The simplistic use of culture (and terms such as ethnicity) as static and unchanging has been vigorously critiqued [1, 4, 27]. As reified markers of difference they can lead to what Ahmad [1] has suggested is a loss of fluidity and dynamicism. There is also the resultant loss of explanatory power in research, caused by rigid notions of what it means to belong to a specific cultural and/or ethnic grouping and the assumed related behavioral mechanisms involved [14]. Within cross cultural research care therefore is needed to avoid these conceptual and practical pitfalls, as Lambert and Sevak argue, "culture is made as much as given" [19, p. 149] pointing to the conceptual fluidity which takes into consideration new circumstances, life events, observations and information. Without this context, often health and illness conditions are explained in terms of cultural difference without acknowledging the many other facets of social and economic experience, such as inequalities, and can prove to be a diversion away from more insightful in-roads to experience.

Helman succinctly states "culture can be seen as an inherited 'lens', through which the individual perceives and understands the world. . ." [10, p. 2] – and cross-cultural research aims to analyze the view from within and outside these lenses.

As a further cautionary note, Gunaratnam has reframed some of the complexities of cross cultural research by identifying what she calls "insecurities of meaning" [9, p. 137]. The need to work across cultures requires the establishment of meaning across them, and this has often led to the assumption that there is a pre-established reality which can be reflected in language. Cross cultural research on this basis then has as its goal the grasping of that reality as fully as possible [24]. This overriding need for shared meaning can, as Shields [26] argues ignore forms of power relations in the research settings, and obscure the dynamic and context driven nature of "culture."

Cross cultural research is useful across a range of areas, and as raised earlier, Kleinman's anthropological work has been notable in this arena for the combination of researching psychiatric morbidity across cultures using a medical anthropology framework. This type of 'clinical social science' [16] has been utilized in several countries where mental illness across cultures has been the subject of research and investigation. The underlying theoretical basis that grounds this work is the anthropological and sociological conceptual distinction between *disease* and *illness*, the former being rooted in traditional biomedical notions of biological and physiological malfunctioning. The latter is the personal, interpersonal, and cultural reaction to the disease. Eisenberg's [8] early distinction between these two entities is still the basis of much research into health, and also has particular purchase when examining cross cultural ideas. Because of the socially and culturally embedded nature of illness – psychological or otherwise – cross cultural research needs to be informed by a variety of critical disciplines which can perform the function of illuminating experiential arenas from both within and outside the experience. Practitioners and theorists alike can then begin to unpack what exactly it is we mean by cross cultural research and plan health psychological and somatic health interventions that have both utility and meaning.

Cross-Cultural Studies

Stelios Papayiannis, Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Definition

Cross-cultural studies are research designs that compare human behaviors across two or more cultures.

Description

Cross-cultural studies involve the systematic comparisons of different cultures that aim to understand variations of human behavior as it is influenced by cultural context. This research approach is primarily concerned with examining how our knowledge about people and their behaviors from one culture may or may not hold for people from another culture [1].

Cross-cultural studies share methodological similarities as any other scientific research study. However, a specific methodological parameter that differentiates cross-cultural studies from other research studies is the sample; specifically, the participation of individuals from different cultural backgrounds. In effect, this methodological distinction reveals the philosophy that cross-cultural studies bring to scientific research. As Matsumoto and Juang [1] have noted, "cross-cultural research not only tests similarities and differences in behaviors; it also tests possible limitations of our traditional knowledge by studying people of different cultures. . .the cross-cultural approach is concerned with understanding truth and psychological principles as either universal (true for all people of all cultures) or culture-specific (true for some people of some cultures)" [1].

Theoretical Orientations in Cross-Cultural Studies

The above distinction of principles in cross-cultural research can be conceptualized by the etics and emics

concepts, which were originated in the study of language by Pike (1954) and used by Berry (1969) to describe aspects of behavior as either universal or cultural specific, respectively [1]. Etics and emics approaches gave rise to a debate regarding theoretical perspectives in cross-cultural research. These theoretical orientations in cross-cultural studies have been identified by various writers in the terms of absolutism, relativism, and universalism.

Absolutism refers to a general orientation that says behaviors and the underlying processes that influence behaviors are essentially the same across cultures. In general, the assumption is that people everywhere are pretty much alike and the role of culture in behavior variation is limited. In contrast, the relativist position claims that human behavior is culture specific and should only be studied within culture. It assumes that behavior is influenced solely by cultural variation and pays little attention to any other factors. The position of universalism adopts and combines the working assumptions of both absolutist and relativist orientations. Specifically, universalism holds that the basic processes underlying behavior are common in all humans, though their manifestations are likely to be influenced by cultural factors.

Types and Methods of Cross-Cultural Studies

The debate on the theoretical orientations in cross-cultural studies has also a relative parallel on the methodological level of cross-cultural research, expressed in qualitative versus quantitative methodology. Qualitative methodologies are prominent in cultural research and mostly conducted by cultural anthropologists in the form of ethnographies. Ethnographies involve observation and field-work within the cultural context and require descriptive qualitative analysis. Despite the richness of information obtained from qualitative research the issue of validity plagues this methodology also in cultural research. Berry et al. illustrated the limitations of qualitative methodologies in the following; "experiment and measurement are de-emphasized; reality is portrayed as subjective, and the person of the researcher, including the values he or she represents, are made part of the research process. Moreover, the focus is on the construction of meaning rather than on the explanation of behavior or underlying psychological processes. . .By virtue of the absence of standardized and replicable methods, the entire research process (selection of events, assessment, and interpretation) to an important extent becomes concentrated in the person of the researcher" [2].

On the other hand, quantitative methodologies are mostly used in cultural comparative studies and follow the traditional model of hypothesis testing with comparable samples, using standardized procedures and measures, to obtain scores that are quantitatively analyzed. Van de Vijver and Leung [3] distinguished four common types of comparative studies. The first distinction in these types of cross-cultural studies is the orientation between hypothesis testing and exploration studies. Hypothesis testing studies are based on theoretical conceptions and data have to be gathered from various cultures to test the hypotheses derived from the theory. In studies oriented towards exploration the research study is driven by the instruments used in order to evaluate differences on some scale by collecting data from individuals in two or more cultures. The second distinction is whether studies consider contextual factors or not, that is, whether cultural factors would be included in the study and their relevance accounted for the obtained findings [3].

Although a distinction has been made here, and an ongoing debate exists regarding the use of qualitative and quantitative methodologies, they do not necessarily need to be mutually exclusive, but rather complementary.

Theoretical and Methodological Issues in Cross-Cultural Comparative Studies

In this section issues regarding cross-cultural comparisons studies are presented, since these are among the most common procedures used in cross-cultural research. Most of the issues in cross-cultural research are also a concern of all scientific research with humans and behavior; however, some additional issues pertain solely to the conduct of cross-cultural research, which in turn increases the challenge of carrying out such studies.

Two concepts that are of significant importance in the conduct of cross-cultural research are bias and equivalence. Bias refers to the common problem in the assessment of nonequivalent groups that scores obtained in different cultural groups are not an adequate reflection of the groups' standing on the construct underlying the instrument. If scores are biased, their psychological meaning is group dependent and group differences in assessment outcome are to be accounted for, at least to some extent, by auxiliary psychological constructs or measurement artifacts. A closely related concept is equivalence which refers to the absence of bias and hence, to similarity of meaning across groups [4].

Van de Vijver [4] identified three sources of bias in cross-cultural research. The first is called construct bias; it occurs when the construct measured is not

identical across groups. The second is called method bias, and can result from sample incomparability, instrument characteristics, tester and interviewer effects, and the method of administration. The third is called item bias, and can be due to anomalies at item level (e.g., poor translations) [4].

Similarly, Van de Vijver and Leung [3] identified four different types of equivalence. The first type is labeled construct equivalence. It amounts to comparing constructs that have the same meaning in all cultures under study. The second is called structural (or functional) equivalence. An instrument administered in different cultural groups shows structural equivalence if it measures the same construct in both groups. The third type of equivalence is called measurement unit equivalence. Instruments show this type of equivalence if their measurement scales have the same units of measurement and a different origin (such as the Celsius and Kelvin scales in temperature measurement). The fourth type of equivalence is called scalar (or full-score) equivalence. In scalar equivalence direct comparisons can be made and it is the only type of equivalence that allows for the conclusion that average scores obtained in two cultures are different [3]. For a comprehensive review on sources of bias and types of equivalence the reader is referred to Van de Vijver and Tanzer [3, 5]. In addition, linguistic equivalence is considered when conducting studies in multiple languages. Versions of an instrument in different languages show linguistic equivalence if these have the same characteristics that are relevant for the measurement outcome such as meaning, connotations of words and sentences, comprehensibility, and readability [4].

Earlier on an emphasis was given on the methodological parameter of sample selection in cross-cultural studies. Indeed, this primary distinction of cross-cultural studies from other research studies is of major importance and particular attention should be paid since it is not always carried out without errors. Specifically, and most often, cross-cultural researchers obtain samples of individuals from different countries and automatically assume that the participants are representative of the culture they intend to study. Two issues are noted here; firstly, countries do not always amount to culture. Culture is defined by most cross-cultural scholars as the set of attitudes, values, beliefs, and behaviors shared by a group of people, but different for each individual, communicated from one generation to the next [1]. The second issue is whether the specific sample of individuals selected is representative of the particular culture. A question arises; are the characteristics of individuals selected from a particular location of a country, the same as other individuals in other parts of that country? Matsumoto and Juang [1] objects and cautions to the, "unrealistic and unacceptable assumption of homogeneity among group members (that) can only serve to perpetuate stereotypic impressions and interpretations based on the findings" [1].

To address the issue of sampling in an ideal manner (randomly access all members of any given cultural population), especially in cross-cultural studies, would be a huge and taunting task regarding effort and cost. Consequently, the real issue is whether researchers undergoing cross-cultural studies have a grasp on the difficulty of achieving this ideal and on exercising the relevant caution when attempting to interpret the findings obtained from cross-cultural research.

Conclusion

Cross-cultural studies main importance is to advance and expand our knowledge beyond the confinements of our particular surrounding context, encompassing a universal perspective in understanding human behavior. Cross-cultural research provides benefits that transcend the limits of the traditional research approaches. Theory and method of cross-cultural studies provide a framework in which cross-cultural research is developed, along with the challenging issues that cross-cultural researchers face when conducting such studies. Many of those issues are simply extensions of the general scientific research with human behavior, and others are specifically pertinent to cross-cultural studies. Despite the problems and limitations, the benefits and advantages of cross-cultural studies far outweigh the difficulties.

Cross-Culture Perspective on Bereavement Springer

Anne Fierro Vanderlaan
Saybrook University, Meridian, ID, USA

Synonyms
Grief; Mourning; Sadness

Definition
The reactions to bereavement or loss of loved one from death or loss of a relationship. These feelings of loss may bring about grief.

Description
Various cultures have diverse ways in the way they experience bereavement. There are many ways that grief or mourning may be expressed. In the United States, for example, the families of the deceased may continue to talk about the person as if he or she were still alive. The cross-culture perspective on bereavement depends upon various ways cultures suffer losses. There can be phases of natural grief that may be universal (Bowlby and Parkes, 1970); these are described as feelings of numbness, desire, longing, seeking combined with incompetence, inadequacy and anguish. Grief is not an illness and various individuals may need time to recoup their loss. Some people are never able to totally feel whole again. Cross-cultural differences transcend culture in expressions of grief. What may be normal for the way one person reacts to suffering may be abnormal in another. There are healthy and unhealthy ways in which people respond to the grieving process. In Kaliai, people describe death by suicide or violence as magic or sorcery. Some cultures believe that the dead continue to live on in another world. The Balinese never display any grief. In Mexico, The Day of the Dead is celebrated. Many cultures also see the ghosts of their loved ones. African Americans grieve more openly in comparison to other cultures in the United States. Mutilation is also common in some cultures. In India, a widow may burn herself to death at the funeral pyre of her husband. In Bumbita Arapesh, a young man bereaves 10 years after the death of his father because of his belief that no one could show him how to live as a successful adult. The son also felt in some way it was his fault that his father had died because he did not protect the father when he was sick against evil sorcery. The questions remain how people grieve, what is the meaning of death and how one remembers or forgets the loved one and it varies from culture to culture and person to person. A broader focus on religions in culture will play an important part in the cognitive process in the existential adjustment of the mourner. One element that helps with bereavement is to have a personal narrative of the death of the loved one. If a person dies of old age most often there is an acceptance of growing old and living a long life. Those who may die suddenly (i.e., a car accident) allows family members to reflect on whether the person had not been driving or had not left the house. As an example, a young couple had to travel a long distance and had a car accident; the wife died upon impact. While preparing for the funeral, a note was found on her computer explaining how she would want her funeral arrangements to be accomplished. This letter gave the family a personal narrative because they thought the women had somehow known she was going to die. They also had a religious belief that the earth had a veil over it so that people could not see into the next life where the dead live in another realm. They believed that her spirit would live on forever and that they would be together in the life after death. They celebrated her death into the passing on to the next life.

Cross-Race Friendships

Matthew J. Taylor
University of Missouri-St. Louis, One University Boulevard St. Louis, MO, USA

Synonyms
Interethnic friendships; Interracial friendships

Definition
Cross-race friendships are personal relationships based upon mutual affection, caring, concern, and/or trust that occur between individuals of different racial backgrounds.

Description
The most basic definition of cross-race friendships is relatively straight-forward and easily described. In kind,

these types of relationships are not all that different than any other friendship circumstance in that they are characterized by the universal elements of friendship: interpersonal connectedness, mutual caring and concern, and fondness, to name a few. However, these scenarios move beyond the fundamental notion of friendship within many societies due to historical, social, and political meaning-making systems. That is, cross-race friendships frequently represent more than the relationship between the two individuals, but rather how these relationships are viewed and interpreted (i.e., either accepted or rejected; fostered or discouraged) is symbolic of and influenced by broader, societal nuances and themes that relate to race relations.

Race: A Socially Constructed, Biologically Triggered Concept

A more in depth analysis of cross-race friendships begins with a general understanding of race. Race is frequently considered to be a purely biological construct and a variable rooted in genetics; surmised from parental genotype and subsequently revealed through an individual's physical appearance (i.e., phenotype). And while there is clearly some link between parental genetic contribution and eventual physical appearance, the full reality and meaning of race moves beyond perceived appearance, an increasingly less than foolproof method of determining lineage and cultural background with a growing multiracial population, and ultimately into socially constructed definitions. In short, an individual's perceived appearance triggers interpretive tools which subsequently give "the biological" cultural meaning; that is, biology triggers socially constructed meaning and interpretation. A society's racial ideology is rooted in what Omi and Winant [10] term "racial etiquette", which is this set of interpretive codes; codes of behavior, attitudes, values, and beliefs. These culturally defined codes offer meaning to physical characteristics; for example, describing someone as "black" in the United States means something very different than "black" in Australia, South Africa, or Kenya.

Present day racial ideology has to be understood through its earliest sociohistorical lineage. Racial appearance, social hierarchy, and power have been interrelated since early European exploration (and later colonization), that resulted in contact with a number of indigenous societies, who were universally deemed as primitive and inferior. Race and overt appearance were not only used to distinguish the (White) Europeans, with all of their "positive" traits and qualities from all others, but it also became the means and "marker" from which infer a host of innate characteristics about groups and individuals. "Scientific" evidence and justification of this designation and hierarchy was provided by early biological theories, such as those of: Carolus Linnaeus, whose *Systema naturae* (1735) presented a classification system for plants, animals, and minerals; and Charles Darwin, who's *Origin of Species* (1859), set forth the theory of natural selection ("survival of the fittest"). Racial appearance became "an outward mark of innate and permanent inferiority" [14].

As societies around the globe took shape under the framework of colonization, a racially-based "system of appearance" developed that was more rooted in social, economic, and political forces, and whose implementation simultaneously led to societal and individual discrimination, both of which maintained a social hierarchy [10]. Simply put, humans gave race and racial appearance its power; and with the resultant links to value judgments and conclusions about "others", it has become one of the most important and meaningful contributory factors in human relationships. These early notions of race, and perceived phenotype, provided the basis for a recurring pattern of control and oppression that would later come to be the sociological and psychological foundations of cross-race relations.

The Meaning of Cross-Race Friendships

As noted before, the meaning of cross-race friendships is, in large part, related to how society views the groups involved and the associated collective traits (e.g., stereotypes) ascribed to them. Of consideration is how these societal meanings and beliefs are transmitted to and incorporated by children into their conceptual understanding of others. It is clear that young children learn preconceived notions of others, whether directly or indirectly, from socialization agents (e.g., parents, other caregivers, peers, media), which results in the expression of specific racially-based ideologies [4, 15]. It is important to note that these perspectives may (initially) be less rooted in a young child's individual belief system and be more of a reflection of the internalized messages received from socializing agents and other influential sources.

The concepts of assimilation and accommodation suggested by Jean Piaget in his theory of cognitive development shed some light on this process of understanding others. Assimilation is the cognitive process through which children incorporate or add new information into their current constructions and understandings of the world. Utilized among younger children, it is a relatively unsophisticated cognitive undertaking, such that information that does not fit with prefabricated frameworks or schemas is disregarded. An example of this is the finding that younger children typically consider members of racial groups as more similar to each other, meaning that

they see little variation within groups and conclude that others are "all the same" [1]. As a child/adolescent's level of cognitive sophistication develops, there comes an increased ability to adjust and modify these other-schemas, and in doing so, account for new ideas and information; this is called accommodation. It is through this process that one can begin to more clearly account for and comprehend variation within a category or group. With older children, some research has concluded that they not only note fewer differences between racial groups, but are also better able to see beyond group stereotypes and see group members as individuals [1].

Children and Cross-Race Friendships

Generally speaking, cross-race friendships occur less frequently than same-race ones and decline in frequency and closeness as children get older [2]. A child's environment (e.g., family, peers, school) plays a significant role in their view on and access to others, and ultimately on cross-race friendships. Of noteworthy influence is the family, such that a child's perception of her caregivers' racial attitudes was found to be related to her own attitudes about intergroup contact and the ensuing likelihood of engaging in cross-race friendships [3]. Moreover, children with less biased attitudes about others are more likely to have cross-race friends [2]. Another contributing factor to cross-race friendships is a child's amount of intergroup contact. A racially diverse classroom (or other smaller setting) seems to offer the most consistent and intimate opportunity for children to develop cross-race friendships [8]. Students who attend more racially diverse schools regularly report more friends from different racial backgrounds; with minority students typically reporting more cross-race friendships than European-Americans [13]. However, attendance at a racially diverse school does not automatically yield an increase in cross-race friendships, and may not always be the most conducive to developing these. Size limitations, lack of intimacy, and threats of friendship segregation exist in large, loosely organized heterogeneous environments, and may result in racially-segregated "neighborhoods" of student groups [8].

A variety of research has shown that within diverse school settings, there are differential effects and outcomes on cross-race attitudes and friendships based upon the racial background of the child. For example, McGlothlin et al. (2005, as cited in Ref. [5]) concluded that European-American (white) students who attended diverse schools were less likely to view cross-race dyads as potential friendships. Moreover, European-American students attending diverse schools reported fewer school friends, which may suggest some discomfort with the diversity within the student body [13]. An outcome of this could clearly be a decrease the likelihood of cross-race friendships. Finally, exposure to a diverse school environment for European-American students does not seem to result in a greater perception of variability within other racial groups, although it does for minority youth [6]. An inability to view someone as an individual and not as a representation of their racial group reinforces their status as different and other. This in turn decreases the likelihood that similarities with another are noted and it is these commonalities that would form the foundation of a (cross-race) friendship. These influences contribute to the fact that European-American children are less likely than their minority peers to engage in cross-race friendships [2]. These conclusions further suggest and highlight decade-old findings that majority group students may be at greater risk to develop racial biases, given the support of these biases by societal messages and images, which would decrease their ability and/or desire to enter into cross-race interactions or friendships [15].

Importance of Cross-Race Friendships

The world is shrinking and physical access to diverse cultures is a daily reality for many. The growth of a skill set that affords an ability to function in a multicultural setting and to successfully negotiate interpersonal interactions with a wide array of people is fast becoming one of the most critical developmental tasks for twenty first century humans. It is not surprising that cross-race friendships not only result in the reduction of prejudice among children, but also have a significant impact on adult attitudes and behaviors [2, 12]. Recent work has suggested that a reduction in racial bias, which could conceivably be both a precursor to and an outcome of cross-race friendships, results in less anxiety and more psychological comfort while in intergroup contexts [7, 11]. Cross-race friendships have also been found to have a positive impact on academic achievement for minority students [9].

Cross-Sectional Research

Carol D. Daniels
Emporia State University, Emporia, KS, USA

Definition

Cross sectional research is a study in which subjects of different ages are compared at the same time. It is often used in developmental psychology, but also utilized in many other areas including social science, education and other branches of science. This type of study utilizes different groups of people who differ in the variable of interest, but share other characteristics such as socioeconomic status, educational background and ethnicity [3, 4].

Description

Researchers studying developmental psychology may select groups of people who are remarkably similar in most areas, but differ only in age. By doing this, any differences between groups can presumably be attributed to age differences rather than to other variables [3].

While the design sounds relatively simple, finding participants who are very similar except in one specific variable can be very difficult [2]. Additionally, groups can be affected by cohort differences that arise from the particular experiences of a unique group of people. Individuals born in the same time period may share important historical experiences, while people born in a specific geographic region may share experiences limited solely to their physical location [3].

Cross-sectional research differs from a longitudinal research in that cross-sectional studies are designed to look at a variable at a particular point in time. While longitudinal studies involve taking multiple measures over an extended period of time, cross-sectional research is focused on finding relationships between variables at a specific point in time [1].

Relevance to Childhood Development

The benefit of this type of research is gaining an understanding of specific variables at various points in life. The data is gathered from generations of people who share the same cultural experiences, in which these shared events may play a role in development. The purpose of this type of research is to gain an understanding how age may impact a specific variable in order to understand the development of individuals over the lifespan.

Cultural Assimilation Model

Silvia L. Mazzula
John Jay College of Criminal Justice – City University of New York, New York, NY, USA

C

Synonyms

Cultural adaptation; Second-culture acquisition

Definition

Cultural assimilation models describe changes that occur for immigrants as they encounter and interact with a host culture [1]. In the 1920s, sociologist Robert Park was the first to describe cultural assimilation as a unidirectional process of adaptation whereby immigrants endorsed the values, behaviors, and ideals of the host culture, and simultaneously lost the values, behaviors and ideals characterized by the immigrant's culture of origin. At that time, cultural assimilation and notions of "one people, one culture. . .one nation" were the prevailing view in American society, mostly comprised of White ethnic immigrants. Immigrants were expected to adapt, assimilate and eventually resemble members of the host culture: those that retained any characteristic of the culture of origin were considered un-American [1, 2]. At that time, most immigrants in the USA were considered White ethnics and assimilation was feasible so long as immigrant communities were able to shed more obvious signs of immigration, such as accents or speaking a language other than English. Immigrants of Color were often marginalized because they were unable to assimilate in the same way as White ethnic groups because of their skin color or phenotype [2]. However, in the 1960s, the USA was marked by key historical events, such as the civil rights movement and the onset of Black Nationalism, which prompted acceptance of ethnic heritages other than White European heritage and also challenged cultural assimilation models. Currently, scholars and researchers who write about cultural adaptation criticize cultural assimilation models because these do not capture the experience of individuals who are bicultural, a phenomenon that is very likely to occur for many Americans, as the USA continues to become a multiracial and multiethnic society.

Cultural Bias

Tom E. Yingst III
University of Texas, San Antonio, TX, USA

Synonyms

Attitudes; Behaviours; Beliefs; Social practices; Systemic bias that is associated with a partiality to a sub-group or particular group values

Definition

Cultural bias involves a prejudice or highlighted distinction in viewpoint that suggests a preference of one culture over another. Cultural bias can be described as discriminative. There is a lack of group integration of social values, beliefs, and rules of conduct. Cultural bias introduces one group's accepted behavior as valued and distinguishable from another lesser valued societal group. Cultural bias has been found to be a factor in determining where particular persons live, and what they have available as educational and health care opportunities.

Description

Cultural bias highlights differences among persons and groups. Cultural bias groupings can be identified in differential characteristic preferences. They may include differences in levels of socio-economic status, language, race, ethnicity, religion, or sexuality. Cultural bias can support myths or stereotypes of cultures and in similar fashion may lead to racial and ethnic profiling. For example, a standardized test that offers an unfair advantage; it may beneficial one cultural group but disadvantage those who are not of that cultural group.

Cultural bias is often found in classrooms. Instances include: books and story line representations that suggestion that one group is of less valuable than another.

Relevance to Childhood Development

Cultural bias is learned and develops as the child understands and functions comfortably within an immediate group (society). By the age of 5, children are aware of their cultural and ethnic background as well as the differences between themselves and others. These differences and how they are introduced to the child set the stage for cultural bias may be observed in their speech and behavior toward those who are different. Bias is introduced in how the child has been taught to value or de-value the identified cultural difference.

Relevance to Parent–Teacher Relationships

Cultural bias may be addressed by encouraging parent–teacher communications to help the early childhood professionals better understand parent's cultural perceptions and expectations of their child in relationship to the school program.

In sum, cultural bias reflects preference of one culture over all other and is designed to segregate societal systems.

Cultural Deficit Perspective

Sarah Kozel Silverman
The Ohio State University, Columbus, OH, USA

Definition

A cultural deficit perspective is comprised of two parts: (a) the attribution of an individual's achievement to cultural factors alone, without regard to individual characteristics; and, (b) the attribution of failure to a cultural group. In other words, a cultural deficit perspective is a view that individuals from some cultural groups lack the ability to achieve just because of their cultural background.

Description

Deficit models in general suggest the cause of underachievement lies within the individual rather than the individual's environment. For children in learning situations, the environment may include the learning context such as the safety or comfort of a classroom, the teacher or parent and his or her presentation of new material, or other external factors. The cultural deficit perspective in particular places the cause of underachievement within an individual's cultural group. Some cultural groups have been highly susceptible to cultural deficit explanations of their relative underachievement in academic settings whereas other groups have been stereotypes as consistent high achievers.

Cultural deficit models have been used in a variety of ways. Public policy reports provide an apt illustration. Although these models are often presented in an effort to explain socioeconomic or educational disparities, they can ultimately be harmful to children of non-European ancestry because they impede efforts to promote equality [1]. A report by U.S. Senator and sociologist Daniel Patrick Moynihan in 1965 sparked debate in the United States regarding the role of the federal government in promoting equality between Black families and White families [2]. Although Moynihan's report was designed to provide solutions for strengthening the often poor African American family, it suggested the "disintegration" of the family was to blame for inequity. Later in Great Britain, controversy over the treatment of Afro-Caribbean children in the British education system led to the development of the Swann Report of 1985 [3]. The Swann report concluded that it was neither the students themselves nor the experiences of their cultures that led to low achievement. Instead, it was implicit stereotypes on the part of the education system, such as teacher expectations of failure or mediocrity and other race-based bias.

Employment of a cultural deficit perspective places the burden of underachievement on the culture rather than the social institutions in which underrepresented minorities do not succeed. As a result, the employment of such a paradigm in the study of child development may hinder rather than enhance a parent, teacher, or other community member's ability to work towards achievement equity for all individuals, regardless of cultural group membership.

Cultural Difference

Anthony Jackson, Norma S. Guerra
University of Texas, San Antonio, TX, USA

Synonyms

Eccentricities of a ethnic or racial group; Ethnic tradition; Lifestyle mores; Specific folkways

Definition

Cultural difference involves the integrated and maintained system of socially acquired values, beliefs, and rules of conduct which impact the range of accepted behaviors distinguishable from one societal group to another [1].

Description

Cultural differences contribute to persons' relationship with their external environment. The result of these groupings can be characterized in identifiable behavioral, and personality differences. Addressed as social competencies, they may include differences in levels of self-disclosure, assertiveness, willingness to cooperate, maintain positions of individual or shared interpersonal style. For example, the culture that dictates that individuals dominate their environment in contract with the culture that promotes living in harmony. Worldviews may as well reflect cultural differences. While one culture values the contributions of their forefathers in response to current societal needs another invests in their youth to seek solutions to the same societal demands.

Relevance to Childhood Development

Cultural competence develops as the child understands and functions comfortably within an immediate grouping (society). By the age of 5, children are aware of their cultural and ethnic background as well as the differences between themselves and others. Further, they are able to demonstrate these skills in speech and behavior. Examples include: established appropriate social relationships with family, friends, learned use of categorical and symbol systems, and developed abilities to organize and regulate their own behavior in situations that are either unfamiliar or familiar [3].

Cultural differences can also be found in individual classrooms, so it is important to consider the child's heritage and any developmental or maturational differences as separate and apart from culture. The valuing of cultural differences can be introduced in the classroom through group activities, for example, inviting the children to share their own cultural heritage. This type of activity encourages the children to value the unique qualities associated their cultural tradition, promotes cultural pride and facilitates a greater self-understanding [2].

Relevance to Parent–Teacher Relationships

Invite teachers and parents from different cultural groups into the home to help the child become comfortable with persons that are different. Encourage parent teacher communications to help the early childhood professionals better understand parent's perceptions and expectations

of their child in relationship to the school program and differences in culture. Be mindful of stereotypical remarks about cultural differences and the social injustices than are often associated with cultural differences.

In sum, cultural differences reflect distinct integrated societal systems.

Acculturation; Cultural learning; Enculturation; Socialization

Definition

Cultural transmission is the process through which cultural elements, in the form of attitudes, values, beliefs, and behavioral scripts, are passed onto and taught to individuals and groups.

Description

A Brief Definition of Culture

Culture represents a collection of attitudes, values, beliefs, and behavioral scripts that are generally agreed upon by a group of individuals. It can include everything from language, marriage practices, and governmental configurations, to definitions of family, greeting behaviors, housing structures, and death rituals, to name a few. A primary role of culture is to provide a consistent and stable environment or framework whose goal is to ensure or, at the very least, enhance, the survival of the group. At its broadest level, culture represents mainstream tendencies, but there can be "culture within a culture" whereby smaller segments of the population (i.e., subcultures) have cultural themes that differ from the mainstream. An example would be an ethnic neighborhood in a large urban center where there is the maintenance of the heritage culture; language of origin is often spoken, traditional foods are readily available, and other cultural practices (e.g., multigenerational households) are still followed.

While culture largely represents a group-related venture and construct, it also has a uniquely personal and individual sense to it. There is a great deal of subjectivity in comprehension, interpretation, and incorporation of cultural themes, as individuals vary in their degree of adherence to broader cultural notions. Related is the fact that there is a bi-directional, reciprocal relationship between individuals and culture. On-the-one-hand, we are products of our culture; molded and shaped by its influences. That is, we frequently represent the outward manifestation of our cultural background and experiences. Conversely, individuals have the ability to call for and bring about cultural change, as evident throughout human history (e.g., slavery) where social change has taken place and cultural values have shifted [1].

The Conveyance of Culture: The Processes of Enculturation and Socialization

Cultural elements and themes are not innate to the human experience, but are rather learned and taught. Generally there are three types of cultural transmission: vertical, oblique, and horizontal [2]. Vertical refers to the passing on of cultural knowledge from parents/caregivers to children. Oblique is the more diffuse, intergenerational transmission of culture, whereby unrelated individuals from one generation pass on culture to the next. And horizontal transmission is akin to peer learning, as members of the same generation pass on cultural elements to each other. Regardless of cultural transmission type, there two primary areas of foci: (1) the processes involved; and (2) the entities who utilize these processes. In terms of the former, the two processes through which culture is learned and taught are enculturation and socialization. Enculturation refers to the process through which an individual learns

aspects of a culture based on what is (made) available to her [3]. This process is non-deliberate, informal, and indirect, meaning that there is no prescribed set of outcomes to be attained, but simply that an individual learns cultural elements by virtue of being exposed to them. An example of this is language, such that we generally develop our primary capacity for the language that we grow up most exposed to. Another example of this process is where children will often display attitudes, values, and beliefs similar to parents and caregivers, prior to attaining a real in depth understanding of them from their own perspective.

The companion process to enculturation is socialization. It too represents a means though which an individual learns about culture, but with one significant difference: the individual is specifically and intentionally led to develop culturally endorsed attitudes, values, beliefs, and behaviors. Socialization is a more deliberate, goal oriented process which involves a degree of teaching an individual about culture. Citizenship classes attended by immigrants en route to becoming citizens are one example. Additionally, enrolling children in religious instruction classes is another example of socialization; conversely, having children attend religious services with family is more enculturation. Enculturation and socialization are not always mutually exclusive processes and can take place simultaneously. The aforementioned example of language as enculturation is an example of this, as it can also be related to socialization; given many formal educational settings have a language and grammar component which is linked to deliberate tutelage.

The goals of enculturation and socialization are related. They both: prepare individuals to become successfully functioning members of society; teach culturally desirable behaviors; guarantee that important traditions will be passed to future members of society. In sum, enculturation and socialization are lifelong processes that occur in a wide variety of contexts. They both influence every facet of our lives and contribute to our development across the lifespan.

Variations in Cultural Transmission

While cultural transmission is a universal process, exactly *what* information is transmitted is more culture specific. Variations in cultural transmission occur because of differences in what is available to be learned and what is deemed necessary for an individual to know. Perhaps most easily seen are the variations that occur between cultures, particularly ones that are viewed as fundamentally dissimilar. Offered as an example are the types of information and knowledge made available and considered as necessary for success within a hunting-gathering tribal culture (e.g., foraging and hunting techniques) compared to an urban-industrialized one (e.g., negotiating the use of public transportation). However, variations in cultural transmission can also occur within cultures, as different groups of people (e.g., families, peer groups) may have variable access to cultural elements, different interpretations of them, or may place a different value on what is viewed as essential for survival. A key element of cultural transmission is that it is, in part, transmitted across generations, or at the very least, between individuals. These sources of cultural information are known as socialization (or socializing) agents. They represent the entities that have the ability to educate and indoctrinate us into the cultural milieu and can include; family, peers, teachers, community elders, and media sources, to name a few.

To further understand the nuances of cultural transmission, one must consider that it occurs within a sociocultural context and this influences and dictates potential outcomes. Two theories that present a framework from which to grasp the length and breadth of the influence of a cultural context with the resultant variations in cultural transmission come from Bronfenbrenner [4] and Super and Harkness [5]. Bronfenbrenner's ecological model of human development describes four nested systems of influence, which are arranged like the concentric rings within a tree, and impact the individual, who is found at the centermost point. In order of proximity to the individual and immediacy of influence, they are the microsystem, mesosystem, exosystem, and macrosystem. Each layer is affected by another and these eventually impact the individual at the core. The layers further away from the individual offer more indirect influences. For the sake of simplicity, we will focus on the micro and macro-systems. The microsystem is the "closest" system to the individual and is comprised of those entities and persons that represent immediate and daily (e.g., face-to-face) interactions, such as family, peers, and school to name a few. The macrosystem, which is the most distant and complex of the systems, is akin to a society's culture, and is comprised of culturally based values, attitudes, and beliefs. Of note is the interaction that occurs between the micro- and macrosystems and its resultant impact on cultural transmission. At the microsystem level, families may recreate and "pass on" the culturally based messages that are rooted in the macrosystem; and may do so with little alteration of their original meaning. However, another response could be that families or peers alter or counter macrosystem influences and messages, especially if there is the

perception that they are potentially negative, not useful, or unnecessary for successful functioning. For example, consider an individual who is female and lives in a gender conservative country (macrosystem), yet whose family (microsystem) does not strongly adhere to this cultural value; as such, they (enculturate) and socialize her in accordance with this microsystem value structure, which differs from mainstream notions.

A similar theory which also provides a means for the conceptualization of sociocultural influences upon cultural transmission is the development niche theory of Super and Harkness [5]. It is comprised of three components or subsystems: setting, customs, and psychological characteristics of the caregiver. Setting refers to the context of influence upon an individual and includes both physical (e.g., climate, available objects – such as toys and technology) and social (e.g., family structure, size of peer group). Customs are defined as culturally determined practices and behaviors. And caretaker psychology refers to the attitudes, beliefs and characteristics (e.g., parenting style) of socializing agents. Not only are each of these domains impacted by broader cultural themes, but they also interact with one other. Variations in cultural transmission could result from any number of changes within each of these components or in their interaction. For example, say a family relocates to a different part of a country, this would represent a change in setting, and within this new location, there may be variations in what broader cultural themes are conveyed from the community. Furthermore, in spite of the influence of this hypothetical community there would still be the influences of caretaker psychology, which would also create variations in what was selected to be transmitted and how.

Acculturation: Cultural Transmission from Outside One's Own Culture

Up until now we have discussed and framed cultural transmission as taking place within a particular culture and done largely by other members of the same group through enculturation and socialization. However, another means of cultural transmission is acculturation, which is a process by which different cultural groups come into contact with one other and results in a cultural change of either one or both. Most often acculturation is framed in terms of two groups, an acculturating group, such as immigrants, and the dominant culture, that is, the group established in the new location that sets the mainstream cultural tendencies. As a result of this intercultural contact, the transmission of the new (dominant) culture to the acculturating group occurs, whereby the group may shed its original cultural customs and traditions and adopt cultural nuances more similar to the dominant one. Graves [6] suggests that acculturation produces cultural changes on two levels, group and individual, the latter of which is termed psychological acculturation. Group level acculturation involves changes in the overall culture of the group, such as newly acquired political freedoms, biological changes due to an alteration of diet, social changes (e.g., alterations in marrying practices), or economic shifts, to name a few. Psychological acculturation represents the psychological shifts of individuals within acculturating groups and represents the degree to which they participate in the group cultural shifts. It is more related to individual outcomes from the acculturation process and is characterized by changes in individual identity, values, and behaviors. As such, there is a great deal of variation in how individuals within a group respond to acculturation and the impact of another culture.

Within psychological acculturation there are four acculturation strategies, that in some ways could also be viewed as outcomes the acculturation process: integration, assimilation, separation, and marginalization [7]. These strategies relate to the degree to which an individual accepts and gravitates toward the new culture, while simultaneously, they shed or unlearn elements of their original culture. These processes involve more than an individual making a conscious effort or attempt toward a specific outcome, but are also influenced by attitudes, values, and beliefs, and behaviors of the dominant culture in relation to the acculturating group. Integration is defined as the circumstance when an individual maintains cultural elements of their original culture and at the same time develops nuances of the dominant culture. Individuals who utilize this acculturation strategies display similar adeptness in cultural competency with both their original culture and the dominant one. The process of assimilation involves little maintenance of original culture and a movement towards or into the dominant culture. Symbolic of this are scenarios where individuals change their names to ones that sound more like those of the dominant culture; or when people intentionally do not speak their native language in lieu of the dominant one. There have been instances of forced assimilation of certain groups by the dominant culture; the American Indian boarding school movement, where children were taken from their families and sent to residential schools to be "Americanized", is an example of this [8]. The acculturation strategy or outcome of separation occurs when an individual or a group maintain their original culture and make little attempt, if any, to inculcate elements of the dominant culture into their cultural repertoire. Separation is a more viable outcome when individuals have a strong

base of their original culture, along with ready access to its features; such as an ethnic enclave or neighborhood nestled in a large urban center (e.g., Chinatown), or another locale culturally distinct from the mainstream (e.g., a military base located within another country). Marginalization, the last potential outcome or acculturation strategy, is when an individual is unable to maintain ties with their culture of origin, perhaps due to enforced cultural loss, and they also do not adopt the ways of, or are not afforded acceptance within, the dominant culture, possibly due to exclusionary attitudes or practices. Regardless of the degree to which individuals and groups acculturate, it is a process inexorably linked to the relationship between non-dominant and dominant cultures and is further influenced sociohistorical and sociopolitical themes.

Culture

Stacy A. S. Williams
State University of New York at Albany, Albany, NY, USA

Synonyms

Customs; Ethnicity; Traditions

Definition

The customary beliefs, social norms, and material traits of a racial, religious, or social group.

Description

The way we live our lives, the decisions we make about family, friends, and work, or the way in which we parent our children are all influenced by our culture. In essence, we are by nature the sum of childhood experiences which invariably are linked to the values and traditions of our families. It follows then that culture can be defined as "a group's common beliefs including shared traditions, language, styles, values and agreement about norms for living" [5]. In many ways, culture identifies what is considered acceptable and unacceptable behaviors. It provides the markers by which behaviors are judged and group membership is cemented. Overall, culture defines one's thinking and behavior [5].

Although members of a social group may share common values and/or traditions, there exist subcultures within any social group. Cultural groups often demonstrate greater intra- versus inter-variability. To further complicate the influences of culture on human development, members of a subculture may differ from each other in terms of education, socio-economical status, regional residency, or immigration history [2, 5]. Hence, one is often cautioned against generalizing about groups due to the variability that exists within all groups. Despite the variability within groups, there appears to be some concrete markers of cultural group membership that differ qualitatively between groups. For example, this may be manifested in the way competition and cooperation are viewed and in the verbal and nonverbal style of language.

The study of culture is often juxtaposed as the cultural uniqueness of western versus non-western cultures. Western culture is said to value individualism. In this sense, members of this group are said to foster independence and individual achievement; promote self expression, individual thinking and personal choice; develop egalitarian relationships and demonstrate flexibility in roles; view the physical world as separate from the spiritual world; and associate private property with individual ownership. In contrast, individuals who are members of non-western cultures are said to value group collectivisms (e.g., many immigrant cultures in the United States). For this reason, members value interdependence and group success; promote adherence to normative behavior, respect authority/elders, and group consensus; develop stable hierarchical roles (dependent on gender, family, background, age); believe that the physical and spiritual world are in harmony; and associate shared property with group ownership [3].

The prevailing US culture is dominated by western values and ideals. Competition is the key to survival and individual survival is prized above all else. Although this is

the prevailing value system of the US culture, America is home to many groups from non-western countries, many of which retain their respective inherent culture that is predicated on the group. As such, survival of the fittest becomes survival of the group. Group cohesiveness, above all things, becomes important for survival and group social mobility.

Ogbu argues that one's immigrant history further adds to the differences in value system between mainstream American society and non-mainstream groups. He notes that these differences are a by-product of interactions with the host country, especially if subordination by another group is involved. He argues that groups that have been subjected to subordination develop an oppositional frame of reference, in that they perceive barriers to overcome as identities to be maintained. This is in contrast to groups who develop a non-oppositional frame of reference by which language and cultural differences are viewed as barriers to overcome. These cultural frames of reference are developed as a function of one's immigrant history. Ogbu identifies three types of immigrant groups: autonomous, immigrant or voluntary, and non-immigrant or involuntary. Autonomous monitories are minority groups who may be culturally and linguistically distinct, but are not economically, politically, and socially marginalized (e.g., Jews and Mormons). Voluntary minorities are people who have moved to the United States for a better life. The individuals are bringing with them the values of their home country and may in fact retain many of their traditions while living in the host country (e.g., Chinese and Punjabi Indians). Involuntary minorities are those groups who are part of the American culture due to slavery, conquest, or colonization, rather than a choice (e.g., African Americans, Native Americans, and Native Hawaiians). Involuntary minority cultures in some ways develop in response to treatment by the majority culture [2]. For example, Smitherman defined African–American language as "an Africanized form of English reflecting Black America's linguistic-cultural African heritage and the condition of servitude, oppression and life in America [4]." Here the language which is a cultural marker is born out of the experiences this group has had in US culture [4].

The way in which we communicate utilizing either nonverbal or verbal skills is just as important as our beliefs and value system. Miscommunication often arises between groups based on a lack of shared understanding of language nuances [1]. For example, American Indians, Asians and Hispanics are said to speak softly, Whites tend to speak loudly and fast, and Blacks use affect when attempting to get the point across [6]. More times than not Black tone is misperceived as argumentative by others, while many may wish Asians to speak up to get their point across.

In summary, we are all the sum of our experiences (i.e., country of origin, family background, educational status, economic status etc.). Culture is a group's beliefs and values, its language (i.e., verbal and non-verbal cues), style, traditions, and acceptable norms for behavior. There are more within group variances in cultures creating subgroups/subcultures. In addition, within a subculture, individuals may differ from their reference group based on their own unique experiences [5].

Culture Development

Definition

The processes of understanding ways of thinking, developmental ways in problem solving, and examination of human development; the cultural historical involvement in traditions, historical events and understanding cultural communities and one's own individual process of development.

Description

Cultural development is the directional progression of thoughtful consideration to the cultural progression in human expansion, through changing contributions in cultural activities of one's everyday human experiences. This process can be accomplished by first examining one's assumptions of how things should be done. This involves understanding that there are values, traditions and others ways to accomplish goals or tasks. Cultural procedures are connected by multifaceted functions that depend on many variables. These can include economics, community development, the community's acceptance of what is normal or abnormal and the constellations of the family. The idea or ways of doing things are a continuous process that are changeable. In culture development, one does not have to abandon what they feel or think; an individual can be

open to change or understand how other cultures work. This understanding can help an individual move beyond ethnocentrism and consider the value of knowledge. Understanding one's own culture either from a collectivist or individualist culture is also a dramatic issue.

Relevance to Childhood Development

By studying cultural processes and how they change can help children to learn about aspects of the various origins of one's own identity, gender, communities, and how this occurs globally. In many countries of the world, children take care of other children at very young ages. They learn at a young age to reason other children. Children as young as 3 years old take care of infants in some cultures. Parents need to decide what is best for them and do that which is right and understand that there are different ways of doing in teaching their children. There are also various ways cultures think in terms of sleeping with an infant. In some areas of the world, it is not a common practice to have a child sleep away from the mother alone in a crib. The biological processes of sleep differ. In some cultures, infants sleep whenever they desire; in other cultures there is a set rule of 8 h/day. There are questions about the infant sleeping with its mother which may be connected to Sudden Infant Death Syndrome (SIDS) in those infants who sleep by themselves [2, 3]. Every culture looks at the way they think as important. Cultures have different views of how they are part of a community; others teach children to be independent. Children can learn about cultural differences and that everyone is born into a culture by being exposed to ready.

Curiosity

Thomas G. Reio, Jr.
College of Education, Florida International University, Miami, FL, USA

Synonyms

Cognitive curiosity; Collative motivation; Inquisitiveness; Novelty seeking; Sensory curiosity

Definition

Curiosity is the desire for new information and sensory experience that motivates exploratory behavior [4]. External stimuli with novel, complex, uncertain, or conflicting properties (i.e., collative stimuli) create internal states of arousal that motivate exploratory behaviors to reduce the state of arousal [1]. Through the process of being curious and exploring the environment, then, information and experiences are acquired and learning ensues.

Description

Curiosity is the fuel of learning, development, and adaptation throughout the lifespan [4]. Even our distant ancestors, motivated to satisfy their curiosity, explored the uncertain, novel properties of objects in their respective environments to learn, adapt, and thereby survive. More than ever, being curious and exploratory are the cornerstones of modern societies, as it serves to induce not only scientific, but also social, cultural, and spiritual inquiry [2].

There is a long line of systematic research demonstrating that curiosity is vital for learning and development in both animals and humans. Researchers have illustrated that animals prefer novel stimuli and contexts even in the face of being hungry or frightened [1]. Humans, too, prefer stimulating environments where they can find new information and avoid boredom for the sake of learning.

There are two major kinds of curiosity: cognitive and sensory [3, 4]. Cognitive curiosity is the desire for new information and knowledge; sensory curiosity, in turn, concerns wanting new thrills and experiences [5]. Both kinds of curiosity stimulate exploratory behavior for its resulting satisfaction. Cognitive curiosity motivates observation, consultation, and directed thinking (specific exploration) that results in information acquisition and learning [1]. It is associated with convergent thinking, which is finding the one solution to a question or problem. In contrast, sensory curiosity, which is aroused by boredom and a need for stimulation, motivates exploration of the environment through experimentation with novel physical (e.g., scuba diving) and social (e.g., attending a social function for the sake of experiencing different kinds of people) thrills and experiences (diversive exploration) [5]. This type of curiosity is related to imagination, inventiveness, and divergent thinking; that is, finding an array of applicable solutions to a problem. Engaging in sensory curiosity, while primarily motivated by the need to experience new thrills and sensations,

can result in information acquisition and learning. Both kinds of curiosity interact to foster daily learning and development (cognitive, social, physical, and spiritual) and continuous adaptation to salient environmental demands [1, 4].

Even though curiosity is generally thought of as being positive and thus adaptive, it can be problematic and maladaptive when in excess or unsuitably focused. The excessive gobbling of trivia, scientific experiments that harm, and meddlesomeness are linked to cognitive curiosity. Sensory curiosity, on the other hand, is associated with maladaptive risky behaviors like drug experimentation, verbal and physical fighting, and unprotected sex [5].

Curiosity is indeed a powerful motivator of learning in classrooms for children, adolescents, and adults [2, 4]. Teachers and trainers need to design instruction to stimulate learner curiosity because once aroused, the learners become more attentive to new information, explore in greater depth, employ more exploratory techniques (e.g., consultation with peers, Internet surfing), and engage in these activities for longer periods of time. Curiosity serves to not only stimulate exploratory behaviors at the initiation of a learning endeavor, but also throughout the learning process. The key for educators is to capture and maintain learner curiosity for facilitating optimal learning, which can ultimately develop into a joy for learning about a topic area and enduring vocational interests [2].

Parents and teachers need to model how to be appropriately curious to our youth. As a society, we simply cannot afford to assume that everyone knows how to be curious, and properly so, in every context. Modeling how to correctly ask questions, and when, observe a peer perform a task without being bothersome (e.g., How to play a game), and how to reflect productively about a situation, for example, would be productive steps in developing satisfied, lifelong learners.

Curriculum-Based Assessment

Becky Stefanko
University of Detroit Mercy, New Baltimore, MI, USA

Synonyms

Criterion-referenced-curriculum-based assessment; Criterion-referenced assessment; Curriculum-based evaluation; Curriculum-based measurement

Definition

A set of systematic strategies or measurement procedures using direct and repeated observation and recording of ongoing student performance in the local curriculum for the purpose of gathering information to inform educational decisions.

Description

Curriculum-based assessment (CBA) emerged in response to a perception that traditional, standardized testing methods possess inherent limitations in the ability to identify children's educational needs, including a lack of relevance to the curriculum and insensitivity to achievement gains. It is a dynamic, ongoing process of evaluation, conceptualized on the premise that every child can learn and be successful in school when instruction involves the use of materials that are appropriate for each student's unique needs and abilities. The primary purpose of CBA is to improve the match between what is taught and what is being tested in order to facilitate successful achievement for every student (Gickling and Havertape, 1981, as cited in Ref. [11]). CBA represents a shift toward a more direct relationship between assessment and instruction.

Four different models of CBA are commonly identified in the literature: (1) Curriculum-Based Assessment for Instructional Design (CBA-ID); (2) Criterion-Referenced-Curriculum-Based Assessment (CR-CBA); (3) Curriculum-Based Evaluation (CBE); and (4) Curriculum-Based Measurement (CBM) [6, 11]. The primary commonality among each of the models is the direct relevance of assessment materials to the curricula. CBA test items are constructed from material drawn directly from the curriculum being taught, and focus on the process of learning as well as the end product. The assumption is that accurate reflections of student achievement can only be obtained through direct observation and measurement of the skills actually being taught in the classroom [4].

Teacher involvement is viewed as essential to CBA. Gickling and Rosenfield [4] suggest that teachers are crucial for the identification and assessment of a student's difficulties since they are in the best position to observe and interact with the student on a daily basis. Direct assessment of a student's skills in relationship to changing curriculum demands enables the teacher to glimpse the processes employed during learning. When teachers know the precise area of problematic performance, they are able to adjust or modify instruction in that area to accommodate the unique learning needs of the student and maintain appropriate levels of challenge and variability for the student's skill level.

The four models of CBA can be organized into two groups based on whether the focus of assessment is toward long or short-term goals. Three of the models (CBA-ID, CR-CBA, & CBE) rely primarily on short-term, mastery measurement of individual subskills using criterion-referenced items taken from the immediate instructional material. Educational decisions are based on mastery of specific subskills in a hierarchical sequence. Conversely, CBM employs a long-term, general outcome measurement approach of assessment whereby the student's global proficiency across all hierarchical skills in the curriculum is used to identify expected performance of that skill in the future. Educational decisions using CBM are based on changes in performance of a single behavior over time [6, 11].

The final commonality among the four models lies in the use of graphs to represent data obtained on the student's progress. Graphs are important for a number of reasons. First, they provide a visual record of the student's daily performance on a single measure, and allow for comparisons of performance over time [8]. This is important when drawing inferences regarding the potential influences of student performance. Causal inferences can be made with increased confidence when the direction of growth is consistent across variables. Additionally graphs can provide a simple visual representation of the student's growth on single or multiple measures, which is useful in informing instructional decisions and explaining data and programming decisions to teachers, students, and parents (for a more in-depth discussion of progress monitoring using CBA, see Ref. [8]).

Curriculum-Based Assessment for Instructional Decisions

Gickling's original model of CBA (CBA-ID) was designed to remediate the lock-step pace of grade level instruction by tailoring the curriculum to suit the unique needs of each student [5]. The underlying assumption of CBA-ID is that successful achievement is essential for eliciting optimal student engagement with the curriculum and maximum on-task behavior. A student's off-task behaviors are viewed as indications that the instruction and/or curriculum is at a level that is too far above or below his or her current skill level, causing frustration and disengagement [7]. Intervention entails adjusting the instruction to a level that reduces frustration. In contrast to traditional methods of instruction that focus on the areas of deficiency, CBA-ID begins with the student's present level of functioning, and builds upon his or her strengths. This eliminates the frustration resulting from the fragmented learning that often occurs when students are forced to focus on tasks comprised of excessive amounts of unfamiliar material. CBA-ID "assumes that the job of education is to reach students where they are and to teach them effectively and efficiently" [4].

Beginning with entry-level, or instructional level, skills facilitates opportunities for the student to become an active and successful learner. It is a fundamental principle of CBA-ID. Successful achievement is viewed as intrinsically rewarding, and encourages engagement in the learning process and increased on-task behavior. Student engagement and on-task behavior is viewed as essential for the development of optimal skill levels, and is maintained when instruction takes place at a level that is challenging enough to maintain interest without exceeding the student's level of competence. The student who perceives that he or she has the knowledge and skills to be successful is motivated to perform the skills necessary to attain mastery [4].

A student's instructional level can be determined by the ratio of known to unknown elements of academic tasks. Gickling and Armstrong [3] identified three levels of instruction related to dimensions of on-task behavior, (a) frustrational level: "assignments containing less than 70% known elements during seatwork activity and less than 90% during reading activity"; (b) instructional level: "a range between 70% and 85% of known elements for seatwork activity and between 93% and 97% of known elements for reading assignments"; and (c) independent level: "assignments that contain more than 90% of known elements on seatwork activity or more than 97% of known elements in reading". Research generally supports that optimal learning occurs when the ratio of correct items is 70–85% in practiced drill material, 93–97% in reading content, and at least 70–80% in mathematical calculations [2, 6, 9, 11].

The essential purpose of CBA-ID is to identify the student's strengths within the curriculum, and adjust instruction to accommodate his or her unique needs and

abilities to facilitate mastery of curriculum objectives. Assessment focuses on accessing the student's prior knowledge comfortably rather than "pushing . . . to the point of frustration" as with normative assessment procedures [4]. Test materials are drawn directly from instructional material, and designed to be short, and relatively simple to administer. The first step in the assessment is to select appropriate material from the curriculum to identify the student's entry level of skills. The second step uses informal materials to assess how the student interacts with the instructional materials, and identify the processes and strategies used to generate responses. The third step is to use information gathered from the informal, curriculum-based measures to identify the student's instructional level. In the final step, instructional objectives and materials are designed to align with the student's instructional level and remediate areas of problematic performance.

Criterion-Referenced-Curriculum-Based Assessment

Much like CBA-ID, CR- CBA is focused on the direct measurement of a student's skills on a sequence of curriculum objectives for the purpose of identifying appropriate instructional practices [1]. Tests are generally designed to closely resemble teacher-constructed classroom assessments and the content and length varies as a function of the domain that is being assessed. Test items are selected from instructional content, and organized according to increasing levels of difficulty. A single test may assess global performance across the curriculum, or specific subskills within a domain [6]. This model of CBA recognizes the variety of factors that can influence a student's performance at any specific point in time. As a result, multiple forms of the same test are administered on a minimum of three consecutive days to obtain an accurate measure of student performance across variables. The student's performance is compared to a standard or criterion of acceptable performance, and instructional decisions are made according to the student's status within the criterion. Shorter forms of CR-CBA tests can be administered more frequently during the course of instruction to assess the student's progress toward mastery of specific skills [11].

Curriculum-Based Evaluation

Similar to other models, CBE is used primarily for the purpose of informing instructional content. Described by Howell (1986) as a "task analytic model designed to identify which tasks the student is ready to learn as a function of his/her current performance", CBE involves the analysis of subtasks and strategies involved in learning the curriculum. The primary assumption is that the student lacks an essential skill or strategy necessary to succeed in the total task. Students employ both task-specific procedures and general problem solving strategies to achieve curriculum objectives. A student may possess the necessary skills and subskills, but may not know how to organize and employ the resources to recognize errors, plan and generate solutions, or monitor his or her own comprehension. Thus, CBE focuses on the types of errors the student makes in order to identify the underlying strategies as well as the individual skills and subskills.

CBE begins with a survey-level assessment of the student's overall level of performance across a wide range of skills within a curricular domain. This may be completed using a variety of assessment tools, including standardized achievement tests, observation techniques, work product samples, and informal, criterion-referenced tests [11]. The data is reviewed and erroneous strategies are identified. Hypotheses are generated for potential explanations for deficiencies in the student's performance, and those hypotheses are tested with specific-level assessment. In the specific-level assessment phase, criterion-referenced tests are used to evaluate the student's performance on targeted, short-term curricular objectives that will eventually appear in the student's treatment plan. If the hypotheses are correct, remediation focuses on teaching the student the correct strategies for organizing the subskills he or she already possesses into new skills that permit successful task completion, and the student's progress is monitored frequently. If the hypotheses are incorrect, then the sequence should be repeated until targeted strategies can be identified (Howell, 1986).

Curriculum-Based Measurement

Like its counterparts, CBM shares a direct relevance to the curricular methods and objectives employed within a school, and views the student's learning difficulties in relationship to appropriate instruction. Unlike the other forms of CBA that focus on mastery of short-term instructional objectives, CBM is focused on broad, long-term goals of the curricula, including the retention and generalization of learning, in the basic skill areas of reading, mathematics, spelling, and writing. CBM is primarily concerned with the effects of instructional decisions on an individual student's performance rather than the actual content of instruction [10]. Instructional programs are viewed as testable hypotheses about the causes of poor performance. The uncertainty with which diagnostic assessment data can be used as a prescriptive measure of intervention is a major premise of CBM, and one of

the primary reasons why the focus is on evaluation of instructional programs [11]. It is based on research findings indicating a lack of effectiveness in special education programming, and improved achievement outcomes in response to teachers' use of data-driven goals and progress monitoring to guide instructional decisions [10].

Shinn [10] characterizes CBM as "a set of dynamic indicators of basic skills" designed to identify areas of academic difficulties and evaluate the effectiveness of selected interventions. Assessment procedures are narrow in content, short in duration, and drawn from the annual curriculum. They typically employ measures of fluency of key behaviors related to overall academic performance. For example, reading performance may be examined by having the student read aloud from a passage drawn from the instructional material. Performance is scored according to the number of words read correctly in 1 min, and the student's errors are qualitatively analyzed for clues to the underlying processes and strategies employed during reading. The student's entry-level skills and subsequent progress in the curriculum is always evaluated in terms of the relationship to expected outcomes, and the expectation varies according to the considerations of the educational decisions [11].

An important distinction of CBM is the use of valid, standardized assessment methods. Since CBM is used to validate instructional programs, it is important that the methods be valid, appropriate for repeated use, and be sensitive to individual and group performances over time. Standardization assures that each student's performance is measured in exactly the same way with the same test, and increases the reliability that the test will provide consistent, unambiguous results. Standardization and reliability are important for the comparison of a student's performance in relationship to his or her peers, or for comparing the student's performance in a single domain across time. When the student's performance is measured accurately and consistently, one can be reasonably confident in the ▶validity of the results.

Shinn [10] recommends the use of CBM in a problem-solving model, using data-based decisions to describe a student's performance in relationship to expected outcomes. The first step in the process is to identify the problem. This is accomplished through a universal screening measure administered on a school-wide basis. The student's problem is identified as a discrepancy between actual and expected performance rather than as immutable, intrinsic characteristics of the child. Only behaviors that are significantly discrepant from the student's same age/grade level peers are targeted for intervention. To obtain a measure of the student's initial level of functioning, and reduce the effects of confounding variables, multiple samples of the same behavior are assessed over a period of 3 to 5 days. Results are compared to a specified criterion for the behavior, and the problem is clearly and objectively defined in terms of the discrepancy between actual and expected performance.

Once the problem has been identified, the student's performance is analyzed for the appropriateness and/or intensity of remedial or preventative educational services. If the problem is a significant, it is targeted for intervention. This requires some quantification of the data, usually as part of a collaborative effort among faculty members. If the problem is validated, goals are defined in terms of annual performance outcomes, and objectives for the conditions (i.e. setting, time-frame, context) and criteria (level) for improvement of the targeted behavior are written. Instructional programs are put into place, and the student's progress is monitored using short, frequent probes of his or her overall performance in the targeted domains. The data from progress monitoring is graphed, and the student's performance is compared to expected growth and outcome criteria. If sufficient progress is not made, instruction is modified, and goals are adjusted accordingly. Progress monitoring continues until sufficient growth is demonstrated, and/or the student exits the intervention program.

Relevance to Childhood Development

As legislative and social policies demand increased accountability from public educational institutions (i.e. the Individuals with Disabilities Education Act, and No Child Left Behind), curriculum-based assessment is becoming increasingly popular in schools across the United States. The data-based decisions resulting from curriculum-based assessments allow instruction to be guided toward maximum learning potentials for all students, regardless of initial level of academic performance.

Cymbalta

Synonyms

Duloxetine

Definition

Duloxetine is used to treat depression and anxiety disorders in children, adolescents and adults. Duloxetine is in a class of medications called selective serotonin and norepinephrine reuptake inhibitors (SNRIs). It works by increasing the amounts of serotonin and norepinephrine, natural substances in the brain that help maintain mental balance and stop the movement of pain signals in the brain. The medication is usually taken once or twice a day by mouth. The medication can also sometimes be used to treat urinary incontinence.

The FDA has issued a warning for individuals under the age of 24 who take Duloxetine. A small number of children, teenagers, and young adults (up to 24 years of age) who took antidepressants ('mood elevators') such as duloxetine during clinical studies became suicidal (thinking about harming or killing oneself or planning or trying to do so). Children, teenagers, and young adults who take antidepressants to treat depression or other mental illnesses may be more likely to become suicidal than children, teenagers, and young adults who do not take antidepressants to treat these conditions. However, experts are not sure about how great this risk is and how much it should be considered in deciding whether a child or teenager should take an antidepressant. Children younger than 18 years of age should not normally take duloxetine, but in some cases, a doctor may decide that duloxetine is the best medication to treat a child's condition.

Common side effects of the medication may include:

- nausea
- vomiting
- constipation
- diarrhea
- heartburn
- stomach pain
- decreased appetite
- dry mouth
- increased urination
- difficulty urinating
- sweating or night sweats
- dizziness
- headache

- tiredness
- weakness
- drowsiness
- muscle pain or cramps
- changes in sexual desire or ability
- uncontrollable shaking of a part of the body

Cytoplasm

Cytoplasm is the part of a cell that is enclosed within the cell membrane. The cytoplasm is the site where most cellular activities occur including metabolic pathways like glycolysis and processes such as cell division. The inner granular mass of the cytoplasm is called the endoplasm and the outer clear area is called the cell cortex or the ectoplasm.

D

D'Amato, Rik

Matthew J. Holcomb[1], Raymond S. Dean[2]
[1]Ball State University, Muncie, IN, USA
[2]Neuropsychology Laboratory, TC 904 Ball State University, Muncie, IN, USA

Life Dates
Unknown–Present

Introduction
Dr. D'Amato is a well known and prolific write in the field of school and neuropsychology whose work has centered on many topics including the importance of practical applications of neuropsychology and learning within school systems.

Educational Information
Dr. D'Amato received his bachelors of Science degree from the University of Wisconsin-Whitewater in 1979. He attended the University of Wisconsin-Madison and obtained a Master's in School Psychology. In 1987, Dr. D'Amato received a Ph.D. in School Psychology with a specialization in Clinical Neuropsychology from Ball State University. He went on to do post doc work at Mississippi State University's Neuropsychology Laboratory for Evaluation and Therapy. Dr. D'Amato went on to accept a faculty position at the University of Northern Colorado in Applied Psychology and Counselor Education where he taught and researched for 18 years.

Accomplishments
Dr. D'Amato was awarded a *Medal of Achievement* as Editor-in-Chief of *School Psychology Quarterly,* the American Psychological Associations (APA) School Psychology Division journal. While at The University of Northern Colorado he was named an Alber M. and Jo Winchester Distinguished Professor for his University Scholarship. Dr. D'Amato has remained an active scholar and has written and published more than 200 scholarly works. Some of his most important works have included *Essentials of Neuropsychological Assessment: Rehabilitation Planning for Intervention,* the *Handbook of School Neuropsychology,* and *Psychology Perspectives on Intervention: A Case Study Approach to Prescriptions for Change.* Dr. D'Amato was selected as a Senior Fulbright Scholar to train teachers and collaborate on curriculum design at the Liepaja Pedagogical Institute-Higher School in Latvia (the Former Soviet Union), and he has also taught in Indonesia. In 2004, D'Amato was awarded a Lifetime Achievement Award by the National Association of School Psychologists Neuropsychology Interest Group (R. C. D'Amato, personal communication, July 5, 2008).

Current Involvement
Dr. D'Amato was recently appointed Professor and Head of Psychology at the University of Macau, China. He continues to write and publish research and is particularly known for his involvement with student research.

Definition

According to Charles Darwin, natural selection is the chief process by which evolutionary change occurs. It is a naturally occurring, mechanistic model in which those organisms that possess traits that make it more likely for them to survive are more likely to pass those traits along to their offspring, thereby altering the genetic distributions in their populations over multiple generations and resulting in adaptation to the environment.

Description

Although Charles Darwin (1809–1882) was not the first or only biologist to propose a theory of evolution, his theory of natural selection proved to be the most widely influential and accepted. The theory provides such a powerful centrifugal force for contemporary life sciences that is important to remember that in Darwin's lifetime, the mechanisms of genetics were poorly understood and DNA had not yet been discovered. Darwin developed his theory through sharp observations made throughout his travels around South America on the H. M. S. *Beagle* as a young man, and rigorous analysis of his notes and the samples he collected on his voyage. He continued to refine and research his theory for over a decade after his return, first publishing his theory in *On the Origin of Species* in 1859.

The most important distinction between Darwinian theory and those of rivals such as Jean Baptiste Lamarck (1744–1829), is the role of natural selection as the primary process by which evolutionary change occurs. According to natural selection, those organisms that possess traits that make it more likely for them to survive are more likely to pass those traits along to their offspring. This is because these organisms have survived to maturity. Over multiple generations, these traits will become more and more likely to become prevalent in the population, because those same organisms are more likely to have thrived and successfully reproduced. Darwin used the often-quoted phrase "survival of the fittest" to describe this competition, but natural selection need not imply or require bloody, violent contests to occur. It simply refers to the successful competition for limited resources and the opportunity to sire offspring, which can be thought of as adaptation to the environment. It does not predict development of increasingly complex organisms over the course of evolution, and reiterates that evolution is an ongoing, never-completed process. Much of Darwin's theory therefore focuses on microevolution, the changes that occur within a species due to adaptation to the environment via natural selection. The Galàpagos Islands off the coast of Ecuador provided Darwin with the ideal environment to develop his theory, for while each of the islands possesses similar species of animals, the local environment of each island is sufficiently different to have prompted different specializations among each set of species. The islands are geographically close enough to allow migration but distant enough to make frequent mingling and cross-breeding unlikely; therefore the variations in terrain can be deduced as the primary influence on the sort of traits that will become prevalent in the local populations.

Darwin's stress on limited resources reflects the influence of Thomas Malthus (1766–1834), who observed that populations tend to increase in geometric proportions and, if left unchecked, would totally overwhelm their ecosystems. Malthus concluded that death is necessary to keep population growth in check, and works as a natural balance to population increases. This mechanistic model, which reiterates that all resources are limited and therefore must be the objects of competition, is a crucial influence on the development of Darwin's theory of natural selection.

Darwin recognized that artificial selection is a useful analogy to natural selection. Artificial selection refers to the set of strategies used in animal husbandry to develop new strains of animals. Animals with desirable phenotypes are encouraged to breed, and over the course of several generations a new and distinctive breed or race appears. All dogs, for example, belong to the same species but there is tremendous variability in size, weight, fur, and temperament among different dog breeds due to artificial selection. With natural selection, the traits are not chosen by a human breeder but are the consequence of survival itself. This reiterates the mechanistic aspect of natural selection while underscoring the similarity it shares with artificial selection.

Since its publication in the Nineteenth Century, Darwin's theory of natural selection has been supported by a wide array of evidence from the fossil record, geology, comparative anatomy, genetics, and molecular biology. It has also been subsequently refined by other scientists. One of the best-known modifications in the latter part of the Twentieth Century comes from the work of Niles Eldredge (1943–present) and Stephen Jay Gould (1941–2002), who proposed that evolutionary change does not occur gradually, but in a series of sudden changes. These sudden changes are known as "punctuated equilibria" and occur as a result of selective environmental pressures as well as the isolation of a population. Change can then occur more rapidly than predicted under a more gradual development, and the Eldredge-Gould conceptualization of long stable periods in which minimal change occurs is in

accordance with the Hardy-Weinberg principal of the consistency of the proportion of alleles within a given population in the absence of change-inducing factors such as migration and mutation.

Deaf Culture

Gary Schaffer, Lisa Kilanowski-Press
Niagara University, Niagara, NY, USA

Definition

Deaf culture is a term denoting membership in a cultural community comprised of Deaf individuals who utilize American Sign Language (ASL) as their primary form of communication. Like other cultural groups, unique social norms, acculturation processes, and stages of identity development are present within Deaf culture. Whereas the word "deaf" signifies hearing impairment or the absence of hearing ability, the word Deaf, as used in Deaf culture, begins with a capital D, signifying reference to cultural identity as opposed to hearing impairment alone; the Deaf/deaf distinction is critical in conversations regarding Deaf culture. Not all deaf individuals identify with Deaf culture, although espousal of a Deaf identity is linked to usage of ASL as a primary language.

Description

For those of the hearing world, Deaf culture tends to go highly unrecognized and unnoticed. This lack of recognition may be attributed to the fact that only 0.22% (600,000) of people in the United States are considered deaf across all age groups [8]. Of the aforementioned 600,000 deaf individuals, approximately 200,000 to 500,000 share American Sign Language as their primary language, and identify the Deaf community as their primary reference group (Williams & Abeles, 2004). A second factor which may play a part in the limited awareness of Deaf culture in mainstream American society pertains to the usage of the term "culture," which, in Deaf culture, is strongly linked to language and is not being used in its traditional sense. Many hearing people believe culture to encompass a groups' religion, clothing, diet, language, ethnicity, and the geographic location from which they came [19]. However, Deaf culture is diverse in respect to that it transcends economic status, age, gender, sexual orientation, ethnicity, and religious practices [7]. Although members of the Deaf community come from a variety of distinct backgrounds, their culture revolves around the concept that Deaf individuals share their own distinct language (sign language), experiences related to their deafness, a shared history, and common meeting places such as their own schools, clubs, and sporting events [23]. Central to all of these characteristics is the universal belief that being deaf is not a disability or handicap; it is a way of life that should be cherished and accepted [23, 27].

Historically, deafness has been viewed as an "impairment," typically pathologized and targeted for intervention. In hearing schools and in hearing society, deafness is typically conceptualized as a disability. However, according to the cultural model, Deafness is embraced as opposed to pathologized, with members of the Deaf culture taking great pride in shared experiences, values, and language. The notion that deafness impedes successful functioning in society is rejected, as is the sentiment among those in the hearing world that deafness leads to linguistic deficiency. In short, members of the Deaf community do not despair over their inability to hear, and rejoice in the unique aspects of their language and identity as Deaf. Several degrees of association with Deaf culture are possible, and are frequently contingent upon degree of hearing loss, as well as the age at which hearing loss occurred. For example, an individual who has not completely lost the ability to hear may identify more with the hearing world than the Deaf world, and may choose to pursue assistive technology to aide their hearing ability. An individual who becomes deaf later in adulthood

may also associate more with the hearing world than an individual who was born deaf. Some individuals who are Deaf may elect to "code switch" between the hearing world and the Deaf community, identifying with both the hearing and Deaf culture and employing communication strategies unique to each. However, the vast majority Deaf individuals do not seek to utilize assistive technologies, such as cochlear implants, and primarily associate with others in the Deaf community.

Relevance to Childhood Development

Despite the Deaf communities' understandable pride, their small population in a hearing world poses unique challenges, hotly debated issues, and exclusive concerns. These issues have been coming to the forefront of literature, research, and websites since the term "Deaf culture" began to expand in the 1980s [19]. Three concerns related to childhood development that have arisen in the late twentieth and early twenty-first century include: (1) family issues related to having a child who is Deaf/deaf, (2) educating a child who is Deaf/deaf, and (3) the controversy over cochlear implants.

Family Issues

Little research exists on how having a deaf or hard of hearing child affects the family. The lack of empirical articles is alarming considering the fact that three out of every one-thousand infants are born with hearing loss [7]. Even more surprising is that researchers have typically cited that approximately 10% of children who are deaf are born to hearing parents [10, 23]. Contradicting that percentage is an intriguing report by Mitchell and Karchmer [11] suggesting that only 4% of children who are deaf have parents who cannot hear. Whether the parents are hearing or non-hearing can have a considerable impact on the development of a child who is D/deaf. Parents who unable to hear will most likely be better equipped to raise, educate, and locate services for their child's unique needs. Furthermore, parents who are Deaf "may celebrate in neonatal wards upon learning that a child will be unable to hear" [23, p. 137]. Mothers and fathers who are unable to hear may take comfort in learning that their child will be able to completely take part in Deaf culture [27].

The reactions by mothers and fathers who are non-hearing may stand in stark contrast to those of hearing parents who may view their child's deafness as a "disadvantage," "disability," or an "imperfection." Hearing parents who learn their child will be deaf may experience a range of emotions including shock, anger, confusion, fear, sadness, frustration, depression, loneliness, blame, guilt, and powerlessness [21]. Additionally, parents may grieve the lost possibility of having a "perfect child" and may have a feeling that they are "inadequate for the task of managing the child's hearing loss successfully" [21, p. 234]. The feeling of inadequacy that parents experience may be associated with the struggle for mothers and fathers to locate appropriate services for their D/deaf son or daughter. Often parents may have to deal with a number of paraprofessionals who may contradict each other in opinions as to what methods are best to care for their child. On a daily basis, parents of D/deaf children may have to be in contact with audiologists, speech pathologists, pediatricians, special education teachers, general education teachers, teachers of the deaf (TOD), otolaryngologists, and other health practitioners [5]. Frequently the roles and responsibilities of these experts are not made clear to parents [5]. This may lead to further confusion and stress for mothers and fathers.

Additionally, parents may face considerable difficulty in locating experts who are familiar with deafness. Research has indicated that clinicians and the medical community are often inexperienced in dealing with hearing loss and have high rates of turnover [6]. Consequently, many parents struggle with scheduling appointments with knowledgeable specialists concerning their child's deafness [6, 10]. Freeman et al. [6] state that it is important for parents to locate professionals in a timely manner because "children who are deaf or hard of hearing are better able to communicate with family and peers, and function better academically when they and their families receive early services" (p. 37). Many researchers believe that it is just as important for parents to learn sign language and increase their knowledge about their child's hearing impairment early on [10]. Researchers cite that parents who are able to engage in back-and-forth communication with their child are laying the "foundation for their child's acquisition of language" as well as increasing positive interactions with their son or daughter [6, p. 37]. Furthermore, parents who begin learning communication techniques early on are better able to cope with having a D/deaf child and less likely to mourn the loss of their child's hearing [6]. Still, learning American Sign Language (ASL) takes time and effort. Parents may experience considerable stress if they cannot acquire ASL easily [28].

Lastly, the combination of ASL classes along with the high number of specialists a non-hearing child requires for proper support may become a financial strain on the family. Fusick [7] points out that the lifetime cost for hearing loss is estimated to be about 417,000 dollars. Often insurance companies restrict parents from receiving second opinions from audiologists and other

qualified specialists. Moreover, "reimbursement rates are particularly low for Medicare and Medicaid recipients" [7, p. 102]. This does not factor in co-pays to the pediatrician for visits related to deafness.

Often having a D/deaf son or daughter enter into the family is the first time most hearing parents have had contact with a D/deaf individual. Wood and Turnbull [28] cite that less than 10% of hearing parents have had frequent contacts with D/deaf adults. Therefore, the majority of hearing mothers and fathers have never witnessed D/deaf parents interacting with their children and only have models of how hearing parents interact with their sons and daughters. Hearing parent's difficulty communicating with their D/deaf child may lead to feelings of incompetence and frustration [6]. Obtaining early services is crucial in preventing these feelings from occurring. Overall, there are many obstacles and barriers parents have to overcome in order to appropriately obtain services and support for their child who is D/deaf.

Educational Implications

One of the most difficult services for parents to obtain is acquiring a sound education for their D/deaf son or daughter. For centuries, educating the deaf has proved to be a challenge, provoking much inquiry in a hearing world. The Greeks and Romans in the first century AD encouraged the removal of the deaf from society because they felt they were unable to "contribute to a strong citizen state" [14, p. 10]. However, in the late 1400s a record emerged of a deaf person being taught to read and write [14]. Further evidence for teaching individuals with deafness materialized in the 1500s. Still, there remained no school for specifically teaching the deaf until 1755 when the first public school for teaching the deaf was established in Paris, France [20].

Today, in America, teaching the D/deaf remains one of the most controversial issues in education to date. The concern no longer revolves around whether individuals who are D/deaf can learn but where they should learn. Education of the D/deaf has typically taken place in residential schools separate from the hearing population since the foundation of the American School for the Deaf in 1817 [14]. However, with the passage of Education for All Handicapped Children Act (Public Law 94–142) in 1975, public school districts were required to admit and provide education to D/deaf and disabled children [19]. It was from this time on that educating deaf children in "hearing public schools" began to become common. Since 1975, the Education for All Handicapped Children Act has been reauthorized several times, most recently in 2004 and is now known as the Individuals with Disabilities Education Act (IDEA) [26]. With each of these reauthorizations, the term "inclusion" began to take more precedence over educating children who are D/deaf. Inclusion is the education of students with disabilities or deafness in regular education classrooms [9]. This is opposed to having D/deaf students being taught in a separate classroom or school [9].

Within the past two decades, "parents and students now have the option of choosing between local public school programs and residential school placement." [9, p. 393]. The trend appears to be favoring educating children who are D/deaf in public schools. Heward [9], reports that 84% of children who are D/deaf or hard of hearing attend public schools. Interestingly, reports indicate that more than 40% of D/deaf children receive most of their education in a regular classroom [9, 12]. Only 16% of children who are unable to hear attend special schools for the D/deaf and approximately 90% of these students enrolled in these residential schools have severe to profound hearing loss [9]. Still there remains a push by advocates for full inclusion to incorporate even the most severe cases of deafness in the regular classroom.

Advocates for full inclusion see it as an opportunity for students who are D/deaf to interact with the hearing world and make academic progress. Attending public schools will help students with deafness become comfortable in interacting with those who can hear [17]. In addition to learning how to communicate with those who can hear, many researchers and even members of the Deaf community feel that public schools offer deaf students a "richer curriculum" with higher learning goals than residential schools can provide [1]. According to Heward [9], the number of students receiving post-secondary education has risen drastically in the past twenty years. It could be argued that this dramatic rise in numbers is due to more students who are D/deaf attending public schools and receiving fair treatment under IDEA. As of 2002, approximately 69.4% of all students with hearing loss in America graduated with high school diplomas [7]. One final argument for the inclusion of D/deaf students in public schools is that attending a local school allows individuals who are deaf to live with their parents during the week. Many residential schools are out of commuting distance for most students who are D/deaf and require children to live at the school, which can interfere with family boding and the child may feel detached from their parents [17].

Still, much of the Deaf community believes that public schools cannot properly accommodate nor teach children who are unable to hear. According to the National Association of the Deaf [16] "The inclusion doctrine is rooted in ideology and is frequently a blatant violation of IDEA as

it disregards the language and educational developmental needs of the deaf and hard of hearing children." In addition to this statement, opponents of inclusion fear that D/deaf children in the regular education classroom will be seen as a "visitor" or "outsider" to the class [2]. Antia et al. [2] writes that when hearing students treat D/deaf colleagues as visitors, "these students face greater barriers in obtaining a quality education" (p. 215). Non-hearing students may be viewed as "outsiders" because they are a rarity to many public schools. Mitchell and Karchmer [11] report that "53% of public schools serving deaf and hard of hearing students have only one such student in that school" (p. 99).

With such a small number of D/deaf students in public education, studies have indicated that D/deaf children are often ignored, teased, and neglected by their hearing peers [1, 18, 24]. Furthermore, D/deaf students may lack the development of friendships in a regular education classroom. In a study by Nunes et al. [18] 23% of hearing pupils reported having no friends in a general education classroom as opposed to 67% of children who were D/deaf. These negative interactions with hearing colleagues could have a lasting impact on the psychological and educational development of a D/deaf individual's life. Often students who are unable to hear may not be able to participate in class or fear doing so. As a result, D/deaf students may be thought of as "stupid" or not as hard-working by their hearing contemporaries [3]. In sum, students who are deaf in a regular education setting may be at risk for experiencing feelings of social isolation, loneliness, exclusion, and rejection by their peers if their condition is not properly introduced to their classmates [1, 24]. Moreover, deaf students may lack in developing interpersonal relationships and may not be introduced to deaf role models in a regular education setting [1]. The notion of the D/deaf child as deficient, and deafness as an impairment, may be furthered in traditional public schools, with educational emphases placed on remediating hearing and language related difficulties as opposed to communication and learning via American Sign Language.

Another concern that opponents to inclusion have is that of the general education teacher not understanding the D/deaf student's needs. Along with the hearing students in the class, teachers may be at risk for treating the student who is D/deaf as an "outsider." Possession of biases may lead to the child who is D/deaf being rejected not only by the teacher but by his/her peers. Stinson and Liu [25] noted that if the general education teacher offers an unsupportive and unaccommodating attitude towards the student who is unable to hear, other pupils in the class are likely to follow suit. Therefore, it should be noted by general education teachers that being D/deaf does not cause as much harm to a students learning process as much as negative, unreceptive attitudes do. An additional issue opponents of inclusion cite is that teachers in public schools may not properly accommodate for having a student who is deaf in their classroom. General education teachers may not have a good seating arrangement for the D/deaf child, be reluctant use an overhead, or be unwilling to cooperate with the special education teacher or teacher of the deaf (TOD) [25]. Many opponents to inclusion believe that the regular teacher may work against the special education teacher or TOD rather than with them [2, 25]. This uncooperative atmosphere may make the learning process that much more difficult for the D/deaf student. Anita et al. [2] states that in order for inclusion to work both the general education teacher and the special education teacher must "assume the roles of equal collaborators" (p. 221). In creating an equal working environment, both teachers are in a position to best help the student who is non-hearing. Many researchers take the standpoint that there are academic advantages to students who are D/deaf attending regular schools but there are social advantages for the D/deaf who attend segregated educational settings [1, 9].

Cochlear Implants

Since their inception in 1984, cochlear implants have been the most well publicized debate topic between the hearing world and deaf culture [4]. According to Sparrow [23], "cochlear implants are a technology which attempts to 'cure' deafness by bypassing the outer ear through electrical stimulation of the auditory nerve" (p. 135). Originally cochlear implants were used as assistive listening devices for people who acquired deafness later in life and learned to use spoken language before their loss of hearing [4, 14]. However, the emphasis soon shifted from utilizing cochlear implants on late-deafened individuals to a tool that could be used to aid the development of language in D/deaf children. It was the concept of implanting children, with an eye on increasing functioning in the hearing world and, consequently, weakening their association with Deaf culture, that sparked controversy in the Deaf community worldwide. On June 27, 1990, the Deaf community reacted in outrage when the FDA granted permission for toddlers as young as two years of age to be implanted with the device [4, 14]. Eight years later, the age limit for implantation would be lowered to just eighteen months [14]. Finally, as of 2002, children as young as one year of age can be implanted with a cochlear implant [14].

According to the National Association of the Deaf (NAD) [16], approximately 60,000 people worldwide have cochlear implants. In the United States, roughly 13,000 adults and 10,000 children use the device [16]. Although the hostility towards cochlear implants has cooled since the early 1990s, many individuals who identify with Deaf culture still maintain the argument that a device which attempts to "cure" deafness is treating the condition as a "disability" [4, 23]. This assumption has often lead members of the Deaf community to feel like they are second class citizens in a hearing world. Deaf culturists contend that being D/deaf is not a handicap, that they like being D/deaf, and are proud to have the condition because it allows them to take part in Deaf culture [27]. Moreover, many non-hearing individuals maintain that they would not want to hear even if they had the opportunity to do so [23]. Cherney [4] states that the Deaf "do not identify themselves as disabled but rather as members of a linguistic minority" (p. 27). Membership in this "linguistic minority" is not based simply on being deaf but on the precedence of the type of language they use [4].

Because cochlear implants seek to ensure that D/deaf children use spoken language rather than American Sign Language (ASL), much of the D/deaf community views the device as a means of medical genocide to D/deaf culture [9, 23]. Deaf advocates argue that cochlear implants may interfere with or prevent children who are D/deaf from learning sign language. Furthermore, the device may hinder children who are unable to hear from developing their identity as a Deaf person [14]. The Deaf community fears that if children who are implanted grow up to use spoken language instead of sign language and do not associate with Deaf culture, the population of their community will be drastically reduced. Therefore, many non-hearing individuals view cochlear implants as a threat to their culture. In a study of D/deaf and hard of hearing adolescents, Most et al. [13] found that adolescents who had a stronger Deaf identity had more negative attitudes towards cochlear implants than did adolescents who had a weaker Deaf identity. This could be because these adolescents perceived the device as a danger to their culture (Most, Amatzia, Wiesel, and Blitzer, 2007).

Still, receiving a cochlear implant does not necessarily mean automatic acceptance into the hearing world. Tucker [27] attests that cochlear implants do not eliminate deafness altogether and that a child who receives an implant is still deaf. Therefore, "cochlear implants do not change deaf people into hearing people" [14, p. 435]. Individuals who have cochlear implants described sounds and speech as "coarse" or "degraded" compared to sounds received by their hearing peers [14, p. 435]. Many D/deaf individuals with cochlear implants still rely upon sign language, gestures, and speech reading in order to fully understand what their peers are saying [16]. Thus, having a cochlear implant could pose a risk for a non-hearing individual in that this person may not fully be accepted into the hearing world and at the same time be rejected by Deaf culture [23]. This may lead to feelings of isolation and may prove to be a danger to the D/deaf person's self-esteem as they are trapped between two cultures, accepted by neither.

Since the 1990s acceptance of cochlear implants by the Deaf community has become more common. In order to ameliorate the controversy surrounding cochlear implants, NAD issued a position statement on October 6, 2000 [15]. In the statement, NAD recognized that receiving a cochlear implant is a personal decision for an individual not a public one. In regards to parents who are thinking about implanting their child, the National Association of the Deaf offered the following statement:

- The NAD recognizes the rights of parents to make informed choices for their deaf and hard of hearing children, respects their choice to use cochlear implants and all other assistive devices, and strongly supports the development of the whole child and of language and literacy [15].

In recent years, the Deaf community is more focused on having individuals and parents make informed decisions on cochlear implants not on the device itself. NAD (2008) indicates that each family should be informed of the risks and the responsibility of undergoing such a surgery. Moreover, NAD and the Deaf community want individuals who are considering getting a cochlear implant to recognize that this surgery will not make individuals who are deaf, hearing. It will only aide them in successfully straddling the hearing and deaf worlds if utilized correctly [15].

Deaf Overview

Patricia E. Spencer
PSpencer Consulting LLC, Rockport, TX, USA

Persons who are deaf typically lack sufficient auditory sensitivity (hearing) to be able to receive and understand spoken language through audition alone. Being deaf is distinguished from being hard of hearing (in some countries referred to as "hearing-impaired" or "partially hearing") in audiological terms by the degree and configuration of hearing loss. Generally, hearing losses that average 90 dB (decibels) or greater and are sensorineural (occur at the level of the cochlea, sometimes called the "inner ear," or higher in the neurological system) are labeled "severe-profound" or "profound" in degree. Persons with such degree of loss or greater bilaterally (in both ears) are referred to as "deaf," and some specialists expand that term to include children with losses at the 70 dB or "severe" level. Decibel is a measure of the intensity of sounds (perceived as loudness) and indicates the intensity with which a sound must be produced in order for an individual child to hear it. Persons who are termed "hearing" typically perceive sounds at 25 dB or less in intensity. In fact, the intensity required to hear a specific sound or portion of a sound can vary depending on its frequency or pitch. Hearing levels are typically given as an average of the dB necessary for perception at frequencies ranging from 500 to 2,000 Hz as determined for the better ear. This range covers most but not all of the sounds in spoken language. Even using the more restricted definition of a 90 dB loss, persons who are deaf show different levels of ability to receive and to produce spoken language, depending upon their individual response to appropriate hearing amplification (hearing aids), use of cochlear implants, skill at speechreading (also called "lipreading"), history of hearing experience prior to the onset of the hearing loss, and other factors, many of which remain to be explained.

