be related to the exposure under study.

Case-Control Studies

Another commonly used study design in occupational and environmental epidemiology is the case-control study. In this design, study participants are divided into two groups based on disease status: Cases are persons who have the disease and controls are persons who do not. Data regarding past exposures in both groups are then ascertained by a variety of methods, including interviews, questionnaires, medical records, work histories, workplace air or biomonitoring levels, industrial hygiene measurements, or job titles. The distributions of exposures between cases and controls are compared. Exposure status should not be known at the time of defining cases and controls.

Nested Case-Control Studies

In occupational epidemiology, a nested case-control study is an efficient design often used within a well-defined source cohort, generally consisting of workers employed within the same industry or occupational setting. This study base is defined a priori and is fully enumerated before or as part of the nested case-control study. Similar to population-based case-control studies, there are four primary control-sampling methods: incidence density, cumulative incidence, cumulative survival, and case base. In occupational studies, incidence density sampling may be the most appropriate control selection procedure, in which controls are selected for each case among workers who were disease free or did not have health outcome of interest at the time of the identification of the case. Control sampling may be stratified or matched according to selected factors, such as age, gender, race, or occupational group. A nested case-control study is then analyzed using standard techniques applied to the analyses of case-control studies. This design is generally more cost-effective and timely than a cohort study and may allow for more extensive and accurate exposure assessment because the ascertainment of exposure and other information may be more feasible for a smaller number of workers than what would be required for an entire cohort study. On the other hand, there may be greater potential for selection bias in nested case-control studies than cohort studies since controls are sampled from the study base. However, there is less potential for this bias than standard population-based case-control studies because eligible controls are sampled from a well-defined cohort.

Cross-Sectional Studies

A frequently used design in environmental and occupational epidemiology is the cross-sectional study. In this design, disease or other health-related characteristics and exposure are determined simultaneously at a given point in time. Generally, the results of such studies have more limitations in assessing causation than cohort or case-control studies for several reasons. Because cross-sectional studies usually do not involve a time component, the dynamic interaction between exposure and disease can be difficult to determine. In addition, cross-sectional studies are often based on prevalent rather than incident cases although incidence measures can be generated if data are collected that determine the date of disease onset. Most often, this design relies on interviews or questionnaire surveys, which can be a source of both strengths and limitations depending on the implementation of the survey. One advantage of the survey approach is the ability to collect information on exposure, disease, and confounders directly from participants. However, self-reported information can be subject to interviewer, reporting, and recall biases. Validity of information drawn from these types of surveys also can be limited due to low participation rates. In occupational research, cross-sectional designs may be useful for evaluating exposure-outcome relationships of short duration, for example, surveys of respiratory symptoms, musculoskeletal disorders, or other symptom surveys.

Ecologic Studies

In contrast to previously discussed study designs, ecologic or community-level studies use populations as units of analysis rather than individuals. These studies may, for example, compare exposure and disease profiles between geographical units such as countries or may evaluate changes in morbidity and mortality in relation to changes in potential exposure at a population level.

Ecologic studies are frequently conducted in environmental epidemiology mainly because of their low costs and reliance on more readily available and accessible data. In some cases, ecologic studies offer advantages because individual-level studies may not be practical because of exposure assessment considerations or study design issues. Also, the research question may be one that is targeted at the ecologic level, for example, what is the impact of a policy that restricts cell phone use while driving on the rate of motor vehicle crashes?

Ecologic designs have been characterized into three basic types: (1) multiple group design (mapping studies), (2) time-trend design, and (3) the combination of location and time (mixed design). Mapping studies essentially involve comparisons of disease rates across different geographic regions (e.g., variation of female breast cancer across different countries or different regions within countries). In an exploratory sense, this evaluation would not necessarily have a particular exposure under consideration but may generate hypotheses after observing certain trends. More specific hypotheses can be developed by characterizing regions by average levels of environmental risk factors (e.g., industrial emissions, air pollution, pesticide use) or nonenvironmental factors (e.g., diet, reproductive history, alcohol consumption). Time-trend analyses examine changes in disease occurrence across calendar time, and mixed designs combine both geographic and time-trend analyses.

Because of their use of aggregate-level data, ecologic studies are subject to the "ecological fallacy," the inappropriate application or interpretation of an aggregate relationship to the level of the individual. The effect estimates of an ecologic study may not reflect the biologic effect at the individual level. These studies can also be affected by in- or outmigration of the study population, which will limit the interpretation of associations from studies that define exposure in terms of time and place. For example, in a hypothetical study of the association between drinking arsenic-contaminated well water and risk of bladder cancer, the results may be biased toward the null if a large proportion of the population moved into the arsenic-endemic area from an area without arsenic-contaminated drinking water shortly before the population was analyzed. In contrast, findings may be biased upward if a population migrated from an arsenic-endemic area to a study area in which arsenic levels in community drinking water were considered low. Because of these and other limitations, results of ecologic studies are used mainly for the generation of hypotheses and are given much less weight in evaluating cause-and-effect relationships. Some of these biases can be reduced by (1) examining smaller geographic areas where exposures may be more homogeneous and residential mobility/stability can be better characterized and (2) by stratifying data into subgroups that have more homogeneous disease risks.

Ecologic studies, however, can be useful for assessing the overall health of a community and in evaluating overall impacts of community-wide intervention programs (e.g., gun control, seat belt laws, minimum-age drinking laws). Community intervention studies represent a type of ecologic study because an intervention is made at the community level and subsequent disease or outcomes of interest are ascertained through time, before and after the community intervention. A classic example is public water system fluoridation (intervention) and the evaluation of adverse dental manifestations such as cavities. Water supply system fluoridations were initiated in the 1940s and occurrences of dental conditions before and after fluoridation were compared. The rates of adverse dental manifestations decreased after fluoridation intervention at the community level. Furthermore, dental conditions remained elevated in areas that did not receive this intervention.

Cluster Studies

Investigations of cancer or disease clusters are commonly requested of public health agencies by citizens concerned about a potential environmental hazard. A cluster is generally defined as an aggregation of relatively uncommon events or diseases in space and/or time in rates or levels that are greater than could be expected by chance. Potential disease clusters are often perceived to exist on the basis of anecdotal evidence, and epidemiologists and biostatisticians may spend considerable efforts in evaluating whether a true cluster exists. The most commonly used analytical approach is to statistically compare, in the time/location of interest, the observed number of cases in the perceived cluster to what would be expected among the population that generated the cluster if cases occurred at the same rate in a relevant comparison geographical area such as a state, province, or country.

A survey of state health departments in 1997 found that the national total for public requests for cancer

clusters investigations was approximately 1,100. "True" clusters that are tied to a specific agent can be common for infectious diseases but are extremely rare for cancer or other diseases. Thus, studies of environmental exposures and cancer clusters may identify research hypotheses, but rarely have they produced useful information about disease causation because of several common limitations:

- Ascertainment bias is a concern because the media or the local community may conduct special searches for cases, or diagnostic criteria are vague, thus resulting in cases that may be too heterogeneous for a valid study.
- The data are subject to gerrymandering—that is, circumscribing the study area around the identified cluster of cases.
- Insufficient disease induction period—that is, the time between exposure to environmental agent and the manifestation or diagnosis of the disease is too short.
- A lack of statistical power due to small sample size characterizes many perceived clusters.

Furthermore, the exposures under investigation are often poorly characterized, heterogeneous, or even too low in concentration to increase the likelihood of disease.

Bias in Occupational and Environmental Epidemiology Studies

Any systematic error in the design of a study, its implementation, or analysis of the data is called bias. Assessment of bias is critical in conducting and evaluating occupational and environmental epidemiology studies because the presence or lack of bias provides a measure of the study validity and helps determine how study results can be interpreted. Limitations in exposure assessment are a common problem for all epidemiologic studies but are especially relevant to occupational and environmental health research. Several types of bias relevant to all types of epidemiologic research, particularly occupational and environmental epidemiology, are given below.

Selection bias refers to systematic differences in the characteristics between those who are selected for study and those who are not. A special case of this threat to the validity of a study is surveillance bias, which refers to differential disease ascertainment (e.g., through medical monitoring) among those who are exposed compared with those who are not exposed. Selection bias may also invalidate conclusions from surveys that would include only volunteers or persons known to have certain medical conditions.

Misclassification is a type of bias that is created by inaccurate assignment of study subjects to "exposed" versus "unexposed" or "case" versus "noncase" status. Misclassification may occur in two forms. In differential misclassification, the rate of misclassification of exposure is different between cases and controls or the rate of misclassification of disease status is different between the exposed and unexposed groups. In nondifferential misclassification, the rate of misclassification of exposure may be the same for both cases and controls or the rate of misclassification of disease may be the same for both exposed and unexposed individuals.

Information bias refers to errors in collecting data that result in differential accuracy of information about comparison groups. Specific examples of information bias include recall bias, interviewer bias, and nonresponse bias. For example, when asking workers about the frequency of lifting events and lifting requirements (e.g., estimated weights lifted) at work, those who have low-back pain may be more likely to recall lifting events than workers in the same occupation without low-back pain. This is an example of recall bias that may lead to differential misclassification of exposure.

Confounding bias is the error introduced into the evaluation of an exposure-disease relationship by a third factor that is an independent cause of the disease and unequally distributed among the exposed and the unexposed subjects. A confounder is a factor that distorts the effect of the risk factor (exposure) under study. For example, an association observed between work as an auto mechanic and lung cancer might not be due to exposures at work but due to confounding by smoking, which is a cause of lung cancer and associated with this group of workers. Thus, smoking confounds the relationship between occupation (auto mechanics) and lung cancer and is referred to as a "confounder" or a "confounding factor."

The *healthy worker effect* (HWE) is a well-recognized potential bias in occupational studies. The HWE is actually the result of several distinct components: (1) selection of healthier people into the workforce or active employment ("healthy hire effect"), (2) selection of unhealthy workers out of the workforce ("healthy survivor effect"), and

(3) the decline in health with time since hire. The impact of HWE varies by disease outcome with larger impacts expected for nonfatal outcomes such as musculoskeletal conditions, asthma, or other symptoms and noncancer endpoints such as heart disease, diabetes, nonmalignant respiratory disease, and nonfatal injuries. The HWE impact on cancer is assumed to be much smaller. Cross-sectional, *PMR*, and cohort studies that use external comparison groups are more affected than other study designs (e.g., case-control and cohort studies using internal comparison groups). Various analytical procedures have been suggested to reduce the bias due to HWE: (1) use of an internal comparison group, (2) analytical control of employment status (active/inactive), (3) restriction of analysis to groups with longer follow-up, and (4) analytical control for time since hire or follow-up duration. However, bias may still result from more subtle and complex scenarios that require other approaches. For *PMR* studies when cancer is the disease endpoint, use of only cancer data may reduce potential bias introduced by HWE.

Epidemic

An epidemic is a marked increase in the number of cases of a disease relative to the expected number of cases. Epidemic disease is sometimes contrasted with endemic disease, which is the expected or usual incidence of disease in a location. While the term *endemic* is typically confined to infectious diseases, the term *epidemic* is more widely used. Endemic can refer to either the usually observed rate of disease or simply the fact that a disease is present in a locale. For example, hantavirus is endemic to many parts of the United States. A rate of disease that is endemic on one country would constitute an epidemic if it occurred in a country where the disease is ordinarily less common.

The terms *outbreak* and *epidemic* are both used to describe sudden increases in disease occurrence, although outbreak is usually reserved for a localized occurrence of a disease that is typically not present in the population (such as an outbreak illness due to *Escherichia coli*), while epidemic is reserved for more widespread conditions. Both outbreaks and epidemics may be described as being *common source* or *propagated.* In a common source outbreak, there is a single source of disease to which the population is exposed, such as cryptosporidium in a city water supply or the interstate distribution of contaminated packaged spinach. In a propagated epidemic, the pathogen is spread from person to person, such as HIV. Sometimes, an epidemic may have both types of transmission: initial point source exposure that is then passed from person to person.

A *pandemic* is an epidemic that has spread beyond national boundaries. Most often, the term *pandemic* is used to describe influenza, and the most notable pandemic in recent history was the Influenza Pandemic of 1918. However, other diseases such as cholera, bubonic plague, and HIV have similarly demonstrated rapid spread across continents at specific historical periods.

The progress of an epidemic or outbreak is often depicted with an epidemic curve, a graph where time is on the *x*-axis and the number of cases is on the *y*-axis. Figure 1 displays the epidemic curves of

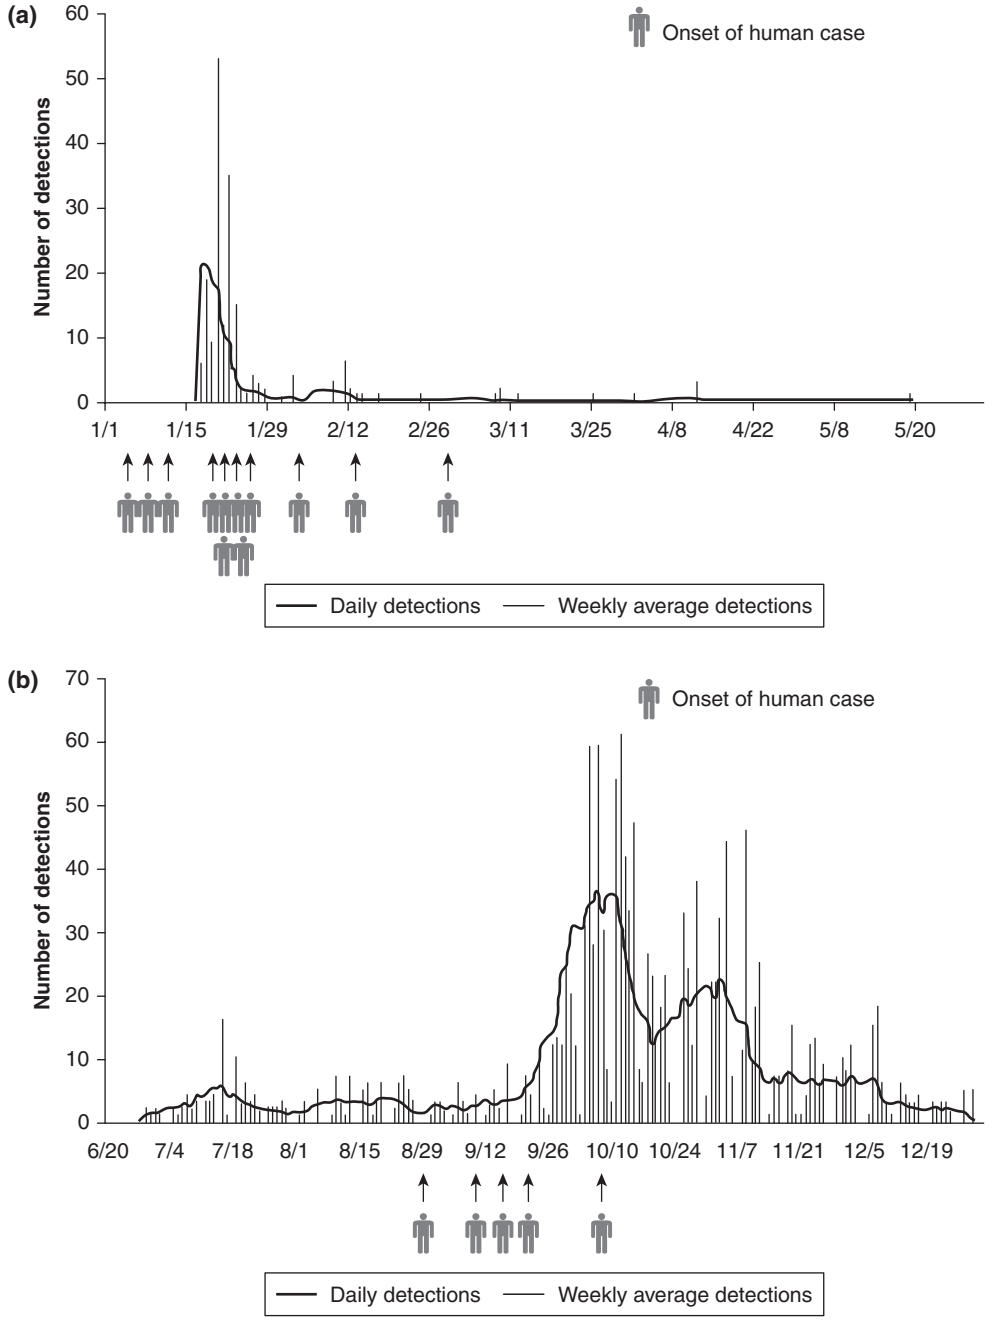

Figure 1 Epidemic Curve of the Confirmed Highly Pathogenic Avian Influenza H5N1 Outbreaks in Poultry in Thailand by Date of Notification

Source: Tiensin et al. (2005).

H5N1 avian (bird) flu in Thailand for two time periods in 2004.

Epidemics are most often caused by infectious agents such as viruses or bacteria, but other causes are possible, including chemical exposure and physical conditions such as extreme heat or cold. Due to improved sanitation, disease surveillance, and medical care, widespread epidemics of infectious diseases are

uncommon in the industrialized world today but still occur regularly in the developing world. Due in part to this shift in focus from infectious to chronic disease, the term *epidemic* is often used today to refer to health behaviors or chronic conditions of widespread concern, such as "the obesity epidemic" or "an epidemic of teenage smoking," or even "an epidemic of child abuse."

Epidemiology, History of

Student: What is epidemiology, father?

Teacher: It is all things to all men, my son . . . The plethora of definitions is the very heart of the problem . . . a structure sturdy enough to . . . shelter physicians, dentists, veterinarians, and nurses; very small (micro) biologists and fat chemists; mammalogists, bugmen, birdmen, and spacemen; traffic directors and city planners; engineers mechanical, sanitary, electrical, stationary, and human; sociologists, psychologists, and anthropologists, cultural and otherwise . . . everything!

—Anonymous (1963)

The preceding satirical barb from 1963, titled "Epidemi(olog)^{2}y*," goes on to define epidemiology ("or epidemiologology") in circular fashion as "simply the study of epidemiology," and hints at why a comprehensive history of the subject has neither been written nor, apparently, even attempted. From the vantage point of 2007, looking back over the past few decades, it appears that epidemiology has further expanded in breadth from the diffusion satirized in 1963. Moreover, it has become increasingly absorbed in methods, mathematics, and models; some critics have charged that it has reached its limitations and is spending too much time nibbling at the edges of public health rather than solving the big problems. It is thus hard to escape confusion about epidemiology's identity and origins. Like the different branches of a tree bending down to examine shared roots, the question can be seen from different vantage points leading to different conclusions about what epidemiology is, what its core techniques are, what constitutes epidemiologic practice, who is and who is not a practitioner of epidemiology, and so on. Moreover, borrowing Thomas Huxley's description of science, it seems that fundamentally epidemiology is "nothing but trained and organized common sense" (1854). Tracing the history of commonsensical solutions to health problems in populations is a subject so broad and so all-encompassing that it becomes almost impossible to grasp *in toto*.

This entry is thus focused narrowly on tracing the roots of core and traditional epidemiologic activities such as those canonized by epidemiology textbooks—notably, disease surveillance, outbreak investigation, and discovery of disease etiology and modes of transmission/acquisition. In this effort, we are led disproportionately to the infectious diseases, which have been the principal shapers of epidemiologic endeavor almost up to the present time, placing less emphasis on, for example, chronic and behavioral conditions, and their relatively newer and still-evolving methodologies.

The term *epidemiology* came into being, or at least came to have its modern meaning only fairly recently, at about the same time medical science began to appreciate that communicable diseases might actually be infectious and that such infections not only were *not* distributed randomly in populations but that their specific patterns of "nonrandomness" constituted powerful etiologic clues. These important realizations seem to have been formed around the time of the second cholera pandemic in Europe (1831–1832). Conveniently for historical purposes, the term *epidemiologie* or *épidémiologie* began to be used in the modern sense in Germany, France, the Netherlands, and probably other countries as well, at around the same time, apparently coming to the English-speaking

world a decade later. The eventful year of 1832 also saw the first proposal to establish an academic chair in epidemiology, reflecting a greatly heightened awareness of the importance of systematic and quantitative study of epidemics. In examining the history of epidemiology in both before and after its "birth" in a recognizable form, it is necessary to avoid the sin of "presentism" (imputing to past observers modern concepts and terms of which they were not aware). Therefore, the terms *proto-epidemiology* and *epidemiology* have been used here to refer to epidemiologic efforts and their antecedents occurring, respectively, before and after the period in which recognizably modern epidemiologic concepts and terms came into common use.

Before the 1830s, there seems to have been no term that corresponded to "epidemiology" in the modern sense of the word. "Loimologia," "loimology," and "loimographia," used in the 17th century, referred to the centuries-old chronicling of *loimos* (λοιμοζ), an ancient Greek term that roughly corresponds to "plagues," "pestilences," and major epidemic/pandemic diseases. "Epidemical" and "epidemial," popular in the late 1700s and early 1800s, were adjectives applied to infectious disease epidemics. The Latin term *epidemiologia* can be found in at least one earlier work (*Epidemiologia española* . . .) published in 1802, but the book's subtitle (. . . *ó Historia cronológica de las pestes, contagios, epidemias y epizootias* . . .) makes clear that this "discourse about epidemics" applies not to epidemiology in any modern sense—an approach to understanding the distribution and determinants of diseases in populations—but to the same compiling of chronological lists of important epidemics. Nevertheless, *Epidemiologia española* fits nicely into a then-growing tradition in medical geography. In the hands of its greatest practitioners, for example, Noah Webster (1758–1843), August Hirsch (1817–1894), and Charles Creighton (1847–1927), medical geography eventually joined medical history—practiced by physicians such as Justus Friedrich Karl Hecker (1795–1850), who wrote histories of plague, *tanzwuth*, and other epidemics—to converge with "true" epidemiology, exemplifying some of the difficulties in tracing epidemiology's roots.

The Early Historic Era

The early historic era corresponds to the appearance of planned agricultural communities, the domestication of animals, and eventually urban crowding, all of which were undoubtedly associated with the first infectious disease epidemics. Such diseases (e.g., measles, tuberculosis) probably arose by host switching of enzootic infectious agents in domestic animals to epidemic/endemic forms in man. With no scientific basis for understanding the resulting outbreaks and epidemics, these human diseases were attributed to angry gods and were dealt with by priests and healers (often the same individuals), whose organized rituals to placate the responsible deities aimed to keep the community safe rather than to investigate causality or even provide rational explanations. Apparent epidemic diseases were noted in Old Testament Biblical times (e.g., the Pharaonic "plagues" in the Book of Exodus, written ca. 1552 BCE, some of which are now speculated to have been infectious). Even then, a growing conceptualization of contagion led to public health actions to isolate persons with ostensibly contagious diseases (e.g., *leprosy*, a term that probably subsumed a variety of skin conditions, many of them, such as psoriasis and eczema, being noncontagious). An early "clinical trial" showing the effect of diet on health was even documented in the Book of Daniel (Book I, pp. 3–16, written ca. 167 BCE).

The Greco-Roman Era

The ancient Greeks made two major conceptual contributions to epidemiology: (1) the observation, attributed to Hippocrates (ca. 460–377 BCE) and outlined in *Airs, Waters, Places*, that epidemic diseases are distinct entities that appear in patterns of either pathognomonic or constellationary clinical symptoms and under particular conditions of season, weather, and geological events and (2) the theory propounded by Democritus (ca. 460–370 BCE) that contagious diseases are spread by tiny invisible particles. One of the most infamous epidemics in human history, the "Plague of Athens" (430–425 BCE), which occurred during the Peloponnesian Wars and may have brought about the end of Greece's Golden Age, was well described by Thucydides (ca. 460–400 BCE). Although the disease has not been conclusively linked to any disease known today, Thucydides's account is a landmark in epidemiology because it represents the first recorded attempt to specifically characterize a disease as a distinct entity on the basis of its clinical and epidemiologic pattern. Thucydides's account includes discussion of variations in disease presentation, distinction

between signs/symptoms and complications, discussion of attack rates, mortality, suspected risk factors, suspected modes of transmission, and other epidemic features and details never before chronicled. In almost obligatory fashion, Thucydides's description came to be discussed and analyzed in countless accounts spanning the centuries since the events in question, still having a profound impact on thinking about epidemics and epidemiology well into the 19th century. Discussions and reviews of the Plague of Athens are still fairly common today, perhaps because of the tantalizing mystery of a disease so richly described yet still escaping attempts to identify it.

Another noteworthy development in this era, credited to the Roman Empire, is the organized population census. When national censuses became commonplace nearly two millennia later (the late 1700s to late 1800s), they soon became essential epidemiologic tools, providing population denominators for calculation of attack and mortality rates, allowing disease occurrence to be described in quantitative terms, and leading to the identification of demographic groups at risk.

The Middle Ages

Although there were no breakthroughs in proto-epidemiologic thinking in the first millennium AD, the lessons of the Greco-Roman Era were not entirely forgotten. In imitation of Hippocrates and Thucydides, epidemics were still being chronicled, however simplistically, and a few of them eventually came to be recognized as distinct nosologic, if not etiologic entities. Disease distinction was a critical first step in the development of epidemiology because without it there could be no basis for studying disease determinants or distributions. Persian-born physician Abū Bakr Muhammed ibn Zakarīyā al-Rāzī ("Rhazes"; AD 860–932), for example, clearly distinguished smallpox from measles. Three centuries thereafter, the Scotsman Bernard de Gordon (ca. AD 1260–1318) drew on Rhazes and the Persian Abu-'Ali al-Husayn ibn Abd Allah ibn-Sina ("Avicenna"; ca. AD 980–1037) to list eight distinct diseases he thought were communicable (six of which he identified correctly: anthrax, *ignis sacer*—probably corresponding to erysipelas, although the term was later applied to zoster and ergotism as well—leprosy, plague, trachoma, and tuberculosis).

By the Middle Ages, there was growing suspicion that because epidemic and endemic diseases seemed to be different and to exhibit characteristic clinical features and patterns of spread, they might be distinguishable from each other, and might, furthermore, have different causes and be responsive to different treatment or control measures. However, there was yet no theoretical or scientific basis for identifying those causes, a reality that—as much as anything else—prevented the emergence of epidemiology.

The most significant epidemiologic event of the Middle Ages was the pandemic of "Black Death" (bubonic/pneumonic plague) that swept much of the known world in the 14th century. The pandemic wiped out an estimated 40 million people overall, including a third of Europe's population, making it the most fatal catastrophe in human history up to the time of the 1918 to 1919 influenza pandemic (50 to 100 million deaths). Historians have shown that this plague pandemic had a profound and complex impact on the subsequent course of human history, leading directly to the European Renaissance and its emphasis on scientific thought and critical reasoning. In addition, it opened an important chapter in public health and created a role for proto-epidemiologic activism. For example, the pandemic's arrival in Europe in 1347 demanded a public health role for governments. Before the pandemic, public health activities such as isolation of ostensibly contagious persons usually fell to religious and charitable orders. But spread of the pandemic from overseas locales into European seaports emphasized and broadened the concept of contagion, thus adding an international dimension to it.

This threat demanded civic action, leading to establishments of the first quarantine (from the Italian *quaranta*, referring to the customary 40 days of vessel sequestration in ports). Moreover, Europeans demanded that planning to prevent epidemic importation become a civic responsibility, as was made clear in the preventive medicine–oriented tractate of Jehan Jacme ("Jacme d'Agramont," d. 1384) dated April 24, 1348. Jacme's tractate, republished and widely read throughout Europe for decades thereafter, acknowledges the several contagious diseases of de Gordon and his predecessors, and goes on to exhort the city fathers as follows:

> Everyone must reflect on and prevent the causes that can produce a universal or local pestilence [an epidemic or an outbreak]. And if perchance these can be removed they must be removed. And to this

> end an effort should be made by the Lords [municipal officials] and their officers whose duty it is to look after the usefulness and well-being of the community. (Jacme, 1348, unpaginated)

Without explicitly realizing it, the generation that suffered the Black Death first articulated a rationale for civic actions that would someday make epidemiology a necessary tool for maintaining the public health.

The Enlightenment

Until the era referred to as The Enlightenment, the historical antecedents of epidemiology had been largely confined to recording, cataloguing, and attempting to distinguish between human diseases, supplemented in the more recent centuries by increasing attempts to prevent diseases whose course of spread might be anticipated, and to investigate those that were not prevented. Around the year 1700, corresponding to the beginning of The Enlightenment, a profound rethinking of all things scientific and phenomenological began to propel proto-epidemiology inexorably forward.

Among the many important events of this era and the decades immediately preceding it were the efforts of John Graunt (1620–1674) and Sir William Petty (1623–1687) to quantify and identify patterns in the causes of death recorded in the English Bills of Mortality; the discovery in 1675 by Sir Edmund Halley (1656–1742) that errors in measuring the positions of stars were actually nonrandom, in fact normally distributed, indicating a concealed order within a universe supposed to be incomprehensible to mortals; the discovery in the same year of tiny living organisms under the microscope by Antonie van Leeuwenhoek (1632–1723); and the development by scientists, such as François Boissier de Sauvages de la Croix (1706–1767), Carl von Linné (1707–1778), and William Cullen (1710–1790), of nosologic schemes to classify and differentiate human diseases. Such nosologic schemes were of enormous importance to epidemiology because in the absence of etiologic concepts, they provided a theoretical basis for differentially diagnosing, treating, and initiating epidemiologic responses to diseases. In essence, in the early Enlightenment, disease nosology was the precursor of etiology and served as an organizational framework for the explosion of knowledge in all fields relating to biomedicine.

Given that epidemiology largely developed and grew in response to the challenges of infectious diseases, it might be considered ironic that some of the first "classic" outbreak investigations were conducted in response not to infectious but to occupational diseases. This was so because in the late 1600s and early 1700s, when the first such studies were reported, it was possible to identify cause-and-effect linkages between certain distinctive diseases and prior occupational/industrial exposures to known industrial agents, whereas, lacking any concept of an infectious agent, cause-effect associations for the more common and more serious infectious diseases were not yet possible.

The 1697 outbreak investigation of Eberhard Gockel (1636–1703) linking *colica pictonum* to lead poisoning in mine workers (20) and the corpus of occupational disease studies of Bernardino Ramazzini (1633–1714) published several decades later anticipate modern epidemiologic studies. A 1751 clinical trial conducted by British Navy physician James Lind (1716–1794) showing that citrus juice could prevent scurvy (an occupational disease of sailors, then of unknown cause) is particularly noteworthy for the use, uncommon up to that time, of controlled experimental methods (clinical trial) in determining cause-effect relationships.

If occupational proto-epidemiology matured earlier than its infectious disease counterpart, an explosion of new information and ideas soon caused the former to be overtaken by the latter. Shortly after Leeuwenhoek's discovery of microorganisms (1675), the mites of scabies and mange were seen under the microscope. While we now understand these conditions to be infestations rather than infections, the impact on thinking about epidemic diseases was profound. Acceptance of contagion mediated by microscopic living entities was soon crystallized by a century-long series of European cattle epizootics, caused largely by rinderpest, and to a lesser extent by foot-and-mouth disease and anthrax. Animal diseases provided better opportunities for controlled study and implementation of control measures, human quarantines being difficult to implement in societies that increasingly demanded freedom of citizens from government interference.

The comprehensive public health responses to these epizootics were targeted specifically to preventing the spread of hypothesized microscopic organisms, for example, by burning and deeply burying corpses of dead animals, by disinfecting fomites, and by forming *cordons sanitaires.* Students in veterinary schools were deputized to conduct epizootic outbreak investigations and initiate control measures long before such activities took place in medical schools and long before outbreak

investigators were to be found in any major city. Particularly in France, several successive decades of attempts to investigate and control anthrax led to a fairly sophisticated epidemiologic understanding of the disease by the 1770s, a century before the causative organism was conclusively identified. By the latter 18th century, effective public health measures to contain these devastating epizootics had been refined and widely implemented, and the epizootics had declined in frequency and severity.

An inspirational and transitional figure at the end of The Enlightenment, intimately involved in epizootic investigation/control, was the physician-anatomist Félix Vicq-d'Azyr (1746–1794), arguably the foremost proto-epidemiologist of his era and one of the more obvious "fathers" of epidemiology. Ennobled shortly after the ascension of Louis XVI, Vicq-d'Azyr spent 2 years in the field conducting epizootic investigations throughout France and was then named "Perpetual Secretary" of the newly created Société royale de médecine. Vicq-d'Azyr quickly set up the world's first international (indeed, national) disease surveillance system, based on "correspondents" who reported regularly from the various provinces and overseas locales, not only on epidemic and epizootic diseases but also on climatic, atmospheric, and other environmental conditions suspected of being associated with their prevalences.

Like the Epidemic Intelligence Service of the U.S. Centers for Disease Control and Prevention (CDC), Vicq-d'Azyr ordered and conducted outbreak investigations either from Paris or the provinces themselves, and from his base as a professor at the Alfort veterinary school outside Paris, he conducted some of the first experimental attempts to transmit diseases in animals. The transmission efforts largely failed, but some 20 years after the revolution (and Vicq-d'Azyr's death), similar experiments were taken up more successfully by the next generation of Alfort investigators, under the influence of Vicq-d'Azyr's work. This eventually led to the characterization of the first epidemic infectious disease, anthrax, by Casimir-Joseph Davaine (1812–1882) and Robert Koch (1843–1910), between 1850 and 1876, and to the intimately related births of microbiology and experimental medicine.

Although few were probably aware of it at the time, the concept of contagion was being refined and advanced throughout The Enlightenment; in retrospect, it is clear that progress was moving in the direction of conceptualizing infectious microbial agents. As noted above, the idea that epidemics were caused by tiny transmissible agents arose in ancient Greece, and was further refined in the Renaissance and Enlightenment by theorists such as Girolamo Fracastoro (1484–1553), who in 1546 conceived of disease propagation by living *seminaria*; Athanaseus Kircher (1602–1680), who propounded a theory of contagious microorganisms in 1658; and Marc Anton von Plenciz (1705–1786), who in 1762 hypothesized specific and distinct contagious *animata* for each different human, animal, and plant disease. At the same time, there was growing appreciation that specific infectious diseases were often followed by lifelong refractoriness to the same disease, but not to other diseases, the observational basis of acquired immunity. Such concepts had become so firmly established by 1720 that when smallpox inoculation was introduced that year from Turkey into Europe and the American colonies, it was not only comprehended but widely accepted, a conceptual advance of such importance that it motivated American scientist-physician Benjamin Franklin (1706–1790) to document inoculation efficacy in Boston by conducting one of the first known historical cohort studies.

At the end of The Enlightenment, as the Industrial Revolution began to swell urban populations, creating fertile ground for urban epidemics, seemingly unrelated events were converging to give birth to "modern" epidemiology. These included the establishment of municipal and national censuses, early surveillance and disease-reporting systems, mounting evidence that contagious diseases were caused by replicating microorganisms, the acceptance in Europe and America of smallpox inoculation (1720), and then of Jennerian vaccination (1798)—the latter implying both cross-species infection and specific immunity—experience with outbreak investigations for a variety of human and animal diseases, experience with quarantine and disinfection, development of comparative and experimental medicine, establishment of public health training for physicians (particularly in France), and, especially in the German states, the growth of state-sponsored preventive medicine ("medical police").

After the Napoleonic wars, a generation of physicians returned to their European homes, some with limited training in the radically new subjects of public health and social medicine, and many of them ready to take up a new type of medical practice aimed not just at curing but also at preventing diseases in all segments of the population, prominently including the poor and disadvantaged.

The Birth of Epidemiology: Paris, 1819 to 1832

Among these returning military physicians were two who would lead, in the 1820s and 1830s, a small group of like-minded Parisians in studying the incidence and prevalence of various health conditions in populations, making use of census data and medical arithmetic, and identifying disease-specific demographic risk factors such as sex, age, locale, occupation, crowding, socioeconomic status, and so on. In essence, these physicians systematically studied the distribution and determinants of diseases in open populations, the first true epidemiology.

Louis-François Benoiston de Châteauneuf (1776–1856) and his young protégé Louis-René Villermé (1782–1863), along with colleagues such as Alexandre-Jean-Baptiste Parent-Duchâtelet (1790–1836), have sometimes been referred to as ''hygienists,'' but their role in inventing modern epidemiology from proto-epidemiologic antecedents is clear from perusal of their works, for example, the 536-page report of the 1832 Parisian cholera pandemic. This work, in fact, appears to have been inspirational reading for young medical students such as John Snow (1813–1858) and William Farr (1807–1883), the latter of whom trained in France, and both of whom would make indelible marks on epidemiology in the next (third) cholera pandemic less than 20 years later. Though not part of this epidemiology circle, the hospital-based Paris clinician Pierre-Charles-Alexandre Louis (1787–1872), immortalized decades later by Sir William Osler (1849–1919) as one of the ''fathers'' of American medicine, was working in parallel with Benoiston de Châteauneuf and his colleagues by using structured observations and medical arithmetic to improve clinical therapy. Thus, the forces that led to the first population-based epidemiology and the first clinical epidemiology, though separate and distinct from the beginning, arose at the same time, in the same place, and in the same European scientific and cultural milieu.

Early Epidemiology Responds to Discovery of Infectious Diseases

Political events in France soon undermined the further development of epidemiology there, but not before influencing health workers in other countries, many of whom had studied medicine in Paris or had at least been reading French texts and journals. In the 1830s, the British Sanitary Movement led to establishment of a national Register of Births and Deaths in England and Wales. By this time, many major European and American cities (e.g., Hamburg) had or were developing sophisticated public health data collection systems and were using them to address public health problems, endeavors that created a need for the further development of epidemiology and an environment in which it could grow and thrive.

Between about 1840 and 1866, the influence of epidemiology exploded in Europe and America. Among other notable epidemiologic milestones of the era, in 1840 the young German epidemiologist Friedrich Gustav Jacob Henle (1809–1885) published a comprehensive treatise that was decades ahead of its time in anticipating infectious diseases, a treatise that also suggested to one of Henle's students, Robert Koch, the principles that would later become ''Koch's postulates'' (or the ''Henle-Koch postulates'') for experimentally establishing that a disease is infectious. Many other young European physicians began to be influenced by epidemiology, seen, for example, in the outbreak investigations of Englishman George Budd (1808–1882) and the disease theories of his younger brother William (1811–1880), who later distinguished typhus from typhoid, and most famously in the studies and theories of John Snow, whose separate investigations of cholera incidence rates by contaminated and uncontaminated London water supplies and of cholera contamination at Soho's Broad Street pump were eventually recognized as landmarks. In Vienna, Ignaz Philipp Semmelweis (1818–1865) used epidemiology to demonstrate the cause and prevention of iatrogenic puerperal fever. In Denmark, the medical student Peter Ludwig Panum (1820–1885) investigated and published in 1847 a remarkably insightful treatise on a measles epidemic, further evidence that the generation that came of age during the birth of epidemiology in the 1820s and 1830s had grasped the importance of, and the great potential for, this new approach.

Many of the studies conducted by these early epidemiologists seem recognizably modern today (2007) because of their use of epidemiologic reasoning, calculations of frequencies and, when possible, incidence rates, and their inductive puzzle-fitting approaches that led inexorably from discrete facts and observations to inferences supporting public health control measures. By the mid-19th century, disease outbreaks

were being investigated with arithmetical techniques, epidemic curves were being drawn and studied, and while cohort studies were not yet common, incidence rates were being compared and contrasted to understand causation and risk variables based on the presence or absence of suspected risk factors.

The most significant conceptual breakthrough for epidemiology during the 19th century, however, was undoubtedly establishment of the "germ theory." Following efforts by David Gruby (1810–1898) and others in the 1840s, between 1850 and 1876 the remarkable researches of Davaine and Koch led to the establishment of the first human infectious disease: anthrax. In the 25 years between 1876 and the end of the century, there followed a burst of microbiological triumphs (e.g., establishment of the etiologies of tuberculosis, plague, and cholera) that led to new public health control measures and to clinical therapies, including vaccines (e.g., rabies, 1885), passive immunotherapies (e.g., diphtheria antitoxin, 1890), and to environmental control (e.g., for yellow fever, shown to be a mosquito-borne infection by Walter Reed [1851–1902] and colleagues).

These advances had a profound effect on epidemiology by creating the ability to identify the etiology and verify the presence or absence of the disease, to study the diseases in populations, and to study the efficacies of prevention and treatment modalities. Microbiology and epidemiology developed in a partnership that was so close that they were often thought of as two aspects of the same discipline. The growing sophistication of epidemiology, and its increasingly close relationship with microbiology, can perhaps be most clearly seen at one point in time and place: the remarkable body of American scientific data produced during the 1918 to 1919 influenza pandemic. As late as the 1920s, American epidemiologists working in health departments saw the microscope as one of the key epidemiologic tools and often used it on a daily basis.

Epidemiology After the Microbiological Era

The 1920s also saw epidemiology develop in response to opportunities coming from different directions, including infusions of interest and expertise from the social sciences, such as more rigorous/better standardized methodologies to link risk factors to outcomes by comparing incidence rates in exposed and unexposed persons (cohort studies), or by comparing prior exposure frequencies in ill and well persons (case-control studies, e.g., those of Janet Elizabeth Lane-Claypon [1877–1967]). In the United States, these developments were heavily influenced from about 1920 to about 1980 by the national experiment in establishing numerous academic schools of public health, and the development of academic population-oriented epidemiology under the leadership of rigorous methodologists such as Johns Hopkins University's Wade Hampton Frost (1880–1938), whereas European epidemiology still reflected a largely clinical orientation.

These changes in the development of epidemiology had many consequences, including increasing sophistication of epidemiologic methods and increasing attention paid to noninfectious disease problems, for example, early-20th-century studies of pellagra, a supposedly infectious disease proven to be a nutritional disease in a series of classic studies by Joseph Goldberger (1874–1929); the series of studies conducted by Sir Richard Doll (1912–2005) and Sir Austin Bradford Hill (1897–1991) on the effects of cigarette smoking in British physicians; the linking of dental caries to inadequate levels of halogens in natural water supplies; and the linking of specific cancers to specific environmental or occupational exposures (e.g., vinyl chloride/hepatocarcinoma, prenatal estrogen exposure/vaginal cancer in offspring). During these years, American epidemiology became a dominant force, in part because of its expansion in academic centers, its development in state and local health departments, and also because of the remarkable growth and influence of the U.S. Centers for Disease Control and Prevention (CDC), which supported and worked closely with health departments and contributed greatly to disease discovery and characterization.

From the vantage point of 2007, it seems likely that epidemiology will continue to expand in the direction of methodological orientation in the United States and also that in the United States and elsewhere, the need for basic practical epidemiology in the service of disease control will remain. Advances in genomics, proteomics, and bioinformatics are likely to strongly shape epidemiology. Although future directions are difficult to predict, it seems likely that the development of epidemiology will remain dynamic for the foreseeable future.

Epidemiology in Developing Countries

The disparity in health across nations is dramatic, as depicted in Table 1 by a 50-year range in life expectancy at birth. Quality of life is also widely varied across nations. What causes these substantial differences in life length and quality? Economic status is a major factor, leading to nutrition- and environment-related risks, injuries, high-risk behaviors, and inadequate health care. These underlying factors cause the infectious diseases, childbirth complications, trauma, and chronic diseases that ravage some developing countries.

Familiarity with the measurements underlying the summary health profiles of each country is essential to understanding the epidemiology of developing countries. Additionally, study methodologies vary worldwide according to the respective needs and cultures, but they are largely limited by the lack of resources in these countries. Also, it is important to consider ethical issues that arise in international study, particularly studies conducted jointly with U.S. investigators.

This entry discusses three aspects of epidemiology in developing countries. The section on burden of disease provides an overview of the epidemiology of developing countries; the section on research methods reviews epidemiology training programs and methods for epidemiologic study in developing countries; and, finally, ethical considerations are discussed in a section on the key components of ethical research conducted jointly by developed and developing nations.

Burden of Disease

While overall mortality rates, years of potential life lost, and life expectancy provide important insight into the health of a population, none provides information about *quality* of life. Rather, they are limited to information about *quantity* of life. Yet disabilities are important considerations when understanding population health. To this end, the World Bank funded the Burden of Disease Study, a collaborative effort of the World Health Organization and university researchers to describe the burden of disease for nations, incorporating both quantity of life and quality of life. The research also pulled together information on the major risk factors for each nation's burden of disease.

Burden of disease is estimated by combining information measured by years of potential life lost (YPLL) and years of healthy life lost due to disability (YLD). This combination of information forms disability-adjusted life years (DALYs), which estimate the years of healthy life lost. For example, if a child dies of pneumonia at age 1, the child has 54 more years of YPLL compared to an individual who dies of pneumonia at age 55. Deaths in childhood have substantial impact on the measure of YPLL; thus, for countries with high childhood mortality, the YPLL and DALY are substantial per capita. Similarly, if an infectious disease, such as onchocerciasis (or "river blindness"), causes blindness of a 5-year-old, the YLD and DALY will be 39 years more than if the same disease causes blindness of a 44-year-old. Combining this information across all diseases in a country creates one summary measure for the country that provides a measure of health. The DALYs can also be computed by gender and for specific diseases and risk factors to understand their relative importance.

Table 1 Life Expectancy by Region and Country, 2006 Estimates

		Mortality Experience	
Region	*Countries (Life Expectancies in Years)*	*Child*	*Adult*
Africa	Angola (38.6)	High	High
	Liberia (39.7)		
	Sierra Leone (40.2)

Source: Based on life expectancy data from https://www.cia.gov/cia/publications/factbook/rankorder/2102rank.txt; categories developed by the Global Burden of Disease Study (DOI: 10.1371/journal.pmed.0010027.t002)

Approximately 58 million of the 6.5 billion people in the world died in 2006. Shockingly, about 20% of these deaths are children, disproportionately from developing countries. Developing countries also have substantial deaths in the adolescent age range, while wealthy countries carry a relatively high death rate among those in young and middle adulthood (ages 15 to 59 years). Infectious diseases, particularly respiratory and diarrheal diseases, maternal and perinatal conditions, and malnutrition, continue to play an important role in mortality for the people of developing countries. Malaria ravages sub-Saharan Africa, currently the second leading cause of death after HIV/AIDS in that region. Tuberculosis also is a growing cause of death and disability in developing countries worldwide, becoming increasingly lethal due to drug resistance and coinfection with HIV. However, many developing countries have undergone a key transition in mortality: With the exception of sub-Saharan Africa and South Asia, chronic diseases now outpace

infectious diseases as the cause of death. Heart disease and cerebrovascular disease are now the leading causes of death. Injuries, including violence, occupation-related injuries, falls, and traffic crashes, also take their toll in lives.

Infectious diseases, malnutrition, chronic diseases, and trauma also impact the quality of life for large portions of developing-country populations. Additionally, mental disorders not typically related to substantial loss of life can have a tremendous impact on the quality of life and, thus, contribute to the measures of DALYs. In the 2001 Global Burden of Disease Study, it became clear that neuropsychiatric conditions (e.g., depression, post-traumatic stress disorder, senility), vision problems and hearing loss, and alcohol disorders had substantial impact on the DALYs, but very little impact on mortality rates. It is estimated that psychiatric conditions account for over 35% of YLD among those 15 years of age and older worldwide. While these conditions are prevalent in developed countries, they have substantially more impact on quality of life in developing countries, as measured by YLD and DALYs. The same factors that predispose people in developing countries to infectious and chronic diseases, including poverty and illiteracy, are also risk factors for psychiatric illnesses.

Adding to the burden of disease, countries that were not historically considered "developing" now meet this description. The post-Soviet East has suffered substantial declines in health since independence starting around 1990. The burden of disease in Russia and Central Asia has increased by over 30% between 1990 and 2000, with this increased disease burden disproportionately affecting men, likely due to excessive alcohol use.

Historically, assessment of population health has focused on the immediate causes of morbidity and mortality, but more emphasis is now being placed on the underlying risk factors, or what are sometimes called the actual causes of death and disability. In 2000, over 15% of DALYs were caused by childhood and maternal malnutrition, including deficiencies in weight, iron, vitamin A, and zinc. Poor eating habits and sedentary lifestyle accounted for about 11% of DALYs, followed by unsafe sex (7%), addictive substances (e.g., tobacco, alcohol, illicit drugs; 9%), environmental risks (e.g., unsafe water, pollution, lead; 7%), and occupational risks (e.g., injuries, carcinogens; 1%). These figures represent worldwide DALYs attributable to such risk factors; however, they are disproportionately important in developing countries. These risk factors are also generally reversible.

Research Methods

Epidemiology Training Programs

First and foremost, developing countries need trained professionals to help build the public health infrastructure and carry out research projects. This mission is championed in the United States by the Fogarty International Program, funded by the National Institutes of Health. The development of the public health infrastructure provides the best opportunity for future progress in health. Physicians typically work with academic epidemiologists in the United States for 6 months to 2 years, including completing course work and developing research projects jointly, followed by mentored research, once formal training is complete. Similarly, the Fulbright scholarship program affords physicians and other health workers the opportunity to experience a well-developed health system and learn about research program implementation from academic and research institutes.

The U.S. Centers for Disease Control and Prevention (CDC) also trains physicians in developing countries through the Field Epidemiology Training Programs (FETPs). These programs are designed to teach applied epidemiology from a public health perspective, with a particular focus on disease control. Epidemiologists from the U.S. CDC work with trainees in their home countries throughout the training and collaborate on public health problems as they arise. Specific training in disease surveillance systems and outbreak investigations are central to the programs. Trainees also are encouraged to develop studies for a range of disease areas relevant to their country's health issues. A particular benefit of the FETPs is the opportunity for epidemiologists in training to network with epidemiologists from across the world. The potential for rapid global transmission of communicable disease outbreaks (e.g., avian influenza) makes it more important than ever to have trained epidemiologists in developing countries who are also connected to a worldwide network of epidemiologists focused on disease control. Furthermore, because the developing country's public health system is typically more disadvantaged than clinical practice, a concerted effort to improve public health

first will advance the infrastructure of the entire health system.

Epidemiology Research in Developing Countries

Epidemiologic research should be driven by the priorities of health officials and scientists from the local public health community. Collaborations that will be fruitful for the country are likely to be successful. Other hallmarks of a successful collaboration include respect for team members' scientific knowledge and approach, and the ability to integrate beliefs. One way to ensure a respectful collaboration is to allow local colleagues to direct the research agenda. While discussion of priorities is always appropriate, invited researchers should be prepared to put their preconceived ideas and plans aside and consider research studies recommended by local scientists.

After discussion with local scientists, the next step in research topic selection is a good literature review. While much information from developing countries is not published in journals, local agencies and scientists may be knowledgeable about previous work and can help identify available information. Experienced epidemiologists recognize that decentralized organizations often have a remarkable amount of data and that preliminary studies may already have been conducted. Once a complete literature review has been performed, supplemented by a search for other sources of relevant data, the study methods can be thoughtfully developed.

Organizational Challenges

Many developing countries regularly undergo political transition. For countries in transition, the Ministry of Health structure also may change frequently resulting in changes in funding priorities and administrative structure that can affect the conduct of research. Thus, conducting even a 5-year follow-up study risks interruption. While impossible to fully anticipate, understanding the administrative potential for research, particularly longitudinal research, is important to contemplate the study design process.

Another challenge is the lack of available public health training and disinterest in public health positions. Financial incentives are often greater in clinical practice, pharmaceutical companies, and Western nongovernmental organizations than in public health research positions. In some developing countries, only physicians can serve as epidemiologists, further limiting the pool of qualified professionals. Additionally, young researchers trained in the West compete for positions in organizational structures that historically honored seniority, creating tensions in the transition to new methods of research.

Methodological Challenges

Study Design

In general, classic epidemiology study designs are the foundation of research in developing countries. Randomized trials remain the hallmark, and this design is recommended when appropriate. When research ethics prohibit randomization, cohort studies, case-control studies, cross-sectional studies, and more complex forms of these designs (e.g., case-cohort, nested case-control) are appropriate to consider.

Cross-sectional designs are often an appropriate starting point, due to their ability to provide basic disease and exposure distribution information, often have a low cost, and provide relatively quick implementation. Additionally, many of the logistics needed to successfully conduct more complex studies can be tested and developed in a cross-sectional design.

Data Collection Options and Validity

Most self-report instruments have been validated only in developed countries and may have markedly different validity in developing countries; thus, local validity studies need to be conducted before measures are used in epidemiologic research. For some measures, this validation is simple and inexpensive, but for other important exposures, such as risky behaviors, it is extremely difficult. For example, in studying injection drug use behaviors as a risk factor for HIV, self-report validity appears good if study participants are identified in a high-risk setting such as a needle-exchange program. Individuals have essentially already identified themselves as injection drug users by using the services; providing information for research about their drug use does not put them at much added risk. These same questions included on a survey for the general population, health care workers, or patients are unlikely to provide valid data on injection drug use. To date, there is no validated questionnaire that provides accurate data on this type of high-risk

exposure in the general population for most regions in the world.

Worldwide, issues of social desirability affect survey responses on sensitive topics. The sensitivity of questions can vary tremendously between countries; thus, researchers need to understand the culture to understand how to collect data and interpret data. For example, in some countries where women are still expected to live traditionally conservative roles in relationships, it is difficult to obtain accurate information about risky sexual behavior. Even if interviews are done by qualified interviewers or the questionnaire is self-administered, we rarely see reports of multiple sex partners from women. For men, multiple partners are more acceptable and the responses about sexual behavior may have stronger validity. Interestingly, in some countries where women are expected to have traditional roles, abortion is widely accepted so information about abortion history (e.g., number of abortions) may be valid. Thus, for accurate measurements to be developed, it is important to understand not only local customs but also the implications of social acceptability of behaviors.

Other data collection challenges are less obvious. For example, in at least one developing country, a child's immunization record may include sign-offs by physicians for vaccines that were never administered. While the frequency of this is unknown, anecdotal evidence suggests that it clearly happens because the caregiver perceives that the administration of vaccine poses a greater risk than the disease due to the reuse of needles and use of multidose vials of vaccine. Lack of proper staff training and monitoring and limited resources can also affect the extent to which the researcher can measure the exposure and outcome accurately.

Epidemiology research methods are comparable for both developed and developing countries, but the methods to capture reliable and valid data may differ. Many developing countries do not have the advanced databases and technologies required for some studies. Conversely, some approaches that are cost prohibitive in developed countries are feasible in developing countries The cost of staff salaries is often substantially (e.g., 10-fold) less in developing countries, while costs of laboratory tests, medical treatments, and computer technologies tend to be comparable with those of developed countries. This inversion of the typical cost structure of a developed country provides an opportunity for researchers to select different methods in developing countries. For example, given a relatively small budget, it may be cost prohibitive to interview 2,000 study participants in a study conducted in the United States, but it may be quite feasible with a relatively small grant in a developing country. In general, medical records useful for epidemiologic research are less likely to be available in developing countries, routine laboratory tests are more likely to have poor sensitivity and specificity, and medical care may be provided through non-Western approaches, making it difficult to measure.

Ethical Issues in Joint Research Between Developing and Developed Countries

Research conducted in developing countries jointly by scientists from developed countries has raised substantial ethical issues and controversies during the past two decades. The issues are important and complex; it is rare for a study to be designed without significant focus on clarifying the ethical issues and reviewing approaches to address these issues.

One ethnical question concerns what should be considered a reasonable standard treatment for which an alternative treatment can be compared in a randomized trial. Early in the HIV epidemic, when it became clear that antiretroviral medications could reduce vertical (mother-to-infant) transmission, researchers decided to conduct a randomized study in Africa that compared no treatment (the current standard in the region) to a single antiretroviral medication (below the standard of care in the United States at the time). The rationale for the study was that the standard of care in the region was no treatment, and if a benefit for the single medication was efficacious, then it might be economically feasible to implement a prevention program based on the study's findings. The study started a controversy that continues to this day. Some believe that there should be one universal "best practices" and that this is the standard from which comparisons should be made. Others disagree. While the controversy continues, a substantial case has been made that researchers from developed countries should not conduct research that uses treatments that are not and would not be acceptable in their home countries.

A second ethical question concerns epidemiologic studies that often use diagnostic tests to identify individuals with infections of interest. If the study does

identify infected individuals but the researchers do not have funding to cover treatment that would be available in developed countries, the ethics of the study can come into question. The details of the study and the related ethical issues need to be carefully reviewed to determine if the study should be conducted.

These are just two examples of significant ethical issues that can arise when research is conducted in developing countries. Even though ethical considerations related to the conduct of human subject research are universal, economic and cultural diversities may result in different ethics issues disproportionately arising more often in developing countries than in developed countries.

Informed Consent

One of the issues all researchers struggle with is obtaining truly informed consent. For example, HIV voluntary counseling and testing (VCT) programs, such as prevention of mother-to-child transmission (PMTCT) for pregnant women, raise concerns about participant recruitment. Women might be too aggressively encouraged to accept VCT by obstetricians and not given sufficient information about their right to refuse. However, most practicing physicians in post-Soviet countries worked during the Soviet era when voluntary services and extensive counseling were not characteristic features of the health system, and HIV testing was mandatory for some population groups, including pregnant women. This is why during the training sessions for health care workers, it is very important to emphasize the principles of voluntary counseling and testing, the concept of informed consent, and the rights of patients to refuse HIV testing and study participation.

Regional variation exists in the comfort level individuals may feel about agreeing to participate in a study without speaking to personal advisors. In some Asian countries, for instance, it is difficult to obtain informed consent from the potential study participant directly, without discussion with family members. Before signing informed consent, study participants often need time to review the opportunity with their families (spouses and even in-laws). In some regions of Africa, tribal leaders need to be consulted before individuals are willing to entertain study participation. In these instances, individual autonomous informed consent is still required. However, understanding the culture provides insight into how to provide a process that maximizes the opportunity for individuals to utilize information sources that are important to them for making decisions. Once these discussions occur, potential study participants need to have an environment when an autonomous decision can be made and communicated to researchers. Researchers need to ensure that such an opportunity exists in the informed consent process.

For collaborative research, institutional review board (IRB) approvals from both the developed country and the local institutions are required. In some countries, research ethics review is strong; in other countries, little experience in reviewing research ethics exists, and the committees tend to be token bodies and lack the expertise to thoroughly review and enforce the protection of human rights. Instead, they may err on the side of simply reviewing the paperwork and records before granting approval; they are unable to thoroughly investigate the human subjects' protection for each study. Further complicating the review process, the IRB members of developed counties often have no international research experience, have never visited developing-country institutions, and often cannot understand the barriers and challenges for research in the developing world. The questionnaire, consent forms, and research protocol are submitted to the U.S. IRBs in English, and their subsequent comments are sometimes hard to translate back to the native language adequately for implementation.

In some cases, verbal consent should replace signed consent. When the study is conducted among less educated persons who cannot read and understand the content of informed consent, the interviewer should carefully explain and obtain verbal consent from the study subject.

Financial Compensation

Developing countries are especially vulnerable with respect to the ethics of financial compensation for participation in the study. In countries where people have monthly income below US$50, it is very easy to obtain consent for participation in research with minimal compensation. This makes potential study subjects vulnerable to coercion and requires careful consideration when offering compensation. Money should not be at a coercive level. Another factor that may potentially influence the participation decision is the potential participant's desire to please his or her doctor. Even in developed countries, there

may be a generational difference in the tendency to accept a physician's direction without question. While not an obvious financial issue on the surface, access to a physician and his or her services may be a financial necessity, thus making the physician's interest compelling for a potential participant.

Trust

It is often problematic to gain the trust of the local community and individual study participants in developing countries. Local researchers born and raised in these communities have a good sense of how to build trust, and they should make every effort to do so before starting the research. People in developing countries often do not believe that the goal of epidemiologic research is ultimately to improve health outcomes in their region. Their first concern is the fairness of becoming a participant of experiments for research of interest only to the scientists of the developed country. For instance, in the 1980s, when HIV/AIDS was the overwhelming concern in the United States and Europe, researchers from these developed regions pushed to have funding strongly realigned with their priorities. At the same time, many sub-Saharan Africa researchers requested that funding be expanded for malaria, a current cause of tremendous morbidity and mortality. However, these requests largely went unanswered until recently, negatively affecting the ability to build strong, trusting relationships. The researcher must present the benefits and risks of participating in a culturally acceptable manner and ensure that potential recruits feel free to ask questions about their doubts and concerns. The development of trust typically starts with researchers and leaders of a community and then expands to potential study participants. The process of building trust, on both sides, involves communication that allows for relevant information about the society and research to progress until all involved find the proposed research a value to the community. It is at this point that the research process can move forward to protocol development and study initiation.

Ethics issues related to international research continues to be an evolving area of thought. Epidemiologists need to routinely reflect on foundational documents of ethics philosophy, such as the Belmont Report, and update their review of the ethics literature as it pertains to their specific area of study. Many epidemiologists also require the study methods and procedures to pass two additional tests: (1) Would the study be acceptable for a family member? and (2) "Can I sleep at night?" used by many researchers to assess their peace of mind with the decisions made. Only studies consistent with the Belmont Report or other research ethics foundational documents, laws of all jurisdictions involved, and these last two tests should be considered.

Epigenetics

When one considers inheritance, typically it is at the level of the DNA, gene, or chromosome: typical Mendelian genetics. However, not all hereditary

information is passed on in our genes. The field that studies these heritable differences in gene expression that do not involve a change in the DNA sequence is called *epigenetics.* This field can include studies of how gene expression is modified as cells divide and differentiate into specific types; how environmental factors (such as chemicals or radiation) change the way genes are expressed; and how patterns of gene expression are passed on from parent to daughter cells.

All multicellular organisms start off from a single cell, which contains all the genetic information present in an organism. However, from this single cell, vastly different daughter cells arise, eventually going on to form all the different tissues in our bodies. One way these differences are possible is via epigenetic regulation of individual cells. The first phenomenon of this type to be described was genetic imprinting, whereby one set of genes in a diploid individual is silenced. This silencing is based on its parental origin: either maternal or paternal. Epigenetic modifications can also include methylation (the addition of methyl groups) to the DNA backbone. The addition of these methyl groups changes the structure and appearance of the DNA itself, therefore, altering the interaction of methylated genes with messengers (such as regulatory proteins) that typically control gene expression.

It has also been suggested that epigenetic regulation plays a role in the development of some cancers and other diseases. Disorders caused by epigenetic mechanisms include Prader-Willi syndrome, which results in short stature and a complete lack of sexual development in adulthood, and Angelman syndrome, symptoms of which include developmental delays, seizures, and frequent laughter and smiling. Both diseases are caused by the loss of expression of a part of chromosome 15, which can be due to loss of a portion of the chromosome or epigenetic imprinting abnormalities eliminating expression of these genes. Beckwith-Wiedemann syndrome, which causes large size, an enlarged tongue, abdominal wall defects, and hypoglycemia, has also has been associated with an epigenetic imprinting abnormality. Epigenetic processes have also been suggested to be involved in various psychiatric disorders, including schizophrenia, bipolar illness, and depression, though these have not been fully characterized.

Research also suggests that certain cancers, including Wilm's tumor associated with Beckwith-Weidemann syndrome, may have an epigenetic origin. By examining DNA samples collected from tumors and normal tissues, researchers have found that the development and proliferation of cancerous tumors may be associated with a loss of imprinting at a number of different loci. As epigenetics is a quickly growing field of research, it is likely that additional epigenetic-associated diseases will be identified in the future.

ESCHERICHIA COLI

Escherichia coli, more often known as *E. coli*, is a bacterium commonly found in the digestive system of humans and animals. There are hundreds of different strains of *E. coli.* Although they are generally harmless, there are some that cause severe illness. The most widely known harmful strain is *E. coli* O157:H7.

E. coli O157:H7 is a shiga-toxin-producing gram-negative bacterium that causes foodborne illness. It is usually found in the intestine of cattle and produces large quantities of the shiga-like toxin, a verotoxin, which causes severe damage to the lining of the intestine in infected individuals. Ground beef is the most common source of contamination, typically caused by the undercooking of beef that became infected during slaughter. Other sources of contamination include unpasteurized milk and juice, lettuce, sprouts, and water.

E. coli O157:H7 was first identified as a source of illness in 1982 in an outbreak of severe diarrhea among 47 people from Michigan and Oregon caused by hamburgers from a fast-food restaurant contaminated with the bacteria. It became a reportable disease in the United States in 1987. Most cases have been reported in the United States, Canada, and the

United Kingdom. However, the largest recorded outbreak of *E. coli* O157:H7 occurred in Japan in 1996. It affected more than 6,300 children and caused two deaths. This outbreak was associated with consumption of radish sprouts served in elementary school lunches in Japan.

Infection is diagnosed by detecting *E. coli* O157:H7 in a stool sample. Infected individuals typically experience symptoms that include severe abdominal pain and bloody diarrhea. These symptoms can last for approximately 5 to 10 days. In severe cases, kidney failure may result, called hemolytic uremic syndrome. While rare, this most commonly occurs in the elderly and young children, and treatment typically includes blood transfusions and kidney dialysis. Although it can affect individuals of all ages, young children are the most at risk of developing serious complications.

Although transmission is primarily foodborne, infection can be secondarily passed from person to person and has been documented in some day care and nursing home outbreaks. Secondary transmissions are typically the result of improper hand washing and poor hygiene, resulting in the transmission of bacteria from fecal contamination. *E. coli* O157:H7 causes approximately 73,000 illnesses in the United States each year and 60 deaths. However, these are likely underestimates of the true prevalence given the numbers of infected individuals who do not seek medical treatment and, therefore, are not captured in the public health surveillance system. Preventive measures such as proper hand washing and thoroughly cooking meat are suggested as ways to minimize transmission of *E. coli* O157:H7.

Ethics in Health Care

Although health care is primarily delivered to individual patients, health care ethics examines issues that relate to many stakeholders, including patients (first and foremost), families, providers, institutions, third-party payers, and society. Ethics in health care can richly overlap with other areas of ethical enquiry such as organizational and business ethics, as well as research and public health ethics. Health care ethics is a young and loosely defined interdisciplinary field with a diverse community of scholars; however, it has been recognized as a field of study within the university, and it has a shared vocabulary, specialized journals, research funding, and an identifiable body of topics of concern. Scholars in the field of health care ethics seek consensus where possible, and when consensus is not possible, the goal is dialogue with mutual respect to advance understanding.

Tasks and Methods

Health care ethics draws on a wide variety of tools from a number of disciplines. The diversity of tasks and methods used in the field can be illustrated by considering the following vignette.

> Mr. Decline is a 48-year-old man whose life is in jeopardy from end-stage kidney disease. In the past, he received dialysis regularly, but he recently discontinued all treatments. His physician has explained that without dialysis he will die very soon. However, Mr. Decline refuses dialysis because he says it is uncomfortable and inconvenient and he generally feels well. He says he will undergo dialysis when he needs it, but right now he feels fine.

Many hospitals in the United States have multidisciplinary ethics committees that provide clinical ethics consultations. The consultative services provided by ethics committees can be used to educate practicing health care professionals, but they are more commonly called on to facilitate the resolution of disputes. Methods for dispute resolution include neutral framing of ethical questions, soliciting additional consultations (e.g., psychiatric or legal consultations), mediation, determining who should make decisions, facilitating discussions, and providing nonbinding advice. In the

case of Mr. Decline, a clinical ethicist would likely review Mr. Decline's chart, interview him and the staff who regularly provide care to him, and request a psychiatric consultation to evaluate his capacity to make medical decisions. If the psychiatric evaluation revealed that Mr. Decline did not have the capacity to make informed decisions, the ethics consultant would likely search for advance directives and/or next of kin for input. If no relatives could be found, the ethics consultant might work with a local court for the appointment of a guardian *ad litem.* On the other hand, if Mr. Decline were found to have decision-making capacity, his wish to decline treatment would be honored. This is grounded in the legal and ethical doctrine of patient self-determination, which recognizes a competent adult patient's right to refuse medical treatments.

Clinical ethicists who work in health care environments frequently play additional roles in cases involving issues such as informed consent and decision-making capacity. For example, they may provide education to staff, may advise on health care policies, or serve as expert witnesses in legal cases that involve related disputes.

Methods of Ethical Inquiry

Health care ethics draws on a wide range of tools from various disciplines.

Philosophical Methods

The discipline of ethics originated in philosophical reflection on the nature of the good and the right. Philosophy typically divides ethics into three categories: normative ethics, descriptive ethics, and metaethics. Normative ethics addresses questions of "ought" and tries to provide answers to the question, "What ought one do?" Descriptive ethics addresses empirical questions such as "How do people in fact behave in a certain situation?" Metaethics is the most esoteric of the three branches. It deals with questions about the meanings of ethical terms and the character of ethical knowledge. Metaethics is the foundation that normative ethics builds on, though it has been observed that greater consensus exists regarding specific moral principles than the metaethical foundations of ethics.

Normative ethics is the heart of ethical analysis, being informed by both metaethics and descriptive ethics. Thus, ethical considerations in philosophy seek to build a normative framework to guide moral decisions. There are myriad philosophical frameworks for guiding the moral life, usually centered on a theory of right action or of good character (virtue). Examples of theories of right action include utilitarianism (briefly stated as the greatest good for the greatest number) and Kantian deontology (acting only according to inviolable universal maxims of right action, such as always treating persons as ends rather than as means). Such simple theories are not commonly advocated today, as they are perceived to be inadequate to many of the complex tasks in health care ethics. Some currently used models are outlined below in the section on resolving ethical disputes.

Additionally, philosophical ethics may engage in clarification of basic concepts or the practical implications of moral rules. In the case of Mr. Decline, the tools of philosophy could be used to address a series of normative and conceptual questions such as "Is a patient morally obliged to accept all treatments that will prolong his or her life, or is it acceptable to forego treatments that are futile or overly burdensome?" When a patient foregoes life-sustaining treatments, is this tantamount to suicide? What is the scope of patient autonomy or of a physician's duty to heal?

Theological Methods

Many theological traditions enrich ethical discourse with a great array of perspectives. There is no one "right" theological method in secular ethics, but secular ethics simultaneously accepts input from many faith traditions. In Western secular ethics, the most common theological voices are those of Christianity and Judaism. Under these models, divine revelation and respect for traditions play central roles. Ethical problems are seen in light of received wisdom, and they are generally solved in the larger context of leading a moral life. The ethical analytic process has much deeper content for members of strongly defined moral communities, and they are generally able to resolve a great number of questions that remain debated in secular ethics. For example, most religious traditions have well-defined norms regarding the provision of health care at the extremes of life (i.e., norms dealing with abortion and euthanasia)—areas in which secular ethical consensus is not likely in the foreseeable future.

For a case such as Mr. Decline's, theology would be likely to ask questions concerning the appropriateness of life-sustaining treatments and the ways in which patients are expected to address illness and suffering.

Legal Methods

Legal scholars in ethics study how law and ethics intersect and inform each other. For instance, if studying informed consent, they would investigate its various manifestations (e.g., as explicit, presumed, or implied), as well as situations in which there might be exemptions such as emergency treatment. Legal ethics scholars are in a position to contribute substantially to policy debates. Some topics that legal ethics frequently discuss include universal access to health care, physician-assisted suicide, pharmaceutical regulation, privacy issues, and pain management. Legal scholarship in ethics helps define boundaries of human behavior through an understanding of case law, constitutional law, legislation, and administrative law. The interaction between law and ethics has been particularly fruitful in the area of medical research ethics. The ethical recommendations in the document known as the Belmont Report heavily influenced the Code of Federal Regulations that currently governs all biomedical research in the United States.

Legal considerations in Mr. Decline's situation would focus on issues of legal competence, advance directives, surrogate decision making, patient self-determination, and the scope of physician duties as defined by constitutional, statutory, and case law as well as standards articulated by the profession.

Qualitative and Quantitative Methods

Qualitative and quantitative methods are used both to describe actual moral judgments and behaviors (descriptive ethics) and to contribute data relevant to normative analysis. Both quantitative and qualitative methods draw from branches of the social sciences such as psychology, sociology, and anthropology. In addition, many quantitative methods also derive from processes found in the life sciences.

Broadly considered, qualitative methods are those methods that do not yield results that can be analyzed statistically. They generally involve asking open-ended questions to small groups of participants. Qualitative research methods seek to discover values and perspectives in populations. Some types of qualitative methods are focus groups, interviews, observation, phenomenology, and ethnography.

Quantitative methods are those that yield data that are best understood by statistical analysis. They ask questions such as "What percentage of patients with Alzheimer's disease retain the capacity to make medical decisions?" Quantitative researchers in ethics frequently make use of surveys and assessment instruments. A great deal of effort must be expended to craft reliable survey or assessment items so that the data gleaned from them will withstand rigorous statistical scrutiny.

Both qualitative and quantitative studies have addressed issues similar to Mr. Decline's. Qualitative studies might explore decision-making capacity, for instance, by interviewing patients to assess how they understand their treatment, prognosis, and options. A quantitative study might apply these findings further by trying to correlate them to objective measurements such as tests of cognitive function.

Topics

Health care ethics addresses a very wide array of issues from many perspectives. Commonly engaged topics include issues surrounding reproduction and the beginning of human life, such as fertility control, prenatal genetic screening, in vitro fertilization, or abortion; end-of-life issues such as futility judgments, code status, organ donation, or palliative and hospice care; the social dimension of health care, such as allocation of resources, managed care, eugenics, or conflicts between patient interests and society's interests; matters pertaining to informed consent, such as decision-making capacity, presumed consent, or children's right to assent to treatment; human research ethics, including the use of placebos in clinical trials, data and safety monitoring, and justice in recruiting participants; and professional responsibilities, such as truth-telling, the protection of confidentiality, and competency. The list of topics addressed within health care ethics will continue to evolve as new technologies develop. While new technologies often solve some ethical problems (e.g., an effective treatment for kidney disease might eliminate a host of ethical issues surrounding kidney donation, allocation, and transplantation), frequently new technologies generate a host of new ethical questions (e.g., our growing ability to diagnose the genetic correlates to diseases for which no cures currently exist poses numerous questions pertaining to cost-effectiveness, beneficence, justice, and eugenics).

Resolving Ethical Disputes

Any problem in health care ethics may include legal, medical, philosophical, religious, and sociological

dimensions. The problems most often identified with ethics are those that involve disputes over competing values, principles, or core commitments. Many patients rely on their faith tradition for answers to bioethical questions, and most traditions provide guidance on a variety of issues. Nevertheless, within the U.S. health care system, health care ethics is most often a secular endeavor embedded in the context of a pluralistic society, and as such it lacks a shared, canonical ethical framework for dispute resolution. However, some proposed frameworks, limited in scope, have been influential in shaping a language of secular ethics discourse.

The following are summaries of some influential theories in secular health care ethics.

Permission-Based Ethics (Engelhardt)

Engelhardt argues that reason has failed to generate a set of universally acceptable principles to guide moral decisions. Therefore, consensus is generally not possible across competing visions of the good because reason cannot mediate outside a particular context. Engelhardt distinguishes two kinds of moral relationships: those between "moral friends" (those who share fundamental convictions) and "moral strangers" (those who embrace nonshared convictions). Because of the failure of reason to establish a consensus on important ethical matters, society must embrace the principle of permission. Many, if not most, morally serious people would have to permit much that they view as unethical for a consensus based on permission to provide an outline of acceptable behavior that interdicts only the grossest of ethical infractions. Because of this provision, Engelhardt sees permission as effectively the lowest common denominator among competing beliefs. This model does not propose itself as a standard to reach for, but rather as the most robust public moral arrangement possible in a postmodern, pluralistic society, if we eschew the use of violence or coercion.

Principlism (Beauchamp and Childress)

Principlism seeks to identify common ground among competing views of morality. It does this in a unique way through the use of four "mid-level principles": autonomy, nonmaleficence, beneficence, and justice. Principlism assumes that competing moral theories do not have a common groundwork and also that they do not necessarily agree on what the proper ends of morality ought to be. Nevertheless, drawing from "common morality," principlism uses principles that emerge across competing theories. These principles may provide a shared language and a conceptual lens for analyzing ethical problems. For example, the case of Mr. Decline might be described as a conflict between patient autonomy (if Mr. Decline is competent to make decisions) and medical beneficence.

Virtue Ethics (Pellegrino and Thomasma)

According to classical virtue theory, virtues are behavioral characteristics that lead human beings to achieve their natural goal of full human flourishing. Pellegrino and Thomasma extrapolated this concept from individuals to the professions, arguing that professional virtues are the characteristics that lead professionals to the attainment of the goals of the profession. For example, if the primary goal of medicine is to heal, then virtue ethics seeks to find what character traits promote that goal. These traits, or professional virtues, should be fostered in professionals because they are essential to achieving the goals of their professions. Virtue ethics does not rely on abstract principles to guide moral actions but instead appeals to society's common frame of reference in the form of virtuous behavior.

Casuistry

Casuistry is a discipline of ethical problem solving that emphasizes looking to past precedent to resolve current disputes. Casuistry has deep roots in Western thought, appearing prominently in the ideas of the sophists against which Plato and other ancient philosophers fought. It has fallen in and out of favor over the centuries and was most recently revived in the 1960s, in part because of bioethics and its need for case analysis. Casuists study myriad facets of cases that have occurred in the past to see their similarities and differences, learn from them, and apply those lessons to the resolution of present cases. There is a strong analogy between casuistry and the legal concept of case law.

Bioethics and the Law

The law can narrow the range of ethical debate on an issue, though some debates continue to rage after the law has addressed an issue (e.g., abortion). Though at

first blush both law and ethics seem to deal with setting boundaries for human behavior, the two have important differences beyond enforcement. The chief separation between law and ethics is how each one sees the purposes of the limits it sets. On at least one account, law sets groundwork and provides punishment for violations, whereas ethics is largely aspirational and seeks to inform good behavior. On the other hand, ethics can help to shape law. Professional standards of practice are one example. Violations of standards of practice are the most common tort causes of action, and ethics contributes significantly to definitions of what constitutes best practice.

Ethics in Human Subjects Research

During the latter part of the 20th century, significant attention was paid to abuses of human subjects and to the development of a system for overseeing human research and a framework for the ethical conduct of such research. The Code of Federal Regulations (C.F.R.) governs much of the research conducted in the United States or by U.S. investigators abroad. Nevertheless, compliance with the regulations governing human research does not guarantee the ethical conduct of research. The regulations require ethical insight to be interpreted and applied appropriately, and regulations may not capture ethical issues that emerge in light of social changes or scientific and technological developments. The Office of Human Research Protections (OHRP), part of the U.S. Department of Health and Human Services, periodically offers additional guidance; professional organizations and institutions may produce codes of ethics or guidelines that address the ethical conduct of research on humans; and several international codes and statements influence discussions of research ethics. In the developed world, it is common for nations to have substantive laws, regulations, guidelines, or policies concerning research.

This entry describes the historical development of ethical principles governing research with human subjects, reviews public policy in this area, and considers specific issues of importance in epidemiology. The ethical conduct of epidemiological research involves balancing the interest in conducting such research so as to understand health and disease and ultimately improve health and prevent disease against individuals' interests in privacy and confidentiality and in avoiding nonvoluntary participation in research.

History

The contemporary approach to the ethical conduct of research grew out of a history of abuses and scandals. The abuses of human subjects that surfaced during the trial at Nuremberg of Nazi physicians and scientists who had experimented on concentration camp victims led to the first significant 20th-century changes in human subjects' protections. The necessity of these protections was demonstrated not only because the often fatal experiments conducted by the Nazis were

made known, but also because as part of their defense, the Nazi defendants spoke of studies conducted by the victorious powers that shared some parallels to their experiments, including the failure to obtain consent.

The Nuremberg Code was developed as part of the judgment against the Nazi physicians and scientists. The Code consists of 10 principles that the court said should be followed when using humans in research, including the obligations to (1) obtain subjects' voluntary consent; (2) allow subjects to withdraw and end their participation at any time; (3) ensure that it is necessary to conduct the proposed research to obtain the information sought and that the research is expected to be beneficial to society; (4) minimize the risks to and suffering of subjects; and (5) ensure that the expected benefits outweigh the anticipated risks.

The publication of Henry Beecher's 1966 article in the *New England Journal of Medicine* was a pivotal event in the history of research ethics. Beecher described 22 biomedical studies that he believed were unethical. In the Jewish Chronic Disease Hospital study conducted in 1963, liver cancer cells were injected under the skin of elderly patients to study immune responses. Most of the subjects suffered from dementia, were not told the truth about the study, and were not asked for permission to participate. At the Willowbrook State School for the Retarded in New York City, where children typically developed hepatitis while living in the institution, children were infected with hepatitis on admission to study the progress of the disease and possible methods of treatment. The study raised a range of issues, including the use of undue influence to obtain parental permission by putting children who would participate in the study on a fast track for admissions and the failure to take basic precautions to prevent the spread of hepatitis in the institution.

Around the time of Beecher's publication, the U.S. Public Health Service (USPHS) began requiring peer review, including consideration of subject's rights and welfare, of all USPHS studies. Despite this requirement, failure to consider the subjects' welfare was overwhelming in the infamous USPHS syphilis study conducted in Tuskegee, Alabama, for four decades starting in 1932. This study prompted radical changes in the regulation of human research in the United States and led to the development of the framework used for assessing the ethical conduct of research. The study enrolled African American sharecroppers in Alabama with promises of meals, free medical care, and burial insurance. Subjects were not told they were participating in syphilis research, were not asked for permission to enroll them in the observational study, and were not given information about the fact that they had syphilis. The study remained strictly observational even after penicillin became widely available for treatment of syphilis. Throughout the course of the study, and especially after the introduction of penicillin, subjects were discouraged and prevented from seeking treatment outside the study sites. A 1972 article in the *Washington Post* informed the public of the study, and significant changes in human research began to occur. In 1972, the Office for the Protection from Research Risks (now OHRP and housed under the Department of Health and Human Services) was created under the National Institutes of Health (NIH) to protect the welfare of human research subjects. In 1974, the U.S. Congress passed the National Research Act, requiring that an institutional review board (IRB) review research protocols and appointing the National Commission for the Protection of Research Subjects of Biomedical and Behavioral Research. The Commission was to identify principles and guidelines that ought to govern research on humans. The Commission published a number of reports, the most well known of which is the 1979 Belmont Report, which identified three basic ethical principles for the ethical conduct of research:

- *Respect for Persons.* The judgments of autonomous persons, those "capable of deliberation about personal goals and of acting under the direction of such deliberation," must be respected. Persons not capable of self-determination must be given special protections (§B.1). This principle generates the obligation to obtain valid, free, and voluntary informed consent for research participation.
- *Beneficence.* One must protect persons from harm and make efforts to secure their well-being. This is the basis of the obligation to ensure that the anticipated benefits (to subjects and/or society) outweigh the risks, that risks be minimized, and the subjects be told of a study's risks (§B.2).
- *Justice.* The principle of justice requires that one avoid denying someone a benefit to which he is entitled and that one avoid imposing an undue burden on a person (§B.3). This principle requires that subject recruitment and selection be conducted in such a way that no group disproportionately bears the burdens of research participation and that no population be denied access to research participation without justification.

Public Policy

The C.F.R. and the *Belmont Report*, on which the regulations are largely based, are of primary importance in the U.S. research environment. A number of codes and international guidelines also influence discussions surrounding the ethical conduct of research, especially the Nuremberg Code, the Declaration of Helsinki, and the Council for International Organization of Medical Sciences (CIOMS) (an organization established by the World Health Organization and the United Nations Educational, Scientific, and Cultural Organization [UNESCO] in 1949) Guidelines.

C.F.R. Regulations

The Department of Health and Human Services regulations at 45 C.F.R. 46.102(f) define research as a "systematic investigation, including research development, testing and evaluation, designed to develop or contribute to generalizable knowledge." Generally, any investigation that is intended to result in the dissemination of information through an article, a presentation, a poster session, or some other means is considered to be aimed at contributing to generalizable knowledge. A human subject is "a living individual about whom an investigator (whether professional or student) conducting research obtains (1) [d]ata through intervention or interaction with the individual, or (2) [i]dentifiable private information." When both conditions are met, investigations are generally subject to the C.F.R. Three main sections of the C.F.R. concern human subjects research protections: 45 C.F.R. 46 (the Common Rule); and Food and Drug Administration (FDA) regulations at 21 C.F.R. 50 and 21 C.F.R. 56. The Common Rule reflects a 1991 decision by 17 federal agencies and departments to adopt common regulations governing human research; the FDA maintains its own set of very similar regulations.

Although the regulations in the C.F.R. govern a significant portion of research conducted on persons in the United States or by U.S. investigators engaged in research abroad, not all research falls under the C.F.R.'s purview. However, all research sponsored by the federal government, conducted in an institution that has a federalwide assurance (FWA), conducted by any investigator employed by an institution that has an FWA, or any research the results of which are to be submitted to the FDA must be conducted in accordance with the C.F.R. A number of scholars, scientists, and government panels have argued that all human research conducted in the United States or by U.S. investigators ought to be governed by the C.F.R.

Institutional Review Boards

A key requirement in the C.F.R. is that research protocols be reviewed and approved by a duly constituted IRB and that IRBs monitor studies on an ongoing basis and review approved protocols at least once per year. Traditionally, IRBs have been housed within the institutions where proposed research will be conducted, such as academic medical centers or hospitals. Today, some institutions contract the review of at least some studies to independent or commercial IRBs. An IRG must have at least five members, at least one of whom must be a scientist and one of whom must not have a background in science. At least one member must not be affiliated with the institution conducting the research. If a proposed study will involve prisoners, at least one prisoner or one person who can represent the interests of prisoners must be on the board, and the majority of the IRB members must have no affiliation with the prison(s) involved in the study. The C.F.R. exempts some research from the requirement of IRB review and allows some research to be reviewed by an IRB in an expedited fashion rather than by the full board. For example, studies using only existing data that will be recorded without identifiers or codes may be exempt from IRB review. Many institutions require that investigators conducting exempt research inform the IRB of their intent to do so and that a representative of the IRB determine that the proposed study meets the criteria for exempt research. Such review can ensure that investigators have appropriate plans to conduct the research such that it in fact qualifies as exempt, for example, that they have plans to anonymize data and protect subjects' confidentiality. Studies that pose only minimal risk to subjects and meet one of nine criteria enumerated in the *Federal Register* of November 9, 1998, may be reviewed on an expedited basis. Examples of research that generally qualify for expedited review include certain studies that involve only venipuncture where limited amounts of blood will be drawn from adults and studies that involve only a survey instrument or other noninvasive means of collecting data.

IRBs review protocols to ensure that they comply with the requirements set forth in the C.F.R. and that any other ethical or safety concerns are given proper

consideration. IRBs are responsible for ensuring that risks to subjects are minimized; the expected benefits of a study outweigh the risks; research participants will be recruited and selected in a fair manner such that no group disproportionately bears the burdens of research participation or is denied access to research participation without justification; investigators plan to obtain and document informed consent appropriately; data safety monitory plans appropriate to a protocol have been developed; and appropriate measures are taken to protect subjects' confidentiality and privacy. The requirements for informed consent vary based on the type of study proposed and the population to be included. If a study will recruit adults who may be unable to make their own decisions regarding research participation because they are unable to understand and appreciate information, appropriate plans to involve a legal surrogate must be made. If a study will involve children, the permission of one or both parents is required, depending on the nature of the study and the reasonable availability of both parents. As appropriate for a given study, the information to be provided as part of the informed consent includes information about the fact that the proposed intervention is for research; the purpose of the research; the number of subjects to be enrolled; the time research participation will require; the research procedures; the foreseeable risks and discomforts and, if appropriate, acknowledgment that that there may be unforeseen risks; the expected benefits to subjects and/or others; subjects' alternatives to participation; confidentiality; the availability of compensation or treatment available to subjects who may be injured; contact information for persons who may help subjects with questions about their rights and who should be contacted in the event of injury; the voluntary nature of participation; the right to withdraw from a study and the consequences of withdrawing early; the circumstances under which a subject may be withdrawn from a study without the subject's permission; additional costs subjects may incur as a result of participation; and the fact that new information obtained during the course of a study will be communicated if it is deemed relevant to subjects' desire to remain enrolled in a study. Particularly, when patients enroll in research, it is incumbent on the researcher to counteract subjects' tendency to misunderstand the purpose of research and assume that research is an extension of their clinical care or that participation in research will give them access to the newest and best treatments (therapeutic misconception), compromising informed consent.

Other Ethical Issues

In recent years, a number of concerns have emerged that are not explicitly addressed in the C.F.R. but that have become important in discussions of the ethical conduct of research. One is that investigators and institutions conducting research may have conflicts of interest or commitments that could interfere with their obligations to patients and/or subjects. Financial conflicts of interest have been scrutinized in the wake of cases in which subjects were injured or died, and it was later revealed that the investigators and/or research institutions had significant financial interest in the research.

Even in the absence of significant financial conflicts of interest, investigators who also serve as clinicians, and organizations that also serve as patient care institutions, may have conflicts between their commitment to and duties of care and their research aims. Following the Kennedy Krieger–led abatement study ruling in Maryland, in which the court asserted that investigators owed a duty of care to the subjects enrolled in the study, there has been much discussion of what duties researchers may have to patients and nonpatients enrolled in research. The conduct of research in developing nations, either with the aim of ameliorating disorders or conditions endemic to those nations or for the purpose of testing interventions that primarily will be used in the developed world, has raised important new questions. For example, after the trials on preventing vertical transmission of HIV in the 1990s, during which a shorter course of AZT was tested against placebo in pregnant women (rather than against Protocol 076, which had become the standard of care in the developed world and according to which pregnant women were given AZT orally five times a day during the last several months of pregnancy and intravenously during labor; newborns were given AZT in syrup form for the first 6 weeks and were not breastfed), a debate emerged about what it means to provide standard of care (e.g., worldwide global best of care or local standard) to subjects and what obligation researchers have to provide standard of care. Finally, there is ongoing discussion of what is owed to research subjects who are injured as a result of their participation and whether sponsors (or others) must make provisions for compensating individuals' research-related injuries.

Epidemiological Research

The regulations governing human research emerged in response to studies that exposed subjects to high levels of physical risk, yet this framework has been applied to all areas of research involving human subjects, including epidemiological research and behavioral and social sciences research. Research in these areas raises some unique ethical concerns, and it may be appropriate to develop a more nuanced regulatory framework for oversight of human research in response to the concerns that emerge in different areas of research. Epidemiological research can raise questions about privacy, confidentiality, informed consent, study design, cultural sensitivity and imperialism, reporting of results, the blurring of the line between advocacy and scientific research, and the possibility of conflicts of interest among funders who expect certain results.

The ethical issues that arise in epidemiological research can be examined by distinguishing three categories of research: studies that (1) use only existing data, (2) involve collecting new data, or (3) are interventional or experimental in nature.

Use of Existing Data

Privacy, confidentiality, and lack of consent are the primary ethical concern raised by studies that involve only the use of existing data, records, specimens, or other information. In many cases, requiring consent of individual subjects would render it impossible to conduct epidemiological research and important information would remain unavailable. If identifying information is not collected with the private information that is gathered from existing sources, many of the confidentiality concerns are resolved and such research is considered exempt under the C.F.R., and informed consent is waived. In many institutions, IRBs make the final determination that such studies are exempt from full board review, and IRBs may examine protocols to ensure that the confidentiality and privacy protections proposed are sufficient. A person's privacy, nevertheless, may be invaded by such research because investigators may initially have access to identifying information even if they record data without identifiers. An emerging area of concern is the use of research involving tissue samples previously collected for research or as part of clinically indicated procedures. The OHRP offers guidance on when research may be conducted using stored specimens, when such research may be considered exempt, when the persons from whom the specimens were obtained must be contacted for consent to conduct the research, and what procedures should be followed when collecting specimens to be stored for possible future research. Because the primary concerns associated with such research involve privacy and confidentiality, research involving specimens that have been de-identified or that cannot be linked to individuals raises fewer concerns than research involving identifiable samples.

Collecting New Data

When epidemiological research involves the collection of new data, consent generally must be obtained, but it often is not documented through a formal consent form. If the new data will be collected from surveys or comparable means, typically investigators must disclose the fact that a person is being asked to participate in research and offer them information about the study. Participants indicate their consent by responding to interview or survey questions. If the data are collected only through surveys or comparable means without identifiers and the research does not involve minors, the research typically is exempt. Individual institutions may require some oversight of such research. Studies involving minors require IRB review and approval, and there is disagreement about how parental permission should be obtained. Some favor approaches that require parents to opt out rather than to opt in as a means of increasing participation; others are concerned that at least some research should require a clear indication that parents have chosen to allow their children to participate.

Interventional or Experimental Studies

When communities are randomized to receive different interventions or to serve as controls receiving no interventions to alter behaviors or practices that affect health as part of interventional or experimental epidemiological studies, additional ethical concerns emerge. Examples of these studies include research aimed at reducing smoking in a community, increasing childhood vaccination rates, or improving cancer-screening rates. Questions about how communities are chosen and randomized and how to show proper respect for cultural practices that may be of interest to epidemiologists emerge. A number of questions revolve around informed consent, including whether there is an obligation to obtain permission from community members to have their community be subject to interventions and

have outcomes measured and compared; if an obligation to obtain community permission exists, how such permission should be obtained and how much information must be disclosed (especially in light of the possibility that disclosing too much information could invalidate the results), and whether all communities or only those subject to experimental interventions must give their permission to participate are questions that need to be answered.

Ethics in Public Health

Public health practice and research raise unique ethical dilemmas. In contrast to medicine, which is patient-centered, public health activities aim to protect and promote population health and must balance risks and benefits to individuals against those to communities or society as a whole. Students and practitioners of public health should recognize the ethical basis of public health activities and make decisions that are consistent with the underlying ethical values and norms of the field. Because key public health threats change over time, ethical values evolve, and multiple disciplines inform the efforts of public health activities, defining a distinctive ethical orientation or normative framework for public health is challenging. This entry aims to reflect areas of consensus that have emerged in recent literature.

Ethical Analysis in Public Health

Public Policy, Law, and Ethical Theory

There is a societal expectation that the government should assume some degree of responsibility for protecting public health. In the United States, public health institutions have legal (police) powers. Legislative statutes, court cases, and administrative policies frequently address public health matters. Ethics, public policy, and law are overlapping sources of guidance for determining acceptable behavior for citizens, professionals, and government officials, allocating limited resources, and defining individual rights and responsibilities. Policies may be inconsistent or outmoded, they may not always reflect society's moral consensus, and they do not provide guidance for decision making in every situation. Some laws may even be considered by certain citizens to be unethical. For these reasons, careful ethical analysis is necessary to provide additional legitimacy for state-sponsored public health activities.

Ethical theories and frameworks are conceptual tools to aid decision making and the evaluation of ethical arguments. They do not provide automatic solutions to complex problems. Theories identify and justify basic moral principles, but in a given situation, facts must be considered, and principles or values can sometimes conflict.

The leading ethical framework in medicine is principlism. The four prima facie principles of respect for autonomy, beneficence, nonmaleficence, and justice are widely recognized as shared professional values from which ethical rights and duties can be derived. Public health shares a commitment to these ethical principles but may weigh them differently in a particular circumstance due to an emphasis on collective

risks and benefits. Additional principles such as utility and consideration of the common good are also characteristic of public health.

Several ethical theories are also relevant to public health. Kantian deontology connects morality and reason; certain actions are intrinsically right or wrong and, therefore, ethically mandated or prohibited. Kant emphasizes individual rights and is perhaps best known for arguing that no person should ever be treated as a means to another's end, but instead, all persons should be treated as "ends in themselves." This emphasis on respect for persons provides balance against considerations of utility and efficiency. In contrast to deontology, for which consequences are relevant only if the action is morally permissible, utilitarianism presupposes that actions are right insofar as they promote the greatest good for the greatest number. For the utilitarian, expected consequences are the primary consideration in decision making. Public health is often described as utilitarian because policies and interventions aim to maximize aggregate health outcomes. However, both Kantian deontology and utilitarianism are somewhat limited in their application to public health because they do not consider collective social goals. Communitarian theory, which asserts that ethics cannot be separated from the shared history, traditions, customs, and institutions of particular communities, may be more consistent with the ethical perspective of public health. Human rights theory may also provide a normative ethical framework for public health, emphasizing universal civil, political, and social rights and recognizing socioeconomic, cultural, and environmental influences on health.

Professional Codes of Ethics

Professional codes of ethics can assist public health practitioners and researchers to recognize and address ethical issues. While professional codes are general and do not provide definitive answers to specific problems, they do outline the basic rights and obligations of citizens, public health practitioners, governments, and other public and private institutions and are therefore useful in setting standards and expectations.

Morality and Health

Public health issues invoke images of virtue and vice. Moral judgments and stereotypes influence public health interventions. Negative perceptions of individuals who engage in risky behaviors affect public attitudes toward policy, funding, and education, including the rhetoric used in interventions and political decisions to criminalize certain behaviors. Prescriptive messages regarding health-related behavior may be judgmental or stigmatizing.

Ethical Principles of Public Health

The fundamental ethical principles underlying public health practice and research include the following: beneficence, respect for the common good, respect for persons, utility, social justice, prevention, commitment to science, honest communication, and community participation. These principles are not weighted in any particular order but rather are all considered prima facie obligations.

- *Beneficence.* One of the basic ethical mandates of public health is to provide benefits. In addition to protecting the population from immediate and future threats to health and safety, public health interventions and research should also avoid causing direct harm and make every reasonable attempt to minimize risks.

- *Respect for the Common Good.* An individual's actions affect not only his or her own health but also the health of other humans, nonhuman organisms, and ecosystems. Most definitions of public health emphasize interdependence and collective action, obligation, and benefit. Focus on the common good (specifically population-level health outcomes) is the primary difference between the ethics of public health and medical ethics. Public health efforts often require pooled resources and cooperation. For example, vaccination can effectively prevent the spread of infectious disease (provide herd immunity) only if a majority of citizens participate.

- *Respect for Persons.* Public health activities should respect individual rights, but autonomy must be balanced with promotion of the common good. In some cases, it may be necessary to override individual rights in order to protect community health. For example, in the case of infectious disease, the population-level benefits of quarantining exposed persons may justify a temporary infringement on personal freedom. However, public health officials must be certain that proportionality is respected and that community benefits outweigh individual sacrifices.

- *Utility.* While not always strictly utilitarian in the classic sense, public health strives to achieve the greatest good for the greatest number and emphasizes producing the maximal balance of benefits over harms and other costs. Efficiency is related to utility; stewardship of limited resources is required. However, the costs and savings of prevention are not always clear, and measurement techniques and metrics vary. Furthermore, efficiency must be balanced with equity.

- *Social Justice.* Public health's social justice perspective supports equitable access to—and equitable distribution of—health care and other resources necessary for health, as well as the benefits and burdens of public health interventions and research. Social justice also provides the foundation for public health's focus on eliminating health disparities, respect for cultural diversity, and protecting the health of vulnerable populations (e.g., children).

- *Prevention.* The public health perspective prioritizes prevention over cure. This focus influences resource allocation decisions. Generally, efforts to prevent disease are prioritized over treatment of those who are already ill. Prevention also mandates thoughtful anticipation and sound scientific research.

- *Commitment to Science.* Public health interventions should be based on scientific knowledge. Public health practitioners have an ethical responsibility to seek out necessary information to the extent possible. However, knowledge is not morally neutral. Facts can be interpreted differently by various stakeholders, and the relationship between facts and values is complex. While knowledge may often demand action, knowledge is not always necessary for action. In some cases, such as an infectious disease outbreak, action may be necessary before all the facts are available.

- *Honest Communication.* Public health activities necessarily involve a great deal of communication. Truthfulness, promise keeping, and transparency about motives and actions promote public trust. Timeliness and accountability are also imperative, particularly in emergencies.

- *Community Participation.* Public health values the participation and collaboration of all stakeholders in planning, implementation, evaluation, and research. Opportunities for community input are particularly important to ensure appropriateness of resource allocation, quality of intervention design, and adequate informed consent for research.

Ethical Challenges for Public Health

Ethical dilemmas familiar to public health researchers and practitioners will be discussed, highlighting those ethical norms that should guide decision making. Examples presented are not meant to be exhaustive but rather illustrative of the types of ethical conflicts arising in public health.

Health Promotion and Disease Prevention

The appropriate parameters for health education and health promotion efforts—and the degree to which governments should regulate health-related behavior—are contentious. Some would argue that the state's only obligation is to protect citizens from imminent threats that necessitate action at the population level (e.g., communicable diseases). Others argue that government paternalism is justified on the grounds of efficiency, utility, and economics as well as the desire of many citizens for assistance in being healthy. However, educational campaigns run the risk of being tyrannical or moralistic and raise ethical questions regarding the appropriateness of moral exhortation, value-laden language and imagery, and excessive focus on individual responsibility. The use of financial incentives or coercive measures (such as the threat of imprisonment) to influence health-related behavior may also infringe on individual rights, stretch governmental limits of power, or violate social justice.

Determining and Valuing Risk

Defining, determining, and communicating risk raises ethical challenges. Determining safe or socially acceptable levels of risk (whether related to behavior, exposure, or interventions) involves value judgment; consideration of various social, political, and ethical factors; and compromise.

The equitable distribution of risk across a population is a matter of social justice. Recent studies suggest that the potential (known and unknown) risks of exposure to industrial pollution and other environmental hazards disproportionately burden low-income populations throughout the world. This inequality exacerbates the health problems of already disadvantaged groups.

Another ethical tension in public health exists between interventions that focus on risk reduction versus those that focus on total risk elimination (or "abstinence" in the case of behavioral interventions).

For example, while some would argue that the only way to eliminate HIV infection among injection drug users is to completely stop (or never start) use, others promote clean-needle-exchange programs as a more realistic and immediate way of reducing transmission. Ethical disagreement also arises over the messages risk-reduction efforts send to youth regarding the safety and social acceptability of unhealthy behaviors.

Public Health Research

The Belmont principles for ethical research with human subjects—respect for persons, beneficence, and justice—were developed with clinical research in mind. They are somewhat inconsistent with public health's emphases on prevention and population health and do not consider community risks and benefits. For example, if research suggests that a certain ethnic group or geographic community is at increased risk of a particular illness or risk behavior, publicizing findings may result in harm (e.g., employment or insurance discrimination, social stigma) not only to study participants but also to any member of the group.

Equipoise, or genuine uncertainty about the comparative merits of two or more interventions, is a condition of ethical research and ensures that subjects are not disadvantaged by research participation. Public health's commitment to eliminating health disparities necessitates consideration of the costs of different types of interventions, and these economic considerations present a challenge to equipoise. A particularly controversial issue in public health (especially international) research is the ethicality of studying or implementing less expensive—and predictably less effective—interventions when a known effective intervention is too expensive for a particular community or country.

Epidemiological Surveillance

Epidemiological surveillance involves the gathering and application of information to determine appropriate interventions and distribute resources for disease prevention. Surveillance is ethically imperative as detailed, accurate information is needed to plan interventions or determine if further investigation is warranted (e.g., in the case of cancer clusters). Surveillance may involve identifying specific individuals or communities to determine the source(s) of the health problem. Like research, surveillance presents risks related to the breach of privacy and confidentiality. However, research guidelines focus on protecting individuals and producing generalizable knowledge and, therefore, cannot be directly translated to the public health setting, where the protection of communal welfare is prioritized.

Infectious Disease Control

Until the emergence of HIV/AIDS in the 1980s, communicable diseases—including sexually transmitted diseases—were handled in a fairly consistent manner. Infected individuals were reported by physicians to local public health authorities, and contact tracing was conducted to identify other exposed and possibly infected individuals. Stigmatization, the labeling of HIV/AIDS as a disease of homosexuals, and the rise of individualism and privacy expectations led to what some have called "HIV exceptionalism." Recently, rising infection rates worldwide have led to the consideration of widespread screening of low-risk populations rather than a turn to rigorous reporting and partner notification practices. However, routine screening does not eliminate ethical concerns related to breach of confidentiality and other risks.

Emergency Response

Emergency response during a disease outbreak or natural or man-made disaster (such as a bioterrorist attack) may involve quarantine, isolation, forced treatment, or other threats to civil liberties. Emergencies may also necessitate breaches of privacy and/or confidentiality such as calling names, providing treatment in open spaces, or publicly disclosing disease or exposure status. Limited health care resources may need to be quickly rationed, and not everyone will receive what they perceive to be adequate and timely treatment. Public discontent may be exacerbated because there is limited information, fragmented communication, and inadequate opportunities for community input.

Emerging Threats

As both an area of moral inquiry and a set of shared professional values, public health ethics continues to develop. Emerging threats to public health, including pandemic infectious diseases, growing health disparities, and the rising costs of health care, will shape

future discourse on the ethical norms and standards of the field.

Etiology of Disease

The etiology of disease refers to the causes or to the study of the causes or origins of disease. The term *etiology* is derived from the Greek *aitiologia* meaning "statement of cause." The roots come from *aitia* "cause" + *logia* "speaking." The primary focus of investigations of disease causation within the discipline of epidemiology has changed over time. However, the elucidation of the relationships between potential causal factors and diseases or health outcomes has remained a central concern in epidemiological research.

Historical Background

Investigations of disease etiology in the modern period of epidemiology have continued to evolve with the dominant paradigms of disease causation of each era. The sanitary era of the early 19th century was dominated by the miasma theory, a view of disease as arising from foul emanations from impure water, soil, and air. English sanitary reformers who held to this theory, such as Edwin Chadwick and Florence Nightingale, were thus mistaken in their understanding of the specific agents of disease etiology; however, their overall emphasis on improving social and physical conditions in the urban industrial environment led to major improvements in public health.

The work of Louis Pasteur and the development of Koch's postulates next contributed to the shift in clinical medicine and public health toward the germ theory, which attributes disease causation to microorganisms. During the ensuing era of infectious disease of the late 19th and early 20th centuries, etiologic research accordingly consisted of searching for single causative agents of diseases. The classic model that reflects the influence of this era of infectious diseases is the epidemiologic triad of agent, host, and environment.

By the mid-20th century, a shift had occurred in more developed countries, with chronic rather than infectious diseases becoming predominant. Etiologic research in the era of chronic disease epidemiology focused on multiple proximate risk factors for chronic diseases in individuals and benefited from advances in epidemiological and biostatistical methods.

The latter part of the 20th century witnessed increasing developments within epidemiology and related fields that have contributed depth and breadth to the field on both a micro- and macrolevel. Advances in the subdisciplines of molecular epidemiology and human genome epidemiology enabled epidemiologists to use findings from the Human Genome Project and to study the specific pathways, molecules, and genes, and interactions between genes and the environment that

influence the risk of developing disease. Concomitantly, a renewed focus on the effects of the social and physical environments on health and an increasing interest in intergenerational influences were reflected in the development of a life course approach to chronic disease epidemiology and the contributions of social epidemiology to a multilevel perspective of disease etiology.

Eugenics

Eugenics, defined as the study of improving the human race through selective breeding, coincided with the Bacteriological Era of epidemiology during the late 19th century into the early decades of the 20th century. As a science, eugenics developed gradually from basic ideas to lofty, and often unfounded, scientific conclusions. Its rapid growth in popularity with the general public and a handful of socially inclined scientists led to a series of events that has permanently influenced the design of modern population studies and the practice and study of medicine.

Nineteenth-Century Origins of Eugenics

Eugenics began when Sir Francis Galton, cousin of Charles Darwin, invented and defined the term *eugenics* in 1883. Many scientists, philosophers, and socialites, including Galton, Herbert Spencer, Charles Davenport, and John Harvey Kellogg, played pivotal roles in legitimizing eugenics and promoting the concept of protecting the human race from genetic and moral decline. England, the United States, and Germany were among the forerunners in the establishment of eugenics, which eventually expanded to more than 30 countries worldwide. People feared diseases and social problems that were thought to be hereditary, including morally inept behavior, congenital abnormalities, and alcoholism, which propelled the eugenics movement forward. Techniques such as sterilization by vasectomy or tubal ligation, forced imprisonment in asylums, and euthanasia were seen by some as ways to cleanse human society.

Scientific advances by three leading figures in the late 1800s led to the initial concepts that would become the cornerstone of eugenics at the turn of the century. Darwin's controversial book *On the Origin of Species*, published in 1859, proposed that inheritance was a natural, controlled process. Darwin's theory of natural selection was based on scientific evidence showing that variation of targeted characteristics in animals influenced selection and survival within a population. While Darwin remained dedicated to studying populations of animals, Galton was increasingly interested in applying selection processes to human populations. He believed that cognitive ability could be increased through improving human biological variation and viewed such improvement as an extension of Darwin's theory. At the time, Darwin thought only on the level of observable traits in a population and did not appear to have considered the complexity of genetics as the driving force behind selection. The only scientist to have recognized the intricacies of inheritance, by studying the transmission of characteristics in peas, was Gregor Mendel. His article on experiments with plant hybridization was published just 6 years after Darwin's book; however, it was poorly understood and disregarded. It wasn't until Mendel's work was rediscovered in the early 1900s that its impact was realized.