Although some deaf persons achieve spoken language abilities, receptively and expressively, this requires an optimal combination of facilitative factors and intensive training. In contrast, visual languages such as natural or native sign languages (examples are British Sign Language, American Sign Language, Sign Language of the Netherlands), signing systems (systems such as Signed English or Signed Dutch that combine natural signs and fingerspelling or newly-created signs to visually represent the meaning units of the local hearing community's spoken language), and other systems that visually represent the sounds of spoken language (e.g., Cued Speech) are more readily learned than spoken language when appropriate environmental input is available. A considerable number of researchers have documented that, when there are adults who interact on a continuous and naturalistic basis with the child using a natural sign language, deaf children develop sign language skills at similar rates and patterns as hearing children develop spoken language. Thus, sign language development of deaf children with deaf parents who use signs fluently tends not to be delayed compared to hearing children's spoken language development [32].

The term "Deaf" when written with a capitalized "D" is used to indicate a cultural and linguistic identity as opposed to the audiological definition of "deaf" given above [38]. Persons who consider themselves to be members of a Deaf community share a sign language in common and tend to socialize and interact frequently. The actual level of hearing loss can differ among members of Deaf communities, and it is not necessarily at the severe or profound range. A strong sense of identification with a Deaf community has been found by researchers to enhance self-esteem and provide support for general social-emotional development. Deaf persons have tended to build communities at least in part based on their shared visual language and the resulting ease of communication. Shared needs and life experiences have also led to the establishment of political organizations to advocate socially and with governmental entities for rights and accommodations to enhance opportunities for persons with hearing loss. Although there has traditionally been a division between persons who consider themselves "Deaf" and use sign language and persons who are audiologically deaf or hard of hearing but depend primarily on spoken or oral language (most of whom also tend to more actively interact with the hearing community), the two groups frequently work together to support needs of all persons with hearing loss.

Frequency and Etiologies of Hearing Loss

Hearing loss is considered to be a low incidence disability, with losses of 70 dB or greater occurring at or soon after birth in only one out of approximately every 1,000 children in the United States and other western countries; however, it is a disability that has a major impact on development. The incidence of hearing loss is undoubtedly higher in non-industrialized countries where medical care is less available and diseases that can cause hearing loss are more prevalent. It is estimated [27] that approximately two third of the world's children with hearing loss live in developing or as-yet non-industrialized countries, although reporting is less reliable in such areas.

The age at which hearing loss occurs leads to different effects, and even a relatively short period of hearing appears to help establish neural pathways that allow more efficient processing of auditory information if it becomes available again due to use of more effective amplification (hearing aids) or cochlear implants [33]. Hearing loss at or shortly after birth results in the most significant challenges to development of spoken language and also, typically, to acquisition of academic skills.

Approximately half the incidence of hearing loss in infancy or early childhood is thought due to genetic factors, and more than 400 forms of hereditary hearing loss have been identified. Genetically-caused hearing losses are not always present at birth but can be progressive, occurring across subsequent months and years. Various genetic etiologies present with varied levels of hearing loss and associated physical and medical conditions, but in almost 70% of cases, genetic deafness is unaccompanied by any other disability [5]. This is not the case when the population of deaf children is considered overall, however, with reports of as high as 40% having some condition in addition to hearing loss. Physical, social, and cognitive disabilities vary in incidence and severity, but the presence of multiple disabilities has been found to present special challenges for development. Viral and bacterial infections as well as prematurity and birth-related difficulties are implicated in many cases of multiple disabilities, although the relative prevalence of one etiology or another varies over time and across the globe. For instance, gestational rubella ("German measles") was previously a common etiology in which hearing loss was accompanied by vision, motor, or cognitive disabilities, but vaccines against that disease had almost eliminated it as an etiology in Western industrialized countries by the end of the twentieth century. Cytomegalovirus (CMV) continues to be a major cause of hearing loss as does meningitis, both of which can also cause other disabilities.

Procedures for Identification of Hearing Loss

During much of the twentieth century, even in industrialized countries, childhood hearing loss was often not identified until at least the age of 2 or 3 years, resulting in very late institution of programming and consequently very delayed acquisition of language skills. By the turn of the century, age of identification of hearing loss had dropped to well below 1 year of age due to the implementation of hearing screening in early infancy, often during the neonatal period. It has been well documented that, if intervention services are provided immediately upon identification of hearing loss, average language and social-emotional development of deaf children has significantly increased, albeit remaining somewhat below that of hearing children [39].

Traditionally, audiological testing was based on behavioral responses to sounds of varying frequency (pitch) and volume or intensity (loudness). Older children and adults could indicate when they heard a sound, while an audiologist conducting the test mechanically produced sounds of varying frequency and loudness. With young infants and toddlers, responses might be eye blinks eye widening, or head turns toward sound. This form of observational testing can be effective in some cases, but it can also be highly unreliable because of fleeting infant attention or because of the observer's difficulty identifying a movement as a reaction to the sound. By 4 to 6 months of age and until about 2 years of age, a procedure called Visual Reinforcement Audiometry can be used. In this situation, the child's correctly indicating a sound is reinforced in some way so that the specific response behavior (again often a head turn but sometimes a more complex activity like dropping a block into a container) tends to occur only when a sound is heard. Testing using this procedure is more reliable than non-reinforced observations [37], but it cannot be accomplished during early infancy and is complicated with children whose development is significantly delayed by other disabilities.

It is known that hearing, when it is intact, functions even prior to birth (e.g., Ref. [11]). This realization has led to efforts to identify hearing loss at the earliest possible age and therefore to begin intervention efforts as early as possible. Early identification of hearing loss, even during the neonatal period, can be accomplished using electrophysiological methods, especially measuring auditory evoked responses (neural responses to repeated sounds) and evoked otoacoustic emissions (mechanical energy created in the inner ear when a sound is heard). These methods can be used at any age and are both non-invasive and non-painful [9]. One or both are used in many neonatal screening programs and, although typical responses to these measure change with maturation (and thus they must be conducted and interpreted by trained specialists) reliability is good, especially when they are used to screen for the possibility of hearing loss and combined with more detailed follow-up electrophysiological and/or behavioral testing.

The above testing procedures assess a person's awareness of sound at different frequencies or pitches, but awareness does not always assure that a sound can be differentiated from those of other frequencies or that meaningful units of sound can be identified. To assess the usefulness of hearing, especially for purposes of processing auditory language, tests of speech perception are necessary. They assess children's ability to detect and discriminate among suprasegmental characteristics of sounds (length, intonation patterns, number of syllables) as well as among vowels and consonants. Behavioral testing as well as a number of parent-response measures are available to measure these skills.

Linguistic and Academic Characteristics of Deaf Children

When no other significant level of disability is present, the average cognitive level of children who are deaf is equivalent to that of hearing children if they are assessed on nonverbal tasks [8]. However, verbal and language skills are typically delayed except in the small (<10%) portion of the population born to signing deaf parents. Even when sign language or a sign system is used at home and at school, deaf children's access to language input tends to be limited by the oft-documented lack of fluency in sign by hearing parents and teachers – themselves usually recent learners. In addition, deaf children are typically not in an environment where there are multiple signers. Language and knowledge acquisition is limited by their inability to "overhear" (or, with signs, "over-see") informational exchanges among people around them. As an outcome, deaf children typically have smaller lexicons (vocabularies) than hearing children of their chronological age, they have many difficulties with the syntax of either the spoken language or the non-fluent signing systems to which they are exposed, and use of language for learning is frequently not developed to expected levels. Accordingly, academic achievement tends to be limited, and despite provision of comprehensive educational programming, deaf students' average reading levels at graduation from high school in the U.S. often remain roughly equivalent to the average for hearing fourth graders (typically 9–10 years old) [36]. Writing skills are similarly delayed. This has also been reported across various countries and is reported for

both children who are exposed to signs and to those in so-called "oral" academic programs that focus on use of spoken language only [21].

Delays have also been reported in acquisition of mathematics skills and areas such as science and social studies. Not surprisingly, performance on written or "worded" math problems is most affected given the need for both reading comprehension and understanding of math concepts and procedures in their resolution. It needs to be understood, however, that despite the delays noted on average, there are deaf children who excel both linguistically and academically. The range of functioning in those areas is quite large. There are indications, moreover, that language and academic achievements can be significantly increased with early identification of hearing loss (prior to 6 months of age if hearing loss is congenital, or present at birth) and immediate provision of appropriate intervention services [24, 39].

The Impact of Early Identification and Intervention

A number of researchers have found that, at least in the early years of life, the "average" for deaf children with early intervention falls within the "low-average" range for hearing children on a variety of language measures [23, 24, 40]. Positive effects have also been found for early literacy skills and for social-emotional development.

Part of the positive impact of early intervention is due to early use of amplification, a practice that seems to assist children's attention to and processing of auditory information. Certain aspects of the auditory neurological system continue to develop after birth and are influenced by receiving input during the early months and years of life [12]. In addition, early exposure to visual language such as a natural sign language or a signing system or cued speech becomes possible when parents know about their child's hearing loss and can begin to learn one of these systems.

Regardless of the type of language system used with the child, it is also important that parents feel confident and competent to provide supportive input. In addition, interactive behaviors that generally enhance language development (even for young hearing children) need special emphasis when the child faces the challenges of hearing loss [23]. Paramount among these behaviors during the earliest stages of development is parents' tendency to provide supportive scaffolding for communication. These behaviors include responding to the child's existing focus of attention instead of beginning new topics that change the focus, imitating vocal and gestural behaviors of the child, providing language to label objects and events in the child's immediate environment, providing time for the infant or child to take a turn in the interaction, and treating infant behaviors that may not be intentionally communicative as though they are. In addition, parents will interact in more natural and supportive ways when they feel positive about their child's potential for development and when they feel they are knowledgeable about their child's abilities and needs. According, early intervention specialists stress that programming is to be provided to the family and not merely to the child him or herself [7]. Among other aspects of intervention, families' social-emotional needs as they react to the child's diagnosis should be addressed and positive support provided. There are indications that such an approach leads to more reciprocal parent–child early interactions and to enhanced child developmental outcomes. It also assists parents in recognizing their own strengths as the true expert on their child – and seeing hearing loss as only one of the myriad characteristics that make up the whole child.

Options for Supporting Language Development

Many researchers and educators recognize that the centuries-long argument about the "best" way to support language development of deaf children has been divisive and had the effect of slowing progress in developing overall methods for promoting language development. The passionate and sparsely data-based arguments have primarily been conducted between proponents of "oral" or spoken language and proponents of sign language or systems of representing spoken language meaning units through manual signs.

Sign languages have developed naturally, separate from spoken languages, in deaf communities throughout the world and, despite significant similarities noted among them in patterns of using spatial representations to express syntactic structure, they are distinct languages. The full "language" status of American Sign Language was argued by Stokoe [35] and much research since has specified semantic, pragmatic, and syntactic structures of that and other natural sign languages. It is obvious that natural sign languages can express the same level of meaning and have syntactic organizations that, albeit using different forms, are the equivalent in sophistication to that of spoken languages.

In addition to deaf communities' natural development of sign languages, educators such as L'Epee in France have since the 1760s created and used systems that combined signs in ways replicating the syntactic structure of the surrounding community's spoken language, thereby hoping to encourage development of linguistic structures to

support both the acquisition of spoken language and of literacy skills. These efforts were seriously dampened when the Congress of Milan in 1880 declared that oral (or use of spoken language only) methods were the most appropriate for deaf children and were to be used throughout the Western countries for educating them.

A resurgence of the combined systems of sign plus spoken language (e.g., Signed English, Signed French) occurred in the last half of the twentieth century as researchers demonstrated that language, academic, and social-emotional development of deaf children with signing deaf parents were at least as high and typically higher than those of children whose parents did not sign [25]. Although researchers have more recently come to question whether these findings reflected to some degree environmental conditions beyond merely parental language use (for example, the incidence of multiple disabilities is lower in children with deaf than with hearing parents), they served to document that use of signs did not depress academic or cognitive functioning. The goal of combining signs with spoken language, theoretically produced in synchrony by hearing people so that either or both signals were available to the deaf child, was to promote communication of meaning while also giving a model of the structure of the community's spoken language. This was expected to assist the child in developing both communication and literacy skills in that language. Unfortunately, literacy levels have not appreciably improved vis a vis hearing children with the use of simultaneous communication (sometimes called, inaccurately, "total communication"). This has been blamed in part on the less-than-fluent use of the systems by most hearing adults (parents and teachers), although benefits to the children have been noted when adults attain fluency [19, 29]. Others have suggested that, because of differences in syntactic devices used in natural sign languages and in spoken languages, systems in which sign and speech are expected to be combined or produced in unison are nearly impossible for most people to produce ([15]; but, cf. Luetke-Stahlman and Nielsen). Johnson et al. have referred to this approach as "sign supported speech," to emphasize that the signs being produced do not replicate full language structures. Despite earlier arguments that children could not process auditory and visual linguistic information simultaneously, this does not seem to be the case [30], and sign supported speech may be of benefit to deaf children especially when cochlear implants or advanced amplification devices are used.

A different kind of method to provide visual input to supplement and disambiguate the incomplete and sometimes distorted auditory information deaf children are able to perceive was created by Cornett [10] and involves use of hand signals to represent the sounds instead of meanings of words being spoken. Use of this system (which has been tailored to fit the sounds or phonology of many different languages) has been reported to support deaf children's language development and their development of phonological skills both in spoken language and in literacy [2, 18]. Most of the positive reports have focused on children using French or Spanish spoken language environments, and best effects have been noted from early and intensive use at home and at school.

The tradition of using only spoken language (or "oral" methods) to support deaf children's language development has continued and continues to have passionate advocates. Traditional oral programs have actually emphasized multi-modal communication in that speech reading (lip reading) has been included among the receptive language skills promoted. Unfortunately, there are limits to the assistance that speech reading can contribute. For example, only about 30–40% of the sounds of English can be recognized by the lip shapes as they are produced [10]. It appears that languages differ in this characteristic, with the phonology (speech sounds) of Spanish for example being both more regular and more visibly available than English. Even in the best case, however, depending upon limited auditory input plus speech reading requires significant cognitive and social abilities to "fill in" missing information. Although there are certainly cases of successful spoken language acquisition by children in oral programming, there have been multiple exceptions, and readers of research in this area should be sensitive to the fact that in many cases children who are not making progress are dropped from oral programs, leaving only the "successes" to be assessed in research. Typically, achievement of spoken language is best predicted by a combination of child non-verbal cognitive abilities, parent education and support of language and education, and the absence of additional disabilities or behavioral difficulties. Since the latter part of the twentieth century, increasing numbers of children born deaf (or becoming deaf during childhood) have benefited from use of technologically advanced, individually programmable hearing aids and/or use of cochlear implants which provide auditory-like information. Use of these devices, especially cochlear implants, has been intensively researched and children using them perform on average significantly better on auditory and auditory-based language tasks than those not using them [13]. Early use (before 2 years of age) of cochlear implants, along with the other positive predictors of achievement by deaf children in general (early intervention, high levels of parent education and

involvement, lack of multiple disabilities, high non-verbal cognitive skills), has often resulted in spoken language achievements that are at levels similar to those of hearing children, at least in the area of vocabulary development [26]. As with children using sign language or signing systems as their primary means of language development, syntactic skills remain more difficult for deaf children to achieve even when using cochlear implants [31].

Although the traditional argument between proponents of oral (spoken only) language and some form of sign language or signed language system has continued across reports of the acquisition of language by deaf children using cochlear implants and advanced hearing aid technologies, benefits seem to accrue from use of these devices regardless of the language system employed. Given significant amounts of spoken language input, children using sign supported speech as well as those in traditional oral programs and in auditory-verbal programs (where dependence on speech reading and other visual accompaniments to spoken language is discouraged) and in cued speech programs have shown advances in language and in acquisition of literacy skills. Despite these advances, however, the achievement gap between deaf and hearing children has yet to be eliminated. In addition, cochlear implants are useful only for children who have profound (and in some cases, severe or severe-profound) levels of hearing loss, not for those with lesser degrees of loss.

Educational Methods and Placement Options

As with the use of various methods to support language development, approaches to educational placement of deaf children have changed over time. Over the past 2 centuries, special or separate schools have been prevalent, based on the assumption that highly specialized programming is necessary to support development of deaf children. These schools were typically focused on use of one and only one of the language approaches discussed above and classes tended to have a low pupil to teacher ratio in order to address individual communication and learning needs. Especially in the schools that used sign language, special schools allowed deaf children the opportunity to interact freely with other deaf children and with adults with whom they could communicate fluently. The special schools often became places in which children developed their identity as deaf persons and to which many developed a strong sense of loyalty.

Prevailing social and educational expectations changed over the course of the twentieth century, with increasing demands for integration of all students within the "mainstream" or general educational settings if it was determined that such settings could meet their academic needs. The assumption was that this would provide more equalized opportunities for learning as well as assimilation within the general population. In most western countries, all children with disabilities (including deaf children) have individualized educational plans designed annually that specify academic objectives, services to support those objectives, and most appropriate educational setting. In the U.S., as in most Western countries, the majority of children who are deaf now attend mainstream or general education schools, whether in separate classrooms with other children with hearing loss, in a general education classroom where the great majority of classmates are hearing, or moving between the special and general classroom for various subjects during the day or week. Those in general education classrooms frequently have special small-group or individualized sessions with a specialist in deaf education at some time during the day or week in which skills are reinforced. For children who use sign language or cued speech, interpreters are provided in the general classroom.

Although it was expected that placement of children who are deaf in classrooms where most students are hearing would equalize access to information and support acquisition of age-appropriate academic skills, research shows that only 1% to 5% (e.g., Refs. [3, 17, 28]) of academic achievement is predicted by type of class placement . Higher general achievement by deaf students in mainstream settings than in special school settings is often reported, but analyses suggest this is due primarily to other pre-existing characteristics of the students and their readiness to learn (e.g., Refs. [21, 28]). Problems that have been encountered include the facts that less information is obtained through interpreted than direct communication [22] and that social isolation is common when communication between deaf and hearing students is difficult [4, 34]. Co-enrollment placements, where a "critical mass" of deaf children (one third or more of the class) are placed together in a general education classroom, where signs (or the deaf children's predominant language system) are taught to the hearing as well as deaf children, and where at least one of the co-teachers is fluent in the deaf children's language system are reported to have better outcomes in the social-emotional area and to not depress the academic functioning of the deaf or the hearing students [16]. This type of placement, while apparently beneficial, requires significant resources – as well as the presence of a number of children who are deaf and of teachers who specialize in deaf education – to maintain. Patterns and effects of various approaches to class placement and delivery of educational services to deaf children critically need more practice-based research.

Social Interaction and Social-Emotional Development

As discussed above, a common goal of early intervention is to assist parents (those who are hearing are primarily at issue) in establishing comfortable and reciprocal interactions with their deaf infants. There are reports of increased parental directiveness, decreased sensitivity to visual attention, and problems with reciprocal turn taking in interactions between hearing parents and deaf infants and toddlers when compared with hearing parents with hearing children. This has been variously assumed to result from parental stress and the apparent need to "teach" deaf infants and from hearing adults difficulties adapting to the visual needs of deaf children. However, several large studies have indicated that early intervention and higher levels of social support decrease those difficulties. In addition, theoretical concerns that a difference between mother and infant/toddler hearing status would disrupt positive emotional attachment have not been borne out in research, and the distribution of attachment categories have not differed significantly between hearing mothers with deaf or with hearing children [23].

Social emotional and behavioral difficulties that have been reported to be of higher incidence in deaf than in hearing children are attributed primarily to the presence of child language delays and/or communication difficulties between deaf children and their hearing parents, siblings, or peers [20]. Multiple disabilities also increase risk for social-emotional difficulties. As in other developmental realms, more positive social-emotional development is documented for deaf children who have higher levels of language development and communication skills, regardless of the modality or modalities through which language is expressed – and a shared communication system between parent and child supports such development. Language delays in deaf children are associated with an impulsive instead of reflective learning and problem-solving style [14]. In addition, development of motivation for communication and learning can be depressed in deaf children when parents are overly protective and do not allow sufficient opportunities for independence and responsibility. Higher self-esteem and resulting educational and social success are more common for deaf individuals whose sense of identity is bicultural, that is, they identify with and value aspects of both deaf and hearing cultures [6].

Beneficial Accommodations and Technologies

In addition to benefits from advanced hearing aid technologies and cochlear implants, deaf children can benefit from other developing technologies. Captioning of spoken language on television programs, movies, DVDs, and similar media can provide access to information that would be inaccessible if available in voice only. It should be noted that such an approach is not thought to actually support initial reading skills but can expand those skills in a meaningful context. Many issues remain to be investigated as to the appropriate rate or speed of captions and the degree to which they should provide verbatim versus modified translations of the spoken content. Real-time captioning in various forms is increasingly available for classroom lectures and similar events and has promise for providing significantly increased access to content in those situations. Currently, questions remain about the most effective ways to provide these services and the degree to which they accurately reflect the spoken language content. Captioning of web media continues to be inconsistent. It can be expected that both accuracy and knowledge about effective use of captions will increase with continued research and evaluation and that domains in which forms of captioning are available will also increase.

Electronic communication devices are used widely by older deaf children as well as by hearing, and text messaging provides ready communication among deaf as well as hearing peers. A study in which pagers were distributed to deaf teenagers showed promise for increasing independence and decreasing parents' concerns about their children's safety when away from home [1]. To date, these and similar devices have primarily been studied in regard to effects on social and communicative functions; however, they also have potential for significant educational/instructional uses. For example, networked laptops and similar technologies are currently in use in some classrooms and can increase deaf students' ability to participate, especially when in mainstreamed classrooms. Web-based instruction has also been found to have positive effects on learning, although effective use tends to require relatively advanced reading skills, and learning is best supported when student engagement is high and when person-to-person instruction is also provided to supplement the media-based instruction.

Summary

Although language and academic performance of deaf children continues on average to lag that of hearing children, gains are occurring with early intervention, use of advanced technologies, and increasingly positive parent and societal attitudes about deaf children's potential for development. Flexibility in choice of language approaches as well as in educational placements and services to meet the characteristics and needs of both child and family

helps to promote development of deaf children. In general, family characteristics such as responsiveness to deaf children's interactive attempts, early and consistent experience with a perceptually-accessible language system, and a high level of parent engagement with the child and his or her educational experiences promote social, linguistic, cognitive, and academic development.

Declarative Memory

Stephanie A. Grote-Garcia[1], Forrest D. McDowell[2]
[1]University of the Incarnate Word College of Education Texas A&M University-Corpus Christi, Corpus Christi, TX, USA
[2]Texas A&M University-Corpus Christi, Corpus Christi, TX, USA

Synonyms

Explicit memory; Long-term memory

Definition

Declarative or explicit memory is one of two categories of long-term memory. The other is **procedural memory**. Declarative memory is the conscious recollection of experiences, events, and information used in everyday living.

Description

Declarative memory stores facts that are consciously known and is separated into semantic and episodic memory. Semantic memory is the storing of general factual knowledge, independent of personal experience. Knowing telephone numbers, foods, capital cities and specific words and definitions are example. Episodic memories include specific experiences, skills and events of a life. Examples are riding a bicycle, attending a music concert or a specific person. The memory types are considered to be connected to and support each other.

Declarative memory is aggressively studied in a variety of academic and medical disciplines such as psychological science, biology, and a variety of studies involving the human brain. Results of these studies are adding to information about the functioning of the human brain in a variety of learning or living situations of humans at all stages of life. There is discussion over the precise terms to be used when discussing the types and functions regarding memory.

Continuing studies in neurological sciences reveal declarative memory is based in cognitive experiences. Memories are transferred through specific parts of the human brain such as the amygdala or hippocampal nuclear structures before long-term storage is possible.

Decoding

►Reading Skills

Decoding Skills

Elisheva Konstam, Devorah Neuhaus
Pace University, New York, NY, USA

Synonyms

Reading skills acquisition; Word attack skills

Definition

Decoding skills are the tools needed to make sense of the spoken or written word. These skills are necessary in order to read, write and speak. The word decoding commonly refers to understanding on the word level and not comprehension of higher meaning.

Description

One important component of Decoding is phonological awareness, which is the understanding of the sound structure, and how words are composed of various sounds [1]. Phonological awareness includes the ability to segment sounds, rhyme, and identify syllables. Another component of Decoding is alphabetic knowledge, or The Alphabetic Principle, which is the understanding that letters are used to represent speech sounds. The third component of Decoding is Orthographic knowledge which is the understanding of the writing system in order to represent language this can include spelling, punctuation and capitalization. Together these components allow a person to properly decode written and spoken word [2, 3, 5].

The primary areas in the brain responsible for decoding include Wernicke's area and the Occipital lobe. Wernicke's area is responsible for understanding spoken language and damage to this area can result in decoding deficits. The Occipital lobe is responsible for receiving and understanding visual stimuli and damage to this area can result in visual decoding (reading) deficits [2].

Relevance to Childhood Development

Children utilize decoding skills when learning how to read, write and speak. If children encounter difficulty decoding either the written or spoken word then this can impede their development [4]. This can cause learning disorders and result in academic difficulties [2].

When damage to the brain causes the inability to read this is called Alexia. Dyslexia or Developmental Dyslexia is a term commonly used for children who have difficulty learning to read due to specific learning disorders, where they did not properly acquire the decoding skills necessary.

When damage to the brain causes the inability to understand spoken language this is called Aphasia. Developmental Aphasia is a term used for children who have receptive language deficits as they have difficulty acquiring the decoding skills necessary to understand spoken language.

Deductive Logic

▶Deductive Reasoning

Deductive Reasoning

Stephanie A. Grote-Garcia[1], Douglas J. Loveless[2]
[1]University of the Incarnate Word College of Education Texas A&M University-Corpus Christi, Corpus Christi, TX, USA
[2]Texas A&M University, Corpus Christi, TX, USA

Synonyms

Deductive logic; Syllogism

Definition

Deductive reasoning is the process of using general premises to draw specific conclusions. For example, *Do not enter a fenced yard that is protected by a dog,* is based on the logic that dogs tend to be territorial and can possibly bite individuals who enter their territory. A second example is the following:

1. Every football player must were a helmet while playing in a football game.

2. Joseph is a football player.
3. Therefore, Joseph must wear a football helmet while playing in a football game.

Description

Reason involves thinking about the world and developing an understanding of it. In deductive reasoning, a series of premises are used to develop conclusions. If a valid form of argument is used and the premises are true, then conclusions will be correct. This reasoning depends on the validity of the premises. If any of the premises are false then so is the conclusion.

Deductive reasoning begins with a major premise or general statement followed by more specific statements known as the minor premises. In order to draw accurate conclusions, one must move from the major premise to the minor. In the example of deductive reasoning given in the definition section above, sentence 1 is the major premise and sentence 2 is the minor premise. These statements are assumed to be correct. Since the two sentences are valid, the conclusion must be true. Argumentation follows this pattern: If 1 is true, and 2 is true, than 3 must be true.

Defense Mechanisms

Janet G. Benton
William Alanson White Institute, New York, USA

Synonyms

Defenses

Definition

"Defense mechanisms" or "defenses" are thoughts, feelings, and/or behaviors used to avoid anxiety about experiencing unpleasant or unacceptable intrapsychic or interpersonal truths. Implicit in this understanding is the fact that anxiety is often a very distressing and disorganizing event in itself, and humans try to protect themselves from enduring this experience [1, 5, 6].

Description

The term defense mechanism was originally conceived early in the twentieth century by Sigmund Freud in his elaboration of the concepts of resistance and "working through." He was attempting to understand why psychoanalysis was such a difficult process. Why, Freud asked, did his patients not benefit more quickly from his efforts to interpret the workings of their minds? Why did they often appear to thwart treatment [1]?

A fundamental tenet of Freud's theory of the mind is that instinctual aggression and sexuality, energies located in the structure of the Id, must constantly be mediated by the functions of other structures, the Ego and Superego. This mediation is attained through the use of defense mechanisms. Most well known from Freudian treatment theory is the defense of "repression," a mental process that keeps content from the instinctual Id from breaking into consciousness and from being remembered upon demand by the patient. This creates a difficulty in Freudian psychotherapy because repression keeps anxiety-producing content, which needs to be experienced and examined, from entering consciousness. This defense thus must be "worked through" by continually repeating interpretations (via the Ego) until the patient can tolerate experiencing the desires of the Id and eventually renounce them [5].

Freud's early conception of Id was that of "chaos, a seething cauldron of excitability" [5] that, at best, could only be contained. Later, in the 1930s Freud suggested that the Id was perhaps more capable of actual development and maturation. His daughter Anna Freud went on to develop these ideas in her book, *The Ego and the Mechanisms of Defense*, originally published in 1936 [4]. One of Freud's disciples, Otto Fenichel, carried the work further in his discussion of "character defenses" [3]. This work by A. Freud and Fenichel led the way to a more interpersonal understanding of defenses as compared with the more strictly intrapsychic concepts originally proposed by Freud. Instead of exclusively understanding defenses as protective of the impulsivity and excitability of the Id, defenses gradually began to be seen in relational matrixes with other people that protect patterns of behavior, thoughts, and/or feelings [7].

Although modified throughout the past century by different personality theorists, the general concept of "defenses" continues to be important in our culture. In addition to repression, other defenses that continue to be in common use include: rationalization (justification of

unacceptable behaviors to reduce guilt), intellectualization (separating feelings from thoughts and using only intellectual responses), projection (attributing one's own thoughts and feelings to others), regression (returning to behaviors and feelings from earlier in development), isolation (separating conflictual thoughts), sublimation (redirecting impulses), denial of reality (refusing to believe or sometimes even perceive a reality outside of one's own understanding), fantasy (gratifying needs through daydreams), displacement (transferring objectionable thoughts, feelings or behaviors from one person or situation to one that is less objectionable), identification, including identification with the aggressor (idealizing others in order to reduce one's own feelings of inferiority), undoing (use of ritualistic behavior to absolve guilt about unacceptable feelings, thoughts or behaviors), and reaction formation (replacing unacceptable thoughts, feelings or behaviors with their opposites) [2].

Delinquency

Gretchen Schoenfield
University of Arizona, Tucson, AZ, USA

Synonyms

Juvenile crime; Juvenile delinquency

Definition

"Delinquency" refers to violations of law conducted by individuals who are found guilty of such acts and are legally defined as a juvenile.

Description

A juvenile is adjudicated "delinquent" when he or she has been found guilty of a crime. Violations under the juvenile justice system fall into two categories: criminal and status offenses. State and federal policies both guide the ways in which these violations are processed, though approaches vary across jurisdictions.

Delinquency has often been treated synonymously to terms such as rule-breaking behavior, antisocial behavior, and conduct disorder. The commonality among these concepts is deviant behavior; however, there are important distinguishing features. Rule-breaking behavior is a non-diagnostic, non-legal term that encompasses a broad spectrum of behavior, ranging from developmentally appropriate to serious violations of the law. *Conduct disorder* is a psychiatric diagnosis that presents as aggressive behavior toward people or animals, willful destructiveness of property, theft, deceitfulness, or serious rule violating behavior that yields severe impairments in social, academic, or occupational functioning [1]. Rule-breaking behavior in and of itself does not constitute a diagnosis of conduct disorder, nor is it necessarily a violation of the law. Further, many delinquent youth do not meet diagnostic criteria for conduct disorder. Antisocial behavior refers to acts that violate social norms and generally is associated with those behaviors that meet diagnostic criteria for conduct disorder.

Prior to the existence of the juvenile court in 1899, there was no legal distinction between young and adult offenders. Police and prosecuting attorneys advocated for a separate juvenile court for this reason. The state could form a presumption of capacity for criminal intent for children between 7 and 14 years-of-age (children under 7 years-of-age were largely protected by an "infancy" defense). For example, a 12-year-old child's attempt to conceal evidence of a crime might demonstrate an awareness of wrongdoing, which would render the child culpable and eligible for criminal prosecution. Age, however, could also reduce or even exculpate the culpability of juveniles. Judges' and/or jurors' sympathy for young offenders often resulted in premature release, automatic case dismissal, or reduced sentences.

Concerns regarding inconsistency of court practices with children and adolescences, as well as concerns from child welfare advocacy groups, prompted the establishment of the first juvenile court in Cook County, Illinois. The overriding rationale for the juvenile court was rehabilitation, and the paramount question was a youth's amenability to treatment [2]. Because the central concern was treatment and rehabilitation, the key actors in the juvenile court were mental health professionals. The initial purpose of the juvenile court was two-fold. Juvenile courts served to protect children accused of crimes from the severity of the adult criminal courts. The second function was to provide services to neglected youth or children suspected of engaging in criminal or deviant behavior [3].

Several causal theories of delinquency have been proposed, with varying levels of empirical support. Some researchers have proposed that delinquency is a response to strain or stressors that serve to alleviate negative emotions associated with stress or strain [4]. Others have proposed that delinquency is a response to an absence of significant relationships with conventional others and institutions [5].

More recently, researchers have examined the dynamic interplay of biological, psychological, and social factors its relevance to delinquent behavior. Researchers have proposed that risk of delinquency is associated with acquired or inherited neuropsychological variation, which may emerge as cognitive deficits, difficult temperament, or hyperactivity. Some theorists suggest that delinquency follows two developmental trajectories – life-course-persistent and adolescence-limited [6]. Life-course-persistent is said to begin early in life and arises out of a combination of high-risk, difficult behavioral patterns, and a high-risk social environment. Throughout childhood and adolescence, individual characteristics and socioenvironmental variables interact and the child develops aggressive and antisocial behavior patterns that persist into midlife.

Adolescent-limited delinquency, according to this theory, surfaces during puberty as a reaction to psychological discomfort associated with desiring more autonomy than is appropriate for their age and developmental level. Most of these individuals eventually transition into adulthood without remnants of anti-social behavior. However, this transition may be hampered if the severity of their delinquency during adolescence resulted in incarceration, substance dependence, felonies, or a disruption in their education.

Dendrite

Robert Walrath
Rivier College, Nashua, NH, USA

Synonyms

Nerve cells; Neurons

Definition

Dendrite (from the Greek "dendron" or *tree*), a thin extension from the cell body of a neuron or nerve cell that allows information to be received from other neurons in the form of electrical or chemical stimulation, which is then sent to the cell body [1]. The branching of dendrites allows the connection to thousands of other neurons through *synapses* [2].

Definition

A drug which lowers arousal ("depresses") the action of the Central Nervous System. While depressants are used medically in the treatment of some anxiety disorders, more commonly they are consumed socially in the form of alcoholic beverages. Depressants effects on the human body include somnolence, unsteady gait, slurred speech, and uncoordinated reflexes.

Description

Depressants include, but are not limited to, alcoholic beverages, along with various medicines used to treat anxiety disorders and situational anxiety, often before an uncomfortable medical procedure. Except for alcohol, depressant drugs are strictly controlled by governments. Depressants can also be addictive. (See ►Addictive Drugs)

Developmental Apraxia

Michelle A. Prosje
Georgia School of Professional Psychology, Argosy University, Atlanta, GA, USA

Synonyms

Developmental coordination disorder; Developmental disorder of motor function; Developmental dyspraxia; Mixed specific developmental disorders

Definition

The term apraxia means without action/doing, from the Greek root "praxis." Apraxia is technically the complete inability to perform learned purposeful movements and is unrelated to impaired motor strength, coordination, comprehension, or sensation [6, 11, 12]. The term is often used interchangeably with ►dyspraxia, which is technically the partial inability to perform learned purposeful movements. Liepmann portrayed apraxia as a disconnection between the idea of movement and its motor execution. Various types of apraxia in adults have been delineated, with the major subtypes of ideational, ideomotor apraxia, and limb-kinetic apraxia [6, 12]. In pediatric populations, ideomotor apraxia and developmental apraxia of speech are considered the main subtypes. Developmental apraxia of speech has gained considerable attention in the literature, is the main pediatric type of apraxia, and has become a key focus of many pediatric speech pathologists and clinical psychologists.

Description

In adults, the ability to perform skilled movements, praxis, is stored in the inferior parietal area of the brain as movement representations [2]. Involving the association cortex, praxis is rooted in the dorsal occipitoparietal pathway and the ventral occipitotemporal pathway, respectively forming the "where" and "what" systems that help the brain determine the spatial location of objects and object identification. More research is underway to determine if the same brain pathways exist in children. In general, if a child cannot perform basic over-learned movements/pantomime actions, he/she is likely to be diagnosed with apraxia [2]. Two types of apraxia have been described in children: apraxia and developmental dyspraxia. Developmental dyspraxia has been defined as the failure to develop the ability to execute age-appropriate complex motor actions [16]. Developmental dyspraxia cannot be diagnosed if the deficits are better accounted for by the presence of ataxia, weakness, involuntary motor activity, selective motor control, or inadequate demonstration or practice [16].

Diagnostically, apraxia and developmental dyspraxia are covered in the classification systems of the American Psychiatric Association (DSM-IV-TR) and the World Health Organization's (WHO) International Classification of Diseases (ICD-10), although neither nosology applies the terms specifically in the diagnosis. Rather, apraxia and developmental dyspraxia fall into the more general categories of Developmental Coordination Disorder in the DSM-IV-TR (Diagnosis code: 315.4) and Developmental Disorder of Motor Function or Mixed Specific Developmental Disorders in the ICD-10 (Diagnosis codes: F83, F83) [5, 17].

Ideomotor apraxia is defined as the inability to perform transitive (requiring use of tools) or intransitive (familiar gestures) movements on command [12]. Frequently, ideomotor apraxia is referred to as impaired pantomime and imitation [2]. To assess for ideomotor apraxia, individuals are often asked to pretend to use common objects (e.g., scissor, key, hammer) or make symbolic gestures (e.g., wave goodbye) [2, 12]. One of the most common errors of ideomotor apraxia is using a body part as object (BPO). For some children, a second attempt at the movement alleviates confusion and promotes successful performance, precluding a diagnosis of apraxia. In contrast, other children who are unable to make corrections and successfully perform movements even after a second attempt are likely have limb apraxia [2]. Regarding brain localization, ideomotor apraxia has been associated with left hemisphere lesions usually in the inferior parietal lobe/supplementary motor area or a lesion of the corpus callosum [2, 12]. Another main apraxia subtype is ideational apraxia, which has been described as the inability to carry out a series of gestures due to a loss of action plan for the movement [12]. For example, when asked to fold a piece of paper, place it into an envelope, seal the envelope, and put a stamp on it, the individual is unable to carry out the movement sequence. Another example would be filling and lighting a pipe [12].

Overall, a diagnosis of apraxia is made when a child is unable to perform simple over-learned motor sequences (e.g., combing hair, waving goodbye, brushing teeth) within the context of a relatively normal neurological profile. Sometimes the movements are performed, but they are awkward, slow, or do not accomplish the desired objective [16]. Six impairment patterns have been identified in children described as having apraxia: "1) difficulty learning general rules or schemata about classes of motor actions; 2) using perceptual cues such as spatial location or object speed/trajectory; 3) organizing somatosensory/vestibular information; 4) problem solving or adaption to new situations; 5) analyzing task requirements and components, using knowledge in an effective fashion; and 6) preparing for upcoming actions [2, pp. 304–305]." Often, children with apraxia or dyspraxia (i.e., the terms are often used interchangeably) are described as uncoordinated or clumsy [2]. Some investigators have identified a group of related disorders called developmental coordination disorder (DCD) [16]. DCD has been defined as an impairment in the quality and functional purpose of movement not accounted for by intellectual ability, age, or other diagnoses of impaired functioning [15]. The fields of occupational therapy and psychology may commonly view DCD as a type of developmental dyspraxia, but many authors caution clinicians about lumping the two disorders [16].

Developmental Apraxia of Speech (DAS)

Apraxia of speech represents impairment in motor programming for speech production, usually resulting in articulation difficulty [12]. Developmental Apraxia of Speech (DAS) is a developmental pediatric speech sound disorder characterized by difficulty voluntarily making precise and consistent movements required for speech sound production, even when no overt neuromuscular deficits are present. Children with DAS do not properly develop skills to select, plan, initiate, and sequence motor patterns of speech. Synonyms for DAS include: Developmental Verbal Apraxia (DVA); Developmental Verbal Dyspraxia (DVD), Developmental Dyspraxia, Articulatory Apraxia, and Childhood Apraxia of Speech.

The diagnosis of DAS is a controversial one lacking consensus as to the essential characteristics and criteria for identification [3–5, 13, 14]. Some investigators acknowledge the importance of considering DAS on a continuum of impaired motor and language abilities, from the most difficult to understand cases requiring augmentative communication devices to the less severe individuals who are easily understood [5]. However, there exists a true need to establish an agreed upon DAS behavioral profile not only to provide reliable criteria for differential diagnosis but also to facilitate participant selection for research and to evaluate treatment efficacy.

Speech and language pathologists routinely evaluate children with DAS and report the most frequently cited behavioral correlates as inconsistent errors, prosodic abnormalities, and reduced phonemic repertoire [4, 5, 13]. Inconsistent errors are potentially the most salient markers for DAS, with considerable variability in consonant and vowel production over repeated syllabic articulations [3]. Inappropriate prosody, particularly with regard to emphasis within words and phrases, emerges as another prominent feature of DAS. Clinicians working in the field of speech and language agree that the prosody and syllable articulation in children with DAS are affected more profoundly and distinctively than other aspects of speech or phonology. In fact, some research has highlighted the critical roles sequencing and timing deficits play in most syllabic difficulties. Additional characteristics frequently cited regarding DAS include: groping (e.g., struggling to produce or imitate sounds or words), inability to imitate speech sounds, and general oral-motor difficulties.

Task complexity, deficit severity, and age add to and alter the behavioral presentation of children with DAS. Thus, considering DAS severity along a continuum is essential [13]. Errors in children with DAS differ from errors of children with developmental speech delay and resemble errors of adults with acquired apraxia of speech. Furthermore, although considered a speech disorder that directly impacts language abilities, DAS may occur in isolation free from associated language deficits [8, 9]. Moreover, while it is important to note that children with DAS do not automatically have deficits in other aspects of language, it is equally important to be aware that they may be at higher risk for developing other language problems. Some research has found correlations between DAS and other language functions (e.g., reading and writing); however, clinicians are cautioned about making assumptions and are urged to view each child with DAS on a case-by-case basis.

Specific indicators of DAS often present at an early age, a time when the child would benefit from early identification and intervention. Delayed speech development, limited expressive vocabulary, restricted consonant sound repertoire, and distorted vowels and absent consonant sounds are observable characteristics [7]. With increasing complexity and length of words and statements, speech becomes more difficult to decipher. Halting speech, hypernasal quality of speech sounds, and inconsistent and unpredictable productions may be evident [3]. Unfortunately, correct first-time articulation gives youngsters and their families false hope for consistently accurate pronunciation. Young children with DAS exhibit behaviors consistent with superior receptive language in contrast to their difficulties with speech output. In addition to the noteworthy inconsistent speech deficits, difficulty imitating facial movements, sounds, and words may be present. Moreover, feeding difficulties are often reported as evidenced by finicky eating habits, possible drooling, and aversion to mixed textures (e.g., tomato and meat sauce) [9].

Various etiologies have been delineated for DAS: neurological (e.g., intrauterine, trauma, stroke, infections), complex behavioral disorders (e.g., genetic, metabolic), and idiopathic neurogenic speech sound disorder. Some investigators assert that DAS arises most likely from a failure in neural maturation and organization, especially in the cortical areas responsible for motor planning and phonemic representation. The deficiency in phonemic representation is thought ultimately to impact perceptual abilities and associated motor programs that are instrumental in facilitating the development of perceptual categorization skills [14]. In contrast to children without DAS, children with DAS appear to process real words in a similar way as how they process nonsense words. In essence, sensorimotor learning deficits emerge and lead to poor prelinguistic articulatory-auditory networks which, in turn, make the establishment of phoneme-specific networks impossible. Weak sensorimotor feedback loops preclude children with DAS from responding to and self-correcting incomplete motor plans, whereas, typically developing children are able to self-motor and benefit immediately from feedback. Children with DAS likely have to initiate a new word production plan for each articulation, adding more time and effort to the child's already existing struggle with speech output.

Diverse treatment approaches have been proposed to help children with DAS [10]. Linguistic approaches targeted at the child's use of speech sounds directly teach the rules to determine sounds and sound sequences

regularly incorporated in language. Motor-programming approaches assist children in acquiring skills to create sounds and sequences of sounds accurately, consistently, and automatically. Some treatments include a combination of linguistic and motor-programming approaches [10]. Most interventions consist of sensory and general cuing techniques. Within the context of specific treatments, other goals may be targeted to incorporate correct word usage, prosody (melody and rhythm of speech), and nasality. Speech and language pathologists are instrumental in assisting children and families by including play-based techniques where families are partners in assessment, planning, and treatment. Overall, early identification and intervention plays a key role in enhancing language development and fostering smoother transitions to school.

Relevance to Childhood Development

Children with any type of apraxia need to be examined carefully to ensure diagnostic accuracy, as clinicians frequently misdiagnose apraxia. It is important to keep in mind the various types of apraxia and the concept of developmental dyspraxia, where a child has failed to learn how to execute complex motor sequences. Treatment provided by occupational, physical or speech/language therapists is indicated.

Developmental Apraxia of Speech

Children with DAS are generally at risk for early and persistent problems in speech, expressive language, and the phonological foundations of literacy. Additionally, many youngsters with severe DAS will become candidates for augmentative and alternative communication and assistive technology. Most children with DAS display highly variable speech performance and lack a consistent improvement in speech accuracy. Such variability emerges as a salient diagnostic marker and requires a comprehensive speech and language evaluation with particular emphasis on the motor act involved in speech production.

Children with DAS generally exhibit language and motor dysfunction which often requires special academic school support [10]. Their organizational problems, poor social use of language, and generally reduced vocabulary repertoire present communication obstacles for not only the child but also his/her peers and teachers. Basic language problems surface and cause significant developmental lags, due in part to the individual's reduced vocabulary size and generally poor expressive as compared with receptive language. Frequently described by parents and teachers as clumsy or sloppy, children with DAS may exhibit notable weaknesses in both gross and fine motor skills. Fine motor skills include chewing and swallowing. In hindsight, many families acknowledge that indications of such gross and fine motor skills were present early on. For example, some infants who had initial difficulty nursing were later described as messy eaters who frequently choked during meals. Physical or occupational therapy is typically indicated for children with motor difficulty in the context of DAS.

Regarding treatment, children with DAS tend to make slow progress and usually benefit from intense sessions occurring numerous times per week [10]. To achieve the greatest communication efficiency, therapy is likely to continue throughout the school years on as intensive a basis as possible. The main goal for children with DAS is to achieve the best possible communication through focused effort on enhancing speech and language skills. DAS represents a lifelong communication problem that needs to be viewed in terms of problem severity and associated remedial services required at specific ages across the lifespan.

For children who present with severe DAS, clinicians question the likelihood of the child's attainment of oral communication [10]. Oral communication may not be a reasonable goal, and alternative means for expression may need to be considered. Such alternatives may include manual communication, sign language, assistive language notebooks with pictures or words, and electronic communication devices.

Children with less severe DAS will gain skills for effective communication and possibly achieve speech characterized by few or no speech errors [10]. The individual with DAS and his/her family need to be advised that inconsistent speech errors will occur occasionally, especially when the individual is fatigued. These DAS-type errors will also emerge as the child develops into a teenager and adult who engages in situations requiring considerable amounts of talking or in circumstances when he or she needs to make an oral presentation.

Definitions

Ataxia: From the Greek word "a taxis" meaning without order or incoordination. Ataxia means lacking coordination. Ataxia may affect fine and gross motor skills as well as oral motor and eye movements. Ataxia may be symptomatic of another condition or may apply to a group of specific degenerative diseases of the nervous system.

Association cortex: The association cortex is the largest area of the cerebrum; it is the interface of the temporal, occipital and parietal lobes. Via the association cortex, information from different sensory modalities (i.e., visual,

auditory, tactile/kinesthetic) is integrated in order to form more complex perceptions.

Dyspraxia: The partial inability to perform learned purposeful movements, unrelated to impaired motor strength, coordination, comprehension, or sensation.

Ideational apraxia: Inability to carry out a series of gestures due to a loss of action plan for the movement.

Somatosensory/vestibular information: *Somatosensory* refers to bodily sensation information. This may include touch discrimination, information about joint and limb position, detection of vibration, perception of pain, temperature and pressure. *Vestibular*, often associated with the workings of the inner ear, refers to one's sense of balance. In addition to issues with balance, vestibular disorders may include dizziness, vertigo, and lightheadedness. Vestibular problems may be primary or may be secondary to other conditions. *Somatosensory/vestibular information* pertains to an individual's sense of bodily sensations and balance.

Definition

Developmental Coordination Disorder is a childhood diagnosis characterized by a marked impairment in the development of motor coordination that is not explainable in terms of age, intellectual level or any other diagnosable neurological or psychiatric condition [2].

Description

The marked impairment in the development of motor coordination which is the key feature of developmental coordination disorder was first recognized in the early 1900s; but received little attention by the empirical literature perhaps mainly due to the early belief that the children would outgrow their problems. Accumulating evidence in the 1990s however, documented that children with motor difficulties do not outgrow their motor problems. In contrast, this evidence documented that children with motor impairments often developed deficits in academic and psychosocial functioning. Growing awareness of the condition, prompted recognition by the World Health Organization and the American Psychiatric Association (1994) [2] of a distinct motor impairment syndrome which they classified as "Developmental Coordination Disorder" [1]. This term was confirmed upon an international consensus meeting held to debate the differing labels that historically have been used to describe the condition. In the course of this meeting it was agreed to use the term Developmental Coordination Disorder in future research reports and clinical practice [8].

The essential feature of Developmental Coordination Disorder is a marked impairment in the development of motor coordination which results in the inability of a child to execute tasks that are age appropriate given normal intellectual abilities [2]. Performance in daily activities that require motor coordination is substantially below that of typically developing children of comparable age and intellectual level. This may be manifested by marked deficiencies in achieving motor coordination milestones (e.g., walking, crawling, sitting), dropping things, "clumsiness," poor performance in academic tasks (e.g., handwriting, organizing seatwork, gym class) and leisure activities (e.g., sports, playground activities). Often combinations of these deficiencies co-exist although children with the condition present a diverse spectrum of difficulties. Also for Developmental Coordination Disorder to be diagnosed, the child's disturbance should not be due to a general medical condition (e.g., cerebral palsy, hemiplegia, or muscular dystrophy) and should not meet criteria for a Pervasive Developmental Disorder. Further if Mental Retardation is present, the motor difficulties should be over and above those typically associated with it [2].

Epidemiology

Epidemiological studies report prevalence estimates ranging from 5–20% of children ages 5 to 11 depending on criteria used and populations tested [2, 3]. This wide rate of prevalence estimates can be explained by the substantial diversity of the spectrum and the current lack of specific laboratory tests; therefore making diagnosis of the disorder one of elimination of all other possible diseases/causes. No gender differences are thought to exist, although males seem to be more likely to be diagnosed.

Etiology

Several lines of evidence suggest that the condition is due to some form of central nervous system pathology which affects the child's ability to move effectively. This pathology is thought by several theorists to be related to prenatal complications such as fetal malnutrition but there is no strong evidence to support this claim. Developmental Coordination Disorder only received increased research attention in the past one and a half decades and consequently there is still little insight into the specific etiology of the disorder.

Comorbid Diagnoses

Developmental Coordination Disorder is often associated with delays in other non-motor milestones. Associated disorders often include Phonological Disorder, Expressive Language Disorder, Mixed Receptive-Expressive Language Disorder, various congenital problems (e.g., premature birth, low birth weight) and Attention-Deficit/Hyperactivity Disorder. However the literature concerning the link between Developmental Coordination Disorder and these various disorders is inconclusive. For instance it is plausible that Developmental Coordination Disorder and Attention Deficit Hyperactivity Disorder are caused by the same underlying mechanism, or Attention Deficit Hyperactivity Disorder may co-exist in some children who have Developmental Coordination Disorder.

Differential Diagnosis

Several disorders have similar symptomatology. The clinician, therefore, in his/her diagnostic attempt needs to differentiate between the conditions of Mental Retardation, Attention Deficit Hyperactivity Disorder, Traumatic Brain Injury, Mild Cerebral Palsy, Congenital Chorea, Decreased Visual Acuity and Orthopedic Abnormality in order to determine a precise diagnosis.

Developmental Considerations

The manifestations of the disorder vary with age and development. For instance children in early childhood may show delays in the development of gross motor skills

and fine motor skills (e.g., those used for running, climbing, and drawing and for self-care activities such as dressing, tying shoelaces, and buttoning shirts). Children in middle childhood may display difficulties with physical activities that require hand-eye coordination (and most likely they will start to avoid such activities), such as handwriting, catching or throwing a ball, balancing on one foot, or riding a bike. Adolescents will most likely avoid or never participate in physical activity with others since their motor skill performance would be well below that of their peers. Young adults may display difficulties in organization, time management and social interaction.

Prognosis

Although the natural history of Developmental Coordination Disorder is not yet well determined, the preponderance of the existing evidence suggests that the course of the disorder varies significantly from case to case and depends on the severity of the disorder. The motor skills difficulties of most children with Developmental Coordination Disorder persist at least into adolescence, while for many the symptomatology will last into adulthood [2, 4, 6]. Furthermore, evidence suggests that although the specific mechanisms are not yet determined, the developmental course of Developmental Coordination Disorder results in children who are more likely to have poor social competence, academic problems, behavioral problems, low self-esteem, and are less likely to be physically fit or to participate voluntarily in motor activities [3, 6].

Treatment

At present there is no known cure for Developmental Coordination Disorder. The line of empirical evidence deriving from clinical studies that utilized large sample sizes and rigorous methodologies to evaluate sensory integration, perceptual motor, and process-oriented treatment methods [5, 7, 10] reached the conclusion that treatment was minimal to non-existent. A single study that documented small improvement in movement skill development suggested that improvement could be attributed to increased confidence and willingness to participate in motor tasks on behalf of the child rather than the treatment itself [9]. Current ongoing clinical trials focus on establishing whether occupational and physical therapy may potentially lead to an improvement in the child's perceived self-competence and willingness to engage in physical activity. Cognitive interventions are also currently under empirical investigation but the evidence for their efficacy is still inconclusive. Future direction for research needs to focus on individualized approaches to treatment given the diverse spectrum of difficulties that characterize children with Developmental Coordination Disorder.

Prevention

Currently there are no known preventative measures for Developmental Coordination Disorder. Nonetheless appropriate prenatal care and healthy nutrition throughout pregnancy could potentially be of help since both of these factors are considered to be of substantial contribution towards prevention of a diverse spectrum of childhood disorders.

Synonyms

Cognitive disabilities; Intellectual disability; Learning disabilities (as chiefly used in the United Kingdom); Mental retardation; Mild mental retardation; Moderate mental retardation; Profound mental retardation; Severe mental retardation

Definition

Developmental disabilities are severe disabilities, first manifested before adulthood, that are attributable to mental and/or physical impairments, likely to continue indefinitely, and which substantially limit the capacity for independent functioning.

Description

The term "developmental disabilities" came into common use in the United States following its appearance in "The Developmental Disabilities Services and Facilities Construction Act of 1970" (Public Law No. 91–517) [3], a federal law that provided for the development of a comprehensive array of basic services designed to meet the needs of individuals who exhibited a developmental disability. A review of the Public Law No. 91–517 indicates that this early definition of developmental disability was closely tied to the concept of mental retardation. Indeed, Public Law No. 91–517 was written to amend the "Mental Retardation Facilities and Community Mental Health Centers Construction Act of 1963" (Public Law No. 88–164) [4], a bill that was signed into law weeks before the assassination of President John F. Kennedy. Whereas Public Law No. 88–164 routinely referred to "the mentally retarded," Public Law No. 91–517 emphasized "developmental disability" and defined it as follows (p. 1325):

> The term "developmental disability" means a disability attributable to mental retardation, cerebral palsy, epilepsy, or another neurological condition (. . .) found to be closely related to mental retardation or to require treatments similar to that required for mentally retarded individuals, which disability originates before (. . .) age 18, which has continued or can be expected to continue indefinitely, and which constitutes a substantial handicap to such individual.

In the succession of laws that followed Public Law No. 91–517, the formal legal definition for developmental disabilities evolved to its current form, as outlined in the "Developmental Disabilities Assistance and Bill of Rights Act of 2000" (Public Law No. 106–402; pp. 1683–1684) [2]:

> The term "developmental disability" means a severe, chronic disability of an individual that – (i) is attributable to a mental or physical impairment or combination of mental and physical impairments; (ii) is manifested before the individual attains age 22; (iii) is likely to continue indefinitely; (iv) results in substantial functional limitations in three or more of the following areas of major life activity:
>
> (I) Self-care
> (II) Receptive and expressive language
> (III) Learning
> (IV) Mobility
> (V) Self-direction
> (VI) Capacity for independent living
> (VII) Economic self-sufficiency; and
>
> (v) reflects the individual's need for a combination and sequence of special, interdisciplinary, or generic services, individualized supports, or other forms of assistance that are of lifelong or extended duration and are individually planned and coordinated.

It should be noted that Public Law No. 106–402 also provides that individuals under the age of 10 years may be considered to exhibit developmental disability without meeting the above criteria, provided that the young child demonstrates significant development delay or specific condition that indicates a high probability that the child, without assistance, would eventually meet the above criteria.

As used today, "developmental disability" emphasizes a generic notion of functional disability, first evidenced during the developmental period, which reflects the person's often lifelong need for individualized services, support, and assistance. Because the "developmental disability" does not specify a precise nature or etiology of the functional disability, persons who are considered to exhibit a "developmental disability" may carry one or more of a variety of relatively diverse individual diagnoses, including mental retardation, autism, more involved forms of cerebral palsy and epilepsy, fetal neurological disorders (e.g., fetal alcohol syndrome), traumatic brain injury, and syndromes secondary to chromosomal abnormalities (e.g., Down, fragile X, Cri du chat, Prader -Willi, Turner).

Epidemiological studies suggest that approximately 1–2% of the population exhibits some form of developmental disability [1], with a 2:1 male to female ratio. Depending on the nature of their developmental disability,

persons often experience a higher rate of physical and/or mental health problems. For example, Down syndrome is associated with a greater risk for congenital heart defects and fragile X syndrome, for social phobia.

Developmental Disorder of Motor Function

►Developmental Apraxia

Developmental Dyslexia

Andy V. Pham, John S. Carlson
Michigan State University, East Lansing, MI, USA

Synonyms

Dyslexia; Learning disability; Learning disorder; Reading disability; Reading disorders

Definition

Developmental dyslexia is a specific learning disability that is characterized by difficulties with accurate and/or fluent word recognition, spelling, and decoding skills.

Description

Symptoms

Individuals with developmental dyslexia have pervasive difficulties with identifying words accurately, letter-sound associations, and spelling. While previous theories of developmental dyslexia include the role of visual processes and the notion that many children with dyslexia "read backwards," current research studies reveal that visual processing is not the core deficit in children with this particular reading disability. There is a strong consensus among researchers in the field that the core deficit in dyslexia reflects the language processing system, where the child has difficulty understanding and distinguishing sounds in language. These difficulties are often unexpected in relation to the child's intellectual abilities and the provision of appropriate classroom instruction. Secondary symptoms may include problems in reading comprehension and reduced reading experiences that can impede the growth of vocabulary and fluency skills.

Prevalence and Incidence

Given the inconsistent definitions of dyslexia during the past several decades, the reported prevalence of dyslexia varies. According to the American Psychiatric Association [1], the prevalence of Reading Disorder (or dyslexia) in the United States is estimated at 4% of school-age children. The British Dyslexia Association [2] also estimates the prevalence of dyslexia at 4%. *The International Book of Dyslexia* [10] revealed statistics from 14 different countries around the world and stated that the range of incidence is from 1% to 11%.

Phonological Hypothesis

Children with developmental dyslexia are believed to have poorly developed phonological processing that make it difficult for them to acquire early reading skills, particularly *phonological awareness*. Related studies also identified additional skills to be associated with reading success such as *rapid automatic naming* (RAN), which is the ability to name visual symbols (e.g., letters, numbers, or colors) quickly and accurately [4]. Thus, Wolf and Bowers [12] proposed the "double deficit" hypothesis, which suggested that individuals with dyslexia have deficits in both phonological awareness and rapid naming skills. Additional studies have also implicated *orthographic awareness,* which is the ability to discriminate the symbolic structure of written language accurately and fluently, as deficient in children with developmental dyslexia.

Causes

There has been recent evidence that developmental dyslexia stems from a neurobiological basis. Researchers have documented the disruption of several neural systems of children with developmental dyslexia across languages and cultures. For example, in individuals with developmental dyslexia, functional magnetic resonance imaging (fMRIs) shows a failure of left hemisphere posterior brain systems during reading activities. These studies also reveal that the word-analysis system, which allows the reader to learn and distinguish sounds system, is localized within

the left parieto-temporal region of the brain. In addition, the word-form system, which allows the reader to recognize whole words automatically, is localized within the occipital-temporal region of the brain. Therefore, the left occipito-temporal system appears to be activated when a child or adolescent has become a skilled and fluent reader, and has put together all the sound and written components of word. However, individuals with developmental dyslexia demonstrate a relative inactivation in both the parieto-temporal (i.e., word-analysis) and occipito-temporal (i.e., word-form) regions of the brain.

Developmental dyslexia also has a strong genetic influence. The disorder is found in 25% to 65% of the children of parents who have the disorder, and approximately 40% of siblings of children with developmental dyslexia are also affected. Interestingly, a higher heritability for developmental dyslexia has been reported in children with higher IQs. The genetic transmission can account for at least 50% or more of the variance explained by genetic factors, while the remaining variance can be attributed to environmental influences. Based on these genetic findings, if a child has a parent or sibling who has developmental dyslexia, that child may be considered at risk for future reading difficulties.

Diagnosis

Practitioners cannot diagnose developmental dyslexia based on a single score from a reading test. Developmental dyslexia is a clinical diagnosis, primarily made by experienced practitioners (e.g., clinical psychologists) who have taken a careful developmental, educational, and family history, observed the child or adolescent reading a passage, and administered a battery of tests that assess the child's cognitive ability and academic skills including reading fluency, accuracy, and comprehension, spelling, mathematics, and language skills [7]. Although attention has focused on the student's difficulties in reading print, the ability to notice, manipulate, and remember sound elements has an important function in reading as well. Therefore, the child may exhibit problems with oral language, though these problems are likely more subtle than observed in reading. Oral language problems include mispronunciations, difficulties in verbal memory and/or producing verbal responses, and confusing words that sound alike (e.g., saying "spill" instead of "still").

Though referral rates in school systems indicate that 60–80% of individuals with reading disabilities are male, this may be due to traditional and biased school-based referral procedures [6]. However, it is important to emphasize that children who are receiving special education services under the category of "reading disability" may not necessarily have dyslexia, which is a clinical diagnosis. Nevertheless, it is suggested that developmental dyslexia occurs at equal rates in males and females if practitioners were to use a common definition and criteria to assess reading disabilities [1]. Without remediation, approximately 70% of students with reading disabilities in third grade may continue to struggle with reading problems through high school and into adulthood [8].

Treatment

A majority of early interventions for children at risk for dyslexia focused on improving skills such phonological processing or initial letter and word identification skills in kindergarten and the first grade. Classroom interventions, pullout remedial approaches, or a combination of both approaches reported positive results in students' reading skills [9]. Many studies suggested that prevention programs that explicitly focus on phonemic awareness, letter and word identification, and meaning of text in the earliest grades of reading instruction reduce rates of at-risk students in elementary school [11]. Although it is difficult to determine whether these young children have dyslexia because they are typically just learning to read, it appears that these systematic prevention programs can significantly improve basic reading skills in the weakest readers at these very young ages.

For older students with developmental dyslexia, research exploring different intervention programs includes direct instruction and strategy-based approaches. Direct instruction consists of extensive professional development component that helps teachers understand rationales for using this particular approach to reading instruction, lesson plans, and group strategies [5]. The curriculum also extends beyond phonics into fluency and comprehension where instruction is mostly focused on for upper elementary school students. Peer-tutoring interventions have often been used to improve reading skills. For example, the *Peer-Assisted Learning Strategies* (*PALS*) has been used to facilitate small group instruction and cooperative learning activities within the classroom [3]. Peer tutors are essentially trained to become reading teachers for their peers in order to increase fluency and comprehension skills.

Since developmental dyslexia represents a disparity between an individual's reading skills and intellectual abilities, accommodations in the classroom are essential for success. A number of studies are currently looking at the neurobiological bases of the disorder; therefore, evidence-based interventions will continue to be developed in order to activate these neural systems that are affected. With accommodations and support from families and schools, individuals with developmental dyslexia can still succeed in many different professions and endeavors.

Developmental Milestones

Jana Sander
Texas A&M University Corpus Christi College of Education, Corpus Christi, TX, USA

Synonyms

Developmental norms; Developmental periods

Definition

A set of specific skills that are age-specific which children should be able to perform.

Description

Developmental milestones usually address children's development of social skills, cognitive skills, emotional skills, and physical skills. Each age level has different skills that are normally exhibited by children. It is important to note that each child progresses at their own pace within the developmental milestones.

For example,

Developmental Neuroscience

Randall R. Lyle
St. Mary's University, San Antonio, Texas, USA

Definition

Developmental neuroscience is that branch of neuroscience that is specifically interested in the development of the nervous system. This ranges from the study of simple invertebrate creatures to humans. As a discipline it is also interested in the development of nervous system dysfunction, pathologies, trauma and aging. Its research methods may include traditional biological research and animal studies as well as in vitro cell generation and computer modeling.

Description

Developmental neuroscience is devoted to research to further the understanding of how neural systems develop and perform their complex tasks. Animal studies are used both to understand the function for the animal but more critically as a means to understand human neuronal development. Developmental neuroscience seeks to explain both normal and abnormal neuronal development as a means to further understanding of human function and as a way to treat, prevent or ameliorate developmental diseases, dysfunctions and pathologies. Developmental neurosciences is also interested in the neuronal changes associated with aging so as to slow or counteract some of the negative aspects of this process.

Relevance to Childhood Development

Developmental neuroscience provides research and understanding into both normal and abnormal nervous system development. This knowledge is critical to developing strategies and programs for facilitating maximum developmental opportunities for children. For example, it was developmental neuroscience that highlighted the critical importance of the frontal lobes in executive function and decision making and how late in the development of the child these structures become fully connected and functional. Developmental neuroscience has also been largely responsible for the creation of Developmental Neuropsychological Assessment tools and tests. Awareness of the findings and research of developmental neuroscience is critical to maintaining a relevant and beneficial approach to childhood development.

Developmental Norms

Marie C. McGrath
Immaculata University, Immaculata, PA, USA

Synonyms

Age equivalents; Developmental milestones; Developmental stages; Grade equivalents

Definition

Defined standards of typical performance by which a child's development in a variety of domains can be measured.

Description

Developmental norms are used to assess whether infants, toddlers, children, and/or adolescents are developing cognitive, communication, motor, socioemotional, and adaptive skills at approximately the same rate as their peers. Developmental measures establish typical levels of performance for the test's target population (based on the performance of the test's norm sample) in each of the age group or grade levels that the target population comprises; test-takers are assigned age equivalent or grade equivalent scores based on the median raw score for that chronological age or grade level. For example, a 36-month-old child whose overall performance on a measure of motor functioning was equivalent to that of the typical 24-month-old child in the norm sample could be assigned an age equivalent score of 24 months. Children who demonstrate delays in one or more developmental domains when compared to peers may, depending on the extent of the delay(s) and on applicable laws in the state or country where the child resides, be found eligible for early intervention, special education, or other services to address their specific needs.

When attempting to interpret test results that are based on developmental norms, it is important to remain mindful of the context in which the test was developed and normed, as well as the diversity of the individuals in the norm sample. The specific behaviors considered to be critical developmental milestones, and when these behaviors typically occur, may vary significantly from culture to culture. Additionally, disparities in individuals' access to resources and environments conducive to learning and practicing various behaviors may impact whether individuals appear to meet developmental milestones at the expected time. For example, some developmental measures assess whether adolescents can successfully and independently navigate their neighborhoods on foot and/or via public transportation; individuals who live in rural areas might possess the underlying skills necessary to successfully perform these behaviors, but have no occasion to do so. Evaluators must attempt to determine whether a child who does not exhibit behaviors generally thought to be typical of that child's age or grade level is not *capable* of performing the behaviors, or simply has not had the *opportunity* to perform those behaviors.

Developmental Test of Visual-Motor Integration

Synonyms

Beery-Buktenica Developmental Test of Visual-Motor Integration; Beery VMI

Definition

A neuropsychological test assessing visuoconstructive abilities. Visual-motor integration tests are designed to assess an individual's ability to integrate their visual and motor abilities. Currently, the most widely used and researched test of this kind is the Beery-Buktenica Developmental Test of Visual-Motor Integration.

Description

The Developmental Test of Visual Motor Integration or Beery VMI is a developmental sequence of geometric forms that are copied with paper and pencil. The purpose of assessing visuoconstructive abilities is to help identify children who may need special assistance, to obtain needed services for them, and to test the effectiveness of educational and other interventions. The Full Form 30-item Beery VMI can be administered either in a group or individual format and typically takes 10 to 15 minutes. The test is used for children ages 2 through 18 years of age. The Short Form 20-item version is available for children ages 2 through 7. Two optional standardized tests, the Beery VMI Visual Perception test and Beery VMI Motor Coordination test, are also available and provide relatively pure measures of visual and motor performance. The Beery VMI is now in its 5th edition, having been standardized five times between 1964 and 2003 with a total of more than 11,000 children. Research suggests that this test is virtually culture-free.

Deviation IQ

Marie C. McGrath
Immaculata University, Immaculata, PA, USA

Synonyms

Intelligence quotient; IQ; Norm-referenced IQ; Standard scores

Definition

A type of normally distributed standard score (with a mean of 100 and a standard deviation of 15) that represents level of performance on tests of cognitive ability.

Description

Prior to the advent of the deviation IQ, cognitive test scores were derived by dividing a child's measured *mental age* by that child's chronological age. Similar in nature to today's age equivalent scores, mental ages were calculated by finding the typical score obtained by children at each age level on a test; children earning the median raw score for a given age were assigned that age as a mental age score. In 1914, William Stern first referred to this type of score as a "mental quotient." Two years later, test developer and intelligence researcher Lewis Terman began multiplying this ratio by 100 to obtain an integer, rather than decimal, score, which he referred to as an "intelligence quotient." Thus, a 9-year-old who obtained a mental age of 6 years on a cognitive ability test would have a measured mental quotient of 0.67 and an intelligence quotient of 67. This type of IQ score is also known as a *ratio IQ* due to the methods used in its calculation.

While ratio IQs are simple to calculate, they have several shortcomings. First, while they can convey that an individual has scored above or below expected levels for his or her age, they do not provide precise information on how an individual has performed relative to peers. Additionally, ratio IQs can shift significantly over time due to lessening or increasing gaps between actual and expected performance; since overall intelligence level is generally conceptualized as a relatively stable psychological trait, these shifts are undesirable. For example, a 4-year-old who obtained a mental age of 6 on a test would be assigned a ratio IQ score of 150; however, if that child was retested 2 years later (i.e., at age 6) and again obtained a mental age score two years above chronological age (i.e., age 8), the child's ratio IQ score would drop to 133. Additionally, given that many cognitive abilities either remain relatively stable or begin to decline in adulthood, the calculation of ratio scores for adults is generally considered inappropriate and potentially misleading.

Given these issues, it is unsurprising that ratio IQ has been largely replaced in modern norm-referenced cognitive testing by the *deviation IQ*, though some researchers working with highly intellectually gifted children continue to calculate ratio scores in order to illustrate the significant difference between those students' actual and expected performance. Deviation IQ scores have a mean of 100 and a standard deviation of 15. As with Terman's ratio IQ score, typical levels of performance are represented by deviation IQ scores of 100; however, deviation IQ scores are calculated via statistical transformation of raw scores to a normal (or Gaussian) distribution of standard scores, rather than by dividing mental age by chronological age. In this system of scores, approximately 68% of IQ scores fall within one standard deviation from the mean (i.e., between 85 and 115), and approximately 95% of scores fall within two standard deviations of the mean (i.e., between 70 and 130). Due to the properties of the normal distribution curve, each deviation IQ score that can be obtained on a test is associated with a fixed percentile rank (i.e., the percentage of cases falling below that level of performance); for example, a score of 130 will always fall at the 98th percentile. Therefore, deviation IQ scores address one of the major shortcomings of ratio IQs by providing information on the typicality of an individual's level of test performance. Additionally, since they represent relative standing within a group, they tend to be more consistent (and thus more reliable) as an individual's age changes than ratio IQ scores. Finally, the use of standardized deviation IQ scores enables more direct comparison of performance levels across tests than ratio IQ scores.

Dewey, John

Phyllis Curtis-Tweed
Medgar Evers College/CUNY, Brooklyn, NY, USA

Life Dates

1859–1952

Introduction

John Dewey was an educator, psychologist and philosopher, who had a profound impact on American education during the first half of the twentieth century. He, along with Charles Sanders Peirce and William James, is recognized as a leading proponent of American pragmatism. Dewey is best known for his progressive approaches to education but wrote on a variety of topics. He was

considered to be a public intellectual and world renowned lecturer who commented on the moral implications of many societal issues including democracy and freedom, women's suffrage, and race relations.

Educational Information

John Dewey attained his early education in the public school system of Burlington, Vermont. He attended the University of Vermont from which he graduated in 1879. After teaching high school, Dewey enrolled in John Hopkins University in 1882 to pursue a doctoral degree in Philosophy, which he completed in 1884. At Johns Hopkins, Dewey studied pragmaticism under C.S. Peirce. He furthered his interest in Hegelian philosophy with George Sylvester Morris and learned the scientific methodology of experimental psychology from G. Stanley Hall. These professors strongly influenced Dewey's theoretical development and approaches to education, psychology, and philosophy.

Accomplishments

Dewey as College Professor

Dewey taught Philosophy at the University of Michigan between 1884 and 1894, with the exception of 1 year when he taught at the University of Minnesota. In 1894 Dewey became Professor of Philosophy and Pedagogy at the University of Chicago. At the University of Chicago, Dewey founded a Laboratory School for prospective teachers in which he was able to apply his educational methods and theories. He also supported Jane Addams' Hull House in which his progressivism was applied. In 1904 Dewey accepted a position at Columbia University as a professor of philosophy. He retired from Columbia in 1930 but continued teaching as Professor Emeritus until 1939. Dewey was a prolific writer who published approximately forty books and 700 articles.

Dewey as Author/Scholar

John Dewey was a political and social activist. He was a president of the American Philosophical Association. He founded and was the first president of the American Association of University Professors, as well as first president of the League for Independent Political Action. He was also a president of the American Psychological Association. He assisted in founding the National Association for the Advancement of Colored People. In 1937, he chaired the Commission of Inquiry into the Russian government's charges against Leon Trotsky. He was also involved in the establishment of the New School of Social Research in New York City.

Contributions

Dewey and Philosophy

Dewey's form of pragmatism, called instrumentalism, proposed that individuals used their cognitive understanding of various experiences as tools or ideas to solve problems. If these ideas or tools were effective in solving problems or improving a situation they were perceived as truths. Because truths varied according to context and experience, reality must also be changeable, as opposed to eternal and static. Realities are progressively reorganized as ideas/truths and empirically applied in various experiences. Dewey believed that morality was an integral part of instrumentalism as it represented the individuals' sense of responsibility in applying ideas and changing realities. Dewey's philosophical and psychological understanding of the impact of lived and practical experience on learning, its relation to moral development and their accompanying impact on society were reiterated throughout his writing. This is particularly pertinent in Dewey's perspectives on education and child development.

Democratic Principles in Education

According to Dewey the application of democratic principles in American Education should reflect the claim that America is a democratic society. He defined democratic principles in education in terms of "the participation of all members on equal terms." He claimed that democratic practices in education should afford individuals a personal interest in social relationships and control and the habits of mind which secure social changes without introducing disorder.

Education and Moral Principles

Dewey argued that schools must prepare students to live a moral life (1909). He defined moral life as a combination of social acumen, the capacity of observe and understand social situations; and social power, trained capacities of control, working in the interest of social motives and concerns. Dewey claimed that moral principles were comprised of both psychological and social aspects. The psychological aspect pertained to individual thought and behavior while the social aspect referred to how the individual might relate to society. The impact of social interests was so powerful that they were, by association, assimilated into moral principles or requirements [3].

The purpose of schooling was to train individuals in moral principles, thereby preparing them for social life, through the replication of typical social conditions [2, 4]. These objectives should be accomplished by reviewing society's needs and determining the school's relationship

to those needs. He viewed school as an embryonic version of society. He noted that school settings should reflect social change [4, 5]. He warned that trying to develop social character without knowledge of society's needs and aims was like teaching a child to swim outside of the water.

Dewey complained that the conception of ethics in education remained aloof from actual social practices and requirements, Schools failed as social institutions because they perpetuated a mythical separation between intellectual and moral pursuits, Dewey admonished that moral behavior in and outside of school involved the same principles. Unfortunately, moral instruction was limited to teaching about selected virtues and attempting to inculcate students with certain values pertaining to those virtues. Dewey [2] observed that moral training in school focused on discipline. He proposed that such training was pathological because it was not representative of social conditions and because it emphasized punishment rather than the formation of positive social habits. He stated that any system that resulted in the recognition of failure over the recognition of achievement was perverse. He classified "promptness, regularity, industry an response for others' rights as school duties not life duties" (p. 17).

Education and Experience

Dewey defined education as the continuous reconstruction of experience [1, 6], He defined three resources within the school that could be used for such instruction; the curriculum, methods of study, and the life of the school as a social institution.

Dewey recommended that studies be judged and adopted on the basis of their potential to enhance students' social consciousness, to train them to perceive social interests and enable them to use their abilities for social motives, He cited manual training as an example of study that would expedite the formation of socials habits. He also advocated the use of group work and self-government to enhance cooperation and promote leadership skills among students.

Education and Moral Development

Dewey [2] identified three levels in moral development through which the individual progressed summarized by Kohlberg [7] as follows:

1. The pre-conventional level of behavior "motivated by biological and social impulses with results for morals"
2. The conventional level of behaviors in which "the individual accepts with little critical reflection the standards of his group"
3. The post-conventional of behavior in which "conduct is guided by the individual thinking and judging for himself whether a purpose is good and does not accept the standard of his group without reflection (p. 670)"

Dewey felt that education's major task was to provide the appropriate catalyst to move children from one level to the next [1, 6]. He proposed that a moral life could be achieved only it the individual was able to perceive his socially-required goals and work toward their attainment. However, Dewey [2, 4] stressed that the significance of explicit moral instruction. Teaching about moral values was relatively minute and unimportant in comparison with implicit moral instruction which was the more critical of the two. Moral instruction entailed the development of character using all aspects of moral life.

Dewey's theory of moral development provided a basis for later empirical and theoretical work in this area, profoundly influencing the work of Lawrence Kohlberg and the fields of moral development and moral education.

Nicholas J. Balogh
University of Missouri, Columbia, MO, USA

Synonyms

Adderall/Adderall XR (mixture with other amphetamines); Dex; Dexamyl (mixture with amobarbital); Dextroamphetamine; Dextrostat; Scop-Dex (mixture with scopolamine); Speed; Vyvanse (prodrug of dextroamphetamine)

Definition

A psychostimulant utilized in the treatment of attention deficit-hyperactivity disorder (ADHD), chemically derived from amphetamine, which has been shown to reduce hyperkinetic or hyperactive behavior, and affect motor activity, vigilance, learning, and mood. Similar to Ritalin, Cylert, and other amphetamines, Dexedrine is a highly-controlled drug under various drug control laws (U.S. Schedule II, UK Class B, etc.).

Description

Introduced in 1937 by Smith, Kline, and French (SK&F), Dexedrine found wide acceptance among physicians in the treatment of ADHD (then diagnosed as "minimal brain dysfunction"), narcolepsy, depression, and ►obesity. A 1950 study of Dexedrine use [1] in children found that 50–60% of the drug's users had become more subdued and 20% showed increased behavior, 60–75% of students showed symptomatic improvement, 10–15% unfavorable responses, and 15–25% no apparent change [1].

In the 1950s, SK&F introduced an extended-release version of Dexedrine, called Dexedrine Spansule, available in 5, 10, and 15 mg dosages. Dexedrine Spansule is a coated capsule containing pellets of the active ingredient. Around the late 1950s, Dexamyl, a combination of Dexedrine and Amytal (amobarbital), a barbiturate tranquilizer, was introduced. In the 1990s, Adderall and Adderall XR, popular treatments for ADHD were introduced. Adderall contains roughly 75% dextroamphetamine and its isomers.

Dexedrine is the active metabolite of Vyvanse (lisdexamfetamine), a prodrug, or inactive drug which is metabolized in vivo into a substance which produces the desired effect with, some claim, less abuse liability through insufflation. Despite this hypothesis, it is similarly classified as a Schedule II drug by the DEA and was FDA-approved in 2008.

Studies in children generally indicate that, like methylphenidate (Ritalin SR-20) and the now-discontinued pemoline (Cylert), Dexedrine "had an effect within 2 h of ingestion, and the effects lasted for 9 h" [2]. In a 1980 study comparing Dexedrine's effects in normal men and normal and hyperactive boys, "both groups...showed decreased motor activity, increased vigilance, and improvement on a learning task after taking the stimulant drug. The men reported euphoria, while the boys reported only feeling "tired" or "different" after taking the stimulant. It is not clear whether this difference in effect on mood between adults and children is due to differing experience with drugs, ability to report affect, or a true pharmacologic age-related effect" [10].

Other uses – including off-label uses – for Dexedrine besides as treatment of ADHD include narcolepsy, palliative care to ease the pain of terminal cancer patients [3], as an appetite suppressant to lose weight [3], mixed with scopolamine to counteract "space sickness" in astronauts [4], and, around the 1960s, as an antidepressant, though, as tolerance to its mood enhancing effects became apparent, it lost efficacy for many patients and today is not commonly used as an antidepressant [3]. Modern use of Dexedrine for weight loss is discouraged and according to some doctors has "no place in the treatment of obesity" [8].

In 1995, the U.S. Army studied Dexedrine [5] for administration to combat aircraft pilots and determined it was effective in sustaining helicopter pilot performance during brief sleep loss, without adverse effects [5].

The specific mechanism of action Dexedrine has in the mind, as with other amphetamines and many pharmaceuticals, is unknown. "We really cannot fully explain, biochemically or physiologically, how the drug works in attention deficit disorder. There are many theories, but they are just that: theories," said Dr. Ron Kartzinel of

Dextroamphetamine (Dexedrine, Dextrostat). Fig. 1
A prescription of Dexedrine Spansules.

Ciba-Geigy, a pharmaceutical company which manufactures the drug [6].

Dexedrine is listed in FDA Pregnancy Category C, and its possible side effects include cardiovascular palpitations, tachycardia, blood pressure elevation, overstimulation, restlessness, dizziness, insomnia, euphoria, dyskinesia, dysphoria, tremor, headache, exacerbation of motor and phonic tics, Tourette's syndrome, dryness of the mouth, unpleasant taste, diarrhea, constipation, anorexia, weight loss, urticaria, impotence, and libido changes [7].

Nonetheless, according to the Associated Press, "most experts agree (stimulants including Dexedrine) are safe and effective" [6] and scientific studies indicate "behavioral improvement that was clearly distinguishable from placebo" [9].

Diabetes

Eva Benmeleh
Nova Southeastern University, Ft. Lauderdale, FL, USA

Synonyms

Diabetes mellitus; Juvenile diabetes mellitus; Type 1 diabetes; Type 2 diabetes

Definition

Diabetes is a chronic disorder of metabolism that causes the body to improperly use the energy or glucose it receives from food.

Type 1 Diabetes Mellitus is a disease in which the pancreas does not produce sufficient amounts of insulin.

Type 2 Diabetes Mellitus occurs when the body fails to respond appropriately to insulin.

Description

Diabetes is a chronic disorder of metabolism that causes the body to improperly use the energy or glucose it receives from food. It is caused by an inadequate production of insulin, which regulates the metabolism of carbohydrates.

Insulin is produced in the beta cells of the pancreatic islets of Langerhans. Damage to the beta cells results in lowered or a complete lack of production of insulin.

Type 1 Diabetes or insulin-dependent diabetes mellitus, is a common, chronic illness in childhood affecting 0.2% of school-age children under the age of 20 [6]. It is an autoimmune disorder where the immune system

attacks itself and destroys the beta cells. A lack of insulin results in high levels of blood glucose also referred to hyperglycemia. When glucose levels are elevated, the body begins to use fat from adipose tissue as its second line of energy. Rapid weight loss, constant hunger, polydipsia (thirst), polyuria (frequent urination), moodiness, and lethargy are common symptoms of ketoacidosis [5]. Many children are diagnosed from the occurrence of these symptoms.

Parents and children must be vigilant in the management of the disorder and can result in risk for hyperglycemia, hypoglycemia or Diabetic ketoacidosis. Hyperglycemia is high levels of glucose not compensated for by insulin. Hyperglycemia or high levels of blood glucose is extremely serious and suggests that too little insulin is present and that the diabetes is not under control. This may be caused by missing medications, insufficient insulin levels, and failure to adhere to a prescribed diet and exercise plan. Symptoms include excessive thirst and urination, headache and nausea. Very high, uncontrolled blood glucose levels can result in coma or death.

Hypoglycemia also referred to as insulin reaction or diabetic shock is described by low levels of blood glucose [1, 4]. It can result from inadequate levels of insulin, strenuous exercise or a missed or delayed meal. Symptoms include dizziness, weakness, impaired thinking, headache, and shakiness. Treatment includes giving the child some form of concentrated sugar.

Diabetic ketoacidosis occurs in response to an insufficient level of insulin. It can lead to coma or death if not treated or if treated improperly [1, 4]. Parents and children's roles regarding the management of Type 1 diabetes are universal across socioeconomic status (SES), ethnicity and gender and seem to become more prevalent when the child enters adolescence.

Historically considered an adult disorder, Type 2 Diabetes or non-insulin dependent diabetes mellitus, is increasingly diagnosed in children [2]. In Type 2 Diabetes, the cells of the body become resistant to insulin, not allowing the insulin to move into the cells in sufficient quantity. The reduced sensitivity to insulin is related to the high levels of insulin in the blood. If the deficiency is diagnosed at this time, the individual can take medication to improve insulin sensitivity or produce less glucose by changing diet, increasing exercise and taking medication. However, if the disease goes unnoticed, insulin replacement therapy is vital to the body's function [2]. Risk factors affecting the onset of Type 2 Diabetes are body mass index in overweight range, family members diagnosed with diabetes, lack of exercise, hypertension, elevated levels of LDL cholesterol, and ethnic background of African American, American Indian, Asian American, Pacific Islander, or Hispanic American/Latino [3].

Sedentary lifestyles and poor diets rich in high fats, cholesterol and carbohydrates are seen as major precursors to T2DM besides the aforementioned risk factors. In contrast, proper nutrition and regular cardiovascular exercise are two preventive factors for this disease [1].

Relevance to Childhood Development

Regardless of age of onset, children as well as their families are significantly impacted by Diabetes. Adjusting to and managing the disorder takes time and effort from the child, parents and other adults in their life. Management of the disorder may include frequent endocrinologist visits, new meal plans consisting of low-fat and/or low-carbohydrate diets, learning about glucose and insulin management, and constant supervision regarding their child's medical adherence, within the context of the typical developmental challenges of childhood. Adherence to Diabetes management is difficult in that the child must be injected with insulin two or more times a day in order to maintain adequate blood glucose levels. The child must learn to become aware of various food and meal planning to balance their blood glucose levels.

Failure to comply with medication, treatment, and lifestyle modifications can occur due to failure to understand the seriousness of the disorder. Ongoing management of the disorder is necessary to adequately control symptomatology. With appropriate monitoring and supervision, these children can lead typical lives.

Dialect

Judit Simo
Case Western Reserve University, Cleveland, Ohio, USA

Synonyms

Cant; Language variety; Patois; Vernacular

Definition

A variety of a language with its own rules, different from other varieties of the same language in terms of pronunciation, vocabulary, and structure.

Description

Dialects are considered regional and social varieties of a language, although in certain linguistic situations it is difficult to draw the line between language and dialect [5]. The most noticeable differences among dialects surface in pronunciation, grammar, and vocabulary. Regional dialects are characteristic of certain geographical areas. The boundaries of a regional dialect, which rely on the co-occurrence of several isoglosses, are often not easy to draw, especially since no person speaks exactly the same dialect [2]. Nevertheless, dialect regions are distinguished where several linguistic variables differ from one area to the next. Regional dialects differ in the extent to which they are likely to pass on features to or inherit them from other areas. This fluctuation also means that most often boundaries of regional dialects are not stable.

A social dialect, sometimes a called a sociolect, is characteristic of a social group. Membership in a social group is mainly determined by education, occupation, and income, although other factors like age, gender, religion, or ethnicity may also influence what social dialect a person speaks. Linguistically, all dialects are equal in that they all perfectly fulfill their function. Nevertheless, sometimes a certain variety of a language is considered more empowered than others because of its association with people who are considered successful economically, politically, and socially. Examples are Standard English, High German, Catillian Spanish, or Parisian French. It is not rare for some dialects to be stigmatized as nonstandard varieties spoken by a group of people who are inferior in some measure. Studies by Dennis Preston allow insights into attitudes of non-linguists towards certain dialects in the United States [3].

Dialects are usually studied through extensive fieldwork involving interviews and questionnaires and are usually called studies in language variation, belonging to the field of sociolinguistics. Initially, dialect studies concentrated on regional dialects, and within those, dialects of rural areas. Studies on social dialects are a later development and were partially motivated by methodological flaws in regional dialect studies [5]. Famous studies on social dialects are those conducted by Labov [1], set in New York, and Trudgill [4], exploring Norwich. As it is widely recognized that people are likely to speak different dialects throughout their lives as their circumstances change or in an attempt to adjust to different social situations by adopting different styles, these studies take into consideration not only the social status of the interviewees, but also the social situation. They achieve this by employing tasks with a wide range of their degree of formality from casual conversation to a more conscious, monitored speech.

Whereas the above mentioned studies mainly focus on pronunciation, variation in vocabulary may be more influenced by the related notions of register and jargon. Whereas jargon refers to the characteristic language of a certain occupational group, and is distinct first of all in terms of vocabulary, register characterizes either the vocabulary favored by members of a certain occupational group or the style adopted in a certain social situation. Finally, beyond all the factors mentioned above, a person's dialect also shows the marks of the speech communities to which s/he belongs.