During the time between 1860 and 1900, Galton promoted the concept of natural selection in humans. At the same time, the two most significant discoveries in epidemiology during the Bacteriological Era were made. First was the transmission of disease by arthropods, generally from an animal source, and second, the transmission of disease from healthy carriers. However, it was the idea that an unsanitary physical environment contributed to disease, a hypothesis presented centuries earlier, that found a new appreciation in Victorian-Era Britain, as well as in other countries around the world. Since

the British ruling classes were viewed as superior and free from unsanitary environments, many people accepted the perspective that biological inheritance determined leadership qualities and social status. Herbert Spencer, an Englishman, championed Galton's ideas and introduced Social Darwinism, which suggested that a proper and discriminating society depended on the quality of the individuals within the society. Spencer's book *First Principles*, published in 1862, attracted a large following. The book drew comparisons between society and biological organisms and implied that the process of selection was entirely natural, even in humans. Spencer relied heavily on the concept of evolution and considered competition as the fundamental element to evolutionary progress.

The rediscovery of Mendel's laws at the turn of the century was perhaps the single most important scientific detail that finally united early eugenicists with scientists in a wide variety of fields. Mendel's laws provided scientists with the ability to predict the transmission pattern of traits and allowed them to understand the basic mechanism driving inheritance. This understanding provided a way to relate eugenics, concerned with purifying human society, to epidemiology, concerned with the occurrence of disease in large populations. At the time, it was believed that diseases such as typhoid, yellow fever, and syphilis could be inherited, and the decision whether to treat and save people afflicted with these diseases was a constant conflict for eugenicists and public health officers.

Eugenics in the 20th Century

In 1904, one of Galton's former students, Charles Benedict Davenport, established the Station for Experimental Evolution at Cold Spring Harbor in Long Island, New York. Research at Cold Spring Harbor was to be concerned with nonhuman genetic and evolutionary studies. However, Davenport was clearly studying the role of eugenics in human evolution, and he used human pedigree analysis and Mendelian principles to predict tendencies toward traits such as feeble-mindedness or disease. In 1906, John Harvey Kellogg created the Race Betterment Foundation in Battle Creek, Michigan, and just 4 years later, in 1910, Davenport established the Eugenics Record Office (ERO) at Cold Spring Harbor, appointing himself as director and hiring Harry H. Laughlin as superintendent. Laughlin was responsible for collecting data on the inheritance of human traits, analyzing census data and population trends, encouraging courses in eugenic principles, and distributing eugenics materials in the United States and Europe.

Between 1910 and 1916, discussion of eugenics spread rapidly in the mass media. Articles published in periodicals written for the average citizen, such as *Good Housekeeping* and *The Saturday Evening Post*, captured the imaginations of housewives and working husbands. In addition, books targeted for public consumption included such works as *The Passing of the Great Race* by Madison Grant (1916) and *The Rising Tide of Color Against White World Supremacy* by Lothrop Stoddard (1920). A prosterilization film, *The Black Stork* (1917), and a Public Health Service film, *The Science of Life* (1922), were released to demonstrate the dangers of passing on defective traits. In 1929, philosopher and mathematician Bertrand Russell, who received the Nobel Prize for Literature in 1950, published *Marriage and Morals*, in which he wrote, ''In extreme cases there can be little doubt of the superiority of one race to another'' (p. 266). Later, Russell turned against eugenics, becoming a leader in the fight against racism. ''Better Baby'' and ''Fitter Family'' contests were held at state fairs as ways to entertain and educate American families, providing a visible distinction between those who were genetically fit and encouraged to reproduce and those who were not. In the 1930s, eugenics was commonly taught in high schools and colleges, and sermons augmenting the virtues of eugenics resulted in its widespread acceptance.

By 1907, the role of politics in eugenics began to appear when Indiana became the first state to pass an involuntary sterilization law, targeting individuals in mental institutions, sex offenders, and the feeble-minded. By 1935, 26 states had similar laws, and others were preparing to pass legislation. When the repeal of eugenics laws finally became a reality in 1979, more than 64,000 individuals had been involuntarily sterilized. A second major area of eugenics political action involved immigration. The Johnson Immigration Act of 1924 (the Immigration Restriction Act) was the most widespread and restrictive immigration legislation to be passed in the United States. Evidence presented to Congress by Laughlin depicted immigrants from nations in Eastern Europe and other countries as undesirable

because they possessed lower intelligence and high rates of negative attributes, including alcoholism and intractableness, which were then thought to be heritable conditions. However, members of the scientific community were not as easily convinced as Congress, and opposition to the eugenics movement increased. In the early 1920s, it was already understood by geneticists that some traits emphasized by eugenicists could not be attributed to a single gene and were the result of complex interactions among multiple genes. Environmental factors were shown to play a large role in gene expression, and, more important, it was found to be mathematically impossible to eliminate a recessive gene in a population; even if involuntary sterilization were to be used, random mutation will occur.

Loss of support for eugenics began in earnest with the occurrence of the Great Depression. When people in the higher echelons of society suddenly found themselves with no money and no job, they realized the false impression that eugenics had made. Their genetic backgrounds did not determine their superiority over those in the lower classes and heredity had little, if anything, to do with economics. Additionally, in 1933 when Hitler and the Nazi party came to power, the similarities between eugenics in America and the eugenic ideals of Nazi Germany became painfully obvious.

Perhaps the most significant impact of eugenics on epidemiology occurred in 1932 when the U.S. Public Health Service (PHS) initiated the Study of Untreated Syphilis in the Male Negro, more commonly known as the Tuskegee Syphilis Experiment. While the study is often criticized for its length (it lasted until 1972, continuing even after the discovery of the use of penicillin for the treatment of syphilis) and poor scientific reasoning, it is an example of a research program in which it is now apparent that eugenics beliefs infiltrated the science. Three PHS officers, Hugh Smith Cumming, Taliaferro Clark, and Raymond Vonderlehr, founded the study, which was conducted in Macon County, Alabama, where more than 400 black males were screened for syphilis and then not treated so that investigators could learn more about the effects of syphilis. Misleading procedures, lack of treatment, and deceptive tendencies flawed the study. However, the largest flaw was that the study was plagued with the presence of race-conscious scientific assumptions and cultural intolerance that influenced its motives and faulted the study from its very inception.

While Davenport and other eugenicists believed that their scientific methods and hypotheses were valid, the eugenics movement serves as an example of the consequences of confusing scientific findings with societal values. Students and doctors who were educated in the principles of eugenics in the 1920s and 1930s continued to believe in and practice eugenics into the second half of the 20th century despite the failure of eugenics as a science and philosophy. Racism was enforced by eugenics, and even with the substantial progress made to dissipate racial tension over the second half of the 20th century, racial issues in science will remain sensitive. The notion that one race can be made better than another through genetic manipulation is incorrect, and it will take constant educating and surveillance to avoid a similar conflict in the future due to the significant progress being made in the field of genetics today.

European Public Health Alliance

The European Public Health Alliance (EPHA) is composed of more than 100 European and international nongovernmental and not-for-profit organizations that work together toward the common goal of protecting and promoting the public health of all Europeans. A second mission of the EPHA is to support collaboration

between European Union (EU) institutions, nongovernmental organizations (NGOs), and EU citizens in support of public health policies in Europe. The EPHA was founded in 1993 and has its headquarters in Brussels. It receives funding from the European Commission, EPHA members, and from its publication subscriptions.

The early work of the EPHA was to increase NGO activity and not-for-profit involvement in public health policy at the European level, in order to enlarge the role these organizations played in the process of making health policy process and to stimulate involvement in important health programs. Members were solicited from national organizations and NGOs with an interest in health or health-related areas. EPHA members come from a variety of backgrounds, including health care professionals, health advocacy groups, caregivers, patients, and consumers. Before the EPHA was created, NGO activity in Europe in health-related programs was restricted to organizations working only on one issue, such as cancer. Through the EPHA, the focus was shifted to viewing determinants of health as key aspects of health policy development.

Since its founding, the EPHA has had a significant impact on the development and strategy of European health policy by monitoring the health-policy-making process within EU institutions and by maximizing communication regarding health promotion and public health policy among institutions and the public. The four key themes of EPHA activities include (1) health, human rights, and social justice; (2) health and sustainable development; (3) health and consumer issues; and (4) health and enlargement process. The EPHA actively represents the public health interests of EU citizens and disseminates information on the public health policies and EU policies that affect the health of EU citizens. Additionally, the EPHA helps raise awareness of the public health element in many other EU policy areas such as consumer protection, environment, and agriculture.

The EPHA has several member groups that focus on a specific public health concern. For example, the EPHA Environment Network (EEN) advocates the protection of the environment as a means of improving public health in Europe. The core of the EEN's work revolves around ensuring clean air and water and reducing noise, pesticides, and chemical pollutants. Topics of other working groups include public health policies, health inequalities, healthy lifestyles, and disease-related issues.

Communication among members is enhanced through working groups, conferences and events, e-mail and the Internet, and sharing of information. The EPHA publishes a magazine, the *European Public Health Update*, bimonthly, in addition to an electronic newsletter for its members, and other briefings and press releases throughout the year.

European Union Public Health Programs

The European Union's (EU) Health and Consumer Protection Directorate General (DG) works with the 25 EU member states to protect and promote the health of the EU's citizens. The responsibility for public health is split between the member states and the EU. The EU directs the overall health policy; however, the delivery of health care is left up to the member states. The EU is advised on health policy by the EU Health Forum, a platform for organizations working in the health field to participate in health policy making.

The main goals of the EU's public health policy are to help EU countries develop expertise on health issues, to share best practices, and to improve coordination within the EU and thus make possible a rapid response to public health threats such as infectious disease outbreaks. Recently, the EU has sought to encourage cooperation between health care systems in EU member states as these systems have become more intertwined than ever before. As the connection between the health care systems grows within the EU, new health policy issues arise, such as quality and access in cross-border care. Also, there are cross-border health threats, such as avian (bird) flu, that require collaboration among member states and a coordinated EU health policy. The EU's Health and Consumer Protection DG is a distinct European

Commission department that is divided into three areas: public health, food safety, and consumer affairs. The Health and Consumer Protection DG (also referred to as DG SANCO) has approximately 800 staff members who are based in Brussels, Belgium; Luxembourg; and Grange, Ireland. The EU Commissioner for Health and Consumer Protection oversees the activities of the Directorate. Within the public health area, laws are developed on matters such as safety and quality of blood, blood derivates, and human tissues and human cells used in medical therapies. There are also laws in place regarding the advertising and manufacturing of tobacco. The Health and Consumer Protection DG is charged with making sure that these laws remain up-to-date. However, enforcement of these laws is left up to the national, regional, or, sometimes, local governments of the EU member states.

The Commission's Health and Consumer Protection DG is divided into the following departments: General Affairs, Consumer Affairs, Public Health and Risk Assessment, Animal Health and Welfare, Safety of Food Chain, and Food & Veterinary Office. The Public Health and Risk Assessment department works to ensure human health protection in EU policies, to take actions to improve public health in the EU, and to prevent human illness and diseases. There are a number of topics that the Health and Consumer Protection DG works on, including communicable and rare diseases, HIV/AIDS, injury prevention, tobacco, nutrition and obesity, bioterrorism, and the environment. The Health and Consumer Protection DG publishes a monthly newsletter, *Health and Consumer Voice*, which covers news on the public health developments in the EU.

On January 1, 2005, the European Commission created an Executive Agency for the Public Health Program to improve the EU's community public health programs. The agency is based in Luxembourg and is charged with implementing the public health programs, managing the budget, awarding contracts and grants, and organizing scientific conferences and expert panels. The Executive Agency collaborates with scientific experts in the field of public health and supports scientific committees that are composed of representatives from the EU member states.

The Health and Consumer Protection DG is the Commission liaison for three EU agencies: the European Food Safety Authority (EFSA) in Parma, Italy; the European Centre for Disease Prevention and Control (ECDC) in Stockholm, Sweden; and the Community Plant Variety Office (CPVO) in Angers, France. The ECDC was created in 2005 to help maintain and improve the health of the EU citizens. The ECDC is the European counterpart to the U.S. Centers for Disease Control and Prevention (CDC). The ECDC provides surveillance of communicable diseases within the EU and partners with national public health agencies across Europe. Its role is to increase existing disease surveillance that was managed by the Commission's Communicable Disease Networks. The ECDC is responsible for (1) epidemiological surveillance and laboratory networking; (2) operating the early warning and response system; (3) providing EU members with technical assistance; (4) responding to disease outbreaks; (5) increasing EU countries in preparedness for health emergencies; and (6) communicating health threats.

On September 23, 2002, the European Council and the European Parliament established the Community Public Health Program for the years 2003 to 2008. The public health program was established based on Article 152(4) of the treaty establishing the European Community. The Director of the Executive Agency manages the public health program.

The three objectives of the EU's public health program are (1) to improve information and knowledge to promote public health and health systems, (2) to improve rapid response capability to public health threats, and (3) to promote health and disease prevention through targeting health determinants. Public health program initiatives include creating an epidemiological surveillance system, addressing problems of antimicrobial resistance and bioterrorism, and developing strategies to prevent communicable diseases. The public health program fosters collaboration with international organizations such as the World Health Organization (WHO). A new public health program for the years 2007 to 2013 was adopted on April 6, 2005, by the EU Commission. The new program extends the current EU's public health program but joins together EU health and consumer protection policies under one framework.

EuroQoL EQ-5D Questionnaire

The EuroQoL EQ-5D questionnaire is a brief utility index designed to measure health-related quality of life and health preferences. The Panel on Cost-Effectiveness in Health and Medicine recommends the use of societal or community preferences to calculate quality-adjusted life years (QALYs) for the reference case analysis in cost-effectiveness analyses. Preference-based health state classification systems, or "utility indices," represent a class of survey instruments recommended as suitable for providing these community preferences for reference-case analyses. While the mechanisms for creating scoring functions vary for different utility indices, these indices all consist of a descriptive health survey on which the respondent describes his or her state of health on multiple domains. The survey is then scored to produce a summary measure, which represents an average preference score of the population in which the scoring algorithm was derived. The preference scores calculated by this class of instruments are suitable for use in QALY calculations to be used in any analysis combining morbidity and mortality into one summary measure of population health, for example, decision analyses and cost-utility analyses.

When completing the EQ-5D, a respondent rates his or her health on five domains; these responses are then scored to provide a community utility. The survey also has a visual analog scale (VAS) on which the respondent rates his or her health, providing the respondent's own preference for health in addition to a community-based utility score. The EQ-5D's brevity and the availability of translations in numerous different languages have contributed to this instrument's popularity; a recent systematic review by Rasanen and colleagues found that almost half (47%) of all studies reporting QALY calculations based on valid assessment techniques used the EQ-5D for the utility values in QALY calculations.

The Survey

The EuroQoL (a contraction of "*Euro*pean *Q*uality *o*f *L*ife") Group, a multidisciplinary, international group of researchers, developed the EQ-5D; this survey has been in the public domain since 1990. The survey was designed to be a self-administered, simple, generic measure of health. Although originally designed to be used alongside other measures to allow comparability across settings, the EQ-5D has also been used as a stand-alone measure of health.

The EQ-5D is currently available in 60 different official language versions, and additional language translations are in development. The U.S. English language version is shown in Figure 1. The survey consists of one question for each of five domains: mobility, self-care, usual activities, pain/discomfort, and anxiety/depression. Each domain has three levels: no limitations in function, some limitation, and extreme limitations or unable to function, giving a total of 243 different combinations of responses.

The EQ-5D has been shown to be valid in a number of populations and health conditions. In general populations, significant proportions of respondents had the highest score possible on the EQ-5D index (a ceiling effect), although in comparison to another utility index, the SF-6D, the EQ-5D index may have fewer people achieving the lowest possible score (a floor effect).

In addition to using the EQ-5D index to derive health utilities for QALY calculations, the survey has been used as a descriptive measure of health status, for example, to describe the health of populations or the impact of health care interventions such as surgical procedures or medical therapies. The index score can be used to provide a summary score across all five domains of health measured, and the function of individuals on the five separate domains of health has also been reported. While the index score gives a summary measure of preference or value for the person's state of health, a preference score alone does not state *why* one state of health is valued more or less than another. The five-question index describes the function of the respondent on the domains of health represented in the survey, allowing exploration of the specific domain differences that may explain differences in the overall score.

The EQ-5D is a generic instrument; it is designed to measure health across a wide range of settings and health conditions. In addition to using the EQ-5D as a stand-alone instrument, use of a generic instrument can be complementary to disease-specific instruments designed to be particularly responsive to changes in status of particular conditions. The EQ-5D and other generic health-related quality-of-life instruments were intended to cover broad domains of health; they may capture important changes in a domain of health

which a disease-specific measure does not cover. Perhaps even more important, use of the EQ-5D adds comparability of the sample in question to other populations. Thus, for example, a sample of patients with depression could be compared on overall or domain-specific health with age- and sex-stratified members of a general population or to patient samples with different conditions.

Scoring the Survey

Scoring algorithms for the five-question index have been developed by surveying a sample of respondents to determine the values that they place on health states as described by subsets of the 243 different possible EQ-5D states. Statistical methods were used to determine the independent contributions of each level of each of the five EQ-5D domains to the overall index score. A number of scoring algorithms are available for the EQ-5D; investigators choosing a specific method to calculate summary scores for the EQ-5D should consider the country or sample the survey will be used in and the health state valuation method that underlies the scoring algorithm. Currently, the EuroQoL Group reports that country-specific scoring protocols are available for eight countries using the VAS to value health states and for six countries using time trade-off (TTO) health utility assessments. Researchers have also developed a VAS-based, single scoring algorithm for six European countries (Finland, Germany, The Netherlands, Spain, Sweden, and the United Kingdom). Investigators comparing TTO-based scoring algorithms have found country-specific differences in values for specific health states.

The underlying valuation techniques used to develop scoring algorithms should also guide the choice among the algorithms. Since TTO assessments are generally considered more theoretically correct assessments of health utility than VAS assessments, a TTO-based algorithm is preferred for use in QALY calculations, for example, for use in cost-utility analyses. Either TTO- or VAS-based scores could be used if estimating formal utilities for quality-adjusted life expectancy is not the goal. Of the English Language surveys, TTO-based scoring algorithms based on nationally representative samples are available for the United Kingdom and the United States. In both these scoring algorithms, a person reporting the best function on all five domains receives a score of 1.0. Those reporting the worst function on all five domains receive scores of −0.594 for the U.K. algorithm and −0.109 for the U.S. algorithm. On a utility scale, 1.0 represents excellent health and 0 represents death, so for both the U.K. and the U.S. scoring algorithms, some states are valued as worse than death. The U.S. scoring algorithm is available programmed for common statistical software through the Agency for Healthcare Research and Quality (AHRQ) Web site.

The VAS is treated as a separate score and is not included in the index score calculation. As opposed to the index score, which represents a community or societal preference for a state of health, the VAS represents the respondent's own preference for his or her state of health. This VAS is anchored by "best imaginable health state" at the top, with 0 representing "worst imaginable health state." The anchor for 0 makes the VAS problematic theoretically for use in QALY calculations, since in the standard health utility metric, death is anchored at 0. However, the VAS can be used as a summary rating of the respondent's health.

Available Data and Norms

Population-based norms data are available for the EQ-5D for 16 countries, including the United States. Recently, Luo, Johnson, Shaw, Feeny, and Coons (2005) have published U.S. population norms using the U.S. TTO-based scoring algorithm in a national sample, and Hanmer, Lawrence, Anderson, Kaplan, and Fryback (2006) used a national sample from the Medical Expenditure Panel Survey (MEPS) to develop U.S. national norms for both the EQ-5D U.S. TTO-based and U.K. TTO-based scoring algorithms.

The MEPS survey Household Component, a nationally representative household survey of the U.S. noninstitutionalized civilian population, included a self-administered written version of the EQ-5D for the years 2000 to 2003. In addition to the EQ-5D, the survey includes other health status information, self-reported health conditions, demographic information, and health care utilization and expenditures. In 2003, EQ-5D data were available for more than 20,000 adults aged 18 years and above. De-identified data are available for public use at the MEPS Web site. In addition to norms data, Sullivan and Ghushchyan (2006) used these data to evaluate the effects of a number of health conditions on EQ-5D scores.

Terms of Use

While the survey and the scoring algorithms are in the public domain, use of the instrument for research or clinical purposes requires approval of the developers. Except for commercial uses, use of the survey is free. Potential users can contact the EuroQoL Executive Office at userinformationservice@euroqol.org.

Evidence, Legal Admissibility of Scientific

Product liability cases and toxic tort cases (e.g., asbestos, lead poisoning) are frequently in the news, and scientific and epidemiological evidence is often presented to support or refute the claim that the product or toxin has caused harm or injury. For a claim to succeed, the law requires evidence of general causation and specific causation. Specific causation usually requires medical evidence directly on point regarding the claimant and his circumstances. General causation takes on the larger issue of whether the alleged product or toxin can actually cause the injury. General causation requires scientific evidence of general causation and usually requires an expert such as an epidemiologist to present the scientific evidence of general causation. Accordingly, epidemiologists serve an important role in establishing or refuting claims concerning whether substances such as tobacco, alcohol, fried foods, silicone, Agent Orange, asbestos, hair coloring, electromagnetic fields, caffeine, and so on are capable of causing the injury complained of. The courts, however, have certain rules determining who can call themselves experts.

The law classifies witness testimony into two types: the lay witness and the expert witness. The legal distinction between the two is that under the Federal Rules of Evidence (FRE) and many state rules of evidence, experts proffering expert testimony enjoy greater latitude than lay witnesses, on two counts: Expert evidence may rely on hearsay, and expert evidence involves an opinion. While the distinction may appear trivial to the layperson, it is nevertheless one of the most critical distinctions at high-stakes trials and complex litigation. Accordingly, who is entitled to provide expert testimony can be a major point in any complex trial. The rules defining expert testimony have proven crucial in the progress of other medical device and pharmaceutical liability cases.

Until 1923, the FRE provision for expert testimony was determined generally by qualifications of the expert. Then, as a result of the ruling in *Frye v. United States*, a 1923 case concerning a novel polygraph test challenged in an intermediate Federal Court of Appeals, the standard became general acceptance of the expert's method or procedure. This general acceptance standard, known as the *Frye* test, prevailed for 70 years, until the decision in *Daubert v. Merrell Dow Pharmaceuticals* (1993).

The current rules governing the admissibility of scientific evidence in law in the U.S. federal courts were developed in response to *Daubert*, based on a lawsuit charging that Benedictin, an antinausea drug taken by many pregnant women to combat morning sickness, was a teratogen (a substance that causes birth defects). Epidemiologists and other scientists involved with the Benedictin litigation created enough confusion on matters of evidence to elevate the legal issues to the U.S. Supreme Court. The Court set about defining what exactly scientific knowledge is within the FRE, and it then gave the trial courts responsibility for ensuring that evidence proffered as scientific knowledge has evidentiary reliability, defined as scientific validity. To help the trial judge determine whether the scientific testimony is reliable and thus admissible under this standard, the Court provided

trial judges with four nonexclusive factors with which the judges may assess scientific validity: (1) testability of the claims made by the expert, (2) error rate of the method of investigation, (3) peer review of the conclusions reached, and (4) their general acceptance. In addition to these factors, the expert must be qualified and his testimony must "fit" the facts of the case, essentially a higher standard of relevance.

The factor of testability (or falsifiability) concerns the question of whether the scientific knowledge is falsifiable. Scientists and philosophers since Aristotle have identified the character of testability as a necessity to enjoy the status of "knowledge" or "science."

For example, if an epidemiologist hypothesizes that aflatoxins are carcinogenic, he can easily test his hypothesis (albeit with some systematic error) through a case-control study. Using the odds ratio as a measure of the carcinogenic effect, the p value as a measure of statistical significance, and a qualitative assessment of the bias inherent in case-control studies, he has tested his hypothesis to determine whether it is true or false.

Known or potential rate of error is a second factor to consider. Error rate suggests quantifiable errors such as the p value or measures of Type 1 and Type 2 errors. In reality, however, these measures of "error" provide information concerning only random error, while an epidemiologist must also account for measurement error and systematic error. Estimation of measurement error may be a quantitative or qualitative process; if quantitative, it requires establishing the reliability and validity of particular methods of measurement. Assessing systematic error or bias requires a qualitative assessment of the shortcomings found in observational studies, including the lack of randomization, the potential absence of matching, and other methodological trade-offs.

There is no simple threshold error rate to determine whether the testimony qualifies as scientific knowledge and is therefore admissible. Furthermore, the rate in "error rate" is probably an oversight, as the Court was not actually contemplating a "rate" in the technical epidemiological sense of frequency per unit of time.

A third factor is peer review. While there is a presumption that published work vetted through peer review evidences scientific knowledge, there are also exceptions to this. The Court recognized that some work is scientifically sound even though it has not been published or peer reviewed, while some peer-reviewed journals publish work that may not be scientifically sound. Furthermore, publication bias may complicate assessment of this factor. Nevertheless, work that is both published and peer reviewed stands a better chance of being admitted as evidence in a court of law. On the other hand, research done for the sake of litigation is suspicious to most judges. With admissibility in law, as in science, there is a hierarchy of credibility associated with journals and other vetting procedures.

The fourth nonexclusive factor is general acceptance. This refers to how credible certain types of studies are regarded within a profession. In epidemiology, hospital-based case-control studies are inferior to population-based case-control studies and cohort studies but are nevertheless generally accepted methods for epidemiological research. Accordingly, evidence derived from hospital-based case-control studies satisfy the general acceptance factor, although they may be more heavily scrutinized under the "rate of error" factor.

Here, general acceptance is the same as the *Frye* test above but operates as only one of several factors to be taken together as a whole in the determination of admissibility, whereas before *Daubert*, it was the only factor.

The Court's opinion in *Daubert* was designed to be used as guidance and not a checklist. On one hand, placing the "general acceptance" test as a mere one-of-four-nonexclusive factors provided a relaxation of general acceptance as the sole criterion for admissibility and therefore the possibility that novel scientific methods may find their way in court (e.g., the novel polygraph test in the *Frye* case). On the other hand, the other factors raised the bar for admissibility since there are more factors to consider. In practice, *Daubert* has been applied to be more restrictive of expert evidence. Two other cases at the U.S. Supreme Court (*General Electric Co. v. Joiner*, 1997; *Kumho Tire Co. v. Carmichael*, 1999) provided further guidance on the application of *Daubert.* In December of 2000, the lessons of these three cases were woven into an amended FRE 702.

Other courts have adopted other rules of admissibility (and rules for sufficiency) based on other jurisprudential notions. One federal judge developed a rule in the Agent Orange litigation cases captioned *In Re Agent Orange.* Judge Jack Weinstein's rule restricted epidemiological risk factor (antagonistic) evidence if it failed to demonstrate a relative risk

(*RR*; or odds ratio) of 2 or more. His basis for such a rule lay in the following analysis: If the incidence of disease *X* is 20 per 1,000 persons in the general population, then the incidence must be at least 40 per 1,000 in the population exposed to a potential risk factor, such as Agent Orange, to justify a claim that the risk factor could *legally* cause the disease *X*. Such an elevated incidence ensures without any further data that for any given member of the exposed population who contracts the disease, there is as much or a higher likelihood that the disease was associated with the risk factor rather than the result of chance. This "*RR* of 2" rule is not recognized in most courts, but it nevertheless is the rule for some jurisdictions.

Even when expert testimony qualifies for admissibility under *Daubert* and any other rules of the jurisdiction (e.g., *RR* of 2), the evidence may be struck through application of other rules such as FRE 403, which permits the exclusion of evidence when its value is substantially outweighed by "the danger of unfair prejudice, confusion of the issues, or misleading the jury." Most judges are reluctant to exclude evidence under FRE 403, because they believe the best place for testimony to be tried is through the strenuous advocacy of each party before a jury. Nevertheless, FRE 403 holds scientists accountable for a proper presentation of their evidence.

An example of scientific testimony that probably could have been excluded through FRE 403 was presented during the Benedictin litigation. As part of his expert testimony, a toxicologist presented a chart consisting of more than 100 confidence intervals (CIs) calculated from small samples. He arranged the CIs in vertical format with each bar representing one of more than 100 rows and arranged the CIs by their upper boundary. The result was that a few upper boundaries fell short of the *RR* of 1, the method and its measure suggesting no relationship between Benedictin and alleged teratogenic effect. A large majority of the upper boundaries, as expected, conveniently drew the eye toward the bottom and to the right where upper boundaries went beyond an *RR* of 100 (due to small sample sizes). The overall visual effect of the chart was extraordinary: a quasi meta-analysis pointing to an extraordinary antagonistic effect. In reality, however, the average *RR* was much less than the cognitive bias displayed by the chart. Presenting numerous CIs in this manner has no basis in scientific practice.

Evidence-Based Medicine

Evidence-based medicine (EBM)—which might better be called evidence-based health care (EBHC) because it applies to all parts of the health care system and not just the practice of medicine by physicians—encompasses a set of tools for the enhancement of the practice of medicine. EBM uses those tools, many of which are drawn from epidemiology and biostatistics, to create a bridge between information gained from the study of populations and communities, on the one hand, and medical care provided to a particular individual, on the other. EBM requires that physicians and other medical professionals be able to critically appraise the medical literature and selectively apply information based on these critical appraisal principles to the individual patient.

Definition and History of EBM

To practice the highest quality of scientific medicine, physicians must bring the best information from medical research (and medical technology) to the patient's bedside. Secondary goals are to improve the health of the public through control of epidemic diseases (whether caused by microorganisms or environmental contaminants) and comforting the patient and their immediate social group in times of illness. In the Glossary on its Web site, the Centre for Evidence-Based Medicine at Oxford University in the United Kingdom defines EBM as "the conscientious, explicit and judicious use of current best evidence in making

decisions about the care of individual patients. The practice of evidence-based medicine means integrating individual clinical expertise with the best available external clinical evidence from systematic research." The Centre also defines EBHC as an extension of EBM "to all professions associated with health care, including purchasing and management" (Centre for Evidence-Based Medicine).

The practice of medicine requires physicians to make correct diagnoses and choose the best treatment to improve the health or reduce the burden of illness for their patients under conditions of significant uncertainty. The health care worker needs to effectively access the best and most current information from the medical literature, critically evaluate this information, and determine how and when the results will be applied to the patient sitting in front of them.

History of EBM

Elements of EBM can be found in the biblical Book of Daniel where a description of a trial of diet is given. The participants were Daniel's friends, and they were "randomized" to eat only vegetables or the king's food. Hippocrates told the physicians of his day to observe their patients and to perform only those actions that could be helpful and would "first, do no harm," implying the ability to distinguish helpful from potentially harmful therapies. An 18th-century British physician, George Fordyce, demanded that the medical profession provide better evidence for the therapies of the day. Captain James Lind, a British naval surgeon, performed a nonblinded but randomized clinical trial on a dozen Navy seamen with scurvy. The results clearly showed that citrus was vastly superior to the other treatments being tested. Pierre Charles Alexandre Louis was a French physician who applied the new science of statistics to show that bloodletting was unlikely to benefit patients with typhoid fever.

More recently, a 1947 editorial by Austin Bradford Hill in the *British Medical Journal* demanded that physicians use mathematics and statistical methods to evaluate the practice of medicine. American epidemiologist John Paul in the United States coined the term *clinical epidemiology* in the late 1930s, but this concept was neither accepted nor used by mainstream physicians and languished in obscurity until the first modern randomized clinical trial in 1948. This trial of streptomycin for patients with tuberculosis performed under the direction of the Medical Research Council of the National Health Service in the United Kingdom showed that the therapy was beneficial. Between 1950 and the mid-1970s, further elucidation of the nature of EBM in modern medicine occurred when Dr. Alvan Feinstein differentiated the science of clinical epidemiology as distinct from the traditional epidemiology of public health. This served as the foundation of the statistical revolution in medicine beginning in the 1960s. The research of Dr. John Wennberg in the 1970s demonstrated the large variation in the quantity of health care provided to populations living in relatively small geographical areas. During this time period, there was an explosion in the number of medical research articles published. Researchers in clinical epidemiology at McMaster University Health performed outcomes and process research, and this paved the way for wider dissemination of clinical epidemiology and developed a curriculum that incorporated clinical epidemiology into the medical curriculum.

The first modern systematic review of perinatal interventions was done in 1986 by a group at Oxford led by Iain Chalmers. Systematic reviews have become increasingly popular as the amount of medical literature continues to increase. A major source of clinical trial information and systematic reviews is the worldwide online Cochrane Collaboration, founded in 1993 and currently composed of more than 6,000 people in 60 countries. Currently, there are more than 30,000 trials entered into the Cochrane Controlled Trials Registry and more than 1,000 systematic reviews.

EBM soon became synonymous with the explicit application of the results of research published in the medical literature to improve patient care for the individual patient. However, Feinstein warned of the danger that EBM could become a substitute for critical thinking skills, and he defined the role of clinical epidemiology as making physicians' thought processes more transparent and explicit and improving the critical thinking required for modern scientific medical practice, rather than replacing it.

Through the 1990s, there has been an explosion in the number of courses teaching physicians how to become more intelligent consumers of the medical literature. These are often traditional epidemiology and biostatistics courses modified through the use of explicit tools of EBM and the use of statistical methods in medical decision making. EBM as a basic principle of medicine teaches all health care workers the application of critical thinking to improve the care of the individual patient. It encompasses clinical

epidemiology, research methodology, narrative-based medicine, ethics, public health, health policy, social and community medicine, and population medicine. EBM bridges the care for populations and communities with that for the individual.

EBM Sources and the Levels of Evidence

Various groups have tried to develop ways to package critically appraised and filtered evidence to make it more useful to individual practitioners. Access to these predigested "EBM reviews" is done through various online databases around the world. A major center for the dissemination of these sources of best evidence in the United Kingdom has been the Centre for Evidence-Based Medicine at Oxford University. The home of several EBM sources, it includes *Bandolier*, a biweekly summary of recent and interesting evidence evaluated by the Centre, which is free to all and available online. The Centre has other easily accessible and free features related to the practice of EBM on its main Web site. The *British Medical Journal* publishes an updated *Clinical Evidence*, a summary of critically evaluated topics in therapeutics that are regularly updated and available online.

Many commonly used preprepared critical appraisals of various clinical questions are found in the Journal Club Bank (JCB) of the Evidence Based Interest Group of the American College of Physicians (ACP) and the Evidence Based Emergency Medicine Web site. This consists of critically appraised topics (CATs) or summaries of research studies and can also be found on the Evidence-Based Medicine Resource Center of the New York Academy of Medicine. The CAT format developed by the Centre for Evidence-Based Medicine is being made available on CD-ROM for use outside the Centre. The University of Sheffield (United Kingdom) has one of the most complete resources listing EBM-related Web sites, "Netting the Evidence." Other medical organizations are beginning to embrace the CAT format to disseminate critical reviews on the Web.

EBM focuses on evidence that will make a difference for the patient. Disease-oriented evidence (DOE) is not necessarily "patient-oriented evidence that matters" (POEMs) because DOE may reflect a change in disease status that has no direct relationship to outcomes that matter to an individual patient; for instance, drugs such as statins lower cholesterol but may not reduce mortality or improve quality of life. POEMs are a format developed by family physicians for the American Academy of Family Practice; further information can be found on the InfoPOEMs Web site.

Evaluation of the strength of evidence for a particular clinical query has led to several methods of ranking different types of studies from most to least important in having the ability to determine causation for the question at hand. The Centre for Evidence-Based Medicine developed the most commonly used scheme of categorization, which depends on the nature of the clinical query. These have been challenged as being too doctrinaire, and users should employ them in a flexible manner and look critically at each study evaluated, regardless of the study design. There is also concern among EBM scholars that the research agenda has been hijacked by proprietary interests such as pharmaceutical and technology companies as the studies sponsored by these groups are frequently randomized clinical trials with biases designed to achieve results favorable to the sponsoring organization.

The Five-Stage Process of EBM

The phenomenal growth in the amount of medical research information available has made it both more difficult and important for physicians to have the tools to assess this information. Breakthroughs in information systems technology, including Internet access to MEDLINE via PubMed and other medical databases, allow physicians to obtain the most current information to answer educational needs more quickly and easily than in the past.

Once an educational need has been recognized, the next step is to develop a clinical question that maximizes the likelihood of finding good-quality evidence through a search of the literature. This is best done using a four-part PICO question, which includes the following elements: patient or population (P), intervention or exposure to a risk factor (I), comparator (C), and outcome (O).

The next step is critical appraisal of the medical literature, which is the heart of EBM and attempts to identify potential shortcomings of the research study being evaluated. Is the study valid or are there sources of bias? The essence of the critical appraisal part of the EBM process is asking if there are other reasonable explanations for the results of the study. Finally, the reader must draw inferences and apply the results of the study to the care of their individual patient and

integrate the evidence into actual practice. The complete understanding of sophisticated statistical testing is less important than the application of common sense and skeptical evaluation of what is read: Understanding research designs and basic statistical methods will allow physicians to critically evaluate most published clinical research and avoid many errors of interpretation. Evaluation of the methodology of a research study is the most important part of the critical appraisal of the literature and does not require any sophisticated mathematical abilities.

Understanding the research study design will help identify most of the problems that can potentially influence the results of a poorly done research study. To determine causation for diseases with multifactorial causes requires showing that (a) the cause and effect are associated with each other more likely than by chance alone, (b) the cause precedes the effect, and (c) changing the cause changes the effect. These three conditions are known as contributory causes and all three are required to prove causation for a multifactorial disease.

The Hierarchy of Evidence: Study Design and Minimizing Bias

Research answers questions about populations by studying samples of individuals from a given population. Individuals have variable characteristics that might affect outcomes of research, and the design of a study will alert the critical reader to potential problems in the design of a study. The best research design is one that minimizes the chance of bias, and it is the responsibility of the researcher to minimize bias in a study. Since this cannot always be done, it is the responsibility of the reader to determine if biases that exist in a study, whether real or potential, are enough to affect the outcome. The conclusion may not be compatible with the research hypothesis when there is a large degree of bias in the conditions of the research.

As many of the population characteristics as possible should be represented in the study sample. In most types of studies, the sample is divided into two groups to test the hypothesis that they are different in some important characteristic. If the two groups are not equivalent with regard to all other characteristics, confounding of the results can occur, leading to an incorrect conclusion. It might be erroneously concluded that a difference in the outcome between the groups occurred because of a presumed causative factor when in reality it was produced by a difference in the baseline characteristics, and bias is present.

The strongest type of study in the hierarchy of study designs is the randomized clinical trial (RCT) because it is most likely to be able to prove causation and least likely to contain biases leading to incorrect or misleading results. In RCTs, the study subjects are assigned to the treatment (exposed) or comparison (placebo or not exposed) on the basis of chance alone using some technique to assure random placement of each participant. This maximizes the probability that the two groups are equal with respect to all the other characteristics that could affect the outcome under consideration. RCTs are the best design to minimize bias but are usually costly in money and time, and are not efficient if the outcome being studied is rare.

In a cohort study, the subjects are identified based on their exposure or lack of exposure to the risk factor being studied. A researcher determining whether cigarette smoking causes brain tumors could take a sample of smokers and nonsmokers and follow them for a period of time to determine the numbers of brain tumors developed by the subjects in each group. The subjects are not assigned to the two groups and may differ on important characteristics: For instance, smokers may have a higher degree of exposure to other toxins than nonsmokers, which could be the contributory cause of brain cancer. Cohort studies usually cost less than RCTs and may allow for the study of issues for which randomization would be unethical or difficult.

Case-control studies begin with cases who have and controls who don't have the outcome of interest; matching is usually performed to make the two groups as similar as possible on key covariates. For instance, a researcher might study 20 patients with brain tumors and 20 of similar age and gender without brain tumors to look at the proportion of cigarette smokers in each group. Bias is more difficult to avoid in a case-control study, but this type of study can be completed more quickly than an RCT or cohort study and is generally less costly especially if the outcome is rare.

A case series is simply the description of the characteristics or clinical course of a set of individuals with a given exposure or outcome. For instance, a surgeon might describe his or her experience using a new operative technique for brain tumors, including the frequency with which the patients were cured or reached some defined outcome. The reader cannot tell if the new procedure is better than existing operative technique without a comparison group of patients

receiving the standard or no therapy. Case series are valuable for generating hypotheses or suggesting necessary studies for future research.

Cross-sectional studies measure the relationship between variables at one point in time and can calculate the frequency of a variable in a sample at a given point in time, its prevalence. They cannot prove the temporal relationship between cause and effect and are used to generate new research hypotheses.

Assessing the Significance or Impact of Study Results

The impact of a study tells the reader the likelihood of an association between the outcomes of the two groups (treatment and comparator or exposed and nonexposed). All the types of studies described above, except for case series, generally include an evaluation of whether the results were statistically significant. However, even with the best attention to study design, a study may find a difference between groups that is not truly present in the larger population or no difference when one really exists but was simply not found in the study sample. These are known as Type I and Type II errors, or alpha and beta, respectively. Common causes of a Type I error in a study are multiple comparisons and composite outcomes. Multiple comparisons done between two groups of patients are sometimes known as "dredging the data" or "fishing for results" because as more tests are done, it becomes increasingly likely that a statistically significant difference between two study samples will be found due to chance, when in fact no such difference exists in the larger population. Composite outcomes, that is, when several outcomes are combined to create a single outcome, may also make a Type I error more likely when the different outcomes do not have the same values (e.g., death, myocardial infarction, and repeat admission for chest pain). Subgroup and post hoc analysis of the data are other ways in which a Type I error can occur.

The most common cause of Type II errors is insufficient sample size, also known as an insufficiently powered study. Because the power to detect a significant difference between groups rests partly on the sample size, a result that is not significant in one study might well be significant in a larger study: Beyond the fact of whether significance was achieved or not, therefore, the reader must also evaluate the possibility of a Type I or Type II error.

Confidence intervals are commonly reported in the medical literature as well as statistical significance: They report how much the estimate of any outcome may vary if the study is repeated with different samples from the same population. This tells the precision of the result and can help the physician and patient make an informed decision on the certainty of the evidence.

Meta-Analysis and Systematic Reviews

Review articles summarize the literature on a topic; however, this is often done in a subjective manner that may include significant author biases (e.g., in the choice of studies included or the relative emphasis placed on particular studies). Systematic reviews critically combine multiple studies that look at the same research question. The results of multiple studies can be examined statistically in a meta-analysis that "transcends" simple analysis to reconcile studies with different results. Meta-analyses of multiple negative studies may uncover Type II errors due to an inadequate sample size of one or more of the studies included in the analysis. Meta-analysis can also help identify a study with a Type I error or that has outlier results as part of a collection of many other studies.

Performance of a meta-analysis starts with an exhaustive search for studies, including both Medline and unpublished studies and dissertations. The studies found are then critically reviewed and graded using a standardized scheme. The statistical results are then compared and the presence of heterogeneity among the studies can be determined. If studies are heterogeneous, they cannot be directly compared, and this process may uncover one outlier among the studies that caused the heterogeneity. The reasons for this will usually be found in the methodology of the outlier study. Finally, summary statistics can be calculated and conclusions drawn. A technique known as cumulative meta-analysis can be done whenever a new study is reported on a given topic. This type of analysis will determine when in time the intervention first shows statistically significant results. Some believe this should always be done for all the previously done studies whenever any research study is published.

Assessing the Usefulness of Diagnostic Tests and Information

Accurate diagnosis is one of the primary duties of the physician. Diagnostic decision making consists of

gathering useful information to create and refine the differential diagnosis and then sharing this information with the patient in a way that facilitates informed decision making. Physicians must critically assess the value of the information gathered to help their patient, and while some of this information appears to be of value, it may be misleading and not discriminate among diagnostic possibilities. The patient's preferences must be added to the diagnostic process to assess the value of diagnostic information.

Useful clinical procedures and tests should be reliable and valid. Reliable tests are reproducible, and a reliable test that is run more than once on the same specimen will lead to the same result. The validity of a diagnostic test determines the ability to truly discriminate between patients with and without a given disease. Diagnostic tests should be judged against a "gold standard" test that conclusively defines the presence or absence of the disease. For example, the gold standard for bacteremia is a positive blood culture and for a malignant tumor a tissue specimen containing malignant tumor cells. Figure 1 shows the distribution of test results in patients with and without a disease. Extreme test results can definitely define who has the disease and who does not. Values near the cutoff point between normal and abnormal will demonstrate significant overlap for diseased and nondiseased individuals. Sensitivity and specificity are the mathematical descriptions of this degree of overlap. Studies of diagnostic tests that report the correlation between a diagnostic test result and the presence or absence of disease are not helpful to the clinician who needs to know the likelihood of illness after application of a diagnostic test.

Sensitivity and *specificity* are two technical terms used to evaluate the usefulness of diagnostic tests. Sensitivity is the percentage of patients with the disease who will test positive and is also called the true positive rate (*TPR* = ratio of subjects with the disease and a positive test to all subjects with the disease) as shown in Figure 2. Specificity or the true negative rate (*TNR*) measures the percentage of people without the disease who test negative and is the ratio of subjects without disease who test negative to all those who don't have the disease. Sensitivity and specificity are considered fixed characteristics of a test for purposes of decision making and usually do not change with the prevalence of disease in the population from which the patient came. In reality, most diseases have varying levels of severity related to different stages of disease leading the diagnostic test to demonstrate spectrum bias and be more sensitive in patients with classical or severe disease and less sensitive in patients with mild or early disease.

A test with high sensitivity, which minimizes the number of missed cases (false negatives), is preferred if the disease is readily treated or has serious morbidity. A negative result of the test will rule out disease. A test with high specificity, which minimizes the number of falsely identified cases (false positives), is preferred for diseases that have minimal morbidity or in those for which there is dangerous or risky treatment. A positive result on the test will rule in disease. Published sensitivity and specificity values are point estimates and should always be accompanied by 95% confidence intervals.

Notes: Sensitivity = *TP*/*D*+
Specificity = *TN*/*D*−
LR+ = Sensitivity/(1 − Specificity) = *TPR*/*FPR*
LR− = (1 − Sensitivity)/Specificity = *FNR*/*TNR*
Bayes's theorem: $O_{pre} \times LR = O_{post}$

The clinician treating an individual patient wants to know the probability that their patient has the disease if the test is positive or negative. This is called the positive or negative predictive value or the posttest or posterior probability of disease given a positive or negative test. Positive predictive value is the ratio of true positive test results to all positive tests results or the fraction of patients with positive tests who really have the disease. Negative predictive value is the ratio of true negative test results to all negative tests results or the fraction of patients with negative tests who really don't have the disease. One minus the negative predictive value, the false reassurance rate is the probability that we are falsely reassuring patients who have a negative test that they are disease free, when in fact they actually have the disease. One minus the positive predictive value, the false alarm rate is the probability that we are falsely alarming patients who have a positive test that they are diseased when in fact they are actually disease free.

Predictive values of a test depend on the sensitivity, specificity, and prevalence of disease in the population from which the patient comes. The pretest prevalence, which is also called the prior probability of disease, is determined from the clinical presentation of the patient or the baseline prevalence of the disease in the population of patients with similar signs and symptoms. This is determined by the clinical experience of clinicians. The most experienced ones are better able to recognize a pattern of disease in patients with atypical presentations.

A direct way to calculate the posttest probability of disease use Bayes's theorem and likelihood ratios (*LR*). The *LR* combines sensitivity and specificity into one number and becomes a measure of the strength of a diagnostic test. The *LR* of a positive test ($LR+$) is the sensitivity divided by one minus specificity, and the *LR* of a negative test ($LR-$) is one minus sensitivity divided by the specificity (Figure 2). Strong tests have an $LR+$ greater than 10 or $LR-$ less than 0.1. Fair tests are those with $LR+$ between 2 and 10 and $LR-$ between 0.1 and 0.5. A test is almost worthless if the $LR+$ is less than 2 or an $LR-$ is greater than 0.5. Bayes's theorem revises disease probabilities using the formula Pretest odds $\times$ *LR* = Posttest odds. Although Bayes's theorem is daunting to most physicians, a nomogram is available to go from pretest to posttest probability using the *LR* without doing any computations. Continuous test results, such as the peripheral white blood cell count, can have their results broken into intervals to preserve test information that would be lost in reducing the test to a single normal or abnormal cutoff. The use of intervals creates multiple *LR*s (interval or *iLR*s) for each interval of test results.

Receiver operating characteristic (ROC) curves compare two or more tests or select the best single cutoff for a diagnostic test. The ROC curve plots sensitivity on the *y*-axis against one minus specificity (false-positive rate) on the *x*-axis for all possible test cutoff points. A perfect test represents 100% sensitivity and specificity, so there are no false positives or negatives. The point at the lower left of the ROC curve corresponds to 0% sensitivity and 100% specificity, and there are no false positives and no true positives. When looking for the best cutoff point or comparing two tests represented by curves that do not overlap, the best single cutoff point or test result is the one closest to the (0, 1) point.

The area under the ROC curve (AUC) represents a mathematical description of the likelihood that one can identify a patient with the disease using that test alone. A diagonal line drawn from the lower left to the upper right corner of the ROC curve has an AUC of 0.5 meaning that the probability of identifying a diseased patient from one without the disease is 50% or the same as a coin toss. The AUC is useful for evaluating two tests whose ROC curves cross or a single test to determine its usefulness in general. Ideally the AUC should be as near to one as possible. Before deciding which test to use, the clinician must assess the trade-off of sensitivity for specificity for each test and cutoff point, balancing the harm of missing a patient with the disease and the risk of treating a patient without the disease.

Expected Values Decision Making

Medical decision making combines the probability of an event with its value or risk. Done for generations of physicians "by the seat of their pants," it can now be done using a mathematical method of determining the optimal decision in medicine. Expected values decision making uses the concept of instrumental rationality to determine the optimal course of action based on the combination of probability of an event and the utility or value of the outcome. Instrumental rationality begins by using a decision tree showing all the possible actions that would be taken for a particular therapeutic or diagnostic decision. The starting point is

a place where the physician must make a decision and then each outcome of the decision is determined. If one choice is surgery, the outcomes could be death during the operation, complete cure, or some intermediate outcome such as relief from symptoms but shortened life. A probability and a patient value or utility is associated with each of these outcomes. After the tree has been constructed, the probability is multiplied by the utility for each branch until one gets back to the starting point, and a final expected value is obtained for each decision. The one with the highest value would be the preferred decision. A sensitivity analysis for the tree, incorporating plausible ranges of values for probability and utility for each of the decisions, should be done. If the final outcomes are pretty much the same for these different values, the tree is said to be "robust" and the results considered reasonable.

The Threshold Approach to Diagnostic Testing

Pauker and Kassirer (1980) introduced the concept of the threshold approach to diagnostic testing to help clinicians decide on whether to perform a test. Using this method maximizes the effectiveness of diagnostic testing and limits unnecessary testing. If the clinician judges the prior probability of disease to be below the testing threshold, then the patient is so unlikely to have the disorder that a diagnostic test would not raise the probability sufficiently to change the decision not to treat for the disease. For prior probabilities below this level, the test should not be done. If the clinician judges the prior probability of disease to be above the treatment threshold, then the patient is so likely to have the disorder and a diagnostic test would not lower the probability enough to change the decision to treat for the disease. For prior probabilities above this level, the patient should be treated and the test should not be done. If the prior probability is between the two thresholds, the patient should be tested and treatment should be based on the test result. Thresholds are determined by balancing the benefits and risks of appropriate therapy, the risks of inappropriate therapy and of doing the test, and the test sensitivity and specificity using formal decision analysis.

Exposure Assessment

Exposure assessment is a critical component of epidemiologic research, and unfortunately for many studies, it is this component that introduces many limitations. Exposure assessment has been defined by Last (2001) as the "process of estimating concentration or intensity, duration, and frequency of exposure to an agent that can affect health" (p. 66). It involves preferably quantitative, but often qualitative, procedures to estimate and assign an individual's past or current exposures. Various types of exposures are studied in epidemiology. Some common examples are summarized in Table 1.

A person's behavior, dietary patterns, smoking history, family history, personal characteristics, and exercise are frequently studied in epidemiologic research as potential exposures, risk factors for exposure, and potential confounders. However, generally the area of exposure assessment in epidemiologic research refers to its application in occupational and environmental epidemiology.

Exposure assessment is also used for purposes beyond epidemiologic research such as risk assessment and regulatory compliance. As an element in risk assessment, exposure assessment has been defined by Jayjock, Lynch, and Nelson (2000) as "the activity that describes the nature and size of the various populations exposed to a chemical agent and the magnitude and duration of their exposures" (p. 26). In regulatory compliance, exposure assessment serves as a quantitative method by which measures of exposure can be compared with established exposure limits. This entry discusses exposure assessment in the

Table 1 Types of Environmental Agents or General Factors to Which One Can Be Exposed

Agent Type	*Examples*
Chemical	Solvents, pesticides, acrylamides, drugs
Metal	Arsenic, nickel, chromium, lead, cadmium
Physical	Radiation, temperature, noise, ergonomic, physical force
Particulate	Dusts, fibers, molds, silica, fumes
Biological	Viruses, fungi, parasites, bacteria, prions
Psychosocial	Violence, stress, social networks
Nutritional	Fiber in diet, meat consumption, vegetable consumption
Behaviors	Smoking, alcohol consumption, exercise
Family history	Family history of specific disease
Personal characteristics	Height, weight, race, sex, body mass index (BMI)

Source: Adapted in part from Rom (1992) and Plog (2002).

context of occupational and environmental epidemiologic studies, although these principles can be applied to all types of epidemiologic research.

Epidemiologic Approaches to Exposure Assessment

Exposure assessment in epidemiology can be broken into various phases that include (1) identification and characterization of the exposed population; (2) evaluation of potential exposure pathways; (3) assessment of the frequency, intensity, and duration of exposure; and (4) exposure classification.