Dialectal Thought

Dialectal thought is a method of argument central to eastern and western philosophy since ancient times. The word dialectic originates in ancient Greece and was popularized by Plateau's Socratic dialogues. Dialectic involves the practice of a dialogue between two or more people holding different ideas and desiring to persuade each other to shift to the idea of the other. A dialectical argument presupposes that participants, even if they do not agree, share at least some meanings and principles of inference. Different forms of dialectal thought have emerged in the east and west as well as during different eras of history. Major forms of dialectic reasoning are Socratic, Hindu, Buddhist, Medieval, Hegglin, Marxist and Talmudic.

Diathesis-stress Model

Anisa N. Goforth, Andy V. Pham, John S. Carlson
Michigan State University, East Lansing, MI, USA

Synonyms

Gene–environment interaction; Stress-diathesis model; Stress-vulnerability model

Definition

The diathesis-stress model describes a resulting interaction of genetic vulnerabilities and environmental stress on a person's physical and mental health.

Description

The diathesis-stress model describes how genetic or biological factors interact with environmental stress which results in a disorder or condition. Specifically, this theory purports that an individual's biological vulnerabilities, or predispositions, to particular psychological disorders can be triggered by stressful life events. If the individual is resilient or has low biological vulnerability for a particular disorder, it would take extremely high levels of stress to trigger symptoms of that disorder. On the other hand, if the individual has high biological vulnerability to the disorder, then it would take lower levels of stress for symptoms to be exhibited. Until this critical level of stress is reached, the individual will function normally, and the biological vulnerability would not manifest. Therefore, this model helps to explain why some, but not all, people exhibit psychological disorders, even though they may all experience similar environmental stressors. In addition, there is a reciprocal relationship between stress and the psychological disorder; life stress exacerbates the disorder, and in turn, the disorder makes life more stressful.

Examples of biological factors that are often considered with this model include the person's genetic makeup, cognitions, personality, family history of psychological disorders, brain abnormalities (e.g., birth complications, learning difficulties, traumatic brain injury), or neurological problems. Environmental stress, on the other hand, can be characterized as acute or chronic, which can include parental neglect or abuse, death of a family member or friend, relationship/marriage difficulties, or witnessing a traumatic event. One stressful life event is usually not enough to trigger a psychological disorder, but when negative events become more chronic, a vulnerable person may develop the disorder.

Relevance to Childhood Development

Though the diathesis-stress model has been frequently used in the research literature to describe anxiety, post-traumatic stress-disorder, and schizophrenia, there has been extensive research on this model in explaining symptoms of childhood and adolescent depression. Current research suggests that it is not genetics or environmental factors alone that contribute to the risk of depression. Rather, it is more likely that the genetic component along with stressful environmental factors leads to the higher likelihood of depression [2].

Biological risk factors for childhood depression include maternal depression, anxiety, coping ability, and low self-perception. In particular, the child's cognitive perceptions of a stressful event can be considered a biological risk factor as they affect how a child views

environmental stressors either positively or negatively. Such biological vulnerabilities may interact with chronic or acute environmental stressors. For example, a child may experience various stressors, including maltreatment [4], parent conflict [3], and/or lack of peer friendships or peer bullying [1, 5]. These environmental stressors may thus trigger biological vulnerabilities, which would lead to the child or adolescent to exhibit symptoms of depression. If two children are exposed to the same level of environmental stress, a child who is not biologically vulnerable to depression would be less likely to develop symptoms as compared to a child who is biologically vulnerable.

The diathesis-stress model has been utilized in the field of child development as a way to explain why an individual may have a predisposition to a particular disorder. The interaction between biological factors and environmental stressors varies significantly for each person, child or adult. This model also allows practitioners and researchers to understand the etiology of mental health disorders by considering the biological, psychological, and social domains of the individual.

Diazepam

Nicholas J. Balogh
University of Missouri, Columbia, MO, USA

Synonyms

Diastat; Valium; Valrelease; Zetran; 7-chloro-1, 3-dihydro-1-methyl-5-phenyl-2H-1, 4-benzodiazepin-2-one [1]

Definition

A benzodiazepine drug used to treat acute anxiety, induce sleep, and relax muscles. Valium (diazepam) was FDA approved in 1963 to treat anxiety disorders and skeletal muscle spasm, among other conditions. During the ensuing years, Valium was prescribed very liberally, and eventually there was a public backlash by patients who believed they had not been fully informed of the potentially addictive nature of the drug. Today it is available generically and remains a mainstay in hospitals and pharmacies worldwide.

Description

Valium was Leo Sternbach's second benzodiazepine invention at Roche. After Librium (*see CHLORDIAZEPOXIDE*), he "perfected" the molecule and came out with Valium.

Prior to Valium, tranquilizers such as the barbiturates and meprobamate consumed the market. Barbiturates were depicted, rightly, as addictive and easy to overdose on. The book (first published in 1966) and film (1967) *Valley of the Dolls* was a roman á clef that detailed young women's addiction to barbiturates ("dolls") both entered into the public lexicon.

Between 1969 and 1982, no other prescription drug was more popular in America [2]. As written in *The New Yorker:* "Part of Valium's appeal was that, unless it was mixed with other things, Elvis style, it was non-toxic, as Robert McFarlane, Reagan's national-security adviser, discovered during the Iran-Contra scandal, when he attempted to kill himself by downing a couple of dozen Valiums; he recovered several days later, embarrassed but well rested" (ibid. 2).

By 1974, the *New England Journal of Medicine* reported that 15% of American adults between the ages of 18 and 74 have used the drug in a 1-year time period [3], though former FDA officials reassured the public, saying U.S. physicians were "relatively cautious in their prescription of such drugs," [3]. "Relative safety," read a 1974 *New York Times* article, "is cited as chief factor in its huge sales" [3].

However, a backlash was brewing. Although Valium was a novel drug, invented by "an innovator's innovator" [2], and less deadly in overdose than previous tranquilizers, it was not without its problems. With liberal and sometimes careless prescription of Valium by doctors for the most minor ailments, some patients soon discovered that their Valium habit was excruciatingly difficult to kick.

Senate hearings in September 1979 revealed "heavy Valium promotional efforts sometimes targeted at people experiencing such everyday anxieties as 'marital discord and financial tensions'" [4]. An anonymous professional

in Washington said she uses the drug "about once a month. If you break up with a boyfriend, for instance, it's required. It's like oxygen" [7].

Media coverage heightened, exaggerating Valium's risks, but perhaps only to the extent that some doctors and ads underplayed them. "Valium Abuse: The Yellow Peril" [5], "The Uppers and Downers of Middle-Class Prescription-Drug Addicts" [6], and "America's Psychic Aspirin; Valium: Problems with America's 'Perfect' Drug" [7] were some of the sensational titles that led tales of Valium withdrawal being worse than street drugs and the like.

The tone of the media exposés arguably led to negative opinions about Valium and other tranquilizers. A 1980 University of Massachusetts study reported that:

- Seventy percent believe "tranquilizers don't really cure anything; they just cover up the real trouble."
- Eighty-seven percent believe "it is better to use willpower to solve problems than it is to use tranquilizers."
- Eighty percent believe "long-term use of tranquilizers can cause physical harm" [8].

The study also found that "the less education a person has, the more a person believes that 'taking tranquilizers is a sign of weakness'" (ibid. 8).

Later in 1980, "in a striking trend that is a source of growing comfort to many public health experts, American doctors are sharply cutting down their prescriptions for a broad array of sedatives, tranquilizers, painkillers and other psychoactive drugs," [9].

Throughout the 1980s tranquilizers like Valium were still scorned in public, but remain useful in patients with anxiety that interferes with their lives, not "everyday troubles." But, come late 1988, Prozac's introduction took America's short pharmaceutical attention span away from Valium and the benzodiazepines, and onto the new generation of antidepressants: selective serotonin reuptake inhibitors (SSRIs).

Valium is a drug with a well-publicized history of addiction and abuse, but reading all of these headline-grabbing case studies can make one forget the unparalleled usefulness of benzodiazepines in anxiety disorders. When used with moderation and under professional supervision, in clinical cases of anxiety, Valium can alleviate crippling fear and greatly increase a person's mental well-being.

Diencephalon

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Definition

The Diencephalon is a division of the brain that is located just above the brainstem and includes the Thalamus, Hypothalamus, and Epithalamus, which together influence the regulation of motivated behaviors, internal states, and sensory input.

Description

The Diencephalon constitutes the inferior portion of the brain that includes the Thalamus, Hypothalamus, and Epithalamus. It is located at the head of the brainstem connecting the Cerebral cortex with the lower structures of the brainstem [6]. The Diencephalon, in combination with the Cerebral cortex, Limbic System, and Basal Ganglia constitutes the Forebrain which is the highest functional level of the brain. Functionally, the Diencephalon plays a role in the general regulation of water, body temperature, sleep, food intake, development of secondary sex characteristics, autonomic responses, and endocrine activity [5]. In addition, the Diencephalon is involved in the relay of visual, auditory, and tactile information, as well as a relay station between the cortex and the cerebellum and basal ganglia [5]. As a whole, it may be said that the Diencephalon energizes and sustains behavior [4]. Specifically, structures in this region are centrally involved in motivation, emotion, and the ANS, and in states of awareness, yet the individual structures of the Diencephalon (i.e., Thalamus, Hypothalamus, and Epithalamus)

play different roles in the modulation of these various functions [1].

First, the Thalamus serves a primary relay station for sensory information, aside from olfaction, as well as motor information [3]. While all sensory information, except olfaction, is transmitted through the Thalamus, different nuclei process different forms if sensation. For example, the Lateral Geniculate nucleus receives visual projections whereas the Medial Geniculate nucleus receives auditory projections. Additional nuclei receive projections for touch, pressure, pain, and temperature projections from the body [4]. Motor information is relayed via the ventrolateral as well as other nuclei [2]. In addition to differing in the nature of sensory and motor information in which they process, some nuclei relay information between cortical areas while others relay information from other forebrain and brainstem regions [4]. Aside from the processing of sensory information, the Thalamus also has a critical role in wakefulness through its connection with the RAS and other activating systems [3]. See Chapter Thalamus for more details.

The second structure of the Diencephalon is the Hypothalamus. Functionally, the Hypothalamus' primary influence is its control of the Autonomic Nervous System and its connections with the Pituitary gland that mediate the neural control of the endocrine system [3]. While this reflects a narrow view of the influence the Hypothalamus exerts, broadly, it takes part in nearly all aspects of motivated behavior, including feeding, sexual behavior, sleeping, temperature regulation, emotional behavior, endocrine function, and movement [4].

The final structure of the Diencephalon is the Epithalamus. While the functionality of the Thalamus and Hypothalamus have been well studied, much less is known about the Epithalamus. However, the Pineal body, which is one structure of the Epithalamus, is known to play a role in the regulation of seasonal rhythms [4]. As a result of this tie, the Epithalamus, and more specifically the Pineal body, has been linked to seasonal affective disorder in which individuals experience disturbances of mood and emotionality in relationship to the changing weather and season. For example, in the winter, when there is less daylight, individuals with seasonal affective disorder will experience increases in depressive symptomatology.

Disability

Maria Assunta Cuffaro
State University of NY: Potsdam, Potsdam, NY, USA

Synonyms

Special needs

Definition

Specific categories of exceptionality prescribed by the federal law. A person with a disability is defined as (1) having a physical or mental impairment that limits significantly them in a significant life activity (2) experienced discrimination as a result of physical or mental impairment [1].

Description

Learning disability: have dysfunctions in processing information typically found in language-based activities. They have average or above-average intelligence, but they often encounter significant problems learning how to read, write, and compute. They also may have difficulty following directions, attending to tasks, organizing assignments and managing time. There are several disabilities listed under the Federal Law they include:

Speech or language impairment: extraordinary difficulties in communicating with others for reasons other than maturation, a speech or language impairment is involved. Students with this disability have difficulty with articulating the pronunciation of speech sounds; they may omit words or mispronounce words.

Mental retardation: limitations in intellectual ability and adaptive behaviors. They learn at a slower pace than do other students, and they may reach a point at which their learning levels off.

Emotional disturbance: significant difficulty in the social-emotional domain- enough to interfere with the students' learning-an eating disorder (ED). Difficulty with interpersonal relationships.

Autism: lack social responsiveness from a very early age. Avoid physical contact and do not make eye contact. May display repetitive body movements.

Hearing impairments: the inability or limited ability to receive auditory signals called hearing impairments when students are hard of hearing; they have significant hearing loss but can capitalize on residual hearing and do not benefit from tradition devices such as aids for hearing. They use sign language, speech reading and other ways to help them communicate.

Visual impairments: inability or limited ability to receive information. Some have partial sight and can learn well using magnification devices or other adaptive materials; students who are blind do not use vision as a means of learning and rely on touch and hearing.

Deaf-blindness: significant vision and hearing impairments because of their learning needs in the area of communication and they require highly specialized services.

Orthopedic impairment: physical conditions that impair their ability to move about or to complete motor activities.

Traumatic brain injury: wide range of characteristics of special needs, limited strength or alertness due to developmental delays, short-term memory problems, hearing or vision loss.

Other health impairments: someone who has a disease or disorder so significant it affects their ability to learn in school; the category of disability addressing these needs is called other health impairment.

Multiple disabilities: someone has two or more disabilities. They often have mental retardation and a physical disability.

Developmental delays: someone who has significant delays in physical, cognitive, communication, social-emotional, or adaptive development [2].

Discipline

Elizabeth Levin
Laurentian University, Sudbury, ON, Canada

Synonyms

Baumrind's parenting styles; Control; Instruction; Parenting styles; Punishment

Definition

The word discipline is derived from the Latin *disciplina* which means instruction. This word is itself derived from *discere* which means to learn and from which *discipulus* or pupil arises. Discipline, in the field of child development thus refers to instructing a child in the correct ways of behavior including moral behavior.

Description

The goal of discipline is to serve as a guide to acceptable behavior and discipline aims to teach the child self-control and to act responsibly. Discipline aims to make a child capable of behaving appropriately even when the parent or adult is not there to provide guidance [4]. The most important component of good discipline is to praise the child and reward the child's good behaviors rather than focusing on the misdeeds. Psychology has shown that rewards reinforce the rewarded behavior; that is, the behavior is displayed more often in order to continue getting the rewards and good behavior is the goal of discipline [1]. Discipline aims to teach self-control, to respect the rights of others, to act responsibly and to enjoy freedom within limits. When children are behaving well, they should be praised. They do not want to only hear criticism. A parent should aim to catch the child being good, not bad and then reward this behavior.

Parents seeking advice on how best to discipline will encounter a wide range of ideas ranging from very liberal to very strict approaches. These approaches may have their origins in psychology, sociology, anthropology or religious views. Parents frequently rely on their memories of their own child-rearing experiences as guides.

Effective discipline has a number of characteristics [1, 4]. First the parent or authority figure has to determine which behaviors are important. This is the most important first step because these are the behaviors for which there will be expectations for good behavior. These are the behaviors that will have demands or rules attached to them and for which compliance will be expected. As part of this first step, it is important to set the limits and establish the specific guidelines for what is and is not acceptable behavior. It is important for the authority figure to determine exactly what is acceptable because if the adult does not know what is expected, the child cannot know this either. In determining the expectations, it is important to make sure they are reasonable for the developmental level of the child. For example, a 10 year-old can be expected to eat with a fork and use a knife but a 4 year-old cannot. Similarly a 6 year-old can be expected to put socks and underwear in a drawer but not iron a shirt. It is important to recognize that a child will test the rules to see if they are in effect so if rule setting is new in the home, some resistance should be expected when the rules are first introduced [1].

Other components of effective discipline include the following strategies. (1) Offer choices whenever possible. Choices not only help teach responsible decision-making, they allow the child to have a say. For example one can allow a choice between two suitable outfits that the parent finds acceptable rather insisting that the child wear a particular one. It is better to save parental authority for more important decisions. (2) If the misbehavior is trivial it may be better to ignore it. Paying attention to minor infractions may inadvertently reward or reinforce the misbehavior because the parental attention is itself rewarding. In these cases it is better to teach alternatives to misbehavior by being clear about what behavior is preferred. (3) Parents need to be careful not to nag nor discipline by mood. This means that it is hard for a child to figure out what is acceptable behavior if something that was permitted a week ago is not permitted now because the parent is tired, cranky, etc. And like everyone else children tune out nagging, whining voices. A parent needs a child to listen especially when it is important so a child needs to know that when a parent says something that the parent means it, and that no nagging is necessary. (4) This then means that there should be no empty threats, and parenting must be consistent; if the parent says there will be a consequence there must be a consequence, but the consequence should fit the crime. Natural or logical consequences can mean having cold hands if the child refuses to wear the mittens provided. Turning off the television when children cannot agree on the program to watch is another logical consequence. Informing a child that she cannot attend a birthday party in 2 weeks time because she would not eat her vegetables is not a logical consequence and due to the time delay, not only will the child be unable to relate the punishment to the misbehavior, there is a high likelihood this will end up as an idle threat. (5) Time-out is a popular technique that allows a child to calm down and regain self-control. The purpose of

time-out is not to punish the child for misbehaving, but to allow the child to regain the ability to continue participating in the activity. Model the kinds of behavior you expect. Do as you want your child to do. Your child wants to model you so set the right example.

Discipline is not the same as punishment [2, 3]. While discipline should guide a child to appropriate behavior, punishment deals with unacceptable behavior. Punishment involves external control of behavior while discipline or self-regulation comes from within [5]. The goal of discipline is to prevent misbehavior from occurring in the first place. The goal of punishment is to hurt the child after misbehavior has occurred. Punishment means presenting an aversive stimulus to reduce the frequency of a behavior like yelling at a child to stop her from throwing food. This is the opposite of reward, where a positive stimulus such as praise is used to increase the frequency of the desirable behavior. Punishment also refers to removing a positive stimulus like presenting a fine or docking an allowance to punish a misdeed and prevent it from happening again. Punishment, for example, spanking is not highly effective in the long term although it may work in the short term [2–4]. So punishment may lead to immediate compliance but not change the child's behavior in the long term. Punishment teaches that the biggest or most powerful person can inflict harm. Children may try to become devious to avoid punishment, but they still misbehave. They may for example avoid swearing in the presence of the punisher but they still swear. They may lie about their misdeeds. Consider that many adults still speed and only slow down in the presence of the police.

The most controversial approach to discipline involves physical punishment typically in the form of spanking. Spanking is illegal in many jurisdictions however parents and others continue to spank their children. The research evidence strongly suggests that spanking or corporal punishment is not the most effective technique [2–4]. While it may lead to obedience in the short term it fails to guide behavior in the long term. Frequent and severe physical punishment is always ineffective; there is less agreement that occasional mild spanking in the context of a loving parent-child relationship has long term negative consequences. However physical punishment can quickly escalate so that what started out as a small slap may become abusive and thus there are better alternatives to be used.

Relevance to Childhood Development

One of the primary goals of parenting is to teach children how to behave or to discipline the child. Most children can be expected to misbehave from time to time. It is not unusual for a child to lie, steal or fight or cheat. What is more significant in the long run is how long the behaviors persist and how they are handled. Everyday a child has to make choices between right and wrong and it is inevitable that sometimes the child will choose the wrong choice. Setting limits when children are young teaches children to acquire self-discipline which permits children greater self-direction in later life.

Discrimination Learning

Kimberley Zonneveld[1], Ivy Chong[2]
[1]University of Kansas, Lawrence, KS, USA
[2]Florida Institute of Technology, Melbourne, FL, USA

Synonyms

Conditional discrimination; Discriminate; Discrimination; Stimulus control; Stimulus discrimination

Definition

The process by which animal or human organisms learn to differentially respond to various antecedent stimuli.

Description

Discrimination learning occurs when an organism engages in a particular behavior in the presence of a specific stimulus (also referred to as a discriminative stimulus) but not in the presence of another stimulus (also referred to as stimulus delta). The process of reinforcing a specific behavior in the presence of one stimulus and not any other is referred to as *discrimination training* [1].

Discrimination training refers to reinforcing a specific response in the presence of a particular antecedent stimulus and not in the presence of any other stimulus. When the training procedure is consistently applied, the organism will respond in the presence of the discriminative stimulus, but not the stimulus delta. That is, the organism is less likely to emit the response in the absence of the stimulus in which the response was reinforced. In other words, the antecedent discriminative stimulus comes to evoke the reinforced response more readily in its presence upon future presentations of the stimulus. The momentary increase in the frequency of the reinforced response lasts only as long as the stimulus is present. Thus, the behavior is less likely to occur when a different stimulus or stimuli are present.

A common example used is that of the rat in the operant chamber: Upon the presentation of a light, key-pressing behavior is reinforced with a pellet of food. In the absence of the light, key pressing behavior is not reinforced (e.g., food is not delivered). Over time, the rat begins to press the key *only* in the presence of the light and not in its' absence.

Yet another example might be that of a young child learning to label the letters of the alphabet. For instance, to teach a child to identify letters, the teacher might use the letter "A" as the discriminative stimulus condition and any of the other 25 letters as the stimulus delta condition. Flashcards or any other teaching materials displaying letters from the alphabet could be presented to the student. The vocal response "A" from the student when the teacher holds up the flashcard displaying the letter A would be reinforced (e.g., the teacher might praise the child). However, the vocal response "A" to any other letter would not be reinforced (and might actually be punished by a verbal reprimand such as "no that is not right"). Similarly, only correct vocal responses corresponding to the letter presented would be reinforced for the remainder of the letters of the alphabet (e.g., vocal response "B" to the presentation of the letter). Over time, the student begins to respond "A" in the presence of the letter A and not in the presence of any other letter.

Relevance to Childhood Development

Discrimination learning is essential in childhood development. Understanding the process by which young children learn to discriminate stimuli in the environment can help parents and professionals to develop educational goals when the student is having difficulty acquiring concepts. Although the previous description has been a simplified explanation of the discrimination learning process, it begins only begins to demonstrate the process of concept formation [2].

Disengaged Parenting Style

▶ Indifferent Parenting Style

Dishabituation

Brady I. Phelps
South Dakota State University, Brookings, SD, USA

Definition

Any unconditioned response that is elicited in response to an unconditioned stimulus will show habituation if the stimulus is repeated. That is, measures of the response will show orderly decreases in magnitude as the stimulus is repeatedly applied. Dishabituation refers to the fast recovery of a response that has undergone habituation, typically as a result of the presentation of a novel, strong or sometimes noxious stimulus; dishabituation cannot be divorced from habituation and any description of dishabituation has to be framed within a context of also discussing habituation. Both habituation and dishabituation are observed in the withdrawal responses of invertebrates to tactile stimulation, in the defensive responses of rodents to auditory stimuli, and in the orienting responses of human infants to complex auditory and or visual stimuli, and are some of

the most fundamental properties of behavior [3, 9, 10]. More simply put, habituation is process in which a stimulus loses novelty and decreases in responsiveness to the stimulus are seen when the stimulus is presented repeatedly or for an extended time period. An organism ceases to engage in attending or other responses to the stimulus; the stimulus comes to be ignored. Dishabituation tells us the organism can "tell the difference" between differing stimulus events; one stimulus has become familiar and is no longer responded to, the novel stimulus still elicits a response due to its novel properties. The recovery of the habituated response in dishabituation, which is separate and distinct from spontaneous recovery, is argued to involve either the removal of habituation's effects, the development of sensitization or both [4].

One of the most apparent trends in recent psychology has been the attempt to redefine basic behavioral processes in terms of un-necessarily complex "cognitive processes"; as a result, habituation and dishabituation used to be considered "non-associative learning," since only one stimulus-event was involved but has been termed "implicit learning" by some writers [11].

What Are Some of the Properties of Habituation and Dishabituation?

The formal study of these processes goes back nearly a century being described by writers in the early twentieth century, with the basic properties being outlined in the 1930s and again in the 1960s and 1970s. Some nine basic features were formally outlined and have come to serve as a formal definition of habituation and its corollary process dishabituation [12]:

1. If a specific stimulus elicits a response, repeated presentations of that stimulus result in decreased response or habituation; the decrease is typically an orderly function of the number of stimulus presentations.
2. If the stimulus is subsequently withheld, the response showing habituation will tend to return or recover with the passage of time, termed spontaneous recovery.
3. If the habituation experience and subsequent opportunity for recovery are repeated in a series, then habituation will progress more rapidly.
4. With all other variables held constant, the higher the frequency of stimulation, the more rapid and pronounced is habituation.
5. With weaker stimulation, habituation will progress more rapidly and be more pronounced.
6. The effects of habituation training may progress below baseline measures of the response.
7. If habituation occurs to a specific stimulus, then habituation to similar stimuli via stimulus generalization also occurs.
8. Presentation of an irrelevant stimulus will result in the recovery of the habituated response, termed dishabituation.
9. With repeated presentation of the dishabituating stimulus of #8, the degree of resultant dishabituation is decreased or shows habituation itself.

A modified list of defining features was put forth with the following additional defining characteristics [7]:

1. The process of habituation will be disrupted by any unpredictable changes in the eliciting stimulus.
2. Habituation will occur more slowly to stimuli that are presented in a varying manner relative to stimuli presented in a constant, unchanging manner.
3. Spontaneous recovery may occur faster after more rapid rates of stimulus presentation relative to slower rates of stimulus presentation.
4. Spontaneous recovery may be incomplete recovery in that some habituation will persist over a long-time period.
5. Habituation will be observed for most if not all animal species; habituation occurs in response to most stimuli, including events without ingestive consequences such as lights and noises. The rate at which habituation will be observed will differ as a function of the species, the stimuli employed, the responses being measured as well as the individual subject.

As defining features, any behavioral stimulus–response contingency is said to display habituation if the response decrement shows these properties.

How Are Habituation and Dishabituation Studied with Human Infants and Children?

In general, studies of human infant habituation and dishabituation will employ variations of some basic themes [3]. In measuring the rate of a reflex such as the sucking reflex, researchers will measure the initial baseline rate of sucking to a pacifier equipped with transducers to measure muscle contractions applied to it. Then an auditory stimulus will be presented such as a human voice uttering a speech phoneme such as "pa." In response to a novel stimulus such as this, the rate of sucking will predictably increase but come to decline to baseline levels as "pa" is repeatedly presented, showing habituation. If the phoneme "ka" were to then be presented, the rate of sucking would again increase, demonstrating

dishabituation that the infant can discriminate between these two stimuli.

To measure more complex responses, slightly different procedures are used. When an intense or novel stimulus is presented, an orienting response is elicited and an infant (or any person) turns to look and fix their gaze at the source of a visual stimulus or turns their head towards the source of an auditory stimulus, as well as show changes in heart rate, EEG patterns and other autonomic responses. Initially, infants will show this orienting (or orientation) response to a stimulus but after repeated trials of stimulus presentations, infants will no longer respond to the stimulus, showing habituation of the orienting response. The subsequent presentation of an extraneous visual stimulus would predictably re-elicit the orienting response, again illustrating dishabituation [5]. Researchers in human development have used measures of the orienting response as assessment tools of complex human development, which will be described in the next section.

The Role of Habituation–Dishabituation in Human Development and Learning

Habituation–dishabituation procedures have increasingly been employed to assess the covert-behavioral abilities of preverbal infants to study the development of perception, remembering, and what is termed "information processing" as part of basic developmental research [5]. In addition, the performance of infants on habituation–dishabituation tasks has been shown to be a reliable and independent predictor of long-term development. Indices of the speed or efficiency with which infants show habituation and dishabituation have been shown to predict outcomes in behaviors such as language acquisition as well as more general behavioral outcomes such as verbal and non-verbal intelligence. Infants who show difficulty during habituation or habituation at slower than normal rates or a failure of dishabituation have been found to be at increased risk for a range of significant developmental delays. Populations of infants with Down syndrome, teratogen-exposed infants, malnourished infants and premature infants have been studied. Some researchers have found that at an age of 16 months, high-risk infants show rates of habituation comparable to newborn infants. Full-term infants have been shown to have more favorable measures of habituation indices than did preterm infants (birth weight $< 1{,}750$ g) at 5, 7 and 12 months. Despite its widespread use, some writers have argued that the precise psychometric parameters of habituation–dishabituation need to be established before any definitive and significant dialogue on the predictive value of habituation and dishabituation can be conducted. Some such studies have also been criticized for using highly artificial events as stimuli, such as an artificial voice box, instead of a stimulus with higher ecological validity, recordings of actual human utterances as auditory stimuli [1, 2].

In spite of cross-study comparisons being obfuscated by procedural differences as well as in the response being measured and that normally-developing infants show a range of individual variations in habituation, acceptable measures of test–retest reliability have been obtained for some measures of habituation and dishabituation. Unfortunately, few such data exist for populations of high-risk infants, among whom the pertinent data would be of greater interest [8].

Why and How Do These Behavioral Processes Occur?

The observation that habituation and dishabituation are so ubiquitous points to an obvious and basic adaptive-significance [3]. Constantly responding to meaningless stimuli would be taxing and wasteful to any organism; learning to not respond to biologically-irrelevant events while still responding to events that are biologically-significant-novel has clear survival value. The genome equips every organism with innate responses but natural selection has favored those individuals with flexibility in even the most "hard-wired" responses such as reflexes. Thus, the tendency to habituate to the familiar while still showing dishabituation to the unfamiliar has been selected for and is now a basic property of behavior [10].

As stated briefly above, dishabituation has been argued as involving either the removal of habituation's effects, the development of sensitization or both, depending upon the source consulted. For some stimulus–response contingencies that show habituation, the physiological mechanisms have been identified and while habituation has 9 (or 14) [7, 12] defining features, only one established physiological process has been elucidated for habituation. In studies of simple reflexes of invertebrates, such as a defensive-withdrawal reflex to tactile stimulation, the organism ceases to respond as the repeated stimulation causes a sensory neuron receptor to no longer release the necessary neurotransmitter to an effector motor neuron for the response to occur. The sensory neuron (presumably) will continue to release its neurotransmitter in response to a different stimulus as the basis for dishabituation; as a result, the reflex will still occur to a different stimulus but not to the stimulus to which habituation has occurred [3, 6]. That is, the observed change in responsiveness will be stimulus specific but show stimulus generalization to physically similar stimuli [12].

In terms of identifying the biological bases of habituation and dishabituation in vertebrates, less progress has been made but research so far points to similar neural events taking place in distinct lower brain areas depending upon the sensory modality of the stimulus and the nature of the response undergoing habituation and subsequent dishabituation. Little if any research has been conducted into the biological basis of habituation in humans but the infrahuman models of habituation are considered more or less applicable [3, 6].

Dishonesty

Victoria Talwar
McGill University, Montreal, QC, Canada

Synonyms

Corruption; Deception; Duplicity; Fraudulence; Lying; Untruthful

Definition

Dishonesty is an act without honesty; to cheat, lie or be deliberately deceptive; lacking in integrity; to be corrupt or treacherous.

Description

Dishonesty is usually viewed as a moral infraction and socially reviled behavior [2]. Yet is a behavior that we all engage in from time to time. Dishonesty such as lie-telling is a common feature of day-to-day social interactions [6]. Dishonesty incorporates a range of behaviors including lying, cheating, and other acts of deception. These can range from the innocuous (e.g., "white lies") to the very serious (e.g., fraud).

Overall, we generally perceive dishonesty as being bad and give negative evaluations of individuals who are dishonest [12]. Nevertheless, depending on the context perceptions of dishonesty fall along a continuum, while many dishonest acts are self-centered, carried out to protect oneself from harm or for personal gain, they also sometimes benefit others, such as telling a lie to be polite or trying to protect another from harm. While the former is considered socially and morally unacceptable, when the intention behind the act is prosocial in nature these acts are considered more socially acceptable. Our evaluations of dishonest behaviors are influenced by our judgments of the cost or harm to others and the intentions behind the behavior. For instance, cheating on test is judged harshly by society, while a lie to a colleague about their ugly outfit told to avoid hurting their feelings is judged less harshly. Thus, dishonest acts can be deemed antisocial in some situations, and occasionally prosocial in others.

However, it is when this behavior is chronic or of a serious nature that dishonesty becomes of particular concern. Indeed, the occasional dishonest act can be of material or psychological benefit to the individual if they are not caught. The costs associated with dishonesty generally come when one is unsuccessful in the deception, usually resulting from the hidden information or transgression being discovered, and these costs can be high. Besides the potential legal or professional consequences in some cases, there is also the social cost of losing credibility. That is, one whose opinion was valued and was frequently sought may no longer be consulted once it is revealed that the individual never offered an honest opinion. Similarly, one who lies frequently to get out of trouble may not be believed when denying later wrongdoing. Thus, lie-telling of any type can lose its strategic social advantages, once the lie teller loses credibility. Just as the story of the "Boy who cried Wolf" tells us, if one is often caught in a lie than eventually we are no longer believed and are considered

untrustworthy. Honesty is a cornerstone of our communication. This is one of the most fundamental conventions governing interpersonal communication – the Maxim of Quality [8]. This maxim states that one should be truthful and inform, not misinform, communicative partners. Telling a lie is a major violation of this cardinal rule of communication and getting caught in that lie could result in a loss of trust and a negative image of the liar. This could jeopardize social relationships, create an image of the liar as someone who lacks integrity or credibility, and lead to social isolation, thus further perpetuating an individual's anti-social behaviors.

Relevance to Childhood Development

Amongst children, dishonesty is also a frequent behavior. Studies with children have found similar ratings of honesty to those of adults. Children understand the importance of honesty although younger children tend toward moral absolutism, rating all dishonesty very negatively. But with age, older children and adolescents begin to gradually take into consideration the social context and the intention of the perpetrator when evaluating dishonesty [4, 9].

Developmental research specifically on children's dishonest verbal statements has found that children begin telling lies in the preschool years, with some lies appearing as early as 2 years of age. For instance, in one study 74% of children between 3 and 7 years of age lied about a transgression they had committed [15]. The earliest lies children tell are those that allow them to escape imminent punishment. Children will also be dishonest to obtain a reward. This may first be motivated by a desire for material benefits (e.g., stealing a cookie from a forbidden cookie jar), and later by a desire for social rewards (e.g., self-presentation lies).

Research has found children's lie-telling and their ability to tell a plausible, believable lie is related to children's abilities to understand the mental states of others and executive functioning [14, 16]. Lying requires the ability to instill a false belief in another and to tactically adapt one's communication to take into account the listener's beliefs and knowledge in order to tell a plausible lie. It also requires one to remember the content of the lie to maintain congruency in all subsequent statements as well as inhibit any behavioral response that may reveal the information being concealed. Thus, to be dishonest and to do it successfully (i.e., not to be caught) requires some degree of cognitive complexity. While preschoolers start to tell lies, their lies are easier to detect and they are less sophisticated in their ability to maintain their lies. For instance, a 4-year-old who has stolen a cookie from a cookie jar may fail to conceal the evidence of crumbs on their shirt or explain why the chair has been moved up to the counter. However, as children increase in age, they become more adept at maintaining their lies and giving plausible explanations. As in the previous example, an 8-year-old may try to conceal the evidence such as wiping away the crumbs and putting the chair back or if caught try to give a plausible story such as they were moving the chair to reach the sink in order to wash their hands. Thus, the initial emergence of dishonest behavior like lying may related to children's growing cognitive sophistication.

Children's dishonest behaviors may change over time. While preschool children's dishonest behaviors may be related to negotiation of game rules and play, property rights of toys, and concealment of transgressions such as rule violations, as children become older their dishonesty can include behaviors for personal gain such as cheating on a test or assignments. Estimates of academic dishonesty suggest that as many as 50–70% of students engage in academic dishonesty at least once. However, the prevalence of dishonesty in academic setting increases with age as the benefits of dishonesty and pressures to succeed increase. Academic dishonesty is of greatest concern in high school and post-secondary where it is most prevalent. While only a small percentage of children cheat in the elementary school, this increases to as much as 70% in high school. Children's motivation may be affected by whether they expect negative consequences for being dishonest versus positive consequences for being honest. According to Bandura's social cognitive theory of moral action, children go through a process of socialization as they begin to internalize moral standards held by their parents and society [1]. Younger children will be most affected by external physical factors (i.e., punishments), older children who have not yet internalized the moral standards will be most affected by external social factors (pleasing another person), and finally older children and adolescents who have internalized the moral standards will be most affected by internal social factors (pleasing oneself by doing the "right" thing).

While the average individual engages in occasional dishonest behaviors (e.g., "white lies") from time to time, some acts of dishonesty fall within the realm of criminal behavior. Such malingering can lead to involvement with the law and can be associated with antisocial behavior. For instance, lying has been found to be related to truancy, aggression, and delinquency [7]. When ranking children's problem behaviors in terms of seriousness, teachers, clinicians, and parents place dishonesty at the top of their lists [13]. Frequent dishonesty may be a secondary behavior used to cover up other antisocial acts. Children who exhibit behaviors such as delinquency

and aggression often focus on short term benefits and immediate gratification which may lead these children to be more likely to commit transgressions which they later attempt to conceal through deception.

Socialization factors may affect whether children will engage in more or less dishonest behaviors. Dishonesty is generally regarded as a negative behavior and is discouraged in children. For this reason, parents directly socialize children about the inappropriateness of such behaviors. For instance, paternal warmth and authoritarian parenting may increase honesty [3]. It has also been suggested that exposure to a harsh disciplinary style, maternal rejection or parental stress may be related to the development of deception [5]. Besides parenting influence, children may also be influenced by their peers and the social consequences of being perceived as dishonest. Peer pressure may influence some children to engage in dishonest acts as they try to follow the norms of their peer group [11]. In fact, one the most influential factors in a child's decision to cheat is the perception of peers' academic honesty [10]. However, peers may also encourage children to be honest. Thus, a child who frequently lies and is perceived as being dishonest may suffer grave consequences in their social relations and their perceived trustworthiness. For instance, children's trustworthiness has been found to be related to their school adjustment and to the number of friends they have. Similarly, a child who believes that their peers disapprove of cheating is less likely to cheat.

Disorganized/Disoriented Attachment

Tasha R. Howe
Humboldt State University, Arcata, CA, USA

Synonyms

Attachment disorder; Insecure attachment; Reactive attachment disorder

Definition

Disorganized/Disoriented attachment is characterized in Ainsworth's "strange situation" task as a child who exhibits behavioral disorganization or disorientation in the form of wandering, confused expressions, freezing, undirected movements, or contradictory (i.e. "unorganized") patterns of interaction with a caregiver. Most of these children have histories of maltreatment and may exhibit fear of the caregiver.

Description

In Mary Ainsworth's original work on attachment classifications [1] three categories of infant–parent attachment were elucidated. The majority of children were securely attached and showed appropriate distress upon separation from mother, willingness to explore in mother's presence, and fear of strangers. Mothers of securely attached infants can readily soothe a distressed child and children feel comfortable exploring new environments while in their mothers' presence. The other two categories represented insecure relationships, with appeared to be avoidant in nature, or ambivalent, alternating between approach and avoidance during laboratory observations of the "strange situation" (a series of manipulated separations and reunions).

Mary Main and Judith Solomon [2] noticed that a fourth category could be reliably coded during strange situation procedures. They noted that a small minority of children (about 5%) could not be placed into the original three attachment categories and often appeared to dissociate or show stereotyped movements in the presence of the caregiver. Many of these children appeared afraid of the mother, wandered away from her, showed variable affect, often avoiding the mother and then approaching her with intense desire for interaction. These children show no "organized" pattern of relationship with their caregiver and often appear disoriented during laboratory observations. While any type of family can develop a disorganized/disoriented attachment style, most work finds that parents of disorganized children are abusive or neglectful, and exhibit frightening or unpredictable behavior toward their infants. Moreover, these parents often have histories of past trauma and unresolved attachment problems in their own childhoods [3].

Because insecure attachments are related to poor child outcomes including emotional, cognitive, and behavioral dysfunctions, recent research is attempting to prevent attachment problems through parent education and training programs [4] and through brief interventions such as video feedback sessions in the home [5]. These methods are felt to be effective because attachment problems are related to parents' lack of understanding of child development, little warmth or responsiveness to infants' needs, as well as parental stress and psychopathology [6].

Distractibility

Despina Stavrinos[1], Benjamin K. Barton[2]
[1]University of Alabama at Birmingham, Birmingham, AL, USA
[2]University of Idaho, Moscow, ID, USA

Synonyms

Inattention; Inattentiveness; Susceptibility to interference

Definition

Distractibility refers to inability, or difficulty, in maintaining attention and resisting interfering stimuli. Developmental differences are notable: older children generally are less distractible than younger children [5]. Distractibility also affects adolescents and adults, occasionally resulting in dangerous behaviors (e.g., while driving and conversing on a cell phone). Extreme distractibility that impairs one's level of functioning in the school or home environment has been characterized as a hallmark of the childhood behavioral disorder known as attention-deficit/hyperactivity disorder (ADHD). A variety of assessment techniques have been employed to measure susceptibility to distraction.

Description

Attention is vital for day-to-day functioning at all points in the human lifespan. Vision is not well-developed at birth. Infants' vision is typically out of focus and movements, patterns, and colors in their field of view are very distracting. However, infants soon gain greater control over their ability to direct and sustain attention. Although distractibility remains high throughout the early years, the ability to direct and control attention helps infants form social bonds with caregivers and to acquire language.

Distractibility decreases as children grow older but remains part of normal human cognition into adulthood. The natural limitations of human performance guarantee distracting stimuli will have some negative effect [2, 11]. We cannot always maintain complete control over our ability to prioritize and allocate cognitive resources [6]. In some circumstances, distractibility can result in increased risk for injury. For example, a young child is distracted by the sheer volume of visual information at a pedestrian crosswalk, an adolescent is easily distracted by passengers in their vehicle, and an airline pilot can easily become overwhelmed by the number of stimuli demanding attention in the cockpit.

Most theorists believe susceptibility to distraction varies along a continuum. All individuals may be susceptible to some level of distraction depending on the context and the attentional capacity available to complete a certain task (e.g., [4]). Those who are more frequently distracted may have greater difficulty ignoring irrelevant information coming from both internal and environmental sources. Extreme distractibility is characteristic of ADHD. Children with ADHD often are easily distracted from schoolwork or play, often daydream, and have difficulty paying attention across different settings such as in a classroom as well as at home.

The development of behavioral inhibition also plays a role in distractibility. Young children are still developing the ability to control impulses and urges and therefore exhibit more interference from distracting items. With the development of inhibitory mechanisms needed to resist interference from distracting stimuli, people are less susceptible to distraction. A very young child is more likely to be "captured by" distracting stimuli while an older child may be "directed toward" something distracting [8]. Inhibitory control processes may be important for maintaining attention longer and being effective at resisting distraction [6]. Inhibitory ability tends to sharpen across development [10] and a parallel pattern of development generally exists for susceptibility to distraction. That is, younger children tend to be more distractible than older children [5].

Assessment of one's susceptibility to distraction has been traditionally examined by cognitive-perceptual tasks (e.g., Stroop task, dichotic listening task). Distractibility results in longer response times or more errors. In applied cognitive models, distraction in various forms (e.g., other peers, cell phones) is assessed by limits to human performance in a number of settings such as road-crossing [1, 9] and driving [7] where distracted children may make riskier crossing or driving decisions. On the other hand, distraction techniques have been used for children in a positive manner such as for pain and anxiety management for medical procedures [3]. For example, when preparing for an injection, parents may relieve a child's anxiety by talking to them or distracting them with a toy.

In sum, distractibility is an important component of human functioning that may have associated positive or negative consequences.

Divorce

►Divorce-Stress-Adjustment Perspective

Divorce-Stress-Adjustment Perspective

Amy B. Rosenberg
Nova Southeastern University, Davie, FL, USA

Synonyms

Divorce; Family dissolution; Separation

Definition

The stress-adjustment perspective of divorce is a theory that describes divorce as a process that includes the full spectrum of events that precede and follow a divorce. It considers the multitude of stressors that are associated with the parental divorce process, and it suggests that these stressors leave children at increased risk for various problems before and after the divorce [4].

Description

Even before divorce occurs, there seems to be a substantial difference in the lives of children whose parents will eventually divorce when compared to children whose families remain intact [3]. These differences, rather than the actual divorce, are likely a source of childhood difficulties which may render negative consequences in later life. As parents proceed along the path toward divorce, their ability to

provide for their children is diminished. Parents' ability to invest time, effort and resources into parenting becomes compromised, often having a detrimental effect on the children [3].

The stress-adjustment perspective of divorce postulates that parental divorce is a continuous process which begins while a couple is still living together and ends long after the legal dissolution of a marriage [1]. Throughout the course of a divorce, there are several stressful events that occur which require children to continually adjust [4].With these stressors comes the additional risk that children will become negatively impacted by the divorce, either emotionally, behaviorally or physically [1]. While the process typically takes an unsettling toll on all family members, there are several key factors that influence an individual's successful adjustment to divorce [1]. Children of divorce who are thought to have successfully overcome the turmoil of their parents' former marriage, are those persons who have been able to adapt and function within a new family, as well as those who have been able to perform well in school and work roles [4].

For each child, the peak emotional impact of the parental divorce will occur at a different time. Older children, in particular, may experience a great deal of stress prior to the actual divorce, as this is the point in which he or she witnessed greatest amount of disagreement and unhappiness between his or her parents. In contrast, for a younger child, the departure of one parent from the home may be the ultimate anxiety-provoking experience, as he or she may have been unaware of the difficulties which were taking place in the home [1]. Since each individual experiences stress and adjustment in different ways, it is likely that the parental divorce will impact each child in a unique manner.

During the time in which a marriage is dissolving or immediately afterward, a number of events or mediators have the potential to influence emotions, behavior, and health. Protective factors, or moderators, help to assuage the relationship between divorce-related events and the way in which the individual experiences the associated stress [1]. In particular, resiliency factors such as coping skills, social support, and community services help to alleviate the negative impacts associated with divorce. These factors are thought to reside not only within the individual, but in interpersonal relationships, structural roles (e.g., employment, community services, and supportive government policies), and settings as well [1]. As such, the way in which an individual is able to utilize his or her coping skills, social support network, and support within the community, plays an influential role on the impact of the divorce [4].

Relevance to Childhood Development

Divorce is a confusing and complicated event for children. Not only is their primary support system disrupted, but they also face the possibility of losing their home, their school and even their friends [2]. Furthermore, divorce can lead to less effective parenting, a decrease in involvement with the noncustodial parent and a decline in economic resources. Moreover, children are frequently confronted with intense feelings of insecurity and abandonment. A multitude of unanswerable questions are posed as the stability of the family changes. Many of these difficult questions yield complex emotions, such as guilt and self-blame [2]. With divorce being seen as an ongoing process rather than an isolated, distinct incident, it is important to look beyond the legal dissolution of the marriage and focus on the conditions that children were exposed to prior to and following the official termination of the marriage. Since children who have experienced the parental divorce process tend to exhibit more difficulties in maintaining resiliency both prior to and subsequent to the divorce, it is essential that this information be considered in order to fully understand the long-term ramifications of divorce on children [4]. Last, the divorce-stress-adjustment perspective postulates that for the majority of individuals, the termination of a marriage is a stressful event regardless of whether or not tension occurred prior to the legal dissolution of the marriage, was short-lived or was accompanied by positive outcomes [1].

Dizygotic (DZ) Twins

Merry Sleigh
Winthrop University, Rock Hill, SC, USA

Synonyms

Double-egg twins; Fraternal twins; Non-identical twins

Definition

Twins that result from the individual fertilization of two different eggs.

Description

During her menstrual cycle, a woman typically releases one egg, or ovum, at ovulation. Dizygotic, or fraternal, twins result when a woman releases two eggs within a 24 h period (termed multiple ovulation), which are fertilized by two separate sperm. Because of the 24 h window, it is possible for two eggs to be fertilized by sperm from two separate fathers. Each fertilized egg is called a zygote, and the term dizygotic means "two zygotes." Each zygote develops its own placenta, chorion, and amnion, the support system to feed and protect the fetus during gestation. Dizygotic twins may be the same sex or opposite sex, and share the same number of genes as any two siblings.

Monozygotic twins result when one zygote splits into two genetically identical individuals. Monozygotic twins are thought to occur randomly throughout the human population. In contrast, the tendency to release more than one egg is believed to be partially inherited. Follicle stimulating hormone (FSH) facilitates the ripening and release of eggs housed in the ovaries. Women who are biologically wired to manufacture elevated levels of FSH are more likely to have fraternal twins. Similarly, older, premenopausal women are also more likely to have fraternal twins, as FSH levels rise with age. Because of the strong association between fraternal twins and FSH levels, the mother is a more influential than the father in determining whether the couple will produce fraternal twins.

Fraternal twinning is probably a multi-causal event, and many additional factors have been linked to this outcome. For example, fraternal twins are conceived in higher numbers following a period of sexual abstinence, such as soldiers returning from war. Fraternal twins also are more common in partners who have intercourse very frequently, as intercourse may stimulate the hormones associated with egg release. A low sperm count can decrease the incidence of dizygotic twins. Ethnic background influences twinning as well. Among Caucasians, about one third of twins are monozygotic, while the remaining two thirds are dizygotic. The percentages for dizygotic twins are higher in African populations, and lower in Asian populations.

Outside of fertility treatments, twins occur in about one out of every 80 to 90 births. The incidence of dizygotic twinning is on the rise in today's western society, with the increased use of technology to treat infertility. An infertile woman may be given drugs to encourage ovulation (e.g., Clomid, Pergonal), sometimes resulting in the release of multiple eggs. In other common procedures, eggs are fertilized in the laboratory and then multiple zygotes or gametes are transferred into the woman's body for gestation. For example, in Gamete Intrafallopian Transfer (GIFT), eggs and sperm are joined in a petri dish and then injected into the fallopian tubes. In Zygote Intrafallopian Transfer (ZIFT) newly fertilized eggs are transferred to the fallopian tubes. Procedures such as these usually result in multiple births.

A woman does not necessarily give birth to twins with every multiple ovulation cycle. Although more than one egg is released, only one egg may be fertilized by a sperm, resulting in a single birth. In addition, sometimes twins experience "vanishing twin syndrome," where one twin is spontaneously reabsorbed by the mother's body during the first trimester. This event happens so early in development that the mother may not even be aware that she was carrying twins.

Gestating twins is a greater challenge than carrying a single fetus to term. Mothers of multiples are more likely to experience complications during pregnancy, such as gestational diabetes or pre-eclampsia. Pregnancy also is challenging for the developing twins. One twin may benefit from better blood flow (bringing oxygen, nutrients, and antibodies) due to its position in the womb, while the other twin sustains a deficit. Twins are more likely to be miscarried, be stillborn, be born prematurely, require interventions during labor, and be low birth weight. Twins are typically born about 4 weeks earlier than singletons. Although the risks are higher than average for twins, most twins are healthy and suffer no long-term consequences of their unusual gestation.

Dopamine

Edalmarys Santos[1], Chad A. Noggle[2]
[1]Middle Tennessee State University, TN, USA
[2]SIU School of Medicine, Springfield, IL, USA

Definition

Dopamine is a neurotransmitter that originates from the substantia nigra and adjacent tegmental areas of the midbrain [2] and is predominately important in controlling voluntary motor behavior.

Description

Dopamine is a neurotransmitter within brain that plays a vital role in the modulation of motor behavior [4]. While dopaminergic projections originate in the substantia nigra and adjacent tegmental areas of the midbrain [2], the nigrostriatal, mesolimbic, and mesocortical tracts serve to supply Dopamine throughout a number of cortical and subcortical regions of the brain [3]. The scope of these projections are best exemplified by the breadth of functional domains which Dopamine impacts. For example, while Dopamine is primarily linked with the regulation of voluntary motor behavior it has also been linked to working memory, forming complex associations, mood and psychological regulation as well as attention [6]. In addition to its' ties with voluntary movement disorders, Dopamine alterations have been associated with several neuropsychiatric syndromes as well [5].

Decreased levels of Dopamine have been associated with impairments in voluntary movements such as excessive rigidity, tremor, and bradykinesia (i.e., slowed movement). Parkinson's disease is a presentation many are generally familiar which is related to decreased dopamine production and utilization, thus leading to a constellation of symptoms that include those manifestations previously noted. In comparison, excessive amounts of Dopamine have been linked with neuropsychiatric presentations such as Schizophrenia, ADHD, and Tourette's [5]. The link between excessive Dopamine and Schizophrenia is so prominent that many of the antipsychotic agents utilized to treat this manifestation serve to decrease Dopamine levels within the system [1].

Double Blind Design

Xenia Anastassiou-Hadjicharalambous, Maria Stylianou
University of Nicosia, Nicosia, Cyprus

Definition

The double-blind design describes an experimental procedure in which neither the participant nor the experimenter are aware of which group (i.e., experimental or control) each participant belongs to. The key that indicates in which group each participant belongs to is kept by a third individual and not given to the experimenter until the study is over.

Description

A Double-blind design designates a rigorous way of carrying out an experiment in an attempt to minimize subjective biases on the part of the experimenter and on the part of the participant [2–7]. A Double-blind design is most commonly utilized in medical studies that investigate the effectiveness of drugs. Participants are randomly assigned to the control or experimental group and given random numbers by a third party, who encodes the drugs with matching random numbers. The investigational drug is administered to the experimental group and the placebo substance (the word placebo derives from a Latin word meaning "I shall please" is administered to the control group). The placebo has an identical appearance (i.e., color, taste, etc.) with the actual drug. Both the participants as well as the experimenter are blind to who receives which treatment, until the study is completed and the random code is broken.

Double-blinded procedures are considered to minimize inadvertent biases such as placebo effect, experimenter expectancy effect and experimenter bias and in effect produce higher standards of scientific rigor. The *placebo effect* describes the process in which the participants preconceptions that the treatment would be effective

rather than the treatment itself results in significant treatment outcomes [3]. The effectiveness of the placebo in the treatment of several conditions is well documented in the empirical literature. Numerous reports have documented appealing evidence of significant treatment gains for individuals that received the placebo rather than the treatment drug; but the specific mechanism (or mechanisms) involved in the placebo effect are yet to be determined. Current research shifts the attention to the question of how the brain responds to placebo in order to delineate the mechanism/s in operation.

The *experimenter-expectancy* is a phenomenon similar to the placebo effect but it derives from the experimenter rather than the participants [1–3]. The experimenter may inadvertently communicate expectations to the participants resulting in the influence of the participants responses in a way that gives biased results. For instance the experimenter investigates the effect of a mneumonic technique on students learning performance. The researcher believes that students with higher grades will have a better performance. With verbal and non verbal cues the researcher may unconsciously trains students with higher grades in a more intense way. Consequently, the experimenter expectancy is substantially implicated in the outcome rather that the manipulation of the independent variable, placing a substantial threat over internal validity (i.e., the soundness in inferring that the change in the dependent variable is produced by the manipulation of the independent variable).

In more general terms the experimenter is and remains human. Human nature is by definition unable to remain completely objective. Consequently, *experimenter biases* are plausible in any phase of research including the idea-generating phase, the problem-definition phase, the procedures-design phase, the observation phase, the data-analysis phase, the interpretation phase, and the communication phase [4]. Double-blind designs are often generated in the attempt to combat these biases to the degree most possible.

Down Syndrome

Chris Leeth
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Down's syndrome

Definition

A genetic, chromosomal disorder and common cause of mental retardation. Although it is a cause of mental retardation, Down Syndrome is considered a medical condition.

Description

Down Syndrome is a common genetic disorder occurring in children. Estimated rates are about one in 600 children. Down Syndrome is also a very common cause of mental retardation, as Down Syndrome accounts for about one-third of all children diagnosed with mental retardation. Additionally, Down Syndrome may lead to other cognitive or physical deficits that can cause further hardships for the individual, as well as family members.

Down Syndrome can be diagnosed based on the presence of physical, bodily abnormality (such as in the face and hands) and through the use of genetic testing. Physical characteristics of Down Syndrome include small head, enlarged tongue, slanted eyes, and flattened nose. The cause of Down Syndrome stems from the presence of an extra Chromosome 21. The risk of Down Syndrome increases as the mother's age increases.

Notable effects of Down Syndrome include impaired speech, understanding, and memory. Individuals with Down Syndrome may have learning difficulties in addition

to poor social skills. However, through psycho-social interventions, individuals with Down Syndrome can adapt and learn new behaviors.

Relevance to Childhood Development

Children with Down Syndrome will appear physically different than their peers. In addition, children with Down Syndrome may have difficulty in school as well as in peer groups or social situations.

Dramatic Play

Rebekah R. Pender
San Antonio, TX, USA

Synonyms

Creative dramatics; Fantasy play; Pretend play; Pretension play; Socio-dramatic play; Symbolic play

Definition

Dramatic play permits children to fit the reality of the world into their own interests and knowledge. Dramatic play gives the child the opportunity to release his/her emotions while feeling less threatened and exposed owing to the distance that dramatic play creates from his/her problems [1, 3].

Description

Dramatic play includes role-playing, puppetry, and fantasy play. It does not require interaction with another. By acting out experience, he/she comes into contact with reality. It is constructive for the child to remember situations through play and to have the opportunity to repeat them and work through them. Socio-dramatic play is dramatic play with the additional component of social interaction with either a peer or teacher [1]. Creative dramatics involves spontaneous, creative play. Children frequently reenact a scene or a story.

Relevance to Childhood Development

One of the purest forms of symbolic thought available to young children, dramatic play contributes strongly to the intellectual development of children [1]. Symbolic play is a necessary part of a child's language development [1]. Creative dramatic play is structured and incorporates the problem solving skills of planning and evaluation. Planning and evaluating occurs in creative dramatics [1]. Porter [2] and Dunne [2] regard dramatic play as a form of play that offers the child client the opportunity to grow by acting out situations and dramatizing in a safe, non-threatening environment. Krüger [2] uses pretension play and symbolic play as terms interchangeable with dramatic play. To use this form of play effectively, the therapist should have a clear picture of the child client's situation. A great deal of inventiveness is also required of the therapist. Dramatic play is especially suitable for use in the change-oriented phase of helping as it focuses on problem solving. This process may lead to emotional growth, development and mastering, for instance, when the child acts out the first visit to a parent after divorce. New or specific roles can be learned when exercising these through dramatic play. While the child is playing, the therapist has the opportunity of evaluating current role behavior. This is followed by helping the child to practice new possibilities. The therapist may even model new roles. Dramatic play creates a special means of communication between therapist and child client. Important information can come to the forefront, for instance, while playing with a doll's house. During dramatic play, the child can manage his/her world as he/she likes. By playing through situations over and over again, insight

into certain aspects of his/her situation may develop. Often, the child's questions are answered during dramatic play. A tape recorder can be used in conjunction with dramatic play. While listening to his/her own play, the child may develop insight. Porter [2] claims that aids and apparatus are not so important for this type of play. They can be used, though, to make interviews interesting and full of fun. Therapeutic aids must be chosen according to each child's stage of development, age, motivation for therapy and intellectual ability. For example, Van der Merwe [4] has found that dramatic play was the ideal form of play for some of the respondents in research that she conducted on children of divorced parents. One child dramatized almost all the time. She was creative and had a good imagination. Her mother planned to remarry and the respondent would then go to boarding school. She acted this situation out with dolls. She also made a book containing all the pictures that she had drawn of the stories that she made up. Other respondents did not respond as well to this play form. They never progressed further than tidying up the doll's house. This again stresses the importance of individualization when determining the forms of play to use in an intervention plan. Van der Merwe [4] also established that children generally personalize the dolls quickly by talking to and about them as, for instance, mom and dad. It was also a common occurrence for children to talk softly while they played with the dolls, therefore making it easy for the researcher to keep track of their playing. Some children talk to the dolls in a kind of a teacher/instructor manner [4].

Draw-a-Man DAP

►Draw-A-Person Test

Draw-A-Person Test

Crystal Short[1], Kathy DeOrnellas[1], Robert Walrath[2]
[1]Texas Woman's University, Denton, TX, USA
[2]Rivier College, Nashua, NH, USA

Synonyms

Draw-a-man DAP; Goodenough/Harris drawing test; Human figure drawing; House-tree-person (H-T-P)

Definition

The Draw-A-Person test is a projective drawing task that is often utilized in psychological assessments of children. Although there are a number of variations, an individual is typically asked to draw a picture of a person. Results are analyzed to develop hypotheses about the subject's cognitive, developmental, and emotional functioning, as well as personality style.

Description

Draw-A-Person tests have been used in assessment since Goodenough created the Draw-A-Man Test in 1926 [3] to estimate cognitive development. In 1949 [7], Draw-A-Person was the first instrument to use a drawing technique as a means of interpreting personality based on the projective hypothesis [4]. Since that early beginning, a number of approaches have been used, including drawing a person of the same sex, drawing a person of the opposite sex, drawing a person doing something (kinetic), or telling a story about the drawing. Draw-A-Person tests are typically easy to administer and quick to complete. There are two major approaches to interpreting Draw-A-Person tests. The first (originating with [7]) involves drawing inferences from isolated features of the drawing such as the eyes or hands. In this approach, aspects of a drawing are believed to indicate suspiciousness, preoccupation with sex, etc. [7]. A more global approach is recommended by Koppitz [3], who developed a scoring system for children's drawings; thirty separate indicators could be summed for a total score indicating degree of maladjustment [5, 6].

The *Draw a Person Test: Screening Procedure for Emotional Disturbance* (DAP: SPED) created by Naglieri et al. in 1991 [6], is one of the few Draw-A-Person tests to provide normative data and is considered psychometrically advanced when compared to other figure drawing techniques [1]. The DAP: SPED can be used for a number of screening purposes, including identifying individuals

who may need further psychoeducational evaluations and identifying students who may need individual or group counseling [1]. The authors of the DAP: SPED recommend that administrators have previous experience in test theory and in administration of individual and group assessment procedures. In the DAP: SPED, participants are asked to draw three separate figures, a man, a woman, and self. Each figure is scored using scoring templates and a total score is derived from the individual drawing scores. Discriminate validity was examined by the authors of the test and found that the DAP: SPED significantly discriminated between students placed in a special education setting and a controlled matched "well adjusted" students from the standardization sample. The authors also provided internal consistency and standard errors of measurement for each age group [1].

Currently, the DAP is rated the fifth most frequently used technique by psychologists with children and adolescents, while the HTP ranks fifth. In school settings, projective drawing techniques rank highest in use by school psychologists [9].

Criticisms of the DAP and other projective drawings center on the lack of psychometric properties for these procedures (despite extensive research) and the lack of consistent measures of reliability and validity.

Despite its wide spread appeal, a problem with Draw-A-Person techniques (as with other projective techniques) is the absence or paucity of reliability and validity. Analyses have shown interrater and test-retest reliabilities to be variable across studies while validity has been shown to be negligible [6]. The latter is especially true with regard to the Machover approach of looking for signs in drawing details. The more global approach to scoring (i.e., Koppitz and Naglieri) has been found in some studies to differentiate between children with maladjustment and those without.

Drinking

Nathaniel John Cooney
Oklahoma State University, Stillwater, OK, USA

Synonyms

Ingestion; Intoxication; Oral consumption; Under the influence

Definition

Drinking refers to the ingestion of a liquid substance through oral consumption. Colloquially, it refers to the specific practice of consuming alcoholic beverages.

Description

Alcohol consumption is a common social phenomena in many countries and cultures around the world. Different cultures view alcohol consumption with varying degrees of acceptability, and many countries regulate the sale and consumption of alcoholic beverages due to the intoxicating effects of the psychoactive drug ethanol, which is the primary ingredient in the beverage. The strength of an alcoholic beverage is a measure of the ratio of ethanol to total volume of the beverage, a calculation referred to as alcohol by volume or ABV. In the United States, the strength of the beverage is commonly indicated by its "proof" which is a number equal to twice the ABV percentage (when measured at 15°C). For example, a distilled spirit (such as the beverage "vodka") might be measured as containing 40% ethanol by volume, and would be labeled as 80-proof.

Because the ABV ratio can vary greatly depending on the type of alcoholic beverage, drinks are commonly served in standard sizes such that each serving is approximately equal to one "standard drink." In the United States, a single standard serving of an alcoholic beverage contains 17.7 ml of pure ethanol (approximately 14 grams or 0.6 fluid ounces). This roughly corresponds to one 5 oz serving of wine, one 12 oz serving of regular beer, or one 1.5 oz serving of 80-proof liquor. Once ingested, the alcohol quickly enters the bloodstream and is distributed throughout the body.

The ratio of ethanol in a person's blood stream is referred to as blood alcohol concentration or BAC. A person's measured BAC depends on a number of factors including the amount of alcohol consumed (and over what duration of time), the amount of food in the stomach at the time of consumption, the metabolic system of the individual, her/his body size, and others. Typically, a single standard drink of alcohol will quickly raise a person's BAC by 0.02–0.05%. Because ethanol is eliminated from the blood at a rate of 0.015–0.06% per hour, alcohol can typically be eliminated from the body at a rate of approximately one standard drink per hour. However, one potential area for concern with respect to drinking is that many individuals are unaware of the types and quantities of alcohol that make-up a single standard drink, causing them to over-pour and underestimate the actual amount of alcohol they may have consumed [5].

Prevalence

U.S. Epidemiological data from 1990 to present have consistently shown that more than two out of every five high school students surveyed had consumed alcohol during the previous 30 days; with a steady increase observed from the ninth grade year (approximately one third of students reporting drinking) through the 12th grade year (with over half of all students reporting drinking). Average age of first alcohol use for U.S. adolescents ages 12–20 is approximately 14 years, with little variation across demographics of sex, race, or geographic region. The same sample reported drinking an average of six of the last 30 days and consuming approximately five alcoholic beverages per drinking occasion. Further, approximately 20% reported binge drinking (consuming five or more drinks during a single two-hour period) on at least one occasion during this same 30-day period. Nearly 30% reported riding in a vehicle with someone who was under the influence of alcohol during this period, and almost 10% indicated they had driven a vehicle while under the influence of alcohol at least once during the last 12 months [3].

Similar high usage of alcohol by adolescence has been found in numerous other countries as well. The European School Survey Project on Alcohol and other Drugs (ESPAD) has collected data on adolescent drug use in 35 European countries. This study sampled students approximately 15 years of age from schools throughout Europe. Findings varied significantly across countries, with proportions from 20% to over 80% of students reporting alcohol consumption during the previous 30 days. Additionally, approximately 8–60% of students reported being drunk during the previous 30 days; 15–60% reported binge drinking during this period; and 5 to nearly 40% of students reporting that they had been drunk at least once prior to the age of 13 years. When comparing these data to those obtained from comparable studies in the U.S. Turkey exhibited consistently lower prevalence rates of alcohol consumption than the U.S. whereas each of the other 34 countries typically (on most though not all variables) exhibited higher prevalence's of adolescent alcohol use than the U.S. [1].

Consequences

The consequences of alcohol use during childhood and adolescence are many. Individuals ages 12–20 consume alcohol in higher quantities per drinking occasion than do individuals 21 years and older, often resulting in increased risks associated with the drinking. Further, young adults ages 18–20 have the highest prevalence rates of alcohol use disorders compared to all other age groups. With more than half of adolescents in the U.S. having reported drinking in the past month (and in many cases even higher percentages of teens engaging in drinking internationally), the U.S. Surgeon General in 2007 issued a Call to Action to Prevent and Reduce Underage Drinking [7]. The report documents that alcohol is the substance of choice for children and adolescents; being used at rates higher than cigarettes, marijuana, or illicit drugs and making it the most-widely used substance for this age group.

The report further documents some of the many adverse consequences associated with underage drinking, among which includes more than 5,000 alcohol-related deaths for individuals under the age of 21 annually, making it the leading cause of injury-related deaths for this age group. Alcohol use in this age group is also associated with increased use of tobacco and illicit drugs; academic, social, familial, and health problems; increased risk of being involved in physical and/or sexual assaults; and increased risk of homicide or suicide. Because adolescence is also a critical period for physical development, alcohol use during this time has also been correlated with significant

physiological consequences including decreased levels of growth and sex hormones; lower bone mineral density; elevated levels of liver enzymes associated with liver disease, and abnormalities in both the hippocampus and corpus callosum of the brain. Alterations in the structures and functions of the brain and other vital organs during this period of development are believed to result in consequences that extend significantly beyond adolescence as well [2].

Risk Factors

A number of risk and protective factors have been identified in the development of alcohol use problems among children and adolescence. While it should be noted that these factors are correlational rather than causal, their association with alcohol use has been well established in the scientific literature. Perhaps most notable among the risk factors identified is that children of alcoholic parents are 4–10 times more likely to develop alcohol dependence themselves. Certainly family influence plays a significant role in shaping children's perceptions about alcohol. Children who are raised in homes where parents consume alcohol and hold positive views concerning alcohol are also more likely to consume alcohol at an early age themselves. Conversely, children whose parents are supportive, involved, and attentive toward their activities are less likely to engage in drinking behaviors during childhood and adolescence.

As individuals develop from childhood into adolescence, familial influence (particularly that of the parents) tends to decline and is often replaced by other influences, most notably that of their peers. The extent to which an individual's peers drink, or hold positive views related to drinking is strongly associated with that individual's decision to drink her/himself. Adolescents' expectations play a significant role in their decisions to drink or not, how soon they will begin drinking, and how much they will consume when drinking. Those who hold positive expectancies related to the perceived consequences of drinking (seeing the consequences as more beneficial than harmful) are more likely to begin drinking at a younger age and in higher quantities than those who do not. Studies have demonstrated a consistent trend whereby children's expectancies regarding alcohol tend to shift between ages 9 and 13 from negatively held beliefs to positive ones, suggesting social phenomena may play a contributing factor to shaping these beliefs. Youth also are more likely than adults to be exposed to media that promotes drinking behaviors, including television, radio, and internet advertising, which is more ubiquitous among programs that market to young people.

Other risk factors include a number of variables related to the individual. Certain personality and behavioral traits in particular show strong associations with increased adolescent drinking. Specifically, increases in behavioral disinhibition and externalizing behaviors (oppositional and conduct related problems) also are associated with alcohol use disorders. Self-regulation processes may be one of the key elements underlying these issues, as these processes have been shown to be at a critical developmental period during adolescences when the frontal lobes of the brain mature. It is during this period that many adolescence increase their risk-taking behaviors, which may be related to increases in alcohol consumption.

The presence of one or more other comorbid psychological disorders is also a strong indicator. Those disorders that show the highest concordance with alcohol and/or substance abuse in adolescence include Oppositional Defiant Disorder (ODD), Conduct Disorder (CD), Antisocial Personality Disorder, and other substance use disorders. Further, there is some evidence to suggest that individuals with some internalizing disorders including depression and anxiety may be at an elevated risk of using alcohol, likely as a mechanism for coping with their distress. Perhaps, the single best predictor of alcohol use problems, however, is age of first alcohol consumption. Adolescents who report drinking prior to the age of 15 are at least four times more likely to meet criteria for alcohol dependence at some point during their lives than individuals who abstained from alcohol consumption until after the age of 21 [2].

Assessment and Intervention

According to the 2002 National Survey on Drug Use and Health, an estimated 1.4 million adolescents ages 12–17 met diagnostic criteria for alcohol use disorders. The same survey found that only 227,000 (about 16%) of those individuals received any services for their alcohol-related problems [4]. Among the many challenges in intervening with adolescent alcohol use is that a vast majority of research related to alcohol assessment and intervention has been conducted on adult populations, and may not generalize to adolescents who differ developmentally. Similarly, the diagnostic criteria also reflect adult pathology and may not fully capture adolescent symptomatology, further suggesting that the prevalence figures identified above likely reflect low estimates of actual problems.

Intervention for adolescent drinking takes various forms including prevention efforts, individual and family based interventions, and systemic interventions. Studies regarding primary prevention for child and adolescent drinking have been targeted primarily toward

family-based and school-based interventions. Of the two, the family-based interventions have shown much more promising data with respect to long-term efficacy in reducing later misuse and/or abuse of alcohol. These interventions work by influencing the behaviors of both parents and children at both the individual and environmental levels. They include such practices as increasing awareness of the risks and consequences of underage drinking, clarifying expectations regarding alcohol use, implementing behavioral management practices, encouraging parental involvement in children's activities, and reducing availability of alcohol while increasing the costs associated with underage drinking. School-based interventions traditionally have shown little efficacy and tend to report small effects. However, those that have yielded some favorable results have tended to focus on some of the more social aspects of drinking; addressing social norms, social influences (peer pressure), and interactive peer-led components.

Systemic and environmental interventions tend to take a similar approach to that of the family-based prevention efforts previously described. They seek to reduce the availability of alcohol while increasing the costs associated with underage drinking. Increased monetary expenses (such as raising the cost of alcohol or taxes imposed on alcohol sales) as well as stiffer legal penalties for alcohol-related offenses have both been associated with reductions in alcohol use and associated problems. A number of studies have also documented that community-focused interventions that enforce zero-tolerance social and legal policies (for example, targeting businesses that sell alcohol to minors) can significantly reduce the supply of alcohol available to minors, and have been shown to be associated with reductions in alcohol-related injuries and deaths and fewer alcohol-related arrests among adolescent and young adult populations [2]. Perhaps what is most apparent in each of the interventions described so far is that the most favorable outcomes have been observed in those interventions that addressed the availability and social acceptability of underage drinking. A report by the U.S. Surgeon General illuminated the issue of social acceptability stating: "the perception that alcohol use is socially acceptable correlates with the fact that more than 80% of American youth consume alcohol before their 21st birthday, whereas the lack of social acceptance of other drugs correlates with comparatively lower rates of use"[6].

Individual intervention for adolescent alcohol use can be a complex matter as there is no single pattern of drinking associated with this population. Such factors as age of onset of the problem, frequency and quantity of drinks consumed, and comorbidity of additional substance use and/or psychological problems can all bear direct impact on the type of intervention best-suited to the individual. However, current evidence suggests that the best interventions for children and adolescents tend to be brief and available to the child in her/his existing environment (home, school, or primary care setting rather than inpatient or other extended care settings). Family and systemic approaches, cognitive-behavior therapy, and Motivational Interviewing are among the approaches currently favored in research outcomes. The research also suggests that combinations of these interventions may also be effective and particularly warranted in higher-risk cases [2].

Summary

Alcohol consumption among child and adolescent populations is a complex problem with far reaching consequences. The prevalence of alcohol misuse and associated problems among these populations has been well-documented on a global scale and speaks to the seriousness of the problem. Current research suggests that the problem should be considered from a developmental framework, taking into account that unique facets of both physiological and psychological changes that occur during adolescent development, and the reciprocal impact alcohol and developmental processes can have on one another. The best available evidence suggests that individuals who begin drinking earlier in life are far more likely to experience more negative outcomes in the long-term. Further research is needed to address the shortcomings in current assessment and diagnostic criteria that do not fully account for the complexities of adolescent behavior. Despite this need, it is abundantly clear that the magnitude of adolescent drinking and associated consequences is of grand proportions and is deserving of both careful attention and continued research efforts. Changing the trajectory of this problem likely requires interventions at a number of levels including individual, family, and systemic approaches; and the developmental aspects of adolescent drinking suggest that social components must be addressed in changing the cultural acceptability associated with adolescent drinking behaviors.

Dwarfism

Synonyms

Little people

Definition

Dwarfism is short stature resulting from an abnormal medical condition. It is sometimes defined as an adult height of less than 4 feet 10 inches (147 cm).

Dwarfism can be caused by about 200 distinct medical conditions, such that the symptoms and characteristics of individual dwarfs vary greatly. In the United States, people with dwarfism are often called little people.

Disproportionate dwarfism is characterized by one or more body parts' being relatively large or small in comparison to those of a normal adult, with growth abnormalities in specific areas being apparent. In cases of *proportionate* dwarfism, the body appears normally proportioned, but is abnormally small; the term *midget* originally described proportionate dwarfs. Hypotonia, or a lack of muscle, is common in dwarfs, but intelligence and lifespan are usually normal.

Achondroplasia is a bone-growth disorder responsible for 70% of dwarfism cases. In achondroplasia, the limbs are disproportionally short compared to the trunk (abdominal area), with the head larger than normal and characteristic facial features. Conditions in humans characterized by disproportional body parts are typically caused by one or more genetic disorders in bone or cartilage development. Extreme shortness in humans with proportional body parts usually has a hormonal cause, such as growth-hormone deficiency, once called *pituitary dwarfism*.

There is no single treatment for dwarfism. Individual abnormalities, such as bone-growth disorders, sometimes can be treated through surgery, and some hormone disorders can be treated through medication, but usually it is impossible to treat all the symptoms of dwarfism. Lifestyle changes often are needed to cope with the effects of dwarfism. Such devices as specialized furniture often help people with dwarfism to function normally. Many support groups help sufferers of dwarfism cope with the challenges they face and with developing and maintaining their independence.

Dwarfism is a highly visible condition and often carries negative connotations in society. Because of their unusual height, people with dwarfism are often used as spectacles in entertainment and portrayed with stereotypes. For a person with dwarfism, heightism can lead to ridicule in childhood and discrimination in adulthood.

Short stature can be inherited without any coexisting disease. Short stature in the absence of any abnormal medical condition is not generally considered dwarfism. For example, a short man and a short woman who are in normal health will tend to produce children who are also short and in normal health. While short parents tend to produce short children, persons with dwarfism may produce children of normal height, if the cause of their dwarfism is not genetically transmissible or if the individual does not pass on the genetic mutation.

Dynamic Assessment

Douglas K. Symons
Acadia University, Wolfville, ON, Canada

D

Synonyms

Graduated learning; Learning potential assessment; Mediated learning; Scaffolding; Testing the limits

Definition

Dynamic assessment is used in educational settings to assess a child's ability to profit from instruction. It is based on the educational theories of Lev Vygotsky, who proposed the children learn best when the teaching-figure is instructing the child on how to do something within the child's zone of proximal development, and learning is scaffolded [1].

Description

Traditional assessment of child intelligence using tests such as the Wechsler Intelligence Scale for Children is static: it is an assessment of what a child's cognitive abilities and problem-solving strategies are. In dynamic assessment, performance is evaluated, but tasks have performance-contingent feedback and instructional components. Dynamic assessment thus assesses the degree to which a child performs better as a result of this instruction in addition to level of performance. It is seen as an interactive approach to conducting assessments, as well as a philosophy for conducting assessments and evaluating teaching more generally. Dynamic assessment is not seen as a viable replacement for traditional ability testing, but should be used in conjunction with it [3, 5, 6].

A wide range of problem-solving tasks are used in dynamic assessment. These are typically evaluated in a pretest-intervention-posttest format in which evidence of learning is based on how much better a child's posttest performance is over their pretest levels. This assessment approach is seen favourably by educators as this is essentially what teachers are doing: taking a child with a specific skill set, teaching them new problem-solving strategies, and then hoping to see improvements in performance. In dynamic assessment, it is important that the instruction or series of problem-solving prompts be scripted so that the intervention can be operationally defined and delivered in a standardized way to different children. In fact critics of dynamic assessment pointed out that it is only when instruction is standardized that

reliable and valid assessment data can be collected. The concept of dynamic assessment is also applicable to educators who wish to evaluate the effectiveness of teaching as actual educational content from the curriculum could be assessed before and after it is taught. In addition to a child's final knowledge base, it is their improvement in performance that indicates their ability to profit from instruction.

Dynamic assessment has been found to have predictive validity of future performance above and beyond that of traditional static measures [2, 7]. It seems particularly suited to children who have a variety of developmental disabilities and learning problems. It may be tailored to assessment in a specific domain, for example, in reading [4] or mathematics, which are two common achievement domains children have learning problems in that also vary on relevant cognitive processes. For example, phonological processing that affects word attack skills (i.e., "sounding out" words) is relevant to reading and not numeracy. In addition, students with poor metacognitive skills may benefit from dynamic assessment, and in fact metacognitive training and problem-solving strategies are part of the instructional component of the assessment process. So it has been argued that dynamic assessment is better suited to provide educational recommendations than traditional static assessment methods. This is because dynamic assessment addresses whether instruction is effective or not, and if so, which kind? It is less dependent on background experience and language skill, so it may be less discriminatory towards disadvantaged groups of children who may be weak in these areas.

Dynamic Psychotherapy

Janet G. Benton
William Alanson White Institute, New York, USA

Synonyms

Psychodynamic therapy; Psychotherapy; Therapy

Definition

Dynamic psychotherapy refers to modes of therapy in which patients emphasize understanding interpersonal and intrapsychic patterns in their lives and how these affect their thoughts, feelings and behaviors. Although different psychodynamic therapies may have different theoretical positions and use different techniques of practice, the basic therapeutic goal is similar, i.e., to help a patient gain self understanding [2, 4, 5].

Description

Early in the twentieth century, Sigmund Freud established himself as the father of dynamic therapy when he theorized about the structure of the mind, describing the Id, Ego, and Superego and how they worked with and against each other. Psychoanalysis was the technique used to bring the workings of this structure to consciousness and eventually bring a patient to better self understanding. Psychoanalytically oriented, dynamic therapy is a less intensive form of treatment than psychoanalysis. It emphasizes how past history, especially relationships, influences current functioning.

Freud's basic psychodynamic ideas influenced the development of psychoanalytic theory (ego psychology in the middle of the century followed by developmental psychologies, more recently interpersonal and relational psychologies) and other personality theories in his own generation (e.g., Carl G. Jung's analytic and Alfred Adler's individual psychologies) and throughout the century (e.g., Carl Rogers and Abraham Maslow's humanistic and Rollo May's existential psychologies). [1] Although, again, there are differences between specific types of therapy and between nuanced understandings about "free will," implicit in the practice of dynamic therapy is the concept of agency or choice. Patients ultimately are responsible for the choices they make in living [1–3].

Dynamic therapy is more fully understood when contrasted with behavioral therapy, which questions the possibility of scientifically understanding the interior workings of the mind. During the 1920s and 1930s, at the same Freud was developing his theories on the structure of the

mind, the American psychologist John B. Watson, following in Ivan Pavlov's footsteps, emphasized the importance of conditioning. He believed that study of behavior is the only reliable way to gain understanding. [1] Behavioral therapies, therefore, have traditionally focused on changes in behavior and symptom relief rather than on self understanding. Behavioral therapies, like dynamic therapies, have become increasing refined throughout the twentieth century and into the present, (progressing from Skinner's work to current cognitive-behavioral theories and techniques) and increasingly have embraced concerns about self understanding and personal responsibility.

Dyscalculia

Nava R. Silton[1], Denise E. Maricle[2]
[1]Fordham University, New York, NY, USA
[2]Texas Woman's Hospital, Denton, TX, USA

Synonyms

Learning disability in math; Math deficit; Math difficulties; Math disorder; Math dyslexia

Definition

Dyscalculia includes a wide variety of math difficulties including the inability to comprehend the meaning of numbers and their quantities, and the inability to comprehend basic addition, subtraction, multiplication and division calculations. Acalculia refers to the total inability to do math, whereas, dyscalculia refers to less severe difficulties in performing math problems.

Description

Dyscalculia is thought to involve problems with language and visual centers of the brain. Theories have suggested that it may either be inherited or may be due to insults in normal brain development such as prenatal or environmental toxins. Proof of a genetic component has been shown in studies of monozygotic and dizygotic twins which demonstrated that MZ and DZ twins were 12 and 8 times more likely, respectively, to have dyscalculia than the general population. Preterm birth and low birth weight have also been cited as risk factors for the development of dyscalculia. Some suggest that poor teaching and environmental deprivation may also be implicated in its etiology.

The term "developmental dyscalculia" (DD) has been created to distinguish the problem of dyscalculia seen in children from that evident in adults following specific insults to the brain.

Studies have estimated that approximately 3–6% of the population is affected by DD. It is seen equally in both boys and girls, despite the fact that learning disabilities are generally more prevalent in boys. Dyscalculia, like dyslexia, usually becomes evident during the first few years of grade school. It has been associated with a number of co-morbid conditions such as attention deficit and hyperactivity disorder (ADHD), anxiety disorders, Fragile X syndrome, Turner syndrome, Gerstmann's syndrome and epilepsy.

Of those children with DD, only about 1.8% possess pure DD. The remainder have comorbid dyslexia, as well. Aster and Shalev [2] suggest that this is due to a difference in the pathophysiology. In those with pure DD, there is most likely a genetic predisposition resulting in a numerical core-system deficit. Those with combined dyslexia and DD likely possess additional mechanisms which involve delayed speech and language development.

One classification scheme for dyscalculia divides it into five subtypes: [1] alexia and agraphia for numbers [4] spatial dyscalculia [5] anarithmetia (loss of numeric values or their manipulation) [6] attentional sequential dyscalculia and [7] mixed type. Although these distinctions are rarely utilized clinically, it allows one to better comprehend the spectrum of difficulties that those with DD may encounter.

Neuroimaging affords researchers the ability to localize areas of deficit in children with DD. Typical children tend to show activity mainly in the left frontal and parieto-temporal regions of the brain. However, patients with DD tend to show defects in the left parieto-temporal area. Additionally, when participants with DD were asked to perform certain arithmetic tasks, the intraparietal sulcus and left middle frontal gyrus were highlighted as the most active areas of the brain. In contrast, controls showed activation of the intra-parietal sulcus bilaterally and minimal activation of the left frontal gyrus. Further imaging studies have suggested that children with DD attempt to

recruit "substitute" regions of the brain to compensate for the lack of normal activity. Unfortunately, these efforts are typically ineffectual.

A number of theories have been proposed to explain the development of DD. According to some, there are three underlying origins of dyscalculia. The most common is a visual processing weakness. Visualizing numbers and situations is crucial to the proper understanding of math. People with a weakness in visual processing often have difficulties with spelling and handwriting, as well. The second origin is difficulty in sequencing or in organizing specific pieces of information, a necessary task in mathematics. People with sequencing difficulties often also experience difficulty with memorization in general which may lead to spelling weaknesses, as well. The final origin is simply a phobia of math. This may be due to prior negative experiences, an inconsistency in one's education, or merely a lack of confidence.

Others postulate that the cause of DD is related to a defect in the acquisition of skills necessary to carry out mathematical operations. The first of these is *foundational skills*. This involves visual perception, visual memory and logical thinking. Children with DD may have difficulty with visualizing and distinguishing mathematical symbols such as +, −, ×, ÷. The second aspect is *mathematical skills*, concepts that must be learned such as counting, addition and subtraction. These skills must be learned in a sequential fashion – one cannot add or subtract until one first learns how to count. If skills are not mastered in the proper order then subsequent steps cannot be grasped correctly. The third piece is *knowledge*, ideas that a person must simply know. For example, theorems and definitions must be learned and remembered.

Another theory proposes that number acquisition occurs by a four-step process and that DD is due to a defect in this mechanism. The first step that takes place is inherited. It involves number sense and the ability to discriminate small sets of objects from large sets of objects. This skill is present from infancy and is necessary for the proper progression of number acquisition. It provides the basic meaning of numbers. If step one fails to be established (possibly due to genetic vulnerability), then children may be able to memorize the names of numbers, but may be unable to assign numerical value to those names. The second step, which occurs during the preschool years, involves the process of language development for numbers. Children with deficits in this stage have difficulty in counting and in sequencing of number word elements (i.e., 235). Because stage two entails a language component, children who don't fully develop language properly, may also have comorbid dyslexia. The third step entails the acquisition of the respective symbols for each of the numbers. This occurs during the early schooling years. It is important to properly progress through this stage so that a child can distinguish similar numbers (i.e., 25 versus 52). A failure to develop an appropriate system of symbols results in an inability to progress to the fourth step, which allows one to create a mental number line. This provides a representation of the ordinal position of numbers.

People with DD may demonstrate a wide array of symptoms, depending upon their age. Some may have difficulty in performing certain mathematical tasks whereas others may find it difficult to understand arithmetic concepts. Additionally, those with DD may reverse or transpose numbers – i.e., 56 instead of 65; 743 instead of 437. Other manifestations include difficulty in using a calculator, difficulty with counting money and with financial planning, and an inability to judge the passing of time. Some children may show a poor sense of direction and may also have difficulty in estimating the measurement of an object – i.e., approximating the distance from point A to point B. Although people with dyscalculia have difficulties in understanding concepts related to numbers, their general ability to learn is equal to, or even greater than that of their peers.

The diagnosis of DD is based upon an assessment of the child's arithmetic skills. If there is a significant difference between the child's intellectual potential and his or her arithmetic achievement or if there is a discrepancy of at least 2 years between the child's chronological grade and his/her level of achievement, then a diagnosis of DD can be made. Standardized arithmetic tests are the acceptable methods to assess a child's abilities. During the process of diagnosis, it is imperative that one determine whether DD is a primary diagnosis or a symptom of a greater disorder (i.e., Fragile X syndrome). Moreover, comorbidities should be carefully identified so that they may be treated, as well.

Treatment of DD relies upon a number of factors. Nonacademic skills are important to all students, especially those with learning disabilities. These skills include assuming accountability for one's own behavior, arriving prepared for lessons, meeting deadlines, maintaining appropriate school behavior, following directions, and completing homework assignments. Refining these skills can have long-term benefits. Children with syntactic deficits with numbers require verbalization of concepts. For example, in order to fully comprehend the number 47,632, it will need to be stressed to the child that the "4" represents the ten thousands place, the "7" the thousands place, the "6" the hundreds place and so on and so forth. Interactive learning

tools like the MASTER (Mathematics Strategy Training for Educational Remediation) program can help children with DD to comprehend the concept of mathematical operations. This program utilizes the idea that children with DD can learn arithmetic when provided with number concepts and problem-solving strategies. Additionally, assistive technology such as calculators, digital clocks and calendars should be made available to children with DD.

There is little information regarding the prognosis of dyscalculia. However, fifth grade boys and girls with DD who were followed for 3 years were found to perform in the lowest quartile of their class in 95% of cases. Forty-seven percent of them performed in the lowest fifth percentile. Factors associated with the persistence of symptoms are the severity at initial diagnosis and the presence of arithmetic difficulties in siblings.

Relevance to Childhood Development

Dyscalculia can affect people in different ways in school and throughout their life.

Dyscalculia can be identified at a young age, although it may go unrecognized because it is a less well-known learning disability. According to the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (DSM-IV-TR) [1], children with below average intelligence can be classified as having mathematics disorder if math ability falls substantially below that expected for the student's chronological age, measured intelligence, and age-appropriate education. Dyscalculia is often initially identified by a teacher when a student is struggling in school, and subsequently the student is assessed by a professional trained in identifying learning disabilities.

In the early years of school, students with dyscalculia may have difficulty solving mathematical equations, remembering and retaining math facts, and understanding how to apply their knowledge and skills to solve math problems. If basic mathematical facts are not mastered, this can result in difficulty for adolescents and adults in mastering more advanced math problems. When students need special education, special services are provided by the school under the category of Specific Learning Disability (SLD).

Math interventions for students are emerging for both foundational math skills and higher-order problem solving skills. Interventions for math disabilities often consist of not only skills training, but also explicit instruction in strategies such as self-regulation and mnemonic devices [5]. Deciding which interventions to use is a highly individualized process that is dependent on the student's developmental level, current math skills, and requirements of the school district's math curriculum.

Dysgraphia

Raychel C. Muenke, Denise E. Maricle
Texas Woman's University, Denton, TX, USA

Synonyms

Agraphia; Disorder of written expression; Handwriting; Spelling disabilities; Writing learning disability or specific learning disability (LD)-written expression

Definition

Writing is a complex skill that combines elements of visual-motor coordination, fine-motor coordination, and executive planning. Dysgraphia is a term that is used to describe an inability to produce legible text with minimal effort, and is generally used to describe a disorder of written expression with an onset during childhood.

Description

The research on disorders of written expression is very limited and has been hampered by definitional issues such

that there are no clear operational definitions that address all the components of the written language domain [2]. According to the *Diagnostic and Statistical Manual of Mental Disorders-fourth edition, text revision (DSM-IV-TR)* [1], a disorder of written expression is defined as: assessed writing skills substantially below those expected based on a person's age, intelligence, and education; the writing difficulty significantly interferes with academic achievement or daily activities; and exceeds any present sensory deficits. Therefore, dysgraphia both interferes with handwriting ability, and creates a significant impairment in a person's ability to function in school and/or daily life. Deficits in written expression often co-occur with deficits in oral language, reading and mathematics, and most children identified with learning disabilities demonstrate deficits in at least one academic skill in writing, whether it is handwriting, spelling, or composition [5]. In addition to difficulty writing coherently and neatly, individuals with dysgraphia have problems with spatial orientation and directionality [3].

Although dysgraphia is broadly defined as difficulty with writing, there are three main types of dysgraphia: dyslexic dysgraphia, motor dysgraphia, and spatial dysgraphia [4]. Dyslexic dysgraphia occurs when a child has difficulties with written text and spelling, but drawing or copying text is normal, and fine-motor speed is normal. In motor dysgraphia a child has difficulties with written text, copying text and/or drawing, and fine-motor speed, but spelling is normal. Spatial Dysgraphia occurs when a child has difficulty with written text, copied text and/or drawing, but spelling and fine-motor speed is normal. Thus, academic skills deficits can involve handwriting, spelling and composition or the expression of ideas at the level of text [5].

	Written text	Oral spelling	Drawing/ copying	Fine-motor speed
Dyslexic	Illegible	Poor	Normal	Normal
Motor	Illegible	Normal	Problematic	Abnormal
Spatial	Illegible	Normal	Problematic	Normal

Note: From [4] © 1995 Sage Publications

Dysgraphia can only be diagnosed by a qualified professional. Although specific tests are not well developed, there are many methods for assessing handwriting, spelling, and composition. Qualitative assessments of legibility are most often used to assess handwriting, but simple examination of a student's handwriting does not serve as a basis for diagnosis. It is important to observe a child in self-generated handwriting, drawing, and copying of text through the use of standardized measures such as the *Test of Written Language, third edition* (TOWL-3) or the written expression scale of the *Oral and Written Language Scales* (OWLS). In addition, it is important to perform a motor skills assessment through the use of tests like the *Beery–Buktenica Developmental Test of Visual-Motor Integration, fifth edition*, or *Bender Visual-Motor Gestalt Test.* The child may also be referred to an occupational therapist for further assessment of fine-motor activity. Standardized achievement tests, such as *the Kaufman Test of Educational Achievement-second edition* (KTEA-II), often evaluate spelling using a single word dictation approach and composition is usually evaluated with a spontaneous writing sample that is evaluated for subjective components of written narrative, but handwriting is rarely assessed.

Results from a study conducted by Volman, van Schendel, and Jangmans [8] demonstrate that two different mechanisms may underlie the quality of handwriting in children with and without dysgraphia. While the best predictor of success in children without handwriting difficulties appeared to be fine-motor coordination, the best predictor of success for children with handwriting difficulties was visual-motor integration. Therefore, interventions for children with dysgraphia should include both fine-motor coordination, and an improvement of visual-motor integration.

Relevance to Childhood Development

Written competency, a critical skill, is important for success both in school and throughout adulthood. In a study conducted by McHale and Cermak [7] it was reported that 30–60% of an elementary student's time is spent engaged in fine-motor activity, with writing as a major activity. Reporting the results from several studies Karlsdottir and Stefansson [6] estimate the prevalence of dysfunctional handwriting in school children to be 10–25%. In addition, 66–88% of the children with handwriting difficulties are boys. However, very little is known about the etiology, developmental course, and prognosis of writing difficulties, and even less is known about the long term outcome of writing interventions.

Currently, it is thought that to have successful handwriting, there must be an interaction between the child and instruction. The child must have the motor, cognitive, and attentional abilities to produce adequate handwriting, and the school must provide adequate instruction to assist the child in this process. If a student has been exposed to adequate instruction and still displays difficulties with written expression, then s/he may qualify for special education services under a specific learning disability (SLD) as defined by the Individuals with Disabilities Education

Improvement Act (IDEIA, 2004). Under the IDEIA a student may be diagnosed with a learning disability in written expression via several methods including standardized testing or using a response to intervention (RTI) method. Although, it is important to note, that a difficulty with handwriting alone would not qualify an individual as having an SLD under the IDEIA's criteria.

After qualifying for services, a student may be eligible for accommodations and modifications. For example, a school psychologist may recommend interventions like: shortened writing assignments, extra time for completion of writing assignments, and/or additional instruction. In addition, an occupational therapist may assist the student with proper positioning, handwriting, and/or the use of assistive technologies.

Dyskinesia

Anthony P. Odland, Wiley Mittenberg
Nova Southeastern University, Fort Lauderdale, FL, USA

Synonyms

Hyperkinesia syndromes

Definition

Dyskinesias encompass a cluster of disorders, often involving pathology of the basal ganglia, characterized by abnormal uncontrolled performance of muscular movements that may be excessive or repetitive in nature; specific symptom manifestation is distinguished by underlying pathophysiology.

Description

Patients with dyskinesia may display either hyperkinetic or hypokinetic signs and symptoms. Presentation may include orofacial dyskinetic movements in areas such as the tongue, muscles of the lips, jaw, or other areas of the face. Dyskinesia may also be observed as myoclonus or choreoathetoid movements in the trunk and upper or lower extremities, patients may have tics, tremor, ballismus, display dystonic movements, stereotypies, athetosis, akathisia, grimace, or have ataxia. There may be dyskinetic movements in the diaphragm or manifest in other areas of the body such as the legs. Dyskinesia may manifest in a variety of the aforementioned symptoms coinciding with its underlying pathology, which is often associated with basal ganglia involvement. Unilateral focal basal ganglia lesions are likely to result in abnormal movements contralateral the lesion. Dyskinesias may be congenital in nature, and associated or induced from other external stimuli such as through the use of antipsychotics. Specific disorders such as schizophrenia, mental retardation, cerebral palsy, autism, or Tourette's syndrome may involve abnormal movements as part of their associated symptom presentation. Acquiring baseline data prior to the inception of treatment may facilitate differential diagnosis when a dyskinesia is suspected. Also, collecting follow-up data is useful in determining the course and effects of treatment. In children with cerebral palsy, dyskinetic movements may be differentiated from spastic movements by a smaller than normal step profile, a wider more variable base of support, and by an increased and more variable maximal lateral acceleration [7].

Chorea

Often due to basal ganglia degeneration, insult, or abnormality, chorea (Latin for "dance") is characterized by involuntary hyperkinetic movements that tend to be transient, rapid, abrupt, or arrhythmic, and advance unpredictably from one muscle or area of the body to another interrupting normal movement. Although choreic movements are purposeless, patients may attempt to integrate them into their behavioral repertoire to mask or make them less noticeable. Choreic movements in the

arms such as flailing, flinging, or thrashing are referred to as ballism or ballismus. Ballismus has classically been observed in patients with lacunar infarcts of the subthalamic nucleus, but may be the result of other lesions. Hemiballismus may be observed in patients contralateral to a basal ganglion lesion such as in the subthalamic nucleus.

In children and adolescents, chorea may be due to a number of conditions including paroxysmal dyskinesias, perinatal hypoxia, immune-mediated conditions such as Sydenham's chorea or systemic lupus erythematosus, or hereditary disorders such as juvenile Huntington's disease, Wilson's disease, dentatorubropallidoluysian atrophy, or benign hereditary chorea. Choreic movements may be present in metabolic abnormalities including hyper and hypothyroidism, hyperglycemia, hypoglycemia, hyponatremia, or mitochondrial cytopathy. Symptoms may also manifest in postcardiopulmonary bypass. Drug or toxin exposure such as through use of neuroleptics, anticonvulsants, contraceptives, cocaine, and excessive dosages of L-dopa may evoke choreic movements. Chorea may develop with the introduction of infectious agents including syphilis, encephalitis, Lyme disease, neoplasms, vascular dysfunction, degenerative disorders, as well as other conditions that affect the basal ganglionic structures. Also, hemichorea may occur contralateral to a focal lesion in the basal ganglia. A specific and homogenous pathology subsuming variable disease states and their coinciding choreic manifestations has not been established; accordingly, a uniform treatment regimen is not feasible. Current treatment of chorea focuses primarily on increasing levels of acetylcholine and gamma-aminobutyric acid, or by reducing dopaminergic stimulation. Likewise, the prognosis for chorea is highly variable and dependent upon underlying pathology. For example subsequent to streptococcal infection, dyskinetic disorders such as Sydenham's chorea may be accompanied by neuropsychiatric difficulties which may require therapeutic intervention in addition to pharmacotherapy [6]. Although chorea may be the most common type of dyskinetic movement observed subsequent streptococcal infection, evidence suggests a high prevalence of other dyskinetic symptoms including dystonia, myoclonus, stereotypies, motor tics, and opsoclonus.

More common in developing countries, Sydenham's chorea is one of the most prevalent types of acquired chorea affecting children. In patients with Sydenham's chorea a history of rheumatic fever may be common. Involuntary movements, hypotonia, speech difficulties, impairment in writing, balance difficulties, as well as other symptoms may present within 4 months following infection. Onset is likely to occur in childhood to late adolescence, and appears to be more common in females. Some have hypothesized that Sydenham's chorea is due to a cross reaction between antistreptococcal antibodies and striatal neurons. Anticonvulsants have been shown to facilitate improvement and overall outcome in patients; however, following the first attack of Sydenham's chorea as many as 37% or more of patients may experience and additional attack [8]. Prophylactic penicillin treatment may be efficacious in preventing subsequent episodes.

Dystonia

Dystonia is a rare disorder of enduring muscle contraction(s) exteriorized in sustained distortions of movement such as abnormal posturing, twisting movements, other distortions, or slowed movements in the trunk, face, or limbs. Symptoms may be sporadic and intensify with activity. Dystonias are classified as generalized, focal, multifocal, segmental, or unilateral, and may be idiopathic or be secondary to another condition such as another movement disorder, part of a hereditary degenerative disorder, toxin induced, psychogenic, or paroxysmal Drug-responsive dystonia usually presents within the first 12 years of life, and often involves the muscles of the feet. Differentiating drug-responsive dystonia from cerebral palsy is important because it can be alleviated by low doses of levodopa [11]. The most prominent form of dystonia in children is idiopathic torsion dystonia, which has a mean onset at 12–13 years of age and is believed to have a genetic basis [13]. Symptoms are typically evident in the legs prior to the arms, and may become more generalized or segmental. Anticholinergic medications may be helpful for patients with primary dystonia in alleviating symptoms, while neurosurgical treatment may be necessary for more severe presentations. In contrast, treatment with levodopa treatment has been shown efficacious in specific secondary dystonias. Treatment may vary depending on the underlying pathology.

Tics

A tic is an abrupt motor or vocal expression that is heralded by a compulsion and followed by feelings of appeasement. Vocal tics may manifest as coughing sounds, grunting, barking noises, or even through obscenities (coprolalia). Tics may be either simple or complex. Whereas simple tics are single and isolated occurrences, complex tics involve patterns or sequences of behaviors. In children, vocal and motor tics are commonly observed in Gilles de la Tourette's syndrome. Symptoms may include echopraxia, echolalia, coprolalia, palilalia, and other

motor and vocal tics. In contrast to transient tics, Tourette's syndrome tends to persist and may alternate between periods of exacerbation and relative remission. Tics may increase with stress. The male to female ratio in Tourette's syndrome may be around 4:1, with a mean age of onset around 7 years of age, and overall prevalence rates of about one percent [14]. Tourette's syndrome may have a higher than expected rate of comorbidity with other psychiatric disorders. Treatment for Tourette's syndrome involves at educating the patient and significant others. In circumstances in which a patient's symptoms become especially severe pharmacotherapy may be necessary. Dopaminergic antagonists and behavior therapy have been shown to significantly alleviate symptoms.

Stereotypies

Stereotypies refer to an array of nonpurposeful repetitive behaviors, either verbal or nonverbal, that may result in difficulty functioning or interfere with everyday activities. These behaviors may be simplistic or involve multiple parts of the body, and last for minutes in duration. Children with stereotypic movement disorder exhibit nonpurposeful and nonfunctional behavior for at least 4 weeks, their symptoms are not better accounted for by another disorder, the physiological effects of a substance, or a general medical condition, except for mental retardation if the symptoms are severe enough to warrant an additional diagnosis. In addition, these symptoms must significantly interfere with normal activities or result in self-harm [1]. Stereotypies in patients with mental retardation may include behaviors that result in self-harm such as hair pulling, eye gouging, or head banging. Stereotypies may also be observed in children with Rett's disorder in hand washing or rubbing movements. The presence of stereotypies in patients with autism spectrum disorders is common, with some children developing them before their first birthday. In children with autism finger-flicking, hand-flapping, body rocking, clapping, and head shaking may be common. Similar to patients with mental retardation, stereotypies may become self-destructive. Behavioral programs may be useful in the treatment of stereotypies by reducing the frequency of undesirable behaviors. Stereotypies may also be observed in other disorders such as schizophrenia, or as continuous stereotypy in neuroleptic-induced tardive dyskinesias.

Akinesia, Bradykinesia, and Hypokinesia

Akinesia refers to an absence of motion in a patient, whereas hypokinesia refers to a reduction of the frequency or amount of movement. Bradykinesia refers to a slowed initiation or completion of motion. Unilateral lesions to the supplementary motor area may initially result in either global bradykinesia or akinesia. Either ventral, bilateral caudate, or globus pallidus vascular lesions may result in akinesia. Right frontal lobe lesions can result in bradykinesia and left-sided hypokinesia. A form of neuroleptic-induced Parkinsonism may include symptoms of akinesia, hypokinesia, or bradykinesia. Treatment for the development of neuroleptic related akinetic symptoms may include either a reduction in dosage or the introduction of an anti-Parkinsonian medication. Other disorders featuring akinetic movements include fetal akinesia and neuroleptic malignant syndrome.

Due to basal ganglia involvement, about one third of patients with Wilson's disease develop signs of neurologic involvement including bradykinesia or hypokinesia. Other symptoms may include chorea, rigidity, tremor, dystonia, dysarthria, ballism, dysphagia, disinhibition, delusions and hallucinations, attentional difficulties, as well as other associated complications. Wilson's disease is an autosomal recessive disorder involving abnormal copper metabolism. As a result of altered metabolism, copper accumulates and affecting the brain and liver, as well as various organs throughout the body resulting in neurologic, psychiatric, and renal signs and symptoms.

Tremor

Tremors are characterized by oscillatory rhythmic movements that tend to be bidirectional. Tremors can be classified as resting tremors, postural tremors, or intention tremors. Resting tremor may be observed in a part of a patient's body while they are relaxed or stationary. Once a patient initiates movement the resting tremor will subside or attenuate. Due to the fact that resting tremor does not affect patients while they are in motion, the tremors may not directly impair daily living. Postural tremor occurs during muscle contraction, for example when actively holding a hand suspended in a particular position against gravity. Intention tremor occurs during directed goal oriented behaviors in which a patient experiences abnormal, swaying, or oscillating movements en route their intended target. The tremor typically increasing in intensity as the hand approaches its destination. Rubral tremor, in which a patient has difficulty maintaining posture or initiating movement, may be caused by brain infarcts, Wilson's disease, or multiple sclerosis. In Wilson's disease, asymmetrical resting, postural, or intention tremors are often accompanied by wing-beating movements. Rubral tremor is believed to be due abnormalities in the red nucleus or due to interruption of the fibers that traverse the red nucleus. Tremors may also be medication-induced, due to stroke, traumatic brain injury, brain stem

tumor, vitamin E deficiency, psychogenic in nature, or due to physiological reactions such as a fear response. Tremor is uncommon in children. Treatment of tremors varies depending on subtypes and underlying etiology. In patients with postural tremor β-adrenergic antagonists may be useful, while L-dopa and anticholinergics may be useful in patients with resting tremor. In patients with Wilson's disease penicillamine, trientine, or zinc acetate may be useful in alleviating tremor.

Athetosis

Athetosis refers to a cluster of abnormal involuntary movements that may include dysarthria, postural instability and impairment of postural reflexes, and other continuous, writhing, sinuous, or slow movements or impairment predominantly in the distal muscles and in the tongue, face, trunk, and neck. Athetoid movements may be associated with additional signs and symptoms depending upon the underlying pathology. These can include speechlessness, deafness, intelligence deficits, and other difficulties that are due to neurological trauma. Symptoms may manifest months or years following brain insult, and are likely to occur in the developing brain rather than adult brain. Athetosis in children may accompany medication-induced dyskinesias, lesions to basal ganglionic structures including the putamen and caudate, in kernicterus, ataxia telangiectasia, metabolic disorders, hypoxia, or in those with paroxysmal dyskinesias, as well as other disorders such as athetoid cerebral palsy. Athetosis may be differentiated from chorea by the lack of irregular, quick, and jerky movements, and is likely to involve muscles responsible for complex movements. However, if athetoid movements combine with choreic movements they are labeled choreoathetoid.

Myoclonus

Myoclonus refers to abrupt, rapid, and involuntary jerky movements of a specific muscle or group of muscles. Myoclonus can be unilateral, bilateral, or focal. There are two types of myoclonus; positive myoclonus refers to jerky spasmodic movements caused by acute muscle contractions, while negative myoclonus refers to movements or inhibitions resulting from muscle relaxation. Presentation of myoclonus is highly variable, occurring either frequently or infrequently, isolated or in a pattern, and usually occurs while a patient is at rest. However, myoclonus may be precipitated by a specific external stimuli or be self-induced through voluntary movement. Myoclonus may be mild or severe enough to disrupt daily movements and functioning. Myoclonus is further classified as action myoclonus, cortical reflex myoclonus, essential myoclonus, palatal myoclonus, progressive myoclonus epilepsy, reticular reflex myoclonus, stimulus-sensitive myoclonus, and sleep myoclonus. Myoclonus may also be classified as either epileptic or nonepileptic. Myoclonus may ensue following exposure to toxins, injuries to the central or peripheral nervous systems, be due to hypoxia, renal defects, lipid storage disorders, cancers, Creutzfeldt-Jakob disease, or in childhood disorders such as multiple sclerosis, epilepsy, and early myoclonic encephalopathy (EME). Specific anatomical structures involved may include the basal ganglia, cerebellum, cortex, brain stem, or spinal tract. A wide variety of pharmacological treatments are used to reduce symptoms of myoclonus including tranquilizers and barbiturates, but milder forms of myoclonus may not require pharmacotherapy. Myoclonus may also necessitate more than one medication depending on specific symptom presentation and underlying etiology.

EME is a rare epileptic disorder that develops usually within the first 3 months of life, and is typically characterized by sporadic, fragmentary myoclonus and other types of seizures, delays in psychomotor development, and hypotonia. Symptom presentation may become more complicated with increasing age. A suppression burst pattern is often observed during electroencephalography in patients with EME, and may be of diagnostic utility in differentiating if from other epileptic disorders. EME may be idiopathic or associated with metabolic defects such as nonketotic hyperglycinemia, D-glyceric academia, propionic academia, Menke's syndrome, molybdenum cofactor deficiency, and methylmalonic academia. Magnetic resonance imaging and laboratory workup may be helpful in determining underlying pathology and aid in differential diagnosis. When understood, targeting of the specific originator(s) with pharmacological treatment can prevent EME symptom expression. Although aggressive treatment may be beneficial, overall prognosis is poor with frequent death before the age of one with approximately 50% mortality before the age of two [12].

Paroxysmal Dyskinesias

Paroxysmal dyskinesias (PxD) refer to rare hyperkinetic disorders that manifest during consciousness that are typically characterized by fleeting symptoms such as dystonia, chorea with ballismus, or choreoathetosis. Dystonia may be most prevalent. Dyskinetic movements are more often unilateral than bilateral. Paroxysmal dyskinesias include kinesigenic or nonkinesigenic, hypnogenic, choreoathetosis with episodic ataxia and spasticity, benign paroxysmal torticollis of infancy, or exertion-induced. Attacks may last for as long as days or be seconds in duration, and may be precipitated by a specific trigger.

Some patients may experience an aura preceding an attack. Paroxysmal kinesigenic dyskinesias may be more frequent in males than in females ranging from 3 or 14:1, respectively. Paroxysmal dyskinesias most commonly present from childhood to adolescence, and onset may vary from days to years depending on the underlying pathophysiology. Paroxysmal dyskinesias may be observed as early as two and one half years of age or younger. Exertion-induced PxDs and paroxysmal kinesigenic dyskinesias appear to be associated with epilepsy in children. Although exact etiology is not uniform, several genetic loci have been implicated [3]. In addition to idiopathic and familial PxDs, manifestations may stem from peripheral or central trauma, vascular lesions, kernicterus, multiple sclerosis, metabolic abnormalities, or other types of insults. A specific treatment is not established; however, anticonvulsants, clonazepam, or botulinum toxin injections may be effective treatments for specific patients. Anticonvulsants may be more effective for patients with paroxysmal kinesigenic dyskinesias than those with paroxysmal nonkinesigenic dyskinesias.

Primary Ciliary and Biliary Dyskinesias

Primary ciliary dyskinesia, most often an autosomal recessive genetic disorder, stems from ultrastructural defects of the cilia that are believed to produce a mucociliary clearance dysfunction. The abnormal mucociliary clearance may affect both the upper and lower airways and is often associated with respiratory symptoms, chronic infections, airway obstruction, chronic respiratory airway disease, as well as other complications.

Biliary dyskinesia, hypothesized to be due to dysfunction of the sphincter of Oddi, is diagnosed if symptoms associated with biliary colic are present without the presence of gallstones. Patients with biliary dyskinesia may suffer from abdominal pain, intolerance to fatty foods, flatulence, nausea, vomiting, fatigue, or other symptoms. A cholecystokinin test with measuring ejection fraction is often useful for making diagnosis. Laparoscopic cholecystectomy has been shown to be very efficacious in relieving associate symptoms in more than 70% of patients [5].

Neuroleptic-Induced Dyskinesias

Neuroleptic related dyskinesias may range from mild to severely incapacitating, and transient or chronic in course. To increase diagnostic homogeneity and facilitate a more uniform communication of research, a set of six provisional categories for tardive dyskinesia (TD) we developed. These categories were constructed to provide information regarding observable changes in the expression of dyskinesia, temporal relation to symptoms, signs, and medication, and alterations to medication dosage. To meet criteria for *probable* TD patients should have a history of neuroleptic use for a period of at least 3 months, must present with moderate dyskinetic movements, the symptoms should not be better accounted for by another disorder associated with abnormal movements, and the patient may or may not be currently receiving pharmacotherapy. Criteria for *masked probable* TD is met when criteria is fulfilled for probable TD; however, following an increase in dosage level moderate dyskinetic movements are no longer present. When criteria is met for probable TD, without the presence of moderate dyskinetic movements following a 3 month period, and the patient is not currently being treated with neuroleptics or dosage levels have not been raised (applies to patients currently receiving neuroleptics) a diagnosis of *transient* TD may be given. A diagnosis of *withdrawal* TD is applicable when there are no observable dyskinetic movements during pharmacotherapy, but symptoms arise within 2 weeks after cessation of treatment. Withdrawal TDs are often reversible and may also be accompanied by other withdrawal features such as nausea and vomiting. To meet criteria for *persistent* TD all criteria for probable TD need to be met for more than 3 months. Lastly, *masked persistent* TD is present if all criteria are met for persistent TD, however, within 3 weeks following either an increase in dosage level, or with the resumption of medication for those not currently on medication, moderate abnormal movements are no longer present [15].

The primary indication for prescription of neuroleptic medication is for the treatment of psychosis. However, in adolescents and children neuroleptics may also occasionally used to treat anxiety disorders, mood disorders, behavioral disorders, hyperkinesis, to attenuate undesirable behaviors associated with mental retardation and autism, and for other neurological and gastrointestinal disorders. Although it is understood that dyskinesias may be related to neuroleptic use, the exact underlying mechanisms are not completely understood. Evidence suggests that TD may be due to dysfunction in the dopamine system. In addition to neuroleptic-induced dyskinesias, other medications that block dopamine receptors such as selective serotonin reuptake inhibitors (SSRIs), antihistamines, calcium channel blockers, as well as other medications such as anticonvulsants may be associated with the development of TD or dyskinetic movements.

Evidence suggests higher rates of dyskinesia associated with typical versus atypical antipsychotics in both children and adolescents. Cumulatively lower dosages and temporal exposure to antipsychotics in children may explain

their lower incidence of tardive dyskinesia compared to adults. Neuroleptic-related withdrawal symptoms may also not be a significant risk in younger populations [9, 16]. However, duration and dosage do not necessarily dictate whether or not dyskinetic movements will manifest. Patients may develop dyskinetic movements without long exposure to neuroleptics or may never develop signs of dyskinesia after long-term neuroleptic use. In patients with childhood-onset schizophrenia, greater premorbid impairment, positive symptoms, and subsequent greater exposure to neuroleptic treatment may be risk-factors for the development of either tardive or withdrawal dyskinesia [10]. Some evidence supports a relationship between pre and perinatal complications with the development of tardive and withdrawal dyskinesias [2]. Lower IQ may also be a risk factor for developing antipsychotic related dyskinesias [4]. Neuroleptics such as clozapine and haloperidol may suppress dyskinetic symptoms, but withdrawal dyskinetic symptoms may reemerge with subsequent cessation of drug treatment. Anticholinergic medications may suppress symptom manifestation in as little as 30 min, and are the primary treatment for tardive dyskinesia.

Dyslexia

Sherry Mee Bell, Tamara Bowlin
University of Tennessee, Knoxville, TN, USA

Synonyms

Developmental dyslexia; Reading disability; Reading disorders; Word blindness

Definition

The term *dyslexia* refers to a ▶learning disability in reading characterized by weak decoding skills, slow reading speed, and poor spelling. Dyslexia is *not* due to limited intelligence, poor instruction or brain damage.

Description

According to Sally Shaywitz of the Yale Center for the Study of Learning and Attention, dyslexia is the most common type of learning disability [1]. Individuals with dyslexia exhibit difficulty with reading, writing and spelling. Historically, people thought of dyslexia as a visual problem reflected primarily by the reversals in reading and spelling [1]. However, the reversals exhibited by struggling readers and writers tend to be caused more by problems with auditory memory, sequencing, and sound-letter association than by visual perceptual problems per se [2]. Dyslexia, as described in the formal definition adopted by the

International Dyslexia Association is "characterized by difficulties with accurate and/or fluent word recognition and by poor spelling and decoding abilities. These difficulties typically result from a deficit in the phonological component of language that is often unexpected in relation to other cognitive abilities and the provision of effective classroom instruction. Secondary consequences may include problems in reading comprehension and reduced reading experience that can impede the growth of vocabulary and background knowledge" [3].

A prominent characteristic of dyslexia is difficultly decoding single words, usually associated with weaknesses in phonological processing. Individuals who have dyslexia typically have difficulty recognizing and manipulating individual units of sound (►phonemes) within the spoken language. They may also have difficulty recognizing rhyming words and breaking words into syllables. In addition to difficulty with phonological aspects of language, individuals most at risk for dyslexia also have difficulty with rapid automatic naming (RAN) tasks. That is, they have difficulty quickly and accurately recognizing and naming series of visually presented information such as familiar objects, numbers and letters. Individuals who have both phonological and rapid naming deficits are most at risk for reading difficulty, according to Maryanne Wolf, proponent of the "double deficit hypothesis" of dyslexia [4].

For many years dyslexia has baffled the educational and medical communities and has been the subject of debate. However, there is a consensus on several points. Researchers tend to agree that dyslexia is a language-based learning disability of biological origin, which can persist into adolescence and adulthood. Dyslexia has perceptual, cognitive, and language dimensions. While persons with dyslexia have problems with decoding, they exhibit typical functioning in many other cognitive and academic areas [5]. In fact, Shaywitz refers to dyslexia as a weakness in a "sea of strengths" (p. 58) [5].

Growing research evidence indicates that there is a neurological basis for dyslexia [6]. Genetics studies (i.e., studies examining incidence of dyslexia in families and in twins) indicate that reading disabilities tend to be inherited. Further, results of brain imaging (►functional magnetic resonance imaging or fmri) studies show that individuals with dyslexia tend to process information while reading in different areas of the brain than those not identified. Specifically, individuals with dyslexia rely more than same-age normally reading peers on the parts of the brain involved with sounding out and analyzing words and less on regions associated with automatic recognition of words. Encouragingly, some fmri research has shown changes in brain functioning after children with dyslexia participated in academic interventions designed to improve automatic word recognition. Though neurobiological in origin, dyslexia is not a result of disease or brain damage. Rather, it occurs normally in a small percent of the population and is observed across cultures and languages. Estimates range from as low as 5% to as high as 25% of the population, depending on severity.

Diagnosing Dyslexia

Though brain imaging studies yield valuable information about the neurobiological underpinnings of dyslexia and the reading process, it is premature to use this technology for diagnostic purposes. When a parent or teacher suspects dyslexia, a referral should be made for a psychoeducational evaluation by a psychologist or educator with expertise in assessment and remediation of dyslexia. Unfortunately, there is no single, valid, assessment instrument that yields measures of all the relevant skills and abilities [2]; consequently examiners must select from several assessment batteries. Diagnosis requires assessment of academic skills (sight word recognition, phonetic word decoding, reading fluency, reading vocabulary and comprehension and spelling) and cognitive skills (phonemic awareness, rapid automatic naming speed, and short term and working memory and long term retrieval). Language skills and fluid reasoning (i.e., visual spatial abilities) should also be assessed. And finally, detailed family and educational history yield highly relevant information for diagnosis. It is important to rule out inappropriate or insufficient teaching as a cause of reading problems before considering difficulties within the child.

Interestingly, a link between dyslexia, creativity, and/or visual-spatial strengths has been noted anecdotally by many and by several researchers [1, 7]. For example, John Irving, bestselling author (*The World According to Garp* and *The Cider House Rules*), Charles Schwab, CEO of a large and successful investment services corporation, and Patricia Polacco, bestselling children's author (*Thank You Mr. Falker*) all describe themselves as having dyslexia. Wolf makes a compelling case that Michelangelo had dyslexia [7].

Remediating Dyslexia

If persons with dyslexia are to successfully learn to read, early assessment and intervention are critical [8]. To avoid reading failure, preventive and early intervention techniques should be implemented in kindergarten and first grade. Fortunately, there are a variety of effective teaching techniques for students with dyslexia. The Center for the

Study and Treatment of Dyslexia recommends "explicit instruction in phonological awareness, ample repetition and practice to assure learning to mastery, very small increments in new linguistic concepts, integrated decoding and spelling, and direct systematic teaching of all aspects of the sounds of English" (p. 1) [9]. Interventions that focus on improving reading fluency (i.e., speed, accuracy and prosody) have received increasing attention [10]. In addition, technology including hand-held spell check devices and computers with text-to-speech capabilities are increasingly available. Individuals with dyslexia may be eligible for technological assistance from Recordings for the Blind and Dyslexic [11]. Research indicates a balanced approach to reading instruction (i.e., emphasis on both basic reading skills and reading for comprehension) is the most effective for most students [10]. However, extra instruction in basic reading skills and fluency may be required for students with significant dyslexia characteristics. With early intervention, individuals with dyslexia can make significant gains in reading and related skills. And, as they progress through school, use of technological innovations can help decrease barriers to learning that otherwise negatively affect self-esteem.

Dysmorfia

▶Dysmorphia

Dysmorphia

Ashlea Smith
Phoenix College, Phoenix, AZ, USA

Synonyms

Beauty hypochondria; Body Dysmorphic Disorder (BDD); Dysmorfia; Dysmorphic; Dysmorphophobia; Dysmorphic syndrome; Dysmorphology; Muscle dysmorphic disorder

Definition

Dysmorphia, from the Greek word dysmorfia, is the congenital malformation or the perceived belief that a bodily part is abnormally shaped, disfigured, or flawed that can tend to lead to a preoccupation with one's appearance.

Description

The classification of the term dysmorphia can be viewed in two different lights. The first incorporates the medical model as a physical medical condition where one is born with a birth defect (e.g. congenital). For example, when an individual is born with a malformed ear or limb it would be medically termed as a dysmorphic feature. On the other hand, strongly based out of a psychological perspective, defines dysmorphia as a slight or imagined defect in one's appearance. This obsession with an anomaly in one's appearance and body image can lead to a mental disorder called Body Dysmorphic Disorder (BDD). The DSM-IV-TR (Diagnostic and Statistical Manual of Mental Disorders, 4th Ed., Text Revision) [1] defines BDD as (a) an obsession with an imagined defect in appearance, (b) the flaw causes major distress in all areas of functioning, and (c) the signs and symptoms are not otherwise explained by another existing psychiatric disorder. Individuals with dysmorphia can develop particular grooming rituals and behaviors as a way to disguise or hide their perceived flaw in their appearance, such as wearing excessive make-up, baggy clothing, or using a limb to cover the body part as some examples. BDD joins the category of Somatoform disorders, which are mental disturbances

with co-occurring physical complaints such as pain or nausea etc. that cannot be explained by a general medical condition [7]. Diagnosis of a Somatoform disorder implies that the root of an illness is based out of psychology distress; otherwise explained by psychosomatic symptoms. The most common areas of focus are: "facial features, skin blemishes, thighs, stomach, breasts, buttocks, and genitals", but virtually any part of the body can be viewed as being the defect [2, p. 66]. Additionally, observers usually do not notice the source of imperfection although the flaw is magnified for the person experiencing the dysmorphia. In general, BDD affects 1% of all adults from the population, with students accounting for 2% to 13% of those diagnosed, and 13% of patients in psychiatric facilities [5]. Many people with dysmorphia, especially those with BDD, often seek out treatments such as cosmetic surgery and dermatologic treatments to fix what they perceive as a physical problem when in reality mental health practitioners are needed to cope with a psychiatric problem.

The causes of dysmorphia can be linked to several different factors. The cause is not entirely known, but theories suggest people with strong body image dissatisfaction, the experience of childhood trauma or teasing, or genetic hereditary factors may contribute to this form of dysmorphia [3]. Body image concerns are commonplace, especially for young girls and women. It is when these concerns are markedly excessive and consume one's ability to function properly in everyday life constitutes dysmorphia, which can lead to a more serious psychiatric condition BDD.

Relevance to Childhood Development

As children progress into the adolescent stage of development when developing one's identity and a sense of conformity are at the forefront; body image and appearance can be used to measure one's sense of self worth. During adolescence, some can experience teasing related to whether or not their body size, body weight, or appearance mimic those often preferred by peer groups or societal standards of beauty. If one experiences teasing because of their lack of ability to model these preferred ideals, potentially a child could be at risk to develop signs and symptoms of dysmorphia. It is quite common for signs of early onset BDD to begin during the adolescent years. In recent studies, 30% of adolescents would consider having cosmetic surgery themselves as a means to correct some type of perceived flaw or defect (e.g., dysmorphia) with also 68% know someone who has already undergone cosmetic surgery [4]. Adolescents with dysmorphia can develop these grooming rituals and behaviors early on as a method to camouflage the imagined flaw in their appearance, which can potentially lead to the pursuit of medical interventions like cosmetic surgery as a means to "fix" the defect upon entering adulthood.

Dysnomia

Denise E. Maricle
Texas Woman's University, Denton, TX, USA

Synonyms

Anomia; Word finding; Word retrieval

Definition

Dysnomia is a difficulty with, or inability to, retrieve the correct word from memory when need.

Description

Dysnomia impairs an individual's ability to recall words, names or objects. Normal individuals often have some difficulty recalling words, which is often referred to as the "tip of the tongue phenomenon", but dysnomia is more severe and interferes with daily life. A person with dysnomia exhibits normal speech but has severe difficulty in recalling words, names, or objects needed for oral or written communication [9]. Individuals with dysnomia exhibit word finding difficulties characterized by word finding pauses, circumlocution, faulty word selection or the replacement of the word with a synonym in an attempt to express their thoughts without using the word they are having difficulty retrieving, as well as difficulty naming objects and recognizing objects by name [6]. The terms anomia and dysnomia are often used interchangeably [8]. The difference between dysnomia and anomia (defined as the complete inability to name familiar objects) is the degree of dysfunction, such that individuals with dysnomia exhibit a lesser degree of dysfunction than do individuals with anomia. Dysnomia can be a symptom of another disorder, or a long term condition [1]. Dysnomia is often a symptom of conditions and illnesses such as alcohol intoxication, electrolyte imbalance or low blood sugar, concussion, hyperthermia, hypothermia, and hypoxemia, or as a side effect of certain drugs. Dysnomia can be a long term condition as a result of a learning disability, dementia, a brain injury (TBI, CVA), or aging.

Relevance to Childhood Development

In children, the term dysnomia appears most commonly in reference to learning disability, but word finding problems may be seen in students with reading problems, language difficulties, and attention problems, as well as with children with known brain pathology [1]. Lerner [7] reported that students with learning disabilities retrieve words significantly slower than peers and that their word finding problems are life-long sources of difficulty in reading and learning. Word finding difficulties have also been identified in children with specific language difficulties. These children have word finding difficulties in single word retrieval, connected discourse, or both. Word finding difficulties are also common sequelae in acquired or congenital brain injury and are often associated with other memory deficits. Word finding deficits associated with brain injury are most commonly seen with left hemisphere cerebral damage.

Formal assessment of a child's word finding difficulties is needed to develop an individualized intervention plan. Several instruments have been developed specifically to assess word finding. The *Test of Word Finding-Second Edition* (TWF-2) [3] is designed for children ages 4–12 and is fairly sound psychometrically. The *Test of Adolescent and Adult Word Finding* (TAWF) [4] is designed for individuals aged 12–80 and although psychometrically sound its normative population is relatively old (obtained in the 1980s). The *Boston Naming Test*, a part of the *Boston Diagnostic Aphasia Examination-Third Edition* [5] assesses word finding difficulties in adults. Research has shown that rapid automatized naming tasks that measure the ability to rapidly name common objects, letters, digits, and colors, or retrieve words provides an adequate measure of dysnomia in children [2]. Variations of tasks of rapid naming can be found on several standardized measures of intelligence and achievement used with children and adolescents. For example Naming Facility (RAN) on the *Kaufman Test of Educational Achievement-Second Edition* (KTEA II) or Retrieval Fluency and Rapid Picture Naming on the *Woodcock Johnson III Normative Update: Tests of Cognitive Abilities* (WJ III COG NU). Intervention in word finding difficulties needs to be comprehensive with respect to its focus and application. A comprehensive intervention program for a child should focus on three areas: retrieval strategy instruction, self advocacy instruction, and word finding accommodations [2].

2004 Education for All Handicapped Children Act

Lynna Lan Tien Nguyen Do
Walden University, Fremont, CA, USA

Synonyms

Individuals with disabilities education act (IDEA)

Description

Education for All Handicapped Children (EAHC) was first introduced in 1974. The reason that this law was first enacted was that in 1974 many states had laws that explicitly excluded children with certain types of disabilities from attending public school, including children who were blind, deaf, and children labeled "emotionally disturbed" or "mentally retarded."

The EAHC is now known as the Individual with Disabilities Education Act (IDEA). The IDEA is a federal law which ensures early intervention, special education, and other related services for individuals' with disabilities. It addresses the educational needs of children with disabilities from birth to the age of 21. The reauthorization of IDEA in 2004 revised the statute to align with the requirements of the No Child Left Behind Act (NCLB). NCLB allows financial incentives to states who improve their special education services and services for all students. States who do not improve must refund these incentives to the federal government, allow parents choice of schools for their children, and abide by other provisions. Some states are still reluctant to educate special education students and seek remedies through the courts. However, IDEA and NCLB are still the laws of the land to date.

Legislative History

1974 – The Education for All Handicapped Children Act (EAHCA) became LAW. It was renamed the Individuals with Disabilities Education Act (IDEA) in 1990.

1990 – IDEA first came into being on October 30, 1990 when the "Education of All Handicapped Children Act" (itself having been introduced in 1975) was renamed "Individuals with Disabilities Education Act." (Pub. L. No. 101–476, 104 Stat. 1142). IDEA received minor amendments in October 1991 (Pub. L. No. 102–119, 105 Stat. 587).

1997 – IDEA received significant amendments. The definition of disabled children expanded to include developmentally delayed children between 3 and 9 years of age. It also required parents to attempt to resolve disputes with schools and Local Educational Agencies (LEAs) through mediation, and provided a process for doing so. The amendments authorized additional grants for technology, disabled infants and toddlers, parent training, and professional development. (Pub. L. No. 105–17, 111 Stat. 37).

2004 – On December 3, 2004, IDEA was amended by the Individuals With Disabilities Education Improvement Act of 2004, now known as IDEIA. Several provisions aligned IDEA with the No Child Left Behind Act of 2001. It authorized fifteen states to implement 3-year IEPs on a trial basis when parents continually agree. More concrete provisions relating to discipline of special education students was also added. (Pub. L. No. 108–446, 118 Stat. 2647).

Early Academic Skills

►Learning Readiness

Early Childhood

Judah B. Axe
Simmons College, Boston, MA, USA

Synonyms

Infancy

Definition

The period of development from 2 to 6 years of age.

Description

Development

The early childhood period of development is when a child is between 2 and 6 years of age. Physical development during this period is marked with the slowing of body growth rate, increases in fine and gross motor skills, and increases in brain development. Cognitively, children learn to form stable concepts and begin developing mental and symbolic reasoning. Children also develop intuitive thought which explains why they ask many "why" questions. In terms of social development, tantrums are common at the outset of early childhood as children seek greater autonomy. Conscience, gender, and morality develop primarily through interactions with peers and adults.

Education

Early childhood educational programs exist for children from birth to age 8. Language, cognitive, motor, sensory, emotional, and social development are all targeted in early childhood programs. Teaching is often child-centered and focused on learning through play. Families are involved in early childhood programming. Different psychological and educational theories drive early education practices. Two developmental psychologists having a strong impact on early education are Jean Piaget and Lev Vygotsky. Piaget's

main contribution was clustering learning events into four stages of development: the Sensorimotor Stage, the Pre-Operational Stage, the Concrete Operations Stage, and the Formal Operations Stage. The early childhood years subsume the Pre-Operational Stage marked by increases in the development of intelligence, memory, imagination, and egocentrism. Developmentally-appropriate practice is a hallmark of early childhood programs and is achieved by providing classroom experiences with learning concepts typical of the age of the children. Constructivism is a Piagetian educational theory postulating that children form their own meaning and knowledge through interactions with their environment. Vygotsky contributed the notion of teaching in the zone of proximal development, or a level just past the mastery level of the child. Examples of curricula based on constructivism are High/Scope and The Creative Curriculum. Montessori education is based on a maturational theory of learning and the Reggio Emilia approach is a blend of constructivism and maturationism. These programs all share the notion that children learn through their own experiences rather than through instruction from a teacher.

Behavioral psychology, on the other hand, suggests that early childhood educators should directly and explicitly teach skills to children. Direct Instruction approaches to reading, math, and language instruction, such as Distar and Reading Mastery, are common behavioral educational approaches. Head Start, a school readiness preschool program for young children from families with low incomes, has provided comprehensive education, health, nutrition, and parental involvement for nearly 25 million children since its inception in 1965. Young children with disabilities are educated under the Individuals with Disabilities Education Act (IDEA). From birth to age 3, the Individualized Family Service Plan is the contract that stipulates services provided to a child and the family, such as speech and occupational therapy services. When a child turns three, services are provided through IDEA by the school district and the Individualized Education Program is the legal document specifying services. Educational services for children with disabilities from birth on are provided by the states at no cost to families.

Early Head Start

Caroline McKnight
University of North Carolina,
Chapel, NC, USA

Definition

Early Head Start is a federal program created by the Administration on Children, Youth and Families (ACYF) in 1995 as a downward extension of Head Start to include infants and toddlers. The focus of Early Head Start is to promote the development of infants and toddlers with low income backgrounds with a strong emphasis on strengthening families.

Description

Early Head Start, under the umbrella of Head Start, is a community-based program based upon nine principles: a dedication to high quality; prevention of developmental concerns and promotion of health, child and family development; positive relationships with children and their families and continuity of care; encouragement of high levels of parent involvement with particular importance paid to the role of fathers; full inclusion of children with disabilities; respect for the home culture and language of the child and family; comprehensiveness, flexibility, responsiveness and intensity of services provided; establishment of effective transitions to Head Start or other child care programs; and collaboration with agencies within the community and other service providers. The overarching goal of Early Head Start is to improve children's competence in all areas of development. This goal is reached through the enhancement of children's growth and development, relationships between parent and child and supporting families.

To ensure effective service delivery, Early Head Start programs may choose to meet the needs of the children and families through a variety of means. Depending upon the needs of the family, the program may provide home-based services, center-based services, a combination of home-based and center-based as well as locally designed services.

In general, Early Head Start programs are characterized as urban and rural, and are run by non-profit agencies. Although many races and ethnicities are represented in programs, the majority of programs are comprised of Whites, African-Americans and Hispanics. Many of the children and families come to the programs with several risk factors such as single parenthood, unemployment and lack of a high school diploma or credential.

Research has shown that Early Head Start may reduce the risk of cognitive deficits and poor academic outcomes. Other areas of positive influence include children's vocabulary development, social–emotional development, parents' self-sufficiency, father–child interactions and parents' emotional support of their children.

Relevance to Childhood Development

Early Head Start fills a need in service provision to infants and toddlers of low-income backgrounds and their families. For many families, Early Head Start programs are their first crucial link to more positive development across the lifespan. It is a program that helps ensure access to quality child care as well as assisting the child in a larger context of the family.

Early Intervention

Carrie R. Ball
Ball State University, Muncie, IN, USA

Synonyms

Abecedarian project; Prevention; Response-to-intervention

Definition

Early intervention can be defined as the process of detecting early warning signs of potential problems and providing immediate treatment to minimize the impact.

Description

Early intervention is typically practiced within a prevention-oriented approach to service delivery. Prevention technically occurs prior to any demonstration of symptoms, with early intervention initiated at the earliest sign of a potential problem. The two concepts are closely related and are typically provided along a continuum of services. The purpose of providing early intervention is to prevent the development of more serious and costly problems. That is, by focusing on identification of early warning signs and immediate treatment to address the symptoms, more severe and longstanding difficulties can be avoided or minimized.

One hallmark of early intervention models is the incorporation of universal screening procedures [3]. Screening allows identification of early warning signs, measurement of the severity of risk, and potential direction for early intervention services. The specific type of screening depends primarily upon the target problem and the environment in which screening and early intervention occurs. Early intervention within the context of child development is most commonly encountered in medical and educational settings.

Early intervention initiatives have become a central feature of pediatric medicine, particularly with the growing emphasis on managed care and wellness. The American Academy of Pediatrics recommends routine screening for a variety of health-related and developmental difficulties. Examples of screening procedures used in many primary medical care settings include prenatal and neonatal blood tests, tests for exposure to lead, typical development questions during office visits, and regular monitoring of growth. Some pediatricians even administer structured Autism screening questionnaires. When difficulties or significant symptoms are detected, doctors are able to use screening data to make a referral for further evaluation or early intervention. In medical settings, early intervention can take the form of referral to another provider, behavioral consultation, educational classes, support groups, or mental health services [1].

In educational settings, early intervention services have been slower to develop. In fact, until recently, most attempts at early intervention in the schools have been fairly unsystematic. Over the past decade, however, guidelines and frameworks have been developed and implemented in schools to target difficulties related to behavioral [2] and academic skill development. Most educational models utilize a multi-tiered, or response-to-intervention, framework [4, 5]. Such models emphasize evidence-based preventative efforts, universal screening, and increasingly intensive early interventions for children identified as being at-risk. Educational models also include frequent progress-monitoring of at-risk students to document the effectiveness of early intervention services. Although relatively new to the educational setting, early intervention models have demonstrated strong efficacy for preventing and remediating early behavioral and academic difficulties.

Relevance to Childhood Development

Most widely applied early intervention services target young children. In fact, the goal of intervening at the

first sign of difficulty necessitates identifying the symptoms as early as possible. Problems related to developmental delays, learning difficulties, or development of behavioral competence are often detectible in very young children. Understanding the process of universal screening and early intervention can help childhood development professionals and parents to become strong advocates for children with regard to ensuring the highest quality services as soon as a problem is evident.

Early intervention in educational contexts also stands in stark contrasts to a more traditional, reactive approach to identifying difficulties. The more proactive early intervention framework has utility for supporting and successfully educating all students. Educational professionals who understand the efficacy and potential cost-benefit of early intervention may consider adopting a response-to-intervention approach to service delivery.

Eating Disorders

Jennifer N. Hall[1], Chad A. Noggle[2]
[1]University of Central Arkansas, Conway, AR, USA
[2]SIU School of Medicine, Springfield, IL, USA

Synonyms

Anorexia nervosa; Binge eating disorder; Bulimia nervosa

Definition

Anorexia Nervosa: Anorexia is a serious, potentially life-threatening eating disorder characterized by self-starvation and excessive weight loss in response to a significant disturbance in body size and shape perception [7].

Bulimia Nervosa: Bulimia Nervosa is a food obsession associated with repeated episodes of binge eating followed by compensatory mechanisms to prevent weight gain (e.g., forced vomiting, prolonged fasting, excessive exercising, and/or abuses of laxatives, enemas, or diuretics) [2, 5, 9].

Binge Eating Disorder: Binge Eating Disorder is a relatively, newly recognized eating disorder that falls under the DSM criteria of Not Otherwise Specified and is characterized by frequent episodes of uncontrolled "binge" eating of large amounts of food. It is much like bulimia except individuals do not engage in compensatory measures to prevent weight gain [2].

Description

Anorexia Nervosa is characterized by a morbid fear of being overweight that leads to self-starvation, a refusal to

maintain 85% of normal body weight for their age and height, a profound fear of weight gain, a body image disturbance, a cessation of menstrual periods in women (i.e., amenorrhea), and a decreased interest in sex. When anorexia presents in childhood and/or adolescence, rather than weight loss, there may be a lack of making appropriate weight gains expected with development [2]. Many anorexics also exercise compulsively to lose weight while others use laxatives or induce vomiting [2, 4]. Individuals with anorexia typically weigh themselves repeatedly, portion food carefully, and eat only very small quantities of only certain foods. Some other symptoms include:

- Dramatic weight loss
- Preoccupation with weight, food, calories, fat grams and dieting
- Refusal to eat certain foods, progressing to restrictions against whole categories of food
- Frequent comments about feeling "fat" or overweight despite weight loss
- Anxiety about gaining weight or being "fat"
- Denial of hunger
- Development of food rituals, excessive chewing, rearranging food on a plate
- Consistent excuses to avoid mealtimes or situations involving food
- Excessive, rigid exercise regimen
- Withdrawal from usual friends and activities
- In general, behaviors and attitudes indicating that weight loss, dieting , and control of food are becoming primary concerns [2, 7]

Doctors first observed bulimic behavior in several anorexics in the late 1940s, but bulimia was not widely studied until 1980, when the American Psychological Association developed its diagnostic criteria [9]. Bulimia is a cycle of bingeing and purging [5, 9]. During a binge, bulimics may consume anywhere from 3,000 to 5,000 calories in a 2-h period. To control their weight they purge, usually by vomiting, but also by strenuous exercise, restrictive dieting or fasting, and the use of laxatives, diuretics, or diet pills. These episodes occur at least twice a week for 3 months [2]. Depression, thoughts of suicide, and self-induced injuries such as cigarette burns and cutting often accompany this disease. Many bulimics steal money or food to go on binges. Some take syrup of Ipecac to help induce vomiting. Individuals usually feel out of control during a binge-episode. Food is used to numb feelings and help cope with daily life stressors. Unlike anorexia, bulimics are often at or slightly above their normal body weight and have regular menses [8].

Some additional symptoms include:

- Evidence of binge-eating, including disappearance of large amounts of food in a short periods of time or the existence of wrappers and containers
- Evidence of purging behaviors, including frequent trips to the bathroom after meals, signs/and or smells of vomiting, presence of wrappers or packages of laxatives or diuretics
- Excessive, rigid exercise regimen
- Unusual swelling of the cheeks and jaw area
- Scarring on the back of the hands and knuckles from self-induced vomiting
- Discoloration, staining of the teeth
- Creation of complex lifestyle schedules or rituals to make time for binge-and-purge sessions
- Withdrawal from usual friends and activities
- In general, behaviors and attitudes indicating that weight loss, dieting, and control of food are becoming primary concerns [2, 7]

Most bulimics begin to purge during their late teens, although some don't being until their thirties, forties, and fifties. Others may develop bulimia for a brief time during their late adolescence, give it up, and resume it years later [1, 2, 7]. Like anorexia, bulimia was considered a problem of middle-and upper-class Caucasian women, but researchers today recognize that the problem cuts across boundaries of socioeconomic level, race, and gender [1].

Relevance to Childhood Development

In recent years, the visibility of eating disorders among adolescents and young adults has increased [6]. The typical onset of these disturbances is often marked at the onset of adolescence with 86% reporting onset of illness by age 20 (10% reporting onset at 10 years or younger, 33% reporting onset between ages of 11 and 15, and 43% report onset between ages of 16 and 20) [10, 11]. Both anorexia and bulimia appear to be a reaction to society's emphasis on thinness and exercise [3, 9].

The physical and emotional demands placed on the individual suffering with an eating disorder are far reaching. Anorexia involves denying the body of essential nutrients it needs to function normally. This "slowing down" can have serious medical consequences. A slower heart rate and lowered blood presser increases the risk for heart failure. Bone density decreases and result in an increased risk for osteoporosis. Severe dehydration is common which can result in kidney failure. Overall, there is a feeling of fatigue, overall weakness and an increase in

fainting spells. Additionally, dry skin and hair loss is common. A downy layer of hair called "lanugo" sometimes develops in an attempt to maintain body heat [1].

Bulimia nervosa is extremely harmful to the body. The recurrent binge-and-purge cycles can affect the entire digestive system and can lead to electrolyte and chemical imbalances in the body that affect the heart and other major organ functions [7]. Frequent vomiting increases the likelihood of inflammation and rupture of the esophagus. Chronic irregular bowel movements and constipation occur as a result of laxative abuse. An increased potential for gastric rupture also exists. Tooth decay and staining from stomach acids is prevalent due to the acids released during frequent vomiting [1].

Binge eating disorder often results in some health risks associated with clinical obesity. Some of the potential health consequences include high blood pressure, high cholesterol levels, heart disease, secondary diabetes and gallbladder disease [7].

Ebonics

Stacy A. S. Williams
State University of New York at Albany, Albany, NY, USA

Synonyms

African American English; African American Vernacular English; Black Dialect; Black English; Black English Vernacular; Black Language

Definition

Ebonics is the linking or the combination of the terms Ebony (meaning Black) and phonics (referring to sound) and is the term used to define Black speech.

Description

In 1973 psychologist Robert L. Williams introduced the term Ebonics to define the language usage of some in the African-American community. Williams' earlier work was largely based on his analysis of African American children's language usage. In his 1975 publication of *Ebonics: The True Language of Black Folks,* Williams documented the distinctive linguistic patterns and codes spoken by his participants. In addition, Williams documented grammatical and lexicological differences between the language of his subjects and those of mainstream society [4]. Some researchers have hypothesized that Black speech has its roots in African languages and/or sounds originating from West African Hamito-Bantu languages that have been altered over time [1]. Hence, Ebonics or Black speech may be defined in terms of its features that delineate a "pattern of grammar, morphology, semantics, syntax, and phonology in speech used by culturally identified African-Americans" ([7], p. 68). While Ebonics is used as a method of communication, it is also used as a cultural marker [1]. However, to define Ebonics by only its features is to miss the richness of the language defined by the characteristics of the nonverbal gestures, the rhythmic and emotional quality of the speech often referred to as language style [4, 8].

The Oakland Debate

The Ebonics debate is often shrouded in the school board of the Oakland Unified School District in California's resolution to use the home language of its African American students as a bridge to learning Standard American English. While linguists have documented for

years the validity of Ebonics as a rule-governed language form, the discussion of Ebonics in the media crucified the language at its core, invalidating not only the structures but vilifying speakers of the language. News pundits and media outlets, without the aid of expert opinions, quickly denigrated Ebonics as something that was less than. A deficiency perspective permeated the media and the home language of some African American students was relegated to that of a slang or bad English [1, 7].

Due to the failure of large groups of African-American students in the Oakland School District, a Task Force on the Education of African-American Students was appointed by the school board to address serious educational problems. African-American students comprised 53% of the total school population; however, they were overrepresented in special education programs and underrepresented in gifted programs. Additionally, on average they had a grade point average of 1.80 on a 4.00 point scale, the lowest grade point average for any ethnic group in the district. While the Task Force produced a 24-page document focusing on a variety of solutions, the one issue that occupied the school board's attention on December 18, 1996 was the recognition of Ebonics as an independent language that was genetically based [2]. The school board passed a resolution asking the superintendent of schools to implement a program using the home language of African American children as the language of instruction for the combined purpose of maintaining the language of the home while facilitating the acquisition and mastery of Standard English [2]. In fact this resolution was not new, due to the fact that some area schools in the Oakland school district had already adopted a similar program and were successful at producing high-achieving ethnically diverse students [7].

Some have argued that the media tsunami that followed the Oakland Unified District decision was based on the slow news period during December and January. In fact, the debate that started in December 1996 continues to be waged albeit silently in mainstream society. At the core of the Ebonics debate is whether Ebonics is a language, dialect, slang, or a non-standard form of English. Media attention was swift and negative from both sides of the isle, with mainstream media and activists in the Black community decrying the validity of the language form. In addition, although linguists argued that Ebonics was indeed a rule-governed language, they differed in whether it should be used as an intervention and/or bridge to acquiring Standard English [2, 7]. Prominent Black leaders like Jesse Jackson called Ebonics "garbage language," Kweiski Mfume, president of the National Association for the Advancement of Colored People (NAACP) called Ebonics "a cruel joke," and comedian/actor Bill Cosby called Ebonics "Igbobonics" [7]. Additionally Shelby Steele called Ebonics "broken English" and blamed the Oakland school board for emphasizing self-esteem rather than the academic performance of their students [2]. Others saw the Oakland resolution as separatist ideology that would promote segregation and encourage young Black children to not want to learn Standard English. Given the onslaught of public outcry, it was no surprise that the Oakland School District retreated from its original resolution and proposed a compromise to appease the media and critics. In essence, the school board insisted that its intention was not to teach Ebonics in the classroom but to educate teachers in the language of their students, so that teachers would be able to use the child's home language to facilitate English acquisition [2].

Attitudes Towards Ebonics

The debate on Ebonics rests on whether individuals argue from a deficit or a difference perceptive. A deficit or deficient argument operationally defines language as a function of factors such as African-American social class, educational backgrounds, and biological inheritance. In essence, speaking Ebonics is correlated with cognitive capabilities. On the other hand, a difference perspective defines language as a continuation of cultural traditions forged by American circumstances (e.g., slavery, emancipation, or civil rights movement). A deficit perspective views Ebonics as bad English, poor grammar, and views speakers of this language as uneducated; a difference perspective views Ebonics as a cultural marker that is different and distinct [4].

The deficit and difference perspectives continue to permeate mainstream ideas on African-American usage of Ebonics. In a recent survey of Black and White students' attitudes toward Ebonics and Standard American English, results indicated that Standard American English was the preferred mode of communication for all participants. Black participants preferred to interact with Blacks who spoke Standard English over Black English. In addition, Black participants believed that Black speakers who spoke Standard English were more competent. No significant differences in likability, attractiveness, and honesty, regardless of the mode of communication, were noted. The results also indicated that fear continues to exist that speakers of Ebonics are uneducated [3]. In another survey, college students were surveyed regarding their attitudes toward the use of Ebonics. Results indicated that many of the participants associate Ebonics with socioeconomic

constraints. White respondents were more likely to associate speakers of Ebonics with social deprivation (i.e., a deficient perspective); political orientation, age, and media influenced their views the most. The respondents who identified themselves as conservative were less likely to view Ebonics favorably. In addition, graduate students and senior students were less likely to view Ebonics favorably [1].

To summarize, although the linguistic experts view Ebonics as a rule-governed language, this home language of some African-American children continues to be viewed as slang or bad English in mainstream society, due in part to inaccurate media reports. Unless the public at large becomes correctly educated on the features of Ebonics, false assumptions will continue to be made.

Echolalia

Tara Waddell
Niagara University, NY, USA

Definition

The word echolalia comes from a combination of two Greek words. The first is ήχώ meaning "to echo" or "to repeat." The second is λαλιά meaning "to babble" or "meaningless speech." Echolalia is a vocalization in which words and phrases are mimicked and repeated by another person. This repetition can occur either immediately after hearing the utterance, referred to as immediate echolalia, or it may be vocalized at a later time during discourse with another or the same individual, referred to as delayed echolalia.

Description

Echolalia is a repetitious vocal behavior that is most commonly associated with autism. Echolalia affects more than half of the individuals with autism who are able to speak [5]. However, echolalia is also associated with other pathologies such as schizophrenia, Tourette's disorder, Asperger's disorder, aphasia, Rubinstein–Taybi syndrome, and mental retardation. Persistent echolalia is also used as one of the diagnostic criteria for autism and schizophrenia [1, 2]. Echolalia is distinct from palilalia, the repetition of one's own speech, as opposed to another's. This type of echophenomenon is not commonly associated with autism but is with Tourette's disorder and aphasia [13]. Additionally, echolalia is a typical verbal behavior pattern that many children may exhibit when first acquiring and mastering spoken language. When patterns of echolalic vocalizations become a persistent and characteristic pattern of verbal exchange with others, it is considered to be symptomatic of possible psychopathology [6]. Dobbinson, Perkins & Boucher describe echolalia as typically being "lexically, prosodically and syntactically faithful to the model utterance" ([4], p. 300). However, echolalia may take many forms varying from strictly parroting the speech heard by another to changing to the structure of the original utterance by making additions, deletions or substations to the original utterance [9].

The current literature on the function and characteristics of echolalia is mixed. Echolalic behaviors have been described an existing on a continuum varying in severity, intent and the degree in which they are comprehensible [10]. Some argue that echolalia is just meaningless repetition while others assert that it may be functional for the

individual displaying the behavior, demonstrating an attempt at communicating and socializing with others [7].

Kanner [8] originally generated the idea of two separate categories of echolalia, delayed and immediate echolalia. Immediate echolalia is characterized by the instantaneous repetition of another person's spoken verbalizations whereas with delayed echolalia is the term used to describe the repetition of verbal utterances after a significant amount of time has passed. Immediate echolalia is thought not be a meaningless behavior but rather, serve as a way for an autistic child to have social interaction and may be indicative of an attempt to be social and gain meaningful language [9]. Additionally, Prizant, Schuler, Wetherby, & Rydell [11] proposed that immediate echolalia is an important stage involved in children with autism developing "unconventional verbal behavior" (UVB). Delayed echolalia is also thought to have a similar purpose in regards to communicative intent; however the purpose of delayed echolalic responses is much more unclear. Prizant [10] found varying degrees of functionality when examining the echolalia utterances of four boys with autism. At times the use of echolalia seemed to demonstrate an attempt to communicate with others and be involved in discourse but overall, the majority of utterances were lacking features (i.e., turn taking or appropriateness to the current conversation) that were indicative of these children attempting to make social contact through speech.

Overall, the function of any type of echolalia is unclear. The extant literature is rather limited, yields discrepant information, and lack of uniformity in the utilization of an operational definition for echolalic behavior. In comparison, the literature focusing on the treatment of the echolalia appears to be more homogenous. Programs aimed at reducing the amount of echolalic behavior in individuals are generally based on a behavioral framework with the goal to decrease the likelihood that echolalia will be exhibited. However, it may be argued that echolalia in children with autism, may serve an important purpose and may be an important stage in acquiring language. One of the most comprehensive and well-respected treatment programs for children with autism is the SCRETS Model. This model focuses on social communication, emotional regulation and transactional support. As a part of this model, echolalic utterances are replaced by creative responses through social skills training and positive reinforcement of desired behaviors [12]. Other treatments for reducing the amount of echolalic responses focus on targeting specific responses and replacing them with "correct" (i.e., original) responses through constant repetition with flashcards or other techniques that reinforce the use of creative and original responding in conversational discourse [3]. Additionally, research has shown that using cues-pause-point language training can aid individuals with mental retardation and autism learn to use functional and appropriate (i.e., non echolalic) language [7]. This training focuses on using picture cards as cues in order to receive a desired response during a conversation from individuals displaying echolalia. As a whole, behavioral strategies which include positive reinforcement appear to be helpful in decreasing the likelihood of echolalic responses, especially for those with a diagnosis of autism.

Relevance to Childhood Development

It is apparent that limited echolalia may be a normal developmental variant in early language acquisition. However, when it becomes a persistent pattern of behavior, it may be symptomatic of a language deficit associated with disorders such as autism or schizophrenia. Therefore, parents, teachers and childcare professionals should be attuned to echolalic speech patterns and possible co-occurrence of other pathological symptoms. Concerns should be addressed in a timely fashion with a comprehensive evaluation of the child's developmental status, and if necessary, early intervention services promptly employed.

Echokinesia; Echomatism; Echomimia; Echomotism; Echopathy; Echophenomena; Echo-reaction; Imitation syndrome

Definition

Echopraxia refers to a pathological automatic imitative response, or desire to mimic other's behaviors. Echopraxia occurs in a semi-automatic manner and is independent of patient insight.

Description

Echopraxia can manifest in a variety of conditions such as in epilepsy, catatonic states such as those observed in patients with schizophrenia, mood disorders, or autism, during states of fatigue, clouded sensorium, or in other conditions such as Ganser syndrome, as well as in other neurological disorders and frontal lobe diseases. Culture-specific syndromes that may exhibit echopraxia include Latah, amurakh, and Imu. Individuals may exhibit echopractic behaviors that are either indiscriminate or selective in respect to their environment. Although echopractic behaviors may occur while observing another's movements, patients may also echo mental images or perceptual stimuli from previous observations of another person's behaviors. Echopraxia may also be specific in nature, such as observed in echographia. Incorporating these types of actions would broaden the parameters of what comprises echopractic behaviors [4]. Related to echopraxia, imitation behavior may be a more benign type environment-driven response, where patients may be able to deny imitative responses; other non-imitative but environment-driven behaviors include alien/anarchic limb syndrome and utilization behavior. However, there also appears to be a spectrum of awareness with respect to echophenomena. For example, some patients with schizophrenia have been reported to avert their gaze from other's movements, or close their eyes to avoid echoing other's actions. Some have suggested that these behaviors may imply a level of subjective cognizance of their own echo-reactions [4]. In contrast, others may be unable to inhibit imitative behaviors even while explicitly instructed otherwise. With respect to treatment, echopraxia is often the behavioral manifestation of varying underlying pathology, as demonstrated by the numerous accompanying disease states, and as such may abate with treatment of the respective etiology.

In those with schizophrenia, echophenomena may often appear to be limited to those with other catatonic characteristics and may not appear in the earlier stages of the illness. These symptoms may become more pronounced during periods in which communication is difficult. As previously mentioned, some individuals may be subjectively aware of their own echopractic behaviors. In addition, some have suggested that echopraxia may be related to underlying delusional thought processes in

those with schizophrenia [4]. Recently, it has been speculated by several authors that echopraxia in those with schizophrenia may be due to a complex network involving the mirror neuron system, inferior frontal gyrus, and motor cortex that is actualized as echo behavior(s) during periods of increased arousal and decreased inhibition. However, more direct evidence for this theoretical conceptualization is necessary [9].

Echopraxia may be considered a type of complex motor tic, which are usually more coordinated and resemble normal behaviors more than do simple motor tics. As with other patients with echopraxia, those with Tourette's syndrome may also learn the tics of other patients they have observed. As previously mentioned, echopraxia may also not be directly present in a patient's behavior, but instead result in the intentional avoidance of situations in which others may exhibit exaggerated movements, so as to avoid an embarrassing echo-reaction. Persons with Tourette's syndrome and echopraxia may also avoid looking at others with tics or other types of movements that may elicit echopractic behaviors. In fact, those with these complex tics may find themselves compelled to the same behavior (either immediately or after a delay) although they perceive the model's behaviors as distasteful or even annoying. In some circumstances these echo-reactions may become integrated as part of an individual's repertoire of tics. Some have suggested that echopraxia in Tourette's syndrome may be associated with dysfunction in the limbic system or anterior cingulate cortex and supplementary motor area system (e.g., [2, 6]). The prevalence of echopraxia among those with Tourette's syndrome may vary from 10 to 21% [7, 10].

In determining whether or not echopraxia is present, an examiner may perform a movement that is preceded with a contradictive verbal command. Performing the mimicked action rather than following the verbal instructions may suggest the presence of echopraxia in the patient. For example, an examiner may request, as they waive their right hand, that the patient touch their right hand to their nose [1]. If a patient is unable to adhere to the instructions, as observed by examples of mimicking the examiner's actions rather than the verbal commands, the patient may be exhibiting echopractic behaviors. In assessing for echopraxia, an examiner may also attempt to elicit echo-reactions from the patient through the performance of spontaneous or abrupt movements. In addition, other measures of executive control, rating scales, or measures specific to the underlying condition may also be useful in determining whether or not echopraxia is present.

Relevance to Childhood Development

Echopraxia itself is not present during normal childhood development; however, some features of behavioral mimicry may be observed during normal development. Piaget [8], for example discusses imitative behaviors in various stages in the developmental context, beginning in infancy and increasing with age. He suggests that individuals progress from primitive sensori-motor intelligence to a formal operational intelligence, where imitative behaviors transition becoming more of a function of conceptual thinking. Furthermore, instances of behavioral mimicry may manifest later in life as well. For example, an attenuated form of echo behavior may be observed when individuals are intensely focused on another's behavior, and echo subsequent imitative movements. Such behavior could include an individual who observes an athletic event and repeats the motions of the athlete imitatively. However, it is important to note that while there may be similarities between these behaviors and those observed in echopraxia that there are no direct linkages. However, as with adults, echopraxia can be observed in a variety of disorders and states that have a childhood onset, such as observed in Tourette's disease, autism, mood disorders, mental retardation, schizophrenia, and other neurological and psychiatric conditions.

Educational Psychology

Alandra Weller-Clarke
Benedictine University, Lisle, IL, USA

Definition

Educational Psychology is the systematic study of (a) how humans learn, develop, are motivated and affected by educational interventions, and (b) the psychology of teaching, social psychology and research identifying effective instructional practice in schools.

Description

Educational psychology became a field of scientific study in the late nineteenth century through the writings of early psychologists. These pioneers connected early learning theories with practical educational settings [4]. The field has grown dramatically over the past 100 years, and its contemporary application is twofold: to enhance theoretical knowledge; and improve educational practice. Once educational psychologists understand basic psychological processes concerning thinking, learning, motivation, behavior and development, practical application can begin to assess and later identify effective instructional practice [6]. In order to achieve answers to the vast amount of questions that arise concerning teaching, learning, and best practice, educational psychologists apply research methods to collect necessary data and thereby build their knowledge through evidenced-based strategies. These data and strategies are then provided to teachers as principles to allow them to make inferences and predictions about how students may perform and achieve. This understanding helps to explain and predict student behavior [5], thereby giving teachers the tools necessary to interpret, make good decisions, and solve academic, social and behavioral problems in order for children to be successful in school.

Relevance to Childhood Development

The focus of educational psychology is learning. Since learning occurs as a result of an experience creating a relatively permanent change in knowledge or behavior,

the quality of instruction is crucial. When educators possess the information they need to think critically about their craft and make decisions based on evidenced-based strategies, learning environments are created to facilitate learning and achievement to the greatest extent possible [2]. Without recognition of students' motivation, engagement, or developmental readiness, teachers may misinterpret clues of delay, disability, or even giftedness as behavioral problems [1]. In knowing that learning occurs better under certain conditions than other conditions, teachers are privy to opportune learning moments. Even basic knowledge of simple developmental milestones can serve as a catapult for some children whom unsuspectingly need special attention or assessment. Teachers who have a sophisticated understanding of the multitude of factors that affect learning, including motivation, development, environment, socioeconomic status, assessment and teaching represent a front line of defense for best teaching practice. As educators apply their comprehension of educational psychology, their teaching expertise increases in several domains including, but not limited to the following: subject matter competence, goal setting, developmentally appropriate teaching practices, classroom management skills, motivational skills, instructional planning skills, individual variation and differentiation of lessons, working with students from culturally diverse backgrounds, assessment writing and taking skills, etc [3]. These advantages result in a much more intentional, thoughtful teacher; one that is more reflective and careful in pedagogy and instructional delivery. Ground in the theory of educational psychology, these expert teachers leave an enormous positive effect on children's learning, development, character, and possibility for the future.

Educational Therapy

Fatima Watt
Argosy University, Atlanta, GA, USA

Definition

Educational therapy integrates educational and therapeutic approaches in the treatment of individuals with ►learning disabilities or learning problems. Evaluation, remediation, case management, and advocacy services are provided for children, adolescents, and adults with learning disabilities and other learning related conditions [1].

Description

Educational Therapy offers a wide range of intensive, individualized interventions to children and adults with learning disabilities and other learning difficulties in order to remediate learning problems [2]. It places a particular emphasis on understanding and addressing the socioemotional impact of learning disabilities and recognizing and utilizing individuals' strengths. Thus, a major aim is to not only to accurately diagnose and remediate the deficits in learning but also to encourage clients' awareness of strengths so they may utilize those strengths to compensate for areas of weakness [3]. Treatment plans employ and integrate information from a variety of sources including the client's social, emotional, neuropsychological, and psychoeducational contexts [1].

Educational therapists focus on specific aspects of academics and learning including, but not limited to: stimulating intellectual curiosity, reading/writing problems, comprehension of texts across various subject matter, recognition of main ideas, synthesis of information from various sources, problem analysis and problem solving, math related issues, metacognitive approaches, strategies to foster concentration and sustained attention, active learning, organizational skills, short and long-term memory, development of alternative studying approaches, and recognition of positive personal outcomes with proficiency in reading, writing, and math [1]. Social and emotional aspects of learning are also addressed including, but not limited to: understanding the interrelationship between learning and social/emotional functioning in order to bring about positive change, developing competence to improve self-esteem, providing a supportive environment to discuss academic concerns, providing

therapeutic listening, employing strategies to reduce avoidance and resistance, dealing with self-esteem issues, encouraging flexible problem solving, and providing referrals to necessary professionals when needed [1].

The Association of Educational Therapists (AET) is the professional organization of educational therapists, with membership throughout the United States, Canada, Australia, and Republic of Singapore [1]. AET defines the professional practice of educational therapy and establishes ethical and other standards for the professional practice of educational therapy [4]. AET was first formed in California in 1979 in order to meet the needs of a special subgroup of professionals whose work incorporated clinical and educational models of intervention. This clinical/educational teaching model was brought to America from Europe in the 1940s by various pioneers, who had independently trained themselves from the course offerings of two or more disciplines, such as special education, psychology, speech/language, and child development. The lack of university training programs offering this multidisciplinary course of study, as well as the ambiguity in the definition and practice of educational therapy, led to the development of AET. As the only body that formally defines educational therapy and establishes principles of practice and standards for academic and experiential training, AET has worked in partnership with numerous universities and colleges to develop training programs specific to the needs of educational therapists. *The Educational Therapist* is a professional journal published by the AET. It publishes articles and reviews on theory, research, and clinical practice. It also provides information on AET activities and presents issues relevant to the field of educational therapy [4].

Effexor®

Anisa Fornoff
Drake University, Ankeny, IA, USA

Synonyms

Effexor XR®; Venlafaxine

Definition

A prescription medication FDA approved for the treatment of major depressive disorder, generalized anxiety disorder, social anxiety disorder, and panic disorder in adults.

Description

This medication is a serotonin/norepinephrine reuptake inhibitor available as an extended-release capsule (Effexor XR®) or as a tablet (Effexor®).

The recommended starting dose for the extended release form is 75 mg a day taken once a day. Maximum suggested dose of the extended release form is 225 mg a day. The recommended starting dose for the immediate

release oral tablet is 75 mg a day, taken two or three times a day with a maximum suggested dose of 375 mg a day. This medication should only be taken as directed by a doctor. This medication may need to be taken for four weeks before improvement in symptoms is seen.

This medication should be taken® with food and it is best to take it at the same time each day. It is recommended to swallow the extended release capsule whole. Do not crush or chew. Tell your doctor if you have a history of mania, seizure disorder, liver disease, or kidney disease.

Concomitant use in patients taking monoamine oxidase (MAO) inhibitors is not advised. Serotonin syndrome may occur with the use of certain other serotonergic drugs. Elevated blood pressure is a concern with this medication.

Some side effects are listed here: changes in vision, headache, nervousness, dry mouth, chills, constipation, diarrhea, dizziness, loss of appetite, abnormal dreams, and difficulty sleeping. Certain side effects may go away during treatment. Tell your doctor immediately if you notice the following: actions that are out of control, ringing in the ears, mood changes, seizure, chest pain, or difficulty breathing.

If you choose to stop taking Effexor®, you are encouraged to tell your doctor and slowly taper this medication to prevent withdrawal symptoms.

This medication should be stored out of reach of children and pets and away from light, heat, and moisture.

Relevance to Childhood Development

Effexor® is not FDA approved for use in children. Children under the age of 18 treated with this medication are recommended to have their weight, height, blood pressure, and cholesterol monitored regularly.

A medication guide must accompany this medication containing information related to the increased risk of suicidal thinking and behavior in children, adolescents, and young adults compared to those not taking the medication. Doctors will monitor patients closely for worsening of symptoms, change in behavior, and thoughts of suicide. Patients are strongly encouraged to notify their health care provider to report sudden changes in mood, behavior, thoughts, or feelings.

Women should let their doctor know if they are pregnant or planning to become pregnant. It has been shown that neonates exposed during the third trimester have developed complications requiring prolonged hospitalization including respiratory support and tube feeding. It is not recommended to breastfeed while on this medication.

Elavil®

Anisa Fornoff
Drake University, Ankeny, IA, USA

Synonyms
Amitriptyline

Definition
A prescription medication FDA approved for the relief of symptoms of depression.

Description
This medication is a tricyclic antidepressant available in tablets.

The recommended starting dose for this medication is 50 or 100 mg taken once a day at bedtime or in divided doses three to 4 times a day. The dose for adolescents is typically 10 mg taken 3 times a day and 20 mg taken at bedtime. Maximum suggested dose is 300 mg a day for adults and 100 mg a day for children and adolescents. This medication should only be taken as directed by a doctor. It may take several weeks before you begin to feel better.

Elavil® may be taken with or without food. Avoid drinking alcohol and grapefruit juice. Tell your doctor if you have a history of a kidney disease or liver disease. Serotonin syndrome may occur with the use of certain other serotonergic drugs.

Some side effects are listed here: drowsiness, changes in sleeping habits, weight gain, constipation, dry mouth, difficulty urinating, and blurred vision. Certain side effects may go away during treatment. Tell your doctor immediately if you notice the following: low blood pressure, muscle stiffness, or rash. Your doctor may monitor your blood sugar levels while on this medication. Signs of an overdose of this medication are slurred speech or confusion, severe drowsiness, low blood pressure, and seizures. If these should occur, seek medical attention immediately. This medication may make you more sensitive to sunlight. There are many drug interactions with this medication. Be sure to tell your doctor or pharmacist about all medications you take.

If you choose to stop taking Elavil®, you are encouraged to tell your doctor.

This medication should be stored out of reach of children and pets and away from light, heat, and moisture.

Relevance to Childhood Development
Elavil® is not FDA approved for children under the age of 12. There are many unapproved uses for this medication. Be sure to discuss all the risks and benefits with your doctor before taking this medication.

A medication guide must accompany this medication containing information related to the increased risk of suicidal thinking and behavior in children, adolescents, and young adults compared to those not taking the medication. Doctors will monitor patients closely for worsening of symptoms, change in behavior, and thoughts of suicide. Patients are strongly encouraged to notify their health care provider to report sudden changes in mood, behavior, thoughts, or feelings.

Women should let their doctor know if they are pregnant or planning to become pregnant. Talk with your doctor if you plan to breastfeed. Use of this medication while pregnant or breastfeeding is not recommended.

Electroencephalogram (EEG)

Lauren Connell Pavelka
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms
Brainwave test

Definition

An electroencephalogram (EEG) is a test that uses electrodes attached to a person's scalp to detect abnormalities in electrical activity of the brain.

Description

The EEG records electrical impulses generated by cel lular activity in the brain. Neurons produce tiny electrical impulses that can be recorded by the EEG and presented as wavy lines (frequencies) on a computer monitor. The frequencies recorded by the EEG are then interpreted, and can be used to diagnose or rule out various brain disorders such as epilepsy/seizure disorders, brain tumors, head injury, encephalopathy, encephalitis, stroke, memory impairment, and sleep disorders. An EEG can also be used to confirm brain death of comatose patients.

An EEG test is painless and safe, typically lasting 35–40 min. For patients receiving an EEG during a period of sleep, the procedure may last longer.

Relevance to Childhood Development

There is no reported risk for administering an EEG to children. It is advisable, however, to explain the procedure in advance to reduce potential anxiety with pediatric patients.

Embedded Figures Test

Synonyms

Group Embedded Figures Test; Children's Embedded Figures Test; Preschool Embedded Figures Test

Definition

Measure of field independence versus field dependence involving visual search for simple figures or objects embedded in larger, more complex figures.

Description

The task was originally developed in 1950 by H. A. Witkin as a measure of cognitive style. Cognitive style describes how individuals think about and process information; according to Witkin, either globally or analytically. Witkin's theory of cognitive style was based on the unidimensional field dependence-independence model. His embedded figures test and group embedded figures test measured an individual's ability to distinguish figures from a distracting or confusing background/field. Individuals having an easier time with the task were considered field-independent types. Those having difficulty were deemed field-dependent types. Field independence has been linked to development of stronger cognitive restructuring skills and better analytical thinking skills. In the learning environment, it is suggested that field independent learners are successful in unstructured settings, whereas field-dependent learners require instructor and peer support for learning. Research has demonstrated a correlation between performance on the embedded figures test and other standard intelligence tests.

The embedded figures test contains 24 (two sets of 12, Form A and Form B) color figures embedded within more complex figures. Individuals have to identify the hidden images as quickly as possible. Their average time per card is converted into a standard score. On the group administered version, Group Embedded Figures Test, individuals are required to identify and trace over 8 embedded images as quickly as possible. The original test versions are appropriate for individuals aged 12 years and older, although younger versions have been released and are aimed at children as young as 3 years of age. The embedded figures test has good internal reliability and test-retest reliability.

Emergent Literacy

Carrie R. Ball
Ball State University, Muncie, IN, USA

Synonyms

Early literacy; Early reading; Reading development

Definition

Emergent literacy is a model describing the process of learning to read.

Description

Two basic models exist regarding the development of early literacy skills: reading readiness and emergent literacy. The reading readiness model represents a traditional perspective, suggesting that children begin learning to read only after they have reached a certain threshold of maturation. According to this model, learning to read begins at a discrete point in time; readiness can be accelerated somewhat via early learning experiences but relies primarily on individual development [6].

The reading readiness model has been deemphasized over the past several years with the introduction of an emergent literacy model. Emergent literacy espouses a more fluid model of reading development, proposing that children acquire early literacy skills through a gradually occurring process, which is not necessarily initiated at a particular developmental threshold. According to the emergent literacy model, very young children who do not read text are nevertheless engaged in the development of important pre-reading skills. Therefore, early learning experiences can play a significant role in building early literacy skills [2].

Emergent literacy researchers have identified a continuum of skills that facilitate successful reading development [3, 4, 7]. During preschool and first grade, children begin developing alphabet knowledge, phonemic awareness, and print awareness. That is, they begin learning the names and sounds of the letters in the alphabet. They also become more adept at isolating and manipulating individual sounds in spoken speech (i.e., alliteration, rhyming). Finally, young children learn about the structure of books (e.g., front and back book cover, directionality of text) and the idea that print is used to communicate meaning.

During first and second grade, children begin developing more conventional literacy skills. Their phonemic awareness is typically well developed, and they often have a strong knowledge of phonics, or letter-sound correspondence. This allows them to decode unfamiliar words and recognize basic sight words. Their level of print awareness also permits them to read brief text with comprehension and to understand basic punctuation.

Children in second and third grade enter into the final phase of early literacy. They generally have a fairly large sight word vocabulary and can decode unfamiliar words accurately. Two major skills characterize this stage of literacy development. First, children begin to read with fluency, demonstrating the ability to read grade-level texts with automaticity. Second, they are capable of self-monitoring as they read. That is, they can pay attention to whether or not the text makes sense. This facilitates comprehension and allows children to quickly detect and correct mistakes.

Relevance to Childhood Development

Knowledge of emergent literacy can assist childhood development professionals in two key ways. First, understanding early literacy as a continual developmental process can assist educators and parents in selecting age-appropriate early literacy activities. For example, toddlers and preschoolers benefit from shared book reading activities that focus on developing an understanding of book structure and the purpose of print. Older preschoolers can engage in reciting nursery rhymes or reading books with rhyming or alliterative content. They also benefit from alphabet books and other activities that encourage them to practice letter names and sounds. As children become

older and demonstrate basic early literacy skills, the focus of activities can also shift to focus on word recognition and decoding. By understanding the developmental trajectory of early literacy and recognizing children's individual progress, activities may be tailored to meet their learning needs [1].

Second, understanding a typical developmental trajectory can help early childhood and elementary school professionals to identify children who are not progressing normally. Successful reading development is critical to academic achievement, and students who lag behind their peers in the middle of elementary school are at-risk for long range academic difficulties [5]. When students can be identified as having difficulties during preschool or early elementary school, extra activities and more intensive, age-appropriate instruction can be provided to remediate early literacy deficits.

Emotional Abuse

Lindsay Weymouth, Tasha R. Howe
Humboldt State University, Arcata, CA, USA

Synonyms

Psychological abuse; Psychological maltreatment; Verbal abuse

Definition

A persistent pattern of negative behavior directed at child by a caregiver, which diminishes a child's integrity and well-being.

Description

A type of abuse in which a caregiver degrades, corrupts, berates, belittles, rejects, threatens, ignores, exploits, assaults, spurns and/or terrorizes a child in a repeated pattern [1, 2]. Emotional abuse may also consist of denial of psychological treatment, extreme verbal punishment, unreasonable expectations, and/or lack of responsiveness. This pattern of behavior from caregivers may adversely affect the child cognitively, emotionally, and socially. A caregiver may make a child feel unloved, flawed, or worthless through name calling and/or scapegoating or may be unconcerned with a child's troubles [1, 5]. The presence of emotional abuse may adversely affect later development of the child including symptoms of aggression, depression, poor emotional regulation, eating disorders, substance abuse, social impairment, learning disabilities, and suicidal behavior [3, 5].

In the United States, toddlers, preschoolers, and young adolescents are most commonly emotionally abused, versus other age groups [4]. Emotional abuse can have a multidimensional impact a child's development. Abused children may have insecure attachments to their caregivers and have

problems with emotion regulation, which may lead to alterations in the limbic system of the brain [6]. Poor emotion regulation may influence children to show aggressive or withdrawn patterns with their peers. Without proper intervention and treatment, children who are abused may be affected well into adulthood. As adolescents and adults, they may abuse substances, show symptoms of psychiatric disorders, and engage in criminal behavior [4].

Emotional Bond

►Emotional Connection, Parent-Child

Emotional Connection, Parent-Child

Theodora Koulenti,
Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

Attachment; Emotional bond

Definition

Emotional Connection (or attachment) refers to the special emotional bond with another person that is generally powerful and enduring. It is often used to describe the relationship between infants and their mothers [7].

Description

Scientific evidence provides support to the notion that infants and their caregivers are biologically prepared to relate in ways that promote their relationship. In most of the cases, caregivers are extremely perceptive in understanding their babies' signals and needs and they correspond in appropriate ways that will help them fulfill these needs and will promote social interactions between them and their children. On the other hand, infants are sensitive to "parental emotional-social signals." These types of interactions between caregivers and infants form the basis for early attachment, a unique emotional bond and connection. Successful human development and adjustment is partly based on the quality of the relationship between parents and children, beginning with early attachment [8].

Attachment Theory

Attachment theory, which is the result of the joint work of John Bowlby and Mary Ainsworth, focuses on the development of the child's attachment, during the first year of life, and secondly on the qualitative differences of this attachment [1]. Bowlby, with his evolutionary attachment theory, argues that it is essential for human species to become attached, as infants, with the person who plays the role of the principal caregiver [2]. Attachment behavior has evolved through a process of natural selection because of the need for protection and survival [1].

More specifically, at birth, the infant is equipped with specific behaviors, such as crying, that operate to attract the proximity of the caregiver [2]. Even though infants, during the first weeks of life are unable to understand themselves and others as coherent objects, because of their caregivers caring and interaction, infants instinctively organize their behavior around them. Even in the first weeks of life, infants demonstrate an innate propensity for interaction, expressed by their responses to the sound of voices or to human touch. However, it is the interaction with the primary caregiver that facilitates, in this stage, maturational processes [3].