The first issue to consider in exposure assessment is choosing the group that represents the most appropriate and feasible population to study, given the specific research questions. Often, worker populations are selected because of the availability of exposure information and the fact that higher exposures typically occur in workplace settings; however, it may be more appropriate to study specific community members, consumers, or the general population depending on the research question. Most environmental or occupational epidemiologic studies estimate exposure for groups of individuals who are expected to share similar exposure characteristics (e.g., levels, variation).

The second issue to consider is the potential route of exposure, which can include dermal uptake, oral intake via ingestion or mouthing (for children), inhalation, or a combination of pathways. In the case of physical agents (e.g., electric or magnetic fields), simply being present in a field or experiencing a physical force constitutes the route of exposure. For exposure to occur, a "complete" exposure pathway must exist. Examples of incomplete pathways, which prevent exposure to contaminants, include a concrete cap in a foundation that could prevent intrusion of a soil contaminant into a home, or vegetative cover that could reduce release of metal-laden dusts. The amount of agent taken into the body depends on various characteristics such as particle size (for inhalation), bioavailability, human behavior, whether natural barriers or personal protective equipment prevent actual exposure, and whether the substance is transformed within the body.

If complete exposure pathways exist, information on the duration and frequency of exposure can significantly improve a study's ability to assess health risks to a particular agent. Peak exposures, or those occurring over a short time frame, may be important for short-term or intermittent tasks or exposures to some types of chemical or physical agents. For example, a worker injury may result from short-term exposure to a high force. For tasks that are longer in duration or conducted on a more frequent basis, time-weighted averages (TWA) might be more appropriate. For example, for a worker conducting similar tasks on a daily basis over a typical workday, an 8-hr TWA is likely the most appropriate metric. Often the cumulative exposure over a worker's career is estimated as average exposure multiplied by the duration of exposure. When data are available, period-specific variation in average exposure is accounted for in the calculation of cumulative exposure. Similarly, exposures to the general population from agents in the environment might be best characterized by lifetime exposure.

Exposure data can be classified into three categories depending on the detail of information: quantitative, semiquantitative, and qualitative. Quantitative methods for exposure classification include the use of personal or biological monitoring, which collects concentration or dose information for individuals.

Qualitative exposure classification methods often use contemporaneous or historical environmental/industrial hygiene data, surrogates of exposure or exposure proxies, models, questionnaires, personal interviews, or diaries to obtain qualitative data regarding an individual or group exposure. Surrogates of exposure can include historical occupational history records or residence information, chemical inventory records, environmental discharge data, job exposure matrices (which provide estimated job-specific exposure levels based on job titles), use of a certain product, or duration in a job title or geographic location. It is highly recommended that studies using exposure proxy variables include a validation substudy to compare the correlation between the actual exposure and the exposure surrogate values and to assess potential exposure misclassification that may result when relying on proxy measures of exposure.

Finally, direct but qualitative methods can also include collection of personal interview, diary or questionnaire data that specifically query about exposure history/experience. These data may be classifiable only into a "yes/no" category or may be useful in assigning individuals into high, medium, and low categories.

Quantitative methods can be used to estimate specific concentrations or doses, which can be expressed

as average or cumulative exposure levels such as ppm-years or milligram per kilogram (continuous). Groups can be qualitatively classified as ever/never exposed (dichotomous) or as being high/medium/low-exposed (semiquantitative). Either quantitative or qualitative data can be used to place individuals within exposure categories that are then assigned a score (ordinal ranking) representing a range of exposures (e.g., 0 to 5, with 5 being the most highly exposed group).

Exposure Measurements in Occupational or Environmental Settings

Exposure measurement highly depends on the type of exposure, route of exposure, available measurement technology, and practical issues such as access to study subjects and method of data collection (e.g., "expert" observer, self-report). In the case of instrumentation, data can be limited by the "limit of detection" inherent in the method, instrument, or analytical laboratory for quantifying the concentration of a contaminant. In the use of self-report, accuracy can be affected by recall bias, or the ability to remember events accurately.

Measurement of exposure in air can be conducted for fumes, smoke, mists, gases, and vapors that would be expected to enter the breathing zone of workers and inhaled. Table 2 provides a list of the types of air sampling that can be conducted. Air sample results are usually reported in ppm (parts of vapor or gases per million parts of contaminated air by volume at room temperature and pressure) or milligrams or micrograms per cubic meter (milligrams or micrograms of substance per cubic meter of air).

Wipe sampling can be conducted if either dermal or oral exposure from the hand-to-mouth pathway is suspected. Wipe sampling can be conducted by wiping a specified area with an appropriate wipe. Results are usually reported in mass/wipe, which can then be converted to mass/area if the area is known. In general, wipe sampling to assess chemical exposure is not common, but it is most often used to assess lead or other metal contamination on surfaces.

Biological monitoring involves measurement of changes in composition of body fluid, tissue, or

Table 2 Types of Air Sampling

Type	*Description*	*Examples*
Active	Air actively drawn through sampling media; contaminant of interest is deposited	Battery-powered pump draws air through appropriate device
Passive	Natural air movement sufficient for deposition of contaminant on sampling media, or air movement is unnecessary (e.g., radiation badges)	Dosimeter badge adsorbs contaminant
Grab	Small volume of air rapidly drawn through sampling media or into a bag/canister	Stain (colorimetric) detector tube measures contaminant concentration in air (i.e., changes color)
Short-term/ long-term	Air contaminant collected over a variable time period (e.g., during specific task, entire shift)	Radiation badges worn daily and analyzed periodically to assess cumulative exposure
Area	Sampler placed in a single area	Stainless steel canister under vacuum opened to collect air sample
Personal	Sampler placed as close to contaminant's portal of entry as possible (e.g., breathing zone)	A filter cassette attached to pump placed on worker's lapel to assess particulate exposure
Continuous	Direct-reading instrument logs contaminant concentration at specified intervals	Continuous noise data logger logs sound power levels to determine peaks in noise level
Average	One concentration value obtained per measurement period	Device collects contaminant over a work shift; mass/volume calculated to provide time-weighted average concentration

Source: Adapted in part from Plog (2002) and Nieuwenhuijsen (2003).

expired air to establish absorption of a contaminant. For example, lead concentrations in urine and blood are often used to determine lead exposure. Specific biomarkers of chemical or metal exposure will provide more accurate and reliable estimates of historical exposure than nonspecific biomarkers, which can reflect exposures to various agents. In addition, the half-life of the biomarker and the representativeness of samples with respect to a person's entire exposure history should be considered when evaluating biomarker information.

Exposure simulation involves recreating or simulating exposures to certain contaminants during specific activities and is usually performed if it is not feasible to conduct present-day sampling (e.g., products or conditions no longer exist) or if historical data are not adequate or available. Simulation tests may involve conducting an activity suspected of generating a certain contaminant in an enclosed chamber with a known ventilation rate.

Models are often used when sampling or simulation is impractical or when exposure has already occurred but no sampling data are available. Plume modeling is an example of a type of modeling that predicts the spread of a contaminant through a community when there has been a release.

Exposure Classification, Summarization, and Analysis

The final phases of the exposure assessment process involve (1) assessment of the accuracy of exposure assignment and (2) the summarization and analysis of the exposure data. Exposure misclassification can occur in two forms: differential and nondifferential. With differential misclassification, one group in the study (e.g., cases or those exposed) has a higher probability of misclassification than another group (e.g., controls or those not exposed). Nondifferential misclassification, on the other hand, occurs when there is equal probability of exposure misclassification in the different study groups. In general, exposure misclassification of either type will reduce study power.

The impacts of exposure misclassification depend on the type of misclassification and whether exposure is measured as a dichotomous, ordinal, or continuous type variable. Nondifferential exposure misclassification with a dichotomous exposure variable will lead to bias in the relative risk estimate. The direction of this bias will be toward the null value. For other exposure conditions (i.e., ordinal or continuous exposure variables), this "rule of thumb" does not necessarily apply, although the assumption of nondifferential exposure misclassification and bias toward the null is frequently invoked, but rarely are data provided to verify this assumption. The impact of differential misclassification is much less predictable and dependent on the specific situation in each study.

The final aspect of exposure assessment is the manner in which exposure data are summarized. Various strategies are commonly used when some form of continuous data are available. Continuous exposure data can be modeled in its original form in epidemiologic analyses. Such data can be used to classify the exposure group as those from the top percentile category of exposure (e.g., 90th or 75th percentile) or can used to define the exposed group based on a biological/clinical/physical basis (i.e., if exposure exceeds a certain threshold or the safety level). Another aspect in the classification of exposure is the consideration of the latency period or the time between exposure to the agent and onset of disease. This is especially relevant in cancer epidemiology. If it is assumed, based on biological and clinical considerations, that a disease has a minimal latency period (e.g., 10 years), then exposure occurring within this period prior to disease onset will not be relevant. Exposure windows, another time-dependent variable in exposure assessment, refer to specific points in time for which a person is classified for exposure status. Some examples of exposure windows include exposure during fetal development, adolescence, and other periods of life.

Exposure assessment methods are critical in determining overall study quality in assessing health risks. The need to accurately reconstruct historical exposures makes this one of the most challenging aspects of epidemiologic research. Continually advancing technologies in exposure biomarkers to evaluate current and past exposures, geographical information systems for visualization of proximity to contaminant sources, and statistical modeling to predict likely exposure concentrations and outcomes should help to improve future exposure assessment.

Factor Analysis

Not all research is focused on hypothesis testing. Sometimes researchers are interested in identifying the structure of a particular phenomenon. For example, suppose a team of researchers were interested in developing a tool that would adequately measure and reflect the concerns of women considering undergoing genetic testing for familial breast cancer. A literature review indicated to these researchers that the structure of this construct called *concern* had been identified and described for other populations (e.g., adult caregivers of cancer patients) but needed to be redefined for their population of interest: women at risk for familial breast cancer. The methods of factor analysis can be used in developing such an instrument.

Characteristics of Factor Analysis

Factor analysis is not a single statistical method. Rather, it involves a complex array of statistical procedures that provide a way to identify interrelationships among a large set of observed variables. Much subjectivity and artistry are involved in this technique. The goal of factor analysis is to arrive at a parsimonious set of factors that have common characteristics and that summarize and describe the structural interrelationships among a set of identified items in a concise and understandable way. A *factor* is a cluster of related, observed variables that represent the underlying dimension of a construct that is as distinct as possible from other factors in the solution.

Exploratory Versus Confirmatory Factor Analysis

Factor analysis can be used for theory and instrument development and for assessing construct validity of an established instrument when administered to a specific population. There are two basic forms of factor analysis: exploratory and confirmatory. In exploratory factor analysis (EFA), the researcher does not know initially how many factors are necessary to explain the interrelationships among a set of characteristics. EFA is used, therefore, to explore the underlying dimensions of a construct. It is available in a number of statistical computer packages, including SPSS and SAS.

In contrast, confirmatory factor analysis (CFA) is used to assess the extent to which a hypothesized organization of identified factors fits the data. It is used when the researcher has prior knowledge about the underlying structure of the construct under investigation. CFA could also be used to test the utility of the dimensions of a construct identified through EFA, to compare factor structures across studies, and to test hypotheses concerning the structural relationships among a set of factors associated with a specific theory or model. To undertake CFA analyses, the researcher needs to use a structural equation modeling program, such as LISREL, AMOS, or EQS. Because CFA is addressed elsewhere (see the entry "Structural

Equation Modeling''), the focus of this discussion will be on EFA and, specifically, its use in instrument development.

Assumptions of Exploratory Factor Analysis

A basic assumption of EFA is that within a collection of observed variables, there exists a set of underlying factors, smaller in number than the observed variables, that can explain the interrelationships among those variables. Because the initial steps of EFA are performed using Pearson product moment correlations, many of the assumptions associated with this correlation coefficient are applicable to factor analysis (e.g., large sample sizes, continuous distributions and sufficient variation within the items, and linear relationships among the correlated variables). Since the response categories for each individual item are often constructed using dichotomous *yes, no* responses or ordinal-level Likert scales, normality of distributions is not always a strict requirement.

Sample Size Requirements

EFA is not a technique to be used with small sample sizes. Typically, it is expected that there will be 10 to 15 subjects for each item that is initially being considered. Comrey and Lee indicate that a sample of 50 is very poor, 200 is fair, 500 is very good, and 1,000 or more is excellent. Realistically, the number of available subjects may be restricted especially when the researcher is examining disease entities in which there are small numbers in the population. For example, it may be very difficult to identify and recruit 1,000 subjects who are considering undergoing genetic testing for cancer.

The Process of Exploratory Factor Analysis

There are eight basic steps to EFA. The first two, specifying the problem and generating the items, are undertaken prior to data analysis and are major determinants of a successful factor analysis. The following is a brief overview of these eight steps. For greater detail on the process for undertaking a factor analysis, the reader is referred to the suggested readings.

1. Specifying the Problem

Often, researchers think that they know the dimensions of the construct they want to measure—until they begin to specify the problem and to generate items related to that construct. During this initial phase, the observed indicators of the construct of interest need to be conceptualized and operationally defined. *What is it, exactly, that the instrument will measure? Are there other constructs that are related to this construct? Will the instrument measure the construct broadly or a specific aspect of the construct?* These questions must be addressed before undertaking a factor analysis. Without careful conceptualization, the resulting instrument will likely have poor construct validity.

2. Generating the Items

The next step is to generate items or empirical indicators that accurately reflect the construct of interest. These indicators need to be organized with a meaningful format that will allow data to be collected effectively and efficiently. Pilot testing of the instrument, its format, design, and layout with respondents who are similar to the target group will help set the stage for a successful factor analysis.

3. Evaluating the Adequacy of the Correlation Matrix

Once the data have been collected, the variation in item responses should be carefully examined. Without adequate variation, the interitem correlations will be low and the utility of conducting a factor analysis questionable. The correlation matrix also needs to be evaluated to determine whether there are adequate correlations among the items to justify a factor analysis. Several approaches are available in the statistical packages to assess the initial factorability of a correlation matrix. These include an evaluation of the determinant, Bartlett's test of sphericity, and the Kaiser-Meyer-Olkin test.

4. Extracting the Initial Factors

Assuming that the correlation matrix is factorable, the task of the beginning extraction process is to determine the number of initial factors that appear to represent the dimensions of the construct being measured. This extraction process begins with an

initial estimate of the total amount of variance, or *communality*, in each individual item that can be explained by the extracted factors. These communality estimates can range from 0 to 1.0 with higher values indicating that the extracted factors explain more of the variance in an individual item.

Initially, these communalities are unknown; they cannot be identified until after a factor analysis has been run. Yet to begin a factor analysis solution, estimated communalities need to be placed on the diagonal of the correlation matrix. There are two basic approaches to estimating these communalities: principal components analysis (PCA) and common factor analysis.

Principal Components Analysis (PCA)

PCA assumes that potentially all the item variance can be explained and that there is as much variance to be analyzed as there are observed variables. Since each item, if standardized, has a mean of 0 and variance of 1.00, the initial estimate of communality for each item is 1.00. This is what appears on the diagonal of the correlation matrix when using PCA.

Common Factor Analysis

Common factor analysis assumes that only the common variance that an item shares with other items in the correlation matrix can be explained by a small number of underlying factors. The variation that is unique to the item including error variance cannot be explained. Because common factor analysis focuses on the common variance shared among the items, the amount of variance that can be extracted from the correlation matrix by these estimated factors is less than 100%. Therefore, initial values less than 1.00 will appear on the diagonal of the correlation matrix. One common solution in common factor analysis, principal axis factoring (PAF), places the squared multiple correlation (R^2) of each item with all other included items on the diagonal. These squared multiple correlation coefficients (range: 0 to 1.0) provide an initial indication of the strength of the interitem relationships.

Eigenvectors and Eigenvalues

Whether using PCA or common factor analysis, each extracted factor is represented by an *eigenvector*. An eigenvector is a column of weights, each weight of which is associated with an item in the correlation matrix. If there are eight items in the matrix, there will be eight weights in that eigenvector. These weights are called *factor loadings* and represent the correlation of each item with the given extracted factor. Table 1 presents an initial factor-loading matrix generated in SPSS for Windows from an 8×8 correlation matrix using PAF. Item c6, for example, has an initial factor loading of .712 with Factor 1.

The *eigenvalue* associated with an extracted factor is equal to the sum of its squared factor loadings and represents the amount of variance in the items that can be explained by that particular factor (Table 1). Dividing the eigenvalue by the number of items indicates the proportion of total item variance accounted for by a given factor. For both PCA and common factor analysis, the eigenvalues for each extracted factor are typically largest for the first factor extracted and lowest for the last extracted factor. Table 2 presents a computer-generated output using SPSS for Windows for the total variance explained for the same 8×8 matrix using PAF. The initial eigenvalues presented in Table 2 are similar to those that would be obtained in a PCA. However, because only common variance is being extracted in PAF, the extracted eigenvalues are smaller.

Extracting the Factors

Extracting factors from a correlation matrix is an iterative procedure that consists of repeatedly refining the factor analysis solution until suitable eigenvectors and their associated eigenvalues are obtained. The factor extraction process differs depending on the type of factor analysis undertaken (e.g., PCA or PAF). Typically, the majority of the variance in the items is accounted for by a relatively small number of factors. In Table 2, for example, 48.968% of the shared variance in the eight items can be accounted for by two extracted factors generated in PAF. If PCA had been used, 57.349% of the total variance would have been accounted for by the same two factors.

Selecting the Number of Initial Factors to Retain

The goal of a factor analysis is to reduce the number of factors such that the maximum amount of variance can be explained with the fewest number of factors.

While the goal is simple, there is no precise solution to determining the number of factors to extract.

Table 1 Factor-Loading Matrix Generated in SPSS for Windows From an 8 × 8 Correlation Matrix Using Principal Axis Factoring

Extraction Method: Principal Axis Factoring

a. Initial eigenvalue #1 = 3.046

b. Initial eigenvalue #8 = .306

c. Extracted eigenvalue #1 = 2.725

d. Percentage extracted = 48.968

Given the same data set, a team of researchers might arrive at very different solutions. Several guidelines can be used to help determine the number of factors to retain: the amount of explained individual and cumulative variance, the scree plot, and factor interpretability and usefulness.

Amount and Percent of Individual and Cumulative Variance Extracted. One solution to determining the number of initial factors is to select only those factors for which the eigenvalue is > 1.0. This means only those factors will be retained that explain more than one item's worth of variance. In Table 2, this criterion would result in two factors being extracted. A second solution is called the 5% criteria: Only those factors would be retained that explain at least 5% of the variance in the items. Three factors meet that criterion with the PAF solution. A third approach is to establish a threshold for maximum variance extracted (e.g., 65%). Because only shared variance is evaluated in PAF, none of the seven extracted factors meet this 65% criterion (Table 2).

Examining the Scree Plot. A scree plot is a plot of the initial eigenvalues in descending order of magnitude. To use a scree plot for determining how many factors to retain, a straight line is then drawn through the lower values of the plotted eigenvalues. This allows the researcher to identify distinct breaks between the steep slope of the larger eigenvalues and the trailing off of the smaller ones. Figure 1 presents a scree plot of the eight initial eigenvalues shown in Table 1; two factors appear on the steep slope distinct from the slope of the smaller values and would be retained using this criterion.

Factor Interpretability and Usefulness. There is no easy solution to deciding on the number of factors to retain. This decision is based on a careful evaluation of the statistical indicators and the factors' theoretical coherence. The ultimate criteria for determining the number of factors are factor interpretability and usefulness both during the initial extraction procedures and after the factors have been rotated to achieve more clarity.

5. Rotating the Factors

Unrotated factor solutions often do not provide meaningful clusters of items. Factor rotation improves the interpretation of the generated factors. Factor rotation is the process of turning the reference axes of the factors about their origin to achieve a simple structure and theoretically more meaningful factor solution. *Simple structure* is one in which, ideally, each item has a high loading on one factor only and each factor has high, meaningful loadings for only some of the items. There are two broad classes of rotation, *orthogonal* and

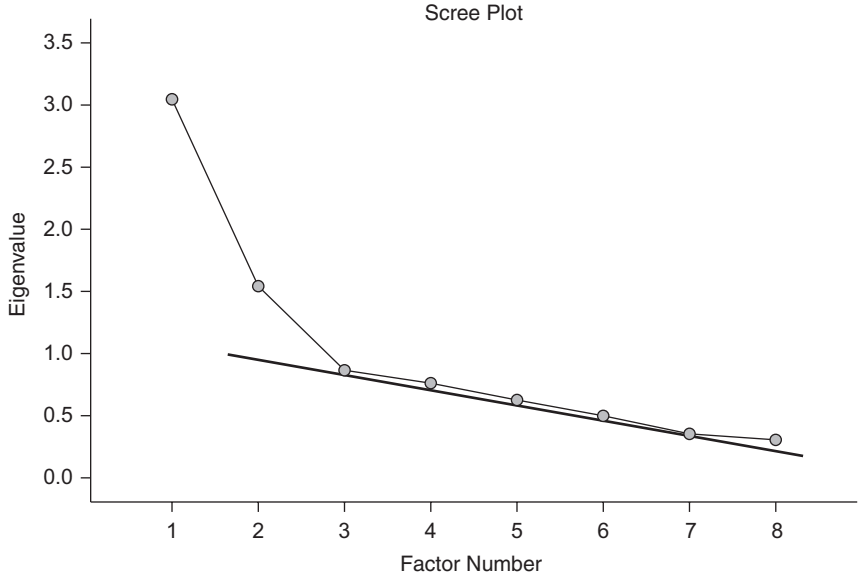

Figure 1 Scree Plot of the Initial Eigenvalues (Table 1) Plotted Against Their Factors

oblique. Each has different underlying assumptions but share a common goal of simple structure.

Orthogonal Rotation

In an orthogonal rotation, it is assumed that the generated factors are independent of each other (i.e., they are uncorrelated). The factors are fixed at 90° angles to one another and rotated to obtain an optimal fit with the distributions of the items in space. Because they are maintained at right angles to one another, these newly rotated factors are uncorrelated and, as a result, produce a single rotated factor loading matrix. The correlations among the items have not changed. Only the loadings of the items on the newly rotated orthogonal factors have changed.

Varimax is the most commonly used orthogonal rotation. This approach maximizes the variances of the loadings within the factors while maximizing differences between the high and low loadings on a particular factor (hence the name *varimax*). Higher loadings on a factor are made higher and lower loadings are made lower. Table 3 presents a two-factor unrotated and rotated solution of the factor-loading matrix in Table 2 using a PAF varimax rotation. The factor loadings have been sorted according to size for ease of interpretation. The higher factor loadings from the unrotated solution have been made higher while the low loadings are now lower in the rotated solution.

Oblique Rotation

Although orthogonal rotations often produce attractive simple solutions, these rotations rest on the critical assumption that the factors are uncorrelated.

Table 3 Unrotated and Rotated Two-Factor Solution: PAF With Varimax Rotation

Rotation Method: Varimax With Kaiser Normalization

a. Two factors extracted; 18 iterations required.

b. Rotation converged in three iterations.

This assumption is rarely met in epidemiological research since researchers are often dealing with conceptually different but nevertheless correlated dimensions of a construct.

One popular oblique rotation is *Oblimin*, which uses the parameter *delta* to control the degree of correlation among the factors. Each original factor is rotated separately by different amounts. As a result, two different factor-loading matrices are generated: a *factor pattern matrix* (a matrix of loadings that are like partial standardized regression coefficients) and a *factor structure matrix* (a matrix of simple correlations of the items with the factors).

There are differences of opinion as to which matrix, factor pattern or factor structure, should be evaluated for simple structure. Some writers argue that the *factor pattern* matrix should be used to determine the extent to which simple structure has been achieved since the difference between high and low loadings in the factor pattern matrix is more apparent than in the structure matrix. Other writers maintain that the factor structure matrix is more stable because it is unaffected by changing the size of the correlations among the factors.

The author suggests that both matrices be examined to determine which makes the most sense. Table 4 presents the two-factor structure and factor pattern matrices generated using the same data as in Table 3. This was a PAF solution using an Oblimin rotation. The items were sorted according to size, and absolute values $< .30$ were suppressed. This presentation allows the pattern of high and low item-to-factor correlations to become more distinct. The weaker item-to-factor correlations are not deleted; they remain in the background and are included in calculations of item communalities and percentage of variance explained by the factors. Their absence from the table just makes it easier to view the patterns of factor loadings. Table 4, for example, indicates that the factor pattern matrix has generated loadings that are more easily interpreted. The correlation between the two factors was $-.328$.

An advantage of oblique rotations is that the factor axes can be rotated to any position without changing the correlations among the items or their shared communalities. Kline suggests that correlated factors reflect the real world. If it is found after oblique rotation that the factors are orthogonal, the researcher can be confident that the result is not an artifact of the choice of rotation.

6. Refining the Solution

In most factor analyses, several factors will likely emerge as potential descriptors of a set of items. Ideally, each item will load strongly on a single factor following factor rotation. In reality, even with factor rotation, items will sometimes demonstrate weak loadings on all factors or will load strongly on several factors. To refine the obtained solution, both the strength of the item loadings with the factors and their consistency with the original conceptualizations before the factor analysis began need to be closely examined.

The factor pattern matrix in Table 4 indicates that five items load on the first factor and three items load on the second factor. The loadings that remain in view are strong, ranging in values from $-.882$ for Item c7 to .396 for Item c8. A similar pattern of distribution of items was also observed when a varimax rotation was generated (Table 3). The only difference was that Item c6 had loadings $> .30$ on both factors. The challenge will be to determine where best to place this item if the varimax solution is chosen.

When items load strongly on more than one factor, it is best to either delete the item entirely or place it with the factor that it is most closely related to conceptually. Reliability coefficients (e.g., Cronbach's alphas) for the group of items that load on a given factor can be used to evaluate the factor's internal consistency and to decide where to best place an item with strong loadings on several factors.

7. Interpreting and Naming the Factors

Naming factors is a poetic, theoretical, and inductive effort that should follow from the theoretical considerations that have led to the definition of the construct. There are no definitive statistical tests in factor analysis to indicate whether an item is *significant* for the purposes of factor interpretation. Usually, three or four items with the highest loadings on a factor are selected and studied. *Is there a theme or common element that these items share?* If so, then a descriptive name might be selected that is representative of these items. When the highest loadings on a factor are low (e.g., $< .60$), the researcher is faced with potentially weak interpretations.

In selecting a name for the factor, it is best that the interpretation remain simple but suggestive as to what dimension that factor represents. If the items for the factor analysis were theory driven, the researcher should return to that theory for guidance in naming

Rotation Method: Oblimin With Kaiser Normalization

a. Rotation converged in five iterations.

the factors. *How useful is the factor? Is the content too broad to be of use, or is it too specific and limited in scope? How does this identified construct fit with other identified taxonomies in the field? What is missing from this construct? In what areas do we need to direct our future factor analysis activities?* Clearly, the naming of a factor is not a simple task.

8. Reporting and Replicating the Results

The key to a successful factor analysis is the reporting and replication of the results obtained. Enough information must be reported about the development of the instrument to allow other researchers to verify the results. Although limited by the constraints of

a research journal, a report of a factor analysis should include at the very least the following information:

- a theoretical rationale for the use of factor analysis;
- detailed descriptions of the development of the items, sampling methods, and participants;
- an evaluation of the assumptions of factor analysis;
- justification for the choice of factor extraction and rotation methods;
- an evaluation of the correlation matrix;
- decisions regarding cutoffs for meaningful factor loadings;
- presentation of the structure and pattern matrices;
- descriptions and interpretation of the factors;
- report of the internal consistency of the identified factors; and
- assessment of the study limitations and suggestions for future research.

Using factor analysis involves an ongoing commitment to a research program. One must not assume that all the items that define a factor have been delineated in a single study. Many studies must be undertaken to determine if all items of the factor have been derived and correctly interpreted.

Family Studies in Genetics

Family studies may be considered a key entry point for research into the role of inherited genetic variation in disease. There are three major kinds of family studies: (1) evaluations of the extent to which a disease or other trait of interest aggregates or clusters within families, and how it is transmitted across the generations; (2) linkage analyses aimed at pinpointing the specific location on one of the chromosomes of a gene containing a mutation that has a major or moderate effect on disease risk; and (3) association studies aimed at finding common gene variants that have smaller but still medically important effects on disease severity or disease incidence. All three of these kinds of family studies are considered in this entry.

Analysis of Aggregation or Clustering

One of the first questions that investigators need to ask when considering genetic studies of a disease or some other trait of interest is "What is the evidence that inherited genetic variation has an important influence on the trait?" A necessary but not sufficient condition required to demonstrate the importance of genetic variation is the occurrence of *familial aggregation* of the trait. We know from the simple rules of Mendelian inheritance that family members tend to share genes in common. For example, siblings share 50% of their genes inherited identical by descent from their parents, and cousins share 12.5% of genes inherited from their common grandparents. Therefore, if genetic variation really is important for the development of a disease (incidence) or its severity, then we would expect to find the disease co-occurring or "clustering" among family members more often than among randomly drawn unrelated individuals in the population. One way this is often formally tested in research studies is to compare the frequency of disease in relatives of persons with the disease compared with the frequency found in relatives of matched healthy controls. If disease frequency is not at all elevated in relatives of cases, then it is unlikely that most cases of the disease in the population have a substantial genetic basis. On the other hand, familial aggregation of disease is

evidence that the trait has a genetic basis but still does not constitute definitive proof. This is because in addition to sharing genes, family members also usually share similar environments (diet, exposure to toxins, etc.), and it is possible that the aggregation of disease in relatives is caused by their common environments rather than by shared genes. Investigators can measure environmental exposures that are suspected to be risks for the disease in cases, in controls, and in their relatives and attempt to statistically adjust for these effects in data analyses. Alternatively, if the disease is sufficiently common, studies of monozygotic and dizygotic twin families offer a very powerful design that can provide very powerful capability to distinguish between environmental and genetic causes of variation in disease risk.

For some forms of very severe single-gene (Mendelian) disorders there may not be a positive family history if transmission is dominant and clinical symptoms onset at a young age. People with such diseases are unlikely to reproduce so patients with the disease frequently have arisen via a new mutation not present in their ancestors. On the other hand, with recessive diseases, the parents, not surprisingly, usually do not know that they are carriers for the recessive mutation and the disorder may be new to the family. An exception to this rule is for recessive diseases occurring among cultures with consanguinity (e.g., first-cousin marriages) where occurrence of the disease may not be surprising. Studies of consanguineous families can be very useful for gene-mapping studies.

It should be noted, however, that even if no evidence of familial aggregation or heritability is obtained from family studies, this does not rule out the possibility that a small subset of disease cases (e.g., 1% to 5%) might be caused by a mutation in a gene that causes a major increase in disease risk. In fact, strong familial aggregation may exist for this small genetically based subset of cases, but this is obscured by the majority (95% to 99%) of disease cases for which genetic variation has little or no influence on disease risk. For example, most cases of breast cancer lack familial aggregation, and in twin studies there is little evidence of heritability, but relatively rare mutations in BRCA1 gene and other genes have a very major effect on cancer risk in individuals who inherit these mutations. Furthermore, sometimes the same genes that are involved in the rare inherited forms of a disease are mutated somatically in nonhereditary cases. Therefore, understanding the biological mechanisms involved in rare hereditary forms may have great importance for developing improved methods of diagnosis, prognosis, and therapy for both hereditary and nonhereditary forms of the disease.

When a disorder shows familial aggregation that appears not attributable to shared environmental exposures, a statistical method called *segregation analysis* can be used in an attempt to estimate the mode of inheritance—autosomal recessive, dominant, or codominant; X-linked dominant or recessive. This technique has been successfully applied to many simple (single gene) disorders, but it has only limited value in studies of complex diseases where multiple disease susceptibility genes interact to influence disease risk. Segregation analyses usually need to assume *homogeneity*, meaning that the same type of gene is responsible for causing the disease in all families included in the study. If, in fact, some families have inherited a gene that acts dominantly while other families in the data set have inherited mutations at either the same gene or a different gene where risk is recessively transmitted, segregation analysis will be unreliable. Even with relatively simple disorders, the method has serious limitations. First, one must be aware of and appropriately adjust for the way the families and family members were selected for study (ascertainment bias). Second, there is the problem of unrecognized shared environments (noted above), and, for quantitative traits, deviations from assumptions of normality can lead to incorrect inferences about the mode of transmission. The method has been modified in recent years in an attempt to address these weaknesses, but it has nonetheless been largely supplanted in genetic epidemiological research by family studies that incorporate DNA markers.

Linkage Analysis

When a single gene has a major effect (e.g., $>$ 10-fold increase) on the risk of developing a disease, and when the disease is relatively uncommon in the population, then the method of linkage analysis can rapidly lead to successful gene identification. *Linkage-mapping* families are evaluated for the cosegregation of polymorphic DNA markers (either short tandem repeats or single-nucleotide polymorphisms) with the disease phenotype. Linkage mapping depends on the fact that recombination during meiosis occurs only rarely between markers that are located physically close (linked) to the disease gene. Recombination occurs increasingly more often as markers are located

farther away (> 10 Mbp) on the same chromosome as the disease gene or located on a different chromosome altogether. It is possible to detect linkage with as few as 12 to 16 informative individuals when the disorder is highly penetrant (i.e., nearly every person who inherits the mutation gets the disease), when there are few phenocopies (i.e., hardly anyone who does not inherit the mutation gets the disease), and if the density of markers is sufficiently high. Most often, a single sufficiently large extended family is not available, so several unrelated families may need to be combined, especially when attempting to map a recessive trait. In some special circumstances, consanguineous (inbred) families may allow investigators to use an approach called *homozygosity mapping* to localize a recessive disease gene. For example, in offspring of first cousins, about one sixteenth of the genome is expected to be homozygous. The specific homozygous genome regions would be random in affected offspring of different sets of first cousins, except for the region that contains their recessive disease gene. This region would be homozygous in the offspring of all the offspring, so by evaluating only a limited number of such offspring, a disease gene can be mapped. Linkage analysis has had some success for oligogenic diseases (i.e., those with only a few genes involved). Unfortunately, despite major investments of resources and years of effort, studies of complex disorders that are likely to involve multiple genes of smaller effect (e.g., twofold increase in risk) and potentially involving gene-gene and gene-environment interactions have usually been disappointing.

Association Analysis

Mathematical analyses and several recent disease studies have shown that *association mapping* methods can provide good statistical power for identifying genes that underlie complex diseases while requiring much smaller numbers of patients and their relatives than would be required for linkage analysis. Association mapping can be performed using either small or large families or unrelated cases and controls. The only catch is that instead of needing only a few hundred polymorphic DNA markers to cover the entire human genome, the association strategy requires several hundred thousand such markers assayed on each subject. Fortunately, molecular genetic technologies have been developed that can meet the challenge of producing these massive amounts of data, and the International HapMap Project ("HapMap" being an abbreviation of "haplotype map") has cataloged this variation in several human populations and made it freely available online for researchers wishing to tap into this rich genomic treasure chest. In the first phase of this project, the frequency of DNA variants was measured at more than 1 million locations distributed across the human genome in European, African, and Asian subjects. DNA variants that are located near each other on the chromosome often are correlated with each other, so if an investigator determines the DNA sequence for a subject at one position, the DNA bases at the neighboring variant positions often can be predicted with a high degree of confidence. This phenomenon is known as *linkage disequilibrium*, and the HapMap Project has determined where these patterns of correlation among neighboring DNA variants exist for a large portion of the human genome. Armed with this information, investigators interested in studying inherited variation at a candidate gene for their disease (or searching through all genes in the entire genome) need not undertake the large effort of conducting assays for all known variants in their clinical subjects. Instead, they can use computer algorithms on data derived from the HapMap Project to measure most of the inherited variation present in the genome at a substantially reduced cost by identifying an optimized subset of DNA variants that serve as statistical "tags" for many other variants that are not actually assayed in the laboratory. The National Institutes of Health and other organizations responsible for support of biomedical research are currently developing plans for a major expansion of whole-genome association studies to a wide range of diseases and to drug side effects and therapeutic responses (pharmacogenomics). Family studies are certain to play an important role for these exciting initiatives in the future of genomic medicine.

Ethical Issues

There are many important and complex ethical issues that arise when performing family studies. Members of families need to be carefully educated about the risks, both social and cultural, of participating in family studies, which include providing information on their relatives. Although investigators will have obtained approval from an institutional review board responsible for protecting research subjects, such review boards generally focus on possible outcomes from the genetic (biological) information that will be obtained and may

not always fully consider the possibility of altered family dynamics that may arise as a consequence of participating in the study. Anticipatory counseling of prospective families can enhance participation rates and minimize stressful effects on family dynamics.

Farr, William
(1807–1883)

William Farr is one of the major figures in the history of epidemiology. A British physician with an unusual knowledge of statistics, Farr was appointed Compiler of Abstracts at the General Register Office of England and Wales, which registers births, marriages, and deaths. He worked almost 40 years in analyzing statistics from England and Wales and pioneered the quantitative study of morbidity and mortality.

Farr developed a classification of causes of death, constructed the first English life table, and made major contributions to occupational epidemiology, comparing mortality in specific occupations with that of the general population. In a report presented in 1864, Farr addressed the disproportionate high number of deaths among miners in Cornwall, showing that at each age level, the rate of mortality attributed to pulmonary diseases among miners was much higher than among males exclusive of miners, with the difference being higher at higher ages. He concluded that pulmonary diseases were the chief cause of the high mortality rate among the miners. From the fact that excess mortality from pulmonary diseases reached its maximum after mid-age, when mine conditions had had sufficient time to produce their effect on the health of miners, Farr concluded that it might be confidently inferred that these diseases were due to labor conditions inside mines.

Being a conscious reformer, Farr opposed the gloomy Malthusian views then in fashion. Against the idea that population grows geometrically while food can grow only arithmetically, he argued that human inventiveness can increase productivity, and, moreover, that plants and animals that constitute food also grow geometrically. Against Malthus's idea that men reproduce like rabbits, without concern for consequences, Farr showed with statistics that the average age at marriage in England was 24 to 25 years, about 8 years after the onset of the reproductive age of women, and that more than 20% of men and women reaching reproductive age never married.

As the statistician in charge of analyzing mortality data, Farr argued in an official report that hunger was responsible for many more deaths than shown in the statistics, since its effects were generally manifested indirectly in the production of diseases of various kinds. Although he was a supporter of the miasmatic theory of disease and initially claimed that cholera was transmitted by polluted air, Farr was finally persuaded otherwise by John Snow, and in 1866 produced a monograph showing how cholera cases were much more frequent in Londoners receiving water from particular sources.

Being fluent in French, German, and Italian, Farr represented Britain in a number of statistical congresses, and in his later years was considered a major authority on medical statistics and public health. Today, he is considered one of the most prominent figures of the movement of social medicine in Victorian England and a major author in the history of health statistics.

Fertility, Measures of

In demographic terms, fertility is the actual reproductive performance of members of a population. Fertility is one of the three major components of demography, along with mortality and migration. Fecundity, on the other hand, reflects the physiological ability of a woman to reproduce (often referred to as fertility in lay conversation).

Several measures of fertility exist, of which the most frequently used include birthrate, age-specific fertility rate (ASFR), and total fertility rate (TFR).

Birthrate

Birthrates, also known as crude birthrates, represent the actual number of live births per 1,000 population per year. It is mathematically represented by the following equation:

$$\text{birthrate} = \frac{n}{p} 1{,}000,$$

where n represents the number of live births in that year and p is the population size in that year.

Similarly, the general fertility rate is the number of live births per 1,000 women of reproductive age (usually ages 15 to 44 or 15 to 49) in a given year.

Age-Specific Fertility Rate

The ASFR is a measure of the average number of births per year per 1,000 women in specific age groups (generally ages 15 to 19, 20 to 24, etc.). The following equation represents the calculation of ASFR:

$$\text{ASFR}_i = \frac{n_i}{w_i} 1{,}000,$$

where n_i represents the number of live births during a given year by women in age group i, and w_i represents the number of women in age group i.

Total Fertility Rate

The TFR measures the average number of children who would be born alive to a woman completing her childbearing years based on ASFRs in a given year. Thus, TFR is not an actual rate of live births but an estimate based on the assumption that women will continue childbearing at the ASFR in that year. Mathematically, TFR is calculated from ASFR:

$$\text{TFR} = \frac{\sum \text{ASFR}_i \times x}{1{,}000},$$

where ASFR_i represents the fertility rate for the ith age group and x is the number of years in the interval of age group i.

TFR is often referred to in the context of replacement-level fertility, the TFR necessary to sustain current population size. In industrialized nations, a TFR of 2.1 indicates a level of fertility where each couple bears only enough children to replace themselves in a population, representing equilibrium between birth and death rates. Replacement-level fertility in developing countries is less defined, particularly due to varying death rates in the context of HIV/AIDS.

Other Measures

Other measures of fertility include the following:

- *Completed Fertility Rate.* The actual number of children born to a cohort of women at the end of their childbearing years.
- *Gross Reproduction Rate.* The average number of live female births that would be born during a woman's lifetime if she passed through her reproductive years conforming to ASRF in a year.
- *Marital Fertility Rate.* The actual number of live births to married women per 1,000 women of reproductive age in a year.

Fetal Death, Measures of

The World Health Organization defines a fetal death as the death of a production of conception prior to complete expulsion or extraction from its mother, regardless of length of pregnancy. Factors that indicate a fetal death after separation from the mother include no breathing or evidence of life by the fetus, pulsation of umbilical cord, or voluntary muscle movement. The distinction between fetal and infant deaths is based on the place of death; a fetal death occurs in utero.

Fetal death can be measured in terms of time of death: death prior to labor, antepartum mortality, and death during labor. According to the National Center for Health Statistics, measures are operationalized in terms of gestational age: A death at or after 20 weeks is considered a fetal death. An early fetal death is at 20 to 27 weeks, while a late fetal death is at or greater than 28 weeks.

In the United States, fetal death reporting requirements vary by state. The 1992 Revision of Model State Vital Statistics Act and Regulations recommends that each fetal death of weight 350 g or more or, for unknown weight, 20 weeks of gestation or greater should be reported. However, the standards are not consistent. Thirteen areas (including states, cities, and territories) specify the requirements for fetal death as stated in the above act. Eleven areas report any expulsion or extraction of the product of human conception as a fetal death, while others base the requirements only on gestational age or use a different combination of gestational age and weight.

Field Epidemiology

The term *field epidemiology* describes the application of epidemiologic methods, usually by representatives of a public health service, to address specific health-related questions in community settings. Many, if not most, field investigations address urgent or acute health problems. However, many others are conducted as planned studies addressing less urgent needs. All field investigations have in common the aim of conducting scientifically rigorous studies, sometimes under difficult circumstances, to answer very specific epidemiologic questions with the ultimate aim of planning, implementing, or evaluating public health interventions.

Outbreak investigations are a prominent example of field epidemiology studies and serve to illustrate many of the characteristics common to all field investigations. An outbreak investigation, like other field investigations, has the following goals: (a) to determine the cause and etiology of the disease, (b) to limit the spread and severity of illness of the disease, and (c) to prevent future outbreaks. In addition, investigations of this sort can serve to identify new modes of transmission of illnesses, identify new pathogens, and monitor the effectiveness of prevention activities.

Field epidemiology also includes investigations conducted in several different types of community settings, each involving its own challenges. These settings may include health care facilities, child care settings, occupational settings, and even areas affected by natural disasters.

Investigations in health care settings, such as hospitals, rehabilitation centers, transitional care centers, outpatient settings, and long-term care facilities, differ from other field investigations in several ways. First of all, most of the infections encountered are endemic to the setting and are unlikely to be completely eradicated. Patients affected in these settings typically have additional medical conditions that render them more susceptible to adverse sequelae than healthier community-based individuals. The infectious agents involved in health-care-related outbreaks are a greater danger to the patients and health care workers in the

facility than to the general public outside the facility. Finally, an outbreak in a health care facility may require even more rapid identification and control than a community-based problem, not only because the risk of litigation is higher but also because of the greater vulnerability of the patients to the infection. These distinctions aside, the methods used to identify and control an outbreak in a health care setting are basically the same as for a community-based outbreak.

Child care settings present issues similar to those in other care facilities, though the "at-risk" population is not confined to the facility itself. Epidemiologists need to be aware of the potential spread of illness beyond the children and child care providers to family contacts and children encountered in other settings such as schools, community playgrounds, and the like.

Field epidemiology may also be conducted in areas affected by disasters, either natural or man-made. Such investigations typically involve, at least initially, the gathering and summarizing of data about the needs of the affected population: What food is available or needed? Are water sources available? What medical conditions and/or injuries are prominent or likely to occur, and what medications, treatments, and medical personnel are needed? Early data such as these can be used to guide humanitarian and relief efforts, matching available resources to the needs. In addition to assessing the needs of the populations, epidemiologists may be called on to assist in preventing further adverse health effects, to evaluate the effectiveness of relief programs in meeting the most immediate needs of the population, and to assist in contingency planning. Epidemiologists may also need to quickly establish surveillance systems, monitoring ongoing health risks and adverse events, evaluating the effectiveness of clinical interventions, and identifying potential risk factors for developing adverse outcomes. Opportunities exist as well for studying the natural history of a disaster and its potential for long-term health impacts. In the setting of a natural disaster, field epidemiologists may serve as a communication and coordination hub for medical personnel, relief effort coordinators, and other decision makers, making skills in communication, coordination, and public relations key.

Epidemiologists may be called to investigate illnesses or injuries in a workplace setting as well. There may be instances of a previously recognized work-related illness or injury occurring in a given occupational setting. Or, there may be illnesses or injuries occurring that haven't yet been identified as being work related. Epidemiologists may be asked to investigate whether a particular process or exposure causes the illness in question. Or, as in the other field investigation types described above, the investigation may involve the evaluation of intervention or prevention efforts.

Field investigations in occupational settings present several other challenges that distinguish them from field investigations in other settings. In the other types of investigations, the investigator usually has some idea what he or she is looking for with regard to the disease involved. The pathogen involved, the epidemiologic characteristics of the disease, and the clinical and laboratory methods are usually known or narrowed down to a few likely suspects. In addition, the stakeholders are generally cooperative and supportive of the investigative efforts. However, an investigation in an occupational setting may involve looking for a completely unknown agent or mechanism causing the illness or injury. Potential agents may be part of the production process, may be a contaminant, or may be the product itself. And the illnesses or injuries may be taking place in a setting where the epidemiologist has no prior knowledge or detailed understanding of the various manufacturing processes, the internal politics, and the various stakeholders' allegiances. In addition, there are unique legal issues involved dictating the circumstances and extent to which employees may be interviewed or examined and special considerations with regard to confidentiality issues. An epidemiologist may have to simultaneously deal with union representatives, management and ownership representatives, legal counsel, and the media while attempting an epidemiologic investigation in a workplace setting. Certain stakeholders may be supportive of the investigation, while others may be obstructive or uncooperative, further complicating the efforts to identify and minimize the impact of the illness or injury process necessitating the investigation.

Regardless of the precise setting of the field investigation, each has in common with the others many methods. Overall, each study has as its aim to rigorously collect valid data from which hypotheses about the cause of the illness may be made. Analytic methods are then used to test the hypotheses. Data collection can be accomplished using any of several methods. For example, data from written records such as physician or hospital notes or employer records may be abstracted onto standardized data collection

forms. Questionnaires may be developed and used to collect uniform information during subject interviews. Physical exams of affected persons and/or of a group of comparison subjects may be conducted. Biological samples may be gathered from physical exams or from existing samples, and environmental samples may also be collected. The analytic portion of the investigation may be conducted using either case-control or cohort study methods. Case-control methods are especially relevant if the investigator wishes to evaluate several potential exposures and their associations with a single outcome and are often used in infectious disease investigations. Case-control studies may also be nested within larger cohort studies in situations where conducting a case-control study with the whole population is not feasible. Cohort studies are more common in occupational investigations, where a group of workers may be followed over time to evaluate the effect of a particular exposure on subsequent health events. In all cases, the cohort of subjects to be studied or the source population of cases needs to be as clearly defined as possible, and a clear case definition should be formulated to identify affected persons as readily as possible.

Firearms

Injuries and deaths due to firearms are an important public health concern in the United States. The Centers for Disease Control and Prevention (CDC) identifies the need for improvements in four areas that have a particular focus on firearm use: suicide, homicide, physical assault, and weapon carrying among youth. While firearm-related deaths and injuries have decreased since peaking in the late 1980s, they are still a significant problem in the United States, especially among low-income African Americans living in urban areas.

Firearm Mortality

Suicide

According to the CDC's Web-based Injury Statistics Query and Reporting System (WISQARS) (2005), suicide is the fourth leading cause of death for individuals aged 10 to 14 years, the third leading cause of death for individuals aged 15 to 24 years, and the second leading cause for individuals aged 25 to 34 years, with nearly half of the suicides among 25- to 34-year-olds being completed with a firearm. Most firearm suicides by youth occur at home, and the presence of a firearm in the home is associated with an increased risk of firearm suicide. The use of a firearm for a suicide attempt results in death approximately 80% of the time.

Firearm suicide is most prevalent among males, particularly white males. However, an exception to this is among males aged 20 to 29 years. In this group, the rate of firearm suicide is highest for black males.

Homicide

Homicide is the third leading cause of death for individuals aged 10 to 14 years, the second leading cause of death for individuals aged 15 to 24 years, and the third leading cause for individuals aged 25 to 34 years, with approximately 80% of the homicides among 25- to 34-year-olds being completed with a firearm (CDC/WISQARS, 2005).

Homicide caused by firearm is most prevalent among adolescents and young adults, males, and blacks (see Figures 1 and 2). Homicide, driven primarily from death due to a firearm, grew to epidemic proportions in the late 1980s through the early to mid-1990s in the United States. Since the early to mid-1990s, homicide due to firearm has declined.

However, from 1999 through 2003, firearm homicides have stabilized, showing, if anything, a slight increase in the early 2000s. Furthermore, the changes in firearm homicides have not affected all demographic groups in the same way. For example, from 1999 to 2001, the 10- to 14-year-old males and females in each CDC race category showed a decline

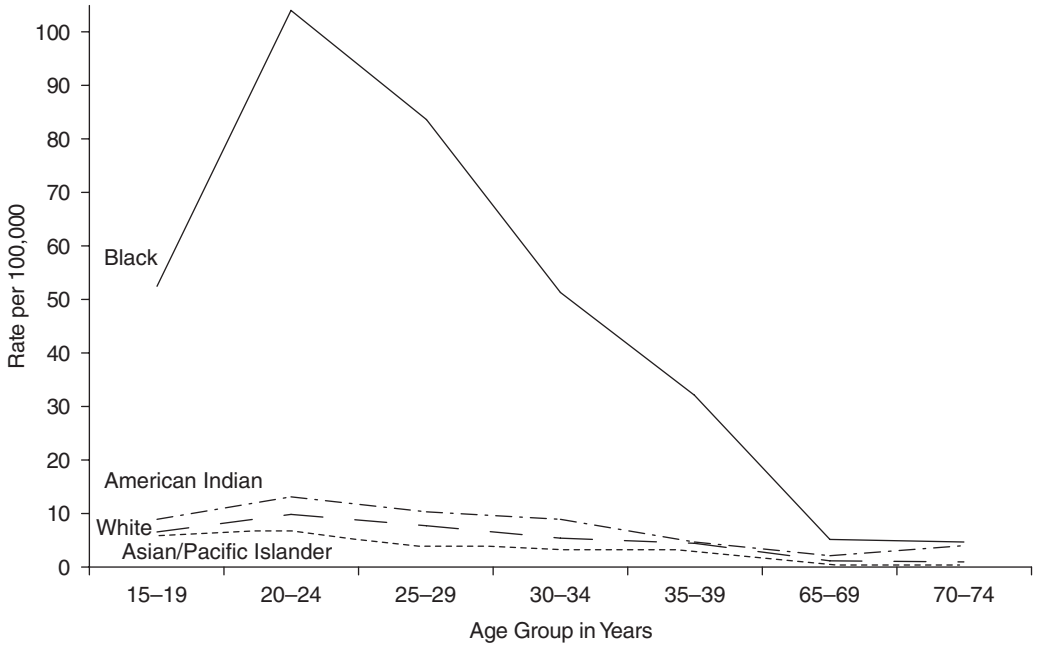

Figure 1 Average Firearm Homicide Rate (2001–2004) by Race and Selected Age Groups: Males

Source: Centers for Disease Control and Prevention, National Center for Injury Prevention and Control (2005).

in firearm homicides from 1999 to 2001, followed by a small but steady increase in homicides over the next 2 years. A similar pattern is seen among youth between the ages of 15 and 19 years across racial groups. However, both black and white males between the ages of 20 and 25 years have shown little change in this time period, while white females and black males aged 25 to 29 years have shown a steady increase in firearm homicide between 1999 and 2003.

Firearm Morbidity

Similar to firearm mortality, firearm morbidity is most prevalent among adolescents and young adults, males, and blacks. Firearms are responsible for a considerable amount of nonfatal injury among individuals between the ages of 10 and 29. The rate of nonfatal injury due to firearms among males increases from approximately 11 per 100,000 among males aged between 10 and 14 years to approximately 101 per 100,000 when the male is aged between 15 and 19 years. This risk peaks at approximately 139 per 100,000 among males between 20 and 24 years and then steadily drops as males get older. Adolescent females experience a similar pattern with an increase in a firearm-related injury risk of 3 per 100,000 at ages 10 to 13 per 100,000 at age 24.

Possession of Firearms Among Youth

Juveniles are more likely to posses a firearm than adults, with handguns being the most popular firearms. Nationally, approximately 6% of high school students reported bringing a gun to school in the past month. For males alone, this increases to more than 10% among both white and black males (*Morbidity and Mortality Weekly Report*, Youth Risk Surveillance Survey, 2004). Most firearms owned in the United States were manufactured here. A large proportion of guns are obtained through illegal purchase, making estimates of gun possession prevalence challenging.