During the last half of the first year infants go through a new stage of development in which locomotion and directed reaching and grasping emerges, in order for the proximity with the caregiver to be enabled. During this stage, cognitions and behavioral expressions are

developed, in relation to the physical and emotional availability of the primary caregiver, and the infant forms its first inner representation of the primary caregiver [2]. Throughout the 1st year of life, this dyadic relationship is further developed and the child engages in exploratory activities around the "secure base" of the caregiver [3]. The infant gradually develops "working models" or "expectations of regularities" in what happens to him/her in relevance to the physical environment, attachment figures and itself [2].

Attachment of the Child Beyond Infancy

The emotional connection between parents and children does not come to an end after infancy. As children continue to develop their cognitive skills, after the age of 3–4, they start to realize parents' plans and motivations. Therefore, children are now enabled to persuade caregivers to change their plans and adjust them to their own. Moreover, language development enables parents and children to communicate their plans and wishes and agree for mutually acceptable plans. This development of communication facilitates the children's confidence in the stability and mutual understanding with the primary caregiver and now the child is at a position in which he/she can handle separation from the parent with less distress [2].

There is a gradual declination of the intensity and frequency of attachment behaviors through early and middle childhood, meaning that physical proximity becomes less important. However, caregivers' supporting role does not end here. They continue to sustain their children's secure-base behavior and they need to be aware of their child's emotional needs in order to be accessible and responsive. As children grow older they start playing a more active role for maintaining their secure-base behavior and both children and caregivers start sharing the responsibility for regulating their between contact [5]. As the child grows older, and develops in relevance to locomotion, is able to explore and relate to other people as well by venturing away of the secure base of the caregiver. This is more obvious during adolescence when the young person begins the search for partnership. However, even then, the attachment and emotional connection to parents does not disappear, but, even as adults, most people continue sharing a meaningful association with their parents [2].

Attachment Variations

Research findings have revealed that differences in the quality of care provided to children may lead to differences in the quality of attachment relationship. More specifically, punctual and effective caregiver responses to the infants' signals are associated to secure attachment and less maladaptive behaviors at home. On the contrary, less sensitive care is associated with insecure attachment. Additionally, emotional unavailability and emotional rejection of the caregiver is associated with anxious-avoidant attachment and, finally, interfering, ignoring and unreliably responsive care is related to anxious-resistant attachment. Variations of the quality of attachment between caregivers and infants may influence individuals' social and emotional functioning as adults. Concerning social adjustment, in the cases of infants who receive a responsive emotional care and communication with the caregiver, in the first months of life, they are more probable, as adults, to develop confidence in the ability to communicate needs directly, see themselves as worthy of care and develop responsiveness to the social world. On the contrary, infants who do not meet these criteria may not be provided with the experiences needed in order to develop skills for communicating and eliciting social responses [3].

Moreover, children with secure attachment histories, research evidence has shown that are more determined, excited and competent in problem-solving as toddlers, more flexible in preschool and more goal-oriented in early childhood than children who experienced an insecure form of attachment [3]. Additionally, research findings on adolescents, has revealed that detachment from parents is related to negative behavioral and mental-health outcomes [6]. Infants who did not have available and responsive to their needs caregivers, are more at a risk for experiencing later difficulties in developing stable relationships or establish a secure-base attachment relationship with their own children [4].

Emotional Disorders

►Emotional Disturbance
►Psychological Disorders

Emotional Disturbance

Xenia Anastassiou-Hadjicharalambous, Nikos Georgiou
University of Nicosia, Nicosia, Cyprus

Synonyms

Behavior disorders; Emotional disorders; Mental illness/disorder; Psychiatric illness

Definition

The term *emotional disturbance* encompasses diagnosable mental disorders of sufficient duration to meet diagnostic criteria specified within the *Diagnostic and Statistical Manual of Mental Disorders* (DSM).

Description

Section 300.7c(4) of the *Individuals with Disabilities Act* (IDEA, 1997) (The *Individuals with Disabilities Education Act* (IDEA) is a United States federal law that governs how states and public agencies provide early intervention, special education, and related services to children with disabilities.) defines *Emotional Disturbance* as ". . . a condition exhibiting one or more of the following characteristics over a long period of time and to a marked degree, which adversely affects educational performance: (a) An inability to learn that cannot be explained by intellectual, sensory, or health factors; (b) an inability to build or maintain satisfactory interpersonal relationships with peers and teachers; (c) inappropriate types of behavior or feelings under normal circumstances; (d) a general pervasive mood of unhappiness or depression; (e) a tendency to develop physical symptoms or fears associated with personal or school problems. The term includes schizophrenia but does not apply to children who are socially maladjusted, unless it is determined that they have an emotional disturbance" [7].

For the child or adolescent to be characterized as emotionally disturbed, it must be determined that his/her condition results in functional impairment, substantially interfering with his/her abilities to function effectively in social, familial, and educational contexts [7]. *Emotional Disturbances* encompass all psychiatric diagnoses. Following are some of the considered as most common emotional disturbances.

Anxiety Disorders

Anxiety disorders are characterized by various forms of pathological fears and anxieties that inflict on the affected individual's psychological well-being. Large-scale epidemiological studies have provided corroborative evidence of a prevalence of 18% in community samples [8]. The most recent revision of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-R) encompasses a wide variety of *anxiety disorders* that reflect differentiated foci of anxiety [2].

Generalized anxiety disorder is characterized by persistent and excessive worry and anxiety (at least 6 months) that is not related to any specific situation [2]. For instance children with *generalized anxiety disorder* may worry excessively and unrealistically for things like grades, performance in sport, and family issues. Symptoms may include restlessness, muscular tension, insomnia, fatigue, irritability, difficulty concentrating, abdominal upsets, and dizziness [2]. Prevalence rates for *generalized anxiety disorder* in the child and the youth is estimated to be in the range of 2.9–4.6% for younger children (younger than 11) and 3.6–7.3% for adolescents [13].

Panic disorder is characterized by recurrent unexpected panic attacks. A panic attack is characterized by sadden intense fear or discomfort for no apparent reason, accompanied by at least 4 of 13 somatic or cognitive symptoms including trembling or shaking, palpitations, sweating, confusion, dizziness, nausea, shortness of breath, fear of dying or losing control and chills and hot flashes [2]. A diagnosis of *panic disorder* also necessitates that attacks have severe chronic consequences such as worry over the attacks' potential implications, persistent fear of future attacks and resulting significant changes in behavior [2].

Specific phobias are characterized by excessive fear of a specific object (i.e., spiders, snakes) or situation (i.e., heights, shots) that is usually inappropriate to the situation and that is recognized by the sufferer as being irrational [2]. A *specific phobia* can result to avoidance of typical everyday situations and is diagnosed if the fear persists for 6 months and interferes with the individual's daily routine [2].

Agoraphobia is characterized by being in a place or situation where escape is difficult or embarrassing or where help may not be available in the event of having a panic attack or panic-related symptoms (e.g., fear of having a sudden attack of dizziness) [2]. Agoraphobia often takes place in the context of a panic attack and

quite often is precipitated by the fear of having a panic attack [2]. The provoked anxiety often results into pervasive avoidance of a variety of situations such as being alone outside the house or being home alone, being in crowed of people, traveling in a car, airplane, or bus, being on a bridge or in an elevator. These pervasive avoidance behaviors can often lead to serious consequences such as being confined to one's home.

Social phobia is characterized by an intense anxiety provoked by exposure to social or performance situations [2]. Social anxiety often manifests specific physical symptoms, including extreme perspiring, blushing, heart palpitations, and faintness [2]. Those suffering from social anxiety will attempt to avoid the source of their anxiety. In severe cases the individual can be lead to complete social isolation.

Obsessive compulsive disorder is characterized by repetitive obsessions (distressing, persistent, and intrusive thoughts or images) and compulsions (urges to perform specific acts or rituals which serve to neutralize anxiety) that are severe enough to be time consuming (i.e., more than hour per day) or induce marked distress or significant impairment [2]. Adults with *obsessive compulsive disorder* have at some point recognized that the obsessions or compulsions are excessive and unreasonable. In children this criterion is not necessitated for diagnosis of *obsessive compulsive disorder* because they may lack adequate cognitive awareness to make such a judgment.

Post-traumatic stress disorder is characterized by reexperience of an extremely traumatic event accompanied by increased arousal and avoidance symptoms [2]. Individuals with *post-traumatic stress disorder* often find themselves reliving the experience through nightmares or flashbacks, avoiding places related to the trauma, and/or detaching themselves from others through emotional numbing, and/or experiencing problems with sleeping, irritability, and poor concentration. Symptoms usually begin within 3 months of the trauma, although sometimes 6 months and even years can pass before the appearance of symptoms [2].

Separation anxiety disorder is characterized by exacerbated and inappropriate levels of worry over being separated from parental figures as manifested by at least three of the following symptoms: (a) Unrealistic worry about possible harm befalling major attachment figures; (b) unrealistic worry that an untoward calamitous event will separate the child from major attachment figures (e.g., killed, kidnapped); (c) persistent reluctance to go to school in order to stay with attachment figures; (d) persistent reluctance to go to sleep without being next to a major attachment figure; (e) persistent avoidance of being alone in the home and emotional distress if unable to follow major attachment figure around the home; (f) repeated nightmares involving a theme of separation, (g) Complaints of physical symptoms on school days; (h) Signs of excessive distress upon separation, or when anticipating separation from major attachment figures; and (i) social withdrawal, apathy, sadness, or difficulty concentrating when not with major attachment figure [2]. For a diagnosis to be made symptoms need to persist for at least 4 weeks.

Mood Disorders

Mood disorders encompass psychiatric conditions in which disturbance in mood is the primary feature [2]. The *major depressive disorder* is characterized by one or more major depressive Episodes (i.e., depressed mood accompanied by at least four additional symptoms of depression for at least 2 weeks). These symptoms include: feelings of helplessness and hopelessness, feeling useless, inadequate, bad, constant questioning of thoughts and actions, an overwhelming need for reassurance, being vulnerable and "over-sensitive," feeling guilty, a loss of energy and motivation that makes even the simplest tasks or decisions seem difficult, self- harm, loss or gain in weight, agitation and restlessness, loss of sex drive, finding it impossible to concentrate for any length of time, forgetfulness, a sense of unreality, physical aches and pains, sometimes with the fear that you are seriously ill, difficulty with getting off to sleep, or (less frequently) an excessive desire to sleep [2].

Dysthymic disorder is characterized by a chronic (i.e., at least 2 years) depressed mood that occurs for most of the day for more days than not and it is accompanied by additional depressive symptomatology that is inadequate to meet criteria for a major depressive disorder. In children the mood may be irritable than depressed and the minimum duration is 1 year [2]. Prevalence of *dysthymic disorder* is estimated to be around 6% (with and without *major depressive disorder*) [2].

Depressive disorder not otherwise specified is designated for coding disorders with depressive features that are impairing but is inadequate, contradictory or do not meet criteria of any other depressive diagnoses (i.e., *major depressive disorder, dysthymic disorder, adjustment disorder with depressed mood, adjustment disorder with mixed anxiety and depressed mood*), or depressive symptomatology that is inade [2].

Bipolar Disorder

Bipolar disorder is characterized by abnormally elevated mood (i.e., mania, or, if milder, hypomania), one or more major depressive episodes, or mixed episodes in which

features of both mania and depression are present at the same time [2]. In most individuals with *bipolar disorder* these episodes are separated by periods of "normal" mood while in others depression and mania rapidly alternate (i.e., rapid cycling) [2]. Acute manic episodes can sometimes lead to psychotic symptomatology such as delusions and hallucinations. The *bipolar disorders* include *bipolar I, bipolar II, cyclothymic disorder*, and *bipolar disorder not otherwise specified*. These differential bipolar diagnoses are based on the nature and severity of mood episodes experienced. Prevalence rates vary from 1% for *bipolar I*, 0.5–1% for *bipolar II* and *cyclothymic disorder*, and 2–5% for *bipolar disorder not otherwise specified* [2]. The onset of full symptomatology typically occurs in late adolescence or young adulthood.

Conduct Disorder

Conduct disorder is characterized by a repetitive and persistent pattern of behavior by which the basic rights of others are violated or age-appropriate societal norms or rules are disobeyed [2]. This must be manifested by the occurrence of at least three features from four categories of behavior for the past 12 months, and at least one criterion present for the past 6 months. The four categories of behavior include (a) aggression to people and animals, as manifested in bullying, threatening, or intimating others, initiating physical fights, using a weapon that can cause serious physical harm to others, being physically cruel to people, being physically cruel to animals, stealing while confronting a victim (e.g., mugging, purse snatching, or armed robbery), or forcing someone into sexual activity; (b) destruction of property, as manifested in deliberately engaging in fire setting with the intention to cause serious damage, or deliberately destroying others' property; (c) deceitfulness of theft, evidenced in actions of breaking into someone else's house, building, or car, often lying in order to obtain goods or favors or to avoid obligations, or stealing items of nontrivial value without confronting a victim, such as shoplifting; and (d) serious violation of rules, as indicated by staying out at night despite parental prohibitions before the age of 13, running away from home overnight at least twice, or school truancy before the age of 13 [2]. These behaviors must cause clinically significant impairment in social and occupational functioning, and usually be present in a variety of settings, including home, school or the community [2]. *Conduct disorder* is among the most common child and adolescent psychiatric disorders, affecting approximately 4–14% depending on age group, gender, and setting [4]. After the age of 18, *conduct disorder* may develop into *antisocial personality disorder*. Robins and colleagues [4] found that 71% of children who displayed severe *conduct disorder* (8 or more symptoms) at *age 6* showed evidence of *antisocial personality disorder* ("... a pervasive pattern of disregard for, and violation of, the rights of others that begins in childhood or early adolescence and continues into adulthood" [2].) in adulthood. Fifty-three percent of children whose symptoms began between the ages of *6 and 12* displayed *antisocial personality disorder* in adulthood. Forty-eight percent of those who developed symptoms after age 12 showed evidence of this disorder as adults.

Attention Deficit Hyperactivity Disorder

Attention deficit hyperactivity disorder (ADHD) is a neurodevelopmental disorder characterized by developmentally inappropriate levels of Hyperactivity/Impulsivity and Inattention. Symptoms of Hyperactivity/Impulsivity include: (a) Fidgety, squirming in seat; (b) leaving seat in classroom or in other situations in which remaining seated is expected; (c) running about or climbing excessively in situations in which it is inappropriate; (d) having difficulty playing or engaging in leisure activities quietly; (e) being "on the go" or often acting as if "driven by a motor"; (f) talking excessively when inappropriate to the situation; (g) blurting out answers before questions are completed; (h) having difficulty awaiting turn; interrupting or intruding on others. Symptoms of inattention include: (a) failing to give close attention to details; (b) focusing on unimportant information; (c) having difficulties in sustaining attention in tasks; (d) not listening when spoken to; (e) having trouble managing simultaneous stimuli or switching from one task to another; (f) not following through on instructions and failing to finish homework, chores, or duties in the workplace; (g) having difficulty in organizing tasks and activities; (h) being reluctant to engage in tasks that require sustained mental effort; (i) losing things necessary for tasks or activities; (j) getting easily distracted by extraneous stimuli; (k) being forgetful in daily activities [2].

On the basis of these clusters of symptoms the most recent revision of DSM (DSM-IV-R) classifies three subtypes of ADHD: (a) *ADHD predominantly inattentive*; (b) *ADHD predominantly hyperactive/impulsive*; and (c) *ADHD combined* [2]. The diagnosis of *ADHD predominantly inattentive* type is based on the presence of at least six of the symptoms of inattention. The diagnosis *ADHD predominantly hyperactive/impulsive* type is based on the presence of at least six of the symptoms of hyperactivity/impulsivity. For the combined type six symptoms of hyperactivity, impulsivity and inattention (combined) are required for diagnosis. These symptoms need to be present for at least 6 months to a point that is disruptive

and inappropriate for developmental level [2]. Prevalence of ADHD is estimated at 3–5 percent of the elementary age population and it occurs more often in males than females, with the sex ratio being about 4–1 [9].

Schizophrenia

Schizophrenia (deriving from the Greek words σχίζειν, "to split" and φρεν-, "mind") is characterized by positive symptoms (that are present and should not be) and negative symptoms (that are not present and should be) [2]. Positive symptoms in children include gross disturbance of thought process or thought content, whereas delusions most possibly appear (or become apparent) with increasing age [5]. Negative symptoms include flat affect, and paucity of speech and thought [1]. Younger children with childhood-onset schizophrenia are considered to have less delusions and catatonic symptoms, but they display hallucinations, disordered thought process and flattened affect [6]. Sparse epidemiological data suggest that schizophrenia with onset during middle to late adolescence is in the range of 0.5–1.5% [2]. Childhood-onset schizophrenia is reported to be no more than 1% [10].

Causes of Emotional Disturbances

Emotional disturbances vary significantly in nature and their causes are difficult to delineate. They are considered to derive from a complicated set of risk factors including genetics, personality, brain chemistry and life experiences. For instance for *Schizophrenia* the preponderance of evidence suggests that it evolves from a genetic predisposition, a prenatal insult to the developing brain, and stressful life events. For *anxiety disorders* the evidence provides support for inherited differences in specific brain circuits and neurotransmitter systems, an inherited highly reactive *behavior inhibition system* (The Behavioral Inhibition System (BIS, first characterized by Henri Laborit in the early 1970s) may be viewed both as a cognitive and physiological system (Gray 1982). Cognitively, the BIS inhibit behavior that would lead to deviations from expectation. Physiologically, the function of the BIS is associated with the septohippocampal system. Input to this system comes from the prefrontal cortex, and output flows through the noradrenergic fibers of the locus coeruleus, and serotonergic fibers from the median raphe (Gray 1994).), coupled with psychosocial influences (parents model behavior, intrusive parenting, insecure attachment) [3]. For depression neuroendocrine system dysregulation along with psychosocial stressors are implicated [14].

Modern psychiatry eschews the misleading dichotomy of environmental versus biological predisposition and holds that *emotional disturbances* derive from a complex interplay of biological and environmental factors. For some of these disturbances there is some degree of understanding about the interaction of implicated factors. For others it is recognized that still little is known about the pathophysiology of the disorder in question, the pattern of interplay of environmental and biological factors, as well as the potentially diverse developmental trajectories.

Treatment

The treatment of emotional disturbances begins with a complete psychological evaluation that includes a review of one's physical health history. The possibility that specific medications and/or medical conditions are causing the symptoms of *emotional disturbance* is then ruled out. Next, the patient provides the nature and history of the symptoms and a mental status evaluation follows. The outcome of the psychological diagnostic evaluation will determine the choice treatment approach. Often the children and adolescents who meet criteria for *emotional disturbances* carry multiple diagnoses. Crucial for the development of a treatment plan is to determine the comorbit symptomatology. If for instance the patient is presented with psychotic symptoms that are secondary to depression s/he will be prescribed with antidepressant (e.g., selective serotonergic reuptake inhibitors – i.e., flouxetine, paroxetine, sertraline, fluvoxamine, clomipramine). Often, the use of antipsychotic medications in addition to the use of antidepressants or mood stabilizers is indicated in psychosis that is secondary to depression. While medications can be of value, they do not negate the need for psychosocial interventions individualized to each individuals' needs. Psychosocial interventions have demonstrated substantial gains for the treatment of certain emotional disturbances but not all. For instance for the treatment of depression interpersonal psychotherapy and *cognitive-behavioral therapy* have gained empirical support [12]. For the treatment of anxiety related disorders *cognitive behavior therapy* has been documented to result into significant gains [12]. However, for some specific anxiety relates disorders (e.g., specific phobia) reviews on psychosocial treatment approaches revealed that no treatment meets the efficacious criteria [12].

School Interventions

Beyond treatment approaches that are utilized in mental health clinics mostly in an individual basis, school interventions are often in place to meet the needs of certain students whose needs cannot be met in the typical schools. In the United States the IDEA guarantees the provision of *Free Appropriate Public Education* (FAPE) (Free

Appropriate Public Education stands for the provision of *Individuals with Disabilities Education Act* (IDEA), *Americans with Disabilities Act* and the *Rehabilitation Act* of 1973 to provide to students with emotional disturbances with an educational program that is individualized to a specific child, designed to meet that child's unique needs, and from which the child receives educational benefit.), which is an educational program that is individualized to the emotionally disturbed child. FAPE is designed to meet that child's unique set of needs, and from which the child gains substantial educational benefit. To provide FAPE, schools must provide students with an "... education that emphasizes special education and related services designed to meet their unique needs and prepare them for further education, employment, and independent living" (http://www.ed.gov/about/offices/list/ocr/docs/edlite-FAPE504.html).

These special educational programs for children with emotional disturbances aim to develop social skills, increase self-awareness, self-control, and self-esteem. They provide a structured environment where students are able to experience success, rules and routines are predictable and students are consistently rewarded for appropriate behavior. Behavior management techniques, such as positive reinforcement, token economies, contracting, and time-out, which rely on direct measurement and monitoring of behavioral change, are systematically utilized in these programs. The assessment and systematic teaching of social skills through modeling, discussion, and rehearsal are frequently generated to enable students gradually develop self-control, self-awareness and improve their relations with others.

Beyond school interventions, there are also community based treatment approaches that are utilized for the treatment of serious emotional disturbances. For instance the Pennsylvania's family based program has a structural family therapy approach and clinician training focused on appreciation of individual culture. Reports evaluating treatment outcome indicate significant treatment outcome of such innovative initiatives [12]. However these treatment outcomes are best described as evaluations of internal programs rather than in the form of an empirical inquiry intended for peer-reviewed rigorous studies.

Despite the substantial gains often reported from studies addressing treatment approaches for children and adolescents with *emotional disturbances* there is an urgent necessity for methodologically rigorous controlled treatment studies that will be evaluating the efficacy and long-term outcome of the treatment approaches. There are however substantial obstructions to rigorous treatment outcome research in this field. The disturbances of children with emotional difficulties tend to be of varied nature, often they are characterized by multiple psychiatric diagnoses and consequently it is complicated to assess the effectiveness of a specific treatment approach [12].

Emotional Intelligence

Norma S. Guerra
University of Texas, San Antonio, TX, USA

Synonyms

Emotional self-efficacy; Social intelligence

Definition

Emotional intelligence (EI) is an extension of social intelligence that describes a person's innate cognitive ability to perceive, identify, assess, understand, manage, and explain emotions in order to reason, guide thinking and action, solve problems, and regulate behavior. Empathy, or the understanding of other's feelings, is a critical characteristic of EI. Proponents of EI theory argue that it is the best predictor of success in life and creates the best social relations. EI influences behavior in a wide range of domains including school, community, and the workplace [1].

Description

History

Intelligence quotient (IQ) tests are administered to measure cognitive abilities, including verbal/numerical memory and reasoning and other problem solving skills. For a long time, the results of these tests were considered the primary predictor of future success. However, some researchers proposed that IQ results alone were not always the best indicator of high levels of success. One of those was Psychologist Reuven Bar-On, who coined the term "Emotional quotient" as an analogue to IQ. How well an individual was able to cope with the social and emotional factors should also be considered. This thinking led to the development of EI.

While the concept of EI can be traced to literature of the early 1900s and to scientific references dating to the 1960s, the term first appeared in scholarly research in the form of Wayne Payne's 1985 doctoral thesis, *A study of emotion: Developing emotional intelligence.*

Study of the concept grew in the 1990s after John Mayer and Peter Salovey broke down EI into four skill areas or branches:

1. Perceiving emotion: an individual's ability to accurately recognize and identify emotion in self and others.
2. Using emotion in thinking: an individual's ability to use emotion to influence or facilitate thought, which involves knowing when to include and exclude emotions.
3. Understanding emotion: an individual's ability to label, categorize, and describe emotions, then associate them with socially appropriate actions.
4. Managing emotion: an individual's ability to regulate emotions to achieve goals [4].

EI gained widespread popularity outside academia in 1995 with the book entitled *Emotional Intelligence: Why It Can Matter More Than IQ*, by Daniel Goleman [2]. This book expanded the original EI definition to include 25 characteristics, which some researchers claim overstated the power of EI and eroded the concept because those characteristics included personality traits as well as emotions. Since then, EI theory has been applied to several fields, including business management and education [3]. Goleman suggests that individuals are born with a general emotional intelligence that determines their potential for learning emotional competencies. Similar to the four-branch model, Daniel Goleman has defined five emotional levels:

1. Self-awareness: Recognition of an emotion, comprehension of how functioning is affected, which leads to decision-making.
2. Managing emotions: The ability to use strategies to manage emotions and to change to a more desirable emotion as necessary.
3. Motivating oneself: The driving force to act in order to manage emotions. Persons high in this area tend to be more productive and less impulsive.
4. Recognition of emotions in others: A skill necessary to read another's emotions in order to express appropriate responses such as empathy.
5. Handling relationships: Responding in appropriate ways to affirm another's feelings. Involves the ability to inspire, influence, and develop others while managing conflict.

How EI is Measured

The first assessment tool used to measure *verbal* emotional expressiveness was the Beth Israel Hospital Psychosomatic Questionnaire, which asked patients to react to emotional scenarios by answering open-ended questions. The test was used to diagnose patients with *alexithymia,* a

condition characterized by the failure to recognize and verbally express emotions. Other scales that have been developed based on this model include: Schalling-Sifneros Personality Scale, Gottscalk-Gleser system, and the Minnesota Multiphasic Personality Inventory, State and Trait Meta-Mood Scales, and the Toronto Alexithymia Scale. One of the criticisms of all the scales is that they focus exclusively on measurement of negative emotion rather than being inclusive of both negative and positive emotions [2].

Assessment of *nonverbal* emotional expression has taken the form of the Affective Communication Test, the Affect Sensitivity test, the Communication of Affect Receiving Ability Test (CARAT), the Profile of Nonverbal Sensitivity (PONS), the Diagnostic Analysis of Nonverbal Accuracy Scales (DANVA and DANVA-2), and the Japanese and Caucasian Brief Affect Recognition test (JACBART). Criticism of these tests includes the fact that they yield results that cannot be correlated consistently. As such, critics suggest that they may not be testing the same underlying skills.

Bar-On believed that the level of one's emotional intelligence correlates with his/her level of success in areas such as academics, environmental demands, and problem solving abilities and with proper training it could be improved upon. Additionally, he developed one of the first reliable self-reports, the Emotion Quotient Inventory (EQ-i) to measure emotional intelligence.

The Mayer-Salovey-Caruso Emotional Intelligence tests (MSCEITs) appear to be the most recent standard for assessment. They measure EI by directly relating assessment to four branches: a person's capacity to identify emotions in others, to use emotions to facilitate thought, to understand emotional meanings, and to know how to manage emotions [4].

Challenges to EI Theory

Initially there was support for EI as being an addition to Gardner's Multiple Intelligences, which classify human potential in children. Specifically, Gardner proposed that interpersonal and intrapersonal intelligences reflected an individual's ability to understand the feelings and emotions of oneself and others. However, ongoing research suggests that emotion may be more accurately labeled as a skill.

While emotions naturally seem to be a primary driver of human evolution, some educational researchers dispute that it is the best predictor of success in life due to lack of concrete, correlated scientific evidence [1].

Relevance to Childhood Development

For Students

Overall, emotional intelligence represents an ability to validly reason with emotions and to use emotions to enhance thought, which can significantly impact a child's development. Proponents of emotional intelligence feel that unlike IQ, EI can be taught and, therefore, can have a greater impact on levels of success. Studies show that implementing emotional intelligence curriculums in school not only enhance a child's emotional intelligence, but also increases academic abilities. They also suggest that students who demonstrate healthy EI adjust, integrate, and regulate their emotions as they strive for goals throughout their development. They realize that emotions - negative or positive - are temporary states that lead to better understanding and growth. Emotionally intelligent students better prioritize their thinking and are more equipped to solve problems with creativity and flexibility. On an individual level, EI has also been linked to work performance as well as the ability to communicate effectively, build meaningful relationships, and make moral decisions. Interest levels are heightened when there is a social or emotional connection to something. They are drawn to careers that involve social interactions, like teaching and counseling.

The proponent's claims are supported by the following research:

- EI is a consistent predictor of social and academic success in children.
- There is a positive correlation between identification of nonverbal emotion and cognitive ability assessed by students' standardized tests [3].
- Individuals with high EI tend to exhibit lower engagement in problem behaviors and avoid self-destructive, negative behaviors, such as smoking, excessive drinking, drug abuse, and violent episodes involving others.

For Teacher Utilization

EI proponents dispute the historical belief that rational logic is more important than feelings or emotions. While early philosophers posited that emotions make people weak or vulnerable, proponents of EI argue that instead, it allows people to better cope with change and conflict. They propose that healthy emotional intelligence begins with teachers, who should recognize, understand, and validate the importance of emotions and feelings. In doing so, they can create a positive learning environment that may better equip students to deal with decision-

making regarding such real problems as substance abuse and violence.

Advocates have found success in implementing a social and emotional learning curriculum (SEL). SEL aids students in understanding emotions and becoming problem solvers. SEL also looks at social and self-awareness, which are related to Gardner's inter- and intra- intelligences. One way teachers implement a SEL curriculum is through the use of literature. Students can easily relate their lives to that of the characters in different stories.

Emotional Lability

Nicholas Bolt
Fordham University, Bronx, NY, USA

Synonyms

Affect lability; Emotional incontinence; Pathologic emotionality; Pseudobulbar affect (PBA)

Definition

Emotional lability is a disorder characterized by involuntary emotional displays of mood that are overly frequent and excessive, often the result of various neuropathologies.

Description

Historically, emotional lability has been difficult to categorize as a distinct psychological disorder. The term is often used interchangeably with pseudobulbar affect (PBA), although PBA more generally refers to excessive emotions that may or may not correspond with the underlying mood. PBA also encompasses a broader range of emotions including anger and irritability, while emotional lability generally refers only to emotions characterized by laughing and crying.

Although the definitive cause is still unknown, most hypotheses point to the loss of voluntary, cortical inhibition over brainstem centers that produce the facio-respiratory functions associated with laughing and crying as the anatomical basis for this syndrome. This loss of cerebral control results in a dissociation of affective displays from the subjectively experienced emotional states.

A more specific neurological explanation cites bilateral corticobulbar motor track lesions as the main cause. The lesions uncouple cranial motor nerve nuclei and supranuclear integrative centers from their cortical control. Almost all cases of emotional lability involve neurological systems with motor functions, and associated lesions are always multifocal or bilateral. The most common neuroanatomic structures involved include the internal capsules, the substantia nigra, the cerebral peduncles, and the pyramidal tracts. The lesions are most commonly correlated with multiple sclerosis, Alzheimer's disease, stroke, and traumatic brain injury.

The excessive emotional displays associated with the disorder can have a profoundly negative social impact. These displays often impair social and occupational functioning, lead to social phobias and withdrawal, and eventually become socially disabling.

To date, the inability to locate a definite cause for the disorder has impeded direction and treatment. Three scales measuring emotional lability have been frequently used and statistically validated: the Pathological Laughing and Crying Scale (PLACS), the Center for Neurologic Study-Lability Scale (CNS-LS), and the Emotional Lability Questionnaire (ELC). Attempts to reduce the symptoms of the disease often include anti-depressants and dopaminergic agents, with individual case reports suggesting some improvement in symptoms. However, no neuropharmaceutical treatment has conclusively shown to be effective in large, controlled trials.

Emotional Self-Regulation

Tammy L. Sonnentag, Mark A. Barnett
Kansas State University, Manhattan, KS, USA

Synonyms

Emotional self-control; Emotional self-monitoring; Regulation of emotion

Definition

Emotional self-regulation refers to the complex process of initiating, inhibiting, and modulating the conscious aspects of emotion to effectively achieve one's goals. Although this concept, at the most basic level, refers to controlling one's feelings, theory and research on emotional self-regulation have addressed various cognitions, physiological processes, and behavioral outcomes associated with individual differences in the capacity to effectively manage one's emotions.

Description

Although the ability to regulate one's emotions emerges at an early age and evolves throughout the lifespan, significant differences have been found in individuals' tendencies to control their emotions. The following brief review describes some of the factors that contribute to the development of, and individual differences in, emotional self-regulation during childhood and beyond.

Age-Related Differences

Young infants rely on others to regulate their emotions. For example, a mother may closely monitor an infant's exposure to potentially stimulating events and may withdraw him or her from situations that are over-arousing and stress-inducing. Furthermore, when infants' facial expressions or cries connote distress, frustration, or fear, parents and other caregivers frequently regulate infants' emotions by holding, soothing, and/or distracting them [4].

The capacity for emotional self-regulation slowly emerges during infancy and early childhood, and the individual's coping skills tend to become more effective and appropriate to the specific situation. Infants and toddlers show early signs of emotional self-regulation in distressing situations by averting their gaze, self-soothing (e.g., sucking a thumb), or clinging tightly to an object or caregiver that provides a sense of security [2]. During early childhood, children continue to develop and improve their ability to inhibit, minimize, or intensify the duration of emotional reactions, and this ability increases considerably with the capacity to use language. In comparison with their younger counterparts, older children are more likely to have internalized the coping strategies suggested by their caregivers. Furthermore, older children are better able to use language to express their desires and concerns to caregivers who can offer them assistance in regulating their emotions [3].

The child's developing language and cognitive abilities are associated with the selection of more mature, appropriate, and effective strategies for controlling emotions. For example, whereas younger children tend to regulate their emotions primarily by using behavioral strategies (e.g., engaging in a distracting activity), older children are also able to use cognitive strategies (e.g., adjusting goals, thinking positively, engaging in mental distractions) to adjust to challenging situations. Accompanying the increase in available coping strategies, children develop a greater awareness that the appropriateness of a particular approach for regulating their emotions is influenced by social norms, their specific goals, as well as the nature of the specific situation that confronts them [1].

Biological Influences

Age-related changes in emotion self-regulation are at least partly due to the increasing maturation of the neurological systems, including the portion of the frontal lobes that are essential to managing attention and inhibiting undesirable thoughts and behaviors. Specifically, the functioning of the prefrontal cortex contributes to the capacity for emotion regulation, as it responds to the limbic system and parts of the brain such as the amygdala where powerful emotions (e.g., fear, anxiety)

are formed and processed [5]. Moreover, some theorists and researchers contend that the neurological development associated with emotional self-regulation is experience dependent, such that children's unique experiences serve to establish the neural connections that contribute to the ability to control emotions. Although research on neurological development and the monitoring of emotions is quite limited, the interaction of neurological maturation and the child's unique experiences appears to play an important role in developmental gains and individual differences in the ability to self-regulate emotions.

Socialization Influences

As suggested by the earlier discussion of age-related differences in emotional self-regulation, socialization experiences contribute to individual differences in children's tendencies to control their emotions. Early on, some parents regulate their infant's emotional states by reading their emotional signals, providing appropriate stimulation, modulating levels of arousal, and reciprocating and reinforcing appropriate expressive reactions [2]. Later, these parents may use emotion coaching to encourage the development of emotional self-regulation. A parent who uses emotion coaching labels and explains emotions, uses induction to explain why the child's emotions in a particular setting are appropriate or inappropriate, and reinforces the child for proper emotional responses. In contrast, some parents may inadvertently practice emotion dismissing wherein they deny or ignore their child's displays of emotion, and fail to adequately assist their child in learning to express his or her feelings in a socially acceptable manner.

Emotional Dysregulation

Emotional dysregulation refers to the inability to adequately initiate, inhibit, or modulate emotions. Failure to adaptively regulate one's emotions, especially those that are intense and negative, may lead to behaviors that are unacceptable and antisocial. For example, some preschool victims of physical abuse have been found to imitate their parents' lack of emotional and behavioral control by responding to crying peers with personal distress and aggression rather than empathy and helping.

Research has suggested that several forms of psychopathology may be associated with the dysregulation of emotion in children [3]. For example, the externalizing problems (e.g., conduct disorder) and internalizing problems (e.g., extreme shyness and withdrawal) of some children may be associated with affective instability and the failure to effectively regulate intense emotions. Furthermore, the failure to learn to adequately self-regulate emotions in childhood may evolve into broader expressions of emotional dysregulation and psychopathology during the adult years (e.g., generalized anxiety disorder). Consequently, individual differences in the ability to properly regulate emotions during childhood may serve as an important precursor of individual differences in emotional and behavioral adjustment throughout the lifespan.

Empathy

Anne Fierro Vanderlaan
Saybrook University, Meridian, ID, USA

Synonyms

Compassion; Sympathy; Understanding

Definition

Empathy is when a person cognitively places him/herself emotionally into the experience of another person by

understanding the persons view of the world and imagining the same feelings.

Description

Empathy is what makes humans different than other organisms. Showing compassion and empathy is not only being in someone else's shoes. It is the principle of understanding someone else's situation, which requires interpreting an individual's basic beliefs. This includes the ability of identifications of assumptions, and grasping the cultural, social, historical background of another's feelings or difficulties. Having empathy is internalizing with sympathy and compassion in true understanding.

Relevance to Childhood Development

As children increase empathy, they can become more caring about others. Without empathy, conflict resolution is difficult and a child may become selfish and uncaring. Empathy is something that can be mirrored to children. Teaching a child by example as well as helping the child to be compassionate by doing for others in small ways. A parent and child relationship can be the template for teaching for humanity the concepts of generosity and empathy.

Encephalitis

Lena Prinzi, Wiley Mittenberg
Nova Southeastern University, Fort Lauderdale, FL, USA

Definition

Encephalitis is a neurodegenerative disorder associated with physical, cognitive, behavioral, and social impairments. The disease can originate from virus or bacteria. Arboviruses carried by mosquitoes, mites, and ticks are responsible for the most common forms of viral encephalitis [6]. The disease can be fatal, especially in infants and children.

Description

Encephalitis begins with an infection that leads to inflammation of the *parenchyma,* or neural tissue of the brain [9, 13]. Bacterial encephalitis occurs secondary to an injury inflicted on the brain by penetration, fracture, or opening of the skull. Bacteria infect the cerebral tissue through contact and encephalitis subsequently develops [1]. Viral encephalitis is more common than bacterial encephalitis and can present as two differently originated diseases: primary infection or secondary, *postinfection.* Arboviruses that cause encephalitis are contracted through bites from mosquitoes, tics, and mites. There are about 500 such infectious arboviruses. Most infections occur between June and September ([6, 11]). Eastern equine encephalitis, Western equine encephalitis, St. Louis encephalitis, and California encephalitis are the most prevalent arboviral encephalitis infections in the United States [6]. California encephalitis is a complex of related viruses, including the LaCrosse virus that is prevalent in the Midwest and causes encephalitis in children [4]. Mumps, measles, and influenza are examples of diseases that could lead to a secondary postinfection [6]. There have been a few cases of postvaccinal encephalitis occurring in infants, but it is extremely rare [4].

After the virus has entered the body, viral transport can occur through blood or nerve cells [3]. In neural pathways, the virus kills the host cells after entering the cell. However, the cell death occurs differently depending on the type of encephalitis. In lysis, or *necrosis*, the cell membrane ruptures and cell death occur faster than in apoptosis, a programmed cell death that leaves the actual cell membrane intact until late stages of the infection [3]. Shortly after infection, inflammatory cells accumulate at the infection site and enhanced lysosomal activity becomes apparent. The immune system attacks the infected site. Extensive numbers of lymphocytes and plasma cells in the area of inflammation infiltrate the inflamed connective tissue. This inflammation is characteristic of encephalitis [3]. The rate at which inflammation progresses of depends on the type of encephalitis present. Herpes simplex virus type 1 produces an acute inflammation that progresses rapidly, causing severe symptoms that include olfactory or gustatory hallucinations, memory loss, and disordered behavior [8]. Subacute sclerosing panencephalitis (SSPE) following the measles or measles

vaccination is a postinfectious encephalitis. It proceeds much more slowly, gradually causing chronic inflammation and atrophy [1, 3]. The cerebral spinal fluid and cerebral spinal fluid glucose appear normal in encephalitis, but cerebral spinal fluid proteins, white blood cell levels, and intracerebral pressure are elevated [9, 11]. Bacterial encephalitis appears to affect the parenchyma focally while viral encephalitis has a more diffuse impact [1].

There are milder versions of encephalitis that can go unnoticed in a patient who recovers without any greater impairment from the disease. However, encephalitis can also become a very serious and in many cases fatal disease that leaves lifelong debilitating symptoms for the patient. Encephalitis may present with a variety of symptoms that can include headache, fever, drowsiness, sore throat, bone pain, delirium, muscle pain, myopathy, tremors, vomiting, photophobia, vertigo, tinnitus, paraaesthesia, and nucal rigidity [6, 8, 9]. The symptoms are not necessarily consistent across the different types of encephalitis and this presents difficulty when diagnosing the disease. Patients with HIV-1 encephalitis tend to show apathy, depression, social withdrawal, and hyperreflexia. In herpes simplex virus encephalitis, the patient can have headache, fever, and delirium, but may also present with amnesia and Klüver-Bucy syndrome [9]. SSPE is characterized by ataxia, tremors, spastic paresis, and slow, sinuous movements [12]. Edema and congestion are early symptoms of the eastern equine encephalitis; later symptoms include stupor, coma, convulsions, and high fever. After the acute phase of encephalitis, coma can occur for several days [11].

It is important to consider four aspects when diagnosing encephalitis: (1) how the viruses entered, (2) how the virus chooses its host cell, (3) progression, and (4) how the response of the immune system affects overall pathology. The first two aspects are especially important when distinguishing the specific type of encephalitis present [3]. Questions need to be asked regarding travel history, animal exposure, community epidemics, immunization history, and vector exposure [11]. Neuropsychological assessment of encephalitis is necessary to determine the degree of cerebral involvement. If a chronic disease is present, the influence of that disease on neuropsychological or cognitive function should be considered. Postinfectious encephalitis tends to produce focal cerebral dysfunction, as do bacterial abscesses. A cerebral abscess can also cause more generalized pathology beyond the location of focal involvement [1]. Differential diagnoses of encephalitis involves ruling out alternative causes such as acute cerebellar ataxia, meningitis, acute disseminated encephalomyelitis, and Gullain-Barre syndrome, and collagen vascular disease. Symptoms from drug ingestion can also be mistaken for early stages of encephalitis, especially recreational drugs such as methamphetamine and cocaine [11].

Most types of encephalitis cause diffuse damage. The damage creates widespread neuropsychological dysfunction, making it difficult to determine the origin. Diagnosis is usually made using a lumbar tap, electroencephalography (EEG), magnetic resonance imaging (MRI), or computed tomography (CT). When considering herpes simplex virus, a brain biopsy may be carried out [6]. A history of respiratory illness within the past 2–3 weeks may be an important indicator of mycoplasma encephalitis [5]. Different types of encephalitis are more prevalent in different stages of life. Although a specific etiology of encephalitis should not be excluded based on the patient's age in most cases, it is an important factor to consider when excluding differential diagnosis: St. Louis encephalitis is more common in adults than in children [8], SSPE occurs mostly in children [9], Herpes simplex virus I, Herpes simplex virus II, and Eastern equine encephalitis is most prevalent in infants [8]. Herpes simplex encephalitis occurs in 12% of children between ages 6 months and 10 years of age [8].

Symptoms of encephalitis can occur after 24 h up to 1 week postinfection depending on whether the onset of the disease is acute or insidious. If not treated immediately, the overall mortality rate is 50–70%. Mortality rates are particularly high in young children [6]. For example, 68% of children under the age of 10 are affected by Eastern equine encephalitis do not survive the disease [8] compared to the overall mortality rate of 30% [6]. Recovery from encephalitis is otherwise probable and follow-up neurological assessments should be considered after recovery [1]. Postencephalitis, most patients have severe sequelae such as motor impairments, deafness, seizures, mental retardation, hyperkinesias, developmental retardation, and shortened attention span [8]. Memory impairment, similar to that caused by bilateral temporal lobe damage, may be present, but is not always be recognized in postencephalitis assessments [14].

Initially, the patient may need intensive care hospitalization. There are few efficient treatments for viral encephalitis [11], but it is important to monitor for adequate fluid and electrolyte intake, continuously check vital signs, such as blood pressure and respiration [7], intracranial pressure [6] and treat seizures occurring in encephalitis aggressively with anticonvulsants [2]. Three or more seizures, focal neurological findings, high cerebral spinal fluid protein, delayed presentation, and longer coma is indicative of poorer prognosis [11, 12]. Pharmacological treatment is

not available for most viral encephalitis, but there are exceptions among the herpes viruses [10]. Herpes simplex encephalitis is effectively treated with the antiviral acyclovir, which reduces mortality rates to 20% [12]. Bacterial encephalitis is effectively treated with antibiotics [11].

Relevance to Childhood Development

Viruses can be transmitted during pregnancy. Rubella virus can affect the fetus' central nervous system during the first trimester. Poliovirus, western equine encephalitis, West Nile virus, and herpes virus can enter the placenta during the last days of pregnancy, although that is rare [1, 15]. If the onset of the encephalitis is in infancy, the disease can produce neurological impairments that are extremely resistant to treatment [1]. Children affected by encephalitis in infancy have also been shown to have greater developmental impairments than children who were affected during, or after, preschool [13].

Children suffering from encephalitis may require therapy in their areas of deficits. These services may include speech therapy, special education, and physical modifications to the environment [6]. Preventive measures that can reduce the incidence of encephalitis include immunizations, use of mosquito repellant, and the reduction of breeding areas for tics and mosquitos. Vaccines against Japanese encephalitis, tick-bourne encephalitis, Eastern equine encephalitis, Western equine encephalitis, and Venzuelan equine encephalitis exist [11]. It is also important to provide preventive information to teachers and others that come in contact with children who may have had the measles, mumps, or influenza in order to recognize subtle symptoms of postinfectious encephalitis [6].

Encopresis

Lisa Kilanowski-Press
Niagara University, Niagara, NY, USA

Synonyms

Fecal soiling; Primary encopresis; Secondary encopresis; Soiling

Definition

Encopresis is characterized by the involuntary, and in some cases voluntary, passage of fecal matter in inappropriate places. Encopresis most commonly takes two forms, primary encopresis and secondary encopresis. Primary encopresis involves unintentional soling on the part of children over the age of four who have never attained autonomy in voiding (e.g., who are not toilet trained). Conversely, secondary encopresis pertains to fecal soiling among children who have attained autonomy in voiding (e.g., have been successfully toilet trained).

Description

According to Philiohi [12], the term encopresis originates from the Greek word *kopros*, which is used to refer to stool. Encopresis is characterized by the involuntary, and in some cases voluntary, passage of fecal matter in inappropriate places. This elimination disorder most commonly

takes two forms, primary encopresis and secondary encopresis. Primary encopresis involves unintentional soling on the part of children over the age of four who have never attained autonomy in voiding (e.g., who are not toilet trained). Conversely, secondary encopresis pertains to fecal soiling among children who have attained autonomy in voiding (e.g., have been successfully toilet trained). Secondary encopresis may be further categorized as two distinct types: retentive versus non-retentive. Retentive encopresis is described as fecal soiling with constipation and overflow incontinence, while non-retentive encopresis pertains to soling without constipation and overflow incontinence (American Psychiatric Association, 2000). Most commonly, children who present with retentive encopresis evidence "loose stools" and discharge in their undergarments. The elimination of whole stools of normal constitution into the undergarments is most often observed in cases of non-retentive encopresis, with the "escape" of stool from clothing into the child's surroundings following elimination frequently reported.

Medical and psychological diagnosis of encopresis is not considered rare and is somewhat common in the general population. Recent estimates of incidence indicate that between 1 and 2% of children between the ages of 4 and 11 are diagnosed with encopresis, with higher rates (5–8%) found among children treated for psychological concerns on both an inpatient and outpatient basis [7, 12]. It has been suggested that 24% of cases seen by pediatric gastroenterologists involve fecal soiling [11]. Diagnosis of encopresis is more prevalent among boys than girls, and typically occurs between 1 and 5 years after the initial occurrence of elimination difficulty. Identification of encopresis is unusual among youth over the age of 16, although some cases have been reported.

Etiology and Diagnosis

The etiology of encopresis encompasses both medical and psychological domains and is contingent upon presenting concerns and behavior. Unlike many disorders, the underlying cause of encopresis in some patients may not be identified, particularly in non-retentive cases where the elimination difficulty is conceptualized as having psychological underpinnings, or in cases where common medical causes for the disorder, such as chronic constipation, have been ruled out. Most often, encopresis results from physiological as opposed to psychological difficulties, with approximately 95% of reported cases stemming from constipation. Such findings indicate that retentive encopresis is more common than the non-retentive subtype [4]. Regardless of the etiology, encopresis may be diagnosed in both medical and psychological arenas. Medical causes of the disorder should be first investigated and ruled out by physicians prior to psychologist referral; however, research supporting distinct and consistently identifiable psychological underpinnings is scant. In the absence of a discernable medical cause, potential psychological causes may be investigated, with the DSM-IV TR diagnosis for encopresis reflective of both medical and psychological etiologies.

Within the medical arena, chronic constipation has been determined to be primary cause of most cases of encopresis, and in young children, is often caused by painful defecation experiences; 63% of youth diagnosed with encopresis have reported painful bowel movements [11]. When constipated, a child's rectum may become distended as a result of hard feces, which in turn leads to painful defecation, potentially causing the child to refrain from toileting activities. Efforts to retain feces (withholding) cause temporary expansion of the anus, however, prolonged retention and limited room for expansion results in the involuntary propulsion of fecal matter. Chronic and severe retention of feces as a result of painful defecation experiences can, over time, lead to fecal impaction, which is described as the impaction of feces into the colon rectum as a result of the child's efforts to abstain from defecating [4, 7, 12]. Psychogenic megacolon is a term used to describe instances where fecal withholding incites the constipation itself, resulting in painful defecation, impaction, and finally, encopresis and leakage. Often, fecal impaction leading to encopresis may be misdiagnosed as diarrhea, as watery leakage (overflow incontinence) resulting from the impaction may be found in the child's undergarments as opposed to solid stools. Impairments in anorectal functioning as a result of malformation correction, poor muscle tone, as well as sphincter muscle contraction (as opposed to relaxation) during bowel movements can each lead to constipation, but are uncommon [12].

Psychological diagnosis of encopresis, as per the DSM-IV TR [1], requires the presence of each of the following: "1) repeated passage of feces into inappropriate places whether involuntary or intentional; 2) at least one such event a month for at least 3 months; 3) chronological age is at least 4 years; and 4) the behavior is not due exclusively to the direct physiological effects of a substance or general medical condition except through mechanisms involving constipation" (p. 116). Murphy and Carney [10], as well as Zarnegar [14] highlight the differentiation that exists within the DSM-IV definition discerning between retentive and non-retentive types. This DSM-IV differentiation echoes aforementioned etiologies of the disorder, with acts of uncontrolled defecation after toilet training due to

constipation coded 787.6 (with constipation and overflow soiling) and those unrelated to constipation and potentially linked to oppositional defiant disorder or conduct disorder coded 307.7 (without constipation and overflow soiling). However, despite the classification schema espoused by the DSM-IV, the tendency among many medical practitioners, as opposed to mental health practitioners, is to classify any form of soiling after toilet training as encopresis regardless of the etiology. When differentially diagnosing encopresis without constipation, Zarnegar [14] encourages consideration of the following: Hirschprung disease, neurological disorders, hyperthyroidism, hypercalcemia, diseases of the smooth muscle, anal fissures, fecal soiling as a depressive symptom, ADHD as a concomitant factor, and childhood psychosis (if non-accidental smearing occurs).

Encopresis as a Result of Mental Health Concerns

The field of psychology has long held numerous assumptions regarding the psychological etiology of encopresis not caused by physiological abnormalities. However, despite the wealth of hypotheses regarding psychological underpinnings of encopresis, few have been supported in the literature. In essence, despite years of assertions that encopresis stems from mental health concerns, relatively few studies have indicated that such is the case; fewer have been able to directly link mental health disruptions with resultant encopresis. Often, when no discernable medical cause can be found for encopresis, psychological underpinnings are considered on default.

Principal among purported psychological etiologies is the long held notion that encopresis results from sexual abuse. While indeed those who have been sexually abused are at increased risk for constipation and fecal impaction, children who have been sexually abused have not been found to demonstrate increased risk for encopresis far beyond same-age peers. In a study of children in a residential treatment center, history of sexual abuse was found to be nearly as common among children with encopresis as those without encopresis [9]. However, histories of sexual abuse were higher among youth who engaged in the sexual assault of others. Certainly, without a substantive body of literature supporting or refuting the link between sexual abuse and encopresis, practitioners should exercise due caution when making any such inference.

The co-existence of encopresis with other behavioral or emotional disturbances is well documented. However, despite comorbidity between encopresis and mental health concerns, no definitive causal link has been established between psychological distress and the onset of encopresis [5, 6, 8]. Any differences between the emotional and behavioral functioning of children with encopresis and matched controls has been found to be eliminated following treatment for encopresis [13], and no longitudinal differences in mental health functioning between children with and without encopresis have been found to exist [7]. Such findings suggest that encopresis may account for mental health challenges as opposed to disruptions in psychological functioning causing encopresis, with some noted exceptions including toilet phobia. Some have asserted that sudden and extreme trauma, loss, or separation can lead to lack of bowel control [14]. General psychological concerns frequently found to exist co-morbidly with encopresis include depression, anxiety, negative self image, a tumultuous relationship with parents, perceived lack of control, acting out behavior, diagnosis of ADHD, oppositional defiant disorder, conduct disorder, and psychosis, among others.

Treatment

Treatment of encopresis is wholly contingent upon the identified etiology and presenting concerns of the individual child. In cases where a medical origin has been identified, such as constipation, physicians employ medical treatment options combined with behavior management techniques. Conversely, in cases with no discernable medical cause, behavioral interventions are typically utilized. Regardless of etiology, multimodal intervention methods including medical, educational, and behavioral approaches are recommended. Given the lack of causative data regarding mental health challenges and encopresis, interventions or psychotherapy targeted toward treating emotional or behavioral difficulties alone in hopes of remediating encopresis is not advised. Certainly, in cases where a child presents with extreme psychological needs or distress, such issues should be addressed prior to remediating comorbid encopresis. Treatment and recovery from encopresis, regardless of modality or combinations of interventions used, may span 3–9 months, with longer treatment durations more common. Advising parents, teachers, and other invested professionals of the long treatment and recovery duration is of utmost importance, as many caretakers believe that treatment is not working when symptoms do not quickly dissipate.

Medical Approaches

Medical treatment for encopresis stemming from constipation includes a variety of approaches typically commencing with a complete bowel evacuation. In cases where fecal impaction has occurred, medical disimpaction under the care of a physician should be conducted prior to

the utilization of any laxatives at home. Most often, laxatives, enemas, and suppositories are prescribed to ensure that stool is removed from the rectum and lower colon in cases with and without fecal impaction [12]. Once fully cleansed, routine maintenance therapy consisting of laxatives, stimulants, and lubricants should be employed to ensure regular and soft bowel movements. Over time and with proper management, the child's rectal caliber will return to normal, and regular defecation patterns will resume [12]. Though examination of a child's diet is a positive endeavor when working with all children, diet alteration in children with encopresis has not been found to successfully remediate the disorder. Dietary changes, particularly sudden increases in fiber intake, should not be employed except under direction of a physician, and in fact, may increase symptoms of encopresis [12].

Education

Frequently, children with encopresis suffer from a vast array of social and emotional sequelae stemming from fecal soiling accidents, and are often blamed for their toileting difficulties. Parents and children alike have been found to initially deny the existence of long term soling difficulty, believing that the condition is something temporary that the child will eventually outgrow; longitudinal research regarding encopresis yielded the finding that 46–53% of children with encopresis deny the fact that they have toileting difficulties [3]. A tendency to shame children with encopresis also exists along side of parental belief patterns related to emotional and personality characteristics as the cause of toileting difficulty. Such belief patterns tend to be widely prevalent, as parents have been found to routinely identify laziness, carelessness, and emotional problems as primary contributing factors to their child's encopresis [3]. Given the plethora of misinformation and misunderstanding that surrounds diagnosis of encopresis, parent and child education regarding the disorder, causes, and treatment options should be a key first step following initial diagnosis. Friman et al. [4] suggest that direct instruction regarding the elements of successful and disordered bowel function, the impact of treatment mechanisms on the child and bowels, as well as clear and direct discussions regarding inappropriate blaming of the child for retentive elimination difficulties, are critical aspects of education for retentive types of encopresis. Likewise, agreement to cease punishment for bowel related accidents, regardless of whether they are perceived to be "unintentional" or "intentional," is strongly advised (p. 266). Parental involvement in intervention development and medical planning is critical to success, and will aide in increasing treatment integrity, including medication management and adherence, domains that are frequently mismanaged and lead to relapse.

Behavior Management

Research has found that behavior management combined with medical treatment is more effective in treating retentive encopresis than medication alone [2]. Consequently, a multimodal behavior management plan for encopresis is recommended in addition to medication; those in treatment for non-retentive encopresis benefit from behavior management alone once medical origin has been ruled out. Principal among behavior management techniques in treating encopresis is the establishment of a toileting schedule [4, 12]. Establishing a toileting schedule where the child is required to visit the bathroom two to three times per day for 5–10 min should be required, and should ideally occur 20–30 min following meals. Although some do not believe that scheduled toilet times should occur during the school day, depending upon the severity of encopresis, such arrangements may be necessary. At home and at school, children should been given privacy in the bathroom; use of a nurse's bathroom or other private one stall bathroom is strongly recommended at school and special permission should be obtained to use such facilities. For small children whose feet may not touch the floor while seated on the toilet, use of a small stool to level their feet will facilitate posture for appropriate bowel movements [4]. Charting of the child's bowel movements, accidents, as well the consistency of feces passed both accidentally and intentionally should be maintained and provide insight into needs for plan refinement and successes. Routine checking of underwear for soling is a helpful addition to such plans and facilitates behavior management. In cases where the child has soiled, a plan for child involvement in clean up should be established. Positive reinforcement, including rewards and praise for accident free periods of time, are a strong addition to toileting plans, and can become part of the child's charting and progress monitoring plan.

Enculturation

►Cultural Transmission

Endophenotype

Endophenotype is a genetic/behavioral biomarker demonstrating differences in outcome for similar genetic variables based upon the pressure of environmental phenomena. The concept was developed to efficiently divide behavioral symptoms into stable phenotypes with clear genetic connections and was originally borrowed from insect biology. A number of related terms are often used as well to reflect similar meaning but not stressing genetic connection including intermediate phenotype, biological marker, subclinical trait, vulnerability marker and cognitive marker. In particular, for complex behavioral and psychiatric conditions, endophenotypes for similar genes vary significantly based upon experience.

Endorphins

The term endorphin consists of two parts: Endo and orphin. These are short forms for the words endogenous and morphine. This is intended to mean "morphine like substance originating from within the body". Endorphins are endogenous opioid polypeptide compounds. They are produced by the pituitary gland and the hypothalamus particularly during exercise, excitement, pain, orgasm or even consumption of spicy foods. They resemble opiates in their ability to produce analgesia and a feeling of health. Endorphins are suggested to work as natural pain relievers.

Enuresis

Steuart T. Watson, Dale Brown
Miami University (OH), Oxford, OH, USA

Synonyms

Bed-wetting; Urinary incontinence (term most commonly used when referring to adults)

Definition

Enuresis is the repeated voiding of urine into the bed (nocturnal enuresis) or clothes (diurnal enuresis). It is not diagnosed until a child reaches a chronological or developmental equivalent age of 5 years.

Description

The word "enuresis" is derived from the Greek word "enourein" which literally means to void urine. Specifically, it is used to describe a condition wherein bedwetting is repeated at least two times per week for at least 3 consecutive months or involves clinically significant emotional distress, social or academic impairment, or impairs other significant areas of functioning. Enuresis is said to be occurring as long as the voiding of urine is not due to the intake and resulting physiological side effects of a substance, a general medical condition such as urinary tract/bladder infection, diabetes, or neurological or urological disorders. The prevalence of enuresis is the highest in children between the ages of 5 and 7 years and then tends to drop off sharply. It is more common in boys (7% at age 5 years) than in girls (3% at age 5 years). Enuresis tends to be a self-limited disorder as it often disappears on its own as the child, and their nervous system, matures. However, enuresis can spontaneously reoccur, most commonly after the age of 7 years, or again after the age of 12 years.

Enuresis can be further described in several different ways. Primary enuresis occurs when the individual never actually obtains control of the urinary sphincter muscle, and therefore, the bladder. This skill is referred to as urinary continence. Urinary continence is usually said to have occurred when the individual exhibits urinary control for a period of 6 months to 1 year. Secondary enuresis is when symptoms of bedwetting occur after urinary continence has been exhibited for at least 6 months to1 year. Nocturnal enuresis is far more common than diurnal enuresis. Although it is rare, some individuals may have both nocturnal and diurnal enuresis.

Enuresis may also be voluntary (intentional) or involuntary (unintentional), with the majority of cases being involuntary. Involuntary enuresis may be either primary or secondary. Although no specific genetic link has been found, rates of enuresis are higher for children for whom one parent was enuretic and even higher if both parents were enuretic. Involuntary enuresis is a result of failing to learn to control the urinary reflex. Voluntary enuresis is almost always a form of secondary enuresis and may be related to other psychological/psychiatric symptoms.

Treatment of enuresis generally fall under two categories: behavioral and pharmacological. Of the two, behavioral treatments have a higher success rate, lower recidivism rate, and higher social acceptability due to the lack of expense relative to the cost of medications. Behavioral treatments generally consist of at least one or a combination of the following interventions. One of the most effective options is to use a urine alarm which has one end attached to the child's underwear and the other end to an unobtrusive part of the outer clothing or wrist. The urine alarm has a moisture detection mechanism which sets off the alarm and alerts or awakens the child. Other techniques include reinforcement for dry nights (or days). This is often implemented with a "star chart" where star stickers are placed on the chart for each dry time period. After a pre-established number of stars are achieved, the child receives a reward. In addition to these interventions, other "common sense" techniques are often used such as restricting fluid intake before bedtime, teaching urinary retention techniques, and waking the child up at night periodically to go to the bathroom. Although these techniques may be useful adjuncts to the urine alarm, they are unlikely to be successful in and of themselves. Psychopharmacological treatments typically consist of tricyclic anti-depressant medications such as imipramine, oxybutynin chloride (to help control bladder spasms), or desmopressin (an antidiuretic hormone). Although initially effective, return of enuresis symptoms is common after the medication is removed.

Epicanthic Fold

An epicanthic, picanthal or epicanthus fold is a skin fold of the upper eyelid from the nasal bone to the inferior side of the eyebrow. It covers the inner core of the eye. It is a normal trait for a large percentage of humans. This lower fold of the upper eyelid gives the eyes of some east Asians an appearance which seems relatively narrower and almond shaped in comparison to most Caucasians and individuals from the sub-Saharan African desert. Their eyes seem wider due to a higher upper eyelid fold.

Epidemiology

Synonyms

Community study

Definition

Epidemiology is the study of the frequency of a disorder and its distribution in various populations.

Description

The scope of epidemiology is wide and includes: establishing dimensions of morbidity and mortality; quantifying the risks of developing a disease; identifying and defining syndromes; describing the natural history of diseases; identifying factors which influence or predict clinical course; searching for causes of disorder and related disability; and evaluating methods of disease prevention and control [17]. As such, epidemiological studies should help to enhance our understanding of the causes, treatment, and natural history of psychiatric disorders.

The main advantage of epidemiological research using samples from the general population is the ability to produce findings of greater generalizability than studies of clinical samples. Data from clinical settings are generally not representative of individuals with psychiatric disorders because of the bias in service attendance through restrictions in evaluating, access, and selection processes in terms of help-seeking behaviour, symptoms, and chronicity [5]. Samples from the community and clinical settings may also differ in the risk factors, comorbidity, natural history, and response to treatment of their psychiatric disorders. An additional problem with using clinical samples is that children's referrals to clinical settings may partly be related to parental characteristics. Additionally, the finding that most children in the community with significant problems do not receive adequate help [5] underscore the importance of epidemiological studies.

Much progress has been obtained in epidemiological studies involving children and adolescents in recent years. This progress is strongly influenced by related developments in adult psychiatric epidemiology [19], including:

- Greater specificity of diagnostics of psychiatric disorders since the introduction of ninth edition of the *International Classification of Diseases* (ICD-9) and third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) that permits the operationalization of specific diagnostic decisions instead of broad, unspecific decision about "caseness."
- The development of reliable diagnostic assessment instruments such as the National Institute of Mental Health (NIMH) Diagnostic Interview Schedule for Children which have been modelled after the instruments used in adult epidemiology. These instruments not only reduce the observer, information, and criteria variance when using less standardized diagnostic instruments, but they also allow comparison of results across studies.
- The application of adequate research designs by estimating the prevalence of psychiatric disorders in the general population, including the use of a lifetime approach in addition to several levels of cross-sectional diagnoses. These methods enable the determination of the occurrence, clustering and sequence of syndromes and disorders over the subject's life span. Such approaches, originally introduced and used in the Epidemiologic Catchment Area study and used in numerous adult epidemiological studies world wide, have been adopted in child epidemiologic studies.
- Systematic co-ordination of information taken from various informants, including parent, teacher, clinician, and child.

Despite the above developments, there are some inconsistencies and unresolved problems in interpreting existing data on the epidemiology and risk factors of psychiatric disorders. First, despite the use of comparable criteria, the threshold for defining a "case of psychiatric disorders" varies from one study to the other, including the number of symptoms [12], need for treatment, social impairment, or definition of caseness. Second, studies vary in the way in which they combine information from different sources (parents, teachers, and children) [7]. Third, the time frame covered ranges from current symptomatology to lifetime. Fourth, differences in the sampling frame.

Case Definition

The three approaches commonly used to define the "case" with psychiatric disorders include the assignment of a diagnosis to the respondents by a clinician (i.e., the clinical approach); the use of a checklist or a questionnaire to assess symptoms or syndromes of psychiatric disorders (i.e., the dimensional approach); and the administration of a standardized diagnostic interview (i.e., the categorical approach). Since none of these approaches can be regarded as the gold standard for assessing and defining caseness, some studies have used combinations of these approaches.

The Clinical Approach

In studies that use the clinical approach, the children and their parents are interviewed by a clinician. By using the clinical interview techniques and clinical judgement, aspects of the child´s functioning not covered by standardized assessment procedures can be determined. Furthermore, respondents´ answers due to misinterpretation of the questions can be dictated. However, a major disadvantage of this approach is the cost and time involved in having clinicians do interviews on a large scale.

The Dimensional Approach

This approach uses checklists and questionnaires which have been designed to elicit some specific symptoms of a particular disorder. Individuals with high problem counts or syndrome scores can be considered cases. A strength of this approach is that the assessments are standardized and can be as general or specific as the investigator wishes. Two problems with the dimensional approach are that it does not allow the formulation of a clinical diagnosis of a psychiatric disorder, and that the cut-offs used to indicate caseness can be arbitrary.

The Categorical Approach

The categorical approach involves identification of psychiatric disorders within the DSM and ICD systems, and favours the use of standard diagnostic interview which can be administered by trained lay interviewers. Numerous epidemiological studies have been conducted with children and adolescents using structured interview schedules diagnoses based on DSM-III, DSM-III-R, and DSM-IV criteria.

Epidemiological Studies

Numerous epidemiological studies of child and adolescents have been conducted in various countries in the past three decades, which have contributed to our understanding of the prevalence and distribution of psychiatric disorders in children and adolescents.

The Isle of Wight Studies, UK

This seminal first large-scale epidemiological survey aimed to establish the prevalence of psychiatric disorders in children aged 10 and 11 years, using a two-stage design [8]. Parents and teachers of all of the 10–11 year old children who lived on the Isle of Wight completed a set of questionnaires about the child´s emotional and behavior problems. Children at high risk for psychiatric disorders were selected for more detailed assessment. Psychiatrists and other clinicians were used as interviewers for the detailed assessments, and made diagnoses based on the ICD.

The New Jersey County, USA

This two-stage epidemiologic study was designed to estimate the lifetime prevalence of selected psychiatric disorders [18] among 5,108 (2,564 boys and 2,544 girls) school children aged between 14 and 17 years who were recruited from eight secondary schools in the New Jersey County. During the first stage of the study, the following questionnaires were used: the Leyton Obsessional Inventory Child Version, the Beck Depression Inventory, Eating Symptoms Inventory, Eating Attitudes Test, and items to elicit symptoms of panic disorder. Additionally, some items were developed to assess anxiety and some items were taken from the Framingham and Tocorna Scales to measure Type A and Type B behavior patterns. Other questions included those used to elicit sociodemographic characteristics, school attendance and grades, and personal and family health. The questionnaires were administered by the teachers during the classroom hours. Those with positive results on more than one screening test (N=468) had a strong chance of being selected for the second stage interview. The interview, which was conducted by 13 clinicians, began with having each student completed the Youth Self-Report form of the CBCL, followed by questions for the assessment of eating disorders, depression, anxiety disorders, and obsessive-compulsive disorder according to DSM-III criteria. Psychosocial impairment was assessed by the clinician using the Children´s Global Assessment Scale.

Columbia, MI, USA

The sample consisted of 150 adolescents aged 14–16 years who were randomly selected from public schools in Columbia [9]. Interview with the adolescent and one parent was done at home with the diagnostic interview for children and adolescents. The parent also completed the Child Behavior Profile. The adolescents completed several questions including the Parental Bonding Instrument, the Conflict Resolution Scale, and the Piers-Harris Children's Self-Concept Scale. General dysfunction and the condition's seriousness were rated by a clinician, using a scale developed to score the adolescent's need for treatment. "Caseness" was defined by the presence of psychiatric diagnosis based on the DICA, and who were judged by two independent clinicians as in need of treatment.

The Ontario Child Health Study, Canada

A simple random sample of 2,317 children was taken of children aged 6–16 who attended public schools in an industrialized, urban setting [14]. A total of 1,751 parents completed the problem checklists and gave informed

consent to obtain teacher assessments. The questionnaires were mailed to the teachers to complete. A stratified random sample of participants for stage 2 assessments, which took place 1–3 months after stage 1, were done on the basis of age, sex, and high versus low symptom scores on the Ontario Child Health Study Scales. Altogether 251 of the 329 children who were selected for stage 2 agreed to participate. During stage 2 assessments, parents and children/adolescents completed problem checklists and were administered the revised version of the Diagnostic Interview for Children and Adolescents 2 times at 3 weeks apart. The clinicians consisted of five child psychiatrists, who have been trained in using the DICA-R.

The Puerto Rican Child Psychiatry Epidemiologic Study, Puerto Rico

A total of 777 children aged 4–16 were randomly selected from households in the island of Puerto Rico [1]. The study used a two-stage design. During the first stage, the parent and teacher versions of the Child Behavior Checklist were used, and children who scored above the cutpoint on either the parent or the teacher version of the CBCL were randomly selected from the total sample for a second-stage assessment. The interview was done with the mother at home to obtain information related to family composition, and to obtain the parent version of the CBCL, demographic data, and various risk factors of disorders. Clinical assessments in the second stage were based on parent and child interviews with the Spanish diagnostic interview schedule for children. "Caseness" was operationalized by combining the presence of a diagnosis and impairment level. That is, for every psychiatric diagnosis, the psychiatrist also scored each child on the Children´s Global Assessment Scale to measure adaptive functioning. Thus, a child who received a psychiatric diagnosis and had a score below 61 on the CGAS were considered the "definite cases," and those with a diagnosis and had scores ranging from 61 to 70 were the "probable cases."

The Dunedin Multidisciplinary Health and Developmental Study, New Zealand

The sample for this study belonged to a cohort of children born at the city´s maternity hospital between April 1, 1972 and March 31, 1973. The children have been followed from birth to age 21 with a comprehensive investigation including health, mental health, and academic attainment [13]. These children were first assessed at age 3 years (N=1,037), then reassessed every 2 years (5, 7, 9, 11, 13, 15) and three-yearly at ages 18 and 21 years. At ages 5, 7, and 9 years, the children were assessed with the Rutter Child Scales for completion by parents and teachers. At age 11, diagnostic interviews were conducted using the Diagnostic Interview Schedule for Children; whereas at 13 and 15 a modified DISC was used, and at age 18, a modified version of the adult Diagnostic Interview Schedule was employed. This study also included scales to measure family, peer and school attachment, life stress and general background circumstances.

The Christchurch Health and Developmental Study, New Zealand

This longitudinal study has followed a birth cohort of 1,265 New Zealand children born in the Christchurch urban region during the mid-1977 at birth, 4 months, 1 year, and annual intervals to the age of 15 years. Data were available from various combination of informants: maternal, child, and teacher [6]. At ages 15 and 16 years, maternal reports and self-reports of different symptoms were used. Mothers were interviewed at home and children at school by different interviewers. The abbreviated version of the DISC was administered to the children to measure anxiety disorders, oppositional defiant disorder, and attention-deficit hyperactivity disorder, supplemented by additional items to meet DSM-III-R criteria. Conduct disorder was assessed using the Self-report Early Delinquency Scale and substance abuse behavior (tobacco, alcohol, and illicit drug abuse) using survey questions, supplemented by the Rutgers Alcohol Problems Index. Maternal reports of the child were obtained using the DISC interview for anxiety and mood disorders, the Revised Behavior Problems Checklist to measure oppositional defiant and attention-deficit hyperactivity disorders; the parent version of the Self-report Early Delinquency Scale was used to assess conduct disorder. Children's problem with tobacco, alcohol, and illicit drug were obtained from questions about the parent's perceptions.

The Northeastern Study, USA

This study began when a sample of 385 5-year old American children entered kindergarten, and who were re-interviewed at ages 9, 15, and 18 years [15]. The Diagnostic Interview Schedule, Version III-R was used to provide a lifetime diagnosis of major depression, anxiety disorders, and substance use disorders according to DSM-III-R criteria. Parents completed questionnaires and/or interviews when the children were aged 5, 9, and 15 years old. Teachers' reports and school records of grades were gathered for the period from ages 6 to 15 years. Multiple sources of information used included a structured clinical interview for assessing psychiatric disorders

and ages of onset, self-report questionnaires for evaluating current functioning, and school records for academic performance and suspensions or expulsions. The mother gave information about the children's health for prenatal period to age 5 years. Ten trained interviewers with either research or clinical experience administered the DIS for DSM-III-R to the 18-year old adolescents. Indices of current behavioral, emotional, academic, and social functioning were assessed through self-report measures and school records: (1) The Youth Self-Report form of the CBCL provided overall emotional and behavioral functioning; (2) Self esteem was measured by the Rosenberg Self-Esteem Scale; (3) Interpersonal problems were assessed by the Interpersonal Problems Scale; (4) Information about course grades were taken from school transcripts; (5) School suspensions or expulsions in the preceding year were taken from school records and self-reports; and (6) Arrests in the previous year or involvement in the juvenile justice systems were based on self-reports.

The New York Child Longitudinal Study, USA

A total of 975 children in the age range of 1–10 year were originally sampled in 1975 from the upstate New York countries [2]. The first follow-up interview was done 8 years later, and the second interview when the children were aged 9–18 years old. Diagnoses were determined using the DISC, including attention deficit hyperactive disorder, conduct disorder, oppositional defiant disorder, overanxious disorder, alcohol abuse and major depression. The data from the two informants were aggregated to provide a single diagnostic set using the "or" rule. That is, symptom is considered present when either the mother or the child answered positively to the symptom. Children who met a diagnostic criteria and additionally had the scale scores more than one or two standard deviations above the population mean were given "moderate" and "severe" diagnoses, respectively.

The Oregon Adolescent Depression Project, USA

A total of 1,710 high school students (mean age=16.6 years) in three cohorts (1987, 1988, 1989) were recruited for the study, of which 1,508 participated in two interviews [11]. The schools were located in two urban communities with a population of about 200,000, and three rural communities in West Central Oregon. The schools were chosen because of their locations, all being within 100 miles from the project center. Sampling was designed based on parental consent and proportional stratification according to gender, grade and school size. The diagnostic interview used during the first interview (Time 1) was the Schedule for Affective Disorder and Schizophrenia for School-age Children. At a follow-up investigation (Time 2), done a year later, the LIFE interview was used to determine the course of the psychiatric disorders present at Time 2 and the onset of new disorders since Time 1. The participant's psychological, social, and occupational functioning and the need for treatment were evaluated by the interviewer using the Axis V Global Assessment of Functioning. The interview was conducted by one of 27 interviewers with advanced degrees in clinical or counseling psychology or social work, who had finished a 70-h didactic and experiential course in diagnostic interviewing. To determine the clinical significance of episodes of affective disorders, all adolescents with a current diagnosis of affective disorders were rated by three child psychiatrists with respect to "current level of functioning," "highest level of functioning during the past year," "severity of depression," and the "need for treatment."

The Cambridgeshire Study, UK

A total of 1,060 girls aged 11–16 years were recruited from three secondary state schools- one urban and two rural-within the county of Cambridgeshire [3]. The Mood and Feelings Questionnaire, was administered in the classroom, and was used to identify mood disturbance. A stratified random procedure was used to select the subjects for a more detailed interview. For each year within each school, subjects were divided into three groups in terms of their score on the Mood and Feelings Questionnaire. All those in the top 10%, one in two of the next 10%, and one in ten of the remainder were selected for interview. All interviews were conducted by three trained interviewers who had experience in working with young people in health care, education, or both.

The NIMH Methods for the Epidemiology of Child and Adolescent Mental Disorders (MECA) Study

The sample consisted of 1,285 pairs of youths aged 9–17 years, and their caretakers, who have been drawn from four geographic areas in the United States: (a) Hamden, East Haven, and west Haven, Connecticut; (b) DeKalb, Rockdale, and Henry counties, Georgia; (c) Westchester County, New York; and (d) San Juan, Puerto Rico [10]. The computer-assisted version of the DISC was used to diagnose psychiatric disorders based on DSM-III-R criteria. In the second part of the interview, the youths completed a set of instruments that comprised of demographic factors, patterns of service utilization, barriers to service utilization, social and instrumental competence, functional impairment and potential risk and protective

factors (e.g., family environment, family history of psychiatric disorder, parental supervision, life events, and pubertal development). The youths also completed the Peabody Picture Vocabulary Test-Revised.

The Bremen Adolescent Study, Germany

The Bremen Adolescent Study is a longitudinal study of the epidemiology of psychiatric disorders among 12–17 year olds [5]. The specific aims of the Bremen Adolescent Study are to estimate the prevalence, risks, course and outcome of psychiatric disorders, to determine their age of onset and severity, to examine the comorbidity patterns of disorders, and associated psychosocial impairment, as well as service utilization patterns. The children and adolescents were administered the computerized Munich version of the Composite International Diagnostic Interview to make diagnosis of current and past disorders according to DSM-IV. Participants were randomly recruited from 36 schools in Bremen, Germany. Data collection for the first wave of the study took place between 1996 and 1997, and for the second wave, about 15 months later. The data used in the first wave of the study comprised of 1,035 adolescents (421 males and 614 females), and for the second wave, it was 523 adolescents (195 males and 328 females). Parents provided information about themselves (education, occupation, health status), their family and the child via a set of questionnaire which they completed at their home.

The Zurich Epidemiological Study of Child and Adolescent Psychopathology (ZESCAP)

The main aim of the ZESCAP (Steinhausen et al., 2007) was to examine the prevalence of psychiatric disorders on a sample of 1,964 pupils living in the Canton of Zurich, Switzerland. The cohort was a stratified randomized sample which represented 12 counties of the canton, the school grades, and the types of school. Based on 158 schools, 2,780 parents were contacted by letter, for which a total of 2,192 (78.8%) of the parents expressed willingness to participate in the study. This study used a two-stage procedure, in which parents were asked to respond to the Child Behavior Check-list in the screening phase. The following cut-offs were used: (1) the 90th percentile of the attention problem scale (score 27), (2) the 95th percentile of the anxious-depressed scale (score >9) and (3) the 95th percentile of the total score of the aggressive and the delinquent behaviour scale (score >19). In the second stage, structured interviews were performed with 399 parents representing both screen positive and control children. DSM-III-R diagnoses were derived by using the German version (6) of the Diagnostic Interview Schedule for Children-Parent Version (DISC-P 2.3).

The Great Smoky Mountains Study of Youth

The main aim of The Great Smoky Mountains Study (GSMS) was to examine the development of, need for, and use of mental health services in children and adolescents in an area of the southeastern United States [4]. It used a multistage, overlapping cohorts design, in which 4,500 of the 11,758 children aged 9, 11, and 13 years in an 11-county area of the southeastern United States. Children who scored in the top 25% on the screening questionnaire, together with a one in ten random sample of the rest, were recruited for four waves of intensive, annual interviews (n=1,015 at wave 1). In addition to this sample, all American Indian children aged 9, 11, and 13 years who attended reservation and public schools. The screening measure consisted of the "externalizing" broad-band scale items from the child behavior checklist. The following constructs were measured in the study: Risk for mental health service use; service use, access, and barriers to care; family resources, family functioning; psychiatric symptoms, and family burden; Child's physical health and development; adversity and traumatic events; and community resources.

Children were screened and interviewed close to their 9th, 11th or 13th birthday. Families recruited for the interview stage of the study were visited at home by two interviewers. Following the wave 1 interviews, families were contacted by telephone every 3 months, in which they were asked about any service use during the intervening period, and any change of address, school, or family structure.

The Quebec Study [16]

The main aims of this study are to examine: (1) the prevalence of DSM-III-R diagnoses among adolescents, (2) differences in the reporting of psychiatric diagnoses across informants, and to (3) examine the impact of including an impairment criterion on the prevalence of adolescent psychiatric disorders. During 1986 and 1987, 1,201 mothers and teachers of 4,488 French-speaking kindergarten children in the province of Quebec, Canada completed a set of questionnaires. Two thousands of these children were randomly selected for annual assessments throughout childhood and into adolescence. Between 1995 and 1997, mothers and their children (ranged in age from 14 to 17 years) were interviewed using the French translation of the Diagnostic Interview Schedule for Children to obtain the prevalence of DSM-III-R disorders and perceived impairment associated with these disorders.

Epinephrine

Edalmarys Santos[1], Chad A. Noggle[2]
[1]Middle Tennessee State University, Murfreesboro, TN, USA
[2]SIU School of Medicine, Springerfield, IL, USA

Synonyms

Adrenalin

Definition

Epinephrine is a neurotransmitter and hormone that is most strongly linked with the chemical triggering of the "fight or flight" response of the sympathetic division of the autonomic nervous system.

Description

Epinephrine represents one of a class of neurotransmitters referred to as the catecholamines [1]. Also known as adrenalin, functionally epinephrine's primary role is in the activation of the "fight or flight" response [2]. As such, epinephrine exerts its influence on the sympathetic division of the autonomic nervous system, which itself is one division of the peripheral nervous system. Originating in the adrenal glands, epinephrine is synthesized from norepinephrine [1]. When released by the adrenal glands, in a period of stress, epinephrine serves to activate the system to respond by increasing blood flow, heart rate, respiration, and blood pressure [3]. Once the system perceives the threatening situation has been negotiated to some extent, Epinephrine levels decrease, in turn, deactivating the sympathetic division and activating the parasympathetic division of the autonomic nervous system.

Rivier College, Nashua, NH, USA

Synonyms

Autobiographical memory

Definition

Memory for specific events and episodes, connected to a particular context such as time, date, location, etc. including autobiographical memory.

Description

Episodic memory is differentiated from *semantic memory* (the knowledge of facts) as it includes "calling back into consciousness a. . .lost state that is then immediately recognized as something formerly experienced [1]," it allows for reliving of the original experience or for re-experiencing of the remembered event [2]," and can be "distinguished from knowledge of the past [2]."

Erikson, Erik H.

John Snarey, Sarah Poole
Emory University, Atlanta, GA, USA

Life Dates

1902–1994

Introduction

Erik Erikson stands as the most renowned psychologist of child and adolescent development of the twentieth century. His theory of eight psychosocial stages of human development provides a framework for understanding both the physical and psychological needs of humans as well as the social factors that contribute to personality development. Identity is at the core of Erikson's developmental model. He coined the term "identity crisis," which involves a "renegotiating of one's values, as they are oriented around other individuals and society at large" [16, p. 150]. The chronology of his research interests, to a significant degree, parallels Erikson's own life history and personal struggle for identity.

Biography

Erikson was born June 15, 1902, in Frankfurt, Germany, to an unnamed father, who was a Protestant Dane, and to Karla Abrahamsen Salomonsen, a Jewish native of Denmark. Karla was not married to Erikson's Father, and she raised Erik as a single parent for 3 years in Buehl, Germany [13]. She then married Theodor Homburger, a German pediatrician and president of the local synagogue, who adopted Erik and changed his surname to Homburger. Erikson's distinct appearance – tall with blue eyes and blond hair – provoked ridicule from his Jewish peers [16, pp. 146–151]. Erikson was not told that Theodor was not his birth father until he was an adolescent, although he had his own suspicions.

Growing up in Germany, Erikson attended the Karlsruhe *Vorschule*, or primary school, from ages six to ten, and the Karlsruhe *Gymnasium* from ages ten to eighteen. He received an *Abitur*, a certificate that gave him permission to enroll in a university [13, 18]. Immediately after graduation, Erikson hiked in the Black Forest. In 1921, 1year later, Erikson enrolled in *Badische Landeskunstschule* (Baden State Art School) in Karlsruhe to receive formal training in art [2, 14, 19]. Before completing his training, Erikson left Baden to attend Kunst-Akademie, a famous art school in Munich. Two years later, Erikson moved to

Florence, and for the next few years of his life, Erikson "wandered through Europe sketching, making woodcuts, painting and visiting museums" [17, p. 147]. In 1927, at the age of 25, Erikson left Florence and returned home to Karlsruhe to study and teach art. Erikson referred to the 7-year period of his life after the *Gymnasium* as a *Wanderschaft*, in which he had the opportunity to wander and reflect. This un-rooted period continued until Erikson received an invitation from his good friend Peter Blos to help him run a small school in Vienna [2, 14, 19].

In 1927, Anna Freud, Sigmund Freud's daughter, hired Erikson for a job as an art teacher at the Hietzing School in Vienna, Austria. While teaching there, he earned a diploma in 1932 from the local Montessori teacher training school. This was the only formal degree Erikson earned after receiving his *Abitur* [14, p. 67], although he also took liberal arts and teaching classes at the University of Vienna. Erikson's observations and analysis of child behavior during his experience as a teacher sparked some of his initial insights into child psychology. After being psychoanalyzed by Anna Freud and receiving encouragement from his peers, Erikson pursued psychoanalytic study with Sigmund Freud and other psychologists at the Vienna Psychoanalytic Institute, graduating in 1933 [14, 17].

In 1930, Erikson married Joan M. Serson, a Canadian dance teacher at Hietzing School who had completed her master's degree in sociology at the University of Pennsylvania. She was in Europe investigating various schools of dance in anticipation of pursuing a doctorate in education at Columbia University and, when Erikson and Joan met, she was visiting Vienna to research new European dance movements for a possible doctoral thesis [2, 19]. Joan and Erik influenced one another to such an extent that their relationship "wedded their two fields of psychology and sociology, therein giving birth to *psychosocial* theory" [17, p. 147]. In addition to these professional influences, Joan's Protestantism and support of religiosity helped Erikson to steer clear of the anti-religious persuasions of Freud.

In 1933, as the Nazi regime began to threaten Austria, Erikson and his family left Vienna and eventually moved to the United States. He accepted a position with the Boston Psychoanalytic Society, and became the first child analyst in Boston. During this time he also became a research assistant at the Harvard Psychological Clinic, where his work focused on issues related to personal identity. In 1936, Erikson moved to Yale University where he worked on his developmental theory [17].

Three years later Erikson relocated once again, accepting a position at the Institute of Child Welfare at the University of California, Berkeley. Shortly thereafter, he began teaching graduate seminars and opened a private practice in the San Francisco area. Also in 1939, he formally changed his last name from Homburger to Erikson. Throughout this time, his ideas about ego development started to crystallize as he developed the concepts of *ego identity* and *identity crisis*. In 1949, he became a full professor at Berkeley. The security of a tenured position was, however, short lived. The turbulence of the McCarthy era affected all spheres of American life, and academia was not immune to the "red scare." After World War II and the fall of Chiang Kai-shek's regime to Chinese Communists, the Cold War fight against communism grew more intense [2, 14]. Anxiety about communism permeated the academy, with universities in California requiring their employees to take an oath of loyalty. Having affirmed his allegiance by signing a constitutional oath and an oath to the state of California, Erikson saw no legitimate reason to sign another pledge at Berkeley. In his view, these measures reflected a growing madness over communism [19]. Erikson believed the role of a professor was to encourage students to examine all sides of an argument rather than simply acquiesce to the "official truth." Erikson studied similar instances of hysteria with his students, and his conscience would not allow him to participate in this frenzy without a protest. Erikson understood that his students watched their professors' responses in historical moments like this [2, 19]. Erikson wrote a resignation statement in June 1950 explaining his refusal to sign the oath, and this statement was eventually read to the American Psychoanalytic Association. He wrote, "I would find it difficult to ask my subject of investigation (people) and my students to work with me, if I were to participate without protest in a vague, fearful, and somewhat vindictive gesture devised to ban evil in some magic way – an evil that must be met with much more searching and concerted effort" [2, p. 158]. In essence, Erikson would not sign an oath that he believed reflected hysteria about the growing fear of communism, and his unwillingness to sign the pledge led to his resignation from his tenured position. This protest not only confirmed his American identity, but it brought to the surface "the conflictual nature of a discordant identity struggling to see itself as whole," which set the framework for further exploration of the identity crisis in his later works [19, p. 67].

From the 1930s through the 1950s, the Eriksons watched their first three children, Kai (b. 1931), Jon (b. 1933), and Susan (b. 1938) develop through the first stages of the life cycle. Their last child, Neil, was born with Down syndrome and was institutionalized immediately after his birth in 1944. The Eriksons initially told the

other children that the baby had died. The subsequent revelation of the truth regarding Neil's birth provoked a crisis in the Erikson family, causing strife between the parents and children, while bringing Erik and Joan together to collaborate on the development of the life cycle. While Erik's parenting experiences had contributed to his ideas about human development, Neil's birth and abnormalities may have precipitated the completion of the life cycle model. Creating a model that highlighted the "normal" process of human development, one biographer has suggested, provided an escape from the family crisis of having an "abnormal" child [14].

In 1951, Erikson accepted a position at the Austin Riggs Center, a mental health facility in Stockbridge, Massachusetts, where he remained until 1960. During these years Erikson became more vocal regarding the positive role of "religious traditions as a transmitter of values and psychological well being across the life span" [17, pp. 147–148]. After a brief stint as a part-time teacher at Massachusetts Institute of Technology in 1958, Erikson was offered a professorship at Harvard University. Drawn to opportunities to work with researchers across various disciplines, Erikson accepted the challenge and joined the faculty in 1960. The students admired him, and many of his new colleagues hoped that his interdisciplinary approach would bring together many scholars from various fields [2, 14].

Childhood and Society: Erikson's Exploration of Childhood and Youth Development

Throughout the 1950s and 1960s, Erikson published his theories of human development, paying special attention to childhood and adolescence. *Childhood and Society*, published in 1950, is the first text that outlines Erikson's model of the life cycle. Stemming from his training in Freudian psychoanalytic theory, Erikson created a model of human development that extended Freud's psychosexual stages of development, integrating "both psychobiological and sociocultural factors" [17, p. 146]. Unlike Freud's theory, Erikson's model of eight psychosocial stages of development encompassed the entire life span, demonstrating his belief that people moved through stages at particular times in their lives. Erikson posited that ego strength comes from the mastery of earlier developmental stages [13] (see ▶Erikson's Stages of the Life Cycle).

In the 1960s, Erikson published two other texts, *Youth*: *Change and Challenge* (1963) and *Identity*: *Youth and Crisis* (1968), which extended his research on childhood to adolescence, the stage at which youth must master the crisis of identity. In *Youth*: *Change and Challenge*, Erikson emphasized the strength of fidelity found in adolescence. The paradox of openness and focus, or the adolescent's desire to find trustworthy and reliable people, coupled with the ability to narrow and focus their commitments, provides a source of strength for adolescents as they gain perspective on their own lives and the world [2, 6]. *Identity*: *Youth and Crisis* examined the intersection between social reality and ego identity. Ego identity, in part, deals with the ability to accomplish what society deems important for future success, and, thus, one must be able to feel good about the future in the context of the current social reality [8, pp. 48–49]. Ultimately, Erikson integrated the importance of social context into his outline of the various crises a person faces from childhood to adolescence.

Beyond Childhood and Adolescence

Erikson's work extended beyond issues of childhood and adolescence. For example, between 1957 and 1962, Erikson wrote five essays that were eventually published under the title *Insight and Responsibility* [7]. This volume emphasized ethical, political, and historical concerns. "[H]e spoke as a psychoanalyst first – but one who also insisted on being an ethically concerned citizen, and a professional man very much involved with contemporary and historical *events* as well as clinical *problems*" [2, p. 267]. This work demonstrates Erikson's continued commitment to interdisciplinary study, which enabled him to engage ideas outside of psychoanalysis. In 1957, Erikson took a year-long sabbatical from teaching during which he and Joan went to Mexico so that he could write what he called a "study in psychoanalysis and history" [5]. Erikson attempted to study the actions and words of Protestant reformer Martin Luther through a psychoanalytic lens in order to illustrate and expand concepts such as identity, identity crisis, and moratorium. Erikson's examination of Luther centered on the years prior to his notoriety, exploring trends and patterns in his life that would explain how he was able to accomplish such sweeping historical reforms. He also sought to investigate the ways Luther resolved inner conflicts in search of his own identity [2, 14, 18]. Finally, Erikson's text on Luther demonstrated "the power of psychoanalytic approach and its concepts to integrate a wide diversity of information and make sense of it" [18, pp. 93–94]. *Young Man Luther* was published in 1958 as Erikson's first psychobiography, a literary form in which the author incorporated psychoanalysis with a person's life story [14].

The 1960s marked a ripe period for society to discover Erikson's work. The intense social, cultural, and political realities of the era opened the door for concepts that explored the intersections between self and society.

Erikson's diverse and broadening interests drew historians, theologians, biologists, sociologists, and philosophers to his research. At a time when the nation was at war, both the domestic war for civil rights and the global war in Vietnam, Erikson began a new book, *Gandhi's Truth* [2, 14].

Sparked by a trip to Ahmadabad, India, in 1962, Erikson [9] began to examine a strike led by Mohandas Gandhi three decades earlier. Summoned by mill workers in 1918, Gandhi went to Ahmadabad to organize a strike against mill owners. The mill hands suffered low wages and were willing to participate in a strike under the leadership of Gandhi, and they agreed to the conditions he asked them to follow during the protest. However, fearing that the mill hands would break their agreement to nonviolence, Gandhi decided to fast from food until the strike was over. Gandhi's fast affected both the mill workers and the mill owners. Erikson, drawn to Gandhi's ability to mobilize groups of people, wanted to search for the truth that inspired Gandhi's political and spiritual leadership. *Gandhi's Truth* was Erikson's second attempt at psychobiography. Although Erikson began the book in 1965, *Gandhi's Truth* was not published until 1969. Making little reference to the life cycle, Erikson chronicled Gandhi's life experiences in order to explore the ways he negotiated identity amidst great crisis. Erikson sought to discover Gandhi's truth by exploring the various sites he frequented when he was alive. Ambalal, Gandhi's benefactor and opponent in the strike at Ahmadabad, welcomed Erikson into his house as a guest as he constructed the psychobiography. Erikson also tried to understand pertinent concepts such as *dharma*, *Satyagraha*, *Artha*, and *Moksha*. As Erikson attempted to understand Hindu principles, cultural sensitivity guided his research. Lectures at Cape Town University in 1968 and Harvard University in 1972 underscored the didactic nature of *Gandhi's Truth*. Erikson challenged what he termed "pseudospecies" by highlighting Gandhi's response to crisis in his later years. Erikson [8] defined *pseudospeciation* as "man's deep-seated conviction that some providence has made his tribe or race or caste, and, yes even his religion 'naturally' superior to others" (p. 298). As Gandhi confronted these attitudes, he responded to social circumstances by drawing on inner virtues that stressed mutual respect, honesty, and the humanity of all people. *Gandhi's Truth* won Erikson his first Pulitzer Prize on May 4, 1970, as well as a National Book Award [2, 14].

Not only did Erikson look favorably on Gandhi's campaigns in India, he also "found some salutary effect in the Black Muslims' effort to restore African American identity; he would not dismiss black nationalism out of hand" [14, p. 399]. As a result, Erikson was open to his son Kai's insistence on a meeting with Huey P. Newton, leader of the Black Panther Party. In January 1971, Kai arranged for Newton to conduct a seminar for Trumbell College students, with his father in attendance. Due to the exaggerated national media coverage, the seminar did not go well. Therefore, Newton arranged for Erikson to meet him at a friend's apartment in Oakland, California. During the dialog, they discussed American racism, and while they disagreed on several points, Erikson and Newton respected each other. *In Search of Common Ground* records the dialog between Newton and Erikson [12]. Erikson, nevertheless, ended the friendship with Newton when he learned of his involvement in violence against civil authorities [14, pp. 399–401].

After he retired from Harvard in 1970, Erik and Joan moved back to Stockbridge, but spent summers at a home in the Cape Cod town of Cotuit [14]. Three years later, they moved back to California, living a short time in Belvedere and then Tiburon. "Old Tiburon" afforded them both an opportunity to write while living in a serene community of professionals and artists. However, during this period the Eriksons encountered financial difficulties. Erikson's work also received scathing critiques from feminists, psychoanalysts, psychologists, and a variety of other sources, and he attempted to respond to his critics through journal articles. At the same time, he continued to receive invitations to give lectures and engage in research. Nevertheless, health problems made it difficult for him to write or travel. Joan became involved in a nearby Episcopalian parish and Erik met with local clinicians to assist them in reviewing case files on schizophrenic patients [14, 18].

The Life Cycle Completed: Erikson's Encounter with Old Age

Although a major portion of Erikson's work focused on child and adolescent development, he also emphasized adulthood and old age in his description of the life cycle. Perhaps Erikson's examination of such issues was a sign of his own development as he entered the later years of his life [15, pp. 928–930].

In 1982, at age 80, he published *The Life Cycle Completed*: *A Review*, which summarized his most salient concepts [10]. This book demonstrated Erikson's personal need to reconsider old age and the death that he would eventually face. The text extended Erikson's understanding of the concepts of wisdom and integrity to include a rich holistic inner and outer vitality. Erikson emphasized the connections between early infancy and old age. In addition, the book demonstrated a distinct shift to historicism. Even after publishing the first edition of *The Life*

Cycle Completed, Erikson continued to gain new insights about the later stages of development; he scribbled notes on the pages of his own copy with the hope of eventually writing a new edition. Erikson collaborated with Joan Erikson and Helen Kivnick to engage in further research on what sustained elderly people's involvement in their own lives. Their research centered on interviews from 29 octogenarians who, as children, had participated in an earlier study in 1928. By revisiting these research participants, the Eriksons and Kivnick were able to investigate people who had experienced most stages of the life cycle. This new research was published in *Vital Involvement in Old Age* in 1986 [11]. When it became apparent that Erikson could not write an updated edition of *The Life Cycle Completed*: *A Review*, Joan Erikson updated the book by writing new chapters to add to the original version. The new chapters included a ninth stage of development that focused on the life cycle of individuals in their eighties and nineties as well as a focus on caring for the elderly and gerotranscendence [13]. Overall, both *Vital Involvement in Old Age* and *The Life Cycle Completed* reflected the thoughts that Erikson reconsidered and reformulated about the later stages of life as he himself encountered old age [14, 19] (see ▶Erikson's Stages of the Life Cycle).

In the 1980s, Erikson received various honors for his contributions to the field of psychotherapy. The founding of the Erik H. and Joan M. Erikson Center in conjunction with Cambridge Hospital psychiatry department and Harvard Medical School prompted the Eriksons' move from Tiburon back to Cambridge in 1987. Dorothy Austin, director of the Erikson center, offered the Eriksons an "intergenerational home," where she and Diana Eck, a young Harvard professor, would serve as caregivers should Erikson's health deteriorate [19, pp. 463–464]. Excessive sleep and loss of hearing signaled a decline in Erikson's health. As the interest in services offered by the Erikson center declined, and Austin and Eck pursued other career interests, Joan found herself overwhelmed with providing care for her husband. Erikson, nevertheless, continued to engage in intellectual activity as he experienced the integration between old age and infancy, in which he had to depend on the consistent care of others. One of Erikson's final tasks was the clinical supervision of Harvard doctoral student David Wilcox, to whom Erikson passed on the significant lessons he had learned during his own training. This supervision ended in 1990, and marked a shift in Erikson's accessibility to the outside world and the outside world's access to Erikson [14]. Erikson conceded to Joan's control over their lives, specifically her role as an intermediary with those seeking access. Often, Joan would make presentations for him and limit his contact with persons with whom she felt uncomfortable [14]. In 1992, Erikson fractured his hip and underwent surgery, after which he found it difficult to walk. After this fall, his health continued to decline. Stevens [18] speculates that Erikson may have been experiencing the early stages of Alzheimer's disease (p. 13).

In 1993, Joan placed Erikson in a nursing care facility in Harwich, Massachusetts, and purchased a nearby home to remain close to him. Erik could only move with a wheel chair and his health continued to fail. Erikson's final transition came in 1994 when he caught an infection that led to his death. On May 11–12, Joan held Erikson's hand and sang to him through the night. At four o'clock in the morning, Erikson died at the age of 91. Erikson's created ashes were interned and a funeral service was held on June 15, 1994, at First Congregational Church of Harwich. Several commemorative services and forums followed the memorial [14, pp. 471–473]. Ultimately, his accomplishments and contributions to the field of child development have left a legacy that will endure for generations.

Accomplishments

Erik Erikson was considered a "cultural hero" during his lifetime [18, p. 13; 14, p. 396]. In 1970, he occupied the cover of the *New York Times Magazine*. Presidents Johnson and Nixon invited Erikson to the White House. Various universities awarded him honorary doctorates, including Yale and the University of California, Berkeley. The University College of London appointed him to the first Freud Memorial Chair. The San Francisco Psychoanalytic Institute renamed its reading room after Erikson. The American Psychiatric Association invited Erikson to speak in 1984. In 1987, the Psychiatric Clinic of Karlsruhe (Germany) dedicated an adolescent unit in his honor [2, 13, 17]. These accomplishments highlight Erikson's ability to touch many arenas of society.

Erikson's research proved relevant to the public, private, and academic arenas of life. His theory gained such wide acclaim because it emphasized the human person in all aspects of life, from childhood to old age. Not only did his theory touch the intrapsychic development of persons, it also included the ways society informs, promotes, and hinders identity formation.

Contribution to Child Development

In Erikson's theory, childhood stages are an essential aspect of the life cycle. Childhood builds the foundation for adulthood, and the formation of values begins in these early stages. For example, Erikson's theory about child's play introduces a new outlook to psychology. To Erikson,

the activity of child play is valuable for the child because it represents a space where the child can make sense of the world, and it incorporates both problem-solving and meaning-making. It also reveals what children prioritize [2, pp. 129–131, 4, 6]. Unlike adults who view play as vacation *from* work, play *is* work for a child. Recognizing play as worthwhile challenges families and academic institutions to not only value play, but to provide space where children can engage in play as a means for development. Erikson's studies on childhood influenced DeMause [3], Ariès [1], and Hunt [15] in their own studies of the history of childhood [19]. Erikson [9] also makes explicit connections with the "relationship of childhood play to political imagination" (p. 11). These connections enhance the understanding of the contributions of social institutions to childhood development. Erikson [4] emphasized that unless a child experiences proper development in the earlier stages, the person experiences the conflicts at later stages as more and more difficult to overcome. In many ways, the health of a person depends upon the successful integration of earlier childhood stages.

Furthermore, Erikson's life-cycle model creates a framework for researchers to interpret and analyze children's behavior and development. Using his model as a lens enhances one's understanding of contemporary issues such as juvenile delinquency. For example, Erikson's "triple book-keeping" method of looking at physiological needs, social context, and psychological processes has many implications for understanding the behaviors and attitudes of dispossessed, disenfranchised, and underprivileged youth. Erikson acknowledged that external circumstances influence the emotional states and overall health of children. In addition, society plays an integral role in Erikson's theory because society provides the conditions in which children develop. This acknowledgement yields responsibility and moral accountability to parents and society as a whole for the development of children. In essence, Erikson's model provides a foundational framework with which to analyze the behaviors and attitudes of children while simultaneously acknowledging the parental and societal contributions to childhood development.

Erikson's contributions to childhood development have affected a wide range of issues related to the formation and growth of children. Not only did Erikson add to the content pool of research; he also contributed his own research method. As Stevens [18] explains, Erikson's sensitivity to the way his clients felt revealed a concern for people that prevented a myopic focus on research. Erikson became "not just an interpreter but a medium through which they can work through what conflicts they feel" (p. 107). He demonstrated that the subjectivity and social contexts between client and therapist are valuable and relevant to analysis [18]. In essence, Erikson attempted to exemplify some of his own concepts in the way he conducted research, concepts that stressed the societal role of child development.

Erikson's Stages of the Life Cycle

Sarah Poole, John Snarey
Emory University, Atlanta, GA, USA

Synonyms

Ego development stages; Stage sequence of ego epigenesis; Stages of identity development; Stages of psychosocial development

Description

Developmental psychologist Erik H. Erikson constructed a theory of the human life cycle composed of eight stages, each of which represents a particular period in human development. Erikson theorized that an individual's development relies on three processes: "the biological process of the hierarchic organization of organ systems constituting a body (*soma)*; . . . the psychic process of organizing individual experience by ego synthesis (*psyche)*; and. . . the communal process of the cultural organization of the interdependence of persons (*ethos*)" ([8], pp. 25–26). A developing body, a developing mind, and dynamic sociocultural milieu are the three primary processes underlying a person's identity formation and psychosocial development.

Erikson based his developmental theory on the biological logic of "epigenesis," which refers to the prenatal process by which, through a sequence of structurally elaborated stages, a fertilized egg cell develops into a fetus. Erikson saw a parallel between Freud's understanding of the biologically-based development of psychosexual modalities (oral, anal, phallic, latency, and genital) and the development of more general psychosocial modalities (trust, autonomy, initiative) but, with new insight, Erikson proposed that the epigenetic process continues throughout the entire life cycle. The structure of biological growth and psychosocial development, that is, follow analogous, interactive patterns across the lifespan. In Erikson's theory, a time of ascendancy in each stage of development affects the whole hierarchy of development. Ascendancy refers to the gradual, sequential way a child naturally grows in accordance with both outer (biological) and inner (*psyche*) laws of development in relation to persons and institutions (*ethos*) [5]. Erikson theorized that *every* person would encounter each of the eight stages in the same sequential order, although the chronological age and cultural content could vary due to maturational differences in biological growth and cultural differences in the content and timing of social expectations.

Each new stage is characterized by a period of development during which the child must resolve a psychosocial "crisis" (turning point) in order for him or her to mature in terms of ego identity and related ego strengths or virtues. A psychosocial crisis results from the organic pressures on the psyche of a person, which arise from physiological changes, coupled with new age-related social expectations that stem from the larger sociocultural system. These pressures create the conditions necessary, but not sufficient for, the next stage of personality development, including the attitudes that individuals have about themselves and the world [8]. Character dimensions, such as trust and mistrust, emerge throughout the life cycle, and Erikson [6] recognized that the task of each stage is to integrate the dimensions in a ratio that favors positive character virtues over negative (e.g., trust over mistrust). The ratio of dual character dimensions associated with each new stage influences a person's ego identity. Ego identity refers to the process whereby "the accrued confidence that one's ability to maintain inner sameness and continuity (one's ego in the psychological sense) is matched by the sameness and continuity of one's meaning for others" ([2], p. 95). Erikson extended his theory of the life cycle to relate each stage to institutions in the larger society [5]. The character dimensions and virtues produced within the stages, in some sense, prepare or teach people how to live in and contribute to society as a whole. (See Chapters, Psychosexual Development and Erik H. Erikson for more information.)

Psychosocial Stages

Stage 1: Basic Trust Versus Basic Mistrust

The infant relies on others to provide basic nourishment needs. At this "oral stage," the infant learns how to get and take in using the mouth and other senses. The infant's apparent query, "Can I trust again?" builds on the infant's biological preoccupation with, "Will I be fed again?" [12]. Having sensations fulfilled faithfully by familiar people engenders trust. Trust implies the attitude of reliance on primary caregivers as well as confidence in one's self. Consistent care and nurture enable the baby to gain a sense of confidence in the future. A baby internalizes the continuity of experience and begins to form attitudes of the world based on having his or her needs met. Erikson tends to emphasize the mother's role during this stage of development. Indications of trust include a sense of ease when feeding that the breast or bottle will provide sufficient milk, and a sense of assurance when sleeping that the nipple will be there again. The balancing character

dimension, mistrust, is a "readiness for danger and an anticipation of discomfort" ([10], p. 15). A sense of mistrust leaves a child feeling deprived, divided, and abandoned; symptoms of mistrust include withdrawal or isolation [5, 6]. Attaining a favorable ratio of trust over mistrust gives rise to the ego strength, or virtue, of *hope*, which is an abiding trust and confidence in others (e.g., caretakers), the self (e.g., trustworthiness), and the future. Hope also entails "the enduring belief in the attainability of fervent wishes, in spite of the dark urges and rages which mark the beginning of existence" [14]. According to Erikson, trust and hope have a natural affinity with the social institution of religion. (See Chapter Trust versus Mistrust for more information.)

Stage 2: Autonomy Versus Shame and Doubt

During the toddler age period, psychosocial autonomy relies on muscular maturation, verbalization, and locomotion. Muscular growth expands a child's development and prompts the psychosocial modality of letting go and holding on. During this period the child develops a new sense of self and the word "No!" — an affirmation of this new sense of relative autonomy — becomes the child's favorite expression. Children develop "from oral sensory dependence to some anal-muscular self-will" and a certain sense of self-control ([8], p. 78). However, if the process of toilet training makes the child overly self-conscious, the child may experience shame and low self-esteem. Shame leaves a child with feelings of restraint, self-doubt, and compulsion; a symptom of shame includes an inability to share. However, a favorable balance of autonomy, or self-governance, over shame and self-doubt leads to a healthy personality. This favorable balance produces the virtue of *will*, which allows the child to exercise willpower, or free choice, as well as self-restraint [6, 8]. Erikson states that "the human being must try early to will what can be, to renounce (as not worth willing) what cannot be, and to believe he [or she] willed what is inevitable by necessity and law" ([8], p. 78). In this stage, parents are the child's strongest social influence; the child internalizes the parental voice, which helps to delineate between his privileges and his limitations in the social order. While the child develops self-will, the child also forms a conscience and the rudimentary ability to distinguish between right and wrong. Law-and-order ethics safeguard the child's developing autonomy. Ultimately, the adolescent and adult's participation in legal and political institutions reflects the ongoing psychosocial task of attaining autonomy on a societal level [2, 6]. (See Chapter Autonomy for more information.)

Stage 3: Initiative Versus Guilt

For children in the period that many societies consider the "play age," Stage 3 is characterized by the psychosocial conflict of initiative versus guilt. After becoming conscious of his or her personhood in Stage 2, the child attempts to make sense of what type of person he or she is going to be. As children at Stage 3 indulge in exploration, they embrace the favorite phrase "Why?" Initiative adds to autonomy the dexterity to plan a task. They move into psychosocial modalities that enable them to make things. Children are eager to collaborate with other children to construct things. Children imitate and idealize adults who play a role in their lives. Working adults replace the heroes of books and fairytales. While the family remains the child's primary social influence, the child's curiosity sparks an initiative to explore beyond the family into the new world [2, 4, 12, 13]. Guilt comes when adults constantly correct or discipline children for exercising their developing locomotor skills and mental power. Symptoms of guilt include inhibition, over-obedience, and repressed hopes and fantasies. The attainment of a favorable ratio of initiative over guilt produces the ego virtue of *purpose*, which is "the courage to envisage and pursue valued and tangible goals guided by conscience but not paralyzed by guilt and by the fear of punishment" ([6], p. 289). Children gain an economic ethos, whereby they recognize adults by their uniform and occupational duties. Because of adults' ability to relate their own childhood dreams to active adult life, Erikson suggests that the realization and support of a favorable ratio of initiative over guilt have a natural affinity with the economic order and political institutions [2]. (See Chapters Initiative versus Guilt and Oedipus Complex for more information.)

Stage 4: Industry Versus Inferiority

Industry versus inferiority marks the psychosocial conflict of Stage 4, which Western societies often think of as the "school age." At this stage, a child loves to learn as well as play – "and to learn most eagerly those techniques which are in line with the *ethos of production*" ([8], p. 75). Industry centers on productivity and specialization in learning. Erikson [2] says the personality crystallizes around the conviction, "I am what I learn" (p. 87). Provoked by curiosity and a desire to learn, the child's questions at this stage are "What is this?," "What is that?," and "How can I do?" [10]. The child's school and neighborhood become the social spheres in which to form friendships and experience other social exchanges. Children make positive associations with people who are knowledgeable and skill-oriented. Inhibition threatens a child's ability to master this stage. Children need to feel free to

explore through play while also facing and overcoming the challenge to learn something new. An unfavorable ratio of industry leads to a sense of inferiority or inadequacy. A symptom of a sense of inferiority is finding one's sole sense of identity and worth in industriousness, or work-like activities. The child who masters this stage, however, gains the ego virtue of *competence*, which is the child's belief that he or she can both begin and complete a project at an acceptable level. Emphasizing a child's abilities can create the type of affirmation needed to gain competence. Children need to find a space in which they acquire the sense that they can do at least one thing well. Erikson believed that psychosocial industry on the societal level and during adulthood was closely related to mastering new technology [5]. (See Chapter Industry versus Inferiority for more information.)

Stage 5: Identity Versus Identity Confusion

The primary task of the adolescent is achieving a favorable balance of identity over identity confusion. In Western societies, identity formation is most often articulated by the question, "Who am I?" If individuals master this stage, they will have a sense of ego identity, in which a unity exists between what one sees inside of the self and their perceptions of what others think or expect them to be [2, 3, 12]. Friedman [11] argues that identity emerges from the intergenerational mutuality that occurs between children at earlier stages and parents or caretakers at the generative stage (which will be discussed under Stage 7). A child's relationship with generative parents creates a framework from which the child can draw various identifications, which later converge with whom one senses himself or herself to be ([11], pp. 225–226). The primary social influence at this stage is the peer group. In this stage, individuals are able to embrace others with different values and ideas without fusing one another's identities. An unfavorable balance leads to role confusion, symptoms of which are delinquency, cynicism, apathy, and inability to settle on an occupational identity. Mastery of the psychosocial conflict gives rise to the ego virtue of *fidelity*, which is a "sense of commitment to a self-chosen value system and the capacity to maintain loyalties freely made in spite of unavoidable contradictions of value systems" ([12], p. 150). In other words, the adolescent "learn(s) to be faithful to something" ([10], p. 12). Because of such faithfulness, he or she must eventually confront ideology. The grasp for identity is visible across the lifespan on the societal level and, according to Erikson [2], in the social stratification of society as well. (For more information, see Chapters on Identity Achievement, Identity Crisis, Identity Moratorium, and Ego Identity.)

Stage 6: Intimacy Versus Isolation

This stage marks the period of romance during "young adulthood," in which the psychosocial crisis is intimacy versus isolation. The articulated question of this stage is "Who can I share my life with?" The conflict exists between one's desire for intimacy in a long-term relationship, and one's commitment to not losing one's self in the process. The primary relational influences are intimate relationships and work connections. Although romance is a component, this stage extends beyond sexual attraction to the formulation of relationships in which inner resources are mutually shared. Erikson clarified that the capacity of young adults "to lose themselves so as to find one another in the meeting of bodies and minds, is apt to lead sooner or later to vigorous expansion of mutual interests and to a libidinal investment in that which is being generated and cared for together" ([8], p. 67). In some sense, this stage flows from the previous stage of gaining a sense of self and feeds into the next stage of generativity. When individuals do not master this stage, they feel isolated or seek to distance themselves from others. A symptom of such isolation is the avoidance of intimacy and exclusivity. If this crisis is mastered, the young adult realizes the ego virtue of *love*, understood as "mutual devotion" ([5], p. 137). Relationship patterns in the larger social world reflect the intimacy gained during this stage [5]. (See Chapter Intimacy versus Isolation for more information.)

Stage 7: Generativity Versus Stagnation

The psychosocial preoccupation of the middle adulthood years is between generativity and stagnation. At this stage, the question "Whom or what can I care for?" correlates with the person's need to be needed. The psychosocial tasks are to create, to take care of what has been created, and to contribute to the next generation. Generativity manifests itself in the desire to guide the next generation. While Erikson places a focus on parental generativity, he also clarifies that even those who are childless can become generative socially. Societal generativity comes in the form of shepherding, mentoring, guiding, or nurturing what society has produced. The social sphere of influence during this stage comes primarily from work and family. When people do not become generative, they tend to become stagnant and self-absorbed. Symptoms of stagnation include excessive self-love and possible stage-wide regression [4]. The ego strength that arises from the successful resolution of the crisis of generativity versus self-absorption is *care*, which is "a widening commitment to *take care of* the persons, the products, and the ideas one has learned *to care for*" ([8], p. 67). Productivity and

creativity characterize mastery of this stage. The psychosocial generativity that arises during this stage of the life cycle is reflected in the societal generativity produced by the social institutions of art, education, and science [5]. (See Chapter Generativity versus Stagnation for more information.)

Stage 8: Ego Integrity Versus Despair

The older adult's apparent question, "Has my life been meaningful?," stems from the psychological preoccupation with facing death. Those who have a sense of personal integrity from the contributions they have offered during their life experience the rich depths of this stage. Only the one who has taken care of things and people, and has adapted himself or herself to the triumphs and disappointments of being, develops ego integrity. Persons in this stage value not only life, but their life within history. If a legacy can be established, there is no need to fear death. Integrity in this stage also manifests itself in guarding oneself against the experience of a diffused *soma, psyche*, and *ethos*. Despite numerous physical and psychological changes, a person must remain an integrated and whole individual, even as they come to understand the "integrative ways of human life" ([8], p. 65). In essence, integrity lends itself to creating order and meaning. The radius of social interaction extends to the cosmic world order. In contrast, the person who lacks ego integration expresses fear and despair at the thought of death. Regretting missed opportunities contributes to the level of despair one may feel, while embracing life as having been well-lived contributes to the level of felt integrity. One who dwells in regret of missed opportunities will feel high levels of despair, whereas one who reflects fondly on his or her life and legacy will feel high levels of integrity. With a new awareness of the transience of life, the person acknowledges their inability to have another chance to live life over again. Those who have not attained integrity may cover their despair with an attitude of cynicism [2]. Later, while experiencing old age himself, Erikson [8] reformulated the "antipathetic counterpart to wisdom" as disdain – "a reaction to feeling (and seeing others) in an increasing state of being finished, confused, helpless" (p. 61). Furthermore, in some sense, older adults connect with the infantile stage of trust again, bringing human development full circle. The ego strength or virtue associated with ego integrity is "wisdom," which is "an informed detached concern with life itself in the face of death itself" ([8], p. 61). On the societal level, Erikson saw integrity reflected in philosophy [5].

Ego Transcendence

During their later years, Erikson and his wife, Joan, speculated about the possible existence of a "ninth stage" of ego transcendence. In some sense, elders revisit and confront the more challenging elements of each stage all over again. The negative and positive tendencies are reversed. The major crisis of this stage is overcoming the sense of loss elders eventually feel. Loss of physical functions produces decreasing levels of self-esteem and confidence. Weakened bodies lead elders to ask daunting questions: "What am I good at?" "What am I good for?" "Who do others think I am?" Despair may follow as they begin to mistrust their own capabilities. Loss of autonomy over their bodies and life choices may evoke shame and doubt. Without the enthusiasm of earlier years and the ability to initiate new and creative projects, feelings of guilt and inadequacy may arise as the individual grieves the sense of lost purpose and incompetence. Identity becomes vague because the role a person took when young no longer fits who the person is in the elder years. The awkwardness that others feel when relating with elders who are experiencing "incapacities and dependencies" may lead to isolation of the elder ([8], p. 111). Because society usually ascribes generativity to active adults, society releases elders from the role of caretaker; this "not being needed may be felt as a designation of uselessness," which generates a feeling of stagnation in elders ([8], p. 112). What elders can or cannot physically and mentally engage in because of aging becomes a major concern when they look back over their lives. Healthy concerns and other forms of daily functioning may hinder thorough retrospection. Additionally, the loss of loved ones invokes sorrow and a sense of despair [8].

Joan Erikson [8] pointed out that when societies do not integrate the elderly into social life and ostracize and neglect them, the oldest adults may become "embodiments of shame" instead of "bearers of wisdom" ([8], p. 114). Nevertheless, despite the increasing sense of outer and inner loss, some elders welcome each new morning with a renewed sense of hope. Elders who adequately overcome the elements of mistrust, shame, doubt, guilt, inferiority, identity confusion, isolation, stagnation, despair, and disgust can experience "gerotranscendence," in which elders shift their focus from physical aspects of life to more transcendent aspects, which in turn leads to a deeper level of satisfaction [1, 8, 9].

Relevance to Childhood Development

Erikson's life cycle model established that the early stages were just as valuable as later stages. Unless children master these early stages, they may never develop the types of

skills necessary to master crises later in life. Erikson emphasized what he believed were the critical sociocultural factors in child development. Caregivers' consistent care and nurture, such as providing children with space for exploration, and caregivers' self-awareness of their childrearing strategies, each contribute to development of a healthy sense of self in relation to the world.

Erikson's stages also give parents, teachers, and mentors insight into the types of conflicts that children engage in as they develop. Forming healthy bonds between teachers, parents, and community members is one way that society can work together to provide a healthy environment that will promote healthy development. Knowledge about human development allows parents and teachers to be intentional about the type of learning and home environments they create for children. For example, teachers who learn how to alternate between play and class-work create a balanced environment in which children of school age have the conditions necessary to master their psychosocial crisis. On the contrary, when a child is unable to participate fully in stage-appropriate development, he or she may regress instead of developing [8]. Additionally, the behavioral and psychological patterns that children engage in during their development mirror social institutions in the external world. Therefore, encouraging children to engage in appropriate activities during each developmental stage prepares them for entry into a social world that engages in similar activities. Prohibiting engagement of appropriate activities makes transitioning into the adult world an even more arduous task.

Overall, healthy child development breeds competent individuals who can exhibit leadership in society. Erikson [2] wrote that to "assure continuity of tradition, society must early prepare for parenthood in its children; and it must take care of the unavoidable remnants of infantality in its adults" (p. 405). Additionally, Friedman [11] identified Erikson as creating a life cycle that "concerned the bonds of trust and sharing that facilitated adolescent identity (stage five) and old-age integrity (stage eight)" (p. 222). Erikson [2] argued that healthy children will not fear life if their elders have integrity enough not to fear death. The intergenerationality of the cycle not only teaches an awareness of self in relation to others, but also teaches a person how to parent. Healthy personalities enable children to gain ego identity and to develop the virtues that lead to morally conscious citizens.

Errorless Learning

Judah B. Axe
Simmons College, Boston, MA, USA

Synonyms

Errorless teaching

Definition

A teaching arrangement minimizing errors by initially providing and then fading cues and prompts to evoke a desired behavior or skill.

Description

Errorless learning primarily comes from an operant psychology approach to teaching individuals to make discriminations [1, 2]. An example of a discrimination is teaching a child to identify a picture of a car when shown many pictures and told to "find the car." Discrimination learning is a paradigm used to examine the ways organisms learn and has implications for teaching children and adults with developmental delays. Traditionally, discriminations were taught with trial-and-error learning. In this situation, a reward is given when a correct selection

is made and no reward is given when an incorrect selection is made. Making errors is inherent in this approach to learning. Researchers have found that when children with developmental disabilities make errors, they occasionally exhibit aggression, emotional responses, and withdrawal from teaching. Errorless learning occurs when opportunities to make errors are reduced. This can be accomplished in a number of ways.

In describing errorless learning strategies, it is useful to call the correct item the S+ and each incorrect item an S−. Most errorless learning strategies involve the gradual fading of a stimulus or prompt. With stimulus fading, the S+ is originally presented more prominently than the S− and the S− is gradually faded in. For example, when presenting four pictures to a child and telling her to "find the car," the car is first placed closer to the child. On successive trials, the three other pictures are placed closer and closer to the car. With stimulus shaping, the stimulus gradually changes shape from a known item to an unknown item. An example is gradually, upon successive trials, altering a stimulus from a car to the letter "c." Superimposition is placing a known item with an unknown item and gradually fading out the known item. Superimposition with fading can be used to teach a child to find the "d" from among a few letters. A dog (previously known) can be placed behind the d and gradually faded out with correct selections. Two errorless strategies involve the movements of other people. A prompt is a cue to the S+. Delayed prompting is an errorless approach as the prompt is first provided immediately after the instruction and the time between the instruction and the prompt is gradually increased. Finally, response prevention is physically blocking a child from making an incorrect response.

Essential Amino Acids

Definition

An essential amino acid is an amino acid(building blocks for proteins) that cannot be manufactured in the body or are manufactured in insufficient quantities, and therefore must be supplied in the diet. Essential amino acids are usually supplied by dietary protein, and in humans include histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. A *conditionally* essential (not normally required in the diet, but must be supplied exogenously to specific populations) amino acid is arginine. arginine is required by infants and growing children.

All essential amino acids are required for normal growth and development.

Estrogen

Chris Leeth
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms
Hormones

Short Definition
A female sex hormone found in people and animals.

Description
Estrogen is a hormone found primarily in females and is the equivalent hormone of testosterone in men. For women, estrogen plays a role in puberty, menstruation, ovulation, and reproductive behaviors. Additionally, estrogen has a role in the development of female genitalia prior to birth, as well as secondary sex characteristics during puberty. When using birth control, the amount of estrogen in a woman is manipulated in order to prevent pregnancy.

Ethical development; Ethical reasoning; Moral development; Morals

Definition
Ethics are a system of moral decision-making informed by a set of moral principles and standards of conduct.

Description
The broad field of ethics is a branch of philosophy that has been addressed within the discipline of psychology by theorists such as Piaget [6], Kohlberg [5], and Turiel [7]. A primary endeavor of these scholars was to come to an understanding of how a child develops ethics, also known as moral development.

There are several fields of thought when it comes to ethical development and reasoning in children. Despite varying theories about how ethics develop in children, most theories recognize moral development as occurring in stages. Piaget identified moral development in children through observation, mostly while the child was at play. Piaget postulated this development occurs as a mixture of cognitive processing and environmental observation. He further reasoned children learn about ethics and morals as they relate in social context and surroundings. The basis of Piaget's understanding of children's behavior centered largely on naturalistic observation, therefore, later researchers suggested the added dimension of children's reasoning was a missing component.

John Dewey theorized a method by which science and ethics might merge into one solid perspective of the world. Dewey searched for a way in which individuals might allow themselves to grow by discovering not only the ethics, rules and morals of society but also continually searching for purpose in life. This system of testing and pressing limits is often seen in children as they learn expectations of society, family and of themselves. Dewey's philosophy regarding moral development influenced the development of Kohlberg's theory on stages of moral development [2].

Kohlberg built upon Piaget's theory by including the impact of justice, equality, human rights and societal welfare. Kohlberg reasoned children are influenced by these factors as they grow older and develop a greater understanding of the "world" around them and their function in this society. Kohlberg outlined six stages of moral development which fall into three levels (preconventional morality, conventional morality, and postconventional morality). The two stages under preconventional morality are obedience and punishment orientation, and individualism and exchange. In this first level the child considers ways to escape punishment and how to benefit from a situation. The second level is conventional morality, which contains stage three, good interpersonal relationships, and stage four, maintaining social order. In this level the child begins to examine the labels applied based on actions (e.g., good vs. bad), and the rules of society. The third level, postconventional morality, is comprised of stage five, social contract and individual rights, and stage six, universal principles. In the third level moral development begins to become more insight oriented and socially conscious. The idea of social contracts and over arching ethical considerations and principles enters into the decision making process [1]. While Kohlberg's theory is more holistic than Piaget's theory, it is not without criticism. One such criticism directed to Kohlberg's research comes from Carol Gilligan [3]. Gilligan found Kohlberg's research to be heavily weighted based on gender, as the participants in Kohlberg's studies were predominately male. Conversely, subsequent theorists criticized Gilligan's work for its feminist approach [4].

Gilligan suggested care, as opposed to justice, as the center of moral development and ethics in children. As a result, Gilligan labeled her theory stages of ethical care, rather than referring to them as stages of moral development. Unlike Kohlberg, Gilligan does not assign age brackets to the stages, and she added the dimension of transitions between stages. The stages are preconventional, conventional, and postconventional. The preconventional stage relates to a goal of surviving, and is followed by the transition from self serving to more awareness of a responsibility to others. Once the transition occurs, the individual enters the conventional stage and gains an understanding of the intrinsic value of self sacrifice. During the transition following the conventional stage, the child develops an understanding of who they are as a person and what they deserve from society and life. The final stage, postconventional, is best characterized as lack of nonviolence, and the child has internalized the importance of doing no harm and not being harmed. Gilligan argued that the concept justice did not receive enough attention in Kohlberg's model. Gilligan contributed further to Kohlberg's ideas of development by including the impact of history and roles. Another factor which set apart Gilligan's work from Kohlberg's lies in the basis of the theory. Kohlberg built upon the work of Piaget and his theory of development, whereas Gilligan recognized Erik Erikson's stage model of development as an influence. A final criticism of Kohlberg's work is the way in which the data is reported; the data is often cited as sounding too pristine or adult to be a direct response of a child.

Elliot Turiel explored further into Kohlberg's theory of moral development by focusing his research on anomalies found within the stage sequences. Turiel and his fellow researchers conceptualized their work as domain theory. Domain theory explored the impact of social experiences, social events, and observations which contradict reasoning. Turiel referred to conventional issues and moral issues and the reasoning which occurs when a child is presented with a circumstance which requires a verging of the two ideals. This varied from Kohlberg as Turiel postulated these two are parallel, as opposed to a single entity. Turiel adds that judgments and justice might vary in social situations.

Relevance to Childhood Development

The development of ethics in children is of particular interest to parents and professionals who work with children. Understanding a child's ethical reasoning gives insight to the choices they make and their behavior. This is especially helpful to parents and guardians who are working to build strong ethics and morality in their children, as well as school personnel and mental health clinicians.

Ethnic Identification

►Bicultural Identity

Ethnic Tradition

►Cultural Difference

Ethnicity

Francien Chenoweth Dorliae
Immaculata University, Immaculata, PA, USA

Synonyms

Culture; Race

Definition

Refers to a sense of self-based on cultural traditions and racial group membership.

Ethnic identity consists of three distinct parts: ethnic behaviors, affirmation and belonging, and ethnic identity achievement. Positive Identification with one's ethnic group tends to correlate with higher self-esteem, decreased depression, better mental health and decreased drug use.

Relevance to Race and Culture

Ethnicity is often used interchangeably with culture and race. Culture constitutes values, tradition, and worldviews that have been transmitted over generations. In other words, any group that shares a theme or issue such as language, gender, ethnicity/race, spirituality, sexual preference, age, physical issues, socioeconomic status and survival after trauma. One can have multiple cultural or ethnic identities simultaneously.

Ethnocentrism

Norissa Atingdui
Fordham University, NY, USA

Definition

Ethnocentrism is the act of judging another culture from the perspective of one's own. The other culture is viewed as inferior when compared to one's own. One's own perspective is judged as right while the other is judged as wrong or less than.

Description

The term, ethnocentrism was first coined by William Graham Sumner in 1906 [4]. In this writing he discussed the concept of between group fighting. He believed that the evolution of warfare was due to ethnocentrism and xenophobia. He presented the notion that warfare is possible because one group sees itself as superior and better while viewing the other group contemptuously.

Everyone is born into a particular culture and has learned ways of living that include language, customs, values, beliefs, religions, etc. It is inevitable that these attitudes be adopted as normal. When confronted with new and different ways of thinking, these new and different ways will be viewed as unusual; even odd.

Ethnocentrism is when this view does not only entail a perception of it being different, unusual or odd, but wrong or inferior as well. Studies in the social sciences, especially anthropology, strive to rid itself of ethnocentric views through the practice of cultural relativism, a concept defined by Franz Boas. In this regard, aspects of your own culture are to be judged or understood only in regard to one's own particular culture. Different ways of being are to be respected and valued, rather than judged. Cultural relativism suggests that is to be understood that there is no universal culture and/or way of doing things.

Throughout history we can see many instances in which ethnocentrism served as a driving force to enslavement; even genocide. An extreme example would be how Nazi Germans under the leadership of Adolf Hitler were under the impression that Jewish people were inferior. This led to the Holocaust. In addition, Imperialism is a very real example of ethnocentrism in practice. When European countries first began to visit the African Continent, they termed it, "The Dark Continent." This reference had many negative implications that are still believed today. From the ethnocentric standpoint, African countries were ransacked, people kidnapped, and sold into slavery. Those that remained were imperialized by European governments. Many were forced to stop wearing their traditional African clothes, using their native languages or using their traditional African names. This was all done because the people were seen as savages, because from the framework of the European culture and religion these differences made them appear to be inferior and judged to be unintelligent. Ethnocentrism is often a divisive force that can do harm.

Etiological Attachment Theory

Steve Farnfield, Cecilia A. Essau
Roehampton University, London, UK

Attachment can be defined as a strong affectionate bond that develops between the infant and the caregiver. From an etiological perspective, this attachment bond ensures that the infant maintain close proximity to the caregiver when she/he feels threatened in order to promote the chances to survive. According to the attachment theory, early experiences with their caregivers create the way in which children interpret and make sense of subsequent experiences (i.e., working models of attachment, or the internal representation of relationship). An attachment relationship also provides a sense of internal security and confidence in both self and others. However, this sense may not be stable over the life span and can be challenged by neurophysiological, hormonal, and cognitive changes which occur during development.

Four patterns of adaptations have been identified, all of which result during early infant-parent relationships [1]. The "secure pattern of attachment" (B) is used to described an infant who uses the caregiver as a secure base of exploration. These infants readily separate from an attentive caregiver. As they grow older, they express their emotions directly to others and seek help from others. The "avoidant attachment" (A) is associated with an early experience of being rejected or ignored by their caregivers. Children with this attachment history learn to inhibit emotional signals and tend to avoid emotionally charged situations. Infants with "anxious-resistant" pattern (C) of attachment tend to become chronically vigilant toward their activities; they often show signs of distress in order to elicit caregiver's attention. As they grow older, children with this attachment pattern are often overly anxious and impulsive. The C pattern of attachment occurs as a result of having caregiver who is not consistently available or responsive. Infants with disorganized patterns of attachment (D) have been described as having no clear organized attachment strategy. In the Strange Situation, they show old and contradictory behavior pattern.

Assessing Attachment in Children and Young People

There are two approaches to the assessment of attachment, both of which are grounded in the original model proposed by Bowlby and Ainsworth but which differ in their development of the theory and hence their analysis of the

information gathered by using the available assessment procedures. The two systems are referred to here as the ABCD model (e.g., [7, 46, 63]) and the Dynamic-Maturational Model (DMM) of attachment and adaptation [9, 10, 13, 16, 19]. Both systems begin with the ABC classification of infant attachment behavior proposed by Ainsworth [1] but differ in the ways they explain the behavior of children from unsafe, sometimes dangerous, backgrounds. In particular, the ABCD approach employs a disorganized category (Type D) whereas the DMM expands the Type A and C categories to account for both the degree of threat and the maturation of the child. No elaboration of attachment theory is given here but these differences appear to be increasingly important in the light of recent criticism that the ABCD model should be expanded in order to account for both developmental and environmental changes [60].

Putting the differences in theory aside, there is general agreement about the form assessments should take for children of differing ages and this will be the focus of the remainder of this section. The issue of interpretation is not covered but such is the difference between the two systems that a comparison of their empirical results, even when using the same measures, can be extremely hard.

What is Being Assessed?

Attachment is described in terms of those aspects of the relationship between infants and their main carers that function to protect the child from danger. Hence what is assessed is the child's self protective strategy [18]. Bowlby and Ainsworth established that infants form attachment relationships with a select number of people, and that children prioritize these people in a hierarchical fashion with a primary attachment figure at the top. In the pre-school years the observational measures assess the self protective strategy of a particular child with a particular attachment figure. Children, like adults, can have different strategies with different people (e.g., comfortable and trusting with mother; anxious and defended with father). At some point in development attachment strategies become generalized to take in dangers encountered outside of the home so that by adulthood the Adult Attachment Interview (AAI) provides a more global assessment of an adult's state of mind with regard to their childhood attachments [17, 44]. Quite how and when this generalization takes place is not totally clear but assessments of children aged 6 years and beyond are increasingly likely to incorporate general as well as more person specific strategies.

Who is an Attachment Figure?

For young children, in particular, it is important to identify who among the adults in their life counts as an attachment figure. Howes [35] defined an attachment figure as follows:

- Provision of physical and emotional care
- Continuity or consistency in the child's life
- An emotional investment in the child

As a rule of thumb a good question to ask is: "who looks after the child at night?"

The Need to Assess People When They are Under Moderate Stress

Attachment seeking behavior at any age is activated when we are anxious and feel unsafe. Hence an essential feature of any procedure is that it induces moderate stress in the subject; that is stress high enough to activate self protective behavior but not so high as to lead to panic. Of the procedures outlined below, the separation and reunion procedures with infants and children up to about 4 years of age do this extremely well. On the other hand some play based procedures may not always induce enough stress for the attachment behavioral system to be fully activated. The stressor in interviews, with children and adults, is produced by asking subjects questions about intimate and potentially threatening aspects of their relationships (e.g., "Tell me about the first time you slept away from, home").

A Developmental Approach

Bowlby delineated four phases in the development of attachment behavior; three occurring in the first year of life and the fourth beginning somewhere around the beginning of the fourth year [4]. While there is flexibility in these phases they do represent attachment milestones and have been updated in the light of more recent developmental research by Marvin and Britner [47].

As attachment behavior in humans, as in many other creatures, is a product of experience with specific carers over time, it does not become organized until around 9–11 months. There then follow significant shifts in children's development at around 37 and 72 months and again at puberty and late adolescence. These changes determine both the ability of children to employ increasingly sophisticated ways of processing information about attachment relationships and, consequently, the types of assessment procedure available to professionals. These can be clustered as follows.

Parent-Child Observation

Used from Birth Onwards

Assessment in the first 37 months of life is restricted to observation. In the period of attachment formation (roughly the first 9 months) there is a necessary focus on parent (typically mother) child interaction. Available procedures for assessing carer-child interaction include the CARE-Index for use with children aged 1 day to about 48 months and the Lausanne trilogue play paradigm [28]. The latter is of interest because, while it does not provide a direct assessment of attachment in its current form, it is focused on the mother-infant-father triangle and can be extended to include a second child. Both are play based assessments which means the level of stress on the child is too low to activate attachment behavior. However in the toddler period parents are faced with the problem of keeping mobile children safe, which means the parents and children have to establish who is in control. This is relevant to attachment behavior because it combines the child's safety with conflict resolution and the management of anger [34].

Although Ainsworth began her pioneering work on assessment by using naturalistic, home based observation, the continuation of this tradition has been surprisingly patchy with the majority of efforts going into the laboratory based strange situation procedure (SSP; below). One exception is the attachment Q-set which is an itemized observational measure for use with preschoolers in their own homes consisting of 100 statements about the child's attachment behavior. These are then sorted by a carer or observer into piles denoting characteristics that are least like and most like the subject child [62].

Validity

The infant CARE-Index (0–15 months) is one of the most extensively validated of the DMM procedures with studies of both typically developing and at risk populations of children (e.g., [11, 12, 14, 20, 22, 49, 58]). When compared with results from the SSP, Q set ratings by parents showed a poor match but trained observers were able to distinguish insecure from secure children but not different types of insecurity ([61, 62]; see [54], for a review).

Separation and Reunion Procedures

The classic measure of infant attachment is Ainsworth's SSP which was originally devised to assess the attachment behavior of children aged 11–15 months [1]. The SSP requires a video suite with one way window, camera and three people (a manager, stranger and camera operator). Mother or other carer and child proceed through eight 3 min episodes designed to increase the stress on the infant, culminating in episode 6 when the child is left entirely alone. Considerable attention is paid to the child's behavior on reunion as this frequently lays bare what the child has learned to expect from his or her mother when he is anxious (the internal representational model of attachment).

The SSP is also used to assess attachment in children up to the age of about 60 months although interpreting attachment behavior is particularly difficult in the transition from infancy to toddlerhood (15–20 months) and again at 48 months onwards where the procedure is not always stressful enough to elicit attachment seeking behavior.

The available systems using the SSP are as follows: Ainsworth ABC for infants [1]; the addition of Type D for infants [46]; the pre-school ABCD system [6] which evolved from a system developed for 6-year olds [43]; for review see [56]; Crittenden's DMM approach for infants [9, 10, 12] and for pre-school children [15].

Validity

The original Ainsworth ABC approach for infants has been extensively validated and represents the gold standard against which all subsequent measures have been developed. There is less agreement concerning the extension of the SSP to older children and to those from at risk backgrounds (typically neglected and abused children) [55] although the DMM approach may be better able to discriminate between risk/ low risk populations [21, 52].

The Move to Re-Presentation: Doll Play

A significant developmental shift is in train by about 37 months, described as the move to representation [45]. What this means is that children are able to re-present to themselves and other people how they think about their relationships with attachment figures using appropriate mediums such as doll play, drawing, story telling and so forth. This extends the range of procedures from the observation of behavior to approaches that try to tap into the world in a child's head; both real and imaginary. A variety of approaches have been tried, some of which are given here.

The separation anxiety test (SAT) was devised by Hansburg [33] for adolescents and then developed for use with children aged 4–7 by Klagsbrun and Bowlby [39]. Several studies have used this procedure with children aged between 6 and 12 years (e.g., [8, 45, 66]) and it has recently been extended for use with adults [30]. Related measures are the thematic apperception test (TAT) and tasks of emotional development (TED) (e.g., [38, 48, 64]).

A variation on this approach is the Narrative Story Stem technique; a doll play exercise in which the interview, using a few simple props, sets up the beginning of a story (the stem) and then asks the child to "show and/or tell me what happens next." Story stems have been used by a number of investigators to assess children's representations of attachment and are commonly used with children aged 37 to about 84 months (see [25]).

Other procedures include showing 6 year old children a family photograph [45], asking school aged children to draw their family [8, 29, 41, 42], observing sibling groups in doll play (Mueller, 1989) and adapting the SSP for sibling groups [26].

Validity

All but one [26] of the procedures outlined above use the ABCD classificatory system and, although they all have useful clinical applications, success in validating representational measures of children's attachment to the standard of the SSP has been modest. In the school years, the SAT appears a relatively weak measure of attachment when compared with narrative story stems or interviews [37] and while most of the Story Stem procedures distinguish between secure and insecure attachment they do not, with the exception of The Manchester Child Attachment Story Task (MCAST), differentiate between types of insecurity (MCAST: [31, 32, 53, 65]) and largely fail to identify Type C [5].

The School Years and Introduction of the Interview

The assessment of attachment in the school years has proved problematic. There are a number of reasons for this including gaps in understanding attachment in this developmental period, compared with infancy and adulthood, and the fact that a lack of comparable assessments has made validating new procedures very difficult.

In terms of social development the child's world expands to include peers, best friends, teachers and other significant adults and most procedures try to include these areas in assessment. Neurologically the ability to separate information co-constructed with attachment figures (typical in the preschool years) from information generated by the self begins at about 6–7 years of age and is complete at about 15 years. This shift means that assessments can make increasing use of an interview format that relies less and less on props until the procedure is very similar to the question-answer approach used with an adult.

The interpretation and classification of interviews with this age group is basically derived from the system of discourse (styles of speech) analysis developed for use with adults and the AAI [17, 44]. Hence, coherence of speech is taken to correspond with coherence of mind so that analysis includes not just what interviewees say about attachment relationships but how they think about them (i.e., the mental processes by which the child or adult includes or excludes information). Unlike the speech patterns of speakers whose interviews are assessed in terms of insecure Types A and C, those in Type B (balanced or secure) attachment do not distort (by omission, exaggeration or manipulation) information about difficult or threatening experiences with attachment figures (In the ABCD model the Type D disorganized category drops out in the school years and is replaced in adulthood by the lack of resolution of loss and trauma (see [40, 51, 63]). Quite how this change occurs is not always clear. The DMM makes little use of disorganization at any stage of development, focusing instead on more complex forms of Types A and C organization which may be rendered more or less adaptive (self protective) by loss and/or trauma.).

Child attachment interviews have been used by a number of groups using the ABCD model (e.g., [3, 59]) and clearly demonstrate the validity of applying AAI adapted discourse analysis to children.

Crittenden has developed a School Age Assessment of attachment (SAA) derived from the SAT in which the interviewer shows a series of attachment related pictures (such as a child is bullied or the child's mother is being taken to hospital) and asks the child to first tell a made up story and then to talk about a time "this has happened to you."

Validity

The application of discourse analysis to child attachment interviews produces the ABCD distributions similar to those of adults [3, 59]. However, as with narrative stems, the Type C strategy is less common than expected and it has proved difficult to agree on the coding of "disorganization" [2]. Crittenden's SAA has one preliminary validation study in preparation [23]; see also [24].

Adolescence

By adolescence most assessment procedures focus on an interview format which uses questions adapted from the AAI together with the AAI discourse analysis. Although there has been some experimentation with picture prompts, similar to the SAT and Crittenden's SAA, to assess adult attachment (see the Adult Projective, [30]) this has not, as far as we know, been pursued with adolescents.

A self report questionnaire for use with adults, designed by Hazan and Shaver (1987), has been adapted by an Israeli team and administered to children age 6–12 years [27] and a simplified version of the same questionnaire has been used in a series of studies by Muris and colleagues (see [50] for a review; see also [36]). Cassidy has produced an interview to assess a child's self image [5].

Compared with other procedures self report scales offer a simplified means of assessment but the information they collect is necessarily limited to conscious representations of attachment and there is an ongoing debate about what they actually measure (see [57]).

Summary

Procedures to assess attachment in children and young people are necessarily determined by the developmental age of the child with the most progress having been made by the pioneering observational methods applied to infants and, to a lesser extent, pre-school children. The assessment of attachment in the school years is still under construction but the favored procedure appears to be a blend of the observational approaches used with the under fives together with the discourse analysis devised for use with adults. By mid adolescence satisfactory results can be obtained by minor modifications of the AAI. Hence attachment assessment might be said to be at it strongest at either end of development (infancy and early adulthood onwards) and weakest in the period from about 5 years to puberty.

The need to adjust procedures to match the development of the child holds a mirror to a fundamental debate about how attachment should be construed in terms of both developmental maturity and the increase or decrease of risk in the environment. Of particular importance are the competing paradigms referred to here as the ABCD and DMM approaches. The former is more extensively used but may be less equipped to discriminate between types of insecurity and indeed differentiate between children from at risk compared with safe backgrounds. Comparing the results from studies using these different models is currently extremely difficult.

Executive Dysfunction

Erin K. Avirett, Denise E. Maricle
Texas Woman's University, Denton, TX, USA

Synonyms

Executive function; Executive function difficulties; Executive function disorder; Executive function dysfunction

Definition

Executive dysfunction refers to the problems that stem from impairment to cognitive processes located in the prefrontal cortex (PFC) of the brain, known as executive functions. Impairment to this area may result in difficulties in advanced cognitive and behavioral abilities.

Description

As the name implies, executive dysfunction indicates the difficulties that arise from the impairment of executive

functions. It is difficult to operationalize executive functions; however, they have been equated to both the executive of a company and the conductor of an orchestra because of the organizational and managerial skills that they utilize over constituents [6]. Although there is some disagreement in the literature regarding which cognitive and behavioral components actually make up executive functions, some of the generally agreed upon abilities are as follows: self-monitoring and regulating behavior, initiating and completing novel tasks, setting and achieving goals, planning, organizing, utilizing working memory, maintaining and shifting attention, flexibly changing tasks, inhibiting undesired behaviors, and controlling emotions [2, 3, 6, 9, 14]. Higher order components of language and the control of fine motor skills have also been attributed to executive functions [6].

Ironically, much of what science has learned about executive functions is through what is known of executive dysfunction. Executive dysfunction may materialize from congenital abnormalities or disorders, traumatic or acquired brain injury, or brain lesions [14]. Executive dysfunction may result if damage occurs in one of the frontal-subcortical areas of the anterior most regions of the brain, known as the prefrontal cortex (PFC) [4, 6]. The dorsolateral PFC controls cognitive and behavioral spontaneity, maintaining and shifting attention, organizing, performing multiple tasks simultaneously, retrieving memories, sustaining attention, and inhibiting responses. Damage to this area may result in inattentive behavior, the inability to quickly shift attention or tasks, impulsiveness, unorganized behavior, and difficulty with long-term memory [4, 15]. The lateral PFC controls processes such as selective attention, working memory, cognitive and behavioral monitoring, language, and processing novel experiences. Damage to the lateral PFC may result in inattentiveness, difficulty with working memory tasks, the inability to be self-aware, and resistance to new experiences [5, 6, 8]. The lateral orbitofrontal cortex is involved with social and emotional aspects of behavior such as tactfulness, sensitivity, attention, and activity level. Damage to this area may be related to increased levels of irritability, inappropriate responses to social cues, aggression, and the echoing of others' behavior [4, 8].

Relevance to Childhood Development

The development of frontal lobe activity begins to emerge as early as infancy and continues to develop throughout childhood and adolescence by the growth and pruning of synapses [3]. Neuropsychological assessments have been utilized to measure the components of executive functions in children; however, these tests are often developmentally too difficult to use with children [7]. Nevertheless, researchers have recently begun to realize that problems with the development of executive functions in children may significantly impact several childhood disorders [1]. Attention deficit hyperactivity disorder, marked by problems with inhibition and the processes of attention, has been linked to executive dysfunction in children [12]. Executive dysfunction has also been associated with children with learning disabilities because of difficulties with self-regulation, problem solving, cognitive flexibility, and organizing and prioritizing stimuli [10]. Executive dysfunction has also been implicated in nonverbal learning disabilities because of weaknesses in fluently shifting environments, adapting to novel situations, working memory, self-regulation, and attentional control [13]. In addition, executive dysfunction has been associated with children diagnosed with autism spectrum disorders (ASD). Children with ASD may have difficulties with: fluently shifting attention and tasks, planning, cognitive flexibility, novel situations, appropriately responding to social cues, regulating social interactions, and nonverbal behaviors [11]. In the future, further knowledge about executive dysfunction and its impact on child development is needed for the advancement of successful behavioral, psychological, and academic interventions.

Executive Function

Erin K. Avirett, Denise E. Maricle
Texas Woman's University, Denton, TX, USA

Synonyms

Central executive; Cognitive control; Executive dysfunction; Executive system

Definition

Executive functions refer to the array of cognitive processes that control and monitor specific cognitive capacities and behaviors. Located in the prefrontal cortex (PFC), executive functions are the processes that make the human brain a unique, organized, and sophisticated structure.

Description

There is no global or overarching definition of executive functions due to the abstract and complex nature of the term. In addition, it can be difficult to directly measure executive functions since their role is to maintain more basic cognitive and behavioral skills, and they cannot be tied to any one measurable skill. Historically, most of the empirical information gained regarding executive functions has been obtained after traumatic and acquired brain injuries or brain lesions to the PFC, and the deficits that have resulted from that damage [15]. However, with the advent of various neuroimaging techniques in recent years, such as position emission tomography (PET), magnetic resonance imaging (MRI), and functional magnetic resonance imaging (fMRI) a great deal has been learned about the responsibilities of the executive functions [4].

Due to their roles, the executive functions have been equated to both the executive of a company and the conductor of an orchestra because of the organizational and managerial skills that they utilize over constituents [10]. The executive functions can be considered metacognitive instead of cognitive since these functions do not refer to any single mental set, but rather impart an overlying organization for specific skills.

There are several constructs that are purported components of executive functions. Brain imaging studies have determined that self-monitored, purposeful, and regulated behaviors, the ability to inhibit behaviors, and the control of emotions are located in the PFC [4, 13]. Similar constructs, such as goal setting and planning are also thought to be components of executive functioning [13]. Goal setting encompasses the following abilities: initiating and planning for novel objectives, modifying or changing behaviors due to unforeseen problems, and utilizing strategic behavior to accomplish goals [3]. Planning allows individuals to think of a solution to a novel problem and utilize working memory and the ability to inhibit extraneous stimuli to accomplish the plan. Attentional control is another component of executive functioning and refers to the constructs of selective attention, sustained attention, and response inhibition. These constructs allow individuals to focus on specific stimuli, keep that focus, and refrain from responding automatically or inappropriately [3]. Cognitive flexibility is another constituent that refers to the capacities of working memory, attentional flexibility, and self-monitoring and regulation. Cognitive flexibility allows individuals to temporarily store and manipulate information, easily switch focus among stimuli, and monitor and redirect one's own behaviors [3, 13]. The ability to deem our actions as a success or failure in response to our intentions is also a role of the executive functions [3]. Higher order components of language and the control of fine motor skills have been attributed to the functions of the PFC [10]. In addition, traits of emotional inhibition and response, such as tactfulness, sensitivity, and emotional affect, are also under the control of the executive functions [10, 15].

Within the literature, several models have been proposed to describe the specific interactions of constructs maintained by the executive system [8]. Stuss and Benson [16] illustrated a model that consisted of three components: motivation, the sequencing of information, and the control of those processes. Welsh et al. [18] clustered the

components of executive functions into three different factors representing speeded responding, set maintenance, and planning. Lezak [13] conceptualized executive functions into the four components of volition, planning, purposeful behavior, and effective performance. Boone et al. [5] utilized factor analysis to also specify three components of executive functioning, namely cognitive flexibility, speeded processing, and divided attention/short term memory. Brocki and Bohlin [7] identified three dimensions of executive functions that they interpreted as disinhibition, speed/arousal, and working memory/fluency. Busch and colleagues [8] established three factors of executive function including productive fluency/cognitive flexibility, mental control (working memory), and the self-monitoring of memories.

Neurologically, the processes of executive functions are widely associated with the anterior most regions of the frontal lobes, known as the PFC. Currently, the PFC is considered to be the best connected region of the cortex, directly connected to every functional unit of the brain [10]. Because the frontal lobes are not coupled to any individualized or concrete process, early theorists of cognitive function denied the frontal lobes any real significance, often referring to them as the "silent lobes." However, in recent years the frontal lobes, specifically the PFC, have received a wide array of attention [10].

The components of executive functioning are divided among several frontal-subcortical areas. The dorsolateral PFC, the last area to myelinate in the human cortex, is involved with spontaneity of thought and action, maintaining and shifting cognitive attention, organizing strategies, performing dual task activities, retrieving memories, sustaining attention, and inhibiting responses [6, 17]. The lateral PFC controls processes such as selective attention, working memory, monitoring, language, and novelty [9, 10, 12]. The lateral orbitofrontal cortex is involved with social and cognitive aspects of behavior such as tactfulness, sensitivity, attention, and activity level [6, 12].

Relevance to Childhood Development

Historically, it was believed that executive functions emerged only during late adolescence, and therefore played no significant role in normal and abnormal brain development in infancy and early childhood. However, we now know that the development of frontal lobe activity begins to emerge as early as infancy and continues to develop throughout childhood through the development of new synapses and the pruning of old ones [4]. There are major growth periods within the PFC the first of which is birth to 2 years, followed by another growth spurt from 7 to 9 years, and a final growth period occurring from 16 to 19 years [1, 3]. With ongoing maturation, children tend to also obtain the capacity for efficient processing of information at specific growth periods in their development. Due to varying growth spurts of information processing and executive functioning skills, there is partial development of the components of executive functioning in young children that suggests a limited ability to utilize executive skills much earlier than had previously been considered [3].

Recently, researchers have begun to recognize that executive function difficulties, or executive dysfunction, may play an important role in early childhood disorders and normal brain development [2]. Deficits in executive functions are primary characteristics in numerous disorders of childhood, such as attention deficit hyperactivity disorder, learning disabilities, Tourette's disorder, tic disorders, acquired and traumatic brain injury, and autism spectrum disorders [14]. As a result of this realization, researchers have started utilizing assessments of executive functioning during neuropsychological testing. However, many of these assessments are inappropriate and difficult to use with children. Many of the tasks touted to measure executive functioning were created to be difficult, and thus are developmentally inappropriate for use with children [11].

The emergence of executive functions in childhood does not appear to be a gradual progression, but rather appears to correlate with the age dependent growth spurts of the frontal lobes [2]. Different factors of executive functions appear to emerge at different stages of development. Welsh et al. [18] found peaks of executive functioning that correlated with adult-level performance, appearing at the ages of 6 years old, 10 years old, and adolescence. Organized, strategic, and planning behavior was detected by age 6. The functions of searching in an organized manner and behavioral and cognitive inhibition were seen to mature by age 10. The ability to fluently use language, operate a series of motor tasks in a sequential pattern, and complex planning skills were not identified as being to adult levels until adolescence. These spurts of prefrontal growth during childhood and adolescence make it especially difficult to measure various executive functioning abilities in children, even though deficits in these areas can be apparent [11].

Expressive Dysphasia

Mei Y. Chang, Raymond S. Dean
Ball State University, Muncie, IN, USA

Synonyms

Agrammatic dysphasia; Broca's dysphasia; Cortical motor dysphasia; Primary motor dysphasia

Definition

Expressive dysphasia refers to impaired language production caused by some form of brain damage or dysfunction [4]. Nonfluent output or speech disturbance is the prominent feature of expressive dysphasia, which is characterized by scattered, slow, and hesitant speech with marked disturbances of rhythm, grammar, and articulation. Patients also present with difficulty in finding and/or choosing the right words. Impairment in reading also is exhibited with a halting and jerky flow; disturbances in writing are similar to those in speaking [2].

Description

The original terms of aphasia and dysphasia have different meanings, but in modern usage they are often used interchangeable. In general, aphasia is the preferred term over dysphasia to avoid confusion with dysphagia. Expressive aphasia/dysphasia, commonly known as Broca's dysphasia in the neuropsychology field, is seen as a type of language disorder impairing the ability to produce language. Language difficulties presented in expressive dysphasia are not caused by defects in speech or hearing organs or deficits in sensory or cognitive functioning, but due to brain lesions or developmental impairment in brain areas governing language production. These areas lie in the anterior regions of the brain, including the left inferior frontal region known as Broca's area involved in language expression [2, 4], which is often referred to as Broca's dysphasia. Expressive dysphasia involves the frontal lobe and underlying subcortical white matter [5]. In addition, lesions within the head of the caudate nucleus within the basal ganglia can produce Broca's-like dysphasia [1].

Several common deficits are associated with expressive dysphasia, including poor programming of oromotor movements used to produce speech, agrammatism, anomia, and articulation difficulties [4]. Individuals with expressive dysphasia display impaired spontaneous speech, word finding difficulty, and poor automatic naming and repetition. Their language production is often brief with words omitted and changes in the grammatic function of words. Grammatical complexity is often lacking from their language, and their reading comprehension is inadequate for sentences that require processing of grammatical words [3]. In addition, their reading lacks a steady rhythm and is fragmentary with slurring and occasional mispronunciations. However, while patients with expressive dysphasia may have impaired comprehension of syntax, their comprehension of single words and short phrases is relatively preserved [3]. Their naming of objects is generally impaired but their performance may be improved by prompting with a context or phonemic cueing. Despite these difficulties with language production, individuals with expressive dysphasia are aware of their mistakes and often attempt to correct them. In addition, their comprehension of written and verbal instruction is intact, and their speech that does emerge is meaningful [2]. They are able to comprehend speech much better than they are able to produce it.

Expressive Language

Mysti S. Frazier
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Expressive vocabulary test, second edition; Verbal skills

Definition

Expressive language refers to the way a child expresses him/herself for everyday wants, needs, and feelings. Spoken, written, and body language, including facial expressions and sign language, are all abilities considered to be expressive language skills.

Description

Language and the expression of such is a difficult term to describe because it has a vast connection with children's developmental skills, education, and experience. In essence it is about describing how one learns language and learns how to express him/herself through language, including body language and facial expressions. According to Wise et al. [3], "Expressive vocabulary knowledge includes accessing semantic knowledge in addition to phonological representations; expressive vocabulary knowledge may be more strongly related to word identification performance than is receptive vocabulary knowledge" (p. 1095).

Expressive language difficulties include problems with word retrieval, limitations in knowledge, sentence formation, subject-verb agreement, and grammatical morphology. Also, genetics may be a predictor of expressive language problems [2]. Furthermore, students with minimal vocabulary could have a hard time understanding or identifying words that are not often used or words that they have not seen [3]. Additionally, there is not much evidence to suggest that problems with expressive language occur unaccompanied; in fact these problems can be associated with a lack of language comprehension and/or exposure to variations of words and phrases [2].

DSM-IV Disorders

Expressive language disorder and receptive-expressive language disorder comprise categories in the Diagnostic and Statistical Manual of Mental Disorders [1]. Expressive language disorder includes impairment in development of expressive language as measured by scores on a language assessment, and this impairment interferes with academic, occupational, and/or social communication. Mixed receptive-expressive language disorder includes impairment in both types of development which are significantly below average as well as all of the other criteria that expressive language disorder requires. The difference is that children with this mixed type also have developmental delays in receptive language [1]. The severity of these disorders varies based on the child's abilities and spectrum of understanding language. Due to the variations in children's abilities, it is essential that all aspects of a child's abilities be thoroughly tested and understood before making such a diagnosis.

Development

The development of expressive language is as varied as the definition. Difficulties could begin as early as age one but are more substantially noticed by age 4. At this age children usually understand certain agreement morphemes through grammatical judgment skills [2]. However, these skills require a degree of metalinguistic abilities, which at peak levels require acute sensitivity and specificity to master and are not usually seen until age 6 [2]. Furthermore, research indicates that knowledge of vocabulary is related to reading comprehension [3], which develops around age 6. The variations in abilities make it difficult for researchers to accurately assess specific expressive language impairments, which indicate that more research is required to fully understand the scope of possible problems with expressive language. It appears that disruption to the development of any of a large collection of abilities (e.g., knowledge base, vocabulary, reading, phonemic recognition of spoken words, word identification) can lead to expressive language delays.

Assessment and Treatment

The measures used to classify a child's expressive language abilities have become more advanced over the years and have allowed researchers to better diagnose language disorders [2]. One of the biggest obstacles in using scores to categorize a child's abilities is that testing expressive language impairments is not always as important as testing comprehension, in order to ensure that the child has the knowledge required to complete the test [2]. Treatment approaches often include instruction in word meaning, grammar, context of word use, and numerous opportunities for practice; another approach called "recasting" involves speaking to the child through mimicking his/her

speech with similarly appropriate responses, which allows the child to gain contextual information and distinguish between his/her language and the new responses, thus allowing him/her to develop a greater language knowledge base [2]. Children with language difficulties often receive services from the school's speech-language pathologist to work on specific goals and objectives.

Expressive Language Disorders

Cassandra Means
Capella University, Batesburg, SC, USA

Synonyms

Communication disorders

Definition

A language disorder where there is difficulty in expressing one's self verbally and/or in writing due to inability to retrieve and organize words.

Description

Expressive language disorder, unlike *speech disorders* where the individual has difficulty pronouncing speech sounds, the difficulty lies with expressing one's self due to the inability to retrieve or recall words and organizing them in a meaningful manner [1–6]. An individual with expressive language disorder is better able to understand what is being said to him or her than what he or she is able to express ideas or thoughts [5]. It is part of developmental language delay and can co-occur with *receptive language disorder* [1, 4, 5]. In expressive language disorder, the difficulty lies within the areas of the brain responsible for language processing thus the individual has difficulty processing and successfully making the connection between words and meaning [4]. Due to this, individuals with expressive language disorder will become frustrated and may act out behaviorally due to this [5]. Thus, leaving individuals with expressive language disorder at risk of developing psychiatric disorders due to the emotional and behavioral issues that can stem from the frustration that they experience [2].

Signs and Symptoms

The most common signs and symptoms of expressive language disorder, although each individual will present them differently, include: vocabulary below what is expected for age, difficulty in naming objects (i.e., cup, dog, etc.) or misnaming objects (*dysnomia*) due to difficulty in being able to retrieve words, inability to express ideas or thoughts, not talking much, often or at all, difficulty communicating and interacting with others, difficulty with pronouncing words, difficulty with overall expressive language tasks, particularly complex tasks, to include rules of grammar or *syntax*, change in verb tense or *morphology* and word meaning or *semantics* [2, 3, 5]. It is recommended that one refers back to his or her family physician or pediatrician due the symptoms can mimic those associated with serious medical conditions such as stroke [2].

Causes

Expressive language disorder can be developmental, acquired or genetically based [2, 5, 6]. Developmentally based expressive language disorder is commonly seen in children [5, 6]. Often the signs and symptoms can be picked upon early when the child is not meeting developmental language milestones (severe) or will be discovered once the child has started school and experiences problems with academics (mild) [5]. Acquired expressive language disorder is more commonly seen in the elderly [5, 6]. This is due to acquired expressive language disorder is the result of a medical condition such *aphasia* (the loss of language skills and abilities already acquired), stroke, brain injury or damage, exposures to toxins (i.e., substance abuse, lead, etc.) [2, 5, 6]. There are other cases where the cause is due to inherited conditions or genetics as seen in such disorders as Autism and Down Syndrome [1, 2]. Boys tend to be diagnosed more so than girls with expressive language disorder [2]. It should be noted that expressive language disorder can and does occur in an individual with normal intelligence as well as those with below normal intelligence as seen with *mental retardation*, *congenital disorders* (i.e., *Cerebral Palsy*) and *pervasive developmental disorders* (i.e., *Autism*) [5, 6].

Diagnosis

Expressive language disorder is diagnosed via a battery of evaluations and tests [2, 4]. These often include observations, assessment of cognitive abilities, or psychological testing as well as psychometric testing, diagnostic speech and language as well as writing tests, and occupational therapy evaluations [2, 4]. Due to the emotional and behavioral issues that can and often result from the frustrations that are experience with not being able to express one's self, a psychiatrist may be consulted with in particular in the case of children and adolescents [2].

Treatment

There are several factors that will determine the kind of treatment one with expressive disorder will receive. These factors include medical history in case there is a need for medication, severity and prognosis of the disorder, individual's overall health status, age, and the individual's preference and expectations regarding therapies [1, 2]. Treatments for expressive language disorder include speech and language therapy, occupational therapy, and in some cases mental health treatment [1, 2, 4]. It should be noted that expressive language disorder does not go away with time, rather is a disorder that the individual will have to cope with for the rest of his or her life [5].

Relevance to Childhood Development

For one to be successful socially and academically, one must be able to express him or herself. Children with expressive language disorder do not learn language as quickly as their peers thus have difficulty expressing themselves [4, 6]. Thus, they may display poor social skills, withdraw or isolate, present with acting out behaviors or difficulty with imaginative play and picking up on or expressing such social cues as manners or engaging in a conversation [4]. It is estimated that about seven percent school age children are found to present with notable language deficiencies [1]. Due to these deficiencies, a child with expressive language disorder may struggle academically as well. Although many are able to speak when they start school, in school the child will struggle with such tasks as formulating words which are imperative when presenting an oral report, spelling, writing well which is crucial for such tasks as sentence structure, being able to take adequate notes and written composition which entails one to express abstract ideas as seen with writing an essay [2, 5]. The older the child becomes, the harder the school work will become which means the more difficulties the child will experience [5]. Children with expressive language disorders have a lot to say and want to share with others [5]. However, due to the nature of the disorder he or she may present worse off than what he or she may really be thus school personnel may develop misperceptions regarding the child's true abilities [4, 5]. This can lead the child to not like school and may reject the idea of learning without assistance [5].

Expressive Vocabulary Test, Second Edition

Jessica R. Gurley
Argosy University, Arlington, VA, USA

Synonyms

Expressive language

Definition

The expressive vocabulary test, second edition, is a brief measure of expressive language.

Description

The Expressive Vocabulary Test, second edition (EVT-2) is a brief measure of expressive vocabulary and word retrieval abilities for ages 2 years, 6 months and above. The test can be administered in less than 20 minutes. There are two parallel forms of the EVT-2: Form A and Form B. The manual reports a number of uses for the EVT-2, including the evaluation of language impairments and assessing the knowledge of the English language in non-native speakers. It can also be used as a screening measure for Expressive Language Disorders and can be used with the *Peabody Picture Vocabulary Test*, fourth edition (PPVT-4) to screen for mixed receptive-expressive language disorders [3].

The EVT-2 can be scored by hand or by using computer scoring software. The EVT-2 raw scores can be used to calculate standard scores, percentiles, normal curve equivalents, and stanines. In addition, the raw scores can be translated into age equivalents and grade equivalents. Standard scores can be based on either age-based or grade-based normative standards.

The EVT-2 was standardized in 2005 and 2006 on 5,543 individuals in the United States. The standardization sample was stratified according to 2004 Census data and was representative of the population of the United States in relation to race/ethnicity.

The EVT-2 has strong psychometric properties. The internal consistency (split half reliability) of the two parallel forms are 0.94 (Form A) and 0.93 (Form B). The test-retest reliability is 0.95. Additionally, the EVT-2 correlates highly with the PPVT-4 (0.82) [3].

Relevance to Childhood Development

The EVT-2 can be used to screen children and adolescents for language disorders and language delays.

Extended Families

Stacy A. S. Williams
State University of New York at Albany, Albany, NY, USA

Synonyms

Joint family; Kinship group; Multigenerational family

Definition

An extended family is a family composition that includes in one household near relatives in addition to the nuclear family.

Description

The extended family has been categorized as many things in the research literature. Early researchers defined this family structure as a constellation of nuclear families across two or more generations [1]. Furthermore, it has been operationally defined as a three-generation structure comprised of related relatives: grandparents, parents, grandchildren, and sometimes a fourth generation [5]. However, the aforementioned description defines extended families as a compilation of nuclear families across generations. It should be noted that there are many other variations of the extended family structure. Extended family structures may consist of grandmother/grandfather, aunt/uncle, cousins, one-parent extended families, divorced families, and other kin relations [1]. Each variation operates differently depending on cultural and socioeconomic factors. For example, a Black child growing up in the African-American community may be surrounded by a kin organization including grandparents, parents, aunts, uncles, and cousins [6]. In addition, the Black child may be a part of a matriarchal single-parent extended family.

Extended family structures tend to be prevalent in non-Western societies and minority cultures (e.g., Hispanics, African-Americans, Caribbean-Americans, Asians). Although not the dominant familial structure in Western societies, this structure also plays a role in mainstream society. Many have argued that the formation of the extended family is indigenous to certain ethnic groups. However, the formation and sustainability of the extended family is often facilitated by historical, religious, socioeconomic, and marital factors [5, 6]. For example, people of Indian origin living in Durban, South Africa continue to live in extended family arrangements despite the government's housing development policies that prevent large groups of individuals from sharing residency. Indian

families in this community tend to follow the Mitakshara law which states that "joint families that constitute a coparcenary, who by virtue of association with their biological parents and grandparents, have the right to enjoy and hold the joint property, to restrain each others acts in respect thereof, not to burden it with debts and at their pleasure to enforce its partition" [5, p. 458]. Many families who continue to live within these households do so for familial obligations, safety, and financial reasons. It is often customary for newly married individuals to live within this setting for one or more years before branching out on their own. Interestingly, though couples may branch out on their own, they are often still connected with their extended families through proximity of residence [5].

In the Black community, the formation of the family is a byproduct of the interplay of historical factors such as slavery, marital and interpersonal factors such as divorces, single parenthood, and socioeconomic factors. The most important factor correlated with extended family formation is the persistent and high concentrated poverty of Black parents, especially single mothers [6]. In fact, the establishment of an extended family is one coping mechanism used extensively and disproportionally by Black households to respond to housing affordability and adverse economic circumstances [3]. Transitions in the life cycle may also affect the formation of an extended family. For example, the migration history and the socioeconomic status of the immigrant group may facilitate the formation and sustainability of this family structure. For example, the three-generation families among Cuban Americans have often been seen as the retention of cultural patterns and norms; however, the nature and selectivity of the exodus from Cuba have largely determined the high incidence of three-generation families in the population [4].

Extended families play a pivotal role in the rearing of children whose biological parents are otherwise disposed. Additionally, they offer emotional and financial support [2]. Furthermore, the involvement of extended family members in one-parent families facilitates the biological mother's participation in self-improvement activities (e.g., school and work), increases the quality of childcare, and reduces the negative effects of single parenting. Moreover, living within this family structure also offsets some of the negative effects of adolescent extramarital pregnancy. In addition, the presence of the sensitive grandmother in the home tends to buffer the infant against the influence of the insensitive mother. Extended families tend to be more effective when lines and boundaries are clearly defined. Confusion arises when this is not the case [2]. Although, household mergers can offset the cost of household expenditures, extended families can also reduce the quality of the home environment, by increasing crowdedness and thus limiting privacy [3].

[2]Texas A&M University-Corpus Christi, Corpus Christi, TX, USA

Synonyms

Extrinsic motivation

Definition

Motivation is the activation of goal-oriented behavior. When motivation develops from a source other than the individual, then that individual is externally motivated. Examples of such sources are money, trophies, grades, and complements. Punishments or other negative consequences can also be sources of external motivation.

Description

There are two types of motivation – external and internal. When individuals are motivated by outside sources, they are driven by external motivation. Outside sources may be tangible or intangible rewards. Tangible rewards may include stickers or toys. Intangible rewards may include complements or a round of applause from an audience.

Individuals who are externally motivated may not be interested in the actual task. Instead they may be interested in receiving the tangible or intangible rewards earned by completing the tasks. For example, children who are given allowances for completing weekly household chores may complete their chores, not because they enjoy completing them, but because they are externally motivated by their allowance.

Directly opposite of external motivation is *internal motivation*. Internal motivation accrues within an individual. An individual who is driven by internal motivation are motivated to complete a task without the incentive of receiving a reward. These individuals find satisfaction in completing the actual task.

Theories that are often connected to motivation are the following: *Social Theory* [1], *Transpersonal Theory* [2, 4, 5], *Achievement Motivation Theory* [3, 6, 7], and *Behavioral Theory* [8].

Extinction

Brady I. Phelps
South Dakota State University, Brookings, SD, USA

Synonyms

Extinction burst

Definition

In both Classical Conditioning (also known as respondent conditioning) and Operant Conditioning (also known as instrumental conditioning), the term extinction refers to both a procedure and a behavioral process. Simply put, in Ivan Pavlov's Classical Conditioning, extinction refers to a procedure of presenting a CS, a conditioned stimulus alone, without a US, an unconditioned stimulus, after conditioning has transpired. In effect, this is a procedure of severing the CS–US association. An example would be that of the spoken word "constrict" as a neutral stimulus (NS) followed by a flash of light as a US presented to a person's pupils. After several pairings, the pupillary constriction would occur as a CR, a conditioned response to the spoken word as the word comes to function as a CS. Extinction would then consist of the word "constrict" repeatedly presented in the absence of the flash of light. As a behavioral process, extinction denotes the decrease in measures of the CR, the conditioned response, when the aforementioned procedure is in effect. That is, as a result of the conditioning just described, some measurable degree of pupillary decrease would occur to the spoken word-CS but as the CS were presented alone, the conditioned response of the pupil to the word would show orderly decrements, as a function of each solitary CS presentation [1, 2].

In the operant conditioning of B.F. Skinner, extinction also encompasses both procedure and outcome-process. As a procedure, this term envelopes the breaking or discontinuation of the contingency between an operant response and its formerly contingent consequence. Other writers have described extinction as the removal or unavailability of the reinforcer. In terms of a behavioral process, extinction pertains to a decline in the frequency of the operant response being measured when the extinction procedure is in place. An example would be that of a rhesus monkey lever pressing for a sip of juice. The lever press would be the operant response and the juice would be the consequence, in this case, a positive reinforcer. This contingent relation between response and consequence would maintain some

frequency of lever pressing by the monkey. If lever pressing no longer resulted in any juice, the discontinuation of the juice-reinforcer would be a procedure of extinction and the decline in the frequency of lever pressing that results would be the process of extinction. Under conditions of extinction, responding decreases and can eventually cease or merely return to its pre-reinforcement measures [2, 3].

In both classical and operant conditioning, extinction refers to a behavior weakening procedure and process for acquired or learned responses. Both a conditioned response and an operant that have reduced measures of magnitude or frequency as a result of extinction are said to be "extinguished." Extinction is neither a procedure nor a process performed upon or observed with unlearned behavior. Compare with habituation.

There are other similarities between the extinction process in classical and operant conditioning. In both, the extinguished response will typically display what is known as spontaneous recovery. In classical conditioning, if the CS is presented alone to the point that the CR no longer occurs to the CS and the extinction process is complete, if the animal or human goes through a period of time without any exposure to the CS, a subsequent presentation of the CS will again elicit a CR, albeit in somewhat weakened magnitude. If the CS is again presented alone, the CR will again extinguish but spontaneous recovery may reoccur in subsequent CS presentations following a recovery period in the absence of the CS. In these instances, the re-elicited CR is thought to be due to extraneous environmental events that were still functional as a CS and each subsequent extinction procedure extinguishes the CR to these other CSs. Spontaneous recovery is an expected outcome of the extinction procedure and process in classical conditioning. The boy who has acquired a fear of dogs from a bite can overcome his fear by having repeated exposures to dogs without any further trauma; gradually the fear response to dogs will diminish and no longer be problematic. Nevertheless, if the boy then sees a dog after being away from any dogs for some time, the boy will predictably feel afraid of dogs again as a result of spontaneous recovery [3].

A similar spontaneous recovery occurs with an operant response that has undergone extinction. Many children have the behavior of throwing bedtime tantrums when parents implement sleeping alone in the child's own room; tantruming and crying can result in parental attention, the parents staying in the room, the bedroom lights being left on, etc. Parents who let the child tantrum and do not re-enter the child's room after saying goodnight will eventually see the tantruming behavior subside as they withhold their attention to put the behavior on extinction. Predictably, if the child sleeps at the grandparent's house for a long weekend and subsequently returns to sleeping in their usual bedroom, the tantruming will show spontaneous recovery the first night the child is put to bed at home. If the parents do not reinforce the behavior, the spontaneous recovery of tantruming will be short lived [4].

This example of an operant response undergoing extinction raises the important point of one important distinction between the two processes of extinction. While the response undergoing extinction does weaken in both classical and operant conditioning, before the operant response does weaken due to the discontinued consequence, the response being measured will reliably increase in its frequency, intensity, and variability before weakening. This effect is known as an extinction burst and only occurs during the extinction process of operant conditioning. In the example just provided, the child's tantrums would reliably become louder, last longer, display different forms of throwing a tantrum as the behavior was put on extinction; all of these increases in the behavior of tantruming would be observed before the behavior would decrease. The parents need to withhold any attention for the tantrums to see the desired decrease in the unwanted behavior [3, 4].

Extinction Burst

Robert Walrath
Rivier College, Nashua, NH, USA

Synonyms

Extinction

Definition

Extinction burst refers to the phenomenon of a previously reinforced or learned behavior temporarily increasing

when the reinforcement for the behavior is removed. Learning theory suggests the organism is increasing the frequency of the behavior in an attempt to regain the original reinforcement for the behavior. In the absence of additional reinforcement, the behavior will diminish to lower (pre-extinction burst) levels and eventual cessation.

Extrafamilial Home

►Group Homes

Extrinsic

An extrinsic property depends on the relationship of one thing with other things. The term denotes a property of some thing or action which is essential and specific to that thing or action and which is completely independent of any other object, action or consequence.

Extrinsic Motivation

Pei-Hsuan Hsieh
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

External motivation

Definition

Engaging in an activity with expectations to receive a reward separate from the activity it self, or to accomplish something to make an impression on others by showing one's competency.

Description

When individuals engage in activities that are not personally enjoyable to them but grant them money, prestige, or beauty they are exerting extrinsic motivation. Extrinsic motivation is present when the incentives to engage in an activity are outside the individual and the reinforcement is due to an outside source. For example, when a child is committed to an activity he takes no pleasure in but he receives a reward for his work, he is being motivated to do this task because of an outside source, the reward (either a sticker, a pencil or extra time on the computer). Researchers suggest that extrinsically motivated learners may process information at a superficial level, often performing to meet minimal classroom requirements.

Relevance to Childhood Development

One's development of motivation can be influenced by outside sources. When one is influenced solely from outside sources they are being motivated extrinsically. Extrinsic factors develop when a child focuses on a goal because it might make him popular or he feels pressure from his parents to do well.