Firearm Surveillance

To understand the prevalence of firearm-related morbidity and mortality, the three primary public health

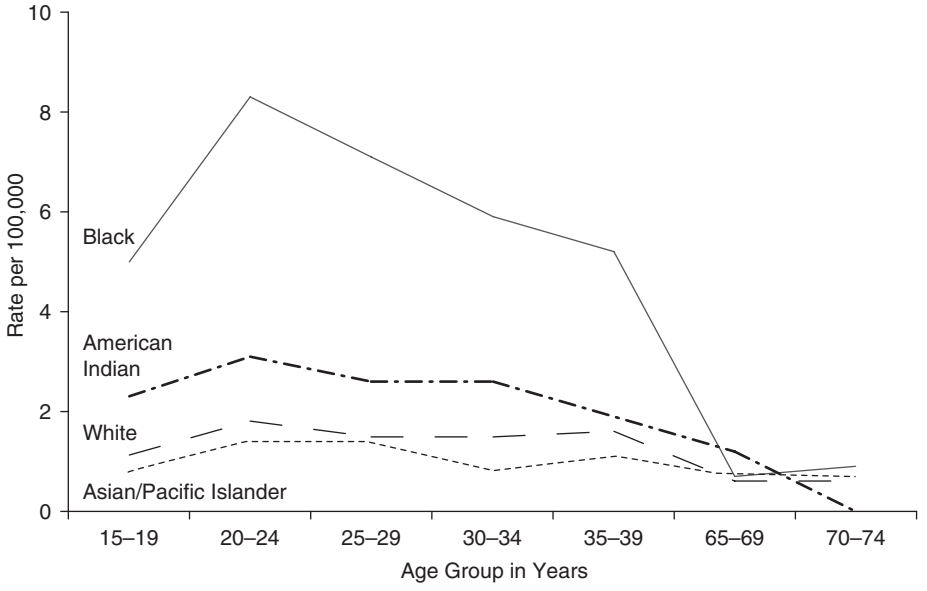

Figure 2 Average Firearm Homicide Rate (2001–2004) by Race and Selected Age Groups: Females

Source: Centers for Disease Control and Prevention, National Center for Injury Prevention and Control (2005).

sources used are emergency room (ER)-treated and –released data, hospital admissions discharge date, and death data from medical examiner reports. Each of these types of surveillances has its strengths and weaknesses. Hospital data, both ER and discharge, use the International Classification of Disease external cause of injury codes (E-codes). Intended originally and currently used for billing purposes, E-codes have been adapted over the years to provide increasing detail regarding firearm injuries including the location, the type of bullet wound, and the intentionality of the injury. The utility of E-codes in providing an improved national picture of the extent of intentional and unintentional injuries has been recently strengthened as more hospitals and regions have created systems to aggregate E-code information.

However, there are three important limitations of hospital data as a source of information about morbidity due to firearms. First, as stated above, E-codes are created for billing purposes and not by researchers or for research purposes. This potentially threatens the validity of these codes when used for firearm research. For example, if an individual receives an additional injury that requires more serious medical attention, the more expensive treatment may only be noted or if the cause of injury is excluded on the chart by a physician who is more intent on describing the injury and treatment than the cause. Second, not all geographical areas and not all hospitals participate in either the collection or inclusion of E-code data for larger statewide and national purposes. Third, in most cases, injury related to firearms results in death, so hospital discharge data are not a useful source for these types of injuries.

Firearm-related mortality surveillance is done through death record review. Death records often provide detailed information that may include the type of firearm used, circumstances of death, and victim and offender information. However, death records are created by either a medical examiner (typically in larger areas) or a coroner (typically in smaller areas). As a result, disparities in detail and accuracy exist in records from different regions. Furthermore, data from detailed death records are difficult to obtain. What is more commonly used are vital record data that have been abstracted from death records. While vital records are more easily obtainable, they may provide less detail about the firearm-related death compared with the full death record.

Another source of firearm-related morbidity and mortality is criminal justice data. The Federal Bureau of Investigation and the Bureau of Justice Statistics

provide national information about firearm-related crimes based on arrests and victimization reports. Similar to hospital data, the consistency and accuracy of firearm data from these sources may vary across police precinct and victim, ultimately impeding a full understanding of firearm-related crime. Recently, the public health and criminal justice systems have collaborated to improve surveillance of violent deaths nationally. The National Violent Death Reporting System provides a means of linking data between medical examiners, coroners, police precincts, and crime labs to provide a better picture of the extent and risk factors surrounding violent deaths.

Fisher's Exact Test

Fisher's exact test (FET) is a nonparametric version of the chi-square test. The most common use of FET is with small data sets, in particular when at least one cell in a cross-tabulation table has an expected frequency of less than 5. Small data sets and sparse cells may render the results reached by a chi-square test invalid, because it is based on asymptotic normality. Because the FET is a nonparametric test, this assumption does not apply to it. The FET calculates the exact probability (p value) of observing the table containing the data or *more extreme* distribution of the data. This probability is calculated by looking at all possible rearrangements of the table (in the direction of the alternative). The row and column totals are held constant when determining all possible *more extreme* rearrangements. Instructions on how to calculate the FET with 2×2 tables are given below. If one has another table of other dimensions, it is best to use a computer package such as SAS.

Finding the Exact Probability of a 2×2 Table

For a 2×2 table, the probability of the table occurring is

$$\frac{\binom{r_1}{b}\binom{r_2}{d}}{\binom{n}{s_2}} = \frac{r_1!r_2!s_1!s_2!}{n!a!b!c!d!}.$$

This probability can be calculated using either combinatorial functions (the left-hand side of the equation) or factorials (the right-hand side of the equation). In the first expression, the numerator counts the number of ways that the first row can occur (expressed by the combinatorial function describing how many ways the b-cell total can be chosen from the Row 1 total) times the number of ways that the second row can occur (expressed as the combinatorial function describing how many ways the d-cell total can be chosen from the Row 2 total) divided by the number of ways that the row and cell totals can be determined with n items (expressed by the combinatorial functions describing how many ways the first column total can be chosen from the sample size). In the second expression, the relevant factorials are simply multiplied together.

2×2 Example

Table 2 contains a 2×2 table of categorical data, representing the number of times two groups of people answered "yes" to a question. The null hypothesis

Table 1 General 2×2 Table

	Column 1	*Column 2*	*Total*
Row 1	a	b	r_1
Row 2	c	d	r_2
Total	s_1	s_2	n

Table 2 Original Data

	Group 1	*Group 2*	*Total*
Yes	13	3	16
No	20	28	48
Total	33	31	64

is that the proportion of *yes* is the same for the two column groups and the alternative hypothesis is that the proportion of *yes* is greater for Group 1 than for Group 2. This is a directional alternative hypothesis.

The exact probability of Table 2, given our assumptions, is

$$\frac{\binom{16}{3}\binom{48}{28}}{\binom{64}{31}} = 0.005274.$$

However, what we want to calculate is the probability of getting a result at least as extreme as this distribution, if the null hypothesis is true. Therefore, we add to this probability the probability of *more extreme* tables under the alternative hypothesis; *more extreme* tables would have the (1, 1) cell—that is, cell "*a*" in Table 2—equal to 14, 15, or 16. These *more extreme* tables are given in Table 3 with their respective probabilities. Note that these tables are found by keeping the row and column totals the same.

The exact p value is $.005274 + .000780 + .000066 + .000002 = .006122$, so at a significance level of 5%, we would reject H_0. So we conclude from these calculations that the proportion of people answering *yes* to our question is significantly different between Group 1 and Group 2.

Table 3 More Extreme Tables With Probabilities

Table With (1,1) Cell = 14		*Probability*
14	2	.000780
19	29	
Table With (1,1) Cell = 15		
15	1	.000066
18	30	
Table With (1,1) Cell = 16		
16	0	.000002
17	31	

Nondirectional Alternative Hypothesis

Although FET can be used for a nondirectional hypothesis test, statisticians do not entirely agree as to how to calculate probabilities in this case. The p value is still defined as the probability of *more extreme* tables, but the definition of "more extreme" may vary. One method is to reverse the a and b values, find the probability of the table, increase the (1, 1) cell to find another table, find the probability of this table, and continue this method until one finds a table with a probability greater than the probability of the original table. Finally, one sums these probabilities to the other probabilities. Table 4 shows *more extreme* tables in the opposite direction of the early example. The table with the (1, 1) cell = 4 has a probability greater than the original table; therefore, the p value for a nondirectional hypothesis is $.002303 + .006122 = .008425$.

Food and Drug Administration

The Food and Drug Administration (FDA) is a regulatory agency charged with enforcing laws pertaining to food, drugs, drink, cosmetics, and medical and therapeutic devices sold in the United States. Now within the Department of Health and Human Services, the FDA is responsible for ensuring the safety and efficacy of drugs in the health care system. Throughout its 100 years of existence, the agency has monitored, and responded to, crises that could have been avoided had the agency been given more funding or broader powers. Following almost every instance of catastrophe, usually with attendant deaths, more accountability has been given to the agency.

In its earliest years, the agency now known as the FDA was concerned with drug regulation. Various measures have been taken to keep the citizenry safe, including early laws requiring customs officials to keep adulterated drugs out of the country. The Bureau of Chemistry, founded in 1863, within the U.S. Department of Agriculture, focused more on the dangers inherent in food items than drugs, and even here, the concern about food items ran toward issues of adulteration more than foodborne illness.

The first time attention was paid to a specific drug problem was in 1902, with the passage of the Biologics Control Act. This act, which ensured the safety of serums, vaccines, and other products, was in direct response to tragedies in St. Louis, Missouri, and Camden, New Jersey. In both cities, children died of tetanus after receiving diphtheria antitoxin made from a horse infected with tetanus. The Biologics Control Act, which ultimately led to the Center for Biologics Evaluation and Research, gave the Bureau the authority to regulate biological products and ensure their safety.

The 1906 Pure Food and Drug Act addressed concerns raised by, variously, Upton Sinclair's novel *The Jungle* and Samuel Hopkins Adams's six-part series on drug adulteration in *Collier's* magazine. After almost 20 years of agitation, these two documents helped push Congress to create a new agency, the FDA, charged with enforcement of both the Pure Food and Drug Act and the Meat Inspection Act. Drug companies helped conceive of the regulations that bound them, 11 drugs were made illegal, and all product labels were required to be accurate and truthful.

Continued problems with the drug and food supply were highlighted twice in the 1930s. At the 1933 Century of Progress World's Fair in Chicago, the FDA's exhibit space focused on the shortcomings and inadequacies of the 1906 acts. In 1935, 107 people died after using Elixir of Sulfanilamide, a sulfa drug suspended in glycol ether, a deadly combination. Congress responded by passing the 1938 Food, Drug and Cosmetic Act that extended FDA powers to include cosmetics and therapeutic devices, as well as advertising of some of these products.

During World War II, new drug discoveries, as well as supply shortages, kept the agency busy. The 1941 Insulin Amendment required the FDA to test and certify the purity and potency of insulin. Since penicillin's availability had been limited during wartime to government rather than civilian use only, the batches were monitored. In 1945, the Penicillin Amendment did for penicillin what the Insulin Amendment had done for insulin: The FDA tested and certified penicillin, to guarantee its efficacy and safety. This process was discontinued in the 1970s, when the safety of the penicillin supply was unquestionable.

In the postwar years, the FDA responded to and enforced new drug and food issues, sometimes carefully and sometimes not at all. The Durham-Humphrey Amendment (1951) delineated which drugs could and could not be used without medical supervision; those that could not were available by prescription only. The designation of prescription versus over-the-counter was a joint effort of many parties. What was not being tracked was the development of the polio vaccine. After large successful test studies in 1954, more than a million children were vaccinated against polio. When more than 200 children became sick and 11 died, researchers discovered that the product from Cutter Laboratories contained live poliovirus. The trials were halted and resumed only after factory inspection and ways to test for vaccine safety were put in place.

The 1960s was a period of averting near disaster time and time again. Thalidomide, used in Europe and being tested for consideration in the United States, was kept off the domestic market through the vigilance of a medical safety officer. Following this scare, the American public, as it had in the past, pushed Congress for more regulations and greater safety. The Kefauver-Harris Drug Amendments of 1962 required drug manufacturers to demonstrate the safety and efficacy of their drugs before marketing them. Never before had there been this level of safety. A backlash against the unprotected nature of the drug market, outrage from the American public helped the

FDA expand their role and presence in the drug regulatory process. In 1966, the FDA expanded its commitment to drug effectiveness: the National Academy of Sciences and the National Research Council began to evaluate more than 4,000 drugs approved by the FDA between 1938 (the Food, Drug and Cosmetic Act) and 1962 (the Kefauver-Harris Amendments). Two years later, with the results of the study on drug effectiveness in hand, the FDA formed an organization to implement the recommendations.

Much attention was paid to drugs and drug regulations in the 1970s, from the first patient package inserts (in oral contraceptives) to the Comprehensive Drug Abuse Prevention and Control Act that recategorized drugs by addictive properties rather than therapeutic value. The Environmental Protection Agency took over some of the FDA's regulatory duties even as the FDA gained new ones with the establishment of the National Center for Toxicological Research, examining the impact and effect of chemicals on the environment. In 1972, the National Institutes of Health transferred the regulation of biologics (serums, vaccines, blood products) to the FDA. The 1976 Medical Device Amendment sharpened language, requiring all companies with medical devices and diagnostic tests to demonstrate effectiveness and safety of their products; in addition, quality control and registration with the FDA were required. Saccharine proved to be a source of continual debate in the 1970s: Initially removed from the Generally Recognized as Safe list in 1972, it was given continued life by a congressional fiat in 1977 under the proviso that products bear a warning noting that it had been found to cause cancer in laboratory animals.

In reaction to the Tylenol scare in 1982, in which several packages were tampered with and death from cyanide resulted, Congress passed tamper-resistant packing regulations. Unaware of what was to become the major focus of drug research in the mid- to late 1980s, and confident in the power of biomedicine to find cures for diseases, Congress passed the Orphan Drug Act in 1982. This allowed the FDA to encourage and support drug research for rare diseases. Three years later, the FDA approved the first AIDS blood test, primarily to prevent patients from receiving blood from infected donors. Also, in response to the AIDS crisis, the FDA changed drug trial protocols for those with serious diseases for which there were no medical alternatives. In 1991, Congress continued to support medical research for certain categories of disease by implementing an accelerated drug review process.

The end of the 20th century witnessed the consolidation and reappraisal of some FDA policies and procedures. The Board of Tea Tasters, impaneled in 1897, was disbanded in 1996. In a cost-saving measure, the agency outlined a 15-year plan in 1998 to streamline the number of laboratories. In response to 9/11, the Public Health Security and Bioterrorism Preparedness and Reponse Act of 2002 called for a coordinated and improved plan in response to public health emergencies. Continuing this public health thrust, the Project BioShield Act of 2004 gave the FDA the power to distribute treatments quickly in response to chemical, biological, or nuclear agents used in a terrorist attack.

Foodborne Diseases

Foodborne diseases are caused by agents that enter the body through the consumption of food or beverages. Many cases of foodborne illness are not reported, so it is impossible to get an exact count of the incidence of foodborne illness; however, the Centers for Disease Control and Prevention (CDC) estimates that about 76 million cases of foodborne disease occur in the United States each year, resulting in 325,000 hospitalizations and 5,000 deaths. The incidence of foodborne disease is believed to be much higher in developing countries, where the World Health Organization estimates that in 2000 alone, 2.1 million people died from diarrheal diseases. Outbreaks of foodborne illness occur in both developing and industrialized countries and can affect large numbers of people. For instance, an outbreak of hepatitis

A in China, caused by the consumption of contaminated clams, affected more than 300,000 individuals, and an outbreak of salmonellosis in the United States in 1994, caused by consumption of contaminated ice cream, affected 224,000 people.

Most cases of foodborne disease are caused by microorganisms, including bacteria, viruses, and parasites. Other agents that can cause foodborne disease include mycotoxins, marine biotoxins, and the toxins occurring in poisonous mushrooms; metals such as lead, mercury, and cadium, which may contaminate food through air, water, or soil pollution; organic pollutants such as dioxin and polychlorinated biphenyls, which are by-products of some industrial processes; and other agents such as the agent causing BSE (bovine spongiform encephalopathy, also known as ''mad cow disease''), which appears to be transmissible through the consumption of tainted beef.

Common Foodborne Diseases Caused by Microorganisms

Salmonellosis is caused by the *Salmonella* bacteria, which is commonly found in the intestines of mammals, reptiles, and birds and is usually spread to humans through consumption of foods of animal origin, including eggs, meat, and milk. Symptoms of salmonellosis include fever, headache, nausea, vomiting, abdominal pain, and diarrhea; in persons with weakened immune systems or poor health, it can be life threatening. The CDC estimates that 1.4 million cases of salmonellosis occur in the United States annually, with approximately 500 fatal cases.

Campylobacteriosis is caused by *Campylobacter* bacteria. In some countries, campylobacteriosis is more common than salmonellosis, and worldwide it is the most commonly identified bacterial cause of diarrheal illness. Campylobacteriosis is transmitted mainly through drinking water, undercooked poultry, and raw milk; because *Campylobacter* bacteria live in the intestines of healthy birds, most raw poultry can be assumed to be contaminated with it. The symptoms of campylobacteriosis include fever, nausea, severe abdominal pain, and diarrhea; major health consequences may develop in 2% to 10% of cases, including neurological disorders and reactive arthritis. The CDC estimates that there are more than 1 million cases of campylobacteriosis annually in the United States, with approximately 100 fatal cases.

Escherichia coli is a type of bacteria living in the intestines of many animals, including humans and cattle. Most strains of *E. coli* are not harmful to humans; an exception is *E. coli* 0157:H7, which lives in the intestines of cattle and can have serious health effects when ingested by humans. This type of *E. coli* is usually ingested in undercooked ground beef, although it may also be transmitted through unpasteurized milk and fruit juice, contaminated water, uncooked produce, and person-to-person contact. Symptoms of *E. coli* 0157:H7 poisoning include severe abdominal cramps and bloody diarrhea; in 3% to 5% of the cases, hemolytic uremic syndrome may develop, which can result in kidney failure and death. The CDC estimates that about 73,000 people in the United States became ill from *E. coli* in 1999 and about 60 died.

Listeriosis, caused by the bacteria *Listeria monocytogenes*, is most often transmitted through milk, soft cheeses and ice cream, raw vegetables, and raw meat and poultry. Because the *L. monocytogenes* bacteria can grow at low temperatures, foods that are refrigerated for long periods of time are particularly likely routes of transmission. Symptoms of listeriosis include nausea, vomiting, diarrhea, and flu-like symptoms. Listeriosis is particularly dangerous for pregnant women, because it can cause abortion and stillbirth, and in infants and persons with a weakened immune system, because it can lead to meningitis and septicemia (blood poisoning). The CDC estimates that about 2,500 people in the United States become ill with listeriosis annually and about 500 die.

Prevention and Control

Major foodborne diseases, including salmonellosis and *E. coli* 0157:H7, are reportable diseases in most states, meaning that infections caused by those agents must be reported to the health department. However, because most cases of foodborne disease are mild and never diagnosed, the reported number of cases is assumed an undercount of the true number of cases. For instance, the CDC estimates that 38 cases of salmonellosis occur in the United States for every case that is reported. Investigation of outbreaks of foodborne disease is a common function of local health departments: Classic examples include food poisoning caused by consumption of a contaminated batch of food from a particular restaurant or supplier.

Many laws regulating the production, transport, and preparation of food are intended to prevent foodborne

disease and limit its consequences; they include laws intended to prevent the contamination of raw food, to mandate its safe preparation and storage, and, if necessary, to close restaurants or food suppliers responsible for disease outbreaks or who fail to follow safe food hygiene practices. There are many means by which raw food may be contaminated, including irrigating or washing produce with unclean water, contamination of meat and poultry with fecal matter during the slaughtering and packaging processes, preparation by food handlers who carry bacteria or viruses on their hands, or using utensils and preparation surfaces that are not clean.

Cooking at a sufficient temperature kills many microbes and parasites; for instance, the U.S. Department of Agriculture recommends cooking eggs until the yolk is firm, cooking pork and ground beef until an internal temperature of 160° F is reached, and cooking whole turkeys and chickens to an internal temperature of 180°F. Microbes may also be present in cooked food (e.g., those introduced during handling after cooking), but this may not pose a health risk if only a small number are present. Most bacteria grow rapidly at room temperature, while refrigeration or freezing keeps them from multiplying (*L. monocytogenes* is a notable exception), hence the recommendations that cooked food be promptly refrigerated to prevent the multiplication of disease-causing organisms.

Formulary, Drug

A drug formulary is a list of pharmaceutical products; formularies are often created for the purposes of drug purchasing, dispensing, or reimbursement. Many different entities involved in the delivery of, and payment for, health care services use formularies, including health plans, institutions, and government bodies. A common reason for creating a formulary is to specify which drugs may be purchased, or which drugs' purchase will be subsidized, by the entity. The use of drug formularies is largely a reaction to increasing prescription drug costs and the multiplicity of drugs produced by different manufacturers that are available to treat common conditions. For instance, the Veterans Administration (VA) of the United States has used a National Formulary since 1997 that indicates which drugs the VA will routinely pay for. The VA will also grant exceptions to the formulary for particular patients, but the individual or his or her doctor must complete an application process and state why the nonformulary drug is necessary for the individual's care (e.g., if the patient has had an adverse reaction to the formulary drug, or if no formulary alternative exists).

In a multitier formulary, the insurer classifies drugs into tiers and grants favorable treatment to drugs in lower tiers, typically requiring consumers to make higher copayments for drugs in higher tiers. In a typical two-tier plan, generic drugs comprise the first tier and brand-name drugs the second tier. In a three-tier plan, generic drugs constitute the first tier, and brand-name drugs are split into preferred drugs (second tier) and nonpreferred drugs (third tier). A study by Strunk and Ginsberg found that in 2002, 57% of employees with prescription drug coverage had health insurance plans that included three-tier formularies. Some companies have four-tier plans, which are similar to three-tier plans with the addition of a fourth tier of drugs whose purchase is not subsidized by the company, but which are available for purchase by plan members at a negotiated price. Use of a drug formulary allows insurance companies to save money in three ways: It is a bargaining tool that allows the insurer to negotiate for lower prices from pharmaceutical companies; it encourages health plan members to reduce drug utilization and use lower-cost generic or preferred drugs; and it produces income from copayments.

Formularies are a contentious issue in the United States because most Americans get their health

insurance coverage through private insurers, many of whom have instituted multitier drug formularies to manage costs. However, the U.S. federal government does not negotiate or regulate drug prices so that a wide range of drugs at a wide range of prices are available for purchase in the United States. Some people feel that the use of drug formularies may endanger patient health by restricting the choice of therapeutics drugs, since the unsubsidized portion of a higher-tier drug may be prohibitive to the patient.

Economic and Health Effects of Drug Formularies

The primary purpose of drug formularies is to control prescription drug costs without harming the health of the insured or increasing costs in another aspect of care (e.g., by causing an increase in visits to the emergency department because a medical condition was not adequately controlled by drugs). Studies by Motheral and Fairman found that moving to a plan with three tiers from one with two tiers reduced prescription utilization and net costs for prescription drugs, without increasing utilization of office visits, hospitalization, or emergency room visits. Other studies have found that an increased number of tiers in drug formularies leads to decreased utilization and decreased company costs, but also increased costs to the insured. They have also found formularies to be effective in shaping consumer behavior, for instance, increasing the use of lower-cost alternatives such as prescriptions-by-mail plans.

It is difficult to fully evaluate the health effects of drug formularies, in part because each formulary is different, and also because health effects would probably be small and difficult to detect. In addition, due to the fragmentary nature of health and insurance databases for most Americans covered under private insurance, gaining access to both medical care and prescription records for individuals, and matching them up, is difficult in the best of cases and frequently impossible. Because of these difficulties, researchers have focused on narrower questions such as the effect of increased tiers or copayments on utilization and continuation of maintenance medications for chronic conditions such as hypertension. Results have been equivocal: Some studies have found no effects, while others have found weak effects for behaviors such as decreasing or discontinuing usage of maintenance medications, either of which could pose a health risk to the individual. However, no studies to date have established that the use of formularies per se harms the health of individuals.

Framingham Heart Study

The Framingham Heart Study is one of the most important epidemiological studies in the annals of American medicine. Its impact on the study of cardiovascular diseases is particularly important: Much of what is now common knowledge about heart disease, such as the effects of smoking, diet, exercise, and aspirin, can be traced back to the Framingham study. Most important, the study has played a key role in influencing physicians to place greater emphasis on preventing, detecting, and treating cardiovascular disease risk factors in their earliest stages.

In 1948, Framingham, a small town in eastern Massachusetts, was selected as the site of a long-term medical study of heart disease and stroke. The project was initiated under the direction of the National Heart Institute, now the National Heart, Lung, and Blood

Institute (NHLBI). Through a contract with the NHLBI, researchers from the Boston University School of Medicine have played an important role in the Framingham Heart Study since 1971.

More than 50 years later, that follow-up study has yielded an incredible amount of information about heart diseases and the risk factors that can lead to them. The original cohort of the Framingham Heart Study included two thirds of the adult population of Framingham, with ages ranging from 30 to 62 years in 1948. The study was designed to track health information on men and women without signs of heart disease. Every 2 years, people enrolled in the study submitted to dozens of medical tests and answered detailed questions about their personal habits. Over the years, researchers recorded who got heart disease and who did not and studied the connections between disease and the data that had been collected. The two groups thus formed were statistically analyzed and compared.

Originally, researchers enrolled 5,209 Framingham residents (known as the Original Cohort), some of whom are still participating more than 50 years later. In 1970, the study added 5,124 new recruits, referred to as the Offspring Cohort, who were children of the original study group and their spouses. A Third Generation Cohort consisting of individuals who had at least one parent in the Offspring Cohort was recruited beginning in 2001, and 4,095 participants had enrolled in this cohort by June 2005. More recently, 500 members of Framingham's minority community have been recruited to participate in the Omni Study that was initiated and has continued to recruit people with the purpose of determining whether the risk factors associated with disease continue to be the same that were identified in the two previous cohorts.

The findings of the Framingham Heart Study have produced a revolution in preventive medicine and changed the way the medical community and the general public view the origins of disease. More than 1,000 papers based on the Framingham data have appeared in important scientific reviews and have inspired many clinical trials that have been crucial to understand how to manage heart disease and how to control major risk factors. In addition to its great contributions in the area of heart research, the Framingham Study has provided very useful evidence to investigate cancer, stroke, osteoporosis, arthritis, dementia, diabetes, eye disease, and the genetic patterns of many other common diseases.

Information gained from analyses of the Framingham cohort changed the views of the scientific community about heart disease. For instance, before Framingham, most physicians believed that since atherosclerosis is inherent to the aging process, blood pressure should increase with age to enable the heart to pump blood through an elderly person's narrowed arteries.

Risk Factors

For the first time, Framingham established beyond all reasonable doubt a relationship between levels of cholesterol and risk for disease. Furthermore, it established a strong positive association between low-density lipoprotein cholesterol with coronary heart disease and a powerful inverse and protective effect of high-density lipoprotein levels. Presently, researchers are working to identify the genes that regulate cholesterol metabolism to discover the mechanisms by which genes contribute to common metabolic disorders such as obesity, hypertension, diabetes, and even Alzheimer's disease. The Framingham study has collected a DNA library of blood samples from more than 5,000 individuals of two different generations, which will help researchers investigate what diseases run in families and identify the genes responsible for several serious disorders.

Research on blood pressure based on the Framingham cohort has dispelled several misconceptions. Before Framingham it was believed that women and the elderly tolerated higher pressures well. However, analyzing the Framingham data, researchers found nothing to support the contention that the elderly fare better than younger persons at a given degree of hypertension nor that women with high blood pressure are at lower risk than their male counterparts.

Framingham researchers found that an unhealthy diet, sedentary living, and weight gain can aggravate disease risk factors and influence the occurrence of cardiovascular problems. They also proved that smokers are at higher risk of having a myocardial infarction or experiencing a sudden death. Moreover, they found that the risk is related to the number of cigarettes smoked each day and that smoking cessation can halve the risk of ex-smokers compared with those who continue to smoke.

Other studies derived from Framingham demonstrated a protective effect on the heart from even low levels of exercise. Weight gain, accompanied by lack

of exercise, was also found to aggravate the effect of cardiovascular risk factors as were hypertension and diabetes.

Frost, Wade Hampton (1880–1938)

Wade Hampton Frost was a pioneering epidemiologist. Following a distinguished career in the United States Public Health Service, he became the first professor of epidemiology at the Johns Hopkins School of Hygiene and Public Health. He made seminal observations on the epidemiology of infectious diseases and major contributions to epidemiological methods.

Frost was born in Marshall, Virginia, on March 3, 1880. He attended the University of Virginia, graduating in 1903 with both bachelor's and medical degrees. After internships in New York, he enlisted in the U.S. Public Health Service in 1905. In 1908, he was assigned to the National Hygienic Laboratory in Washington, the forerunner of the National Institutes of Health.

Frost studied water pollution at the National Hygienic Laboratory. His paper describing a typhoid outbreak in Williamson, West Virginia, in 1910 is an exemplary report of a field investigation. Between 1909 and 1912, he coupled assays of neutralizing serum antibodies with careful field investigations of polio outbreaks in Iowa, Ohio, Kentucky, and New York. From these studies, he formulated the concept that asymptomatic poliovirus infections in children were common and produced immunity. In 1913, Frost was placed in charge of a newly opened station in Cincinnati, Ohio, to study pollution of the Ohio River and other inland waterways. When the 1918 to 1919 influenza pandemic erupted, he directed the Public Health Service's Office of Field Investigations of Influenza, there working with statistician Edward Sydenstricker, who would become a lifelong friend and collaborator. Frost devised the system of tracking influenza epidemics by using reported pneumonia and influenza deaths as a surrogate in the absence of reporting requirements for influenza itself.

In 1919, William Henry Welch recruited Frost to the newly founded Johns Hopkins School of Hygiene and Public Health to become a resident lecturer, the first faculty member in the new department of epidemiology. He was promoted to professor in 1921 and was elected dean in 1931. Frost developed a curriculum based on lectures, case studies of actual epidemics, and student theses that has served as a model for curricula in epidemiology to the present. He was idolized by students for his work with them in case-study laboratories. His initial investigations at Johns Hopkins focused on acute infectious diseases; later, he worked on tuberculosis, studying the natural history of that disease in Williamson County, Tennessee. Out of this work came the first enunciation of the index case concept and the use of life tables to express data as person-years and to estimate secondary attack rates. His best-known work may be his analysis of shifting tuberculosis age profiles using historical data from Massachusetts. With Lowell Reed, he developed the first mathematical expression of the epidemic curve.

Frost died of esophageal cancer on May 1, 1938. Shortly before his death, the American Public Health Association awarded him its prestigious Sedgwick Memorial Medal.

F Test

The F test is used for hypotheses concerning variances. It is used to test whether two variances are equal and is also used in the analysis of variance (ANOVA).

Let U and V be two independent chi-square random variables having m and n degrees of freedom (df), respectively. The ratio $F = (U/m)/(V/n)$ has an F distribution with numerator df equal to m and denominator df equal to n. Two properties of the F distribution are as follows:

- If $X \sim F_{m,n}$, then $1/X \sim F_{n,m}$, that is, the reciprocal of an F random variable is again an F random variable.
- If $X \sim t_m$ (X has a t distribution with $df = m$), then $X^2 \sim F_{1,m}$.

Test for Equality of Variances or Homogeneity of Variances

The F test is used to test whether two population variances are equal ($H_0 : \sigma_1^2 = \sigma_2^2$) versus either a one-tail alternative, upper or lower, $H_a : \sigma_1^2 > \sigma_2^2$ or $H_a : \sigma_1^2 < \sigma_2^2$, respectively, or a two-tail alternative, $H_a : \sigma_1^2 \neq \sigma_2^2$. The test statistic is the ratio of $F = s_1^2/s_2^2$, where s_1^2 is the sample variance from Sample 1 with $df = n_1 - 1$ and s_2^2 is the sample variance from Sample 2 with $df = n_2 - 1$. If H_0 is true, then the ratio would be close to 1. The farther away the ratio is from 1, the stronger the evidence for H_a. (Note that $0 < f < \infty$ since $s^2 > 0$.) One rejects the null hypothesis in the following cases, where $F_{\alpha,m,n}$ is the critical value of the F distribution with numerator $df = m$, denominator $df = n$, and a significance value α:

- $F > F_{\alpha, n_1 - 1, n_2 - 1}$ for an upper one-tailed test.
- $F < f_{1 - \alpha, n_1 - 1, n_2 - 1}$ for a lower one-tailed test.
- $F < f_{1 - \alpha/2, n_1 - 1, n_2 - 1}$ or $F > F_{\alpha/2, n_1 - 1, n_2 - 1}$ for a two-tailed test, although some texts may recommend that the F test statistic be found where the largest sample variance is in the numerator and reject H_0 if $F > F_{\alpha/2, n_1 - 1, n_2 - 1}$.

ANOVA and the *F* Test

In many experimental design situations, the data are analyzed using an ANOVA table. The plethora of problems makes it too difficult to explain each of them here. Instead, the general idea is presented using the one-way ANOVA table. In this situation, one wishes to test if the means are equal versus at least one population mean is different. A sample ANOVA table is given in Table 1. The details of where the values were derived from are not given since the interest is in the F test itself. In general, df gives the degrees of freedom and SS gives the sum of squares. The MS stands for mean squares and is calculated by SS/df. Then, the F ratio is calculated using the ratio of the MS. For example, $F = 48.8/13.6 = 3.58$. The null hypothesis is rejected when $F > F_{\alpha, df_{\text{num}}, df_{\text{denom}}}$. In this case, $F_{\alpha = 0.05, 3, 12} = 4.49$, so in this situation, one would reject H_0.

When given an ANOVA, keep in mind the following:

- Know what the null hypothesis is that the F test is testing. This will change for different situations and the ANOVA tables.

Table 1 Sample ANOVA Table

Source	*df*	*SS*	*MS*	*F*
Variable 1	3	146.4	48.8	3.58
Error	12	163.5	13.6	
Total	15	309.9		

- The F ratio is the ratio of the mean squares (*MS*).
- The numerator *df* for the critical value of the test is the degrees of freedom associated with the mean square value that is in the numerator of the F ratio; likewise, the denominator *df* is the *df* associated with the mean square value in the denominator.

Functional Status

Functional status is a common health measure used in both clinical care and research. The general domains of functional status are physical, mental, and sometimes social. Numerous self-report and clinician-rated instruments for measuring functional status exist in the public health literature. Poor functional status has been shown to be associated with chronic medical conditions, comorbidities, age, and mortality. *Functional status* is a broad term that has come to encompass a number of concepts that can vary with the many different instruments developed for its measurement. Although sometimes used interchangeably, functional status can differ conceptually from health status or quality of life.

Functional status originated as a measure of disability status, but it has come to be commonly used as a health research measure. Some make a distinction between functional status (how one does something) and functional ability (the capacity to do something). Functional status is often based on assessment of individuals' performance of activities without assistance from other people or assistive technology. In addition, functional status measures can be specific to different conditions or generic. Condition-specific measures are intended to assess functional limitations caused by the specific disease/disorder of interest. Generic measures are designed to assess functional status outside of a specific medical context.

Among the most commonly used measures of physical functioning are those that assess activities of daily living (ADL) and instrumental activities of daily living (IADL). ADL are activities related to personal care and include bathing or showering, dressing, getting in or out of bed or a chair, using the toilet, and eating. IADL are activities related to independent living and include preparing meals, managing money, shopping for groceries, performing housework, and using a telephone.

Mental functional status is often based on cognitive function, psychological symptom severity, or social role function such as ability to engage in social activities or in work. Cognitive activities assessed include orientation to date and place, recall, language skills, attention span, ability to calculate, and to identify objects. Commonly assessed psychological symptomatology include feelings of depression, anxiety, phobias, stress, confusion, problems concentrating, problems making or keeping friends, and interacting with others.

Toward the end of the 20th century, and influenced by the social model of disability, assessment of functional status developed to include contextual considerations as in the World Health Organization's (WHO) *International Classification of Functioning, Disability, and Health* (ICIDH-2, hereafter ICF). The purpose of the ICF classification is to allow a unified and standard language for assessing health and health-related components of well-being. It allows a person's functioning and disability to be viewed as a dynamic interaction between health conditions and contextual factors. By integrating multiple dimensions of disability (i.e., structural and functional impairments, activity limitations, participation restrictions, and environmental factors), the ICF is intended to characterize functional status in terms of the interaction between intrinsic individual characteristics and extrinsic social phenomena. The ICF approach is considered by some to be more empowering to individuals because it does not classify people but rather the situations in which they live and experience health and health-related concerns.

Gene

In the early 20th century following the rediscovery of the important work of Gregor Mendel that provided the foundation for the future field of genetics, scientists developed the classical concept of the gene as the entity responsible for many human traits and diseases. It was soon learned that genes are located on the chromosomes and each person has two copies of a particular gene, one on each of the paired chromosomes that are inherited from one's parents, one of maternal origin and the other from the father. The alternate forms of a gene that result from the process of mutation are called alleles.

The 21st century likewise began with significant discoveries in the world of genetics. The Human Genome Project (HGP) begun in the mid-1980s by an international team of researchers led by the U.S. Department of Energy and National Institutes of Health (NIH) announced in 2003 that a map of the human genome was completed. The announcement of the human genome map coincided with the 50th anniversary of the discovery of the DNA helical structure by Watson and Crick in 1953. This latter discovery gave us the basis for the structure of the gene and how it replicates and marked the beginning of the molecular revolution in genetics and in biology and medicine.

Growing knowledge from the HGP and other genomic research will make it possible to diagnose and treat disease and to identify individuals at risk for a certain disease in ways that, until recently, were inconceivable. The HGP discoveries add to our understanding of how disease mechanisms occur so that treatment can focus on the primary dysfunction or disease progressions rather than treating only the secondary manifestations or outcomes. Genetics also plays a role in the prevention of disease and in health promotion. Most diseases and our health are now thought to be the result of the interplay between multiple genes (called polygenes) and the multitude of environmental exposures to which an individual is subjected during development and over the course of life. Some geneticists now think that even single gene (monogenic) diseases and traits are really multifactorial (the result of polygenes and environmental influences) and are complex due to interactions between genes and between genes and environmental factors.

To understand the new knowledge from the map of the human genome and how this knowledge affects society, it is important to have a clear understanding of what a gene is, as we understand it today. A gene is defined as the fundamental physical and functional unit of heredity. A gene is made up of deoxyribonucleic acid, called DNA. If this DNA were stretched out, it would look like a very long circular staircase with millions of rungs. Small sections of rungs are analogous to genes. Each of these sections of DNA is called a gene—a piece of genetic information that does one particular job. That job is the encoding of a chain of

amino acids to form a polypeptide, the major components of the essential proteins of the body. Each gene is a different packet of information necessary for our bodies to grow and function. Our genes also contain the information governing physical traits such as the color of our eyes, how tall we are, and the shape of our ears and nose, and some of the traits that affect our vulnerability to diseases. In humans, genes vary in size from a few hundred DNA bases to more than 2 million bases. The HGP has estimated that humans have between 20,000 and 25,000 genes.

Genetics plays an increasingly important role in the practice of health care. The global concepts of the gene and genetics are not confined to our physical features and the development of rare diseases but rather have become key components of our understanding of most of the major common diseases, including heart disease, diabetes, cancer, and many psychiatric disorders. The classical concept of the gene has given way to the modern molecular concept, and genetics has broadened its horizons as an explanatory factor across all fields of inquiry that attempt to understand biological variation and its basis.

Gene-Environment Interaction

In the field of epidemiology, there has been increasing interest in documenting the results of interaction between specific genes or genotypes and well-understood environmental exposures. Gene-environment interactions are situations in which the combination of an environmental factor, such as exposure to cigarette smoking, with a genetic factor, such as a disease-predisposing mutation, results in a greater risk or severity of the disease in question than either the genetic or environmental factor acting alone. These interactions have been studied in plants and animals for many years. While they have been hypothesized also to occur in humans, they have been documented in humans only fairly recently. In recent years, many examples of gene-environment interaction have been reported in the literature.

There is now increasing acceptance of the idea that it is likely that all human disease is the result of the interaction between the genetic susceptibility to disease and environmental exposures during the course of life. It is important to study gene-environment interactions for several reasons. One is the expectation that it will improve our understanding of the etiology of specific diseases. Second, we might be able to identify populations that are at high risk due to their possessing higher frequencies of genotypes that denote susceptibility to the disease in question. We might also be able to identify modifiable risk factors in the form of environmental exposures. Finally, there is the underlying goal of being able to prevent disease through improved understanding of the risk factors that are involved and the knowledge of the underlying disease mechanisms.

Before we discuss what an interaction is—particularly an interaction between a gene and some environmental exposure—we need some background thinking about what an effect of a genetic factor is and how we should conceptualize the environment. Genetic variation in human populations fits the label given to it by some as the "ultimate public health problem." With the ever mounting discoveries of disease-related genetic variation and the identification of specific genes related to disease, the statement that everyone is at genetic risk for some disease has become an acceptable assessment. In genetic epidemiology, the search for disease-associated genes has been continuing for many years, first through family studies and later through specific analyses involving estimation of heritability and segregation and linkage analysis. More recently, the focus has been on large-scale association studies in populations.

In research on the genetics of human diseases, one might ask what are the measurements for the genotype or, for that matter, for the genes that might

increase one's risk of a disease. Family history, that is, the presence or absence of a family history for a disease in question, is one measure of genotype. However, it is crude at best and susceptible to the misclassification of significant proportions of individuals in an analysis. If a phenotype has been adequately described and the specific features of the disease are well known and easily observed and measured, then the specific phenotype for the presence of the disease may be indicative of an underlying gene or complex of genes for that disease. But phenotypic descriptions of diseases are subject to analytical problems, especially where those diseases are heterogeneous in their expression or represent a spectrum of disorders, such as autism. In such cases, the so-called behavioral phenotype becomes extremely important in studies of the genetic factors in the disease entity in question.

We get the best measures of the influence of genes or genotypes when we can analyze the DNA directly. Even measures based on the product of genes or the biochemical profiles produced by genes are better than data at the level of the phenotype or information about the presence of a family history. The discovery of a specific gene as the cause of a disease unleashes many other research tracks. Some involve the search for the gene product and its function. Allelic variants of the disease can be discovered and described, and their associations with particular health outcomes can be investigated. Finally, there is the basic research required to investigate possible interactions between the disease gene and other genetic loci during early development and in processes that occur in the development of complex adult diseases such as cancer and diabetes.

The measurement of the environment is equally worthy of discussion. In the assessment of environment exposures, we are dealing with a vast array of aspects of the environment that can potentially be involved in disease. They include exposures to chemicals in the air, water, and soil; various nutrients in our diets; a host of infectious agents; drugs used in the treatment of disease; and, during development, the maternal environment and the multitude of chemicals to which the developing fetus is exposed, such as alcohol and drugs taken during pregnancy. Just as there are problems in measuring the genetic influences, the measurement of environmental exposures is fraught with difficulties. We would like to know the exact concentration of a substance that has interacted with specific structures or biochemical systems in the body in a way that induces disease, but we are never able to measure this. Instead, we use surrogate measures. The common approach is to collect an exposure history. This may include a detailed residential history so that exposures to known sources of pollutants can be estimated. In adults, the collection of an occupational history can be an important means of assessing potential exposures to chemicals and other environmental factors on the job. We have witnessed during the past 20 years the accelerated development of biomarkers at the chromosomal and molecular levels to assist further with the assessment of environmental exposures. Indeed, the new field of molecular epidemiology emerged initially from environmental epidemiology and attempts to improve exposure assessment through the identification of biomarkers that could potentially specify that an exposure to a particular chemical had occurred. These biomarkers are a much more accurate way of estimating the concentration of substances that has interacted with specific structures or biochemical systems in the body in a way that induces disease.

Before we discuss the meaning of gene-environment interaction in more detail, it should be explained that an interaction is really a statistical phenomenon. An interaction in statistical terms is perhaps mostly easily grasped in graphic form. In fact, it is one of those instances in data analysis when the graph tells all and the results hit the observer "right between the eyes."

In the third edition of their textbook *Biometry*, Robert Sokal and F. James Rohlf (1995) created an artificial example based on actual experimental data to illustrate the meaning of the term *interaction* in a two-way analysis of variance. The original data are the amount of food consumed by rats (in grams) during a 73-day experiment. The data are classified by two factors, the type of fat in the diet (fresh vs. rancid lard) and sex (male vs. female), with three rats in each diet and sex combination. In the artificial example, a significant interaction is shown between the two factors. Plotting the means for each combination as shown in Figure 1 shows the crossing lines that are observed in some instances when a significant interaction has occurred between the two factors (diverging lines may also be observed when there is significant interaction).

Now consider some data that demonstrate a gene-environment interaction. In the following example, taken from the volume by Bodmer and Cavalli-Sforza

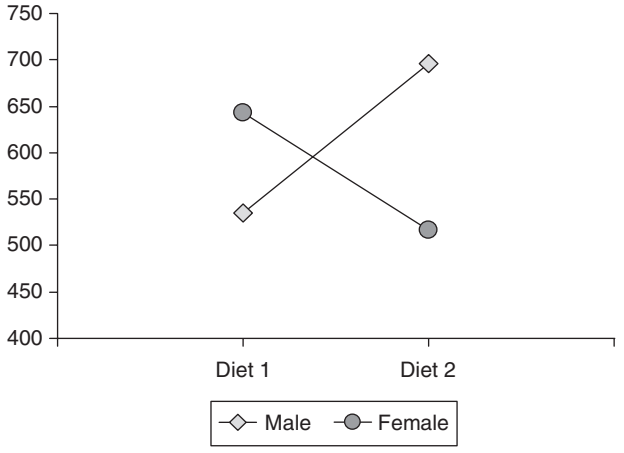

Figure 1 Interaction Between Diet and Sex for Food Consumption in Rats

(1976), we have two genotypes, G1 and G2, and two environments, E1 and E2. Table 1 shows four individuals, two of each genotype, distributed in the two environments.

If we graph these data in Figure 2, they look as follows:

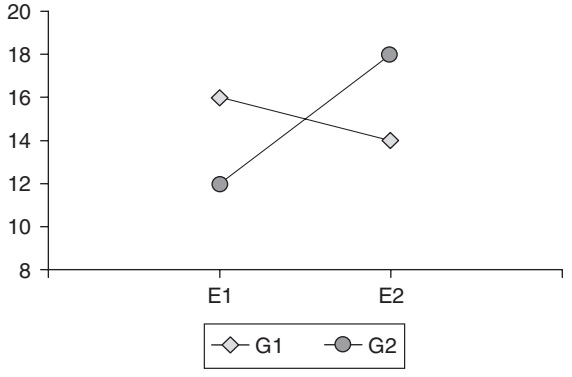

Figure 2 Illustration of Genotype-Environment Interaction

Source: Adapted from Bodmer and Cavalli-Sforza (1976).

Again, this is an example of the graph tells all. Genotype G1 has a higher phenotypic value than G2 when they are each exposed to environment E1. However, this pattern is reversed when the genotypes are exposed to E2, with G2 now having a higher phenotypic score than G1. The plotted lines are similar to what we observed in the diet experiment with rats in that they form the crossing pattern typical of an interaction effect.

Table 1 Phenotype Scores for Four Individuals by Genotype and Environment

Individual	*Genotype*	*Environment*	*Phenotype Score*
1	G1	E1	16
2	G1	E2	14
3	G2	E1	12
4	G2	E2	18

Source: Adapted from Bodmer and Cavalli-Sforza (1976).

Research on gene-environment interaction in human diseases is on the increase. An example of Medline searches conducted in two ways will demonstrate this pattern. One search was conducted for articles by the specific topic gene-environment interaction. The results of the first search specifically for the topic of gene-environment interaction were grouped by decades from 1950 to 1959 through 2000 to the present. A second search looked for articles that combined genetics and environment topics in the same article. The genetics topics included genetic predisposition to disease, genes, or genotype, while environmental topics were environment, environmental exposure, and social environment. The search results are displayed in Figure 3. From the 1980s through the present, there has been a dramatic increase in the number of publications that address gene-environment interaction per se or the combination of both genetic and environmental factors.

One category of diseases that has received much attention in the search for gene-environment interactions is birth defects. Orofacial clefts such as cleft lip and cleft palate result when there is failure to obtain complete closure of the upper lip and/or the palatal ridge inside the mouth during embryonic development. These abnormalities are known to involve both genetic and environmental factors. Early evidence of genetic influences came from twin studies in which concordance rates, the occurrence of the defect in each member of the twin pair, were much higher in identical (monozygotic) twins than in fraternal (dizygotic) twins for both types of orofacial clefts. More

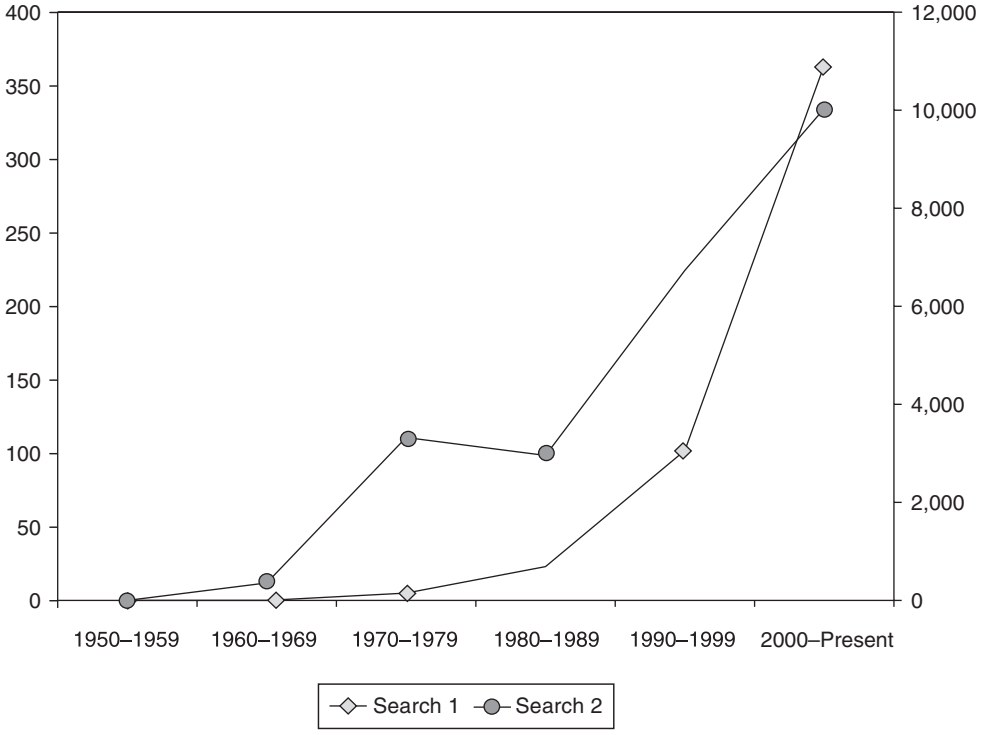

Figure 3 Publications on Gene-Environment Interaction by Decade: 1950 to the Present

Source: Medline search (2007).

recently, increased risk for cleft lip and palate has been observed in individuals with specific mutant alleles, including one for the transforming growth factor-alpha (TGFα) gene. This gene produces a protein that has been linked to oral-facial development. Evidence has also mounted that maternal smoking during pregnancy could be a risk factor for orofacial clefts in infants.

One study that was able to look at both genetic and environmental factors in orofacial clefting produced evidence of a gene-environment interaction. The study was population based and involved cases of orofacial clefts and appropriate controls. Cases were identified through a birth defects surveillance program. Telephone interviews were conducted with the mothers of both cases and controls to collect information that included smoking during pregnancy. Genotyping for the variant alleles of the TGFα gene was also conducted. One of the gene-environment interactions is shown in Figure 4.

The risk of cleft lip with or without cleft palate, as determined by the odds ratio, was the highest in those infants who had the TGFα mutation (A2) shown in previous work to be associated with clefting and whose mothers smoked at least 20 cigarettes a day. Again, the diverging lines in the graph show the interaction.

Failure to account for gene-environment interactions may be a barrier to an understanding of disease etiology. Say that we are interested in examining the relationship of an exposure, substance Q, on the risk of an outcome, disease Y. We may collect data on exposure and disease and determine that exposure to substance Q does not affect the risk of disease Y. In Table 2, column A is the 2×2 table that results from a study of a population of 100,000 of whom 50% are exposed to substance Q.

Since the probability of becoming a case is the same for those exposed or not exposed, the $RR = 1$, and we say that there is no association. If we have a population in which a specific mutation is present in 1% of the population, we might examine separately those who do or do not have the mutation. Columns B and C are the results for the group with the mutation

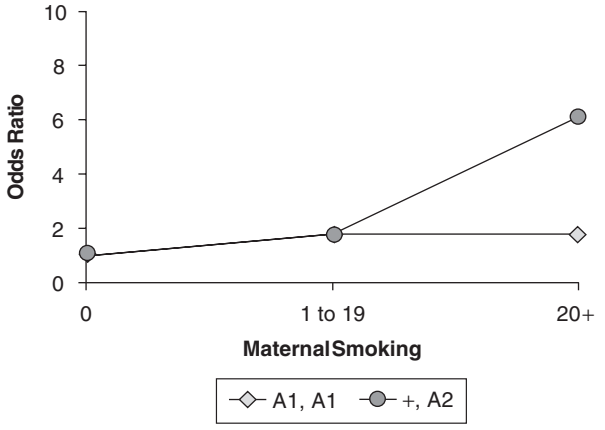

Figure 4 Cleft Lip and/or Cleft Palate Risk Interaction for Maternal Smoking and Transforming Growth Factor-Alpha Genotypes

Source: Shaw et al. (1996).

and the group without the mutation. Again, we have 50% of each group exposed, but in the mutant group the risk of the disease is 5.1 times greater in those exposed to substance *Q* than in those who were not exposed. Among the nonmutants, the probability of disease is equal for the exposed and unexposed. Column D is the sum of columns B and C. In column D, then, the population we are studying includes those with and without the specific mutation, where the frequency of the mutation is low, the likelihood of exposure is the same for those with and without the mutation, and the relationship between exposure and disease is very different for those who do or do not have the mutation. When we calculate the *RR* for this scenario, we find that it is not significantly different from 1, or no association. Therefore, we have missed the strong association of exposure and disease in the mutants because this group is a small minority of the population studied. When we are able to identify those with this specific mutation and examine them separately, we can distinguish this relationship. This would lead to opportunities for disease prevention through targeted prevention of exposure to those with the mutation. When we interpret the results of the studies, we must bear in mind that subgroups within the population who have a different genetic makeup may demonstrate a very different response to exposure providing opportunities for further understanding mechanisms of disease, prevention, and treatment.