Extrinsic rewards may be detrimental to children if they are promised a reward every time they accomplish a task. Once the reward is stopped, the child may lose ambition to engage in that task again; he has no reason to initiate the activity on his own. Tangible rewards can be harmful for young children because they may become dependent on the rewards. Similar to Skinner's theory on operant conditioning, when a behavior is reinforced with a reward it is more likely the behavior will continue. However, once the reward is taken away the behavior decreases or ceases to exist.

Researchers also found that when children were rewarded for activities, their intrinsic motivation was undermined. They suggested that children notice patterns or develop schemas when other people, such as parents, use extrinsic incentives over and over. For example, when a parent offers a reward for a task, the child has the presumption that the task is probably something boring. Such as when a parent tells a child she can go outside and play, but only after she cleans her room. The extrinsic incentives are not always useful for younger children.

In the context of a classroom, students may exert little effort on their work to complete a task if they are extrinsically motivated. If their motivation to do the work does not lie within themselves, meaning they have no interest in the topic, they will provide the minimum amount of effort until the task is complete.

Other researchers found that verbal extrinsic motivators are not as detrimental to the college students as they are to younger children. When students enter college they are often motivated by verbal feedback such as "good work," or "you are an excellent student," which is a form of extrinsic motivation that has found to be helpful to college students. A student will sometimes work harder if he knows he will be recognized for his work.

Extrinsically Motivated Behavior

Steuart T. Watson, Darrell Davis
Miami University (OH), Oxford, OH, USA

Synonyms

Contingency-maintained behavior; Reinforcement-maintained behavior

Definition

Extrinsically motivated behavior refers to behavior that is performed because of rewards that are external to a person.

Description

Motivation speaks to the issue of why a behavior occurs, or the reasons why certain behaviors are performed in lieu of others. Extrinsic motivation ascribes these reasons to external forces or rewards. Thus, behavior that occurs because of the external rewards that are involved are said to be extrinsically motivated. Completing a task for money, recognition/praise, or to avoid punishment are common examples of extrinsically motivated behavior. In these cases, the behavior occurs because of the external rewards, not because of some unseen, unverifiable intrinsic value of the task [1]. Virtually everything that humans do is, in some way, related to the outcomes of their behavior. Even behaviors that seemingly have no immediate external consequence or reward may continue for long periods of time because they have been rewarded in the past. In such a case, an observer may mistakenly believe that the person is engaging in the behavior because they "like" doing it versus the behavior being an infrequently reinforced behavior. Unfortunately, extrinsic motivation is often viewed with less esteem than intrinsic motivation. A person who is intrinsically motivated is often described in more positive terms than a person who is extrinsically motivated.

There is great debate about the effects of external rewards (extrinsic motivation) on internal motivation. This position is attributable to Edward Deci who, in the early 1970s, said that external rewards should not be used because they interfere with a person's natural interest and enjoyment of a task [3]. Three decades and over 100 studies later, the research strongly suggests that external rewards do not harm internal motivation nor do they lead to decreases in performance, enjoyment of a task, or creativity [2].

Relevance to Childhood Development

There is no evidence that providing external rewards for behavior is harmful to children, their development, or their performance in school or in athletics. In fact, genuine praise for performance, effort, or goal attainment enhances a child's sense of competence and esteem, improves their level of satisfaction, and generally leads to other positive outcomes. Tangible rewards do not create a "dependency" on the tangible for the behavior to occur and result in the same positive effects as praise [4].

Eye Fixations

►Eye Movements

Eye Movements

Alicia MacKay
Tulsa Community College, Tulsa, OK, USA

Synonyms

Eye fixations; Saccades

Definition

The voluntary or involuntary movement of the eyes that can be controlled by the individual or the external environment.

Description

There are four basic types of eye movements: pursuit, vergence, vestibular, and saccadic [3]. Pursuit eye movements occur when an individual attempts to track a moving object. Vergence eye movements occur when an individual moves their eyes from a distant object to a near object (or vice versa). Vestibular eye movements occur when an individual's eyes move to compensate for head and body movements. Saccadic eye movements are rapid, ballistic movements that serve to position the eye for visual processing. Visual processing occurs when the eyes are not moving (i.e., fixating). Visual processing is suppressed when the eye is in motion [4].

Relevance to Childhood Development

Researchers analyze eye movements in studies to investigate cognitive processing in adults as well as children and infants. Research with infants has shown that infants become bored with objects with which they are familiar, and they respond to them less and less over time. They spend less time looking at the object and make fewer eye movements to the object. The phenomenon is called habitation. By analyzing infants' eye movements during the viewing of objects, researchers can infer whether the infant recognizes the stimulus. Habituation has been used to investigate visual perception of faces and objects, visual acuity, and contrast sensitivity [2].

A second technique in which infants' eye movements are analyzed is the preferential looking paradigm. An infant is habituated to a stimulus over a number of trials. The infant is then shown a second stimulus that differs from the first stimulus and the looking time is compared for the two stimuli. If the infant looks longer at the second stimulus this suggests that the infant can discriminate between the stimuli. Preferential looking has been used to investigate memory, visual attention, and numbering in infants [1].

Eye–Hand Coordination

Jana Sander
Texas A&M University Corpus Christi College of Education, Corpus Christi, TX, USA

Definition

Coordinating the eyes and hands together to accomplish a task.

Description

Eye-hand coordination is important in many aspects of life. When children are babies coordinating their vision with hand movements ensures that they are able to pick up items. As children grow older their visual acuity directs their hands to draw, paint, catch a ball or put a puzzle together.

Fabry Syndrome

Anthony P. Odland, Wiley Mittenberg
Nova Southeastern University, Fort Lauderdale, FL, USA

Synonyms

Alpha-galactosidase A deficiency; Anderson-Fabry syndrome; Angiokeratoma corporis diffusum; Ceramide trihexosidase deficiency; GLA deficiency; Hereditary dystopic lipidosis; OMIM 301500

Definition

An X-linked disorder affecting multiple organ systems characterized by an enzymatic defect due to a reduction in the catabolism of compounds comprising galactosyl, resulting in a deficiency of the lysosomal enzyme α-galactosidase A. This deficiency leads to pathology in multiple organs.

Description

This deficiency results in the altered metabolism and an accumulation of globotriaosylceramide and other neutral glycolipids in various tissues throughout the body such as the heart, peripheral, and central nervous systems leading to pathology in multiple organs. Fabry syndrome (FS) is an X-linked disorder that manifests in males as well as females. Although symptom presentation in females is variable, some females experience symptoms characteristic of their male carriers. Fabry syndrome was once thought to be asymptomatic in all females due to an unaffected X-chromosome; however, more recent research suggests that symptom presentation may be similar to males [14, 18, 20]). The prevalence of FS may range from 1 in 40,000 to 1 in every 117,000 births and is more prevalent in males [4, 21]. Diagnosis may be aided by measuring the presence of α-galactosidase A activity in plasma or peripheral leukocytes [2]. The accumulation and altered metabolism of globotriaosylceramide may be associated with neuropathic pain, dermatological symptoms, renal and cardiac signs and symptoms, hearing loss and tinnitus, gastrointestinal problems, ophthalmic manifestations, and fatigue. Specific signs and symptoms may include, but are not limited to, severe left ventricular hypertrophy, acute pain attacks, acroparesthesia, diarrhea, heart palpitations and pain, various ocular disorders or difficulties such as clouding of the cornea, corneal dystrophy, cornea verticillata, cardiomyopathies, angiokeratoma, cerebrovascular accidents, lymphoedema, kidney disorders, hypohydrosis, proteinuria, respiratory problems, and other symptoms associated with central nervous system pathology [17, 18, 20, 28]. Neurologic complications may be evident in the central and peripheral nervous systems, manifested in areas such as cognitive impairment, autonomic dysfunction, and ischemic or hemorrhagic stroke. As many as 68% of individuals with FS may have white and gray matter lesions, with increased involvement approaching older age. Magnetic resonance imaging has identified the presence of cerebrovascular involvement in patients by 26 years of age. Cerebrovascular involvement is likely to increase and to encompass almost all patients by 54 years of age, suggesting increased susceptibility to cerebrovascular accidents with increasing age [1]. Damage to dorsal root ganglia neurons and axonal degeneration of small fibers may be responsible for the pain attacks that are often experienced with FS [5, 11]. Without treatment the presence of FS is associated with an average decrease in life span by 15 and 20 years in females and males respectively [17, 18].

Overall health-related quality-of-life in individuals with FS is considerably lower than that of unaffected individuals [22]. Greater than 70% of patients experience pain in the hands and feet, as well as in other areas of the body. Symptomatic pain appears to be more prevalent in males than in females [9]. Pain, tingling, and numbness of the skin may be induced or exacerbated by external changes in temperature [8]. Sensitivity to changes in temperature may make exercise or physical activities laborious [16]. With increasing age there is likely to be more cerebral and renal involvement. Onset of cardiomyopathy in males is up to 10 years earlier than in females. However, most individuals will eventually develop left ventricular hypertrophy [12].

Sam Goldstein & Jack A. Naglieri (eds.), *Encyclopedia of Child Behavior and Development*, DOI 10.1007/978-0-387-79061-9,

Delayed symptom onset and nonspecific symptomatology contributes to misdiagnosis and under diagnosis of FS [20, 31]. Echocardiography may be useful in differential diagnosis between FS cardiomyopathy and hypertrophic cardiomyopathy by a distinctive appearance of left ventricular endocardial border [23]. Left ventricular hypertrophy may be differentiated by features such as acroparesthesia, hypertension, and hypohydrosis [10]. Onset in childhood of early adolescence is most common, but may extend as late as early adulthood, with symptom presentation varying both with age and gender [9]. However, misdiagnoses are common and an accurate diagnosis may not be established for a mean 13–16 or more years after the first symptom presentation [20]. Hearing loss may be insidious and can occur across all frequency ranges, with the sensory threshold increasing with age [28].

Until recently, treatment for FS has been mainly palliative in nature. Studies using enzyme replacement therapy (ERT) have demonstrated improved long-term well-being of individuals with FS. ERT reduces the accumulation of globotriaosylceramide, and attenuates pain associated with FS. ERT has been associated with improved pain-related quality of life [9, 29]. The use of ERT may improve cold and heat thresholds to pain, the frequency of diarrhea, and may alleviate hypohydrosis [7]. ERT may also improve cardiac and renal functioning by reducing globotriaosylceramide and other glycolipid deposit levels. Improved renal functioning may be sustainable with ERT due to reduced glycolipid deposits in renal vascular endothelial cells. ERT is proving to be efficacious for the treatment of FS; however, more research needs to investigate long-term treatment outcomes [29, 30].

Relevance to Childhood Development

Unlike adults with FS, children do not typically experience major organ dysfunction; however, children may experience extremely distressing symptoms related to the syndrome's insidious progression [27]. Symptom presentation in children may appear by 6 and 7 years of age in males and females respectively, but symptoms have been observed as early as the first 3 years of life [24, 25]. Children and adolescents commonly experience hypohydrosis, cornea verticillata, and acroparaesthesias secondary to FS. Acroparesthesia may be elicited by emotional stress, exercise, or fatigue and be present by as early as 3 years of age or younger. Pain often occurs in the soles of the feet and the palms of the hands, which radiates proximally. This pain can produce extreme discomfort and range in duration from days to weeks. Other features of acroparesthesia and painful crises may also be experienced in other areas of the body such as the abdomen. Discomfort is likely due to small nerve fiber neuropathy, which may be misinterpreted as malingering due to its subtle nature [3]. As many as 67% of children with FS may experience vertigo, fatigue, and tinnitus. Gastrointestinal problems are common, and cardiac and renal complications are less present than the aforementioned signs and symptoms. These problems may be present in an attenuated form and develop with increasing age. Presentation in females is similar to males, but may be less frequent [28]. Cerebrovascular complications, such as those associated with increased risk of stroke, have been noted in patients as young as 6 years of age. Cerebrovascular, renal, and cardiovascular signs and symptoms tend to progress with age and increase one's susceptibility to future complications and morbidity [15, 19, 24, 25]. Similarly, white matter lesions may be present in children with FS and are likely to increase in incidence with age [6]. Ophthalmological features may be present in as many as 60% of children with FS. In addition, children with FS may be prone to more behavioral problems, anxiety, and depression [24, 25]. Mild hearing problems may be present and are likely to exacerbate with increasing age [13].

Although specific dosages and long-term effects of ERT have not been entirely established some have suggested treatment as early as possible after the first symptoms present, barring other complications. Since pathology related to the metabolic dysfunction in FS commences at birth, it is efficacious to begin ERT as soon as possible. In young children ERT may prevent the development of future disease processes [2]. Specifically, agalsidase alfa may be well tolerated in both male and female children, and improve manifestations of FS such as pain, heart rate variability, and hypohydrosis. Agalsidase alfa may also reduce the need for antineuropathic analgesics [24–26].

►Facial Recognition

Facial Recognition

Mark Pennick
University of Alabama, Birmingham, AL, USA

Synonyms

Face perception; Facial identification

Definition

Facial recognition is the human ability to recognize a certain face from other faces.

Description

Face recognition is especially interesting because human faces are remarkably similar and yet most typical individuals show considerable accuracy in identifying individual faces. The parts of the face, such as the eyes, nose, mouth, and ears, are very similar from one individual to another. Furthermore, the proportions and configuration of parts of the face are also very similar. Such minute differences in the physical appearance of faces and the fact that humans are able to make precise judgments about the identity of faces despite their similarities has spawned considerable investigation of facial recognition.

It has long been known that infants as young as 4 months of age demonstrate a preference for human faces over other stimuli that are not configured as faces [2]. It has also been demonstrated in brain imaging studies that the human face elicits different neural pathways in the brain than non-face stimuli [4]. This research identified a brain area in the extrastriate cortex which has come to be known as the fusiform face area. Another group of researchers also used brain imaging technology to show that this same area is used by persons who are experts in identifying certain objects [3]. These studies have suggested that face recognition is a highly specialized human skill.

Vicki Bruce and Andy Young have contributed significantly to our understanding of facial recognition. They assert that our ability to identify one face from the other is dependent on the configural and holistic perception of the face. This is supported by studies that show a 95% accuracy rating for identifying familiar faces when viewed upright, but only 50–60% accuracy when viewed upside-down [1]. They also describe the Thatcher Effect to support the idea that configuration of facial features are paramount when recognizing faces.

Another important aspect of facial recognition seems to be distinctive characteristics. There are subtle differences in faces from the basic template of their configuration. Research has shown that faces which deviate from that common configuration are more easily and accurately distinguished [1]. It has also been shown using computer programs which can detect certain deviations from the normal face and enhance those differences to create a caricature, that those images of enhanced differences are actually more accurately recognized than the true picture of the person's face [1].

Relevance to Childhood Development

As children prefer to orient to facial stimuli, it is important to notice if the developing child does not show a preference for faces. This is a sign of abnormal development and could indicate an autism spectrum disorder. Persons with an autistic disorder show impaired abilities to recognize faces.

Failure to Thrive Syndrome

Micah S. Brosbe
Nova Southeastern University, Ft. Lauderdale, FL, USA

Synonyms

Growth faltering; Inadequate growth; Malnutrition; Protein-energy malnutrition; Undernutrition; Weight faltering

Definition

Failure to thrive syndrome (FTT) is a condition in infants and young children in which they do not grow at expected rates. It can be a sign of a general medical condition or can have other biopsychosocial causes.

Description

Failure to thrive is the term generally used to describe a syndrome in which an infant or child does not grow at a rate considered to be healthy. It is generally diagnosed based on size ratio, whether it is weight-for-height, weight-for-age, or height-for-age [7]. Weight-for-age is the most common ratio used to assess FTT. Weights are plotted according to age along a normal distribution curve, and neonates who fall below a certain cutoff score are considered to be failing to thrive. Professionals are not entirely unanimous in what this cutoff score should be, but most of the literature describes cutoff scores as below the third or fifth percentile [1, 7]. It is also important to distinguish between pre and postnatal failure to gain weight because they may have different etiologies and sequelae.

Given the diagnostic definition of falling below cutoff scores on the normal distribution curve of a growth ratio, it is not surprising that overall lifetime prevalence rates are approximately 5% [8]. Neonates younger than two months have higher prevalence rates, approximately 12% for having a low height-for-age ratio and 4.1% for having a low weight-for-height ratio [8].

FTT is categorized based on the etiology of the insufficient caloric intake: organic (OFTT), nonorganic (NFTT), or of mixed etiology (MFTT; 1). Specific associated risks of undernutrition depend on the type of FTT. Children with OFTT or MFTT, for example, may be more likely to have a lower birth weight, and children with NFTT may be more likely to live in poverty and less likely to live with both parents [8]. If the etiology is organic, there could be any of a number of different causes, such as prenatal (e.g., toxin exposure, premature birth, congenital anomalies) or an ongoing general medical condition such as a gastrointestinal or central nervous system disturbance [7].

If there is no medical or physical reason for the growth delay, then the FTT is likely due to low food intake [1]. This is frequently the case, since research has shown a low rate of being able to identify a specific medical illness as the sole cause; in the majority of cases, the FTT had mixed etiologies. Some researchers have found that children with FTT tend to show less of an interest in food, to be somewhat pickier eaters, and to have been weaned later than controls [1, 9]. Inadequate intake may also be caused by feeding problems such as dysphagia, a condition in which children have difficulty with swallowing mechanisms and behaviors [4, 5]. Complications with breast feeding can lead to inadequate growth in infants as well [8].

Other factors that have been associated with FTT include attachment style, presence of abuse or neglect, poverty, and psychopathology and age of the mother [1, 9]. These are controversial, however, and are being debated in the scientific literature.

OFTT or inadequate growth can be caused by any of a variety of factors. The condition may be due to the direct effects of a general medical condition such as heart disease, cystic fibrosis, a persistent infectious disease (e.g., AIDS), or endocrine abnormalities. It could also be due to prenatal exposure to drugs or toxins, or to inadequate food intake secondary to a general medical condition [1, 2, 8].

Gastrointestinal problems that lead specifically to FTT can be divided into two categories: inadequate intake (not eating enough) and excessive losses of nutrients (not absorbing or retaining; 5). Inadequate intake may be caused by pain or discomfort in the esophagus or stomach. Gastrointestinal reflux, or spitting up, is different from vomiting. It is common in healthy children and not usually a problem; if it happens too frequently, however, it can possibly cause malnutrition [4]. For excessive losses, the causes are generally vomiting, diarrhea, or malabsorption. Actual vomiting may be more serious than reflux since it is more likely to be associated with an illness that could lead to poor weight gain. Diarrhea can be a sign that nutrients are not being absorbed properly by the digestive tract, and if severe, can lead to poor weight gain in infants. An example of a disease that has these signs, including poor growth and weight gain, is celiac disease [4].

Some neurological disorders that can cause FTT and poor growth are ►cerebral palsy (CP), tumors of the central nervous system, and myopathy [3]. These can cause a low birth weight and/or motor problems with

feeding behaviors that lead to lower food intake [1, 3]. CP, for example, can cause problems swallowing.

Prenatal exposure to teratogens such as alcohol and other drugs can lead to OFTT. Fetal alcohol syndrome (FAS) can lead to a low birth weight, height, and head circumference [2]. When FAS is not present, the scientific literature on the effects of alcohol exposure on size, growth, and weight is inconsistent. Prenatal exposure to tobacco can cause lower size, weight, and growth rates in infants. Exposure of infants to second hand smoke can lead to growth faltering secondary to respiratory infections [2]. Prenatal exposure to cocaine often causes low birth weight. The literature concerning how well these infants can catch up to normal weights is inconsistent, however. Prenatal exposure to opiates (e.g., heroin) can lead to smaller sizes of infants [2]. Furthermore, when infants are born dependent on opiates, they can have withdrawal symptoms which include vomiting, diarrhea, and disturbances in feeding behaviors.

Since FTT is a heterogeneous condition, it is essential to determine the cause when considering treatment options. Prognosis of OFTT depends on the response to treatment of the underlying condition, as well as the severity of the malnutrition and the number and severity of its causes [7]. Unless there is a specific and identifiable medical condition identified as the cause, interventions tend to focus on parent training for feeding behaviors. In addition to establishing a theory of etiology, it is important to take into account the age and cognitive development of the children when assessing and formulating a treatment plan. With hospitalization and multi-disciplinary interventions, including nutritional rehabilitation, there can be a good chance for rapid growth catch-up.

Relevance to Childhood Development

FTT can be associated with serious outcomes and developmental sequelae if it is not treated. These include medical conditions, delays in psychomotor development, and cognitive deficits. It also may be associated with cardiovascular disease and other heart problems later in life [1, 8].

Nutritionally at-risk infants tend to have lower scores on a psychomotor development index [6]. There is also some evidence to suggest that malnourished children have a lower activity level and are less active, possibly to conserve energy. Not all studies have come to this conclusion, however.

Low birth weight has been associated with poorer intellectual development and cognitive functioning, although studies differ with regard to the extent of this effect [1, 6]. FTT has been moderately associated with lower IQ, even after controlling for birth weight and time of gestation. FTT has also been associated with more cognitive decline in old age. The strength of these associations has not been consistent, however. Malnutrition can also lead to a condition called microcephaly, in which the infant has a small head circumference, as well as cognitive impairments [3]. With regard to social emotional functioning, individuals who had FTT as infants did not demonstrate emotional problems in adolescence, but did in adulthood [1]. These effects were possibly mediated through IQ and their associated physical health conditions.

False Belief Task

Douglas K. Symons
Acadia University, Wolfville, ON, Canada

Synonyms

Appearance-reality task; Emotion false belief; Maxi task; Sally-Ann task; Theory of mind task; Unintended transfer task

Definition

A false belief task is commonly used in child development research to assess social understanding or theory of mind. A wide variety of these have been developed using common play materials and story themes that children feel comfortable with. Their common goal is to determine whether children can distinguish between the thoughts and feelings they themselves currently have with those that can be possibly held by others.

Description

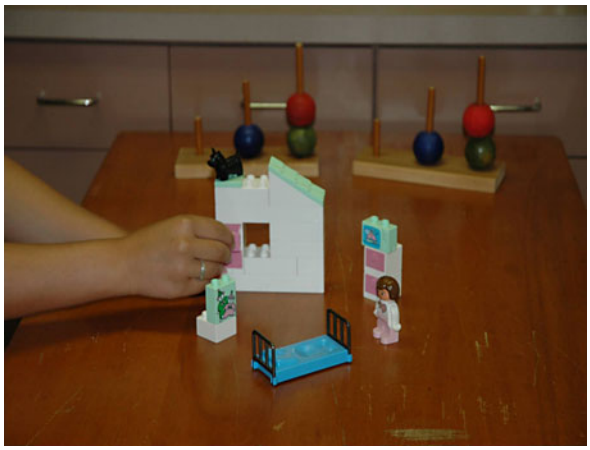
False belief tasks have become widely known and used in child development research [2, 4], although there are many different versions of these tasks. They all have the common feature of creating a situation in which a child is led to believe something about a current set of circumstances, but this belief is different from a belief that should/could be held by others. There are various techniques used to deliver false belief tasks and many have formal scripts associated with them. Many involve the use of household items and toys as props for the task, and most recently, some of these tasks have been converted to a series of pictures so they can be delivered on a computer or without oral scripts or test questions. Typically there are a number of control questions that children are asked, in addition to the essential test question for false belief, and performance is judged on a pass/fail basis from the answers to these questions.

Two common and well-known false belief tasks will be described to show how they work. The first is the "Smarties task" [5], in which a child is shown a closed box of Smarties, the box is rattled to generate interest, and the child is asked what they think is in the box. Children typically answer with the obvious, Smarties. But then the box is emptied out into the experimenter's hand and it turns out to be rocks in the box. This is surprising to the child as the actual contents of the Smartie box are unexpected. The rocks are then returned to the box, and the child is then asked a number of test questions. These include what they think another child new to the scene would think is in the box when the other child first sees the box. In order to answer the question correctly (i.e., that the other child should think it is Smarties), the child participant needs to separate what they know is really in the box (rocks) from the false belief the new child should have (that the box contains Smarties).

A whole series of these kinds of tasks have been developed in which a brick turns out to be a sponge that looks like a rock, an apple turns out to be a candle, an egg-carton contains forks and not eggs, and a pen turns out to be a flashlight. The common feature of these kinds of tasks is that an object is not what it appears to be or contain what it should contain, the deception is revealed, and the child is asked what another child would initially think.

A second kind of task is called the Maxi-task, aka unintended transfer task. This kind of false belief task involves a script often acted out with props in which Maxi is playing with an object of some kind, puts it in a hidden place, and then has some reason to leave the situation. While Maxi is gone, a foil enters the room and moves the object from one location to another hidden location, all in the full view of the participant child but not Maxi. The foil leaves, Maxi returns, and the test questions revolve around where Maxi should look for his toy. The participant passes the task by answering that Maxi should look in the original location and not the new one, but to do so, children must separate what they know to be true (i.e., the object is in location 2) to what Maxi should know (the object should be in location 1 because that is where he left it and he was gone when the foil moved the object). If they make this distinction, then participants are said to have an understanding of the "self" as a mental agent whose thoughts and feelings can either change over time or can be different from those of an "other."

Various versions of false belief tasks exist in which all kinds of objects and toys are relocated, the identity of the foil changes (e.g., monkey, clown), and Maxi is given a name more appropriate to the country where the research is conducted (e.g., Sally-Ann). Figure 1 shows the kinds of materials that could be used in conjunction with this kind of script [13]. Typically a whole series of false belief tasks are administered in what is often called a theory of mind battery, but this varies considerably from as few as one or two, to as many as a dozen or more. Tasks must differ from one another within a battery as many require the participant to be deceived. Each is scored on a pass/fail basis where chance performance is 0.50 (i.e., random response). Typically a false belief score is the average level of performance across these tasks [6].



False Belief Task. Fig. 1

Relevance to Childhood Development

Initial use of false belief tasks took place in theory of mind research on children's cognitive development. This research sought to determine when tasks were passed in an above-chance way, and this was seen as a developmental milestone that indicated a child had transitioned to a higher level of social understanding and "had" a theory of mind that allowed them to distinguish between thoughts of self and those of another. There is variability in when this occurs across studies and cultures, but typically this is around 5 years of age [15]. However, there is considerable variability in when children pass false belief tasks, and research has evolved from examining when children typically pass tasks to treating their performance as an individual difference variable. In other words, different children begin to pass tasks at different ages, and performance can be calculated and then related to other aspects of child development in longitudinal or correlational research. For example, there are a number of other cognitive factors that develop significantly around age five associated with passing false belief tasks, including the executive functions of attention, memory, and inhibitory control [10]. Some of this research has attempted to vary aspects of the false belief task to isolate specific cognitive factors that could affect performance.

In addition, research has focused on experiential factors that are related to passing false belief tasks [8, 9]. Cognitive development in childhood occurs within family, peer, and school social environments, and it is important to consider social factors that relate to passing false belief tasks. Much of this research has focused on talking about thoughts and feelings, which has also been referred to as discourse about mental states, inner state talk, and belief-desire talk [12]. Some of this research has shown that mental state discourse predicts false belief task performance, and thus may contribute to the development of social understanding. Other research has focused on family factors including whether children have older siblings, what kind of disciplinary strategies are used in the home, what kind of language is used when interacting with children in common tasks like play and joint-reading, and cultural factors [14]. Parental factors have also been considered, such as whether a parent tend to describe their child in terms of mental states, that is, in a mind-minded fashion. There have also been a number of training studies in which children who have failed false belief tasks have been exposed to social discourse about competing beliefs and desires, and these children do better on false belief tasks compared to children who receive other kinds of training [7, 11]. There is thus considerable evidence that social talk about thoughts and feelings is related both longitudinally, cross-sectionally, and experimentally to children passing false belief tasks.

Language development more generally has been examined as a factor in false belief task performance. Because language development can be used as an estimate of general developmental level, many studies use a measure of receptive language as a control variable in their analyses. Other research has focused on the grammatical structure of language [2], and how children's development in this area is related to performance and comprehension of false belief tasks. Parental language which is sensitive to and elaborative of children's own language is related to children's social understanding.

A final area of use of false belief tasks is in studies of children with atypical development. This is most well-known in the area of autism [1] due to the serious social deficits and poor false belief performance of children in this clinical group. However, there have been many studies of children with other clinical problems of attention, behavior, and conduct, and false belief performance is also poorer in these children than typically developing children. Because false belief tasks are designed to test social understanding in young children, they are useful for either clinical problems that arise at this age or with older children whose developmental level is at this age.

The false belief task is a tool that has become synonymous with what it is designed to study, that is, theory of mind and social understanding. Because research has spanned all areas of child development and been used with clinical samples, it has been used widely over the past 25 years in both basic and applied research.

Family Drawing

Rebekah R. Pender
San Antonio, TX, USA

Synonyms

Family drawing global rating scales; Kinetic family drawing

Definition

Family Drawing is a widely used test in psychodiagnostic assessment that allows the clinician gain some understanding and awareness into the child's perception of itself; the child's perception of its parents; and "some indicators of the development of its mental organization" [1]. The family drawing is considered an optional tool for the investigation of the child's mental representation of attachment to the parents synchronized with the developmental psychology concepts [1].

Description

The family drawing "projects the image of the family as perceived by the child in its growth" [1]. The family drawing also provides insight into the child's "fantasies that combine the child's subjective life experiences and their meetings with the objective outside world [1]." There are several ways to analyze children's family drawings. One of the most widely used projective drawing techniques is the Kinetic Family Drawing (KFD) devised by Burns and Kaufman in 1970 [2]. The Kinetic Family Drawing involves the therapist asking the test taker, usually a child, to draw a picture of his or her entire family [3]. With the Kinetic Family Drawing, children are asked to draw a picture of their family, including themselves, engaged in some activity [3]. The purpose of "this picture is meant to elicit the child's attitudes toward his or her family and the overall family dynamics" [3]. "The examiner may then ask the child questions about the drawing, such as what is happening and who is in the picture. Certain characteristics of the drawing are noted upon analysis, such as the placement of family members; the absence of any members; whether the figures are relatively consistent with reality or altered by the child; the absence

of particular body parts; erasures; elevated figures; and so on." Another popular method less concerned with the placement or absence of figures is the Family Drawing Global Rating Scales [4]. The FDGRS is a set of eight scales with an assigned numerical rating for the overall pattern of drawing features [4]. These scales rate "the emotional tone and quality of the mother–child relationship portrayed in family drawings" [4]. The dimensions of the FDGRS are "two positive dimensions, vitality/creativity, family pride/happiness, and six negative dimensions, vulnerability, emotional distance/isolation, tension/anger, role-reversal, bizarreness/dissociation, and global pathology" [4].

Relevance to Childhood Development

The non-verbal nature of the family drawing allows the child a safe outlet to express those feelings he/she may not otherwise be able to express verbally, including those aspects of mental representations the child is not aware of on a conscious level [4].

Family Therapist

Bernadette Hassan Solórzano
Our Lady of the Lake University Community Counseling Service, San Antonio, TX, USA

Synonyms

Bowenians; Collaborative; Dyadic therapist; Milan therapist; Social constructionist; Social system; Strategist; Structuralist; Systems therapist; Triadic; Triangular

Definition

A family therapist is a clinician who has received extensive training in working systemically with a group of individuals who live in an interdependent relationship with one another. The definition of family is open to many different interpretations in today's world.

Description

The family therapist assists families with improving communications, parent and child interactions and resolve challenges families confront including traumas, illnesses and normal developmental changes. Family membership normally remains intact even beyond the time the family lives together as a unit. Family therapist is a protected title and can only be used by those individuals who are certified by a marriage and family licensing board. Family therapists usually conduct evaluations and interviews with the entire family and any extended members who wish to work on the family's identified problem. Family therapists are trained to work systemically and incorporate all aspects – developmental, cultural, socioeconomic, health, community, gender – which impact the family. Family therapists must also be clear about ethical challenges when working with more than one individual at a time. There are many different approaches utilized by family therapists. Among the most well known are the object relations therapists, experiential family therapists, Bowenians, structuralists, strategists, Milan therapists, solution focused therapists, narrative therapists and feminist family therapists. Different theories of change focus on different aspects. All family therapists focus on the interactional component of the system. Some models

focus on the insight-action dichotomy while others say change comes when the cognitions change, while others collaborate with the system to find new solutions. Family therapists may work alone or with a team of therapists who will provide reflections to the family in helping them to introduce new perspectives which may lead to change. Many family therapists also believe that small change leads to big change and thus brief therapy approaches are successful in helping families reach their goals. All family therapists concentrate on helping the clients to see they have choices to handle their situations differently and reintroduce hope to the family. Family therapists may work as a part of crisis intervention, brief or long term. There is also outcome evidence being collected to show the utilization of single session, walk in therapy is a powerful way for family therapist to assist families.

Family Therapy

Robert Walrath
Rivier College, Nashua, NH, USA

Synonyms

Conjoint therapy

Definition

Family therapy is the application of therapeutic techniques and theories to the family as client or patient. Family in this instance can be defined as any number of biologically or otherwise related (e.g., by marriage) individuals, including multi-generational relationships, who may or may not reside together.

Description

Early work in family therapy in the 1950s centered on the work of Bateson and his colleagues at the Mental Research Institute [1] studying communication patterns among schizophrenic and their families and with Bowen [2], in a more clinically oriented setting treating schizophrenic patients within the family group. Distinct schools of family therapy have evolved over time (see below), but most share the common aspects of therapists taking an active and sometime directive approach, maintaining a focus on the present, and the premise that all family members somehow play a role in the family dysfunction. The most influential models of family therapy are described below:

Family Systems Therapy

Bowen's [2] theory focuses on the degree of "differentiation" an individual is able to achieve from the family if origin and how t related to emotional and intellectual systems, which may become "used" if the person has difficulty differentiating themselves. Bowen used the term "triangles" to describe how individuals within a family system may deal with anxiety by members "fusing" together to exclude another. Birth order and transgenerational issues are considered important to understand the individual's relationship tendencies. Therapy focuses on gaining insight through interacting in different ways with family of origin members to improve differentiation and "detriangulate."

Strategic Family Therapy

Proposed primarily by Haley [3], strategic approaches to family therapy center around the family's protective and dysfunctional interaction patterns that serve to hold the family together. Therapists provide directive and sometime provocative tasks to challenge the existing patterns and effect change. A family's insight into their difficulties is not considered important and is not a goal of therapy.

Structural Family Therapy

Developed by Minuchin [5], the Structural approach focuses on bringing family interactional patterns into the session to allow the therapist opportunities to influence boundaries difficulties between family subsystems and thereby improve problem solving among family members. He uses terms such as "enmeshment" and "disengagement" to describe aspects of family structure that relate to boundaries and the connection or lack of connection among family members. Minuchin stressed the need for the therapist to "join" the family to help unbalance the dysfunctional system.

Fantasy Play

Nayla Daou
Nova Southeastern University, Nova Southeastern, Fort Lauderdale, FL, USA

Synonyms

Dramatic play; Make-believe play; Pretend play

Definition

Fantasy play is a type of non-realistic play in which children take on different roles and enact various situations.

Description

Fantasy play is nonliteral, meaning it is not realistic. It involves pretense and symbolism and greatly evokes a child's imaginative capacity [3]. In this type of play, children take on different roles and are able to examine and understand various types of interpersonal interactions and social situations. Children may perform activities without the materials and the social context necessary for such activities in reality. Children may also create their own outcomes to the activity they are pretending to perform and may use inanimate objects as animate beings.

Relevance to Childhood Development

Engaging in fantasy play has many benefits for the developing child. This type of play improves the child's understanding of the world, contributes to the development of social understanding, improves emotional development, and exercises imaginative capacity. While engaging in fantasy play, children develop their own narratives and listen to other children's narratives [1]. Through these narratives, they can make sense of the world and learn to guide their behaviors within different social roles. Children take on characters and explore different perspectives for themselves. Through their generated stories, children also learn to negotiate and see themselves in relation to others. Together, children practice planning and negotiating how objects, people, and actions function in their make-believe world. This type of play also allows children to engage in affective role taking, which is necessary for their emotional development [2].

Fascia

Arthur E. Hernandez
Texas A&M University Corpus Christi College of Education, Corpus Christi, TX, USA

Definition

A sheet or band of connective tissue which binds or covers soft structures of the body such as muscles or organs.

Description

Fascia is a sheet of tissue often white and fibrous which acts as a connector, binder or cover for various internal organs and muscles. It is composed of a superficial and a deep layer and is responsible for structural integrity connecting the skin to the structures and organs underneath, serving as a suspension mechanism for internal organs capable of contraction and relaxation. Aponeurosis is generally a type which connects muscle to bone and resemble.

Fathers

Bady Quintar
Nova Southeastern University (CPS), Fort Lauderdale, FL, USA

Literature concerning children's emotional attachment and emotional development has dealt primarily with the mother–infant interactions. Indeed, prior to the 1970s research centering about the contributions of fathers to the psychosocial growth and development of infants has been rather limited. According to Gill [3], studies have reported that both father's presence and absence can have serious affects on the personality development of a child. In our culture infants form more intense attachments to primary caregivers (usually mothers) and slightly less intense attachments to secondary caregivers (often fathers). Such differential reactions displayed by infants is understandable given that soon after birth the infant's basic needs for feeding, physical comfort, touching, changing diapers, and other related activities are performed primarily by mothers. It may also be argued that infants are attached more to their mothers because of the role and expectation that society has assigned to them. What then are the roles of fathers? What does the phrase "to father a child" mean? Does it refer only to the act of insemination but not to the responsibility for raising a child? Is the father's role limited to the sole biological contribution of the moment of conception? Do these questions suggest that what fathers contribute to their offspring after conception is largely a matter of cultural devising and definition? At this point, it may be helpful to make a distinction between two related concepts; namely *father* and *fatherhood*. The term *father* tends to emphasize the biological connection between the progenitor and his offspring, while the concept of *fatherhood* stresses the socio-cultural and psychological obligation that men have to their biological offsprings. At times, we observe a harmonious synergism between these two concepts, and when that happens, positive outcome invariably occurs. When a disjunction or a gap between *father* and *fatherhood* takes place, the risk of deleterious effect increases considerably. Psychoanalytic Object Relations theories are inclined to state that when a father dies, his fatherhood lives on, as a mental representation, in the child's psyche. However, when the father deserts the family his fatherhood leaves with him and the child will be unfathered. Indeed, when a father dies, children grieve and mourn the loss, but when the father abandons the children, they feel anger, anxiety, resentment, guilt, and self-blame.

Richard Gill's book *Posterity Lost* (1997), a well-document scholarly written document underscores the idea that the current structure of the American family life is deteriorating. The rapid rate of divorce, increasing domestic violence and child abuse, early teenage pregnancies, juvenile crimes, drugs, antisocial behavior, suicide, and poor attendance and increasing failures in schools are highly symptomatic of the breakdown observed in our current family life. At the core of this crisis in family life seems to be the roles and functions of fathers. The presence of fathers at home seems to serve as an important stabilizing factor. Gill [3], adds that the explosion of crime and violence among children and teenagers in recent years, is most attributed to the absence of a father in the household. He adds, "Fully 70% of all prison and reform school inmates come from fatherless homes. This is a dramatic finding that underlies the critical importance of a caring and competent father to serve both as a role model and disciplinarian during the often wild teenage years, particularly for young males" (p. 41). Hrdy [5], states, "No matter how Apollo-like the progenitor, how skilled a hunter, how good his genes, how viable his immune system, his absence puts his children at a disadvantage" (p. 235). She adds that in fatherless families one sees higher rates of delinquency for boys and early pregnancies for girls. Gill [3], in reflecting over current American families, suggests that fatherlessness is the most harmful demographic trend of this generation and that it is the engine driving our most urgent social problems. Despite the deleterious effects of fatherlessness in our society, it is a problem which is minimized, ignored, or denied. According to Blankenhorn [1], in 1990, 36.3% of American children were living apart from their biological fathers... Scholars estimate that before they reach age eighteen, more than half of all children in the nation will live apart from their fathers for at least a significant portion of their childhood (p. 18–19).

Relevance to Childhood Development

Regardless of the changing economic and social condition and guided by the desire to stamp out the erosion of fatherlessness, it is incumbent on all of us to take all necessary measures to put an end to such a serious social problem. Efforts should be made to help growing children realize that both parents have equal responsibility in raising them to be trustworthy, honest, and responsible children. Parents should realize that children try to emulate their parents' behavior and that when parents act in a mature, responsible, and a respectful manner children will try to model their behaviors after them. Grinker et al [4], in outlining a cluster of conditions he associates with mental health listed the followings: "satisfactory positive affectionate relationships with both parents, parental agreement and cooperation in child raising, definite and known limitations and boundaries placed on behavior, and strong identification with father and father figures" (p.146). Thus, rather than conveying the idea that fathers are breadwinners and disciplinarian, children should be help to view fathers and their presence in the family as crucial socializing agents who compliment the various maternal functions. Fathers, realizing that in the last few decades have gradually moved from the center to the periphery of family life, must by their actions and behaviors try to reclaim their original position, that of being central to family life. In his very moving statement, Blankenhorn [1], stated, "I pledge to live my life according to the principle that every child deserves a father; that marriage is the pathway to effective fatherhood; that part of being a good man means being a good father; and that America need more good men (p.226)."

Feeding Disorder

Jessica Sparling, Ivy Chong
Florida Institute of Technology, Melbourne, FL, USA

Synonyms

Failure to thrive; Food refusal/selectivity

Definition

A feeding disorder is a disorder in which food intake is insufficient to maintain health.

Description

A feeding disorder is diagnosed when the amount of food consumed or caloric intake is insufficient to maintain

appropriate weight or growth [1]. While the exact etiology, prevalence, and change due to maturation is relatively unknown, various social and biological factors appear to be involved. Feeding disorders tend to be categorized as structural abnormalities affecting ability to eat, neurological or developmental disorders affecting ability to eat, or as behavioral feeding disorders [2]. Feeding disorders are not specific to one population, however, are more prevalent in the developmentally disabled, and may pose a variety of health risks [7]. A variety or problematic behaviors may be associated with feeding disorders, such as vomiting, rumination, gagging, expulsion, negative affect, and tantrums. Often the first course of treatment is a medical approach, however, behavioral interventions have been shown to be effective [3, 5, 6].

Relevance to Childhood Development

Feeding disorders are reportedly one of the most common disorders of childhood, and affect an estimated 25–35% of typically developing children, and 33–80% of children with developmental delays [4]. Evaluation for a feeding disorder often occurs when a child is developmentally delayed, presents with neurological or physical problems or defects, or behavioral issues. Causes may be due to medical disorders such as gastroesophageal reflux, disorders causing malabsorption of food, lactose intolerance, celiac disease, disorders causing persistent vomiting or diarrhea, and cystic fibrosis. Abnormalities affecting ability to swallow or delayed or insufficient oral motor skills may also contribute to the development of a feeding disorder. Social and environmental factors have also been identified, such as conditions unfavorable for eating, inadequate consequences for inappropriate or appropriate eating, parental beliefs regarding nutrition, maternal depression, and social isolation.

Children diagnosed with a feeding disorder are at risk for a variety of health risks, such as malnutrition, lethargy, delayed growth, significant weight loss, failure to gain weight, developmental delays, and cognitive delays. Feeding disorders are often reported to cause parental stress, and are often associated with disrupted or difficult mealtimes. Further, feeding disorders may be linked to an increased risk of eating disorders later in life.

Treatment is oftentimes medical, and involves force feeding, intravenous feeding, and tube feedings such as gastrostomy, oral-gastric, or naso-gastric tubes. Such treatments often serve as stabilizing procedures when life-threatening risk of dehydration or malnutrition occurs. Behavioral treatment is also often effective, and may include components such as prompts to eat, punishment, extinction procedures, and differential reinforcement [5]. Procedures such as manipulating the texture or portion of meals have been demonstrated to be effective in treating feeding disorders. While some issues related to feeding disorders tend to persist, behavioral interventions have shown success in increasing food intake in children with feeding disorders.

Feingold Diet

Jana Sander
Texas A&M University Corpus Christi
College of Education, Corpus Christi, TX, USA

Definition

Feingold diet a controversial diet for hyperactive children which excludes artificial colors, artificial flavors, preservatives, and salicylates.

http://medical-dictionary.thefreedictionary.com/Feingold+diet

Description

This diet requires the removal of any additives or chemicals thought to be the source of ADD or ADHD. Any type of artificial coloring is eliminated because it is derived from petroleum by-products and this is thought to cause hyperactivity. Thus, any food containing an artificial coloring is removed from the diet.

In addition, any food containing artificial flavoring is removed from the diet. The Feingold Association is concerned that these additives may not have had the thorough study of the effects on the behavior of children. Of particular concern is the flavoring vanilla. This flavor is frequently made from the by-products of paper production. Further, Aspartame, the artificial sweetener, is also eliminated from the diet.

No artificial preservatives are allowed in the diet when following the Feingold Diet. This includes BHA (Butylated Hydroxyanisole) and BHT (Butylated Hydroxtoluene). Both of them are derivatives of petroleum.

Initially numerous salicylates are removed from the diet but are reintroduced later. Some salicylates occur naturally such as apples, berries, grapes, oranges, peaches, plums, tangerines, and tomatoes.

The diet is divided into two stages. The first stage includes the removal of all foods thought to cause the disorders. Next, each food is added back into the diet, one food at a time to help determine if it causes the symptoms.

This diet can be very difficult to follow and very time consuming. Sleep disturbances and constipation may occur. Therefore, it is recommended that before a child is put on the Feingold Diet their physician or pediatrician is contacted.

In addition, The Feingold Association of the United States has an in-depth website concerning this diet. This association offers a free e-newsletter, materials as well as numerous resources pertaining to the diet.

Femininity

Ashlea Smith
Phoenix College, Phoenix, AZ, USA

Synonyms

Effeminate; Effete; Female; Femaleness; Feminine; Fertile; Girlhood; Girly; Maternal; Womanhood; Womanly

Definition

To possess a trait or characteristic that has been associated with the totality of being female or womanlike; most often influenced by socio-cultural norms and expectations.

Description

The term femininity encompasses what people perceive as how to look, act, think, and feel to be considered or labeled female. These labels or as some may say constraints dictate how one achieves these feminine ideals set forth by our society, media, culture, and familial factors. Nakash et al. [2] defined femininity as a "concern for others and on connectedness, with attributes such as gentleness,

submissiveness, dependency, and emotionality" being the primary focus of those identifying with the female gender (p. 4). The term takes on a more specific meaning then just the physicality of a female body, but defines personality traits and ways of relating to others for young girls and women to successfully subscribe to feminine ideologies.

Typically, we associate femininity with females of all ages as a group. The perceived primary indicator of whether or not one is feminine relates to one's sex. However, this way of acting female can go beyond the general scope of gender in that males can also adopt feminine traits and ways of being just as females adopt masculine traits. This belief stems from the biological roots in that males need the hormone estrogen and females need the hormone testosterone as survival mechanisms. Additionally, the media and social influences have even created a name for men who incorporate these feminine traits into their masculinity as "metrosexual." Societal pressures and cultural demands most commonly illustrated in different forms of media can dictate how young women should embody these set of expectations to fit the mold of what it means to be a feminine girl or woman.

From the moment that a child's sex has been announced as, "It's a girl!" the female roles and expectations begin to form from the abundance of pink-colored outfits to the sense of being more sensitive and fragile than their male counterparts. Young girls are even taught the correct expression of emotions or the socially accepted toys such as baby dolls and kitchen sets that they should be interested in as children to be considered female. Furthermore, when it comes to females selecting a chosen profession these roles and expectations surface in that it is more socially acceptable for women to enter professions in the helping field such as nurses, teachers, social workers, and secretaries to name a few; instead of becoming lawyers, physicians, engineers, or executives of companies. These ideals of what it means to be feminine and the ability to intertwine femininity into one's sense of self are born. This concept develops as a child progresses into the different stages of development into adulthood.

As a young girl progresses through puberty and becomes "a woman now" with the start of the menstrual cycle and the development of breasts new duties emerge upon entering adulthood such as being a caretaker, procreator, mother, and good wife [3]. In addition, this rite of passage fosters a new source of feminine identity "to create a sense of belonging within society," which is typically "engrained during childhood and inevitably forges a source of connection with one's body that is not necessarily positive or healthy" ([4], p. 41). For young girls, the ability to uphold these obligations upon entering adulthood and possess an identity outside of their physical bodily appearance may create struggles when it comes to embracing one's feminine identity. The female breasts are one of the most represented symbols of femininity even referred to as the "crown jewels of femininity" ([5], p. 3). Not all young girls accept these bodily changes as part of their new identity by wearing baggy clothing to camouflage or hide the appearance of breasts.

It has also been described as impacting one's body, hair, clothing choice, voice, skin, movement, emotion, and ambition [1]. When it comes to the physical female body, femininity has been defined as the distance "between the nipples of the breasts, from the lower edge of the breast to the navel, and the distance from the naval to the crotch" all being units of equal length according to the classical Greeks ([1], p. 23).These specific formulas have even filtrated into the field of cosmetic surgery where asthetic plastic surgeons use particular measurements when creating the newly constructed ideal body part(s) for female consumers based on these standards of beauty. Moreover, when it comes to looking the part of an ideal female or the ability to possess an air of femininity one needs particular clothing to induce "the body to strut about in small, restrained yet show-offy ways" ([1], p. 79). This look can be achieved by wearing fitted yet but not revealing clothing paired with high stiletto heels, and the addition of accessories such as: bracelets, earrings, and necklaces. To complete the look of femininity we must add the use of make-up to accentuate and highlight facial features, and a spray of sweet smelling perfume to create the embodiment of what it means to look and dress female.

Relevance to Childhood Development

Femininity is a term that is automatically associated with young girls and adolescents simply due to the fact of their sex. Young girls are taught at such a young age what it means to be feminine or a "girly girl." It starts with the color pink being the signature color to girls should openly express their emotions; except for those society has labeled as "negative emotions" such as anger, hostility, and jealousy because it is considered impolite to express those in public. This idea of femininity is also woven within the future goals and expectations set forth for girls in part of the social roles or professions to venture into. Femininity is a form of self expression that young girls and women should be able incorporate into the sum total of whom they are based on their personal perception of what it means to be female. Although social and cultural constraints may paint a vivid picture of how

one should look, act, think, and feel to be considered female it is the individuals choice to select which of those ideals they want to include in the personal worldview and identity.

Festinger, Leon

Bernadette Hassan Solórzano
Our Lady of the Lake University Community Counseling Service, San Antonio, TX, USA

Life Dates

(1919–1989)

Introduction

Dr. Leon Festinger earned fame and recognition as a social psychologist. He developed the theory of cognitive dissonance, social comparison theory, and explored the role of propinquity in forming social relationships.

Educational Information

Dr. Festinger was born in Brooklyn, New York on May 8, 1919. He attended Boys' High School in New York City. He earned a Bachelor of Science from City College of New York in 1939. He pursued his graduate studies at the University of Iowa where he earned both his masters and doctoral degree in psychology in 1942. It was during this time he worked with the prominent social psychologist, Kurt Lewin.

Accomplishments

After he completed his degree he stayed for 2 more years at the University of Iowa as a research assistant. During World War II, he worked as a senior statistician for the Committee on the Selection and Training of Aircraft Pilots at the University of Rochester. In 1945, he rejoined Lewin at the Massachusetts Institute of Technology as an assistant professor at the Research Center for Group Dynamics. When Lewin died in 1947, Festinger moved to the University of Michigan as an associate professor and became the director for the Group Dynamics Center. He next worked at the University of Minnesota in 1951 where he became a full professor of psychology. He moved to Stanford in 1955 and in 1968 made his final move to the New School for Social Research in New York where he was the Else and Hans Staudinger Professor of Psychology. He was awarded the Distinguished Scientist Award of the American Psychological Association in 1959 and was also elected to the American Academy of Arts and Sciences that same year. In 1972, he became a member of the National Academy of Sciences and the Society of Experimental Psychology in 1973. In 1980, the University of Mannheim named Festinger the Einstein Visiting Fellow of the Israel Academy of Sciences and Humanities. Also in 1980 he received the Distinguished Senior Scientist Award of the Society of Experimental Social Psychology.

Contributions

Festinger is most well known for the development of the theory of cognitive dissonance. Dissonance, according to Festinger, results when there is a conflict in an individual's belief system. This conflict results in psychological tension which must be resolved. The conflict is resolved using either a rationalization or ignoring the situation. Festinger began his work on cognitive dissonance while he was at Stanford when he observed that people liked consistency in their lives. Festinger also developed the social comparison theory and how group norms exert pressure on an individual's behavior. In association with Stanley Schacter and Kurt Backlund he developed the social network theory which studied that people form association based on their physical proximity.

Fetal Alcohol Effects

Ashley N. Pettoni
Pediatric Psychology, Atlanta, GA, USA

Synonyms

Alcohol exposure; Alcohol related birth defects (ARBD); Alcohol related neurodevelopmental disorder (ARND); Fetal alcohol spectrum disorder; Fetal alcohol syndrome (FAS); Partial fetal alcohol syndrome (pFAS); Prenatal alcohol exposure

Definitions

Fetal alcohol effects (FAE), or ▶Fetal alcohol spectrum disorder (FASD), is an umbrella term describing the range of effects that can occur in an individual whose mother drank alcohol during pregnancy. These effects include physical, mental, behavioral, and/or learning disabilities with possible lifelong implications [1].

Description

FAE is one of a spectrum of neurological impairments that can affect a child who has been exposed to alcohol prenatally [1, 3–5]. One of the most severe effects of drinking during pregnancy is fetal alcohol syndrome (FAS), which is one of the leading known preventable causes of mental retardation and birth defects [1, 6]. From a morphological perspective, children with FAE are not as impaired as children diagnosed with FAS, as they usually lack the distinctive FAS facial features and may have normal intellectual functioning. This is misleading as FAE is sometimes described as less serious. Unfortunately, children with FAE are in fact more likely to have negative outcomes such as trouble with school, trouble with the law, and teen pregnancy. Unrealistic expectations are frequently made with these children since more overt signs of impairments (i.e., facial features) are not present. Thus, children with FAE may be without adequate support and this can lead to detrimental ramifications for these children and their families [1].

Alcohol, which is able to cross the placental barrier, exerts its effects on the developing fetus through multiple actions at different sites. In the developing brain, alcohol interferes with nerve cell (i.e., the neuron) development in several ways, including cells not reaching the final destination and even premature cell death [4]. An embryo's susceptibility to distinct FAE defects seems to be related to the timing of maternal alcohol consumption. Specifically, consumption during critical periods of development for various organ systems, regions, or cell types has been linked to particular defects [4, 5]. Duration of the prenatal alcohol exposure and quantity of alcohol has also been shown to factor into the expression of deficits [3, 4, 6]. Regardless, not all children exposed to alcohol will be affected in the same way [4, 6].

In 1996, the Institute of Medicine (IOM) replaced FAE with the terms ARND and ARBD. Children with ARND might have functional or mental problems linked to prenatal alcohol exposure. These include behavioral or cognitive abnormalities or a combination of both. These deficits are often more subtle than is observed in children with FAS and can include difficulties with mathematical skills, difficulties with memory or attention, poor school performance, and poor impulse control and/or judgment. Children with ARBD might have problems with the heart, kidneys, bones, and/or hearing. The term FASD is now being utilized to accentuate that alcohol can exert its effects in multiple ways on a developing child and that no particular set of impairments is "better" or "worse" and seeks to refer collectively to FAS, partial FAS, ARBD, and ARND [1, 2].

Neuroanatomical differences in children exposed to alcohol in utero have also been found. There is evidence to suggest that the basal ganglia, corpus callosum, cerebellum, and hippocampus have irreversible structural changes following alcohol exposure during development of the fetus. These findings indicate that the structural changes could account for several observed deficits and suggest that are global, rather than specific, developmental abnormalities [4, 6].

Children with FASDs might have the following characteristics or exhibit the following behaviors: growth deficiencies; facial abnormalities such as small eye openings (palpebral fissures), flat midface, thin upper lip, and a flat philtrum (groove between nose and upper lip) [1, 2]; poor coordination [1]; learning disabilities; developmental disabilities (e.g., speech and language and motor

delays) [1, 4, 5]; mental retardation or low IQ; problems with daily living; poor reasoning and judgment skills; sleep and sucking disturbances in infancy [1]. In addition, other researchers have delineated that children with prenatal alcohol exposure demonstrate impairments in focused attention, executive functions [2–4, 6], and visual-spatial ability [4, 6]. Learning and memory is also impaired, as children with FASDs show deficits in immediate recall; however, retention and recognition is generally intact [2, 3].

Emotionally, increased levels of irritability have been observed during infancy [4], as well as hypersensitivity to sensory stimuli and self-soothing problems [5]. Children with FASDs also may display impaired social functioning and psychiatric disorders [4, 5], along with hyperactive behavior [1, 2] and impulsivity [5]. Collectively, these problems often lead to difficulties in school and problems getting along with others. FASD is a permanent condition and affects every aspect of an individual's life and the lives of his or her family [1].

It is difficult to ascertain the exact prevalence rates of FAS and other alcohol related conditions, as it varies widely depending on the population studied and the surveillance methods used. Estimates of FAS prevalence rates vary from 0.5 to 3.0 per 1,000 live births in a majority of populations. ARND and ARBD are believed to occur approximately three times as often as FAS [1, 4].

Relevance to Childhood Development

Unfortunately, there is no cure for FASDs. However, treatment is possible. Due to the range of CNS damage, symptoms, and secondary disabilities, treatment approaches vary depending on the individual needs of the child and family. Comprehensive models of treatment are the most effective, as several types of inventions, such as medical, behavioral, and developmental, are needed to ameliorate the negative effects [5].

While these conditions are serious and pervasive, there are protective factors that have been found to help individuals with FASDs. For example, a child who is diagnosed early in life is eligible to receive appropriate educational services and can have access to social services that can assist the child and his or her family. The children who obtain special education are more likely to achieve their developmental and educational potential. In addition, children with FASDs need a loving, nurturing, and stable home life to avoid disruptions, transient lifestyles, or harmful relationships. Children with FASDs who live in abusive or unstable homes or who develop anti-social behaviors are much more likely than those who do not have such negative experiences to develop secondary conditions [1].

Given that FASDs are preventable, several approaches are aimed at reducing the effects of alcohol on developing fetuses. More comprehensive approaches involve social, cognitive-behavioral, medical, and referral services. Public health models emphasizes three different levels of prevention: primary (attempt to cease maternal alcohol consumption before it begins), secondary (utilize early detection and treatment of problems), and tertiary (programs which attempt to change the pattern of behavior of high-risk women who already have a child with FASD). Universal and selective prevention strategies have also been developed. Universal programs attempt to reach all of society, through the utilization of media and policy and environmental change. An example includes warnings on alcoholic beverages. Selective prevention interventions are intended for those individuals who are at high risk for developing problems. Once these women are identified (usually through questionnaires at clinics); measures can be put in place to assist in change. This form of prevention is similar to secondary prevention [4].

Definition

Fetal Alcohol Syndrome (FAS) is a developmental disorder that results from a developing fetus being exposed to alcohol in utero. FAS is characterized by distinctive neurological, cognitive, and behavioral deficits [8]. In some cases distinct phenotypical traits may also be seen.

Description

FAS is a developmental disorder that affects individuals throughout his or her life. Initially described in the United States by Jones and Smith [3], FAS commonly results in intrauterine growth retardation and physical and neurological deficits. Physical abnormalities may include widely spaced eyes, shortened eyelid length, elongated midface, flattened nose, and a thin upper lip [8]. However, in many children exposed to alcohol in utero, few actually demonstrate the growth and facial abnormalities [6]. Even though they do not have the characteristic growth deficits and other physical abnormalities of FAS, they often exhibit the same cognitive, neurological, and behavioral changes. These features are often referred to as fetal alcohol effects (FAE) or alcohol-related neurodevelopmental disabilities (ARND) [8]. In response to the variability of outcomes in response to prenatal alcohol exposure, many researchers have argued that children exposed to alcohol should be categorized on a continuum [5]. As with most teratogens, the point and magnitude of exposure plays a vital role in the nature of affliction. While the early stages of pregnancy are viewed as the most sensitive periods to adverse impacts of teratogens such as alcohol, exposure at any point prenatal may negatively impact development.

As previously mentioned, children with FAS and FAE often experience neurological deficits. Neurological deficits often include microcephaly, seizures, poor coordination, reduced muscle tone, poor behavioral regulation, below average cognitive ability, inattention, hyperactivity, and learning disorders [2]. Neuroanatomical changes can also occur such as agenesis of the corpus callosum, cerebellar abnormalities, reduced volume of the basal ganglia, damage to the hippocampus, and enlarged ventricles (Randall, 1996).

While factors such as amount of alcohol consumed, frequency of use, and timing of use during pregnancy have all been related to the nature and severity of FAS/FAE residuals, Olson et al. [1] found that a fetus of an alcoholic mother who engaged in "binge" drinking is more at risk for deficits associated with FAS.

Relevance to Childhood Development

Individuals afflicted with FAS often experience lifelong deficits in cognitive ability, behavioral functioning, and adaptive functioning [7]. Infants experience low birth weight, feeding problems, poor sleeping patterns, and irritability while children often experience attention, memory, learning, gross, and fine motor skill deficits. Enuresis (bed-wetting), language and other communication disorders, Attention-Deficit/Hyperactivity Disorder (AD/HD), mental retardation, and learning disorders are also common [8].

Executive functioning also appears to be greatly affected with FAS indicating frontal/ prefrontal involvement. Children with FAS appear to perform less well than same-aged peers when matched for IQ on tasks of verbal fluency, design fluency, cognitive set shifting, and planning [2]. These executive deficits may also contribute to difficulties with proper socialization. This is seen in fact that as children with FAS grow older, poor social judgment, poor interpersonal skills, and antisocial behavior are commonly seen [2].

Recent studies have also found that children with FAS experience greater difficulty on certain tasks of memory and learning. Mattson et al. [4] found that children on a list learning task experienced more difficulty memorizing new information than retaining and retrieving what they had previously learned. Recognition memory and the ability to benefit from priming and cueing also appear to be relatively intact in children with FAS [2].

In sum, children with FAS and FAE experience a great deal of deficits in cognitive abilities such as language, memory, learning, and executive functioning that can contribute to learning difficulties in school. Social skill deficits may also occur which creates further difficulties in proper adjustment and education. It is a lifelong disorder that will continue to create difficulties into adolescence and adulthood. However, FAS is easily preventable with early intervention and education as well as treatment for pregnant mothers with alcohol dependence and/or alcohol abuse.

Fetal Development

Jana Sander
Texas A&M University Corpus Christi College of Education, Corpus Christi, TX, USA

Definition

Weeks 9–40 of gestation or weeks 11–41 of a pregnancy.

Description

The period known as the fetus ranges from week 9 of gestation until birth. During this period the developing fetus grows rapidly. During the third month the head of the fetus is extraordinarily large in comparison to the rest of the body. The eyes move to their proper location and the organs, muscles, and nervous system become more structured. The face is well formed and the eyelids close. The tooth buds also appear. In addition, male and female external genitalia appear. Fine hair, lanugo, begins to develop on the head and bones develop and become harder. Sucking motions are made. Muscle tissue develops and the fetus begins to move its feet, hands, arms, and toes. However, the movements are so slight they cannot be felt by the mother at this point ([2], p. 173, [3], p. 123, [1], p. 89).

The fourth month brings rapid growth in length though, the weight of the fetus does not increase much. The fetus is able to hear and eye movement begins. At this point in the pregnancy, the mother may begin to feel slight movement of the fetus. ([3, 4], p. 124).

During the fifth month fine, silky hair called lanugo cover the entire body of the fetus. Due to increased muscle development the fetus is more active and can be felt by the mother. The lungs develop but are not viable outside of the mother's body ([3, 4], p. 124).

In the sixth month of fetal development all parts of the eye have developed and are able to open and close. Footprints and fingerprints are developing and fingernails are present. The respiratory system is still developing and is able to exchange gas while the nervous system can now control some bodily functions. Toward the end of this month the brain develops rapidly ([3, 4], p. 124).

The fetus begins to gain weight and fill out during the seventh month. The brain can support rhythmic breathing but the lungs are still immature. Eyelashes and toenails grow ([3, 4], p. 124).

In the eighth month the fetus has gained fat under the skin. The lanugo begins to disappear and the fingernails reach the end of the fingertips ([3, 4], p. 124).

During the final month of fetal development, the fetus steadily gains weight and weighs about 7 lb. The lunugo is almost gone with the exception of the upper arms and shoulders. Body structures are being refined and the brain expands during this time ([3, 4], p. 124).

Fetal Distress

Jana Sander
Texas A&M University Corpus Christi College of Education, Corpus Christi, TX, USA

Definition

The fetus experiences some type of complication.

Description

Fetal distress may be caused when the fetus does not get enough oxygen ([1], p. 80) and can be determined by the use of a fetal monitor. Fetal abruption (early separation of the placenta from the wall of the uterus), compression of the umbilical cord, infection of the fetus, or the mother is in a position which puts pressure on the major blood vessels and deprives the fetus of oxygen.

In utero the healthy fetus will have a stable and strong heartbeat. In addition, the fetus will move. A fetus in distress will react by having a decreased heart beat, slow their movements or even stop moving. In addition, the stressed fetus may pass their first stool (meconuim) while still in utero. An oxygen deprived fetus is in immediate danger.

If a mother suspects the fetus is in distress she should count the number of kicks in a 2-h period. If the fetus is not this active the obstetrician should be called. To take pressure off of the major blood vessels the mother can lie down on her left side.

To determine if a fetus is in distress the mother will be put on a fetal monitor. This consists of a large belt like device being strapped around the mother's abdomen. The fetal monitor will determine if the fetus' heartbeat is sufficient. In addition, the mother may be given oxygen and an IV. In case these treatments do not eliminate the fetal distress, a speedy delivery is necessary. This may mean the obstetrician will use forceps in the delivery to extract the fetus. Another possibility is vacuum delivery. A vacuum delivery involves a small rounded cup that attaches to the fetus' head. The cup is in turn attached to a hose that creates a vacuum that then pulls it out of the birth canal. Often an emergency cesarean section on the mother is performed in order to reduce the fetal distress.

Fetal Survival

►Age of Viability

Fetus

Elisheva Konstam, Devorah Neuhaus
Pace University, New York, NY, USA

Definition

A fetus is defined as an unborn or unhatched vertebrate. The word fetus specifically refers to the unborn child during the time when all of the major structures and organs have been formed, typically after the eighth week of pregnancy. Prior to that point, the fetus is referred to as an embryo. The fetal stage continues until birth.

Description

Fetus is the word used to describe unborn offspring in the uterus of vertebrate animals. This stage occurs between seven to eight weeks after the fertilization of the egg. At this time the embryo has taken the basic shape of a newborn and all major structures have been formed. It is also at this point in development that the risk of miscarriage decreases significantly.

During this stage the fetus is surrounded by amniotic fluid that enables it to move. Oxygen and nutrients are provided through the placenta and umbilical cord. Nurtured in this protective environment, the body grows larger and more defined and organ development is completed. At the start of the fetal stage the fetus typically weighs about 8 g and measures 1.2 in. From that point until birth, the fetus continues to gain weight and refine the functionality of their organs. This growth allows the fetus to be less sensitive to damage from the environment than the embryo was. However, exposure to certain toxins can still cause physiological abnormalities or minor congenital malformations. Some of these fetal disorders may cause the birth of an infant before the complete gestational

time period has passed. At the 20 or 22 week point, a fetus is considered developed enough to be viable outside of the womb.

Another interesting phenomenon occurs at the beginning of the fetal stage. From 8 weeks postmenstrual age onward, the fetus begins to move in a distinct pattern. The pattern is identical to the movement patterns of infants immediately after birth. The pattern of these movements have been studied, as alternative patterns are a reliable indicator of brain dysfunction and has been used as a predictor of the development of cerebral palsy.

Filial Family Therapy (FFT)

►Filial Therapy

Filial Therapy

Jeff L. Cochran, Nancy H. Cochran
University of Tennessee, Knoxville, TN, USA

Synonyms

Child-parent relationship (CPR) training; Child relationship enhancement family therapy (CREFT); Filial family therapy (FFT)

Definition

Filial therapy is a method of enhancing family relationships in which mental health professionals (such as counselors, psychologists, or clinical social workers) teach and supervise parents use of key elements of child-centered play therapy (e.g., [1, 4, 12, 17]) to help their own children with behavioral, emotional, adjustment, attachment, and self-esteem difficulties. The American Heritage Dictionary defines "filial" as: of or pertaining to, or benefiting a son or daughter (American Heritage Dictionary, 1982, p. 503). Thus it is a parental therapy for the daughter or son, in which the counselor helps the parent to learn and implement skills for special play time in order to be a therapeutic agent for her or his child. While filial therapy employs the special emotional bond possible between parent and child to help the children with difficulties ranging from normal adjustment issues to trauma, it also improves parental self-efficacy and stress levels as it is an intervention in the parent-child relationship.

Description

Development History and Research

Filial Therapy was introduced and developed by Bernard and Louise Guerney (see [10, 11, 25]) to empower parents

to advance or augment the benefits possible from therapeutic relationships frequently provided by mental health and school counselors, psychologists, social workers and professionals from related fields. The approach has continued to rapid growth in research and application in recent years. Its effectiveness has been demonstrated with child populations defined by various problem or life stress areas including conduct problems, stuttering, learning problems, chronic illness, problems related to immigration status, and learning disabilities [6, 15]. Promising results have been found for parents from differing ethnicities and life situations (e.g., Native American [8]; Chinese American [29]; parents with chronically ill children [27]; foster parents [7]; and incarcerated parents [13, 16]; single parents [2]; nonoffending parents of children who have been sexually abused [5]; and German mothers [9]).

Particularly important to child and family development, the effects of filial therapy have been shown to remain strong over time. For example, Sywulak [26] confirmed that a significant increase in parental child acceptance was maintained after 4 months. Stover and Guerney [25] found an increase in mothers' reflective statements and a decrease in directive statements maintained 12 months after filial therapy. Sensue [24] reported lengthy maintained results. For 16 elementary-age children, the behavioral gains that were demonstrated as the result of 4 months of filial therapy were still present after 3 years.

Rennie and Landreth [21] reviewed the research in filial therapy, looking particularly at changes in parental characteristics (empathy, acceptance, stress, and family environment) and in children (adjustment, behavioral problems, play session behavior, and self-concept). They concluded that filial therapy is a powerful intervention that increased "parental acceptance, self-esteem, empathy, (and created) positive changes in family environment, and the child's adjustment and self-esteem while decreasing parental stress and the child's behavioral problems" (p. 31). In a meta-analysis of the effectiveness of filial therapy, Ray et al. [20] found filial therapy to be an effective treatment for children's problems, reporting a quite high effect size, 1.06.

Brief Overview

In filial therapy, a play therapist trains parents, who become therapeutic change agents by offering their children empathy, genuineness, and acceptance in play sessions [10]. The therapist (mental health professional) takes the role of the parent(s)' guide, teacher, supervisor, supporter and challenger as the parent develops skills to provide a particularly structured, child-directed, child-centered, hour or half hour of weekly play, focused on parent-to-child empathy, unconditional acceptance of the child's self-expression (within limits necessary to maintain safety and to facilitate self-expression, and the parent-child connection). These 30–60 minutes of specialized parent-child interaction/play time is often referred to as special play time (SPT).

In contrast to many parent training interventions that require parents to use new relationship or interaction skills consistently across time, a daunting task for many stressed parents, filial therapy focuses change and new skills in the 30–60 minutes of weekly SPT. The therapist's focus is on helping the parents succeed with the unique relationship provided in SPT. Once that success is well begun, new ways of interacting naturally emanate throughout the week from SPT. Parents benefit from greatly expanded empathy and unconditional positive regard, considered by many in the counseling and psychotherapy field to be the core conditions of therapeutic relationships (especially counselors and therapists with interest in the person-centered approach to counseling, psychotherapy and other relationships – see [3, 22, 23]). Parents also learn empathic methods for limit setting when needed to facilitate the child's self-expression and parental connection in SPT. Practitioners of filial therapy often describe "the filial glow" evident in parents and children once the parent is succeeding in connecting through SPT.

Filial therapy is based on helping parents approximate, as closely as possible, the therapeutic skills of CCPT. Therapists provide significant didactic instruction, demonstration, and mock practice before parents begin SPT with their children under the supervision of their therapist. Therapists also help parents develop a specialized kit of toys, designed to best facilitate the child's therapeutic self-expression in SPT.

Therapists using filial therapy should be well-trained and well-experienced in CCPT. Especially for situations that have included significant trauma for the child, filial therapy is often provided as an addition to CCPT, after the child has achieved mastery stage [19] in CCPT. The primary professional organization focused in promoting filial therapy and associated family relationship interventions is the Association for Filial and Relationship Enhancement Methods (AFREM – afrem.org). The National Institute for Relationship Enhancement (NIRE – www.nire.org) has served as the major training, service and research institute for filial therapy, CCPT and related interventions for the past 25 years. Along with Bernard and Louise Guerney at NIRE, Garry Landreth, of the University of North Texas, is one of the major trainers and scholars of

filial therapy (e.g., see [2, 5, 12, 18]) and the University of North Texas Center for Play Therapy has been the major university based training, service and research center for play therapy since it began in 1988. Landreth [17, 18] developed a 10-week training model that has been well-researched across 14 studies involving more than 400 participants. A meta-analysis of studies utilizing the Landreth 10-session model demonstrated an exceptionally high effect size of 1.57. A commonly used and highly effective parent training manual for filial therapy is *Mastering the Magic of Play*, by Mary Ortwein (1997, Ideals). Another highly recommended filial parent training manual is *Filial Therapy: Strengthening Parent-Child Relationships Through Play, 2nd edition*, by Rise VanFleet (2005, Professional Resources Press).

As Landreth [17] points out, filial therapy can be an effective intervention for parents of children experiencing behavioral and emotionally based problems, but is also appropriate for families experiencing difficult times in normal development, times when the parent needs to strengthen her sense of her child's emotional reactions and needs (e.g., around the birth of a new baby or new adoption, when children from different parents are being blended through a new marriage, during periods of grief and loss, around the time of a family move, and through other significant changes). Filial therapy is considered appropriate through the age ranges projected for CCPT, usually considered ages 3–12 years, with some therapists modifying toys to be more age appropriate for 11 and 12 year children.

While filial therapy is an option for most families, there may be some parents who would likely be unable to use the model. Watts and Broadus [28] quote Garry Landreth as suggesting that exceptions include parents who are severely retarded and may be unable to learn the skills, parents who are excessively angry with their children and may need individual counseling before they could begin the new relationships required in filial therapy, and parents who are out of touch with reality (e.g., severe psychosis). The approach also requires a significant commitment to consistency. It may be that some parents self-select out of the treatment due to an unwillingness or inability to commit to the training required. Practitioners often report that once parents are engaged in SPT, the new relationship is highly self-rewarding to the parent, which strongly encourages consistent application. Additionally, when filial therapy is provided as an addition to child-centered play therapy, parents have usually developed high levels of trust in the therapist, and thus are willing to engage in the necessary training, and many parents are particularly ready to seek ways to greater relationships with their children, after seeing their children succeed in CCPT.

Relevance to Childhood Development

Johnson et al. [14] point out that filial therapy is a family system intervention. They explain that it: (1) requires family involvement, (2) takes the focus off the child as the identified problem, (3) often helps parents see their role in the problem, (4) enhances parental leadership by strengthening the generational boundary between parents and children, (5) increases differentiated relating and reduces polarization between parents and children, and (6) highlights unhelpful systematic sequences.

Filial therapy is one of the most promising therapeutic interventions for troubled children and parents. It capitalizes on the potential of positive parent child bonds through teaching and supervising parents in becoming therapeutic agents for their children. It provides a relatively stigma free way for parents to help their children with behavioral and emotional difficulties in ways that in turn help the parents become more effective and less stressed, especially through forming balanced and healthy parent-child attachments. It appears effective across a wide range of parent-child problems and population groups and may be particularly promising for foster and adoptive families in need. Filial therapy is a dynamic family intervention that provides opportunities for very positive change for families and children in need.

Fine Motor Skills

Maria Assunta Cuffaro
State University of NY: Potsdam, Potsdam, NY, USA

Definition

More precision and steadiness than the skills developed by gross motor skills. Fine Motor Skills Students' proficiency in using small motor muscles for tasks such as writing, buttoning or grasping [2].

Description

Fine motor skills, including reaching, grasping, and manipulating objects, it is in *ne motor skills* can be defined as coordination of small muscle movements which occur e.g., in the fingers, usually in coordination with the eyes. In application to motor skills of hands (and fingers) the term *dexterity* is commonly used.

The abilities which involve the use of hands, develop over time, starting with primitive gestures such as grabbing at objects to more precise activities that involve precise hand-eye coordination. Fine motor skills are skills that involve a refined use of the small muscles controlling the hand, fingers, and thumb. The development of these skills allows one to be able to complete tasks such as writing, drawing, and buttoning [1].

Fire Setting

Micah S. Brosbe, Angela Waguespack
Nova Southeastern University, Fort Lauderdale, FL, USA

Synonyms

Firestarting

Definition

Fire setting is a complex pattern of behavior in which a child or adolescent starts fires, either accidentally or intentionally. Factors in classifying fire setting include

intentionality, damage caused, frequency, and interest in fire vs. actually starting fires. Fire-setting has a variety of contexts and causes, and may be an aspect of the clinical presentation of other psychological disorders such as conduct disorder.

Description

The literature is somewhat mixed as to what exactly is meant by the label of fire setter [5]. The term firesetting is often used synonymously with arson; however, arson is a legal term that is applied in situations when an individual engages in intentional firesetting and is aware of the potential consequences of the behavior [7]. Some fire setters, usually younger ones, do so out of curiosity or accidentally. They do not intend to cause harm and often show remorse [9]. Of those who intentionally start fires, some do it as a cry for help or for attention. These children often have a diagnosable condition such as major depressive disorder or attention deficit/hyperactivity disorder. They may not mean to cause harm, but set fires in an attempt to bring attention to their situation and to express their emotions. These children often have histories of fire play, and lack the skills or abilities to appropriately express themselves and solve problems [9]. For other children or adolescents, fire setting is simply considered a severe form of antisocial behavior [8]. These delinquent fire setters may have an external gain for their behavior. They often engage in other antisocial behaviors and conduct problems as well, and the fire setting behavior may be part of a group activity [9, 10]. Finally, a fourth group of children who set fires have a severe emotional or mental illness such as mania or schizophrenia. For these "severely disturbed fire setters," the behavior is attributable to their mental illness. Pyromania is included under this category, but it is rare to see this in juvenile fire setters.

Relevance to Childhood Development

Childhood fire setting is a serious and prevalent societal problem, exhibited primarily by males. Almost 250,000 fires were set by juveniles in 1993 [10]. Children and adolescents have accounted for roughly half of all arson arrests in recent decades, including 2006 [3, 10]. Previous studies suggest that typically developing children often engage in fireplay and firesetting; however, only a small number of children become repetitive firesetters [7].

Many factors determine whether a child actually engages in fire setting behavior or not [10]. Risk factors for childhood fire setting can be discussed in terms of both individual as well as environmental characteristics (e.g., family). Risk factors appear to be cumulative; the number of risk factors affects the course and prognosis of the fire setting behaviors [8].

High levels of aggression, impulsivity, delinquency, interest in fire, social skills deficits, attention-seeking and risky behaviors, and externalizing emotions are commonly seen in children who light fires [9]. Some other risk factors include past fire play, being around people who smoke, and knowledge of materials that burn [5]. The attention individuals receive after setting fires is often reinforcing, which maintains the behavior [9].

Further, individuals who engage in more persistent fire setting may have poor social judgment, problems in peer relationships, and evidence higher levels of other forms of antisocial behavior. Children who set fires may have social skills deficits or difficulties in appropriately expressing their emotions, thus setting the fires serves this function for them [9]. Many fire setters have high levels of impulsivity and difficulty controlling their thoughts and actions [9]. They may show more aggression and engage in other antisocial acts such as lying and stealing. Individuals who set fires tend to be more impulsive, show less remorse or guilt, and have exhibited more cruelty to animals [5]. Fire setters also often engage in other antisocial behaviors such as property destruction (other than by fire setting), physical aggression, and vandalism [5]. Individuals who exhibit many of these other behaviors in addition to the firesetting are often diagnosed with conduct disorder in childhood or adolescence.

A history of fire involvement and playing with matches is consistently shown to be a predictor of recidivism [4]. Among children who have set fires, impulsivity is the individual characteristic that most often determines whether they continue [8]. Other research has shown that conduct problems, specifically covert antisocial behaviors, predict continuation of fire setting behaviors in children and adolescents [4]. Aggressive acts become more deviant as a child grows older. Age is also a risk factor for future fire setting. When older children and adolescents light fires, they are more likely to engage in such behavior in the future [4].

With regard to parental and family factors, children who have continually set fires often have parents who use harsh and inconsistent discipline, display less warmth, and have interpersonal problems [5, 8]. Poor parental supervision and lax child rearing have also been shown to contribute to the development of fire setting behaviors. In some cases, parents can be hostile and aggressive, and they tend to be less educated [9]. In addition, there may be a higher level of family dysfunction for children who set

fires [5]. There is a correlation between repeated fire setting in children and parental mental health issues and problems in the family. Children who have continually set fires were more likely to have depressed parents and more hostility among family members, including violence among parents [8]. They may be more likely to come from single parent homes [8] and to observe fathers who are alcoholics and/or abuse animals [2]. Living with a person who smokes greatly increases the risk of children becoming involved with fire as well [10].

Interventions utilized with children who engage in firesetting behaviors often include individual, family, and community levels. While treatment outcome studies are relatively sparse in the literature, research suggests that fire safety education programs targeting both children and their families have been found to improve both fire safety knowledge and skills [6] and are often included in treatment planning. Additionally, clinical interventions such as cognitive-behavior treatment and family therapy have been used in order to address behavioral, emotional, and social difficulties of the child, as well as parental and family functioning.

Fixed Interval Schedule

Steuart T. Watson, Christine Griffes
Miami University (OH), Oxford, OH, USA

Synonyms

Scalloped response pattern

Definition

A schedule of reinforcement in which the first response is reinforced only after a set amount of time has elapsed.

Description

A fixed-interval (FI) schedule has two components: (1) it requires the passage of a specified amount of time before reinforcement will be delivered contingent on a response and (2) no responding during the interval is reinforced, only the first response following the end of the interval is reinforced [1].

An FI schedule of reinforcement results in high amounts of responding near the end of the interval, but a much slower rate of responding immediately after the delivery of the reinforcer. This post reinforcement pause and then subsequent acceleration in responding results in a scalloped pattern of responding. B. F. Skinner's early research with pigeons identified the scalloped pattern, which was also consistently found in mice, monkeys, and human children [3]. More recent research is skeptical of

humans responding in a scalloped pattern, however it is agreed that a post-reinforcement pause followed by increased responding is typically found when using an FI schedule [2]. Examples of true FI schedules are difficulty to find in everyday life. First, they must be distinguished from fixed time schedules where reinforcement is delivered only after a certain amount of time has elapsed. Second, there are often other factors that interfere to make the schedule less than a true FI.

In educational and other applied settings, there are devices that provide a vibration to signal the end of an interval and that reinforcement is available for the next target response. For instance, a teacher could use one of these and set the timer for 2 min. At the end of the 2 min period, the student's next correct response would be reinforced. In such a real life setting, FI schedules have advantages and disadvantages. Some of the advantages of an FI schedule are they produce an overall low but consistent rate of responding and they allow for reinforcement to be provided at greater intervals, (i.e., hourly, weekly, etc.) versus a more frequent basis. Some of the disadvantages of FI schedules are that they tend to produce irregular performance and are susceptible to extinction due to infrequent reinforcement. Also, some people may have a tendency to increase their rate of response as the end of the interval (i.e., availability of reinforcement) draws near, which can result in sloppy work or incomplete assignments.

Definition

The ability to solve novel problems using inductive and deductive reasoning abilities, sequential thinking, and quantitative abilities. It includes abilities to draw inferences, identify and classify relationships, and to change reasoning and problem solving approaches based on demands of the situation [2].

Description

Part of the Cattell-Horn-Carroll (CHC) theory of cognitive abilities [1], Fluid Intelligence is considered a *broad* ability composed of a series of *narrow* abilities including *general sequential (deductive) reasoning* (RG), *induction* (I), *quantitative reasoning* (RQ), *piagetian reasoning* (RP), and *speed of reasoning* (RE).

Fluoxetine

Synonyms

Prozac; Sarafem

Definition

A selective serotonin reuptake inhibitor (SSRI) antidepressant most commonly used to treat major depression; however, it is also used to treat obsessive-compulsive disorder (OCD), panic disorder, bulimia nervosa, and premenstrual dysphoric disorder (PMDD).

Description

Depression is believed to be caused by an imbalance of the neurotransmitter, serotonin. Serotonin is known to affect mood, emotions, sleep, and appetite. Fluoxetine corrects the imbalance by preventing the reuptake of serotonin into the synaptic clef; therefore, increasing serotonin in the brain and alleviating depression symptoms.

Fluoxetine has some adverse side effects. It can cause nausea, headaches, insomnia, anxiety, drowsiness, loss of appetite, skin rashes, and vasculitis. Also, blood pressure can increase; some seizures and sexual dysfunction have been reported. When coming off fluoxetine withdrawal symptoms such as anxiety, nausea, nervousness, and insomnia can occur. There is also an increased risk of suicidal ideations. Fluoxetine should not be taken while pregnant or when nursing.

Flurazepam

Flurazepam, also marketed under the brand names of Dalmane and Dalmadorm, is a psychiatric drug of benzodiazepam derivation. Flurazepam possesses anxiolytic, anticonvulsant, sedative and skeletal muscle relaxant properties. Flurazepam produces a metabolite with a very long half life of up to 25 hours. It may stay in the blood stream up to four days. Flurazepam demonstrates effects approximately a half to one hour after oral administration. It is typically used for the treatment of insomnia. It acts by relaxing muscles, reducing anxiety and causing sleepiness. It is typically used on a short term basis and not approved for children under the age of fifteen. It has been used off label to treat anxiety. In many cases, however, it causes sedation for extended periods of time often into the next day and therefore may not be a good long term sleep aid.

Formative Assessment

Susan K. Green
Winthrop University, Rock Hill, SC, USA

Synonyms

Assessment for learning; Formative evaluation

Definition

The monitoring of progress during instruction that includes useful feedback, opportunities for improvement, and information helpful for tailoring future instruction.

Description

The concept of formative assessment [2–4] has been researched and promoted over the last decade as a means of reconceptualizing classroom assessment, and even the teaching and learning process. Formative assessment, conducted during a course of instruction, is often termed assessment *for* learning to distinguish it from traditional summative assessment, such as an end of unit test after instruction (assessment *of* learning). The function of formative assessment is to promote learning. The function of summative assessment is to document learning.

In formative assessment, "activities. . . are undertaken by teachers to provide feedback to students to enhance their motivation and learning. . ." [4]. To qualify as formative, that feedback must offer learners specific suggestions for future actions that will improve their learning. Examples of formative assessment activities might include students explaining their reasoning behind a choice or position on a political issue in a social studies class with teacher feedback, observation of students' performance of a gymnastics routine with both teacher and students making suggestions for improvement, an ungraded quiz covering recent biology

readings for student self-assessment, or quick writes at the end of class asking students to describe their understanding of and questions about the content addressed that can contribute to later discussion and instruction.

Key components of effective formative assessment include student understanding of the academic learning goals, meaningful tasks involving critical thinking and dialogue between teacher and student, and student self-assessment, as well as feedback to students with explicit information on how to close the gap between where they are and what they are aiming for, and then opportunities to close that gap [2–4].

The use of formative assessment in the classroom has been shown to enhance student achievement as effectively or more effectively than many traditional academic interventions such as one-one-one tutoring [3]. Other recent research [5, 8] has demonstrated that formative assessment can dramatically increase student achievement, especially among lower achievers.

To account for these findings, researchers have suggested that emphasizing individual improvement and rewarding growth rather than focusing on comparison to others and competition, leads to stronger motivation, persistence, and engagement [1, 9]. In contrast, evaluation practices such as grading on a curve, giving special recognition to high achievers and emphasizing correct answers more than the process of learning may allow high achievers to thrive, but may influence less gifted students to reduce effort, avoid difficult tasks or classes, and disengage. Thus, quality formative assessment "redefines the emotional dynamics" of assessment [7]. Rather than exclusively using (summative) assessments as a threat to increase anxiety to maximize motivation and learning, use of formative assessment encourages positive emotional states with the intent of producing confidence, optimism and persistence among students. In addition, the emphasis in formative assessment on the development of metacognition, the process of analyzing and thinking about one's own thinking (e.g., using skills such as self-assessment, self-correcting errors, and actively monitoring one's own progress toward a goal) can be especially helpful for lower achievers [6].

Relevance to Childhood Development

Because use of formative assessment strategies has been shown to augment student learning and motivation, the basic elements of formative assessment can be recommended to teachers and incorporated into many types of interventions to enhance children's academic development and improve attitudes toward school and learning.

Foster Care

Stephanie Dvorak, Tasha R. Howe
Humboldt State University, Arcata, CA, USA

Synonyms

Kinship care; Out-of-home placements; Parental rights termination

Definition

Temporary care provided for children who are unable to live with their biological parents and are typically placed by state agencies [4].

Description

In the United States over 500,000 children are currently in some foster care placement [1]. Some of the reasons for foster care placements include cases where children have been abused or neglected, have severe emotional or behavioral problems, or there have been parental problems such as drug abuse, incarceration, abandonment, serious illness, or death [1]. The largest population of children in foster care is African American children who represent two thirds of all children and foster care and are more likely to remain in foster care for longer periods of time [1]. However, two thirds of children in foster care will be reunited with their parents within 2 years. Unfortunately, many children spend years waiting in the system to either go back to their biological families or be adopted. Most states encourage reunification of biological families, but if that is not possible, children can spend years waiting for other permanent placements [1].