Genetic Counseling

The goal of the field of medical genetics is to detect and treat individuals with genetic disorders. There are numerous single gene and chromosome disorders, but genetics also contributes to common diseases such as cardiovascular disease, cancer, and diabetes. Genetic counseling is the process of helping people understand and adapt to the medical, psychological, and familial implications of genetic contributions to disease. This process, as defined by the National Society of Genetic Counselors' Task Force, integrates the following:

- Interpretation of family and medical histories to assess the chance of disease occurrence or recurrence
- Education about inheritance, testing, management, prevention, resources, and research
- Counseling to promote informed choices and adaptation to the risk or condition

Genetic diseases due to single gene defects, sometimes referred to as Mendelian disorders, are grouped into *autosomal* (encoded by genes on one of the 22 pairs of autosomes, or non–sex chromosomes) and *X-linked* (encoded mutant genes on the X chromosome, one of the two sex chromosomes). There are two modes of expression of mutant genes: *dominant* and *recessive*. Dominant refers to those conditions expressed in individuals having only one copy of a mutant allele. Recessive refers to those conditions that clinically manifest only in individuals who carry two copies of the abnormal gene. Of the 10,000 human phenotypes known to be inherited, more than one half is classified as autosomal dominant, about one third is autosomal recessive, and about one tenth is X-linked.

The patterns of inheritance of most Mendelian or single gene traits have been learned by observing the transmission of traits within families. An important reason for studying the pattern of inheritance of conditions within families is to advise members through genetic counseling about recurrence risks or the chance that the genetic disease would be passed on to their children. Generally, dominant conditions carry a 50% risk while recessive conditions carry a 25% risk.

The term *genetic counseling* was coined in the 1940s and, as practiced today, is a multidisciplinary activity involving the provision of services by clinical geneticists, genetic counselors, nurse practitioners, laboratorians, and other health care professionals. The components of a genetic counseling interaction include the following:

- Information gathering
- Establishing or verifying the diagnosis
- Risk assessment
- Information giving
- Psychological counseling

Information gathering involves the collection of a family history from an individual knowledgeable about the family and health status of individuals within the family and is usually recorded in the form of a three-generation pedigree using conventional symbols to represent normal and affected males and females within and between generations and their relationships with other family members. The family history helps clarify relationships, identify other affected individuals, and records information of potential genetic significance (consanguinity or inbreeding, fertility problems, birth defects, ethnicity, mental disabilities). The person bringing the family to medical attention is referred to as the index case or proband.

Establishing or verifying the diagnosis is often accomplished by reviewing medical records before the family comes to the genetics clinic. Family photographs are often helpful. Sometimes, this requires physical examinations of other family members and/or laboratory testing.

Risk assessment is performed by analyzing the pedigree and the results of any laboratory testing. Mathematical calculations are often used to incorporate other information such as age of onset of the condition, population carrier frequencies, and number of affected individuals in the family. *Information giving* involves explaining to the family how the diagnosis was arrived at, what the implications are for the affected individual, what specialized services might be of help to the family, reproductive risks, options for prenatal diagnosis, and any treatment options.

Psychological counseling is often helpful because learning about any medical condition can be frightening and distressing. Genetic counseling strives to help

families make the best possible adjustment to the situation, to reach decisions about how they would prefer to deal with the risks and burdens they face, and to carry out plans. Genetic counseling provides services in a nondirective manner while painting an honest and fair picture of the challenges that a family faces.

The mode of inheritance is often established after constructing and reviewing the family history and pedigree. There are certain characteristics noted when reviewing a pedigree that indicate a specific mode of inheritance. For example, the three specific features of an autosomal dominant pedigree are as follows: (1) Males and females are equally affected, (2) more than one generation with affected members gives the impression of *vertical* transmission of inheritance, and (3) all forms of transmission between sexes are observed—that is, male to male (rules out X-linkage), female to female, male to female, and female to male. In autosomal dominant diseases, an affected parent passes either the normal gene or the disease-causing gene to the offspring, and each occurrence carries a 50% probability. There are more than 5,000 recognized autosomal dominant conditions. Some are common such as adult polycystic kidney disease (occurs 1 in 1,000 individuals) and familial hypercholesterolemia (1 in 500).

The distinctive features of autosomal recessive inheritance are the following: (1) Males and females are equally affected, (2) usually only one generation is involved (i.e., brothers and sisters affected) giving a horizontal pattern of inheritance, and (3) consanguinity. There are more than 4,000 recognized single gene diseases that require two copies of the mutant allele for an individual to be affected. The recurrence risk is 1 in 4 or 25%. There is a two thirds chance that an unaffected sibling is a carrier of the recessive gene in a family.

Three features seen in X-linked recessive inheritance are as follows: (1) Males are exclusively affected, (2) unaffected carrier females pass the genetic disease to one half of their sons giving a *diagonal* inheritance pattern (i.e., uncles and nephews are affected), and (3) affected males cannot transmit the genetic disease to their sons (fathers pass the Y chromosome to their sons and the X chromosome to their daughters). Because females have two copies of the X chromosome and males are hemizygous, most X-linked conditions are more common in males than in females.

Three features are necessary to establish X-linked dominant inheritance. These include the following: (1) Both males and females are affected, (2) the number of affected females in the pedigree may be twice the number of affected males, and females are generally less severely affected than males, and (3) affected females can transmit the genetic disease to one half of their sons and daughters but affected males can transmit the disease only to their daughters.

Thus, there are three major categories of genetic diseases: (1) single gene diseases (autosomal dominant, autosomal recessive, and X-linked recessive or dominant); (2) chromosomal (not discussed here because a particular chromosome abnormality—e.g., deletions, inversions, duplications, translocations—involving the individual pairs of chromosomes generates specific and sometimes unique recurrence risk estimates beyond the scope of this presentation), and (3) multifactorial. Multifactorial causes (combination of genetic and environmental factors) account for about two thirds to three fourths of the morbidity and mortality due to genetic diseases. Multifactorial conditions include diabetes, neural tube defects, congenital heart disease, cancer, obesity, and idiopathic mental retardation. Recurrence risk estimates have been established for most of these multifactorial conditions (e.g., 2% to 4% risk for congenital heart disease).

In addition to the typical Mendelian forms of inheritance, non-Mendelian forms exist. These include mitochondrial disorders, genomic imprinting (e.g., Prader-Willi and Angelman syndromes), and trinucleotide repeat mutations (e.g., fragile X, myotonic dystrophy). Mitochondrial diseases are due to mutations of the mitochondrial genome inherited from the mother and found in the cytoplasm of the cell. Mitochondrial, genomic imprinting, and trinucleotide repeat disorders are known to play a role in neurological and muscle dysfunction. Non-Mendelian disorders require unique disease-specific genetic testing approaches and recurrence risk estimates.

Genetic Disorders

In a strict sense, genetic disorders result from mutations of single genes and include conditions such as cystic fibrosis, sickle cell anemia, and the muscular dystrophies. In a more general sense, however, chromosome abnormalities, multifactorial diseases, and single gene disorders are often thought of as genetic diseases.

The contribution of genetic disorders to human morbidity and mortality varies throughout the life cycle. Chromosomal abnormalities exert their greatest influence during prenatal and early postnatal life. Single gene disorders usually manifest in infancy and childhood. Multifactorial diseases are particularly common causes of adult health problems and include conditions such as coronary artery disease and type 2 diabetes. Most birth defects and other childhood illnesses such as asthma may also be inherited in a multifactorial fashion. As a group, chromosome abnormalities, single gene disorders, and multifactorial diseases are found in about 3% to 4% of all newborns. By adulthood, previously undetected malformations and later-onset disorders have become apparent, and up to 8% of the population is affected by genetic disease. Although a relatively small proportion of individuals in the general population are affected with one of these conditions, they are overrepresented in certain populations such as those with early mortality and those who are hospital inpatients. Genetic disorders are the most common cause of neonatal mortality, surpassing complications of prematurity. They also represent about 35% to 55% of pediatric hospital admissions and about 20% of deaths in neonatal and pediatric intensive care units. As common causes of worldwide morbidity and mortality such as infectious diseases decrease, the importance of genetic disease, especially in developed countries, has received increasing scrutiny as a target of new diagnostic tests, improved treatment strategies, and public health prevention programs.

Chromosome Abnormalities

Standard cytogenetic testing uses light microscopy to identify loss or gain of visible segments of chromosomes, including whole chromosomes and smaller segments. Although this technique readily detects abnormalities of large segments of chromosomal material, the smallest deletions or duplications are beyond the resolution of microscopic analysis. Over the past two decades, new techniques for diagnosis of smaller and smaller chromosome abnormalities have had a great impact on the practice of medical genetics. With the advent of fluorescence in situ hybridization (FISH) technology, it has become possible to detect deletions or duplication not visible through the microscope. FISH uses fluorescent molecules to bind to genes, chromosome regions, or whole chromosomes and detects missing or extrachromosomal material. More recently, fluorescence technology has been used to construct chromosome microarrays, which can detect literally thousands of abnormalities in a single reaction. Among patients who are evaluated for a chromosome abnormality and who have already had a normal cytogenetic analysis, 5% to 7% have a chromosome deletion or duplication when analyzed by chromosome microarray. Such technical advances will increasingly be used to improve genetic diagnosis and to identify mechanisms by which chromosome imbalance leads to human disease.

Although chromosome abnormalities may be found in all age groups, they are particularly common in spontaneous abortions. Among recognized pregnancies, between 10% to 20% are spontaneously aborted; and of these, chromosome abnormalities are present in about half. The great majority, more than 95%, of these abnormalities, involve an entire missing or extra chromosome, which is referred to as aneuploidy.

Aneuploidy is the result of nondisjunction, which is failure of homologous chromosome pairs to disjoin and assort to different germ cells during the first phase of meiosis. The only well-characterized risk factor for chromosome abnormalities is advanced maternal age, which is associated with aneuploidy. Environmental factors such as parental drug use, cancer chemotherapy, and radiation exposures have been investigated, and none of these appears to increase the relative risk for having an affected child. Although chromosome abnormalities may be present in between 5% and 10% of conceptions, they are found in about 0.5% of newborns. The most common abnormalities in liveborn infants are trisomies for chromosomes 21, 18, and 13, while other trisomies such as trisomy 16 and trisomy 22 are rarely, if ever, encountered at birth. The decreased viability of fetuses with these chromosome abnormalities is believed to result from an increased amount of genetic imbalance, as compared with those with viable chromosomal abnormalities. Clinically, those conditions with the greatest quantity of missing or extrachromosomal material also have the most severe phenotypic manifestations. As a general rule, abnormalities of the autosomal chromosomes (the chromosomes not involved with sex determination) are characterized by significant developmental disabilities and birth defects, and sex chromosome abnormalities (involving the X and Y chromosomes) are characterized by abnormalities in sexual differentiation, maturation, and fertility.

The most common chromosome abnormality in humans, and the most studied, is Down syndrome. Down syndrome is caused by an extra chromosome 21 and is often referred to as trisomy 21. Clinically, individuals with Down syndrome have characteristic facial features, mild to moderate developmental disabilities, and variable birth defects such as cardiac abnormalities in 40% to 50%, gastrointestinal abnormalities in 1% to 2%, and other abnormalities of most organ systems. About 95% of individuals with Down syndrome have 47 chromosomes, and the remaining 5% either have a chromosome translocation (an extra copy of chromosome 21 attached to another chromosome, usually a chromosome 14) or mosaicism (the presence of two cell lines: one with the normal chromosome complement and another with trisomy 21). As with other autosomal trisomies, its relative incidence increases with older maternal age. While the general population probability of having a child with Down syndrome is about 1 in 700, the age-specific risk varies from about 1 in 1,500 in women below age 20 years to about 1 in 50 for women at age 45 years. Although the relative incidence of Down syndrome is increased in older mothers, about 80% of affected children are born to women younger than 35 years of age. This is because the sheer number of pregnancies in women younger than 35 years is so much greater than those of older women. As a result of advances in obstetrical practice beginning in the 1970s, women ages 35 years and older have been offered amniocentesis for prenatal detection of Down syndrome. Amniocentesis involves withdrawing amniotic fluid from around the developing fetus and culturing fetal cells for chromosome analysis and potentially for other analyses. Subsequent advances in detection of maternal serum markers during pregnancy have brought about additional changes in obstetric practice. For women in developed countries, maternal serum screening and prenatal ultrasonography are often used to identify pregnancies at increased risk for Down syndrome, trisomy 18, and birth defects such as open spina bifida, anencephaly, and defects of the abdominal wall. Prenatal ultrasonography is also used routinely and in high-risk pregnancies for detection of birth defects and birth defect syndromes. When chromosome abnormalities or serious birth defects are detected antenatally, therapeutic abortion may be elected. There are currently no primary prevention strategies for chromosome abnormalities or for most birth defects.

Single Gene Disorders

Single gene disorders are those conditions that follow the rules of inheritance first identified by Mendel in the mid-19th century. They comprise many familiar medical conditions such as cystic fibrosis, sickle cell anemia, Tay-Sachs disease, hemophilia, and Duchenne muscular dystrophy. Single gene disorders are individually very rare, and as a group, they still affect less than 1% of the general population. Nevertheless, they are the targets of long-standing and intensive study for several reasons: (1) Because their inheritance patterns are readily recognizable, they were among the first human disorders known to have their origins in single genes; (2) early detection and medical intervention have resulted in virtual cures or dramatic improvements in the well-being of some affected individuals; and (3) knowledge of how single gene abnormalities lead to human disease has served

as a paradigm for studying interactions between susceptibility genes and environmental factors that lead to more common diseases.

At each autosomal gene locus, there are two alternative copies, known as alleles, one inherited from each parent. When mutation of only one of these alleles produces disease, the disorder is said to be an autosomal dominant trait. Although most people with autosomal dominant diseases inherit the mutated allele from an affected parent, spontaneous mutation may also produce an autosomal dominant disease in the offspring of unaffected parents. Advanced paternal age, usually considered to be 40 years old or greater, is associated with an approximately 1% risk for a spontaneous mutation that results in the offspring having an autosomal dominant genetic disorder. The reason for this increased risk among older fathers and not mothers is unknown, but its manifestation may be striking. For example, almost all spontaneous mutation for many well-characterized genetic disorders occurs only in the copy of the gene contributed by the father. Advanced paternal age is also a risk factor for spontaneous mutation of genes carried on the X-chromosome. In this circumstance, spontaneous mutation of a gene contributed by an older father to his daughter results in her being an unaffected carrier. Her sons are then at risk for inheriting the mutation and manifesting an X-linked genetic disease.

In autosomal recessive disorders, the disease arises only in people who are homozygotes, which means they possess two mutant alleles. People who have only one mutant allele show no disease manifestations and are commonly referred to as carriers, or heterozygotes. It has long been recognized that certain genetic conditions are more common in consanguineous matings, wherein the parents are related through a common ancestor. The mechanism by which a homozygote receives two mutant alleles from the common ancestor is known as homozygosity by descent. This increased risk of autosomal recessive disease has given rise to a taboo against marrying one's blood relatives in many, though by no means all, cultures. For cultures who promote consanguineous matings, the most common pairing is among first cousins. Although the worldwide burden of genetic disease is relatively small as a result of consanguinity, in families who have a high percentage of carriers for a mutant allele, autosomal recessive disease may be particularly deleterious. General estimates suggest that among all first-cousin matings, there is an approximately 1% increased risk for autosomal recessive disease, when compared with the general population.

Genetically isolated populations are also at increased risk for autosomal recessive genetic disease. Isolated populations are groups that tend to mate exclusively within their group because they are bound by geography, culture, religion, and/or language. The genetic disease that runs within such populations is usually the result of a founder effect, in which a mutation is introduced into the group by a single founder and is propagated throughout the population. Because there is a high carrier rate in the population, the risk of that disease is much higher than in the general population. Founder effects are known to exist for conditions such as Tay-Sachs disease in Ashkenazi Jews and French Canadians, gyrate atrophy in the Finnish population, and variegate porphyria in Afrikaners from South Africa. The high prevalence of genetic disorders in some ethnic groups has led to the development of carrier screening programs to identify people who are at risk for having an affected child. These programs provide members the opportunity to make informed reproductive choices, based on specific knowledge about the individual's carrier status.

Of the approximately 30,000 genes in the human genome, almost 2,000 human diseases are known to be the result of mutations in single genes. The past decade has seen a dramatic increase in knowledge regarding the genetic origin of many clinically recognizable syndromes, the phenotypic spectrum of specific genotypic abnormalities, and the diagnosis of these syndromes through molecular techniques. From a pathogenetic perspective, most of these genetic mutations produce abnormalities in the quantity, structure, and/or function of encoded proteins. The role of the affected protein determines the disease phenotype. Abnormalities of structural proteins are most often associated with birth defects or poor tissue integrity, whereas abnormalities of enzymes or transport proteins usually produce disease through accumulation of deleterious precursors or a deficiency of the end products. These enzyme abnormalities are the focus of newborn screening programs and represent the targets of some of the world's most successful treatment programs for genetic disease. The standard medical treatment for enzyme defects has historically involved dietary or pharmacologic intervention to limit accumulation of abnormal precursors or to provide supplementation of the deficient end product. There are, however, an increasing number of enzyme abnormalities that are being treated by enzyme

replacement therapy (ERT). This type of treatment relies on the intravenous infusion of an artificially produced but bioactively equivalent enzyme preparation that replaces the defective enzyme. The greatest role for ERT has been in the treatment of disorders in which there is abnormal storage of enzyme precursors and progressive organ dysfunction. Beginning with the 1991 approval of a modified form of the enzyme beta-glucosidase for the treatment of Gaucher disease, the number of disease targets for ERT has expanded to include Fabry disease, mucopolysaccharidosis type 1, and Pompe disease. ERT has the potential to eliminate the deleterious effects of any disease that results from enzyme dysfunction.

Multifactorial Conditions

Multifactorial diseases result from a combination of both genetic and environmental factors and represent some of the most common human diseases such as atherosclerotic cardiovascular disease, adult onset diabetes, and birth defects. For most of these diseases, the genetic basis is inferred from studies of familial clustering, but the causative genetic loci are generally unknown. One of the most common methods for calculating the relative contributions of genetics and environment for a multifactorial trait is the relative risk ratio. This ratio is derived by dividing the risk for a disease in a relative of someone with the disease by the risk for a disease in someone from the general population. If the disease is completely unrelated to genetic constitution, the relative risk ratio is 1; and, for increasingly greater genetic contribution, the ratio increases proportionally. For example, a disease with a minor genetic contribution such as juvenile onset diabetes has a sibling relative risk ratio of about 10, whereas a condition with a substantial genetic contribution such as childhood autism has a ratio of > 100. There are a number of other methods by which the heritability (an estimate of the amount of phenotypic variation that is genetic) of a disorder can be quantified. Although these methods are generally useful for quantifying the relative genetic contribution to the disorder, one should be cautious about inferring a genetic causation from relative risk ratios and similar calculations, because in addition to sharing a similar genetic constitution, related individuals often share a similar environment.

Multifactorial disorders are excellent targets for primary prevention strategies aimed at modifying environmental risk factors that contribute to their causation. Some of the great public health successes of the previous century focused on the link between environmental factors and specific multifactorial diseases. Decreases in smoking have resulted in decreased rates of lung cancer and cardiovascular disease; and folic acid fortification and dietary supplementation have been accompanied by dramatic decreases in the occurrence of spina bifida and anencephaly. Identification of genetic risk factors may also be useful for designating a high-risk group that might benefit from general prevention strategies, surveillance, and early treatment. For example, individuals who are homozygous for an abnormality of a gene encoding the protein alpha-1 antitrypsin are particularly susceptible to the pulmonary effects of smoking and can develop a severe form of emphysema if they smoke. Smoking avoidance greatly reduces these risks. Much of our current knowledge about the relative contribution of genetic factors to multifactorial disease has arisen from association studies. These studies examine the frequency of a disease among two different groups: those who carry a genetic variant and those who do not. Such studies have identified an increased risk for Alzheimer's disease in people who carry an allele for apolipoprotein E, for spina bifida in the offspring of women with a thermolabile variant of the methylene tetrahydrofolate reductase enzyme, and for asthma in people with alleles for more than a dozen different loci. The next public health challenge for primary and secondary prevention of multifactorial diseases will be finding ways to influence the expression of these genes or their gene products.

Conclusion

Many genetic disorders are individually rare, but taken as a group, they contribute greatly to the human disease burden. For chromosome and single gene disorders, modifiable risk factors are few, and primary prevention represents a great challenge. Established carrier detection programs will continue to provide informed choices in at-risk populations; and new treatments such as ERT hold promise for secondary prevention of selected genetic diseases. For multifactorial disorders, the identification of complex interactions among environmental and genetic determinants provides opportunities for prevention or amelioration of some of the most common human diseases. As

morbidity and mortality from historically common disorders such as infectious diseases decrease, the treatment and control of genetic diseases will become increasingly important.

Genetic Epidemiology

Genetic epidemiology is an emerging field that developed initially from population genetics, specifically human quantitative genetics, with conceptual and methodological contributions from epidemiology. One of the early proponents of genetic epidemiology, Morton, defines the field as one that addresses the etiology, distribution, and control of disease in groups of related individuals and the inherited causes of diseases in populations. This definition has by necessity been broadened to include the role of the environment by others who emphasize the role of genetic factors as they interact with environmental factors in the occurrence of diseases in human populations. Khoury, Little, and Burke (2003) have recently coined the term *human genome epidemiology* to encompass a system of investigations that use the methods of epidemiology in population-based studies of the influences of genetic variation in both health and disease.

It should be noted that the field of molecular epidemiology stands in contrast to genetic epidemiology, as the former grew out of environmental epidemiology. The rationale for the emergence of molecular epidemiology was the need to identify biomarkers of environmental exposures as an application of molecular biology in epidemiology.

There are a number of aspects that distinguish genetic epidemiology from other areas of genetics from which it developed. The first is the population-based nature of the research, which, together with shared methodological approaches, is one of its key links with epidemiology. Second, newer ways of conceptualizing the field stress the search for combined and interactive effects of genetic and environmental factors. Finally, genetic epidemiology includes the consideration of the biological basis of the diseases into developing models of causation for diseases.

The goals of modern genetic epidemiology have been broadened to include all diseases, whether they are common and complex or supposedly simpler, such as the so-called monogenic disorders. There has been a tendency in recent years in genetic epidemiology to place almost exclusive emphasis on the complex diseases, but some of the best advances in the epidemiology of genetic diseases have indeed involved simple inherited disorders, which are increasingly seen as more complex as we come to a better understanding of epigenetics and interactions of disease genes with environmental factors. In addition, any definition of genetic epidemiology arguably needs to encompass all aspects of the epidemiology of genetic diseases, including studies of prevalence, clinical epidemiology, genotype-phenotype relationships, and disease outcomes and progression. We also need more comprehensive studies of environmental factors that influence outcomes in genetic diseases.

Historically, the field of genetic epidemiology has some of its roots in the interests of medicine

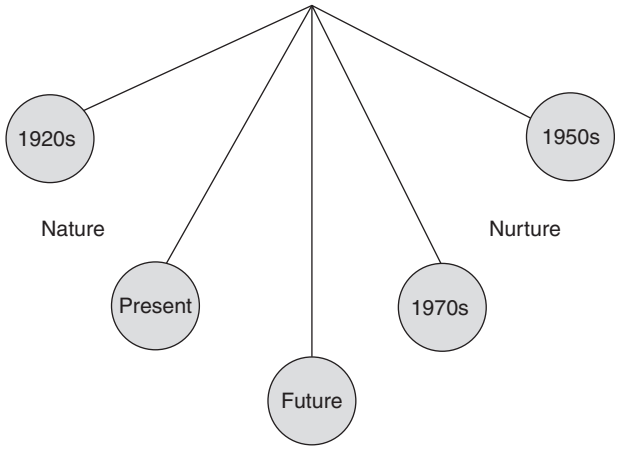

Figure 1 Swings of the Nature-Nurture Pendulum

concerning the causes and heredity of disease. In the days prior to the field actually having a label (i.e., prior to the 1950s), scientists who perhaps would now be labeled as early genetic epidemiologists were trying to unravel the issues of nature and nurture with respect to human diseases. These activities were in contrast to the early practitioners of medical genetics who tended to be oriented toward the clinical and descriptive aspects of what were recognized as diseases with potential genetic involvement and to genetic counseling based on what was known then about the inheritance patterns of some diseases. Early practitioners of genetic epidemiology often looked for associations between diseases such as stomach ulcers and well-studied genetic traits of the day such as blood groups. One of the authors (F. J. M.) took a genetics course in the early 1960s that had the name "Heredity and Eugenics." Interestingly, a faculty member with a medical degree (MD) taught the course, most of which was spent examining what was known then about the genetics of human diseases. This was a time period when the field of medical genetics was in its childhood and genetic epidemiology had barely taken hold, and the legacy of eugenics was still alive in the names of journals and organizations.

The early history of attempts to solve the problem of heredity versus environment, that is, nature versus nurture, in causing human diseases was subject to numerous swings in the so-called nature-nurture pendulum over the 20th century (Figure 1). Both scientific and societal concerns have driven these swings over time. The swings reflect periods of time during which the scientific community and society viewed either nature or nurture as the more important determinant in causing diseases.

In modern times, the controversy about nature versus nurture has been gradually replaced by a view that includes roles for both nature *and* nurture in human disease in that both genetic and environmental factors influence (frequently according to an interactive model) disease susceptibility.

Genetic epidemiology is becoming an increasingly important field in science today. While epidemiologists increasingly recognize the importance of genetic determinants of human diseases, human geneticists are learning about the importance of environmental exposures in all human diseases. There is increasing acceptance of the assertion by Khoury et al. (2003) that most human disease, if not all, is the result of the interaction between underlying genetic susceptibility and exposures to various components of the environment, including chemical, dietary, infectious, physical, and behavioral. The latter would encompass the influences of cultural factors in human behavior and their interaction with other environmental factors.

While human geneticists and epidemiologists continue their search for optimal strategies to identify disease genes and overcome some of the present methodological limitations in dissecting the genetic components of complex diseases, there is little doubt that genetic association studies will become increasingly important in the translation of the results of genomic research into public health. Genetic epidemiology in this sense will continue to increase in its importance in both human genetics and epidemiology.

One of the most important contributions that epidemiology has made to genetic epidemiology is probably the population-based approach. There are obvious advantages of epidemiological methods that can be applied in genetic epidemiology research, such as case-control studies. However, there are some aspects that have yet to be fully appreciated. Some of these include the knowledge base created by prevalence studies done prior to analytical or interventional research. Knowing the distributional characteristics of socioeconomic and other demographic variables provides an effective basis for the evaluation of the samples of cases obtained for clinical description and interventional research. In addition, population-based data on clinical features and outcomes in genetic

disorders have obvious advantages over data gathered on the basis of attendance in specialized clinical centers that may not reach all strata in a population of individuals with the disorder of concern.

Some of the important approaches used today in genetic epidemiology are covered in more detail elsewhere in this *Encyclopedia* and therefore will not be covered in detail here. For genetic disorders inherited in a Mendelian fashion, suffice it to say that linkage studies have been the method of choice for many years. Unfortunately, to date, the same methods have not shown the same overall success for multifactorial diseases in which multiple genes and environmental factors are each assumed to play roles in the disease etiology. These complex diseases account for the vast majority of all human diseases and therefore have received increased attention during the past two decades.

Some have touted association studies as being more powerful than other methods in the detection of susceptibility genes for multifactorial diseases. However, it has not always been possible to replicate the findings of such studies in a consistent manner. The major problem is that in any given multifactorial disease, we may be dealing with genetic loci in the thousands, thereby decreasing the probability of finding an association with a specific gene.

There is some agreement among genetic epidemiologists that there should be evidence for a role of genetic factors in a disease before launching into large-scale studies to identify genes. Twins studies have been a tried-and-true method for establishing such evidence in many multifactorial diseases. Family studies of disease risk in first-degree relatives are also considered preliminary to further research. These should include comparisons of familial risk to risk in the population (i.e., prevalence) and, if controls are available as in case-control studies, to the relatives of control individuals. This is done by computing λ, which is the ratio of disease risk in the relatives of cases (those affected with the disease in question) to the prevalence for the disease in the population.

Another important contribution of epidemiology to the development of genetic epidemiology has been the introduction of traditional epidemiological methods to the mix of study designs. Human quantitative genetics used studies of twins, sibs, half-sibs, and in some cases adoptees to investigate the genetic and environmental sources of variation in human traits and diseases. Application of epidemiological methods such as case-control and cohort studies has further extended these methods for examining genetic and environmental risk factors simultaneously. In any of the methods used, the emphasis on a population-based approach becomes important, whether it is the collection of prevalence data in surveillance programs or enhancing our ability to test how representative a specific sample is through an understanding of the characteristics of the larger population. Many genetic epidemiologists are promoting the use of prospective cohort studies such as the National Children's Study in the United States and other longitudinal research worldwide for their potential to contribute to studies of associations between genes and disease and gene-environment interactions.

If we take into consideration the broad view of genetic epidemiology that includes all genetic diseases, there have been major achievements in the identification of the genetic causes of many genetic disorders during the past 25 years, especially with improving techniques in cytogenetics and molecular genetics. Following the discovery of restriction fragment length polymorphisms in the late 1970s, there came a period of identification of the genes for many genetic disorders. Further advances in molecular genetic techniques have rapidly increased our knowledge of the genes for most monogenic disorders. What remains is the ongoing research on interactions of these major disease genes with other genes and environmental factors as they influence the multitude of disease outcomes in these disorders.

To date, we have not seen the important promised breakthroughs in establishing definitive risk factors for complex traits and diseases, although there are some exceptions to this statement such as the relationship of alpha-1-antitrypsin deficiency to chronic obstructive pulmonary disease. The genetic dissection of complex diseases is proving much more challenging for a number of reasons. The magnitude of any specific genetic effect is usually very small. The involvement of multiple genes alone makes the task more complicated. The increasing evidence for gene-gene and gene-environment interactions complicates the task even further. In addition, the possible modifying effects of phenotypic heterogeneity and developmental processes on genetic associations in complex diseases may not have been taken into account sufficiently in most association studies to date.

Khoury et al.'s (2003) definition of human genome epidemiology increases the scope of traditional

genetic epidemiology by emphasizing the application of epidemiological methods to evaluate the impact of genetic variation on human health and disease. It reflects the new vision of genomics and its expected influence in public health. This will likely have an important impact on the public health burden of common complex diseases. However, the epidemiology of chromosomal and Mendelian genetic disorders also needs to be given continued emphasis under the umbrella of genetic epidemiology. Before we had genomics, there were many important contributions of epidemiological studies of genetic disorders to public health. One of these involved newborn screening, which is likely the most successful public health genetics program to date. A clinical intervention study conducted during the 1980s on sickle cell disease paved the way for expansion of newborn screening programs in the United States to include this genetic disease in the programs of more states. The study was a randomized trial to determine the prophylactic effects of penicillin administration in children diagnosed with sickle cell disease. A reduction in both the incidence of pneumococcal infections and the mortality in those infants who received penicillin compared with the untreated group led to the conclusion that children should be screened in the newborn period for sickle cell disease and receive penicillin early in the first year of life to prevent the infections. This is one of the few instances of the outcome of a clinical epidemiological study driving changes in genetic health services delivery. It suggests that one goal of genetic epidemiology ought to be to produce data that will drive changes in health care services and public health to reach the population at large.

The goals of genetic epidemiology need to be flexible, because new discoveries in genetics and genomics bring different ways of viewing and analyzing the data. For example, some now have proposed that in effect, there are no actual monogenic diseases. This view is supported by the increasing evidence of the effects of interacting genes and environmental factors on the phenotypic outcomes in single gene diseases. If we consider these complications in phenotypic expression, all diseases are complex, although some might be complex and not all that common. The message is that increasing complexity means increasing need for the approaches of genetic epidemiology and the accompanying statistical methods that have traditionally been applied to deal with these complexities. It also means that as the genetic components of human diseases are unraveled, there will be a need for effective ways of translating genetic findings into public health improvements, accomplishing the counseling to incorporate genetic risk assessments, increasing public understanding of the role of genetics in disease, and in turn, developing culturally competent ways of implementing these programs and delivering these messages.

Genetic Markers

Genetic epidemiology aims to identify genetic variation related to risk for disease. Because it is currently not feasible to fully sequence the genomes of every person in a sample, the field has traditionally relied on genetic markers with known locations to act as surrogate information for the surrounding sequence. These markers are typically called polymorphisms to reflect the concept that they are locations in the genome with variability within and across individuals (i.e., they have multiple forms or "spellings"). The ability for markers to act as surrogates for surrounding sequence is a function of a genetic property called linkage and a related concept of linkage disequilibrium, which results in correlation between

polymorphisms and surrounding sequence. Because markers are often simply proxies for unmeasured sequences that can influence risk for disease, marker-based approaches are often termed *indirect association* studies. Emerging technology has greatly increased the catalogue of such variable sites in the human genotype and the ability to accurately and affordably genotype individuals at these markers, such that marker-based genetic epidemiology is now the paradigm for most studies.

The field of genetic epidemiology aims to identify genetic variation that is related to disease. This can be a daunting task, considering that the size of the human genome is around 3 billion base pairs. Finding a single genetic variant that influences risk for a disease would be like finding a single misspelled word among 3 billion letters. This is often compared with trying to find a single misspelling in an entire encyclopedia. While one could carefully read the entire encyclopedia to identify misspellings, this could take an enormous amount of time and many misspellings may simply be overlooked. Furthermore, technology has traditionally limited the ability to sequence ("read") the entire genome of each participant in a study. Instead, the field has relied on genetic "markers" located at known locations in the genome to represent the surrounding sequence. Continuing the encyclopedia example, this would be like marking the first three sentences of every entry, so that the specific location in the context of the encyclopedia is known.

Genetic markers are "polymorphisms," meaning they contain variable sequence (literally "multiple forms") within and across individuals of a population. The most common types of markers in the human genome are single nucleotide polymorphisms (SNPs), simple tandem repeat polymorphisms (STRs), and insertion/deletions (indels) (see Figure 1). SNPs are defined by the existence of more than one nucleotide at a particular position in the genome. For example, at a genomic location with the sequence **ACCTGA** in most individuals, some may contain **ACGTGA** instead. The third position in this example would be considered an SNP with either a C or G allele. Because each individual inherits one copy of their genome from each parent, each person has two copies, and therefore three types of individuals can be distinguished based on this polymorphism: those with two copies of the C allele (homozygous CC

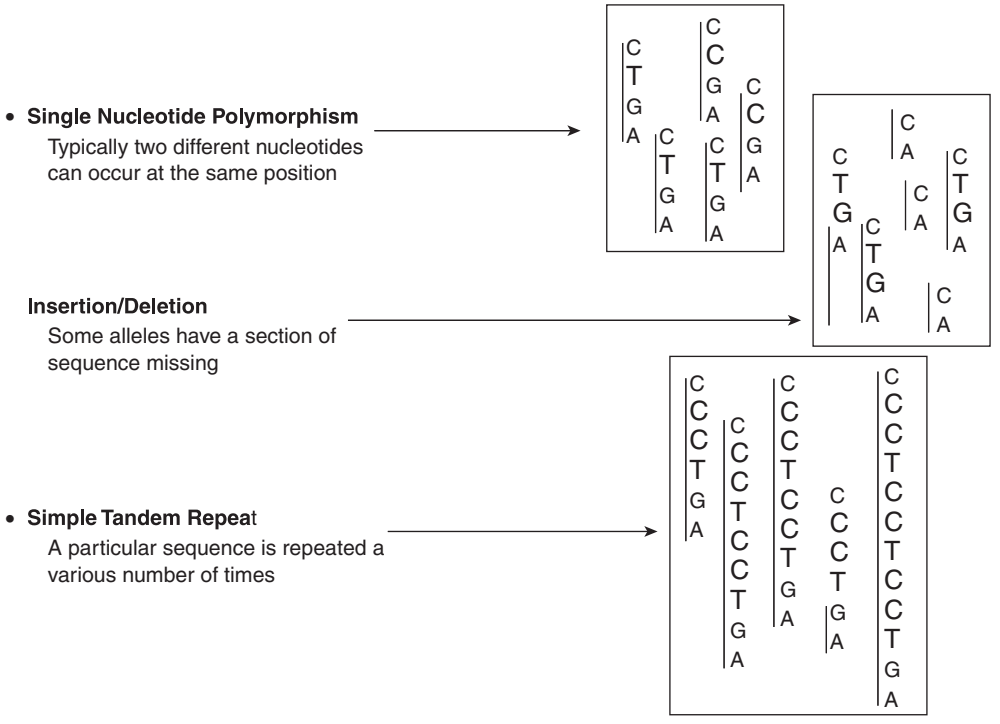

Figure 1 Common Genetic Markers

genotype), those with one C and one T allele (heterozygous CT genotype), and those with two T alleles (homozygous TT genotype). The three genotype groups of this marker can be used as "exposure" categories to assess association with an outcome of interest in a genetic epidemiology setting. Should such an association be identified, researchers may investigate that "marked" genomic region further to identify the particular DNA sequence in that region that has a direct biological effect on the outcome of interest.

STRs are markers where a piece of sequence is repeated several times in a row, and the number of repeats (considered an allele) is variable within and across individuals. For example, a CCT pattern may be repeated up to 10 times, such that individuals in the population may have genotypes at that locus representing any combination of two repeat alleles of sizes 1 to 10 repeats (e.g., $10(10+1)/2 = 55$ different possible genotypes). Indels refer to polymorphisms where a piece of DNA sequence exists in some versions (insertion allele) and is deleted in others (deletion allele) in the population. While each of these additional types of markers are used in genetic epidemiology, the SNP marker is the most common (approximately 10 million in the human genome), is arguably the most affordable to genotype in large samples, and is therefore the most widely used type of marker.

The marker-based approach to genetic epidemiology has often been considered an "indirect" approach, since markers are used as surrogate information for unmeasured sequence variation that directly influences disease risk. While "direct" approaches, in which the polymorphism with known biological consequence is directly measured and related to disease, would be ideal, it is often not possible. Even for genes with well-known function, the particular sequence variation with biological consequences may not be known. Polymorphisms that change the amino acid sequence or the rate of transcription are great candidates, but knowledge about all functional consequences for most sequence variation does not yet exist. Therefore, to maximize the detection of disease-related sequence variation, the field relies on marker-based approaches that allow markers to represent the rest of the genome that is not directly measured.

This "indirect association" approach assumes that markers will provide adequate surrogate information for surrounding sequence that may contain unmeasured disease-related alleles. This would not be possible if correlation did not exist between alleles located close to each other in the genome. Fortunately, such spatial correlation does exist naturally, through the Mendelian property of genetic linkage and the population genetic consequence of linkage that is often called linkage disequilibrium (LD). Under linkage equilibrium, alleles should be independent of each other (no correlation), but for very closely located polymorphisms, correlation does exist due to population genetic

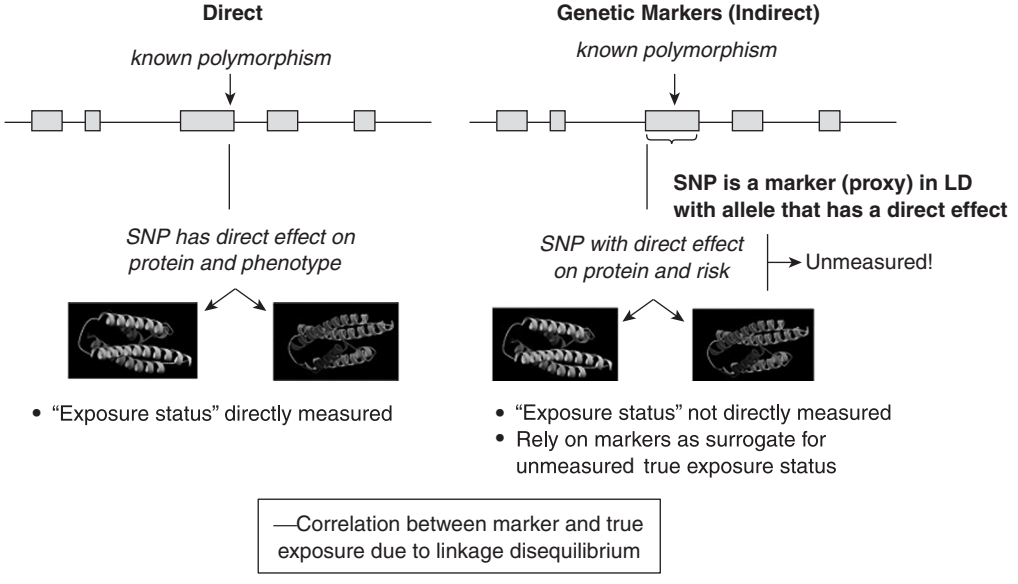

Figure 2 Direct Versus Indirect (Marker-Based) Association

history, and this departure from equilibrium is called linkage disequilibrium. LD patterns have been characterized across the genome in several populations and show wide variability in the length of DNA that shows correlation. However, on average, LD exists in "blocks" of DNA of about 22,000 base pairs in length in populations of European descent. This pattern depends on the genome region and population, but once characterized, genetic markers can be chosen to represents the surrounding sequence within a correlated LD block. The set of markers that most efficiently represents the entire correlated set of sequence (often SNPs) is called "tagSNPs." Various calculations have been proposed to determine the most efficient set of SNPs to "tag" an area of the genome, but in general, these should be chosen based on LD information of the genomic region and population relevant to a particular study sample, with an aim to maximize the proxy information available when using just the tagSNPs compared with all polymorphisms known in the region.

Genocide

Genocide is the intentional destruction of human groups, in whole or in part, by mass killing and other methods. Such, at least, is a shorthand definition based on the United Nations Genocide Convention of 1948. The Convention capped two decades of scholarly work and activist endeavor by Raphael Lemkin (1900–1959), a Polish-Jewish jurist troubled by the failure of international society to suppress atrocities inflicted by states against their own minority populations. Lemkin had a vision of cultural bonds and collective identities as essential to human civilization, and thus his framing of "genocide"—combining the Greek *genos* (race, tribe) and the Latin *cida* (killing)—downplayed the physical killing of individuals, highlighting instead the destruction of communal integrity and identity. This emphasis survives in contemporary conceptions of "ethnocide" and "cultural genocide." It is also reflected in the UN Convention, which defined genocide as "any of the following acts committed with intent to destroy, in whole or in part, a national, ethnical, racial or religious group, as such":

1. Killing members of the group
2. Causing serious bodily or mental harm to members of the group
3. Deliberately inflicting on the group conditions of life calculated to bring about its physical destruction in whole or in part
4. Imposing measures intended to prevent births within the group
5. Forcibly transferring children of the group to another group

The Convention definition is notable, indeed notorious, for its lack of specificity in key areas. How to define the groups covered "as such" by the Convention (national, ethnic, racial, and religious), and why are other groups excluded (e.g., those united by political belief, social class, or gender)? Can groups be "destroyed" by means other than mass killing, for example, by the infliction of "mental harm"? What "part" of the group must be destroyed to qualify as genocide? And how might a genocidal "intent to destroy" be ascertained?

In part because of these ambiguities, the concept of genocide languished for over two decades after the Genocide Convention entered into force in 1951. The renewal of interest in genocide can be traced to two main factors. First, the trial and execution of the captured Nazi Adolf Eichmann, in Israel in 1961 to 1962, spawned a flood of research and commentary on the Jewish Holocaust—for many, still the paradigmatic case of genocide. The analyses gradually assumed a comparative bent, as scholars became interested in other cases of genocide, such as the destruction of the Armenian population of Ottoman Turkey during World War I. Following the publication of Leo Kuper's seminal 1981 work *Genocide: Its Political Use in the Twentieth Century*, a field of "comparative genocide studies" gathered steam, hitting full stride in the latter half of the 1990s and into the 2000s. In part, this reflected the second key factor in the renewed

prominence of genocide for governments and publics: the continued prominence of the phenomenon itself in the post–Cold War era. This was brought devastatingly home by the apocalyptic slaughter of nearly 1 million Tutsis in Rwanda in 1994, and by the less destructive—but European-centered, and hence heavily publicized—mass atrocities against Bosnian Muslims following Yugoslavia's collapse in 1991. Both genocidal outbreaks prompted the formation of international criminal tribunals to try alleged perpetrators. Subsequent initiatives included "mixed tribunals" of national and international judges to preside over tribunals for Sierra Leone, and most recently for atrocities in Cambodia under the Khmer Rouge regime (1975–1979). The new International Criminal Court (ICC) also includes genocide in its jurisdiction.

From the outset, genocide scholars and activists have been motivated by a perceived need to *prevent* genocide as well as to *punish* it. "Early-warning" mechanisms have been devised, along with interventionist strategies aimed at nipping genocide in the bud. Emphasis has often been placed on interventions by individual nations or international (usually regional) alliances. In fact, all major cases of genocide suppression have featured military interventions by national armies or regional bodies. These include the Allies' defeat of Nazi Germany; India's intervention in East Pakistan/Bangladesh in 1971; Vietnam's in Cambodia in 1978 to 1979; Tanzania's in Uganda in 1979; the NATO and EU-led initiatives in Bosnia and Kosovo in the 1990s; and the Australian-led peacekeeping force (under the UN aegis) that brought an end to genocidal violence in East Timor in 1999. Attempts to globalize such interventions have had some success, notably through UN-sponsored peacekeeping and postconflict peace building. But more ambitious mechanisms, such as the "international peace army" proposed by genocide scholar Israel Charny (1999, p. 650), have so far foundered on a lack of political will.

From an epidemiological perspective, several core issues arise in the study and prevention of genocidal outbreaks. A central challenge is to decide whether a large death toll (even if only relative to group population) is by definition an element in genocide, or whether nonfatal and nonphysically injurious phenomena, such as cultural genocide, should also be included. For the most part, cases of alleged genocide have failed to arouse much interest among governments, international institutions, and modern publics, if mass killing is absent. An exception is the forcible transfer of Aboriginal children to white families in Australia, which a commission of inquiry found to be genocidal under the UN Convention definition. Another example, more amenable to an epidemiological framing, is the growing acceptance in international law of sexual violence against women as not only a concomitant of genocide but genocidal in itself. This interpretation was buttressed by the outbreaks of mass rape in the Balkans in the early 1990s—and in Rwanda in 1994, where women and girls were not only physically violated but often infected with the HIV virus by their attackers.

To the extent that mass killing *is* considered essential to genocide, debate inevitably arises over the scale of the killing. To cite just one instance, estimates of Bangladeshis killed in 1971 range from a low of 200,000 to a high of 3 million. Population data—notably censuses carried out before and after a genocide—can help to narrow the range of estimates. Such data have been crucial to determining the number of victims of Joseph Stalin's regime in the USSR (1928–1953) and Mao Zedong's in China (1949–1976). Where genocidal regimes have collapsed, such as the Nazis in Germany and communist rule in the Soviet Union, the documentary record left by the perpetrators has also been vital to evaluating death tolls and degrees of intention in the killing.

An especially significant epidemiological issue is the place of disease, and the structured undermining of public health, in genocidal outbreaks. Many scholars and other commentators have been reluctant to apply the term *genocide* to the destruction of indigenous communities, in the Americas and elsewhere, following Western colonial invasion and occupation. The key sticking point has been the prominence of disease as a mechanism of demographic collapse, which is sometimes presumed to rule out genocidal intent. More recent analyses, however, have stressed the interaction of disease with other factors, such as colonial assaults on the indigenous land-based and nutritional resources, as well as debilitating psychological trauma caused by the destruction of long-established social networks and cultural practices.

A similar conundrum arises when we consider cases of mass famine and material privation. The cases most commonly deployed in the genocide studies literature include (in chronological order) Ireland in the 1840s; the great famines in British India in the late 19th and early 20th centuries; the deaths of

hundreds of thousands of Germans under Allied blockade during, and especially after, World War I; the massive mortality suffered in Ukraine and Soviet Central Asia following the imposition of agricultural collectivization under Stalin (1932–1933), which Robert Conquest alleged was employed by the Soviet regime as a means of crushing Ukrainian nationalism; the famine, probably the largest in history, associated with Mao Zedong's "Great Leap Forward" in China (1958–1961); and repeated waves of starvation in Ethiopia under the dictatorial Dergue regime of the 1970s and 1980s.

In all these cases, debate centers on the degree of intention of the alleged perpetrators and the power they possessed, but chose not to employ, to remedy conditions of famine, pervasive malnutrition, and/or disease epidemics. While many scholars and policymakers are reluctant to stretch the genocide framework this far, it is notable that the hundreds of thousands of Jews who died from starvation and disease in the ghettoes and concentration camps of Nazi-occupied Europe are routinely numbered among the roughly 6 million victims of the Jewish Holocaust.

A final issue worth considering from an epidemiological perspective is structural violence as a form of genocide. Various commentators have held that the structure of global society—in which extreme poverty and curtailed life spans are the lot of hundreds of millions of people—constitutes a form of genocide against the poor. This is implicit in the 2005 statement by the UN Special Rapporteur on the Right to Food, Jean Ziegler, that "every child who dies of hunger in today's world is the victim of assassination" (Ziegler cited in "UN Expert Decries 'Assassination'," 2005, Online); Ziegler referred to the *daily* death of 100,000 people from starvation as a "massacre of human beings through malnutrition." Specific institutions, such as the World Bank and International Monetary Fund (IMF), stand accused of imposing "structural adjustment" programs that inflicted mass debility and mortality on vulnerable populations in Latin America, post-Soviet Russia, and elsewhere. Since the consequences of such measures were fairly predictable, and in any case were observable by those who imposed and then retained them, a *prima facie* case for genocide might be made—although such thinking remains quite far from the mainstream of genocide scholarship. In a similar vein, some have contended that the reluctance to supply lifesaving antiretroviral drugs to developing-world populations afflicted by AIDS constitutes intentional mass killing—hence genocide, or at least a crime against humanity. The UN Special Envoy for HIV/AIDS in Africa, Stephen Lewis, has stated that "those who watch [the AIDS pandemic] unfold with a kind of pathological equanimity must be held to account. There may yet come a day when we have peacetime tribunals to deal with this particular version of crimes against humanity" (cited in Mann, p. 61).

Genomics

An organism's genome could be likened to an enormous set of encyclopedias, and genomics is the science of reading and interpreting all the entries in the set. The entries in the encyclopedia could be equated with the genes encoded in an organism's genome. The genes contained within an organism's genome control every aspect of its life. They control growth, maintenance, and development, and for humans, the genome also includes information that controls

behavior, physiology, and the susceptibility to some diseases. Disease susceptibility or resistance is of great concern and interest in the areas of medicine and public health. Determining the interplay of genetic information and the detection, prevention, and treatment of disease is the combined job of epidemiologists and genome researchers.

A Genomics Primer

Genomics is a field that encompasses many areas of science, simply because it involves the smallest building block of life, DNA. Almost every cell within an organism contains its unique genome. Genomes are inherent in an individual and a species. Every individual or organism within a species has certain derivations of that species' genome. Genomes of individuals within a species are quite similar; for example, all humans are at least 99% genetically identical. Because of this close similarity, it is enough to study one or a few genomes within a species to glean information for the entire population.

Genes contain DNA, and chromosomes are made up of genes. Broken down even further, DNA contains the information to make RNA. RNA contains the information to make proteins. All these different levels of genetic structure make up a genome. DNA is made up of four similar chemicals called bases. These bases are repeated in a different order many times and, in the case of humans, enough times to make up approximately 3 billion base pairs. It is the difference in this order that accounts for the diversity within humans and between humans and other organisms. Within the 3 billion base pairs that make up the human genome, there are approximately 20,000 to 25,000 genes. Genes contain the information to make proteins, and RNA is the template that serves as the mediator in creating proteins from genes.

The cell uses the components of RNA as the building blocks of proteins. Proteins are composed of 20 different elements called amino acids. Proteins are involved in many different facets of the working human body. Proteins act as enzymes that are involved in metabolism. They can also be hormones that are involved in a process known as cell signaling. Cell signaling is a type of communication between and within cells as a response to the environment within the body. This communication guides cell actions.

Proteins also act as transporters. Examples of transporter proteins are antibodies that transport or bind antigens, foreign substances in the body, to the immune system for destruction. Hemoglobin, the protein found in red blood cells, transports oxygen from the lungs to other parts of the body. Proteins are also part of the structural components of the cell. They make up structural tissues such as that in muscles, collagen, hair, fingernails, and much more.

Because not every gene in a genome is recognizable, it is important to derive the entire sequence of a genome. Having the whole sequence of a genome will help scientists recognize what sequence is a gene and how or if that gene has a role in the function of other genes in the genome. Many areas of the genome do not contain genes. Some scientists claim that these areas are "junk" DNA, simply because these regions do not have a designated function or one is not yet known. Studies are being conducted to determine whether there is function associated with "junk" DNA and to propose reasons for why this sequence is retained in the genome.

Branches of Genomics

The advent of genomics and the Human Genome Project has broadened the scope of genomics by creating offshoots into new branches of learning. These other "-omics" disciplines include proteomics, transcriptomics, metabolomics, pharmacogenomics, and many more disciplines are developing as research continues and data are published. Proteomics is the study of the structure and function of proteins. Transcriptomics is the study of the degree of expression of all known genes in an organism, and metabolomics is the study of metabolites, or end products, that result from cellular processes. Pharmacogenomics studies the interaction of genetic variation on drug response and efficacy. The aim of pharamcogenomics is to develop personalized drug therapy based on an individual's specific genome to reduce adverse side effects and improve the response of the body to specific drugs. Apart from creating new disciplines, the Human Genome Project has influenced other scientific areas such as forensics, agriculture, anthropology, and epidemiology.

Genomic scientists analyze the function of genes within an organism to determine how genes create or influence phenotypic outcomes. These scientists have also begun the difficult task of examining the complexities of how the interaction of genes and environmental exposures is involved in the occurrence of disease. Epidemiologists, and especially molecular epidemiologists,

study how genetic as well as environmental factors influence disease etiology. Epidemiologists will apply this knowledge to determine the distribution of disease as well as to develop prevention plans to stem the occurrence of disease within families and whole populations. This knowledge will also help epidemiologists determine better methods for detection of disease and better treatments for disease conditions.

So how does epidemiology factor into the world of genomics? Genomics along with epidemiology will play an important role in deciphering the issues affecting the health of human populations. There are limitations in applying genomic data to human population health. Problems have resulted in translating the findings from the study of genomic data and applying those findings to medicine and public health practices. This is where epidemiology, which is the science and logic behind the institution of public health practice, will be essential. Many epidemiologists believe that epidemiological practices will be necessary to fulfill the promises of the Human Genome Project.

Four small chemicals in DNA contain the information controlling all the cellular actions in the body. Problems that arise during cellular actions as well as the effects that result from gene-environment interactions can lead to disease. The genome of human individuals differs by 1%. This difference or variation in single bases between individual genomes is called a single nucleotide polymorphism, or SNP.

To be considered an SNP, a variation must occur in that gene in at least 1% of the population. SNPs can occur anywhere in the genome, and they show up every 100 to 300 bases in the 3 billion base pairs human genome. These single base changes affect how individuals react to certain diseases; how they react to factors in their environment such as pathogens, chemicals, and toxins; and how individuals respond to treatment. A change in a person's genetic code does not necessarily cause disease in an individual, but it can give information as to the likelihood that an individual will develop a certain disease. Research is still being conducted regarding the effects of SNPs because when it comes to complex diseases such as cancer, diabetes, and heart disease, it is not one gene that is involved but many.

Another facet of genomic research is in the area of genetic disorders. Genetic disorders can result from mutations in a gene, abnormal chromosome number, multiple repeats of three bases, or the defective gene can be inherited from a parent. Mutations can occur at a single base location with an exchange of one base for another, insertions of one or more bases, or deletions of one or more bases. Mutations can also occur at the chromosome level with gene duplications or deletions of large regions of the chromosome, or portions of one chromosome can be translocated or displaced to another chromosome. Mutations, or changes in the sequence of genes, can cause errors when genes are translated into proteins, which in turn can create proteins that are partially functional or not functional at all. Improperly functioning proteins can play a part in the development of disease.

Mutations and SNPs all result in gene variants. Gene variants are essentially the same as other genes, but there are slight differences. Many studies are being conducted on gene variants within families and populations. Case-control studies on the incidence of disease in populations often provide a basis for further research on the discovery of new genes. Application of that data can be used to develop assumptions on how specific genes are related to disease in underlying populations.

Because of the huge mass of published data on genomics and molecular epidemiology, a network called HuGE Net has been established. HuGE Net, or Human Genome Epidemiology Network, is a global collaboration that aims to provide information on human genomic variation and health and on the quality of genetic tests for screening and prevention. The HuGE Net includes journal clubs, journal reviews, fact sheets, case studies, newly published articles, and links to informative Web sites. HuGE Net will be a useful tool for the public as well as scientists in making sense of all the information available on genomics and health.

Epidemiology and the Future of Genomics

Epidemiology will help measure the impact that gene variants have on the risk of disease, and it is hoped that it will be able to draw associations between modifiable risk factors and their interaction with gene variants. Epidemiology will also have an effect on the future of genomic studies. In the field of gene discovery, epidemiological practices will play a role in study design with regard to participant selection and the ability to generalize results to different populations. Epidemiology will also be needed to determine the efficacy and safety of newly developed genetic tests in different populations. Genetic testing will need to be evaluated based on sensitivity and specificity.

Biomarkers, which are substances that are used to indicate the state of the biological environment within the body, will become useful tools in determining measures of exposure. Biomarkers can be specific chemicals present in the body or they can be by-products of the breakdown of chemicals in the body. In the scope of genetics, biomarkers can present themselves as functional or dysfunctional proteins. These proteins could be the result of mutations or SNPs in an individual's genome. Research involving transcriptomes, proteomes, and metabolomes may show correlations with future risk of disease. This research may help bridge the gap between early exposure and the development of disease later in life.

Another promise of genomics is that in the future an individual will be able to go to their doctor and have genetic testing done to determine the risk of disease given their genetic variants. This concept is called genomic profiling. Epidemiological data along with clinical trials will be needed to determine and develop risk estimates and to assess whether genomic profiling will have validity and value.

Genomic profiling has also raised questions on cost-effectiveness. Using genetic information to develop interventions may be no more effective at disease prevention than epidemiologic studies that have developed generic population-wide interventions such as smoking cessation, increased exercise, and institution of a proper diet. Interventions based on genetic information may also be more costly. Other cost-effective issues are raised in the field of pharmacogenomics. Epidemiological parameters will be necessary to determine the value of completing genetic testing prior to the selection of a drug therapy.

Genomics will also affect study design, the analysis of data, and how those data will be interpreted. The effects on study design will include the appearance of large-scale cohort and case-control studies and the development of new study designs such as the case-only study design. The case-only study design has been used to study gene-environment interactions as well as how multigene interactions relate to the cause of disease.

New and emerging methods for complex data analysis are also a result of genomics. Sample size will greatly increase as a result of genomic data. However, within this vast amount of data, only a fraction of the information will likely have any relevance to the aims of the study. Sorting this large amount of information will require the development of new statistical algorithms. These new algorithms must be tested before they can be used to deem them practical in epidemiologic studies. The test will be in proving reproducibility of outcomes. Emerging analytical methodologies include hierarchical regression modeling and Bayesian methods. Interpretation of data will be strengthened by genomic research in the sense that the statistical power of association between environment and human disease will be enhanced. Associations between genetic variants and environmental factors will be extremely helpful in clarifying the complex issue of disease etiology.

Genomics is influencing and will continue to influence epidemiology and epidemiology will have the same effect on genomics. These two disciplines exist in quite separate worlds. Training for scientists in both disciplines will need to be undertaken to keep abreast of the rapidly changing worlds of both genomics and epidemiology. Collaboration will also be necessary to ensure a minimization of bias and to eliminate confounding factors in research being undertaken. Deciphering the genetic code to determine its role in disease etiology will be crucial to understanding health and developing disease preventions.

Applying genomic concepts to epidemiology will have to be done in the context of social and ethical beliefs with an end goal of improving human health. The race to publish the entire human genome is over, and now begins the painstaking review, analysis, and application of the information contained within the code. The generalized population-wide interventions developed by epidemiologists thus far have provided a strong basis for the next stage of epidemiology, examining the complex interplay of genes and environment. It is hoped that this examination will lead to the development of more specific plans for prevention, detection, and treatment of the diseases that plague the world today.

Genotype

The term *genotype* was introduced in the developing field of genetics following the rediscovery and further application of Gregor Mendel's work during the early 1900s. The genotype is the genetic constitution or makeup of an individual. It can be used to refer to the overall assemblage of genes that an individual possesses at all genetic loci, the positions occupied by genes on a chromosome, or more typically, in the specific sense to refer to the genetic constitution at a precise genetic locus in an individual. In the second usage, we refer to the alleles, the alternate forms of a gene, which are present at a specific locus on each member of the chromosome pair on which the gene is located. The introduction of new genetic variation in the base pair structure of the alleles is the result of the process of mutation. Mutations, or mutant alleles, are alterations in the genetic material of plants and animals that can have positive, deleterious, or neutral change effects. Epidemiological studies and medical genetics typically focus on mutations having deleterious or disease-causing effects.

The genetics of the ABO blood group is familiar to most people and provides a useful tool for explaining genotype in relation to phenotype. There are four phenotypic expressions in this trait. Some people have type O blood because their blood does not react with the antibodies for either A or B antigens, the proteins on the red blood cells that cause antibodies to be made. Other individuals have type A or B blood because their blood reacts with antibodies for the antigens in these respective blood types. Finally, some people react to both type A and B antibodies and are deemed type AB. At the genetic locus for ABO on the chromosome number 9 (Chr 9) pair, there are a number of possible pair combinations of alleles A, B, and O that yield any one of six genotypes that account for the four phenotypic expressions. Type AB individuals have the genotype AB, which means on one member of the Chr 9 pair, they have an A allele, and on the other, a B allele. Type O individuals are genotypically OO (an O allele on each Chr 9). People with type A blood may be genotypically AA or AO, as type A is a dominant trait with respect to O. Type B is also dominant, yielding two possible genotypes, BB or BO. A and B are said to be codominant, as both traits are expressed in individuals with this genotype.

Some genetic disorders occur when an individual inherits a single disease-causing allele. These disorders are said to exhibit dominance. For most of these disorders, the disease gene is located on one of the autosomal, or non-sex-determining, chromosomes, and the disorders are labeled autosomal dominant (AD). This means that the mutant allele needs to be located on only one member of the chromosome pair for the disorder to occur (assuming no other complications that sometimes occur in the expression of the disease). Achondroplasia, a genetic disorder causing short stature predominantly due to problems converting cartilage tissue to bone, is an example of a disorder that is inherited in an AD fashion. This disorder is caused by a mutation in the fibroblast growth factor receptor 3 gene.

A second large group of genetic disorders involving the genes located on the autosomal chromosomes is labeled autosomal recessive (AR), due to the fact that for these disorders to manifest, there must be a mutant allele on both members of the chromosome pair. An example of an AR disorder is sickle cell disease, a disease involving abnormalities in hemoglobin, a complex protein in the red blood cells used to carry oxygen. Patients with sickle cell disease have mutations in both the alleles of the Beta Hemoglobin gene.

Finally, there are some disorders that result from mutations in genes located on the X chromosome, one of the two sex-determining chromosomes (the other is the Y chromosome). These disorders may manifest in a recessive or dominant manner and are referred to as X-linked recessive or X-linked dominant disorders, respectively. In X-linked recessive disorders, if a male has the mutation on his only X chromosome (males have a genotype of one X chromosome and one Y chromosome while females have two X chromosomes), he will manifest the disorder. However, for a female to have this X-linked recessive disorder, she must have a mutant allele on both X chromosome. The occurrence of mutations in the same gene on both X chromosomes in female individuals occurs less frequently in populations, such that the majority of individuals affected with an X-linked recessive disorder are males.

With the major advances in techniques of human molecular genetics in the past 20 years, we have witnessed a renewed focus on the genetic factors influencing disease and the potential for treatment, diagnosis, and prediction of diseases through genotype information. Current research focuses on the relationship of the genotypes in individuals affected with a genetic disorder to the phenotypic (chemical, behavioral, and physical expression of the underlying genotype and environmental factors) outcomes, such as clinical findings found by physical examination in patients with the disorder. New methods for detecting mutations in genes have identified mutant genotypes not previously observed in genetic disorders. The Human Genome Project has led to the development of hundreds of new genetic tests designed to identify the genotypic information of individuals thought to have specific genetic diseases. The success of this program and similar initiatives, along with continuing scientific advances in molecular medicine, have moved us even closer to the day when physicians will be equipped with detailed genetic data to assist them in the prediction and prevention, and the diagnosis and treatment, of a broad array of genetic diseases in human populations.

Geographical and Social Influences on Health

There is abundant and growing evidence that places matter to health, over and above the characteristics of individuals. The relevance of places to health has been considered across a wide range, from the national scale down to the neighborhood level. This entry highlights some of the key geographical and social factors (including socioeconomic status, social capital, and income inequality) and empirical evidence that have been explored at the country, state/regional, and neighborhood levels, and that have advanced existing knowledge in the field.

Country-Level Contexts

Geographic contexts at the country level have long been recognized as related to variations in health. Life expectancy and mortality rates from particular diseases are known to vary widely across countries. A half century ago, evidence was gathered that suggested that part of these differences may stem from variations in lifestyle behaviors, which may in turn be socioculturally determined. In the 1950s, Ancel Keys initiated the Seven Countries Study, to examine the relations between diet and cardiovascular diseases within and across cohorts of men in Finland, Greece, Italy, Japan, the Netherlands, the United States, and Yugoslavia (Keys et al., 1967). Using dietary records, considerable variations were found in dietary intakes between countries. Marked variations in mean serum cholesterol levels across countries were furthermore identified. These variations were thought to, in part, account for corresponding differences in incidence and mortality rates of coronary heart disease.

Epidemiologist Geoffrey Rose (1985) made the key distinction between the *causes of cases of disease* within a population and the *causes of incidence of disease*. Rose contrasted the population distribution of serum cholesterol levels in Japan (a country in which heart disease was uncommon) to that in eastern Finland (where the incidence rate of heart disease was relatively high) and observed that the entire population distribution of cholesterol in Finland was to the right of the distribution in Japan. In other words, most of the population in Finland was "hypercholesterolemic" relative to the distribution in the Japanese population. It was this contrast (reflecting the causes of incidence of disease) that could potentially explain the much higher rates of cardiovascular disease in Finland compared with Japan.

Migrant studies have also provided evidence to support the important influences of geographical and social contexts on health, with these differences

arising from members of the same racial or ethnic group. For example, Japanese populations in Japan, Hawaii, and San Francisco have been observed to have very different levels of saturated fat intakes, as well as serum cholesterol levels, body weight, and age-adjusted coronary heart disease rates, which are all respectively higher with closer proximity to the mainland United States. These patterns are consistent with effects of context on dietary intakes, since genetic factors would be relatively homogeneous across these populations of Japanese descent.

Moreover, the vast differences in life expectancy and mortality across countries globally have been attributed to the socioeconomic attributes of these societies, including levels of economic development and economic inequality. Economic development may be related to health through differences in the availability of food and other local material resources and related effects of urbanization. For instance, there is some evidence to support that populations in countries at higher levels of economic development (as measured by the gross domestic product, GDP, per capita) have higher levels of body mass index and serum cholesterol. Among rich countries, variations in average life expectancy are not explained by their GDP levels, and this observation gave rise to income inequality as a possible explanatory factor. Evidence in the 1990s among selected rich countries showed a strong positive correlation between a higher share of total income going toward the least well-off proportion of the population and higher life expectancy. Mechanisms put forth for this relationship have included negative health effects resulting from individuals' feelings of relative deprivation, declines in social cohesion and trust, and underinvestments in public goods such as education and health care, as interests of the rich move away from those of the poor. Nevertheless, since the initial evidence, a number of ecologic studies of the effects of income inequality at the country level have been conducted that have been relatively mixed in their findings.

State and Regional Contexts

State and regional contexts have been proposed to have independent effects on one's health, primarily through policy-related mechanisms. Examples of two such characteristics that have become prominent in the epidemiologic literature by way of demonstrated state-level associations with health in the United States are *social capital* and *income inequality.*

Social capital has been defined as the resources within social networks that can be mobilized for purposeful actions. Alternatively, it has been defined as both the social structures and the associated cognitive resources such as trust and reciprocity. While social capital has been conceptualized at the neighborhood and individual levels, its significant associations with health were first demonstrated at the state level in the United States. U.S. researchers analyzed state-level data from the National Opinion Research Center's General Social Surveys on interpersonal trust, norms of reciprocity, and membership in voluntary associations and determined that these social capital variables accounted for significant proportions of the cross-sectional variations in mortality rates across the U.S. states. Lower levels of trust were found to be associated with higher rates of most major causes of death, including heart disease, cancer, infant mortality, and homicide. Similar associations were observed between death rates and norms of reciprocity (the proportion of residents agreeing that "most of the time, people try to be helpful") and per capita membership in civic associations. These associations further remained after accounting for state differences in median income and poverty rates. Since these initial ecologic studies, exploration of the associations between social capital and health outcomes has rapidly expanded to encompass multilevel study designs, with adjustment for individual-level factors such as one's socioeconomic status (SES); investigate other specific forms of social capital (e.g., bonding and bridging social capital, informal and formal social capital) and health outcomes (e.g., cardiovascular and infectious diseases, and obesity and physical inactivity); and measure social capital at more local levels, that is, the neighborhood and community levels.

The associations for state- and regional-level social capital with individual health are thought to be largely mediated by policy-related mechanisms. For example, the collective efforts of state populations built on mutual cooperation and trust may plausibly bring about the implementation of statewide policies such as greater access to high-quality education and health care, and statewide funding of local resources for physical activity, which in turn could affect the health of state residents.

Building on earlier cross-national studies, studies of income inequality at lower spatial units of analysis have been performed within countries, particularly at the state or regional level. Early investigations were

ecologic in design, whereas more recent investigations have applied a multilevel analytic framework, which have taken into account the spatial correlations between individuals in the same area while controlling for individual-level SES to reduce confounding bias. Notably, most of the studies among developed nations that have found an association between income inequality and health have involved populations in relatively inegalitarian countries, conducted primarily at the state level in the United States, whereas findings at more local levels have been generally less significant. Findings at the regional and local levels in more egalitarian countries such as Japan and Sweden have generally been null and possibly may be due to the lack of sufficient variations in income inequality in these settings.

Neighborhood Contexts

There is growing evidence to support the notion that the levels of socioeconomic resources and amenities across neighborhoods, as well as the levels of social resources such as social capital, may affect the health of individuals, after taking into account the socioeconomic characteristics of individuals. Relevant material resources and amenities include the availability of nutritious foods and green spaces; the quality of housing and of health services; the presence or lack of "incivilities," such as graffiti and litter; and environmental hazards, such as air pollution and noise.

A variety of studies have identified moderate yet statistically significant associations between neighborhood SES (typically measured by aggregating individual-level measures of SES from surveys or censuses) and one's risk of dying from cardiovascular disease and from any cause, with 1.1 to 1.8 times higher observed risks of these outcomes after controlling for one's SES. Other studies have reported significant inverse associations between neighborhood SES with chronic disease risk factors, including smoking, diet, physical activity, and hypertension, and with the incidence of heart disease.

Evidence is also emerging on the effects of specific neighborhood material resources on health. For example, in one multilevel study, adjusting for individual SES and other types of food service places, the presence of a supermarket within one's census tract was found to be significantly associated with a 1.5 times higher relative risk of meeting the dietary guidelines for fruit and vegetable intakes, as well as with higher risks of meeting the guidelines for total fat and saturated fat intakes among African Americans.

Neighborhood social resources, particularly social capital, have also been increasingly investigated as a predictor of health outcomes. Using multilevel study designs, these analyses have suggested protective effects of specific forms of social capital (e.g., bonding and bridging social capital) on health behaviors (e.g., physical inactivity) and self-rated health. Such health effects may potentially occur through the promotion of the diffusion of knowledge about health promotion, by influencing health-related behaviors through informal social control, by enabling greater access to local services and amenities, and/or by contributing to psychosocial processes that provide support and mutual respect.

An additional key factor at the neighborhood level relevant to health is residential segregation, particularly by race or ethnicity. *Residential segregation* by race or ethnicity refers to the segregation of racial or ethnic groups along subunits of a residential area. Such segregation, which in the United States has historical roots for African Americans (e.g., through racial discriminatory practices of federal housing policies and bank lending practices), may affect health by influencing the levels of socioeconomic resources (e.g., levels of health care resources, and educational and job opportunities) available to its residents. Some evidence suggests that low-income African American and other minority neighborhoods have been "targeted" with fast-food restaurants and, prior to tobacco legislation, with the advertising of cigarettes. Furthermore, residential areas that are predominantly African American have been associated with higher rates of infant and adult mortality, although such evidence has primarily been drawn from ecologic (rather than multilevel) studies.

Geographical and Spatial Analysis

All events have space and time coordinates attached to them—they happen somewhere at some time. In many areas of epidemiology, recording the place of individual events and exposure is vitally important. The recent surge in the availability of desktop computing power, geographical information systems (GIS) software, and interest in the effect of neighborhood conditions on development of disease have caused a resurgence of interest in spatial data analysis.

Types of Spatial Data

Spatial data consist of measurements or observations taken at specific locations or within specific spatial areas. In addition to values for various attributes of interest, spatial data sets also include the locations or relative positions of the data values. There are three main types of spatial data. The first type of data, geostatistical data, is measurements taken at fixed locations. In most cases, the locations are spatially continuous, that is, data locations are available in close proximity to each other. An example of geostatistical data would be measures of the concentration of pollutants at monitoring stations. The second type of spatial data is lattice data, which are area-referenced data with observations specific to a region or area. An example of lattice data is the rate of specific types of cancer deaths by state from the National Cancer Institute's cancer mortality atlas. The areas can be regularly or irregularly spaced. Areas are often referenced by their centroid. The third type of spatial data is point pattern data, which arise when locations themselves are of interest. Spatial point patterns consist of a finite number of locations observed in a spatial area. Examples of point pattern data include the locations of women diagnosed with breast cancer on Long Island.

Spatial Scale

The spatial scale or resolution is an important issue in the analysis of spatial data. Patterns observed in spatial data may be the result of different processes operating at different scales. This is known as the modifiable areal unit problem (MAUP). The MAUP consists of both a scale and an aggregation problem. The concept of the ecological fallacy is closely related to the MAUP. The scale problem refers to the variation that can occur when data from one scale of areal units are aggregated into more or fewer areal units. For example, much of the variation among counties changes or is lost when the data are aggregated to the state level. The choice of spatial areas is often arbitrary in nature, and different areal units can be just as meaningful in displaying the same base-level data. Clearly, it is more meaningful to use "naturally" defined areas (e.g., neighborhoods or hospital catchment areas) rather than arbitrary administrative units.

Frequentist Versus Bayesian Analysis

Traditionally, epidemiologists have used the frequentist approach for the analysis of data, including spatial data. However, fluctuations in disease rates may occur because of the sparseness of the data in certain areas. In addition, data are often spatially correlated, meaning there is a tendency of adjacent areas to have similar rates of disease incidence. In many cases, there are no valid or accepted frequentist methods for tackling these problems, or the frequentist methods are complex and difficult to interpret.

In contrast, Bayesian models can easily incorporate spatial correlations. The ability to consider such correlations serves to stabilize estimates of relative risk, making them less vulnerable to random fluctuations in the observed number of events in each area. The Bayesian approach begins by considering our knowledge regarding the parameters being estimated, prior to the collection or inspection of any current data. This

information, termed *prior information*, or simply the "prior," is usually represented by a probability density function that quantifies the investigator's beliefs about the likelihood of any particular value of the parameter being the true value, before we know the current data. This prior knowledge is then revised using Bayes's theorem, based on the new or current data, to obtain posterior information represented by a posterior probability density function. Bayesian analysis is increasingly being used in spatial epidemiology. While there is no debate about the mathematical truth of Bayes's theorem, questions regarding the interpretation of Bayesian results, however, largely center on methods used to define the prior information.

Analysis of Spatial Point Pattern Data

In spatial epidemiology, one pattern of particular interest is the presence or tendency of locations to cluster together, that is, for disease to occur more frequently in cases in close proximity to one another than would be expected from a set of cases with no common environmental exposure. Complete spatial randomness defines a situation where the disease of interest is equally likely to occur at any location within the study area, regardless of the locations of other disease events. To test the presence of a cluster of disease, we determine if disease occurrence follows a uniform distribution across the study area. There are numerous examples of identifying clusters of disease occurrence.

A second approach to the analysis of spatial point pattern data is the use of multilevel models when examining the association of area-level exposures on individual-level disease occurrence. There is increasing interest in the use of area-level characteristics as having an effect on various health outcomes over and above individual characteristics. In multilevel models, an individual, including his or her exposures, covariates, and disease occurrence, is considered to be nested within a spatial area. For example, individuals (Level 1) may be nested within census tracts (Level 2), which are, in turn, nested within counties (Level 3). In multilevel models, the random components are assessed at the individual level and at the area level(s). Multilevel models are able to calculate the variance between areas as a percentage of the total variance thereby providing an indication of the spatial variation. Recent advances in multilevel models also allow for calculation of the median odds ratio that represents the extent to which a person's probability of disease occurrence is a function of the area in which he or she resides. An additional measure, the interval odds ratio, provides for comparison of the importance of the area-level characteristic relative to the variation remaining among areas. Although the multilevel approach is typical of most studies examining area-level effects, it ignores frequently the spatial adjacency between areas and does not effectively incorporate any notion of space.

A third method, the geostatistical approach, considers individuals and areas to be distributed across continuous space that allows for estimation of the spatial scale of the variation in disease occurrence unlike multilevel models and examination of the effect of weighted area-level characteristics on the same outcome. Individuals are positioned at their geocoded location using latitude and longitude and nested within a prespecified spatial area. Area-level characteristics can then be used in circular space around the location of the individuals. This area may exceed the boundaries of the area of residence. Weights are then obtained by means of a decay function to reflect the magnitude to which area-level characteristics at distant locations from individuals have a lower impact than those that were closer to their location.

Analysis of Lattice Data

Lattice data are observations from a random process observed over a countable collection of spatial areas supplemented by a structure describing the location of each area relative to its surrounding areas (i.e., adjacency matrix). Data observed can be continuous (e.g., mortality rate) or discrete (e.g., participation in physical activity).

Examining clusters of disease occurrence using lattice data has been done frequently. The goal for methods based on scanning local disease rates is often to identify areas with unusually high or low local disease rates. There are several approaches to the analysis. First, many studies have used a spatial scan statistic. The statistic uses a window of variable angles and elliptical shapes that moves across the map. The null hypothesis is that event rates are the same in all windows. Clusters are defined as areas having either a lower or higher rate of disease than expected. The process of cluster detection uses Monte Carlo permutations of the data set.

A second method uses a GIS to define a set of grid points covering the study area and calculate

local incidence proportions within circles centered at the grid points. An area falls within the circle if the area's centroid falls within the circle. To assess statistical significance of the local incidence rates, Rushton and Lolonis (1996) use Monte Carlo tests at each location based on an overall constant risk hypothesis where cases are assigned to areas according to the incidence rate observed for the entire study area.

A third method is the use of area-level data for the exposure, covariates, and disease rates as part of an ecological study design. Bayesian methods are frequently used to analyze these data. Area-level relative risks are estimated by integrating local information consisting of the observed and expected number of cases in each area, prior information on the overall variability and/or spatial structure of the relative risks, and the potential effect of spatially defined covariates. The expected number of events is frequently based on the age and sex distribution of the area and a reference set of disease probabilities. The hierarchical statistical model consists of two levels. The first level represents the local variability (within area) and is modeled using a Poisson distribution. The second level consists of a random effect structure that accounts for the extra-Poisson variability due to the aggregated effect of unknown confounders via a spatial ''clustering'' component and unstructured ''heterogeneity'' component. In such studies, a statistical challenge is to account both for potential errors in the numerator and/or denominator of the rates and for unequal population sizes inducing differential variability of the disease rates between areas. Care needs to be taken not to extrapolate to the individual level based on these aggregate data (ecological fallacy).

Gestational Age

Gestational age is the time period in which the fetus grows inside the uterus. Measured in weeks, gestational age has implications for the fetus's growth, as well as cognitive and physical development. The gestational age of a fetus is particularly important when determining the potential negative effects of a fetal exposure to toxins or infection and has a direct impact when planning appropriate medical treatment for such situations.

Gestational age is divided into two periods: embryonic and fetal. Preceded by the embryonic period, the fetal period begins at the gestational age of Week 10 and continues until birth. Prenatal development benchmarks are linked to gestational ages. For example, at the gestational age of 7 to 8 weeks, all the vital organs have begun to form along with the formation of bones and cartilage. By the gestational age of Weeks 9 to 13, the genitalia have formed and the entire fetus weighs about 1 oz. By Weeks 21 to 23, the fetus's eyes have developed and the fetal heartbeat can be heard by stethoscope.

A normal pregnancy has a gestational age ranging from 38 to 42 weeks with a full-term pregnancy considered to be 40 weeks. Infants born at a gestational age of less than 38 weeks are considered premature and are susceptible to increased risks of morbidity

and mortality. For example, the vast majority of infants born at 24 weeks will experience respiratory distress syndrome as the air sacs in the lungs have just begun forming.

Gestational age can be calculated before and after birth. Before birth, gestational age is calculated as the time from the first day of a pregnant woman's last menstrual cycle to the current date. Although often used to determine gestational age, health professionals recognize the potential for inaccuracies using this method due to variations in ovulation dates. Therefore, there are a number of other methods employed to accurately determine gestational age. One such method is the use of an ultrasound whereby growth can be determined through measurements of the head and abdomen. Another method is to determine the date of conception as per the mother's knowledge.

After birth, a newborn's gestational age can be measured using the Ballard Scale or the Dubowitz Exam. The Ballard Scale involves an examination of the neuromuscular and physical maturity of the newborn, while the Dubowitz Exam focuses on the neurological maturity of the newborn.

It is important to note that although gestational age may be accurately determined by the methods mentioned above, developmental growth at each week may vary from fetus to fetus. An estimated 3% to 10% of all newborns are determined to be small for gestational age (SGA) because their birthweight or length was determined to be less than the 3rd percentile. SGA newborns have higher incidence of learning disabilities, autism, and attention deficit disorder (ADD).

Global Burden of Disease Project

The Global Burden of Disease Project (GBDP) draws on a wide range of data sources to produce consistent estimates of the cost of morbidity and mortality worldwide, as defined by the years of healthy life lost due to injury and illness. The GBDP is conducted by the World Health Organization (WHO) and updates the Global Burden of Disease Study for the year 1990, which was commissioned by the World Bank and carried out by the WHO and Harvard University in 1992. Both the original study and the GBDP quantify the burden of disease using the concept of the disability-adjusted life year (DALY), which allows an estimation of the total years of healthy life in a population by combining two types of information. Years of life lost (YLL) represent the cost of premature mortality, calculated as the projected years a person was expected to live; years lost due to disability (YLD) represent the years of healthy life lost due to diminished quality of life caused by illness or disability. One DALY is equivalent to the loss of 1 year of life in full health, so that the DALY cost would be equivalent for a person in perfect health dying 1 year prematurely, or a person living 2 years in a health state judged to be half as desirable as the state of full health.

The primary advantage of using a common metric such as the DALY is that it allows comparison of the costs of disparate medical conditions and the benefits that might be gained by different interventions. It is particularly important that the DALY approach assigns a value to the cost of ill health as well as to death, allowing that an estimation of the societal cost of conditions such as hearing loss are seldom fatal but may significantly reduce an individual's quality of life. This approach is commonly used today but was an innovative concept when included in the 1990 report. The DALY approach allows governments and other policymakers to evaluate the costs of disparate medical conditions, make informed judgments about where to target resources in order to produce the greatest improvement in health for a given investment of resources, and evaluate the comparative effectiveness of interventions targeted at different conditions. Many countries have adopted the global burden of diseases (GBD) approach to guide national priorities in health research as well.

For 2001, the GBD found that, as in 1990, the most important causes of disability in all regions of

the world were neuropsychiatric illnesses, which accounted for more than 37% of YLD for adults above 15 years worldwide. The greatest amount of loss of healthy life due to premature mortality was caused by noncommunicable conditions, including cancers, diabetes, and heart disease: These conditions accounted for almost 50% of DALYs lost in low- and middle-income countries and more than 85% of the loss in high-income countries.

Goldberger, Joseph
(1874–1929)

Joseph Goldberger was the medical detective and pathbreaking epidemiologist in the U.S. Marine Hospital Service (later the U.S. Public Health Service [PHS]) responsible for discovering that pellagra was a nutritional disease. Goldberger's research and controversial experimentation revealed that pellagra could be cured and prevented by eating a balanced diet rich in animal protein or augmenting the diet with brewer's yeast. Later research following Goldberger's death revealed that insufficient nicotinic acid or niacin in the diet caused pellagra.

Born in Giralt, Hungary, on July 16, 1874, Goldberger emigrated to the United States with his parents and three older siblings in 1883 after a plague wiped out the herd of sheep on which the family depended for its living. Among the millions of Jewish immigrants to arrive in the United States in this era, Joseph's parents, Samuel and Sarah Goldberger, opened a small grocery store on New York's Lower East Side. Joseph studied at the City College of New York but soon transferred to Bellevue Hospital Medical College where he received his medical degree in 1895. After several unsatisfying years in private practice in Wilkes-Barre, Pennsylvania, Goldberger passed an entry examination and was commissioned an Assistant Surgeon in the U.S. Marine Hospital Service. He began his career as a federal physician examining immigrants at the Barge Office in lower Manhattan while a scorched Ellis Island was being reconstructed.

Between 1902 and 1906, Goldberger battled epidemics, gaining valuable experience in both field and laboratory. He fought yellow fever in Mexico, Puerto Rico, Mississippi, and Louisiana. While on duty in Louisiana, a colleague, Farrar Richardson, introduced him to Mary Farrar, the daughter of a wealthy Episcopalian New Orleans family and the grandniece of Confederate president Jefferson Davis. Although both families initially opposed the marriage on grounds of religious difference, Joseph and Mary married in 1906, deciding that while they eschewed traditional religion, rationalism, humanitarianism, research, and science would guide their lives together. They had four children.

Shortly after his marriage, Goldberger was assigned to the Hygienic Laboratory in Washington (precursor of the National Institutes of Health) to study typhoid fever. Soon, he was off to Texas after an outbreak of dengue fever and back to Mexico to battle typhus fever. For the third time, Goldberger was felled and almost lost his life to the pathogens he studied. Previously he had suffered from yellow fever and dengue while battling epidemics. From his work in the field, Goldberger observed that the diseases individuals contracted were often related to the conditions in which they lived. In his almost daily letters to his wife, Goldberger frequently shared his observations that poverty, ignorance, and poor sanitation made some populations significantly more vulnerable to disease than others.

Dr. Joseph Goldberger was earning a reputation as a hardworking, bold epidemiologist. His study of Schamberg's disease and discovery that its characteristic red rash was actually the result of tiny mite bites earned him the reputation for being clever. Collaborating with PHS physician John Anderson, Goldberger

demonstrated that Brill's disease was identical to typhus. In their work on measles, they were able to infect monkeys and learned that the disease was caused by a virus small enough to pass through a Berkefeld filter and that the virus could be identified in a victim's buccal and nasal secretions, but that in patients, infectivity decreased as convalescence proceeded.

In 1912, Goldberger's fine work earned him promotion to the rank of Surgeon. Two years later, he was in Detroit investigating an outbreak of diphtheria when he was summoned back to Washington by Surgeon General Rupert Blue, who requested that he direct the government's investigation of pellagra, which was begun in 1912 but was faltering.

First identified among Spanish peasants by court physician Don Gaspar Casal, pellagra was known as *mal de la rosa.* It killed and caused chronic illness among populations in various parts of Europe, the Middle East, Africa, and Asia. The disease was rampant in parts of southern Italy, where it was called *mal del sole* because it seemed to peak as spring arrived. Italian physician Francesco Frapolli dubbed it "pellagra" referring to the "rough or dry skin" that became the basis for diagnosis and for distinguishing the disease from other ailments. By the early 20th century, pellagra was taking thousands of lives annually, especially in the South Atlantic states. Some called it the "scourge of the South," others dubbed it the disease of the four D's: dermatitis, diarrhea, dementia, and death. By 1912, South Carolina reported 30,000 with a mortality rate of 40%. In the years prior to 1940, 100,000 Americans died of the disease.

Goldberger's notes and underlines in state public health reports from Illinois and southern states, as well as in the published essays of Italian physician Cesare Lombroso, suggest that even before Goldberger headed south, this expert on infectious diseases speculated that dietary deficiency and not a germ was pellagra's cause. His pencilings reveal that Goldberger thought that better diets, especially those with ample milk and fresh meat, might make a difference.

Observing pellagrins (persons with pellagra) in the South's orphanages, mental hospitals, and mill towns, Goldberger became increasingly convinced of his dietary hypothesis. He observed that pellagrins in the South often ate a corn-based diet deficient in animal protein. Staff, on the other hand, often had access to eggs, meat, and milk and rarely contracted the disease. The distinction between inmates and staff was not usually made by pathogens.

Goldberger tested his dietary theory in various venues beginning in 1914. He requested shipments of federal food and fed children in two orphanages, one Baptist and one Methodist, a balanced diet. All those stricken with pellagra recovered, and there were no new cases. At the Georgia State Asylum at Milledgville, Goldberger and his assistant, Dr. George Wheeler, performed dietary research using female inmates. They isolated 36 white female pellagrins in one ward and 36 female African American pellagrins in another ward. Both groups were fed wholesome diets of fresh meat, milk, eggs, and vegetables. A control group of 32, 15 nonpellagrous women, including 17 black and 15 white females, continued the normal diet. Fifteen of the control group developed pellagra symptoms. None of the women on the new diet got the disease. Although demonstrations were suggestive, they were not the kind of controlled double-blind experiments that might have persuaded even the most ardent skeptics that pellagra was a dietary disorder. Nor did Goldberger's efforts dissuade some critics from their belief that there was a pellagra germ.

Goldberger designed a bold assault on the germ theory of pellagra to demonstrate that there was a substance the absence of which from the diet induced the disease. In April 1915, Goldberger, with the assent and cooperation of Mississippi's progressive governor Earl Brewer, fed the corn-based diet ubiquitous among poor southerners to 11 volunteers at Mississippi's Rankin State Prison Farm. Brewer granted pardons to inmates who participated. Six of the eleven showed pellagra lesions when the experiment was ended in November. Goldberger had succeeded in producing pellagra symptoms through dietary change alone.

To persuade critics who continued to insist that pellagra was an infectious disease, Goldberger sought to transmit the disease to 14 healthy volunteers plus himself and his wife in April 1916. Calling his experiments his "filth parties," Goldberger injected into himself and his volunteers the blood of pellagrins. Some also swabbed the secretions from pellagrins' noses and applied it to their own and swallowed capsules containing pellagrins' excrement. None of the volunteers got the disease.

In his effort to determine which nutrients were missing from pellagrins' diets, Goldberger and PHS statistician Edgar Sydenstricker conducted epidemiological

investigations pathbreaking in their thoroughness in seven South Carolina mill villages from 1916 to 1919. Data on diet, housing sanitary conditions, and income among other variables offered an unparalleled view of living conditions that contributed to dietary deficiencies possibly causing pellagra. Some still doubted Goldberger's hypothesis, and he could not identify the missing nutrient.

A downturn in cotton prices in 1921 resulted in southern economic hardship and Goldberger predicted a rise in the number of pellagra cases. He was critical of sharecropping and an agricultural system that impoverished families and discouraged growing diversified food crops. He was equally vocal in criticizing mill owners for paying low wages that left workers unable to afford a balanced diet. Southerners objected to the notion that there would be hunger and more pellagra in the South. However, President Warren Harding stood by the PHS.

By 1925, Goldberger learned that small amounts of dried brewer's yeast could prevent and cure pellagra and at a much lower cost than a regular diet of meat, milk, and eggs. Learning that black tongue was the canine equivalent of pellagra, Goldberger and his associates now worked with dogs in the laboratory searching for the nutritional factor that when deficient in a diet could cause pellagra. During the Mississippi flood of 1927, Goldberger repeated his criticism of the southern economic system as he and Sydenstricker urged the Red Cross to send brewer's yeast to the affected areas and then toured the flooded counties. Again, Goldberger attributed the pellagra he saw to a grinding poverty rooted in the tenant system of agricultural labor and landowners' preference for cotton crops because of their profitability. Seasonal fluctuations in tenant income made a steady balanced diet uncertain at best.

Dr. Joseph Goldberger fell seriously ill in 1928. His last public address was at a meeting of the American Dietetic Association, where he reminded listeners that pellagra was primarily a matter of poverty and that medical science alone could never remedy the social conditions at the root of the disease. On January 17, 1929, he succumbed to hypernephroma, a rare form of cancer. Less than a decade after his death, Conrad A. Elvehjem and his associates discovered that a nicotinic deficiency caused black tongue in dogs. Dr. Tom Spies used nicotinic acid to treat cases of pellagra at the University of Cincinnati College of Medicine and at the University of Alabama, Birmingham Medical School. Nicotinic acid is part of the vitamin B complex. Later, biochemists at the University of Wisconsin learned that corn consumption depressed the level of nicotinic acid retained in the body. The corn-based diet did indeed, then, contribute to the prevalence of pellagra in the South. During World War II, the War Food Administration required all commercially produced white bread to be fortified with niacin. And after the war, state legislatures began to mandate flour enrichment.

Governmental Role in Public Health

Public health is the organized societal effort to protect and improve the health of communities. Public health focuses on the health of the entire population rather than on the health of individuals. The protection of population health is a key governmental responsibility at the federal, state, and local levels. Traditional activities include collecting information on the population, making rules to restrict individual activities that threaten the health of the community, and providing health services and educating people in healthy

behaviors that promote health. While health services and education can be provided by private sector organizations, only governmental authorities are authorized to collect official data and to create and enforce rules to restrict individual and corporate behaviors to protect and improve health. Governments also ensure access to health services for vulnerable and underserved populations.

History of U.S. Governmental Public Health

Organized governmental public health activities in the United States date from colonial times. Officials of the Massachusetts and Plymouth colonies mandated the recording of all births and deaths as early as 1639. The Massachusetts Bay Colony passed a law prohibiting the pollution of the Boston Harbor in 1647; other localities similarly created ordinances restricting activities perceived as dangerous to the health of the population, including laws to isolate people with infectious diseases and to quarantine ships in the harbors. However, there were often no effective governmental organizations to enforce the laws that were put in place.

Permanent boards of health were established in cities of the new United States of America as early as 1780, and scientific discoveries about the nature and transmission of disease provided a framework for their decisions to improve community health. However, for many years these boards were voluntary committees with no administrative staff to carry out their mandate to oversee the protection of water supplies and elimination of health hazards. Local health departments with staff began to appear at intervals in the larger cities (Baltimore in 1798, Charleston in 1815, Philadelphia in 1818, Providence in 1832, Cambridge in 1846, New York in 1866, Chicago in 1867, Louisville in 1870, Indianapolis in 1872, Boston in 1873). County health departments, with responsibility for the rural as well as the urban areas, did not begin to appear until 1911.

In 1850, a committee headed by Lemuel Shattuck published the *Report of the Sanitary Commission of Massachusetts*, calling for the establishment of state boards of health staffed by professional sanitary inspectors. The report also recommended laws and systems to collect data on the population and control the sources of disease transmission, programs to address social problems that affected community health, and improved training of medical personnel. Massachusetts then established the first permanent State Board of Health and State Health Department in 1869.

The earliest federal efforts in public health focused on preventing the transmission of disease via the nation's seaports through a system of Marine Hospitals and a National Quarantine Convention. A National Board of Health was created in 1879, but was only authorized for 4 years and was allowed to expire in 1883. The national Public Health Service was permanently established in 1902, and evolved over the years into the current U.S. Department of Health and Human Services.

Governance Foundation of Public Health in the United States

The organizational structure of governmental public health in the United States is driven by the unique structure of the U.S. government. The use of a federal system of governance provides for multiple layers and multiple players in the delivery of public health services. All three levels of the U.S. government (national, state, and local) are involved in governmental public health. The responsibilities, authority, and funding of those levels vary and sets into play a relational dynamic full of many challenges.

A federal governance system is based on power sharing between a central national government and subnational (i.e., state) governments. This system represents a compromise between centralized and decentralized authority with powers derived from a written constitution as opposed to a unitary system of governance such as the one found in Great Britain.

The U.S. Constitution limits federal powers to 14 enumerated powers among which is not found any public health authority. The last enumerated power, the authority of the federal government "to make all laws which shall be necessary and proper," has been used as a grant of implied power to do many things, including the conduct of public health programs.

States have inherent power as sovereign governments. Since the original states preceded the formation of the federal government and granted power to establish the national government, state governments have historically and legally been the central unit of the U.S. government. The 10th Amendment of the Constitution reserves to the states all powers that are neither given to the federal government nor prohibited by the Constitution. Thus, the police powers of government have primarily resided in state governments,

police power being the fundamental sovereign right of a government to promote order, safety, security, health, and general welfare within its territory.

In the troika of the U.S. government, local governments bear the most responsibilities for direct service to citizens but have the least authority. All local government organizations are creations of their state. They are legal entities only under state law with their power derived from state law and, in most cases, only political subdivisions of the state government.

The three levels of government involved in public health constitute a massive network of organizations involved in governmental public health. At a minimum, one must recognize one federal government with multiple agencies and 50 state governments with a collection of various departments involved in public health and related services. And there are no less than 3,000 local public health governmental entities participating in the system.

Federal Role in Public Health

The oldest element of the federal government public health activities is the U.S. Public Health Service, which traces its origins to 1798. Under the administration of President John Adams, a network of hospitals was established for the care of merchant seamen. This loose network was organized in 1870 into a centrally managed and professional medical care entity based in Washington, D.C., under the supervision of what became the Surgeon General of the United States. Today, the Public Health Service is the focal point of federal public health activities emanating from the U.S. Department of Health and Human Services (DHHS). Within DHHS are more than 300 programs covering a wide spectrum of health activities. Many of those program activities focus on preventing diseases, improving maternal and child health, assuring food and drug safety, analyzing health data, preparing for and responding to health-related emergencies, and conducting health and social science research.

One of the primary agencies within DHHS conducting public health activities is the Centers for Disease Control and Prevention (CDC). Founded in 1946 to help control malaria, the CDC remains at the forefront of governmental public health efforts to prevent and control infectious and chronic diseases, injuries, workplace hazards, disabilities, and environmental health threats. The CDC is globally recognized as the nation's premiere epidemiologic agency as well as a public health preparedness leader in the post-9/11 era.

The federal government, by far, represents the largest source of funding for health-related services. A primary role of the federal government is the direct provision of, as well as the payment for, both curative and preventive health services. Through programs such as the Indian Health Service, the Health Resources and Services Administration, and the Centers for Medicare and Medicaid Services, some $12.2 billion were appropriated for health services in 2006. In the area of health research, the National Institutes of Health within DHHS was provided $29 billion in 2006 to conduct medical and behavioral research in pursuit of basic knowledge about the nature and behavior of biological systems. Through various grant programs, DHSS is also a major funder of state and local health agencies.

State Role in Public Health

The primary constitutional responsibility for public health within the United States rests with the 50 state governments. Each state has some agency responsible for public health. No single standard exists for what constitutes a state health agency. In some states, the health agency is a freestanding cabinet department answerable to the governor. In other states, the health agency is part of a larger ("super") social services agency managing an array of health, social, and welfare programs. Mental health authorities and environmental protection services are sometimes assigned by the states to public health agencies. Medicaid administration as well as medical professions regulation may be located in the state health authority. These various organization combinations are based on the constitutional and statutory constructs of each state and reflect specific political cultures and historical developments of a state's region. The structure and placement of state health agencies within these variations will have a direct impact on the specific responsibilities of the agencies as well as the size of the agency's budget as a share of total state resources.

State health agencies play a primary role in determining the nature of services provided as well as the means of service delivery through local health departments. The policy-setting agenda for public health in any state is subject to state-level health agency influence. Most local health ordinances are based on enabling state legislation. State health agencies are

deeply involved in the development and drafting of legislation and even more involved in the promulgation of regulations to implement that legislation.

Functions that state health agencies across the United States have in common include disease surveillance and control, vital statistics, food safety, health facility regulation, public health laboratories, and environmental health. Most of the state health activities are funded by state general revenue and federal grants. One common program administrated by 98% of state health agencies is the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) funded by the U.S. Department of Agriculture.

Local Role in Public Health

The 3,000 local health agencies in the United States are the front line of governmental public health service delivery. As with organizations of state health agencies, no single organization standard exists for local health departments. In some states, the local health department is a direct agency of the state health department. In other states, local health departments can be part of the general-purpose local government within either a city or a county government. Local health departments can also exist as freestanding special-purpose governmental entities with their own tax base and elected board independent of any municipal or county government. Municipal local health departments have a long history, predating the existence of state health departments; however, the long-standing responsibility of local health departments to protect the community's health is often trumped by the legal supremacy of state government over local government.

Local health departments in 21st-century United States exist to carry out responsibilities embodied in state law and in local ordinances that are derived from state laws. Local health departments share responsibility with state health departments under the federal system of governance. Along with that sharing of responsibility comes the obligation of the state government to financially support the local heath department. Again, variations exist across the 50 states as to the extent of financial support provided to local health departments. Most local governmental public health depends on property taxation as its principal revenue source, supplemented by state subsidies and limited federal grants.

The structure of the U.S. governance has allowed the evolution of a rather complicated governmental system of public health. There exist many overlapping roles in this system. Although many functions are shared in this system, several significant problems exist. Decision making is fragmented between levels of government, creating problems of coordination leading to administrative confusion. There is a lack of congruence between organizations and functions. The system leaves the local health department, which is the entity with the most contact with citizens and the greatest service responsibility, with the least authority and the fewest resources.

The Future of Public Health

In 1988, the Institute of Medicine's Committee for the Study of the Future of Public Health published its report, *The Future of Public Health.* This succinct 159-page report concluded that the public health system was in disarray, and it called for a complete overhaul and refocus of the governmental public health functions and organization.

Key among the report's recommendations was an articulation of the core functions of public health as assessment, policy development, and assurance, including recommendations that

- every public health agency regularly and systematically collect, assemble, analyze, and make available information on the health of the community, including statistics on health status, community health needs, and epidemiologic and other studies of health problems;
- every public health agency exercise its responsibility to serve the public interest in the development of comprehensive public health policies by promoting the use of the scientific knowledge based in decision making about public health and by leading in developing public health policy. Agencies must take a strategic approach, developed on the basis of a positive appreciation for the democratic political process;
- public agencies assure their constituents that services necessary to achieve agreed-on goals are provided, either by encouraging actions by other entities (private or public sector), by requiring such action through regulation, or by providing services directly; and
- each public health agency involve key policymakers and the general public in determining a set of high-priority personal and community-wide health services that governments will guarantee to every member of the community. This guarantee should

include subsidization or direct provision of high-priority personal health services for those unable to afford them.

Specific activities were recommended for agencies at the federal, state, and local levels of government, as well as a series of strategies for linkages with other governmental authorities, building system capacity, and educating professionals. Since that report was published, substantial efforts are under way in public health agencies at all levels to strengthen performance in the core functions.

A subsequent report, *The Future of the Public's Health in the 21st Century*, was issued in 2003, calling for strengthening of the governmental public health infrastructure, and the creation of a broader system of public-private collaboration to ensure the health of the population. Steps in that direction are critical to the health and well-being of the population of the United States.

—Margret O'Neall and H. Douglas Adams

Graphical Presentation of Data

Graphs, tables, text boxes, and sentences can all be used to communicate quantitative information in epidemiology. Graphs present the big picture; they show patterns and trends. Tables contain the details, so they are useful for looking up specific values. Although sentences can provide a small amount of numerical data clearly, the numbers are easily lost in a page of text. Therefore, text boxes are useful for highlighting these numbers. This entry discusses how to choose between tables and graphs, the advantages of each, and guidelines for effective tables and graphs.

Choosing Tables or Graphs

Graphs are preferable for some situations and tables for others. The following list points out the advantages of each:

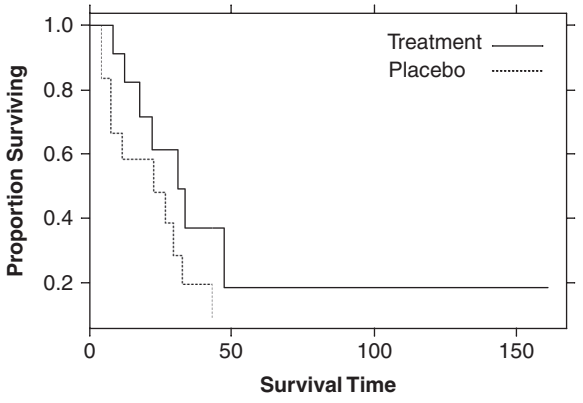
- Graphs show the big picture: patterns, trends, correlations, and the general shape of the data, while tables show exact values and offer precision.
- It is easy to detect extreme values such as the maximum and the minimum in a graph, while it is more difficult to do so with a table.
- Outliers, which are data points far from the rest of the data, are easier to spot on a graph, while they are more difficult to detect on a table.
- Graphs help discover data errors since problems such as an average value greater than a maximum value can be spotted easily. Tables are less effective in highlighting data errors.
- A great deal of information can be shown in a small space with a graph, while this is not true with tables.
- Graphs are appropriate for paper documents, Web documents, computer screens, or projector screens, while large tables are not appropriate for projector screens since the audience cannot see the details.
- Tables are useful for looking up values, while graphs offer only approximate values.
- Tables can accommodate a number of variables with different units of measures more easily than can graphs.
- The reader can use the data from tables for other purposes such as calculations and drawing other figures. This is more difficult with data from graphs.

Designing Graphs

Good graphs are powerful tools to visualize and understand data. Unfortunately, graphs can also confuse, mislead, or even deceive. This section provides principles of graph design to enable the reader to design effective graphs and to avoid common mistakes.

The data stand out in an effective graph. The designer should emphasize the data and de-emphasize

Graph



Table

Subjects With Adverse Events Reported

Adverse Event	*Treatment A # N = 247*	*Placebo # N = 238*
Headache	12	3
Nausea	10	4
Skin Rash	7	2
Dizziness	5	2
Fatigue	2	3

Sentence

The number of patients who received Treatment A was 247, while 238 patients received the placebo.

Text Box

Treatment A	247
Placebo	238

Figure 1 Examples of a Graph, a Table, a Sentence, and a Text Box (Not All the Same Data)

everything else. Grid lines, if used, should be in the background. This can be achieved by making them a pale gray or by using a dotted line. The plotting symbols and lines should be visually prominent; care must be taken so that the symbols are not hidden by tick marks, axes, grid lines, other data points, or other graphical elements. Clutter has no place in a graph. Too many tick marks or tick mark labels are a form of clutter. So are too many decimal places. The number of decimal places in labels should be appropriate for the data.

One form of clutter is adding a pseudo third dimension to bars, pies, lines, or other graphical elements. The unnecessary dimension often distorts the data. It always adds clutter. If bars are drawn with depth, the reader does not know how to read the bar. Is the value read from the front where the arrow on the X bar points or from the back where the arrow on the Y bar points? It turns out that the way to read these bars depends on the software that was used to create them, but the reader rarely knows what software was used. Two-dimensional bar charts are unambiguous. If the designer chooses to use a bar chart and knows the

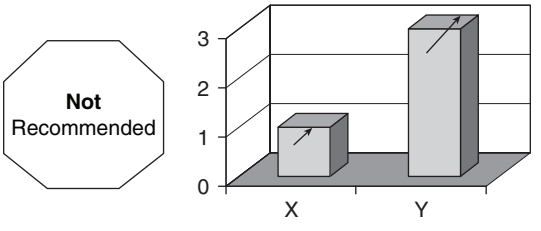


Figure 2 The pseudo third dimension distorts data.

categories and values of the data, then a two-dimensional bar chart should always be the choice.

Another common mistake is using equally spaced tick marks for unequal intervals. For example, if patients are seen at baseline and then after 1 month, 3 months, 7 months, and 1 year, then the figure should reflect these times, and the bars or symbols should not be equally spaced on the horizontal axis.

Color can be a powerful means of distinguishing groups of data, but it can also be a form of clutter. Consistency is important for color as well as for other graphical elements. It is distracting to view a series of graphs when red is used for Treatment A and blue for Treatment B on the first graph and then these colors are reversed in the next figure or completely different colors are used. It is also distracting if each bar or symbol is plotted with a different color for no apparent reason.

One graph can be acceptable by itself but confusing when in a group of charts. When graphs are shown in a group, they should have consistent scales if possible. Sometimes the same scale on all graphs of the group hides the data of some of the figures since the range of data is so different. In that case, the different scales should be emphasized either in the caption or by showing relative scales graphically.

Creating More Effective Graphs by Naomi Robbins (2005) and *The Elements of Graphing Data* by William Cleveland (1994) provide useful graph forms for presenting data and principles for drawing effective graphs. *Visualizing Data* by William Cleveland (1993) discusses graphs useful for statistical analyses.

Designing Tables

Tables are useful tools for storing data, looking up data values, and presenting data to readers who require precision. This section provides a few tips for designing effective tables. *Show Me the Numbers: Designing Tables and Graphs to Enlighten* by Stephen Few (2004) provides excellent advice about spacing rows and columns, using or avoiding grid lines, and other aspects of designing tables.

It is important to round data when presenting them in a table. Too many decimal places clutter the table and distract the reader from the values of interest.

Order the rows and columns in a sensible fashion. Determine the purpose of the table before designing it. If the purpose is data lookup, then alphabetical order is often best. If, on the other hand, the reader needs a sense of the distribution of the data, then ordering by size makes more sense. The order of the rows and columns has a major impact on the understanding of the data and the ease of making comparisons from the information in the table.

Eliminate nonessential information. Clutter interferes with understanding data from tables just as it does with graphs.

Highlight key data. Presentations often include tables without any attempt to direct the reader's attention to the particular numbers that support the point the presenter is trying to make. Highlighting those numbers can help.

Differentiate summary data such as means or totals from the rest of the data. This can be accomplished with spacing or by including vertical or horizontal lines.

Combining Tables and Graphs

It is often useful to show the data in more than one way. Each presentation adds different insights into the data. Including both a table and a graph shows the details as well as the big picture. Richard Heiberger and Burt Holland (2007) propose microplots to help

treatment	*min.*	*m – sd*	*mean*	*m + sd*	*max.*
25.cycle	54.13	61.13	69.83	78.58	86.08
60.cycle	46.31	57.73	65.22	72.71	79.71
faradic	38.89	51.91	57.68	63.45	67.96
galvanic	45.07	52.86	60.13	67.39	73.54

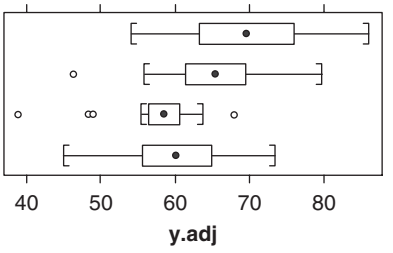

Figure 3 The microplot (on right) helps visualize the results of the table.

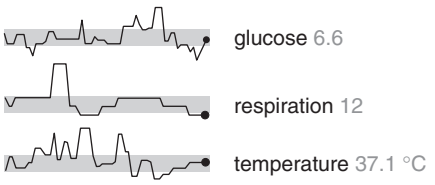

Figure 4 Edward Tufte's sparklines integrate text, numbers, and graphics.

Source: Tufte (2006, p. 47). Used with permission of Edward Tufte.

visualize the results of the tables often included with the results of statistical analyses.

Edward Tufte (2006) suggests integrating text, numbers, and graphics. One way to do that is with sparklines, which are intense, simple, word-sized graphics. The shaded areas represent the normal range of glucose, respiration, temperature, and white blood count readings.

Conclusion

Both tables and graphs are useful for presenting data. It is helpful to include both when time and costs permit since graphs show the forest while tables show the trees. Think about the data and the purpose in displaying them before designing a table or graph so that your message is clear and you emphasize the comparisons that are the most important.

Graunt, John
(1620–1674)

John Graunt was a storekeeper from London, England, who is credited with being the founding father of the science of vital statistics. Before Graunt's time, public health surveillance was unprecedented, and no method was available to quantify disease patterns in the population. Graunt provided a statistical and analytical approach to examine the population's health status. He collected data from the *Bills of Mortality* to study the disease patterns in London. The *Bills of Mortality* were documents that were published weekly by the London parishes and offered information on the number of births, deaths, and cause of death in each parish.

The *Bills of Mortality* were an untapped data source for Graunt, who was able to organize the data to compile mortality tables, allowing him to compare the trends in mortality and natality by the season, year, and geographic area. On the basis of his work, he published a book in 1662 entitled *Natural and Political Observations Mentioned in a Following Index and Made Upon the Bills of Mortality.* This 79-page book provided the first example of descriptive statistics. For example, Graunt was able to determine the number of deaths due to acute or chronic illnesses, the number of maternal deaths during childbirth, and the number of deaths from the plague. He scrutinized the data available and reported on problems with disease classification, reporting bias with regard to some diseases such as syphilis, irregular data collection intervals, and other inconsistencies in data collection and reporting.

Graunt's work was important to public health because he developed principles of epidemiology and demography. He made inroads by discovering patterns of disease and was able to identify diseases afflicting a geographic area or gender. He described and quantified disease occurrence in London at that time, and although he was not trained in mathematics, he was able to interpret the statistics. Graunt reported that more boys were born than girls, women had a longer life expectancy than men, the ratio of boys to girls was stable over time, mortality rates were

highest among infants and older adults, and death rates were higher in urban than in rural areas. He also identified variation in mortality rates by season and year and calculated the population of London at the time.

Graunt was also a councilman and politician. He served as a member of the Common Council of London. More important, Graunt was also a member of the Royal Society. King Charles II was so much in awe of Graunt's work that he recommended Graunt for membership in the newly created Royal Society, which was a forum for the nation's leading scientists. Many of the scientists at the time were opposed to Graunt's membership because Graunt did not have a formal education. However, King Charles overruled the objections, allowing Graunt to become a Fellow of the Royal Society. Graunt died of jaundice at the age of 53.

Gulf War Syndrome

The term *Gulf War syndrome* or *Gulf War illness* refers to a number of symptoms reported by American veterans who served in the 1991 Persian Gulf War, including chronic fatigue, headaches, dizziness, memory problems, gastrointestinal problems, and skin problems. Several studies have shown that self-reported health conditions are higher among veterans deployed to the Persian Gulf than to veterans serving elsewhere, but establishing higher rates of clinically defined diseases has proven elusive. The wide range of symptoms reported, the fact that many of the symptoms could have multiple causes, the lack of objective verification for some of the symptoms, and the wide range of potential causes of the symptoms have made research into Gulf War syndrome difficult.

Military personnel serving in the Gulf War were potentially exposed to numerous health hazards, including dust and sand particles, smoke from oil well fires, insecticides, vaccinations, depleted uranium, and psychological and physiological stress. However, linking exposures with specific health conditions in individuals has proven difficult for several reasons, the most important of which is that data quantifying the exposure of particular individuals to specific health threats are not available. Most estimates of exposure are based on self-report, which is subject to recall and other types of bias. Another difficulty is that only limited medical information is available for the veterans before and after deployment, making it impossible to establish a baseline for health status that would serve as a standard of comparison for health status after deployment.

Numerous studies have been conducted investigating the health of Gulf War veterans and evaluating the effects of the hazards they were exposed to. In 1998, the Institute of Medicine (IOM) began a series of congressionally mandated reports to evaluate and summarize the available scientific and medical literature regarding these issues. Volume 4 of the IOM reports, *Health Effects of Serving in the Gulf War*, summarizes all scientific and medical peer-reviewed literature available in 2006 that addresses the health status of veterans deployed in the Persian Gulf. This report found no evidence for the existence of a unique "Gulf War syndrome," although it did find that Gulf War veterans were at increased risk for anxiety disorders, depression, and substance abuse problems, and found evidence for a possible elevated risk of amyotrophic lateral sclerosis (ALS). No evidence was found for increased cancer rates among Gulf War veterans, although there was some suggestion that brain cancer rates might be higher, and the IOM recommended follow-up studies to examine this connection further. The IOM report found that self-reported multisymptom illnesses were higher for Gulf War veterans both from the United States and from other countries that sent troops to the Persian Gulf. Gulf War veterans were more likely to be injured or die in a traffic accident in the first few years following their return but not in later years. Rates of hospitalization were similar among deployed and nondeployed veterans, and there was no evidence of an increase in

cardiovascular disease or peripheral neuropathy. Evidence on respiratory illness was inconsistent, although some studies found a link between exposure to smoke from oil well fires and asthma. Evidence of the presence of birth defects in children of Gulf War veterans was also inconsistent.

H

Halo Effect

The halo effect refers to an error in reasoning where an impression formed due to a single trait is allowed to influence multiple judgments or ratings of unrelated factors. For instance, the halo effect operates when a rater forms a general impression of another person, based on one outstanding trait, and that general impression is allowed to influence judgments or ratings that should instead be based on specific aspects of the person. For example, people who are attractive may also be judged to be good workers without regard to their actual work performance; the positive impression of their attractiveness clouds the rater's ability to judge the actual quality of their work, although these two traits are not related. These overall impressions misrepresent the specific traits a person may have because they are based on a small amount of information.

The American psychologist Edward L. Thorndike (1874–1949) was a pioneer in studying the phenomenon of the halo effect. For instance, it was clearly present in an experiment conducted with servicemen in 1920, which was reported in his article "A Constant Error on Psychological Rating." In the experiment, the commanding officers were asked to rate their subordinates on their intelligence, physique, leadership, and character without having spoken to them. Thorndike noted a correlation between unrelated positive and negative traits. The service members who were found to be taller and more attractive were also rated as more intelligent and as better soldiers. Thorndike determined from this experiment that people generalize from one outstanding trait a person has to form a favorable view of the person's whole personality.

Another psychologist who studied the halo effect was Polish American Solomon Asch (1907–1996). In his 1946 article "Forming Impressions of Personality," Asch delineated how people form impressions of one another. Asch found that impressions of others were formed by a "primacy effect." First impressions were established as more important than subsequent impressions in forming an overall impression of someone. Participants in the experiment were read two lists of adjectives that described a person. The adjectives on the list were the same but the order was reversed; the first list had adjectives that went from positive to negative, while the second list had the adjectives in reverse order, from negative to positive. How the participant rated the person depended on the order in which the adjectives were read. Adjectives presented first had more influence on the rating than adjectives presented later. When positive traits were presented first, the participants rated the person more favorably; when the order was changed to introduce the negative traits first, that person was rated less favorably.

Hamilton, Alice
(1869–1970)

Alice Hamilton's groundbreaking epidemiologic studies investigating the occupational exposures of workers to poisonous substances used in manufacturing were critical to the development of the field of industrial toxicology and epidemiology. Hamilton's work contributed to the development of regulations enforcing healthier conditions in America's workplaces. Her career powerfully illustrates how epidemiologic research can stimulate and inspire scientific inquiry to serve the public good.

Hamilton was born in 1869 to a close-knit, patrician family in Fort Wayne, Indiana. Trained as a physician in the medical department of the University of Michigan, she joined the faculty at the Woman's Medical School of Northwestern University in Chicago as professor of pathology in 1897. For 22 years, Hamilton was a resident of Hull House, a famous American settlement in Chicago founded to connect the privileged classes and the socially disadvantaged, and this experience cultivated her interest in service and activism. She found her life's work in 1910, when she was invited to lead a state-funded study of industrial diseases, the first large-scale study of this type. She went on to conduct epidemiologic research of industrial diseases as a special investigator for the federal Bureau of Labor from 1911 until her final report in 1940 (see Table 1).

In 1919, Hamilton became Harvard University's first woman professor when she was invited to join the newly created Department of Industrial Hygiene at Harvard Medical School, a position she held until her retirement in 1935. Her professional work in public health continued until she was 80, and a new edition of her textbook *Industrial Toxicology* was published in 1949. Three months after Alice Hamilton died at age 101 in 1970, Congress passed the Occupational Safety and Health Act.

A Research Example: Lead Poisoning in Pottery Trades

Hamilton's monograph, "Lead Poisoning in Potteries, Tile Works, and Porcelain Enameled Sanitary Ware Factories," exemplifies her use of many modern epidemiologic principles, including the influence of case ascertainment and methods of comparing susceptible

Table 1 Selected Monographs Authored by Alice Hamilton for the *Bulletin of the U.S. Bureau of Labor Statistics*

Year Published	*Industry*	*Principal Exposure(s) Studied*
1912	Potteries, tile, and porcelain	Lead
1913	Painting	White lead
1914	Lead smelting and refining	Lead
1914	Battery manufacture	Lead
1915	Rubber industry	Lead, antimony, benzene
1917	Explosives industry	Nitrous fumes, TNT
1917	Printing trades	Lead poisoning, wood alcohol
1918	Stonecutters	"Dead fingers syndrome"
1921	Coal tar dyes and dye intermediates	Aniline, nitrobenzene, toluene, xylene, inorganic compounds (e.g., hydrogen sulfide, hydrogen arsenide)
1922	Steel manufacturing	Carbon monoxide
1940	Viscose rayon	Carbon disulfide, hydrogen sulfide

groups. The report documented her investigation of 68 potteries and factories in nine U.S. states. Information was collected directly from physicians, hospital records, personal inquiries, and examinations. The investigation identified industry practices that increased risk of lead poisoning and compared male and female prevalence of lead poisoning.

As part of the study, Dr. Hamilton identified 18 cases of lead poisoning that occurred in 1910 and 1911 among 314 men employed in Trenton, New Jersey, for a 2-year cumulative incidence of 1 in 31, and compared that with the prevalence in East Liverpool, Ohio, where of 480 men, 31 cases were found in the same time period, or 1 in 15 to 16 employed. (The terminology *2-year cumulative incidence* is used here for clarity. Dr. Hamilton simply reported these as "ratios" or "per cents.")

The report pointed out several potential reasons for the differences between the two cities. Case identification was difficult in general due to absence of employee lists, high turnover in the lead industry, workers' failure to seek treatment, ignorance in the medical community of the symptoms of lead poisoning when medical attention was sought, and in some cases, management cover-up. Hamilton stated that the number of cases in Trenton may have in truth been higher because doctors in Trenton were less aware of whether their patients worked in potteries, whereas in East Liverpool, "everyone knows about the potteries . . . and every doctor has potters and girl helpers among his patients" (Hamilton, 1912, p. 44). Second, because other employment opportunities were available in Trenton, those cases with moderate symptoms may have left the pottery trade for other work, an option that did not exist in East Liverpool. This explanation, whereby only healthy workers are left in an occupation, is now known as the "healthy worker effect." A third explanation offered was that decorating was done more in East Liverpool compared with Trenton, carrying with it greater risks. Finally, the so-called sanitary ware was made in Trenton, but not in East Liverpool. The manufacture of sanitary ware required glazes with lower lead concentrations and practices that created less dust. The report states, "There is no dry rubbing and no dusty gathering and piling together of ware, and no women's skirts stirring up dust, for the employees are all grown men" (Hamilton, 1912, p. 46).

The report also documented higher incidence of lead poisoning in women compared with men in East Liverpool, where the 2-year cumulative incidence was 25 cases per 135 female employees, compared with 31 per 480 males employed. When limiting the comparison to only those employed in the glaze room, the incidence of lead poisoning among women was approximately two times higher than among men (Table 2). She further pointed out that "the contrast between the men and women becomes still greater when one takes into consideration the fact that the average period of employment for the men dippers was 19.5 years and for the women helpers only 2.5 years" (Hamilton, 1912, p. 48).

Table 2 Ratio of Lead-Poisoning Cases Among Dippers and Dippers' Helpers in White Ware Potteries to Number Employed, East Liverpool (Ohio)

Sex	*Employees*	*Cases of Lead Poisoning, and Still at Work*	*Ratio of Cases to Employees of Each Sex*
Male	85	13	1 to 6 or 7
Female	41	14	1 to 3

Hardy-Weinberg Law

Genetic epidemiology aims to understand how genetic variation contributes to disease risk. To best characterize risk relationships, one must first understand how the exposure of interest is distributed within and across populations, before attempting to relate

exposure distributions to disease distribution. For genetic exposure, this involves understanding how genetic variation arises in populations and how it is maintained within and across populations over time. The Hardy-Weinberg law describes a state of equilibrium in allele frequencies at a particular genetic locus over generations that are randomly mating. This law also describes a relationship between the allele frequencies and genotype frequencies within a population as a result of random mating.

Variation at a genetic locus can be described by noting the different "spellings," called "alleles," that exist at the same location among chromosomes in a population. For example, the sequence at a particular site may be AT**C**C in some and AT**T**C in others, which would be referred to as two alleles "C" or "T." When such diversity exists, the location is considered to be "polymorphic." Because humans are "diploid," each person carries two copies of the genome, one from their father and one from their mother. So at any polymorphic location, each person carries two alleles, one from each parent. The particular combination of the two alleles carried by a single individual is referred to as a "genotype." Following the example above, there are three possible genotypes for the C/T polymorphism with two possible alleles: CC, CT, TT. The Hardy-Weinberg law characterizes the relationship between alleles and genotypes in a population due to random mating and the equilibrium state of allele frequencies from generation to generation. It is thus often also referred to as Hardy-Weinberg equilibrium (HWE).

Traditionally, the frequency of the first allele is denoted as p and the alternative allele frequency as q. These are the proportions of that particular allele among all chromosomes in the population (e.g., among $2 \times N$, where N is the number of people), and $p + q = 1$. Under an assumption of random mating in a sexually reproducing diploid population with no other population genetic forces such as mutation, natural selection, migration, or drift, it can be shown that the expected genotype frequencies are a specific function of the allele frequencies p^2, $2pq$, and q^2 (see Table 1) and that these values, p and q, will remain constant over generations. Proof of this result was reported by three separate papers in the early 1900s, by Castle (1903), Hardy (1908), and Weinberg (1908). As an example, suppose a population of 10,000 people contained a genetic polymorphism with alleles C and T, where 11,000 of the 20,000 genomes in that population contained a C allele ($p = 11,000/20,000 = 0.55$; $q = 0.45$). The Hardy-Weinberg law, which assumes random mating, would expect the genotype frequencies in the population to be CC genotype $= p^2 = 0.552 = 0.3025$, or 3,025 people with CC; $CT = 2pq = 2 \times 0.55 \times 0.45 = 0.495$, or 4,950 people with CT; and $TT = q^2 = 0.452 = 0.2025$, or 2,025 people with TT. These genotype proportions based on allele frequencies are often referred to as Hardy-Weinberg proportions.

One can measure the amount of departure from Hardy-Weinberg expectations by comparing the observed genotype frequencies in a sample to those expected under HWE based on the allele frequencies for that sample. This value is considered the Hardy-Weinberg disequilibrium coefficient: DHW = observed genotype frequency − expected genotype frequency. For example, if among 1,000 people, 350 were CC, 400 were CT, and 250 were TT, one could calculate the allele frequencies as $p = (2 \times 350 + 400)/2,000 = 0.55$ and $q = 0.45$. The expected genotype frequencies under HWE would be $E(CC) = p^2 = 0.552 = 0.3025$; $E(CT) = 2pq = 2 \times 0.55 \times 0.45 = 0.495$; $E(TT) = q^2 = 0.452 = 0.2025$. The DHW = observed − expected = $0.350 - 0.3025 = 0.0475$. This could also be calculated using the other homozygous genotype: DHW = $0.250 - 0.2025 = 0.0475$. One could test the statistical significance of this by testing the hypothesis that DHW = 0 versus the alternative $D^{HW} \neq 0$ using a z test:

$$z = \frac{\hat{D}^{HW} - \varepsilon(\hat{D}^{HW})}{SE(\hat{D}^{HW})}$$

or through likelihood ratio testing. Because there are often sparse genotype cells for situations with rare alleles, exact tests or permutation approaches are often employed.

Table 1 Hardy-Weinberg Proportions: Assumption of Random Mating

		Males	
		C (p)	T (q)
Females	C (p)	CC p^2	CT pq
	T (q)	TC pq	TT q^2

Note: Expected genotype proportions: $P(CC) = p^2$; $P(CT) = 2pq$; $P(TT) = q^2$

In practice, human populations do undergo population forces such as mutation, selection, and nonrandom mating, yet the genotype frequencies often approach Hardy-Weinberg proportions, making it a very robust property. Departures from Hardy-Weinberg proportions can be detected under severe violations of the assumptions, such as nonrandom mating due to inbreeding or assortative mating; recent strong natural selection; or genetic drift. In addition, violations of Hardy-Weinberg proportions in a sample may be due to sampling error or sampling bias. For example, if a particular genetic locus is related to disease risk, the genotype frequencies among cases may be enriched for particular risk genotypes and may, therefore, not reflect the general population and not demonstrate Hardy-Weinberg proportions. This point has actually been exploited in some statistical genetics methods to detect genetic risk factors by testing for Hardy-Weinberg violations among cases. Finally, violations of Hardy-Weinberg proportions may simply reflect genotyping measurement error. In fact, examination of Hardy-Weinberg proportions is now a standard aspect of quality assessment for large-scale genotyping projects.

Harm Reduction

Noting that no single, widely embraced definition of harm reduction exists, the International Harm Reduction Association (IHRA) proposes that harm reduction be defined as ''policies and programs which attempt primarily to reduce the adverse health, social, and economic consequences of mood-altering substances to individual drug users, their families, and their communities'' (IHRA, n.d., § 14). Examples of mood-altering substances include heroin, cocaine, methamphetamine, alcohol, and tobacco. Because individuals who use mood-altering substances have engaged in collective efforts to reduce the harm of their substance use independently of programs and policies (and, in fact, these efforts have at times predated, and given rise to, programs and policies), IHRA's harm reduction definition should perhaps be extended to explicitly encompass user-initiated actions, undertaken collectively, that are designed to reduce the adverse consequences of mood-altering substance use. This entry discusses the key harm reduction principles of pragmatism, prioritization of goals, and humanism; reviews the history of efforts embodying these principles; and examines particular examples of harm reduction efforts and their effectiveness.

Harm Reduction Principles

Key harm reduction principles include the following:

• *Pragmatism.* The elimination of mood-altering substance use is not an attainable goal in the foreseeable future. Addiction to, or dependence on, a substance may preclude cessation for some individuals, particularly if treatment is inaccessible; individuals may also choose to continue using a particular substance because of the perceived benefits it brings. A pragmatic approach to reducing vulnerability to drug-related harms thus necessarily encompasses efforts to promote safer drug use practices among active substance users, as well as efforts to support individuals who wish to reduce or cease using particular substances.

• *Prioritization of Goals.* Harm reduction programs, policies, and collective user-initiated actions may prioritize their goals so that the most pressing needs of their target populations are addressed first. For example, efforts designed to reduce the spread of bloodborne infections via injection drug use may prioritize goals as follows: (1) reduce the likelihood that individuals will borrow used syringes; (2) minimize the risk that an individual will transition to injection

drug use from another mode of drug administration, and reduce the duration of injecting among current injectors; and (3) facilitate access to appropriate treatment. Importantly, there is no single, optimal method of reducing drug-related harms for all individuals in a population. Rather, multiple possibilities should be available simultaneously, and the same individual may participate in different harm reduction efforts over the course of his or her life.

- *Humanism.* Individuals who use mood-altering substances can and do make rational choices that further their health and well-being, as well as that of their families and communities. The rights and dignity of all individuals who use mood-altering substances merit respect. Drug users are members of broader communities in which they fill multiple social roles, including those of parent, partner, child, and neighbor; furthering users' health and well-being thus furthers community well-being. Users have been central to the development of harm reduction programs and policies, and their ongoing contributions to these efforts should be recognized, promoted, and respected.

These harm reduction principles guide a broad array of programs, policies, and collective user-initiated actions, including laws prohibiting driving while intoxicated and smoking in specified public spaces; syringe-exchange programs; and collective, user-initiated actions to protect promote users' health and that of the broader communities in which they are embedded. Evidence regarding the effectiveness of some of these harm reduction policies, programs, and collective user-initiated actions is presented.

Harm Reduction in Historical Context

The term *harm reduction* was coined in the mid-1980s; the first published use of the term appears to have been in 1987. This term initially emerged to describe efforts seeking to reduce the spread of infection (first hepatitis and later HIV) among people who injected drugs. Early harm reduction efforts sought to contain hepatitis B and C among injectors; in Edinburgh, Scotland, a pharmacist provided sterile syringes without a prescription to local injectors in 1982 and 1984, and in Amsterdam, Holland, substance users organized efforts to provide sterile injection equipment to active injectors in 1983. These efforts intensified and spread geographically with the discovery of the high prevalence of HIV and AIDS among injectors in multiple cities internationally, coupled with the knowledge that (1) HIV could be transmitted via injection equipment and (2) there was neither a cure nor a vaccine for the infection. The term *harm reduction* now also encompasses programs, policies, and collective user-initiated efforts to reduce a broad array of adverse consequences among users of a wide range of substances administered through multiple methods.

The first emergence of the term *harm reduction*, however, should not be confused with the first emergence of harm reduction principles. These principles—of pragmatism, prioritization of goals, and humanism—have been applied to further users' health and well-being in multiple prior contexts. For example, in the late 1800s and early 1900s, physicians in the United States maintained women and men who were addicted to morphine on the drug out of concern that withdrawal might prove fatal or permanently debilitating. Likewise, in the United Kingdom, a government-appointed committee of physicians concluded in 1926 that the practice of maintaining addicted individuals on morphine and heroin should be continued. The principles articulated in this report (the Rolleston Report) continued to influence British drug policy for the next five decades. Likewise, before AIDS had been discovered by science, injectors in New York City in the 1970s noticed the illness's symptoms, attributed it to shared drug paraphernalia, and altered their injection practices accordingly. The current commitment to reducing drug-related harms among active substance users, then, should be viewed as a resurgence or intensification of an existing approach rather than as an entirely novel phenomenon.

Harm Reduction: Assessing the Evidence

Assessing the evidence for the effectiveness of the full range of harm reduction policies, programs, and collective, user-initiated actions lies beyond the scope of this entry. Here, we briefly review findings from four harm reduction efforts.

Per Se Laws: Drinking and Driving

Traffic injuries and fatalities are among the harms produced by alcohol consumption. A dose-response

relationship exists between a driver's blood-alcohol concentration (BAC) and crash risk: Crash risks are 4 times greater at a BAC of 0.08% compared with a BAC of 0.00%, 10 times greater with a BAC of 0.10%, and 25 times greater with a BAC of 0.15%. Per se laws criminalize driving with a BAC that exceeds a particular cut point. Individuals whose BAC exceeds the limit can be prosecuted and/or have their license suspended or revoked. Evidence indicates that alcohol-involved accidents, injuries, and fatalities decline after the introduction of per se laws and after the reduction of the BAC limit in areas with existing per se laws. The magnitude of a per se law's effect may decay over time, particularly if enforcement is lax, and is enhanced if its passage is accompanied by public education campaigns, active enforcement, and the passage of other alcohol-related laws.

Public Clean Air Laws and Tobacco Smoking

Enacted by states and municipal governments, Public Clean Air Laws restrict the locations in which individuals can smoke tobacco. The restrictiveness of these laws can vary, with some laws prohibiting smoking in all work sites and restaurants, and others permitting smoking in designated sections of workplaces and restaurants. While the main impetus of these laws is to reduce exposure to secondhand smoke, their proponents have hypothesized that they may also reduce the opportunity to smoke among active smokers and increase the chances that smokers will quit. Compared with residents of other states, residents of states with highly restrictive clean air laws have (a) 12% lower per capita cigarette consumption rates; (b) 14% lower mean smoking prevalence rates; and (c) 12% higher mean quit rates.

Syringe-Exchange Programs

Syringe-exchange programs (SEPs) are programs in which individuals can acquire sterile syringes and other injection equipment and dispose of used syringes and equipment. Additional ancillary health services may also be available, including referral to drug treatment and instruction on safer injection methods. A large body of research indicates that SEPs are an effective method of reducing the spread of HIV among injection drug users. HIV incidence among SEP participants is substantially lower than that among nonparticipants (hazard ratio: 3.35; CI: 1.29, 8.65), and SEP participation is association with a two- to six-fold reduction in the odds of engaging in drug-related HIV risk behaviors. There is no convincing evidence that SEPs increase drug use frequency or hazardous drug use, either among participants or others in the local community.

Informed Altruism

Collective, user-initiated harm reduction efforts include "informed altruism." In this social process, individuals who plan to inject as a group and who are faced with an inadequate supply of injecting equipment collectively discuss their HIV-serostatus. The order in which people then share the available injection equipment is sequenced so that HIV-positive individuals receive the used equipment last. To date, no data exist on the impact of this collective action on the containment of HIV (and other infections) among injectors.

Harvard Six Cities Study

The Harvard Six Cities Study was a large-scale study of the effects on human health of fossil fuel

emissions, in particular, sulfur dioxide and respirable particulate matter (soot). It was inaugurated by Benjamin Ferris and involved many faculty members and researchers at Harvard University, including John Spengler, Douglas Dockery, and Frank Speizer. This study provided evidence that, in concert with similar results from other studies, prompted the Environmental Protection Agency to raise air quality standards.

One impetus for the study was a belief in the United States in the 1970s that, due to the Middle East oil embargo, high-sulfur coal would be used more widely as an energy source in the future. Coal was a well-known source of air pollution (e.g., the combination of pollution due to soft coal combustion and a temperature inversion was associated with a temporary doubling in the death rate in the London smog disaster of 1952), but it was uncertain whether the health effects observed were due to sulfur dioxide, particulate matter, or both. The Six Cities Study was designed in part to investigate this question. Ferris had observed methodological innovations used to study the effects of pollutant exposure on the health of coal miners in Wales and had already incorporated those methods into a study of sulfur emissions from a paper mill in Berlin, New Hampshire; he also applied those methods to the Harvard Six Cities Study.

The Harvard Six Cities Study followed a cohort of 8,111 Caucasian adults in six cities in the northeastern and Midwestern United States for 14 to 16 years, beginning in the mid-1970s. The cities included were Watertown, Massachusetts; Harriman, Tennessee; St. Louis, Missouri; Steubenville, Ohio; Portage, Wisconsin; and Topeka, Kansas. Questionnaires were used to collect data, including smoking history, educational level, age, sex, weight, height, medical history, and occupational exposure to gases, dusts, and fumes, from participants at enrollment and 3, 6, and 12 years afterward. Mortality data were collected through the National Death Index. Ambient air pollution was measured through centrally located monitors in each city.

The principal finding of the study was the positive association of air pollution and mortality. In particular, the study found that comparing residents of the most polluted to those of the least polluted city, higher ambient levels of respirable particulate matter and sulfur dioxide were associated with a 26% increase in mortality from all causes and that increased levels of respirable particles were associated with increased mortality from cardiopulmonary disease. In addition, the study found that the increase in mortality risk was directly proportional to increase in respirable particulate matter concentration. Mortality rate ratios were invariant for smokers and nonsmokers, and for people with and without occupational exposure to dusts, gases, and fumes. Increased air pollution was also associated with increase in a number of illnesses, including asthma and lung cancer.

The relationship between air pollution and mortality found in the Harvard Six Cities Study were confirmed in a much larger study, the American Cancer Society (ACS) study. Results from both studies were influential in the development of higher standards for air quality issued by the Environmental Protection Agency in 1997. These new regulations were questioned by representatives of various industries, who claimed that results from the ACS and Six Cities studies results could be explained by poor research design and data collection techniques, flawed statistical methodology, and factors not considered in the studies, such as temperature differences between cities. Because of confidentiality requirements, data from the ACS and Six Cities studies could not be released for reanalysis by industry representatives, so as a compromise, a third-party reanalysis was conducted by a nonprofit organization, the Health Effects Institute (HEI). This reanalysis, led by Daniel Krewski and Richard Burnett, included an audit of data quality, replication of the original studies, use of different statistical techniques, and inclusion of covariates such as climate, socioeconomic characteristics, and presence of other pollutants. The HEI reanalysis confirmed the original conclusions of both studies, although specific measures of risk were in some cases slightly higher or lower than in the original analyses. One new finding from the reanalysis was the association of lower levels of education with increased mortality.

A follow-up study by Francine Laden, Schwartz, Speizer, and Dockery (2006) based on the Six Cities Study found that reduction in respirable particulate matter was associated with reduced mortality. Results were controlled for the increase in adult life expectancy in the study and follow-up periods and found that a reduction of 1 $\mu g/m^2$ in the average levels of PM2.5 fine particulate matter (matter with a diameter of 2.5 μm or less) was associated with a 3% reduction in mortality, a reduction approximately equal to 75,000 fewer deaths per year.

Hawthorne Effect

From 1924 to 1927, Elton Mayo of the Harvard Business School, together with Fritz J. Roethlisberger and William J. Dickson, carried out a series of experiments with the level of illumination in a factory called the Hawthorne works of the Western Electric Company in Illinois. After informing the workers that they would be observed to assess their level of productivity, the level of illumination was varied in the factory. In some cases, during the experiment a person associated with the research remained on the factory floor. The researchers expected to find that illumination correlated with increased productivity; however, worker productivity increased throughout the experiment regardless of the level of light. In fact, in one experiment, the level of illumination was decreased steadily; productivity increased until the lights were so low that the workers complained that they were unable to see well enough to work.

The findings of these studies have been widely reported as proof that people change their behavior whenever they know that they are being observed. Furthermore, there is a suggestion that when people feel included in the decision process (as they were in some of the Hawthorne studies), they are empowered and tend to work harder.

The Hawthorne studies have been criticized for poor experimental design. Not all the experiments included a control group, some studies involved very small numbers of workers, and worker turnover may have influenced the results. Portions of the Hawthorne effect have also been attributed to an observer effect, because of the experimenter who remained on the factory floor. While these criticisms are valid, the Hawthorne effect itself continues to be observed in a variety of settings. It has been cited as an explanation for results of studies in widely divergent areas, including patients' perceptions of postsurgical recovery and quality of life, effectiveness of training on reduction of infection rates in day care centers, and the impact of repeated assessments of smoking on the rates of smoking among adolescents.

The Hawthorne effect should certainly be considered when designing an epidemiologic trial. For example, randomization to experimental and control groups will help control the tendency of people to behave differently while in the study. The schema for the control group should also be as similar to the experimental groups as possible; if a placebo is used in this group, it should be formulated to look similar to and be administered in the same way as the experimental drug. These components of the study design would help address the tendency of patients in the trial both to be more compliant in their medication use during the study than they would be in their daily lives and to report improvements in their symptoms—both of which are possible results of a Hawthorne effect and thus would be observable even in the control group. Because of this tendency, the Hawthorne effect is often equated with the widely publicized "placebo effect."

Hazard Rate

The hazard rate is a measure used to quantify the relative frequency of disease occurrence in a population

and plays an important role in descriptive and etiologic investigations. The definition of hazard rate is given as the instantaneous change in the occurrence of new cases per unit change of time at a particular time point, relative to the size of the disease-free population at that particular point in time. It is a theoretical limit of the rate as the time interval goes to zero and could seldom be obtained in reality. Instead, an *average rate* for a given period is usually estimated and used in epidemiology, analogous to the use of speed as an estimate of average velocity. This average rate is called the *incidence rate*, *force of morbidity or mortality*, or *incidence density*.

Typically, the incidence rate is estimated from studies that involve the follow-up of a population, such as cohort studies. The estimate of incidence rate takes into account both the number of new cases and the size and follow-up time of population:

$$\text{Incidence rate} = \frac{\text{Number of new cases in a given period}}{\text{Total person} - \text{time of observation}}.$$

The denominator is the sum of each individual's follow-up time until the occurrence of disease or until the end of the study. Therefore, the above calculation accounts for the situation that different individuals were observed for different lengths of time. As a hypothetical example, suppose that eight healthy 60-year-old women without coronary heart disease (CHD) were followed up to study the incidence rate of CHD. One of them developed CHD after 1 year of follow-up, two of them developed CHD after 3 years of follow-up, one of them was lost to follow-up without developing CHD after 4 years, and the last four did not develop CHD after 5 years at the end of the study. Then there are three new cases within the 5-year study period and total person-time of observation $= (1 \times 1) + (2 \times 3) + 4 + (4 \times 5) = 31$ person-years and the incidence rate $= 3/31$ person-years $= 0.097$/person-years. For most chronic diseases, especially incurable conditions, such as diabetes and multiple sclerosis, the deathrate, hazard rate, and incidence rate often include only the first occurrence of new cases. For recurring disease such as cancer or heart disease, both first and subsequent occurrence could be of great interest.

The numerical value of hazard rate and incidence rate has a low bound of zero but has no upper bound. Their interpretability depends on the selection of the time unit. The above incidence rate of 0.097/person-years could be expressed as 0.008/person-months, or 97/1,000 person-years. It is thus essential in presenting incidence rates with appropriate time units. For clarity, the numerator is often expressed as a power of 10. Incidence rate should not be confused with prevalence, which is defined as the number of individuals with a certain disease in a population at a specified time divided by the population size at that time.

Health, Definitions of

Epidemiology is often defined as the study of the occurrence and determinants of disease in human populations. Another way to look at epidemiology is to define it as the study of the *health* of human populations, which requires a definition of what is meant by health. The definition of what constitutes health is partly dependent on culture and historical period, so this entry concentrates on two general ways of conceptualizing health that are in common use today in the industrialized world: the medical model and the holistic model.

The medical model defines health as the absence of disease or injury, so a healthy person is one who is not suffering from a disease or injury as defined by current medical practice. This model was common in the industrialized world in the 20th century and is still common in the medical profession. It places an emphasis on treating and curing diseases and injuries after they occur, and it does not focus on prevention. This model also emphasizes diseases that have clearly observable signs and symptoms and that can be treated or cured, and it often places greater weight on physical rather than mental disease and on curing acute diseases rather than enhancing the quality of life of those with chronic diseases.

The holistic model is more commonly used in public health. Those advocating this model often cite the definition of health included in the Preamble to the Constitution of the World Health Organization (WHO), which was adopted in 1946 and entered into force in 1948. The Preamble defined health as "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity" and further stated that "the enjoyment of the highest attainable standard of health" was a fundamental right of every human being (WHO Constitution; unpaginated). Health as a human right was a new concept when this statement was first made, but it has become accepted as a goal if not a reality by many people working in public health.

The WHO definition has been criticized as being both utopian and unmeasurable: Critics point out that every unfortunate aspect of human life, from warfare to religious oppression, could be considered within the scope of "health" by this definition, and further that with so inclusive a definition, the terms loses its meaning because hardly anyone could actually be considered to be healthy. Supporters of the holistic definition counter that many nonmedical aspects of life affect health, and that beginning with a broad rather than narrow model allows consideration of many threats to health, while requiring sound judgment as to which are the highest priority for intervention.

Health Behavior

The major causes of death in the United States and other developed countries are chronic diseases such as heart disease, cancer, and stroke. Behavioral factors are related to all 12 leading causes of death, and behavioral factors are thought to contribute to almost half of the deaths in the United States. According to Mokdad and others, the most common behavioral contributors to mortality, or death, in 2000 were tobacco use, poor diet and physical inactivity, and alcohol use; other significant causes of death include firearms, sexual behavior, motor vehicle crashes, and illicit use of drugs. These behaviors were responsible for nearly 1 million deaths in just a single year. The resurgence of infectious diseases, including foodborne illness and tuberculosis, and the emergence of new infectious diseases such as antibiotic-resistant infections, HIV/AIDS, hepatitis C, and human papillomavirus (HPV) are also largely affected by human behaviors. The social and economic costs related to these behaviors can all be greatly reduced by changes in individuals' behaviors.

Understanding and improving health behavior is key to improving public health and individual well-being. This entry reviews definitions of health behavior, health trends in the United States, and some of the methods used to identify and assess them. It also examines the determinants of health behavior and ways in which such behavior can be improved. In general, behavioral interventions will be more effective if they are adapted to the audiences or communities they are intended for, if they are theoretically based, and if they are carefully crafted and properly pretested. To gain an understanding of health behaviors and to inform the development of behavioral interventions, researchers over the past decade have most frequently made use of the health belief model, the theory of reasoned action and the theory of planned behavior, social-cognitive theory, social ecological models, and the transtheoretical model (or stages of change model). This entry briefly describes these theories and models.

Health Improvement and Public Policy

As chronic disease prevention has grown in importance, so has the role of governments in identifying concerns and goals for health behavior improvement. It was nearly 30 years ago when landmark government-sponsored reports in the United States and Canada called for widespread health improvement through health behavior change. The Health Objectives for the Nation that were published in 1980 stimulated

a dramatic increase in public, private, and professional interest in preventing disability and death through changes in lifestyle behaviors and participation in screening programs. During the same period, data and surveillance systems were established to begin to better track patterns of health behavior and monitor change over time. More recently, Healthy People 2010 was developed and published by the U.S. Department of Health and Human Services to identify public health priorities and specific, measurable objectives. With the overarching goals of increasing the quality and years of healthy life and eliminating health disparities, Healthy People 2010 strongly emphasizes health behavior as central to improving the nation's health. Seven of the 10 top-priority leading health indicators are behavioral: physical activity, overweight and obesity (with roots in eating and activity behaviors), tobacco use, substance abuse, responsible sexual behavior, immunization, and injury and violence.

Definitions of Health Behavior

Health behavior encompasses a large field of study that cuts across various fields, including psychology, education, sociology, public health, epidemiology, and anthropology, and others as well. Several leaders in the field have created working definitions of health behavior. *Health behavior* is defined as observable, overt actions of people that can be reported and measured. However, the field of "health behavior research" often conceives of health behavior very broadly. Gochman defined health behavior as including overt behavior patterns, actions, and habits that relate to prevention, control, and treatment of health problems, as well as the personal beliefs, motives, and emotional states that influence the actual behaviors. A classic typology of health behavior along the health continuum that was articulated by Kasl and Cobb in the 1960s is consistent with the broad health behavior focus. Interestingly, these definitions emphasize the role of the actions of individuals in health behavior. This is in contrast to public health and epidemiological perspectives, which are more often embraced at present and address individuals as part of a larger population or community. Not quite clear on what this means is the point that groups (such as specific communities) can engage in health behaviors, just as individuals can and governmental policies can establish policies that affect health and thus that their policymaking also can be viewed as a health behavior. Health behavior can be something that one does only to oneself, such as putting on sunscreen, or a behavior that affects others, such as putting up a shade cover so that children at the playground are protected from the sun or establishing a smoke-free workplace policy.

Another useful distinction can be made between episodic behaviors, on the one hand, and lifestyle behaviors or habits, on the other. Health behavior can be something that is done once, or periodically, such as getting immunizations or a flu shot. Other health behaviors are actions that are performed over a long period of time, such as eating a healthy (or unhealthy) diet, getting regular physical activity, and avoiding tobacco use. Behaviors that involve a sustained pattern of action over a period of time are usually considered "lifestyle behaviors" or health habits.

Trends in Health Behavior

Although there is more information about what constitutes healthy behavior and risk factors than ever before, this has not always led to people practicing healthier behaviors. There have been some positive changes: In the late 1980s and 1990s, average daily intake of dietary fat dropped from 36% to 34% of total energy, seat belt use increased from 42% to 67%, and the number of women above the age of 40 who had breast exams and mammograms doubled. Tobacco use has declined substantially among adults and seems to have begun to fall among youth. However, not all the news is favorable. More adults and children are overweight than ever before. Diabetes is increasing in near-epidemic proportions. More adolescents are sexually active. One fifth of children below 3 years of age have not received a basic series of vaccinations for polio, measles, diphtheria, and other diseases. Ethnic minorities and those in poverty experience a disproportionate burden of preventable disease and disability, and for many conditions, the gap between disadvantaged and affluent groups is widening.

Surveillance, Monitoring, and Assessment of Health Behavior

Data systems make it possible to track trends in health behaviors and changes in health-related environmental factors and policies in the United States, and in some cases, to link these changes with changes in disease

incidence and mortality. The Behavioral Risk Factor Surveillance System is a state-based telephone survey that is conducted every year, so it is possible to estimate the rates of various health behaviors in a given state and also to compare patterns of behavior between states, regions, and subgroups of the population such as males and females, whites and blacks, and so on. The Youth Risk Behavior Surveillance System (YRBS) is a parallel survey that is conducted in schools to track the health-risk behaviors of adolescents in Grades 9 through 12 in all states. Monitoring the Future (MTF) is a national survey of representative samples of 8th-, 10th-, and 12th-grade students. Other major national health surveys, such as the National Health Interview Survey (NHIS) and the National Health and Nutrition Examination Survey (NHANES), also include measures of health behaviors as well as self-reported health problems and even physical measures of health status. Specialized surveys, such as the Continuing Survey of Food Intakes of Individuals (CSFII) sponsored by the U.S. Department of Agriculture, provide more detailed population-based data about specific health behaviors such as food consumption and eating patterns. A new survey, the Health Information National Trends Survey (HINTS), was first conducted in 2002 and surveys a national sample of adults every 2 years to assess progress in meeting health and health communication goals including the public's health behaviors.

Monitoring and surveillance are core epidemiologic functions that emphasize tracking and interpreting patterns of behavior and health among large populations. However, other goals of health behavior assessment include understanding health behavior among individuals and groups and evaluating health behavior change programs. For these purposes, self-report surveys of defined audiences are the most common approach. Other methods include self-monitoring through health behavior diaries, short-term recall interviews, and real-time assessment using time-stamped technologies such as personal digital assistants (PDAs), the Internet, and instrumented diaries. The use of observation and biological assessments to validate self-report is also essential to improving the accuracy of these measures.

Determinants of Health Behavior

Many questions about how health behavior develops, is sustained, and changes have not yet been answered. An understanding of the determinants of health behavior using coherent theories is critical for developing effective interventions that may reinforce or change behavior. Because the determinants of health behavior are complex and multifaceted, one single theory rarely can explain a health behavior. Therefore, some models have been developed that use multiple theories to help understand a specific problem in a particular setting or context. Broadly speaking, these theories and models can be broken down into two categories: (1) theories of behavioral prediction or explanation and (2) theories of behavior change or action. Explanatory or predictive theories help identify factors that may influence a health behavior; if properly specified, explanatory theories should then be able to predict reasonably well who will be more or less likely to perform a given behavior. In contrast, theories and models of behavior change focus on the change process; these theories tend to detail stages through which individuals progress before achieving lasting health behavior change. Although these two types of theory often have different emphases, they are complementary. For example, knowing the reasons why someone smokes is important for the development of effective smoking cessation materials, but equally important is an understanding of how someone who has made several unsuccessful attempts to quit in the past can progress to becoming a nonsmoker.

The major theories can be classified into roughly three categories: (1) individual level, focusing on constructs such as knowledge and attitudes; (2) interpersonal level, emphasizing social factors, such as social norms or social support; and (3) structural or environmental, emphasizing multiple levels of influence, including access to resources, laws, and policies. The most commonly used theories cut across these levels, and the most widely used theories have also most often been subjected to testing in scientific research, which is important to advancing our understanding of health behavior.

The *health belief model* was originally developed to explain why people took or did not take advantage of preventive services such as disease screening and immunizations. The model suggests that if a person believes that a health threat has severe consequences (i.e., it could cause death or serious illness), and that he or she is susceptible to developing or contracting a harmful health problem (that it could happen to him or her), then he or she will be motivated to act. To take action against that threat (i.e., change their

behavior), the individual must perceive that the benefits outweigh the costs of the preventive action. For example, if a flu epidemic is predicted for the winter, a person needs to feel that (a) he or she could get the flu, (b) it would be a serious problem, and (c) an action (such as a flu shot) would help enough to take the time and undergo the possible pain of getting the shot.

The *theory of reasoned action* proposes that the most proximal indicator of actual behavior is behavioral intention. Behavioral intentions are a function of (a) attitudes toward the behavior and (b) subjective norms regarding the behavior. An extension of the theory of reasoned action, the *theory of planned behavior* includes the idea of perceived behavioral control. Perceived behavioral control depends on specific beliefs about the likelihood that certain conditions might affect the ability to control the behavior, and whether or not those conditions would encourage or constrain behavioral performance. For example, if a person thinks she can afford a mammogram for early detection of breast cancer, she would be more likely to make an appointment for it than if she doesn't have health insurance coverage.

Social-cognitive theory (SCT) posits that people and their environments interact continuously. A basic premise of SCT is that people learn not only through their experiences but also by watching the way other people act and the results they achieve. According to SCT, three primary factors affect behavior. First, individuals must have self-efficacy or the confidence in their ability to perform the behavior (akin to perceived behavioral control above). Second, individuals must have personal goals that provide them with meaningful incentives for change. Third, the perceived advantages of practicing the behavior must outweigh the obstacles that hinder behavior change.

Social ecological models of behavior change emphasize the importance of the interplay between individuals and their environments. Social ecological models suggest that health behavior determinants are at multiple levels, so that individual, social, and environmental forces all determine health behavior. Ecological models are receiving increasing attention as many behavioral epidemiologists and public health experts recognize that behavior is not simply the result of individuals' knowledge, attitudes, and beliefs.

The *transtheoretical model* (TTM)—often referred to as the stages of change model—addresses individuals' readiness to change their behaviors from unhealthy to healthy ones. Its basic premise is that individuals are at varying levels of "readiness" to change. This means that people at different points in the process of change can benefit from different programs for change. In developing successful behavior change intervention, the programs work best if matched to the person's stage at that time. For example, a smoker who has never thought about quitting will need different messages (to motivate the smoker to think about quitting) than a smoker who has made repeated unsuccessful attempts and may need messages that will build self-efficacy with respect to quitting.

It is important to bear in mind that the various theories of health-related behavior often overlap. Not surprisingly, these explanations for behavior and models for change share several constructs and common issues. Among these are the idea of behavior change as a process, not an event; the distinction between initial behavior changes and long-term maintenance of healthier practices; and the notion that people often weigh the barriers to action against the expected benefits when making decisions about their health behaviors.

While policies, laws, and regulations can affect health behaviors, there are also many individual factors to consider in public health efforts. Behavior change is incremental, and lasting changes are not achieved easily. Public health programs need to identify and maximize the benefits, or advantages, of positive change; push or pull participants along the continuum of change; and consider changes in educational programs and environmental supports to help people who have made positive health behavior changes to maintain them over the long term.

Health Belief Model

What does it take for people to act to protect themselves from illness? This is the fundamental question posed by the framers of the Health Belief Model (HBM), and it has continued to be addressed by researchers over the past five decades in the disciplines of public health, health psychology, and health education.

Background

The HBM was originally developed by Godfrey Hochbaum, Irwin Rosenstock, and other research psychologists in the U.S. Public Health Service in the early 1950s as they applied cognitive and learning theory to understanding and predicting health behavior. The original work in this area grew out of an attempt to understand the limited utilization of public health programs for disease prevention and screening (including tuberculosis screening). The HBM is a value-expectancy theory that attempts to describe the valuation of the desire to avoid illness (or treat it effectively) and the types of expectations about health that are essential in influencing preventive (or self-care) behavior. The HBM has evolved over the years from addressing primarily health-screening behavior to applications covering the full range of health behaviors from lifestyle change for primary prevention to management of chronic illnesses and sick-role behavior.

Key Concepts of the HBM

The central variables of the HBM have been redefined over time to incorporate a number of concepts beyond those originally considered (perceived susceptibility to the risk and the perceived benefits of early detection, plus a cue to action) to include the following:

Perceived Threat

Perceived threat is a combination of two concepts:

- *Susceptibility.* This is the subjective perception of the individual's risk of developing an illness. In the context of an existing illness, it includes susceptibility to complications of advanced or recurrent disease, acceptance of the diagnosis, as well as more general susceptibility to health problems.
- *Perceived Severity.* Perceived severity is the sense of how serious an illness is and the consequences of leaving it untreated. This concept includes the perception of the possible physical consequences of an illness (e.g., pain, death) and the broader range of social consequences in a person's life (e.g., disability, stigmatization).

Perceived Benefits

Perceived benefits relate to the anticipated positive effects of taking action. This includes beliefs about the effectiveness of a course of action in reducing the disease threat, as well as other potential benefits not directly related to health (e.g., quitting smoking might be seen as a way to save money or set a good example for one's children).

Perceived Barriers

Perceived barriers are the potential negative consequences or costs associated with taking an action to improve health. The factors that could impede a course of action might include concerns about the expense, possible discomfort or danger associated with the

action (e.g., fears about pain or radiation exposure from a mammogram), and inconvenience or competition with other valued activities (e.g., having to miss work to get to an appointment). The wide range of potential barriers include logistical barriers such as cost or lack of convenient access to services, and emotional barriers such as fears about physical or emotional harm (including fear of getting a cancer diagnosis). In addition, when addressing changes in lifestyle and personal habits that may be rewarding in their own right (eating high-fat foods or smoking cigarettes), the habit strength or the loss of pleasurable activities (if not addiction) may prove to be potent barriers to health behavior change.

Cues to Action

Cues to action (either internal cues such as thoughts, emotions, or sensations, or external events that act as a prompt) were one of the initial concepts in the HBM. Interestingly, this component of the model has not been as systematically studied as several others. Nonetheless, examples clearly exist in effective screening and health maintenance interventions that derive from this concept, such as the success of reminder systems for screening tests. Another example is having a cancer diagnosis of a relative motivate people to obtain a first mammogram or colorectal screening test.

Other Modifying Variables

This category includes an array of demographic and sociopsychological variables that may greatly influence the performance of health behavior directly or may interact with the perceptions of susceptibility or seriousness. One powerful example of this variable is a person's level of education, the addition of which has improved the predictive accuracy of the model. The identification of additional social or psychological variables that may be important independent predictors or modifiers of the other variables is an important area for future research, particularly as the HBM is applied to the maintenance of preventive or self-management behaviors in chronic conditions.

Self-Efficacy

This variable was a relatively late addition to the HBM. The concept of self-efficacy, developed by Albert Bandura in 1977, addresses an additional expectancy that influences the performance of a health behavior. Self-efficacy refers to the level of confidence a person feels regarding his or her ability to perform a behavior. Bandura described a number of processes by which a person's sense of self-efficacy may be influenced, and this issue is particularly important when trying to predict or influence the adoption of new behavior patterns or the changing of lifestyle and habits to improve health outcomes. For example, confidence regarding one's skill at being able to test blood sugar and accurately self-administer insulin is essential to the consistent performance of diabetic self-management.