About one quarter of the children in foster care have serious problems including emotional, behavioral, and developmental delays or disturbances. Over the past few years the number of foster parents available has decreased, while there has been an increase in foster care placement with relatives (kinship care) [1]. Some of the different types of foster care settings include relative and non-relative foster homes, group homes, emergency shelters, and residential facilities. Data from 2005 show that around 70% of foster care placements are relative or non-relative foster family homes. The main goal of foster care is that children will be placed in a permanent setting in which they will have a loving and stable environment in which to thrive [1]. Statistics from 2005 show that of the children who exited foster care that year, over 50% went back to their parents and 18% were adopted [2]. Children can be placed in foster care at any point from birth to age 18. There is a growing problem of children who reach age 18 "aging out" of foster care without the proper educational, emotional, or financial support to maintain lives as productive adults [3].

F

Fragile X Syndrome

Randal J. McCallian, Maria G. Valdovinos
Drake University, Des Moines, IA, USA

Synonyms

FXS; Martin-Bell syndrome

Description

Fragile X Syndrome, originally called Martin-Bell syndrome, was first described by Martin and Bell in 1943 as they described a large family in which multiple males were affected with mental retardation (MR) which appeared to be inherited from women who either were not affected with mental retardation or who were minimally affected with MR. Since that time, Fragile X Syndrome (FXS) has been identified as the most commonly known inherited cause of mental retardation. FXS is caused by a mutation on the fragile X mental retardation 1 gene (*FMR1*), located on the X chromosome. The mutation results in a decrease in, or lack of, production of the fragile X mental retardation protein (*FMRP*) leading to a wide range of learning disabilities, emotional problems, physical features, and high comorbidity with other disorders, such as ADHD and autism. There is no known cure for FXS and the best treatment includes a broad range of behavioral interventions and pharmacotherapy.

Genetics

FXS is the first known disorder to be associated with a trinucleotide sequence (CGG). This sequence is located on the X chromosome at the Xq27.3 locus [9]. Within the general population, the number of CGG repeats varies between 6 and 54. This results in the normal expression of *FMR1* gene and the appropriate production of *FMRP*. However, for some, through a process not entirely understood, an observed expansion in the number of repeats occurs. Specifically, an expansion from a premutation

state (between 55 and 200 CGG repeats) to full mutation may occur when the *FMR1* gene is passed on to the next generation via a female. Those with the premutation were previously thought to be unaffected by the inherited mutation on the *FMR1* gene as the production of *FMRP* is unaltered, however, recent research has shown that those with the premutation may have higher prevalence rates of psychological, cognitive and physical issues than the typical population. For instance, female carriers of the premutation have a higher incidence (20–28% of women carriers) of premature ovarian failure, a cessation of the normal functioning of the ovaries in a woman younger than age 40 (this is not to be confused with menopause as women with premature ovarian failure are much more likely to continue to menstruate, even if irregularly) [9]. Women with the premutation also present with increased rates of depression. Male carriers are prone to develop fragile X associated tremor/ataxia syndrome (FXTAS). This disorder affects 30% of premutation older males and often begins with an intention tremor or ataxia. Then, as the disorder progresses, disruption in activities associated with daily living occurs in addition to a decreased sensation in lower extremities, Parkinsonian features, psychiatric symptoms including anxiety, progressive memory and executive function deficits along with attention switching problems [8].

In females, premutations are unstable and can expand further when passed down to the next generation. Males with the premutation pass the premutation to their daughters (X-linked disorders) but unlike in female transmission, the number of repeats does not expand in size. In female transmission of the premutation, the greater the number of repeats found on the mother's X chromosome, the greater the likelihood of expansion to full mutation in next generation. If the mother possesses more than 100 repeats and passes the mutated X chromosome to her child, that mutation will expand to a full mutation 100% of the time [9]. Once expansion of the trinucleotide sequence CGG exceeds 230, methylation, or silencing, of a portion of the *FMR1* gene and surrounding areas occurs resulting in a disruption in the production of *FMRP*. Not everyone with the full mutation is affected in the same way. That is to say, individuals with the full mutation may experience partial or full methylation which in turn determines *FMRP* production. Nonetheless, the greater the number of repeats the more likely one experiences full methylation.

Another form of inheritance is mosaicism, which occurs in up to 5% of those diagnosed with FXS. In those with a mosaic form of FXS, some cells have unmethylated *FMR1* genes and other cells have fully mutated genes resulting in varying amounts of *FMRP* production. Those with a mosaic inheritance generally present with fewer cognitive deficits and overall higher functioning abilities as *FMRP* production positively correlates with level of functioning [13].

Females, on average, are less affected by the inheritance of the full mutation. This is, in part, due to typical methylation that occurs regardless of mutation status. Since females possess two X chromosomes, inactivation of one of the X chromosomes occurs naturally via methylation in each cell. Contingent on the ratio of cells that possess methylated affected versus methylated unaffected X chromosomes (referred to as the activation ratio), the impact of FXS may be limited as there may be a varying degree of normal X chromosome expression. In other words, more *FMRP* is produced and fewer symptoms are observed when there are more mutated X chromosomes turned off and more unaffected X chromosomes left on [2].

Diagnosing FXS is conducted via DNA testing. Specifically, the *FMR1* gene is evaluated and the number of CGG repeats is determined. This testing enables the diagnosis of either the premutation or the full mutation. As with many disorders, the definitive prevalence rates for those with FXS is unknown, however, recent reports have stated the prevalence for full mutations to be at 1 in 4,000 for males and 1 in 9,000 for females. The prevalence of premutation carriers is greater at 1 in 259 females and 1 in 700 males [9].

Mechanism of Action

Although the FXS brain appears to be grossly normal in comparison to typically matched peers, in the absence of *FMRP*, abnormal dendritic development occurs in which an overgrowth of immature spines is observed [4, 10]. The mechanism by which this occurs is unknown, but is hypothesized to be attributed to enhanced metabotropic glutamate receptor (mGluR) activity resulting from the lack of *FMRP* [3]. Essentially, the activation of mGluR leads to mRNA translation at synapses producing an increase in long-term depression (LTD), a process that decreases synaptic effectiveness, and a weakening of AMPA receptors. *FMRP*, which is widely expressed in a typically developing brain, functions as a repressor of mRNA translation (negative feedback loop). As a result, AMPA is made available at the synapse thereby facilitating long-term potentiation (LTP), a process that increases synaptic strength, rather than LTD [3]. In the case of FXS, in which there are lower amounts of FMRP available or none at all, the overabundance of mRNA translation results in increased LTD and decreased AMPA activity at the synapse resulting in an increased density of immature dendritic spines.

The overactive mGluR signaling is hypothesized to be responsible for many features of FXS such as epilepsy, cognitive impairment, developmental delay, and loss of motor coordination [8].

Physical Phenotype

Those diagnosed with FXS have distinct features which include a long face, a high arched palate, and large and long ears. Also observed in those with FXS are flat feet, soft skin, and hand calluses. A characteristic unique to FXS is the single palmer crease seen in approximately 51% of males. Additionally, an increased prevalence of connective tissue dysplasia is found in those with FXS. This connective tissue dysplasia is thought to contribute to other common physical features of FXS including: hypotonia, hyperextensible finger joints, double-jointed thumbs, mitral valve prolapse, cardiac murmur, hernias, scoliosis and higher than average rates of otitis media. Growth abnormalities are also more likely to be observed in those with FXS. For example, young children with FXS may present with a large head circumference and an initial overgrowth in height and weight; however, during puberty, many with FXS experience a slowing of growth leading to an overall shorter stature. Adolescent and adult males with FXS also tend to develop macroorchidism (i.e., large testicles) sometimes reaching a volume two to three times the normal size [9].

Neurological Presentation

Epilepsy is the most common neurologic abnormality in FXS presenting in 15–20% of males diagnosed with FXS [13]. Seizures typically begin in childhood or adolescence and are usually seen to either occur less frequently by adulthood or have disappeared altogether. Anticonvulsant medications (e.g., carbamazepine (Tegretol)) have been found to be very effective in controlling seizure activity in individuals with FXS. The cause of epilepsy in individuals with FXS is not yet known, however, it is hypothesized that the dendritic spine abnormalities seen in the FXS brain may lead to excessive neuronal excitation and potentially cause seizures [9].

Cognitive Deficits

Males with FXS generally present with moderate to severe intellectual disabilities (mental retardation) displaying deficits in cognitive and executive functioning, verbal reasoning, abstract /visual ability, quantitative skills, short-term memory, adaptive and daily living skills and communication [9]. High functioning males may have typical, or slightly less than typical, cognitive abilities but deficits in executive functioning, attentional control, and math skills are still likely. There may also be issues with mood lability, temper control, and increased levels of anxiety in some males with FXS. It has been found that many males with FXS experience a developmental decline in IQ as they age, although the reason for this is not yet known [8].

Females with FXS are also affected by cognitive impairments with deficits observed in, focusing and maintaining attention, organizational tasks, and a tendency to also have difficulties with math. Females are more commonly affected, than males with FXS, by impulsive behavior, mood lability, avoidant personality disorder, and anxiety disorders [2]. Excessive shyness and social anxiety are also common among girls with FXS and in very severe cases can lead to selective mutism in specific settings. The severity of cognitive impairments, as with most features of FXS, varies greatly among individuals. It is typically seen that females with FXS tend to have a less severe presentation of associated characteristics than males because of the potential for more *FMRP* production.

Strengths for both genders are often seen in the entering and processing of simultaneous information in addition to retrieving information from long-term memory, particularly verbal memory. Those with FXS have also displayed an increased ability to understand the difference between their own personal representations of the world, as compared to that of others [7].

Behavioral Phenotype

Behavioral characteristics that are prevalent in those with FXS include difficulty with social interaction, sensory hypersensitivities, and extreme sensitivity to changes in their environment. This also includes poor eye contact, shyness, and social anxiety particularly in new or unfamiliar environments [11]. Individuals with FXS may have hypersensitivities to visual, auditory, tactile, and olfactory stimuli. Loud noises, obvious or distinct smells and some textures of fabric or food are frequently aversive to those with FXS. Hyper-arousal of the senses may lead to violent outbursts, tantrums, and either self-injurious behavior or outward aggression. Children with FXS are prone to hyperarousal and tend to struggle with even simple transitions, potentially leading to violent behavior [11].

Attention deficit hyperactivity disorder (ADHD) and associated symptoms (e.g., varying degrees of inhibition/impulsivity, hyperactivity, and sustained, divided or selective attention) account for much of the problematic behaviors observed in those with FXS [12]. When compared to other children diagnosed with developmental disabilities (matched for intellectual functioning), a higher prevalence of ADHD has been found in those

with FXS. Research has also found a higher incidence of ADHD in boys with FXS (73%) as compared to girls with FXS (35%); however, it appears that a percentage of older males with FXS outgrow their hyperactivity [11].

FXS also has a high comorbidity with autism. Approximately 30% of males with FXS have a dual diagnosis of autism and FXS. Conversely, approximately 6% of those diagnosed with autism will also possess the FXS *FMR1* gene mutation [9]. Those presenting with a dual diagnosis have more severe cognitive, adaptive, receptive and expressive language deficits [9]. Certain behavioral characteristics of autism (e.g., hand flapping, hand biting and toe-walking) are more common among those with FXS as are certain speech characteristics (e.g., perseveration of a particular activity or topic of speech, echolalia, cluttered speech, mumbling, and self-talk) [11].

Language

Prelinguistic gestures and vocalizations are commonly used well past the usual age (i.e., toddlerhood) at times extending into adolescence or adulthood [1]. Language delays may be more severe in males, although research with females in this area is minimal. Those with a dual diagnosis of autism and FXS show greater language delays with limited receptive and expressive vocabulary skills. For those who do not have a comorbid diagnosis of autism, research has demonstrated that receptive and expressive vocabularies can be strengths [7]. The high frequency of difficult behaviors and psychopathology, such as excessive hyperactivity, greatly impact the acquisition of language and subsequent use.

Treatment

Treatment and appropriate interventions, for the physical and behavioral problems associated with FXS, are currently the best available methods for alleviating the effects of the disorder. An optimal treatment plan involves a multiprofessional approach of physicians, occupational therapists, speech therapists, physical therapists, psychologists, and the involvement of those closest to the person such as family members and teachers. These professionals can provide support to the individual through an individualized treatment plan addressing academic and behavioral issues, motor and language delays, and pharmacotherapy for the psychopathologies and epilepsy associated with FXS [9].

Intervention methods can be very effective for addressing both the emotional and behavioral problems associated with FXS. Treatment may include individual and family psychotherapy, behavioral therapy, group therapy, social skills training programs, and pharmacotherapy [9]. Pharmacotherapy can be used to treat the wide range of attentional, behavioral and neurological issues seen in individuals with FXS. ADHD symptoms, such as attentional deficits and impulsivity, can be treated with stimulant medication (e.g., dextroamphetamine (Dexedrin; Adderall), methylphenidate (Ritalin)) [9]. For some individuals, stimulants may exacerbate problem behaviors in which case medications such as anti-hypertensive drugs (e.g., clonidine or guanfacine) may be prescribed. Antidepressants, such as selective serotonin reuptake inhibitors (SSRIs) (e.g., fluoxetine (Prozac), paroxetine (Paxil)), can be used to treat various problems related to anxiety, compulsive and perseverative behaviors along with mood symptoms and depression. SSRIs are also used to treat the social anxiety and withdrawal symptoms found in many females and high-functioning males with FXS [5]. Atypical antipsychotics (e.g., risperidone (Risperdal)) are also used to treat mood disorders and aggression in those with FXS.

Anticonvulsants (e.g., carbamazepine, valproic acid, lamotrigine, gabapentin, and topiramate) are commonly used to treat epilepsy and have also been shown to be effective in decreasing some of the behavioral problems observed in those with FXS and treating mood disorders in individuals with FXS [5, 9]. Sleep disturbances, including problems with sleep regulation, is a common feature of FXS, particularly in young children for which melatonin use at bedtime is often used [5].

Recent research has been focused towards addressing the cognitive impairments and neurological basis of FXS (i.e., mGluR overactivity). Preliminary research has evaluated the effects lithium, an inhibitor of mGluR pathways, has on behavioral and cognitive traits of those with FXS. Results indicate positive benefits; however, clinical trials are necessary to determine the reliability and validity of these results [6].

Freud, Anna

Rachel Wamser[1], Rachel Hibberd[1], Brian Vandenberg[2]
[1]University Missouri-St. Louis, St. Louis, MO, USA
[2]University Missouri 1 University Boulevard, St. Louis, MO, USA

Life Dates

1895–1982

Introduction

Anna Freud is the daughter of Dr. Sigmund Freud and is considered to be the keeper of her father's legacy [1, 12–14]. She is a pioneer in the development of child psychoanalysis and child developmental psychology. Ms. Freud is known for her theoretical, technical, and scientific contributions to psychoanalysis, child and ego psychology, as well as her initiatives with children in poverty and those in the legal system. Ms. Freud was prolific, with over 200 articles, most of which can be found in *The Writings of Anna Freud* [6], and her book, *The Ego and its Defense Mechanisms* [5], is one of the most widely read psychoanalytic works to this day.

Educational Information

Ms. Freud, originally an elementary school teacher, completed her training as a psychoanalyst in 1920 [14]. She never had formal college training, nor a medical degree, but at that time no formal training programs existed and none would be developed until 1926. She later received many honorary degrees including Doctor of Laws, M.D., and Ph.D.

Accomplishments

Anna Freud was involved in psychoanalytic training, establishing charitable nurseries, and improving legal decisions involving children. Ms. Freud was a training analyst and later the director of the Vienna Psychoanalytic Training Institute, where she was instrumental in training many analysts, including Erik Erikson [14]. In 1947, Ms. Freud and Kate Friedlander founded the Hampstead Child Therapy Training course and later the Hampstead Child Therapy Clinic, subsequently renamed

the Anna Freud Centre, a charitable institution that provided free services.

Anna Freud and Edith Jackson established the Jackson nursery in 1937, one of the first nurseries to provide care for underprivileged children under the age of 2. During World War II, Ms. Freud and Dorothy Burlingham founded the Hampstead Wartime Nurseries, which served over 190 children who had been evacuated due to the war. She received the first Dolly Madison Award at the White House for Outstanding Service to Children.

Ms. Freud taught courses at Yale Law School on family and crime in the early 1960s. Here, she partnered with Joseph Goldstein, Dorothy Burlingham, and Albert Solnit and published *Beyond the Best Interests of the Child*, *Before the Best Interests of the Child*, and *In the Best Interests of the Child* [9–11]. The authors stressed the importance of continuity in children's relationships, argued for how to best construe "the best interests of the child," and helped to define situations in which intervention is needed. *Beyond the Best Interests of the Child*, in particular, had a profound impact on the legal system [11].

Anna Freud was involved in many professional affiliations and had numerous appointments. Ms. Freud presented her first paper, "Beating Fantasies and Daydreams" for admittance into the Vienna Psychoanalytic Society in May 1922 [2]. Ms. Freud held the position of Secretary from 1931 to 1933, at which time she became co-Vice-President. She also was General Secretary of the International Psychoanalytic Association in 1927 and continued in that position until 1934, when she became Vice-President. Following her emigration to London in 1938, she became affiliated with the British Psychoanalytic Society and was elected Secretary in 1944. Ms. Freud was one of the founding editors of *The Psychoanalytic Study of the Child*, and editor of *Journal of Psychoanalytic Education* and *Psychoanalytic Quarterly* [14].

Contributions

Anna Freud was one of a small group of analysts interested in using psychoanalysis with children. In 1927, Ms. Freud established the use of psychoanalysis with children in *Introduction to the Technique of Child Analysis,* based on lectures from her child analysis courses [1, 3]. Ms. Freud viewed children's difficulties as being transient and normal, and urged a conservative use of psychoanalysis with children. Nonetheless, she advocated for a psychoanalytically informed environment for children. Her work emphasized the developmental and technical differences in working with children, as opposed to adults, an uncommon perspective at the time. She recommended the use of play techniques for children, since she viewed techniques used in adult psychoanalysis to be inappropriate. Ms. Freud asserted that not all children's play actions have symbolic significance, and should not be thought of as equivalent to free association in adults. Ms. Freud also argued that transference differs in children, in that children do not develop a complete transference neurosis. Despite some important developmental differences, she argued that a separate theory of child psychoanalysis was unnecessary; that psychoanalytic insights applied equally to children.

Ms. Freud effectively argued for the importance of the ego, in comparison to instincts and drives, in *The Ego and the Mechanisms of Defense,* making the ego a worthwhile therapeutic enterprise [5, 12]. Ms. Freud mapped out the ego's functioning and offered a comprehensive account of psychological defenses. Sigmund Freud had introduced the concept of defense mechanisms; however, it was largely unexplained and he had not expanded the concept since 1900. Ms. Freud added new defense mechanisms to the classic list of defense mechanisms, including sublimation or the transformation of unwanted impulses into something less harmful, altruistic surrender, and identification with the aggressor.

Based on their observations from Hampstead, Anna Freud and Dorothy Burlingham published *Young Children in Wartime: A Year's Work in a Residential Nursery* and *Infants Without Families: The Case for and Against Residential Nurseries* [7, 8]. These works concluded that emotional development was most hindered in institutional life due to separation from caregivers, and consequently a family-like atmosphere was created in the residential nursery. Children were assigned to surrogate families, with one nurse assigned to four or five children. Parent involvement was encouraged as much as possible. Mothers could work as housekeepers so that they could nurse their babies, siblings were not separated, and there were no restrictions placed on visitation. The Hampstead Nurseries provided valuable information about the effects of wartime on children, which led to changes in the treatment of children separated from their parents. For example, English hospital polices were amended to allow parents to stay with their children during long hospital stays.

Ms. Freud was involved in the development of the Hampstead Index, an observational classification system used to record children's feeding, sleeping, bodily development, intellectual development, and formation of relationships [2]. The use of the Hampstead Index lead to detailed developmental charts and histories for each child, and was one of the first to utilize systematic reliable observation of children.

At Hampstead, Ms. Freud and colleagues also created the Developmental Profile, a diagnostic instrument used

to assess normality and abnormality [1]. The Profile includes numerous aspects of psychological functioning, as well as achievements and regressions, in a number of areas of development, such as body independence (independent feeding, bladder and bowel control) and play (from egocentricity to companionship). Prior to this Profile, diagnosis was given little attention in psychoanalysis [2]. The use of the Profile led to more precise diagnoses and conceptualizations for treatment. It also was used to test the effectiveness of analysis, by comparing pre- and post-treatment profiles to each other.

In her last major theoretical statement, *Normality and Pathology in Childhood*, Ms. Freud gives a comprehensive account of her views on abnormal and normal development, including her theory of "developmental lines." [4, 13] Developmental lines are linear progressions in various aspects of development that can be observed in children. The sequence of social relations, for example, runs from the total dependency observed in infants to the ability to form mature relationships in adulthood. Psychopathology is thought to occur when an individual fails to progress in one aspect of development or when there is unevenness along the "lines." Through this theory, Ms. Freud was able to connect normal and abnormal developmental processes [2].

Definition

Friends are individuals who have a close, personal relationship with one another that is characterized by mutual positive feelings.

Description

Assessment of Friendship

Friendship dyads are typically identified using sociometric techniques. Specifically, researchers use some combination of positive nominations, in which children are asked to select their best friends or the classmates they like the most, and peer ratings, in which children are asked to rate how much they like to play with or participate in activities with their classmates. Identification of friends has most frequently been based on mutual positive nominations (i.e., each dyad member nominates the other as a best friend). However, some researchers have classified individuals as friends if they display mutual positive regard for one another through either positive nominations or high ratings. It has been found that operationalizing friendship based on mutual positive nominations is more restrictive, since this technique results in fewer friendships being identified than techniques involving the use of ratings [5]. It is possible that defining friendship based on mutual positive nominations identifies friendship dyads that are qualitatively distinct from the friendships that are identified using more lenient criteria. This proposition is relevant to the question of whether friendship is a categorical or continuous construct [8]. Whereas the categorical view implies that friendship is a distinct relationship, a continuous view implies that there are varying levels of relationships that are labeled as "friendships" (for example, best friends, good friends, acquaintances). The degree to which individuals say they like one another may reflect the level of friendship that exists. It should be noted that some researchers simply ask individuals who their friends are and assume a friendship exists despite the fact that there is no information available regarding whether the identified partner actually has positive feelings for the person.

Nature of Interactions with Friends

Individuals tend to choose as their friends those who are similar to themselves in demographic, behavioral, and personality characteristics. For example, friends are typically similar in variables such as age, race, level of aggression, attitudes toward school, and substance use patterns. It is thought that similarity in features initially attracts individuals to one another and provides validation for one's characteristics. Friends then mutually influence one another in ways that make them even more alike as their relationship develops [3].

There are many ways in which individuals' interactions with friends differ from their interactions with peers who are not friends. For example, there is a greater level of positive engagement with friends than nonfriends, including a higher intensity and frequency of talking, smiling, laughing, sharing, cooperating, and helping. Interactions with friends feature less intense competition and domination than interactions with nonfriends, and there is more emphasis on equality. Interestingly, although the frequency of conflict between friends versus nonfriends does not differ, disagreements between friends are more apt to be resolved using negotiation rather than strategies involving power assertion and standing firm. Consequently, conflict resolution strategies used by friends are more apt to lead to equitable outcomes that help to preserve the friendship [10].

Although friendships are characterized by mutual positive feelings, there is variability in the quality of specific friendships. Compared to those who are poorly accepted by the peer group, children who are well liked tend to enjoy higher quality friendships that involve greater trust and loyalty, more equitable conflict resolution, and greater validation and intimacy [11]. It is also important to consider the identity of an individual's friends, given that whether a child's friends are prosocial or antisocial likely makes a difference in the child's overall adjustment [8]. Indeed, the friendships of antisocial adolescent males have been found to be of relatively low quality and short duration, and are apt to end acrimoniously [2].

Children begin forming friendships during the preschool years, and they tend to identify those with whom they play frequently as their friends. Although young children are likely to describe their friends primarily in terms of their role as playmate, it has been observed that intimacy also characterizes young children's friendships. For example, young children confide in one another about their worries and fears, and friends know more about the likes and dislikes of their friends versus nonfriends. By middle childhood, children begin to emphasize the loyalty aspect of friendship relations. During adolescence, there is a strong focus on intimacy as an important facet of friendship [6].

Throughout the childhood years, children tend to choose same-gender peers as their friends. This seems to result from boys and girls each having distinctive play styles (e.g., boys more focused on rough-and-tumble play) and differing interests in particular toys and activities. However, by early adolescence, cross-sex friendships begin to occur with greater frequency as individuals experience increasing interest in the other sex. Although boys' and girls' friendships are similar in many respects, such as companionship and conflict, it has been found that boys tend to have larger, less intimate friendship networks, whereas girls have smaller, more intimate friendship networks [4]. By late elementary school, female-female friendships are characterized by greater levels of emotional intimacy than are male-male friendships, a pattern that continues throughout the lifespan. In early adolescence, cross-sex friendships tend to be fairly low in intimacy, but by late adolescence female-male friendships show higher levels of intimacy, similar to the levels observed in female-female friendships. It has been suggested that this increase in intimacy in cross-sex friendships may provide a training ground, particularly for males, for heterosexual romantic relationships [12]. Interestingly, the size of adolescents' same-sex friendship network is predictive of the size of their other-sex friendship network. In turn, the number of other-sex friends is associated with the likelihood of adolescents having a romantic relationship, both concurrently and in subsequent years [1].

Relevance to Childhood Development

Friendships serve many important functions in childhood and beyond [7]. Within the friendship context, children typically experience affection and love. Moreover, friendships tend to be characterized by intimacy, as friends share their feelings and personal aspects of themselves. Having a friend to confide in may promote feelings of trust, acceptance, and a sense of being understood. Friends may also be a valuable source of nurturance by providing comfort, solace, and support to one another. Giving such aid may promote feelings of competence, enhance self-esteem, and create a sense of being needed. Furthermore, friends provide instrumental aide as well as a sense of reliable alliance by being loyal to one another and willing to share resources. Finally, friends are frequent sources of companionship, stimulation, and fun. Interacting with a friend affirms one's

competence and value and can enhance one's feelings of self-worth.

Given that interactions with friends provide affection, emotional support, validation, and a sense of belonging, it is not surprising that research has revealed that children and adolescents who have poor friendship experiences are at risk for psychosocial difficulties. Those who do not have a friend or who are involved in a low quality friendship are more vulnerable to feelings of loneliness and depression. Poor friendship experiences are also related to lower self-esteem, higher social anxiety, greater risk for peer victimization, and more difficulties in making school transitions [9]. Because of the critical role that positive friendship experiences play in childhood, there is clearly a need to design interventions that are focused on improving the social skills of children who are having difficulties with friendships.

Friendship

Janett M. Naylor
Fort Hays State University, Hays, KS, USA

Synonyms

Ally; Best friends; Chums; Cohort; Companions; Pals; Peers; Playmates

Definition

A close relationship entered in voluntary and is marked by emotional attachment, reciprocity, and mutuality.

Description

Being liked by classmates is very different from having friends. Close friends provide children with (1) accepting contexts for children to learn and expand basic social skills; (2) knowledge about others and the self not available from other sources (family, siblings, etc.); (3) emotional support in times of need; and (4) a foundation of relationship expectations that set the stage for future relationships (romantic, parental, etc.). Just being liked by others does not necessary insure children will receive the benefits of close friendships. Although no central definition of friendship exists, researchers can agree on several key aspects that separate friendships from other types of relationships. Friendships are reciprocal in which both members must affirm participation in the relationship. Also, friends are tied by emotional bond rather than instrumental bonds (both playing the same sport or having same classes). Finally, friendships, unlike other relationships, are voluntary. Children willingly enter into the friendship and willingly maintain and dissolve the relationship.

Friends play an important role in every stage of development. Toddlers show a clear preference for their choice of playmates and those preferences seem to remain stable over an entire year. Then, in preschool, friendships become more common and more clearly defined. The number of friends children report having increases steadily from preschool, across middle childhood, and into adolescence. The stability of friendships also increases with development with over ¾ of older children naming the same individuals as friends over the course of one school year. Also, across childhood and adolescence, friends are more similar than nonfriends in age, gender, ethnicity, and socioeconomic status, as well as behavioral and emotional traits like shyness, achievement and antisocial behaviors.

Like other areas of social development, children's friendships progress from a playmate to reciprocal partners exchanging personal information. In preschool, children report friends as someone to play with and with whom to share certain activities. Typically, preschool friends are based on a matter of convenience (living next door, going to the same preschool, children of parents' friends) rather than on true selection from a variety of sources. Young children also expect their friends to behave in a manner consistent with their own behavior and developmental struggles.

However, when children enter elementary school, the selection of available friends expands. Children are able now to choose friends based on shared values and attitudes. Because of the selectivity of friendships in middle childhood, friends can stress the importance of mutually liking each other's company. Children also understand the differential power distribution between parent-child relationships and friendships. Therefore, in middle childhood, children conceptualize friendships as relationships that transcend shared activities and time. Children are able to distinguish between supportive, high-quality friendships and one-sided friendships.

From the reciprocal foundation built in middle childhood, adolescents can expand their friendships to include disclosing intimate and personal information, sharing problems and expecting help with psychological problems. Friendships in adolescence provide the basis for future romantic relationships by allowing members to become emotionally tied to non-related people.

Studying children's friendships is of great importance to researchers because having friends is important to children, making friendships impact on development even stronger. In fact, not having close friendships leads to elevated levels of loneliness, depression, anxiety, and loss of self-esteem. Specifically children without friends are more likely to have emotional problems, to be less altruistic, to have deficiencies in social skills, to show poorer school adjustment, and to make fewer educational gains. Several caveats to the link between friendlessness and developmental issues must be addressed. First, being friendless may be just a temporary state thus decreasing the lasting emotional effects. Second, not all children who are friendless will experience the same developmental issues. Some children seem to not need friends to develop appropriately. Last, no true cause-and-effect link has been determined. Not having friends could be due to poor social skills or having poor social skills could lead to not having friends. Causation may actually be more of a circular cycle for children, which once started can spiral out of control leading to loneliness.

Friendships serve different purposes and vary by contextual factors, such as gender. Specifically, girls' friendships tend to be more intimate, and show more validation and emotional sharing than boys' friendships. However, girls' friendships, especially best friendships, tend to be less stable and more vulnerable to dissolution than those of boys. Friendships between males show less exchange of personal information and are based on shared physical activities. In addition, boys' friendships are more integrated into the larger social network, whereas girls' friendships are more isolated from the larger group again making them more vulnerable to dissolution than boys' friendships. Interestingly, when boys and girls are friends, intimacy is higher than when two boys are friends. Again, this supports the notion of friendships serving different purposes and having different contexts.

Fromm, Erich

Janet G. Benton
William Alanson White Institute, New York, USA

Life Dates

1900–1980

Educational Information

Born in Frankfurt, Germany on March 23, 1900, Erich Fromm was a psychoanalyst and social philosopher whose ideas significantly influenced a broad audience, in addition to psychologists and psychiatrists, in the middle of the twentieth century. He was deeply interested in the emotional lives of the individual and of groups and how both related to community and to culture.

Fromm was born into a bourgeois, Jewish background, which he described as "neurotic," but he rejected religion in his mid-twenties [1]. He received his Ph.D. at the

University of Heidelberg in 1922, then went on to train in psychoanalysis at the University of Munich in 1923–1924 and the Berlin Psychoanalytic Institute in 1925. Fromm was deeply influenced by the events leading up to and resulting from of World War I and by the theories of Karl Marx. Although trained as a Freudian psychoanalyst, Fromm would eventually part with Freud and many of his followers because of his beliefs about the influence of culture and social circumstances on personality [1, 6, 7].

Accomplishments

Fromm visited as a guest lecturer in 1933 at the Chicago Psychoanalytic Institute, then left Nazi Germany and immigrated to the United States in 1934. He was never welcome in the orthodox community because of his socialist views and was actively ostracized in 1941 when he published *Escape from Freedom*, which met with critical success in other intellectual communities but not in his own. He went on to write a number of books, including *The Forgotten Language* (1951) about the function of dreams, *The Art of Loving* (1956), and *The Anatomy of Human Destructiveness* (1957) [2–5].

Originally aligned with Karen Horney and the American Institute of Psychoanalysis, Fromm eventually split in 1945 from this group because of controversy about his training as a "lay analyst," i.e., his non-medical doctorate degree in psychology. This was the beginning of a long, politically driven controversy that was not resolved until 1988 after a lawsuit against the American Psychoanalytic Association was won allowing lay analysts to practice psychoanalysis in the United States [1, 6, 7].

Fromm joined Harry Stack Sullivan and Clara Thompson at what is now the William Alanson White Institute for Psychiatry, Psychology, and Psychoanalysis in New York in 1945 and was influential in establishing the interpersonal school of psychoanalysis. He subsequently taught at many different institutions including Columbia University , the New School and New York University in New York, Bennington College in Vermont, Yale University in New Haven, ant the National University of Mexico. He helped found the National Committee for a Sane Nuclear Policy (SANE) [1].

Contributions

Fromm published extensively about many topics, including the importance of social and cultural influence on the development of individuals and groups. He also foresaw difficulties that would eventually develop in the world about energy, famine, and nuclear war. In the theoretical realm Fromm believed in the importance of instinctual drives but rejected Freud's structural model of Id, Ego, and Superego. Instead he emphasized the need for others, transcendence, identity, and frames of orientation. He was somewhat more optimistic than Freud in his beliefs about the "productive frame of orientation" but was also cautionary in his warning about nonproductive frames that include receptive (overly dependent on external gratification and love,) hoarding, exploitative, marketing, and bureaucratic orientations [1, 7, 8].

Frontal Cortex

►Frontal Lobes

Frontal Lesion

Tracey McLellan
University of Canterbury, Christchurch, New Zealand

Synonyms

Brain damage; Brain injury; Frontal lobe dysfunction; Frontal lobe injury

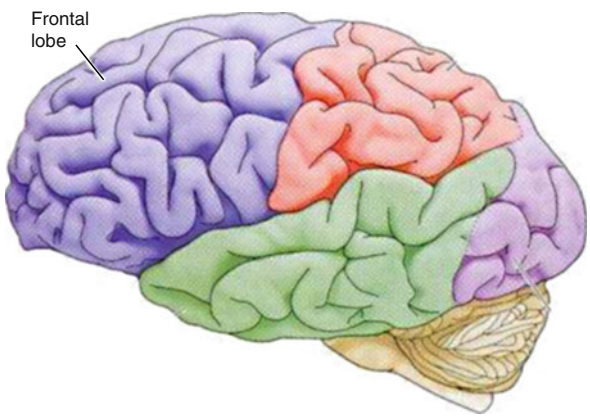
Definition

A lesion, from the Latin word *laesio* meaning injury, is any abnormal tissue or injury. The frontal lobes are part of the cerebral cortex of the brain. Frontal lesions are damage to the frontal lobe region that is usually caused by disease or trauma.

Description

The frontal lobe region of the human brain (see Fig. 1) is the largest lobe and the region accounts for approximately a third of the total human brain surface. There are considerable functional and anatomical divisions within the frontal lobe. Three primary functional regions on the lateral surface are recognized: the motor region, premotor region, and prefrontal region. The prefrontal region can be subdivided into three topographically segregated groups: the dorsolateral prefrontal cortex, orbitofrontal cortex, and paralimbic regions. The limbic/paralimbic region is a forth-functional region that is located deep in the medial portion of the lobe [4].

The cortical surface of the frontal lobe evolves prenatally and then continues throughout the forth decade. The frontal lobe plays a central role in human cognition and is involved in motor behavior, expressive language, concentration and attention, reasoning and thinking, orientation in time, place and person. Frontal lobe functioning, therefore, contributes significantly to the overall psychological and behavioral functioning of an individual [4]. The multidimensional nature of the frontal lobe serves to coordinate and organize brain functioning. This in turn serves the purpose of assisting individuals with goal-directed and self-regulatory behavior, including planning, flexibility and impulse control. The frontal lobes serve a vital role in social behavior, personality and emotion regulation [4]. Importantly, the frontal lobe provides a regulatory function, which effects the integration of multimodality information and the utilization of intellectual resources. Executive function is a cognitive construct adopted as a general description of the types of behavior that reflect frontal lobe activity. Executive functions may be defined as "the ability to maintain an appropriate problem-solving set for attainment of a future goal" [6]. Of central importance is the ability to plan future actions, maintain these in mind until implemented and inhibit other actions. Given the wide range of behaviors that are associated with the frontal lobes, it is not unusual to expect that individuals with frontal lesions exhibit a varied range of functional deficits.



Frontal Lesion. Fig. 1 Frontal lobe.

Frontal lesions are associated with psychiatric (functional) and neurological (organic) disorders. Damage to the frontal lobes can be very disabling for everyday life and dramatic behavioral changes are the hallmark of human frontal lobe dysfunction.

In individuals with frontal lobe lesions, the cognitive abilities may continue to operate and "work" but the individual has difficulty ensuring they can constrain the skills to the task at hand [3]. Being able to control many aspects of behavior is often contingent on working memory. For example, an individual may need to manipulate temporarily held representations to formulate plans or they may need to update task goals when another task must also be performed. Frontal lesions that result in working memory deficits likely cause a wide range of problems in the control of attention and in planning and switching between tasks [2]. Frontal lesions can also result in an individual displaying abnormal behaviors linked to the reduced recognition of affective state in others, as well as associated difficulties with other emotional information and emotion regulation. Likewise, the lack of impulse control can result in the expression of inappropriate behaviors.

Relevance to Childhood Development

Eslinger et al. [1] found that most but not all children who suffered early frontal lesions involving the prefrontal cortex showed chronic and profound impairments that limited their ability to participate fully in school/employment and maintain successful social relationships. Specific deficits involved the application of social knowledge and sustaining friendships, planning and impulse control, learning from experience, and the relative lack of anxiety, fear or empathy. The finding that a wide range of behaviors were associated with frontal lesions emphasized the convergent nature of the function of the frontal lobes. In addition, Eslinger et al. [1] concluded that an early lesion within the frontal lobe is not only a localized event but also the consequences then have an experiential effect on the maturation of other interacting areas of the brain.

Frontal lobe dysfunction has been implicated in many childhood disorders. Deficits in executive function, for example, have been found to be typical of developmental

disorders in general [5] and several studies have examined the contribution of executive function deficits to attention-deficit hyperactivity disorder (ADHD [5]), learning disabilities [7] and conduct disorders [5]. Difficulty in maintaining attention is one of the hallmarks of selective frontal lesions. Developmental disorders of attention, such as ADHD are most notably relevant to childhood development. ADHD is a common referral for psychiatric treatment in children. The disorder is characterized by difficulties sustaining attention, organizing tasks, being easily distracted and forgetful, difficulty waiting a turn, and difficulty inhibiting a response. As discussed, many of these behaviors are associated with frontal lobe lesions in adults.

There is converging evidence that frontal lesions in the dorsolateral prefrontal cortex (DLPFC) are implicated in schizophrenia. The onset of schizophrenia typically occurs in the postpubertal period just after performance on DLPFC-dependant tasks typically reaches full adult potential. The pruning of specific DLPFC neuron connections that occurs during adolescence may confer a selective vulnerability to symptom onset after maturity [4]. In addition, traumatic brain injury (TBI) frequently involves the frontal lobe. Severe closed head injuries, for example, preferentially involve the orbitofrontal areas because the movement of the brain on impact is restricted by the bony skull. Pediatric TBI results in substantial difficulties for survivors well beyond the acute phase of the injury [3].

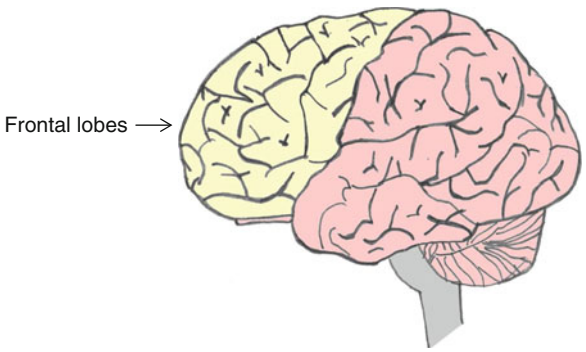
Frontal cortex

Definition

The brain is divided into a left and right hemisphere. Each hemisphere is subdivided into four lobes, frontal parietal, occipital and temporal. Each of the four lobes is thought to have specialist roles for aspects of functioning.

Description

The frontal lobe is the largest part of the cortex. Anatomically, the frontal lobes extend from the central gyrus to the anterior limit of the brain [5] see yellow area in Fig. 1. The frontal lobes include the primary motor, supplementary motor and premotor cortex (involved in planning of



Frontal Lobes. Fig. 1 The frontal lobes in relation to the remainder of the brain.

execution of movement), Brocas area (involved in the production of speech) and the prefrontal lobes (involved in executive functions, social behavior and motivational states [5].

Premotor and Motor Cortex

The Primary motor cortex is principally involved with movement and motor control; it has extensive connections with the premotor cortex. Damage to the primary motor cortex causes loss of fine motor movements [6]. The Premotor area is principally involved with somatosensory information i.e., information about touch. The Supplementary motor cortex is involved in preparation for rapid series of movements i.e., typing. Both the Premotor and Supplementary motor cortex are involved in the planning of movement [5].

Brocas Area

Broca's area is located on the inferior frontal gyrus of the frontal lobes. Damage to Broca's area results in difficulties producing speech, however, the person is still able to understand speech.

Prefrontal cortex: The most anterior portion of the frontal lobes is called the prefrontal cortex. The prefrontal cortex is the only part of the brain that receives input from all sensory modalities. The prefrontal cortex is split into the dorsolateral, orbitofronal and the anterior cingulate each area is associated with specific functions outline below [3]:

A. Dorsolateral prefrontal circuit: The integrity of this circuit is associated with the effective performance of executive functions, the ability to integrate cognitive and perceptual processes across time and space and update goals in the face of new information. Executive functions include working memory, decision making, flexibility, set maintenance, self monitoring and control of ongoing behavior [9–11].
B. The Orbitofrontal circuit mediates socially appropriate behaviors. Personality changes are most commonly seen after disruption of this circuit and may include irritability and changes in mood [7]. Patients with lesions in this area may behave inappropriately in social situations, often failing to respond to environmental and social cues [3, 7].
C. The Anterior cingulate: This circuit is involved in motivated behavior [12]. Patients with lesions in the structures of the anterior cingulate are reported to be apathetic with impaired motivation along with poor response inhibition and may show a reduction in creative thought [3].

Lesions to different areas of the prefrontal cortex can result in a range of deficits depending on the site of the lesion prefrontal (see Table 1 below).

Frontal Lobes. Table 1 Cognitive and behavioral problems associated with dysfunction in the three frontal-sub-cortical circuits (Table adapted from Chow and Cummings [3]).

Circuit	Dysfunction	Impairments
Dorsolateral prefrontal circuit	Executive functions	Poor organizational strategies
		Poor memory search strategies
		Stimulus bound behavior/Environmental dependency
		Impaired set shifting and maintenance
		Poor working memory
Anterior cingulate circuit	Socially appropriate behavior	Personality change
		Emotional incontinence
		Impulsivity
		Irritability
		Mood disorders
Lateral orbitofrontal circuit	Motivated behavior	Apathy
		Poverty of spontaneous speech
		Poor response inhibition
		Reduced creative thought
		Akinetic mutism

Connections with Subcortical Structures

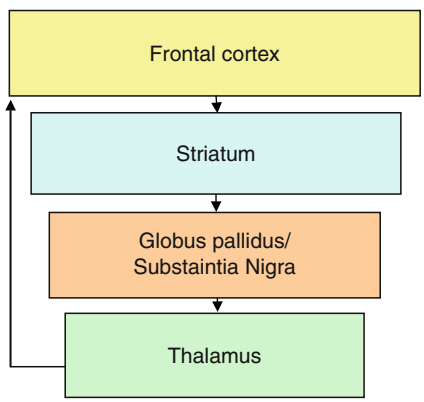
The frontal lobes are also connected with subcortical structures including the basal ganglia and the thalamus (see Fig. 2). The relationship between the frontal lobes and the subcortical structures has been most clearly outline by Alexander, DeLong and Strick [1, 2]. These researchers introduced the concept that the structures of the frontal lobe were involved in five parallel but segregated frontal subcortical pathways. The five frontal subcorticle structures are each named according to their site of origin in the frontal lobes, (1) the motor circuit, (2) the ocular motor circuit (originating in the frontal eye fields), (3) dorsolateral circuit, (4) the Orbital frontal circuit and the (5) Anterior cingulated. The latter three originate in the prefrontal cortex and are dedicated to executive functions.

Each of the five circuit is proposed as having a preeminent, if not exclusive, role in the performance of different functions and all share the same features having direct and indirect pathways, with each loop being segregated, and arising from and projecting to the same area of the cortex (see Fig. 2 for diagrammatic representation of the closed circuit for each pathway only the direct circuit is shown). A large body of research supports the role of these circuits in cognitive and behavioral functioning (for review see Owen [8]). Also, lesions to the cortical areas and at other points of the circuits have been reported as having similar effects. For example, people with Parkinson's disease exhibit many of the deficits associated with dysfunction of the basal thalamo-cortical loops.

Significance to Child Development

Synaptic density in the frontal cortex changes over the life span. Huttenlocher (1979) observed that density increases in the first year of life to well above that of adults and then declines over the next 16 years. There is little change between 16 and 70 years. After 70 years of age the synaptic density declines [4]. This change in synaptic density has been associated with many of the developmental changes seen during childhood and adolescents, particularly the development of emotional and inhibitory control. Some researchers have pointed to the development of the frontal lobe as being directly related to changes such as development of executive functions and theory of mind [11]. Further, disorders such as Attention Deficit Hyperactivity Disorder have also been associated with frontal lobe development, specifically the prefrontal cortex [11].

Given the role of the frontal lobes in development it is important to realize that damage to this area of the brain may have a significant effect on the child's ability to function.



Frontal Lobes. Fig. 2 Diagrammatic representation of the general structure of the frontal sub cortical circuits adapted from Tekin and Cummings [12].

Full Inclusion

Judah B. Axe
Simmons College, Boston, MA, USA

Synonyms
Inclusive education; Mainstreaming

Definition
Educating a child with a disability in a general education classroom for all educational services.

Description
One of the mandates of the Individuals with Disabilities Education Act is educating children with disabilities in the "least restrictive environment." This stipulates a continuum of services ranging from hospitalization to home-based education to resource room to partial inclusion to full inclusion. A student in full inclusion has a disability and spends all school hours with same-age, typically developing students in the general education classroom. A special educator often consults with a student's general education teacher to assess the needs of the student and provide supports allowing the student to benefit from instruction.

Functional Behavioral Assessment

Synonyms
FBA

Definition
Provides a consideration of specific behaviors and behavioral patterns set within an environmental context. It has been defined as "an analysis of the contingencies responsible for behavioral problems" [1, p. 433].

Description
FBA can be conducted with students who have an identified disability and who exhibit problem behaviors, which interfere with their learning and the learning of others in the classroom. The purpose of conducting an FBA is to determine the problem behavior and to identify the factors that predict and maintain the behavior. Such factors include (a) antecedents: events or situations that consistently preceded the behavior, and (b) consequences, events and conditions that result from problem behaviors. The steps in the FBA include the following: Identifying and operationally defining the target behaviors, collecting data, such as frequency, rate, intensity, and latency of the behaviors, identifying the events that precede and follow the target behavior (antecedent-behavior-consequence or ABC analysis), developing a "hypothesis" about the function of the target behavior and developing an intervention plan [2].

Functional Magnetic Resonance Imaging

Lauren Connell Pavelka
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Brain mapping MRI; Brain MRI

Definition

Functional magnetic resonance imaging (fMRI) is a cutting edge type of magnetic resonance imaging (MRI) that measures blood flow and oxygenation in the brain to map brain functioning.

Description

Making its first appearance in the early 1990s, functional magnetic resonance imaging (fMRI) is a procedure that detects the brain's response to neural activity by measuring blood flow and blood oxygenation produced by neurons in different locations of the brain. The emergence of fMRI has contributed greatly to research in neuropsychiatry, neuropsychology, and neuroscience. Currently, fMRI provides the best quality of activity images in the human brain; therefore, it is used extensively in experiments involving functional brain mapping. Some examples of psychological functions that can be measured in the brain with fMRI include: attention, cognition, language, sensation, perception, and emotion.

Relevance to Childhood Development

Functional MRI has gained much popularity among researchers in recent decades because it does not use ionizing radiation. This allows researchers to safely conduct multiple studies on single subjects – including child subjects.

Function-Based Diagnostic Classification Systems: Problem Behavior

Ennio Cipani
National University, Fresno, CA, USA

Introduction

A function based diagnostic classification system contrasts with traditional diagnostic classification systems for child behavior (e.g., DSM-IV-TR). Behaviors are classified as to their environmental function, rather than as a symptom of a syndrome of related behaviors. The characteristics of a function-based diagnostic classification system are the following [1, 2]:

- The diagnosis is of behavior problem characteristics, not child characteristics
- Prescriptive differential treatment is derived from a differential diagnosis
- Assessment data is collected to provide information on context variables, not just rate of behavior
- Assessment phase is concluded with diagnosis phase, in which a function-based category is selected

A unique function-based diagnostic classification system has been developed [1, 2] with major categories and subcategories. The four major diagnostic categories classify problem behaviors according to their environmental function. One parameter for this system examines the reinforcement operation currently maintaining the problem behavior (positive reinforcement operations or negative reinforcement operations). A second parameter examines the manner of access to such reinforcement (directly produced or socially mediated). Problem behaviors that serve a positive reinforcement function are termed access behaviors. Problem behaviors that serve a negative reinforcement function are termed escape behaviors (encumbers avoidance functions). Access can be either socially mediated or direct. Escape can also be either socially mediated or direct.

The following major categories constitute this classification system:

1. Direct access (DA)
2. Socially mediated access (SMA)
3. Direct escape (DE)
4. Socially mediated escape (SME)

Within each category, the following sub-categories are offered.

1. Direct access (DA)
   - DA-immediate sensory stimuli
   - DA-direct chain to tangible reinforcers
   - DA-other
2. Socially mediated access (SMA)
   - SMA-adult attention
   - SMA-peer attention
   - SMA-tangible reinforcers
   - SMA-other
3. Direct escape (DE)
   - DE-Unpleasant social situations
   - DE-relatively lengthy tasks/chores
   - DE-relatively difficult tasks/chores
   - DE aversive physical stimuli/events
   - DE-other
4. Socially mediated escape (SME)
   - SME-unpleasant social situations
   - SME-relatively lengthy tasks/chores
   - SME-relatively difficult tasks/chores
   - SME-aversive physical stimuli/event
   - SME-other

Gardner's Theory of Multiple Intelligences

Daniel Patanella[1], Chandra Ebanks[2]
[1]New York City Department of Education, New York, NY, USA
[2]Florida International University, Miami, FL, USA

Synonyms

Bodily-kinesthetic intelligence; Eight intelligences; Interpersonal intelligence; Intrapersonal intelligence; Linguistic intelligence; Logical-mathematical intelligence; Musical intelligence; Naturalist intelligence; Spatial intelligence

Definition

According to Gardner's theory of multiple intelligences, there are eight different domain-specific intelligences. The eight intelligences are: Logical-mathematical, Linguistic, Musical, Spatial, Bodily-kinesthetic, Intrapersonal, Interpersonal, and Naturalist.

Description

Although the concepts of intelligence and intelligence testing have been reliable cornerstones of both applied and academic psychology for over a century, they have been equally reliable sources of controversy. Once such controversy is whether intelligence is best conceptualized as being a general mental ability (often referred to in the literature as *g*), or a set of mental abilities. The traditional psychometric perspective on intelligence leans heavily toward *g*, yet arguments in favor of multiple intelligences have been offered as an alternative. One of the most influential, and most frequently cited, of these theories is Howard Gardner's theory of multiple intelligences.

In his 1983 book *Frames of Mind*, Gardner (born in 1943) postulated that a multiple intelligence framework better describes human intellectual capacity than the traditional single intelligence as epitomized by such well-known intelligence tests as the Stanford-Binet and the Wechsler Intelligence Scale for Children (WISC) [2]. Using an impressive array of evidence, Gardner argued that humans simply do not display equal aptitude across domains and initially proposed a set of seven intelligences. These intelligences would constitute distinct and separate units with their own measurable and observable abilities. Each type of intelligence would be tailored to specific types of information, possess different developmental trajectories, and individuals would display competencies in these intelligences in different combinations. All intelligences are not only simply biologically based, but must be

Author's Note

Sam Goldstein & Jack A. Naglieri (eds.), *Encyclopedia of Child Behavior and Development*, DOI 10.1007/978-0-387-79061-9,

nourished and developed by societies through valued disciplines. Gardner continued to develop and refine his theory through several publications and, in its most current form stemming from 1999s *Intelligence Reframed*, Gardner lists eight intelligences [3].

The eight intelligences are: Logical-mathematical, Linguistic, Musical, Spatial, Bodily-kinesthetic, Intrapersonal, Interpersonal, and Naturalist. Logical-mathematical and linguistic intelligences are the closest to intelligence as traditionally conceptualized. Musical intelligence is obviously linked to musical accomplishment, whereas spatial intelligence reflects accomplishment in the visual arts such as painting and sculpture and bodily-kinesthetic intelligence manifests itself in physical activity such as dance. Intrapersonal intelligence refers to self-awareness, and Gardner suggests that Sigmund Freud (1856–1939) is an exemplar of this specific type of intelligence. Interpersonal intelligence is related to leadership abilities and working with other people. Finally, naturalist intelligence is related to accomplishments in the study and appreciation of life itself; Gardner indicates that Charles Darwin is an exemplar of naturalist intelligence.

As with virtually every other aspect of intelligence as a topic of psychological inquiry, controversy exists regarding Gardner's theory of multiple intelligences. Recent critics such as Allix [1] and Waterhouse (2006a, b) note that while there are indeed many publications devoted to Gardner's theory, there are comparatively little scientific data to actually evaluate the theory. Morgan [7], while otherwise supportive, stresses the similarity of Gardner's multiple intelligences to earlier conceptualizations of cognitive styles. At the heart of the debate are the differences between Gardner and his critics regarding psychometrics and the experimental method in theory-testing. Gardner's critics take a traditional view of the worth of rigorous psychometric measurement as the core of intelligence research; Gardner is a critic of the standardized tests that result from psychometric development as well as the culture of testing that arose in response to intelligence tests. Gardner's critics regard controlled experimentation as the strongest evidence to be offered in the testing and development of theory; Gardner prefers a more holistic approach that stresses external validity. Given the diametrically opposed paradigms these two positions represent, resolution of the conflict appears unlikely.

Relevance to Childhood Development

As is fitting given Gardner's status as a professor at the Graduate School of Education at Harvard University, his theory of multiple intelligences is quite influential among educators. Multiple intelligence theory is a framework for courses and workshops intended for educational professionals teaching the full spectrum of children from the gifted to the developmentally challenged. Although more data is needed to evaluate the scientific merit of Gardner's multiple intelligences as a theory, his re-conceptualization of intelligence has provided a useful alternative paradigm in which educators may better assist student learning.

Gender Development

Jessie Kosorok Mellor
University of Arizona, Tucson, AZ, USA

Synonyms

Gender identity

Definition

The process of identifying one's subjective sense of identity as male or female [2], neither or both.

Description

On the most basic level, gender identity refers to individuals accepting themselves as male or female. The intersexed (intersexed/intersexuality) community includes a neither or both aspect due to the fact that there individuals are also born with characteristics pertaining to both males and females. Limiting the definition of gender identity to the categorization of solely male or female ignores individuals who do not identify as solely male or female.

Aside from the complicated process of biological sex development, or the development of internal and external genitalia is the social phenomenon of gender development or how individuals identify as male, female, neither, or both. Each child has their own unique development of gender and both biology and social learning play key roles.

Relevance to Childhood Development

In typical western society, children are exposed to gender differences as well as gender reinforcements from before they are even born. Once a mother finds out she is pregnant, it is inevitable that she will be asked if she is having a boy or a girl. Based on the dichotomous answer, friends, relatives and the like will often purchase gifts based on the identified biological sex of the baby. Pink items are given to girls and blue items to boys. Once the baby is born, the hospital often gives pink or blue blankets and identifying bracelets depending on the biological sex. From day one children are bombarded with proper girl toys and proper boy toys and respective colored clothing.

Some researchers believe infants have the ability to distinguish between male and female faces as young as 6 months of age [5]. However, it is not until 24 months of age that toddlers show gender specific activities including verbal differences [6]. Although, when infants and toddlers make gender distinctions, they are using superficial features such as hair length and are reported to not possess the ability to make more sound gender distinctions. This issue is referred to as a lack of gender constancy, or the understanding that being male or female is permanent and unable to change and by 3 years of age most children are still deficient with respect to this concept; however, [2] by age 6 aspects of gender constancy (i.e., gender consistency and gender stability) are evident.

As children develop they are bombarded with ►gender stereotypes and the pressures to adhere to traditional ►gender roles. Boys are not stereotypically encouraged to play with dolls; the majority of western society perceives dolls as girls' toys. Instead, boys are encouraged to play sports, play with trucks, dinosaurs, and similar toys and activities [3]. Girls are encouraged to look pretty, pretend to play house and cook, and take care of their dolls. However, if girls wish to cross the gender boundary and play with stereotypical boy toys or participate in boyish activities, they do not experience negative consequences on the same level that boys do when they choose to play with stereotypical girl toys or participate in girl activities. As children grow and develop and understand various aspects of gender, how to appropriately label different genders and what stereotypically accounts for appropriate gender roles, they begin to adopt what they feel is appropriate behavior with respect to gender. Children often evaluate their own gender as "better" and are more knowledgeable of the stereotypical appropriate behaviors associated with their own gender [4]. In general it is agreed that with increase in age comes an increase in gender flexibility, or the idea that children will make exceptions to gender stereotypes as they grow older and become more comfortable with their own gender identity and what gender identity means. However, research on this topic varies in methodology and how to measure gender flexibility thus giving exceptions to this reported linear relationship [2].

By the time children enter middle childhood and adolescence, their concept of gender identity is more

concrete and they have a more sound idea of what constitutes stereotypical gender roles. Additionally, they have a more concrete understanding of their own identity and what it means to identify as male, female, neither, or both. Occasionally, children and adolescents will have an understanding that their biological sex (that is being born with a penis or vagina) does not match their gender identity (or identifying as male, female, neither, or both). Exhibiting four of the five following symptoms can result in a diagnosis of Gender Identity Disorder [1]: (1) cross-sex behaviors, (2) cross-sex toy and activity preferences, (3) cross-sex peer affiliation, (4) cross-dressing, (5) a stated desire to be the other sex. Each child will come to terms with their gender identity in their own way and understanding. A desire to be the gender that does not match their biological sex can result in many difficult situations for the individual as well as their family; however, there are many resources available to the transgender community to foster a healthy transition for the individual and offer support and education for their family.

Gender Identity

Lisa Kilanowski-Press
Niagara University, Niagara, NY, USA

Synonyms

Gender development; Gender identity disorder; Gender roles; Gender variance; Sexual identity; Transgender; Transsexual

Definition

Gender identity pertains to the degree to which an individual espouses either a male or female sexual identity; it is reflective of the degree to which individuals "feel" or conceptualize their psychological and sexual identity as male or female. Most often, gender identity matches biological sex. In cases where ones' gender identity does not match assigned sex, diagnosis of gender identity disorder (GID) may be explored.

Description

Gender identity pertains to the degree to which an individual espouses either a male or female sexual identity; it is reflective of the degree to which individuals "feel" or conceptualize their psychological and sexual identity as male or female. Most often, gender identity matches biological sex. Specifically, most biological males espouse a male gender identity, and most biological females espouse a female gender identity. However, biological sex assignment alone is not predictive of gender identity in all cases, leading to situations in which ones' gender identity differs from their sex assignment. Gender typical behavior, including dress, mannerisms, and sexual attraction, are some of many factors that comprise gender identity. Stereotypical gender role fulfillment is also viewed by some to reflect gender identity, but is not in and of itself a strong predictor of either gender identity or sexual orientation.

Espousal of gender roles that significantly deviate from ones' biological sex, combined with reports on the part of an individual that they want to be (or feel like) a member of the opposite sex, are early indicators of mismatch between sex and gender identity, and are suggestive of GID.

Gender Identity Disorder (GID) or Gender Dysphoria

Dissonance between biological sex and gender identity may be reported in early childhood, adolescence, or adulthood. According to the APA [1], diagnosis of GID may occur when four or more of the following criteria are met:

1. Repeatedly stated desire to be, or insistence that he or she is, a member of the opposite sex.
2. In boys, a preference for cross-dressing or simulating women's attire; in girls, insistence on wearing only stereotypically masculine clothing.
3. Strong and persistent preferences for cross-sex roles in make believe play or persistent fantasies of the opposite sex.
4. Intense desire to participate in the stereotypical games and pastimes of the other sex.
5. Strong preference for playmates of the other sex (p. 581).

Additionally, "persistent discomfort with his or her sex or sense of inappropriateness in the gender role of that sex" must be manifested, must not be attributed to a physical intersex condition wherein the individual possesses both male and female genitalia, and must result in significant psychosocial impairment (p. 581).

Often, male children with disturbances in gender identity overtly reject their genitalia and express a desire to no longer have a penis; some will indicate a desire to have a vagina. Avoidance of or disinterest in stereotypical male pursuits, such as rough play, engaging in games or playing with toys most often associated with boys, or engaging in play with male playmates, is common. Open interest in stereotypical female interests, including dolls, female play mates, and wearing female clothing is frequently observed. Female children may demonstrate aversion to their genitalia by standing to urinate, suggesting that they may "grow a penis" or someday have a penis, or indicating that they do not want breasts or to menstruate. Active avoidance of feminine clothing and pursuits is also often noted, along with a preference for male dress, haircuts, playmates, and stereotypical male play activities ([1], p. 581). In adolescents and adults, individuals with GID often take active steps to live as a member of the opposite sex for some or part of the time. Many express desire to engage in hormone treatment or surgery in hopes of attaining their desired physical form, and may often indicate belief that they were "born the wrong sex" ([1], p. 581). Individuals with GID may be referred to as transgender or transsexual. The term male-to-female (MTF) is used to denote a male individual who is transgender and is living their life as a female. Female-to-male (FTM) is used to indicate a female who is living their life as a male.

Holistically, children, adolescents, and adults with GID are plagued by social and emotional discomfort resulting from the lack of congruence between their actual and desired sex. In addition to experiencing social isolation stemming from gender related differences and stigma, individuals with GID are prone to depression, anxiety, and suicide or suicide attempt [6]. Many individuals with GID do not actively pursue gender reassignment surgery, hormone therapy (testosterone or estrogen), or the use of implants, but rather choose to live their life as a member of their assigned sex. Some individuals with GID elect to live their "private" lives as the opposite sex, while their "public" gender identity matches their biological sex. The degree to which and individual actively pursues a lifestyle as the opposite sex varies considerably from person to person.

Prevalence of Gender Identity Disorder

Due the lack of comprehensive national data collection systems assessing gender identity in the United States, data regarding prevalence in the US is unavailable. As per Sohn, Hartmut, and Bosinski [5], several researchers have identified prevalence rates in Europe due to the availability of broader, national data collection systems. In the Netherlands, the number of MTF transsexuals is approximately one per 119,000 individuals, with the number of FTM transsexuals approximately one per 11,900 individuals; in Belgium, the number of MTF's is approximately 1 per 12,900, with one per 33,800 persons (p. 1,195). Similar prevalence rates appear to be common across Europe. MTF transsexuals typically outnumber FTM transsexuals by three to one.

Etiology of Gender Identity Disorder

The precise cause of disruptions in gender identity is unknown. Current theory regarding GID highlights the possibility of genetic as well as hormonal underpinnings, with relatively limited and non definitive literature supporting either of the aforementioned.

At present, twin studies have yielded the finding that GID appears to be heritable, with estimates of heritability ranging from 50 to 62% [2, 3]. However, despite the fact that genetic identity disruptions are likely heritable, to date, no research has identified how differences in gender identity are genetically coded [4]. Hormonal hypotheses suggest that prenatal hormone exposure influences the development of sex-typed behavior. However, aside from illuminating potential differences in the development of the hypothalamus as a result of hormone bathing, no definitive hormonal cause has been found.

Gender identity; Transgenderism; Transsexualism

Definition

Gender Identity Disorder (GID) is the diagnosis for persistent discomfort with the gender role of one's birth-assigned sex, concurrent with a strong identification as the opposite gender.

Description

GID is the formal classification identified in the Diagnostic and Statistical Manual of Mental Disorders IV-Text Revision (DSM-IV-TR [1]) for an experience of both extreme identification with one's opposite gender, and a lack of association or comfort with the gender role of with one's birth-assigned sex. Formal assessment of the diagnosis includes a ruling out of a physical intersex experience, and the establishment of a significant level of stress in interpersonal relationships and social interactions as a result of one's gender. A diagnosis of GID by a qualified mental health professional is recommended by the World Professional Association of Transgender Health (WPATH) Standards of Care [8] for determining candidacy and readiness for a medical referral to begin hormone replacement therapy (HRT); while two mental health evaluation of GID are recommended for referrals of transgenders who seek sexual reassignment surgery (SRS).

The prevalence of GID has been estimated by identifying the number of transgenders who seek SRS, which the WPATH Standards of Care have identified as ranging from 1 in 37,000 males and 1 in 107,000 females in an early estimation, to 1 in 11,900 males and 1 in 30,400 females in a more recent estimate. A major challenge in establishing a more precise estimate exists in that the high cost of surgeries, individuals' pre-existing medical conditions, and limited esthetically satisfactory medical options (particularly of female-to-male genital surgery) do not make surgery an option for transgenders who would otherwise meet the diagnostic criteria of GID.

The GID diagnosis has been a subject of some controversy, as many transgender activists and allies have identified it as pathologizing, citing that it is based upon a biased system of diagnosis that posits a binary model of gender [2, 3, 5, 7, 12, 13]. The argument also centers on the role of mental health professionals in assessing candidacy and readiness for hormones surgery, when many transgenders identify that the choice to migrate their bodies in concordance with gender identity should be their own [10]. Additionally, seeking mental health services for the purpose of procuring an assessment of GID is seen as artificial and counter-intuitive to a therapeutic environment of honesty, as many transgenders have identified that they tell therapists what they believe the therapists wish to hear in order to write favorable assessment letters [10].

The identification of gender as a continuum [4, 11] or spectrum [9], rather than a binary model of male and female as discrete and opposite experiences, is gaining attention within the medical and mental health community, as more helping professionals and gender researchers encounter transgender clients who do not meet the full diagnostic criteria of GID, but who identify themselves as existing between the genders. Self-identifiers such as *gender queer*, *genderless*, *bi-gendered*, and *third-gendered* have emerged along with third gender pronouns ("ze" or "sie" – rather than "he" or "she") to identify a range of experiences to that reflect a range of gender possibilities [6]. Cross-cultural examples of third gender experiences include the *hijra* of India, the *kathoey* of Thailand, and numerous examples of two-spirit tradition in Hopi, Navajo, and other Native American cultures (sometimes mistakenly referred to by non-Native researchers using the perjorative *berdache*). The Bugi ethnic group of the Indonesian island of Sulawesi acknowledges five genders that are seen as a foundation for social harmony.

Relevance to Childhood Development

Many adult transgenders report having experienced the features of GID from earliest memory. Such reports include knowledge that one was "different," a desire to play with the toys or games more typically assigned to the other gender, and a desire to dress in the clothes or assume the appearance of the other gender. Clinically, children are referred as young as ages 2–4 [1] for mental health services, generally when gender nonconforming behaviors are a cause of concern for caregivers. Although some of these children do grow-up to identify as transgender and/or to present the features of GID, relatively few pre-school age children who demonstrate cross-gender propensities will continue these behaviors into adulthood. Generally, the malleability of behavior is

relative to a child's age. Although relatively few children who meet the diagnostic criteria of GID will become transsexuals as adults (meaning that they actively pursue hormones and sexual reassignment), many will identify as lesbian or gay in adulthood ([1]; WPATH, 2001).

GID can be a source of tremendous distress for children, with a great deal of stress often precipitated by interactions with parents, siblings, and other children who are antagonistic of the child's expression of her or his gender. Social mistreatment is often cited in teen suicide letters, and is identified as a major cause of Major Depression for transgender adolescents. Referral to a mental health professional who is knowledgeable of transgender experiences and who will be supportive of the child is advisable.

Gender Roles

Kevin L. Nadal
John Jay College of Criminal Justice City University, New York, NY, USA

Synonyms

Gender conformity; Gender identity; Gender socialization

Definition

The behaviors, expectations, and values defined by society as masculine and feminine [4].

Description

Gender roles are defined differently within specific societies and cultures as each society sends messages to its members about culturally appropriate behaviors, norms, and values for men and women, based on gender. Each society or culture has its own concept of gender, which can be defined as the social construct that associates behavioral, cultural, or psychological traits as male or female. Gender is usually determined by one's biological sex (or whether one has male or female reproductive organs). However, it is possible for an individual to accept gender roles that are opposite of their birth sex.

Gender roles are often determined based on traditional stereotypes (e.g., women cook and clean, while men go to work or fix cars). Gender roles may also influence one's career choice (e.g., women are often discouraged from entering sciences or medicine, while men are discouraged from traditionally feminine careers like nursing or secretarial work). Gender roles may also be expressed through clothing or styles of dress (e.g., men wear suits and ties to formal occasions, while women wear dresses to formal occasions). In contemporary times, women may wear pants and dress shirts like men, but these articles of clothing are often feminized and/or fitted differently. Gender roles may be expressed in behavior (e.g., men express their emotions through anger or yelling, while women express their emotions through crying). Gender roles may be expressed in relationships (e.g., men have close friendships with other men where they do not discuss intimate, personal problems, while women have close friendships with other women where they discuss emotions and intimate, personal problems regularly). Gender roles may even influence personality traits that are more desirable for men or women; for example, men are

more desired to act as leaders or be aggressive, while women are more desired to be affectionate or cheerful [1].

Gender role socialization (Gender socialization, Gender conformity, Gender identity) is the process in which an individual learns and accepts roles as a male or a female. There are many ways that individuals are socialized to learn about gender roles, even from a very early age. In many Western societies, baby boys are usually dressed in blue and male toddlers are given toys like trucks and cars; baby girls are usually dressed in pink and female toddlers are given toys like baby dolls and play cooking sets. In adolescence, boys and girls receive messages about how they are supposed to behave. Adolescent girls are encouraged to be emotionally expressive, while adolescent boys are encouraged to be more controlling of their emotions [8]. And in adulthood, men may be socialized to believe that they must be providers or breadwinners of the family, while women may be socialized to believe that they must be motherly and submissive to men.

Gender role socialization may influence one's personality development. Previous literature has supported that men may be more achievement-oriented than women and that men may have a greater internal locus of control than women, but that women may possess more empathy than men [3]. Gender roles may influence achievement-orientation in that men are socialized to be more practical and unemotional; accordingly, they may view a problem or stressor as something to be overcome. Gender role expectations may impact locus of control and worldview; women may learn that stereotyping and discrimination may limit their opportunities and negatively impact their lives. Accordingly, men may perceive that they have more power in determining their present and future lives, while women may perceive that there will be other external forces that may determine their present and future lives. Gender role norms may encourage one's ability to be empathetic and emotionally-expressive. Women may be more able to relate personally and emotionally with others, and may cope by seeking social support, while men may learn that it is more acceptable to have emotional control and cope with problems individually.

Gender role socialization may also influence how individuals cope with stress and/or how mental health disparities occur for both men and women. Previous literature has supported that there is a higher prevalence of depression in adolescent girls, while there is a higher prevalence of substance use and antisocial behavior in adolescent boys [3]. Because women are taught to be emotionally expressive, there is a higher risk of depression. However, because men are not taught to be emotionally expressive of their feelings, it may be more acceptable to cope with their depression or stress by turning to substances and/or acting out in rebellious ways. Additionally, men are likely to be more aggressive, engage in violent behaviors, and/or have conduct problems than women [2].

Gender role expectations may lead to conflict and psychological distress for women. First, gender role expectations for women imply sexism, in that they objectify and demean women, while prevent them from the same opportunities for success or equality as men [6]. Additionally, previous literature purports that women are often in conflict about being societal norms of success for women, which is defined as a woman being "nurturing, physically attractive, and passive" [7]. Additionally, many women may be resistant to be identified as "feminists" because of the negative connotations that are attributed [7]. The manifestation of these gender roles on women may lead to several psychological problems, including a decrease in self-esteem, a decrease in comfort, and feelings of anger and depression [6].

Gender role expectations may also lead to conflict and psychological distress for men. Previous literature on gender role conflict has purported that there are six patterns that lead to mental health problems for men, including: restrictive emotionality, health care problems, obsession with achievement and success, restrictive sexual and affectionate behavior, socialized control, power, and competition issues, and homophobia [4]. Additionally, gender role conflict may manifest in several situational contexts including times when men experience a gender role transition or face difficult developmental tasks, when men deviate from or violate gender role norms of masculinity ideology, or when men try to meet or fail to meet gender role norms of masculinity ideology [5].

Gender roles may vary distinctly across cultures. For example, while women in Asian or Latin American countries are taught to be submissive to men, women in the Philippines are seen as the authoritative leaders and decision-makers of the family. Additionally, while doctors in the US are traditionally stereotyped to be mostly men, doctors in Russia, Taiwan, or Germany are predominantly women. Finally, while men in the US are discouraged from expressing physical affection towards other men, it is common and acceptable for men in Spain or France to hold hands or even kiss to express their friendship. Finally, the practice of androgyny (or the acceptance of both male and female behaviors and physical traits) is common practice in some cultures. For example, many Native American tribes have described their members as "two-spirited" or individuals who fulfill an array of mixed

gender roles (physically, socially, or functionally) in their everyday lives. Two-spirited people may serve as mothers, fathers, healers or medicine persons, pottery makers, fortune tellers, and many other gender-neutral roles.

Gender roles may also have different meanings for various subcultures. Lesbian, gay, and bisexual (LGB) individuals may find themselves balancing various gender roles in their personal, romantic, and family relationships. First, by virtue of identifying as non-heterosexual and behaving accordingly, LGB individuals are already breaking gender role expectations. Second, there may be a spectrum of gender role identities for LGB individuals. Some LGB individuals may maintain strict gender roles; these individuals be involved in same-sex attractions and relationships, but may still choose to behave in "masculine" or "feminine" ways within their romantic, personal, family, or work relationships. For example, a gay man may choose to be the masculine, dominant one in his same-sex relationship (socially and sexually), while a lesbian woman may choose to be the feminine, submissive one in the relationship (socially and sexually). Conversely, some LGB individuals may identify as androgynous or a mix of masculine and feminine gender roles. For example, some lesbian women may choose to dress in gender-neutral ways and desire others not knowing what their gender or biological sex is. Finally, some LGB individuals may enjoy rebelling against gender role norms. For example, some gay or bisexual men may enjoy wearing makeup or entering professions that are considered feminine, while some lesbian or bisexual women may enjoy playing or watching masculine sports or being dominant or aggressive in their sexual and romantic relationships.

Gender roles may also have different meanings for transgender individuals. Transgender persons, whom are diagnosed with Gender Identity Disorder (GID), are defined as individuals whose self-identification as a woman, man, or neither does not match their biological sex. Because transgender individuals may feel like they were born into the wrong gender, they may struggle in accepting prescribed gender roles from a very young age. For example, if a boy identifies as a girl, but his parents force him to wear boys' clothes, play with boys' toys, and play boys' sports, this may cause him significant psychological distress.

Relevance to Childhood Development

Gender roles are introduced in early childhood in both overt and covert ways. Gender roles may be communicated overtly (e.g., telling a boy that "Boys don't cry" or telling a girl "Young ladies don't play rough") or covertly (e.g., buying a boy masculine toys like guns or buying a girl feminine toys like dolls). Gender roles may be learned by children through modeling (e.g., watching how parents and adults interact with each other), through the media (e.g., viewing how men and women relate with each other on television), through religion (e.g., studying messages about gender from religious leaders or historical religious figures), and through school (e.g., understanding messages that one's teacher gives them about gender). When parents, families, and other sources send messages about gender roles to their children, these messages and may have lasting impacts on individual's personality development, worldviews, and self-esteem. Gender roles in childhood may also influence an individual's perception of socially acceptable ways of coping with problems, expressing their emotions, interacting in relationships, or choosing career paths.

Gender roles can be both positive and negative in a child's development. Some gender roles may be positive in that they may encourage affirmative personality traits in children. For example, little girls may learn the importance of being affectionate, compassionate, or sensitive to the needs of others, while little boys may learn the importance of being assertive, self-sufficient, or willing to take risks. However, while these gender role traits may be positive for the gender these traits are assigned to, they may negatively impact children of the other gender. For example, little girls may learn to be submissive, shy, or soft-spoken, while little boys may learn to be competitive, forceful, or dominant.

Finally, parents and families can minimize gender role conflict in individuals by preparing them for the psychological distress that may occur as a result of gender roles. For example, teaching young girls about sexism and discrimination or teaching young boys about the pressures and negative implications of masculinity may lead to better coping mechanisms and an increase in mental health.

Gender Schema Theory

Jonathan Perle, Angela Waguespack
Nova Southeastern University, Fort Lauderdale, FL, USA

Definition

Gender schema theory states that children actively construct mental representations about that which defines males and females by observing individuals in the culture in which they live. Such schemas are incorporated into the child's self concept, aid in the search and assimilation of subsequent information that the child deems schema-relevant, and are constantly changing as the child develops.

Description

First coined by Sandra Bem in 1981 [1], gender schema theory is a cognitive account of sex typing by which schemas are developed through the combination of social and cognitive learning processes. Through observations of individuals within a child's culture, the child is able to observe male and female typical attributes, activities, and actions. These observations which aid in gender segregation and guide the child's gender related actions and activities are incorporated into the child's evolving gender schema.

The developing child begins to label him or herself as either male or female by about age 2 [6], but it is not until about age 7 that the child gains gender constancy [5] and recognizes that his or her sex is unchanging. However, even at age 2, the child is actively developing his or her schemas and incorporating them into his or her sense of self. He/She is constantly evaluating objects and activities as "boy" or "girl" things and forming his/her own schema, thereby integrating those aspects of self-definition that are appropriate for one's own gender. Further, gender schematic cognitions are not only influenced by the child observing others, but are also reinforced by toys, clothing, occupations, and hobbies including sports.

Relevance to Childhood Development

The lens through which children see the world as explained by gender schema theory is used to account for sex-related behavioral differences in boys and girls. Once a child develops his/her schemas regarding proper behaviors for men and women, these schemata guide all subsequent cognitions including information processing, behavior, and memory to specific activities [1]. By assimilating these schemas into their cognitions, children develop self-concepts that include the concepts of gender and gender-specific roles. Such development of self-concept is demonstrated by those gender-schematic children behaving in more gender-typical ways than gender-aschematic children. For these children, gender-consistent information is more easily understood and remembered, while information that contradicts or doesn't fit within the constructs of the schemas are difficult to process and are often not as easily remembered [3]. Gender schematic individuals are also more likely to be able to quickly indicate the gender appropriateness of behaviors and activities and are more readily able to recall gender specific terms and information in free recall tasks [4]. Given these findings, it is hypothesized that the attempted behaviors and associated cognitions of a child are not random, but rather determined by the child to match his/her hypothesized ▶gender identity as determined through his/her schemas.

It has been hypothesized by Sandra Bem that the ideal developing child schema would not be strongly male or female gender typical; with an optimal child having both male and female associations [2]. Such ideals are believed to be possible if the parents partake in behaviors that are cross-sexed. Possible behaviors including taking turns making dinner, both parents taking part in sex-typical hobbies such as watching and playing sports, and making sure that their children have access to both male and female typical colored clothing and toys.

General Cognitive Aptitude Testing

►Intelligence Testing

General Intelligence

The concept of general intelligence began more than 100 years ago with Charles Spearman's (1904) seminal work *General Intelligence, Objectively Determined and Measured.* Spearman proposed that all mental tests are comprised of a factor specific to each test and a general factor of intelligence, noted by *g*. One of the first tests to formally measure general ability was the Wechsler-Bellevue Scales (Wechsler, 1939) which included subtests that differed in their content but were all designed to measure general ability. All of Wechsler's tests that have been published have included an overall total score called a Full Scale score which represents general ability based on 10 to 12 individual subtests which varied in content. The content of the IQ tests developed in the early part of the 1900s included subtests, like the Army Mental Tests, which varied along the now familiar verbal, nonverbal (performance), and quantitative dimensions. Despite the varying content, all tests were intended to measure general ability. For example, some of the tests require knowledge of words and comprehension of verbal relationships; others, memory of the sequence of numbers; and others, reasoning with arithmetic and spatial stimuli. But as Wechsler (1975) wrote "… the attributes and factors of intelligence, like the elementary particles in physics, have at once collective and individual properties (p. 138)." Therefore, despite the individual demands of specific subtests, they form a cohesive whole which is general ability. Wechsler continued writing "the subtests are different measures of intelligence, not measures of different kinds of intelligence (p. 64)". More recently, Naglieri (2003) reminded us that "the term nonverbal refers to the content of the test, not a type of ability (p. 2)." Thus, tests may differ in their content or specific demands (what Spearman [1927] referred to as "indifference of the indicator" [p. 197]) but still measure the concept of general intelligence.

General System Theory

►Systems Theory

Generalization

Gina Coffee
Loyola University Chicago, Chicago, IL, USA

Definition

Generalization is "the occurrence of relevant behavior under different, nontraining conditions (i.e., across subjects,

settings, people, behaviors, and/or time) without the scheduling of the same events in those conditions as had been scheduled in the training conditions" ([2], p. 350).

Description

The concept of generalization is particularly important in child behavior and development when changes in behavior across settings, people, or time, for example, are desired. Historically, generalization was thought to occur passively and naturally, as practitioners adopted the "train and hope" philosophy of generalization [2], whereby they acknowledged the potential for generalization to occur but did not facilitate its occurrence. However, generalization does not appear to occur naturally, so attention has recently been turned to programming for it [1–4].

The seminal piece by Stokes and Baer [2] first called attention to the fact that generalization is rarely a passive process. By systematically reviewing the generalization literature to date, Stokes and Baer [2] developed a classification system of generalization techniques used in research studies. Stokes and Baer's contribution was important not only because it provided a thorough review of the existing generalization literature at the time and facilitated the conceptualization of generalization as an active process, but also because it provided a framework for researchers who sought to bring about lasting and widespread behavioral change in their clients/patients/participants.

Later, Stokes and Osnes [3] modified the classification system by grouping programming tactics within three general principles. That is, Stokes and Osnes reorganized, and elaborated upon, the techniques first presented by Stokes and Baer [2], with the goal of presenting a clearer picture of how to program for generalization. Within the categorization developed by Stokes and Osnes [3], twelve programming tactics fell under the general principles of (1) exploit current functional contingencies, (2) train diversely, and (3) incorporate functional mediators.

The first principle (exploit current functional contingencies) refers to the direct exploitation of the antecedent-response-consequence pathway that can influence the frequency, intensity, and/or duration a given behavior. The programming tactics under this general principle include (1) contact natural consequences, (2) recruit natural consequences, (3) modify maladaptive consequences, and (4) reinforce occurrences of generalization. Contacting natural consequences involves identifying and making use of positive consequences that naturally occur in the environment, rather than employing artificial consequences or consequences that have been programmed by the therapist or change agent. For example, a natural positive consequence for engagement behaviors of a child who is socially withdrawn may be positive peer attention. When natural consequences are not readily identifiable or accessible, it may become necessary to recruit natural consequences – the second tactic within this principle. For example, a student can recruit the natural consequence of teacher praise by directly asking the teacher how he/she performed on an academic or behavioral task (e.g., asking the teacher "How did I do?" after successfully turning an assignment in on time). The third programming tactic of modifying maladaptive consequences is used when existing consequences are working toward maintaining an inappropriate behavior. In these cases, the maladaptive consequences must be changed in order to decrease the frequency, intensity, or duration of the inappropriate behavior. For example, if the consequence for a student's out-of-seat behavior (avoidance behavior) is to send the student out of the classroom, it is likely that this consequence needs to be changed to encourage the student to stay actively engaged in classwork. Finally, Stokes and Osnes [3] proffered that current functional contingencies may be exploited by the reinforcement of generalization occurrences. Specifically, generalization behaviors should be noted and reinforced, such as when a student who has been taught to engage in prosocial behaviors in the lunchroom also engages in these behaviors on the playground.

The second principle (train diversely) involves the institution of less control and rigidity during training conditions. In particular, training diversely encourages change agents to broaden training goals and procedures with the ultimate goal of promoting widespread outcomes. The programming tactics under this general principle include (1) use sufficient stimulus exemplars, (2) use sufficient response exemplars, (3) make antecedents less discriminable, and (4) make consequences less discriminable. A stimulus exemplar is an aspect of training that is associated with the training condition (e.g., a change agent or the therapy room). By using sufficient stimulus exemplars (e.g., multiple change agents or several different therapy rooms), generalization can be enhanced. The literature suggests that as few as two stimulus exemplars may be sufficient. In contrast, a response exemplar can be understood as the behavior that is sought during training. An example of using sufficient response exemplars could be training students to solve a problem in many different ways. Another way generalization can be achieved with this tactic is by training subsets of behaviors that are representative of a particular class of responses. The final two tactics of this principle address discrimination

by indicating that (to enhance generalization) antecedents and consequences must be made less discriminable. In terms of antecedents, the conditions of training should vary and be flexible enough so that target behaviors are not associated only with a specific set of circumstances. For example, training could occur in natural settings at unplanned times. With regard to consequences, schedules of reinforcement should be varied, and reinforcement should be delayed when feasible.

The final principle (incorporate functional mediators) involves the use of mediators to enhance generalization. In this context, "a mediator is a stimulus that occurs between the training and the occurrence of generalization in such a way that it facilitates or mediates that generalization, probably as a discriminative stimulus for the performance of the behavior" ([3], p. 348). A mediating stimulus, then, is a stimulus that is either present in multiple conditions or a stimulus that the client can easily transport between the training condition and other settings. The programming tactics under this general principle include (1) incorporate common salient physical stimuli, (2) incorporate common salient social stimuli, (3) incorporate salient self-mediated physical stimuli, and (4) incorporate salient self-mediated verbal and overt stimuli. Essentially, the principle remains the same, while the types of stimuli differ. In particular, a physical stimulus is a physical object (e.g., a timer); a social stimulus is a person (e.g., a peer, therapist, teacher) or a characteristic of a person (e.g., a gesture someone makes); a self-mediated physical stimulus is something the client can maintain and carry with him/her between training and non-training conditions (e.g., a notebook with procedures or a self-monitoring chart); and self-mediated verbal and overt stimuli are verbalizations, thoughts, and or cognitive strategies used by the client in relevant settings.

Using the techniques put forth by Stokes and Baer [2] and Stokes and Osnes [3], Osnes and Lieblein [4] recently examined the current state of generalization programming by reviewing generalization articles in select journals (*Journal of Applied Behavior Analysis*, *Behavior Modification*, the *Journal of Positive Behavior Interventions*, and *The Behavior Analyst Today*) from 1999 to 2002. In general, they sought to determine whether the field of generalization has moved beyond "train and hope" and found mixed results. Whereas they found researchers are assessing maintenance and incorporating the techniques identified by Stokes and Baer [2] and Stokes and Osnes [3], they also found that researchers are continuing to use interventions that are highly discriminable without long-lasting effects.

Generalized Anxiety Disorder

Jill Driest
Nova Southeastern University, Davie, FL, USA

Synonyms

Anxiety disorders; GAD; Over-anxious disorder

Definition

Generalized anxiety disorder (GAD) is an anxiety disorder that is characterized by excessive worry, more days than not, for at least 6 months. This worry can cause significant distress in both social and academic functioning.

Description

Diagnosis and Classification

Children diagnosed with GAD must experience excessive anxiety and worry occurring more days than not for at least 6 months. These children find it very difficult to control their anxious thoughts and which results in distress at school, home, and other areas of functioning. This worry is observed in restlessness, fatigue, irritability, muscle tension, difficulty concentrating, or sleep disturbances.

Prior to the fourth edition of the Diagnostic Statistical Manual of Mental Disorders, GAD was referred to as Over-Anxious Disorder (OAD).

Core Symptoms

The continuous anxiety and worry characterized by GAD can occur in a variety of areas, including academics, natural disasters, sports, past behavior, or future events. Some children also worry about characteristically adult issues, such as the financial situations of their parents, relationships, punctuality, or perfectionism. When these issues begin to interfere with social adjustment and academic functioning, the anxiety becomes a cause for clinical concern.

The expression of GAD can change developmentally in both the content and the severity of the disorder. Children over the age of 12 years report more GAD symptoms and present with anxiety towards more events.

The worries experienced by children diagnosed with GAD persist despite the fact that the event is unlikely to occur. This can be partly attributed to the fact that these children overestimate the likelihood that a negative event will occur. These children also underestimate their ability to cope with these negative events and tend to catastrophize minor events.

Children with GAD tend to make more negative statements about themselves and require constant reassurance from others. As a result, they tend to present with a negative self-concept.

Physical Complaints

Children diagnosed with GAD are likely to complain about gastrointestinal problems, which include muscle tension, nausea, diarrhea, and stomachaches. Other common physical symptoms include, but are not limited to, sweating, headaches, dry mouth, teeth grinding, and trembling. Due to all these physical complaints, most children with GAD tend to seek out consultation of a physician or an internist [1].

Prevalence

GAD is one of the most common anxiety disorders in children. It is estimated that approximately 2–4% of children in the general population meet the diagnostic criteria for the diagnosis.

Sociodemographic Variables

Data regarding the sociodemographic variables of children diagnosed with GAD are limited. Nevertheless, much of the research from the previous diagnosis of OAD can utilize. Children diagnosed with OAD are typically from middle-to-upper class families. Females are more frequently diagnosed with GAD.

Etiology

The cause of GAD is unknown. However, early twin studies suggest that every anxiety disorder, with the exception of GAD, demonstrated a high monozygotic concordance. Since this study, more researchers have argued that there is a possible genetic contribution in patients with GAD. The genes are responsible for creating a general vulnerability and risk factor for these disorders [4].

GAD has also been associated with a lower metabolic rate in white matter and basal ganglia with brain-imaging studies. Likewise, there have also been some abnormalities with sleep electroencephalogram (EEG). These studies have illustrated that those diagnosed with GAD tend to have decreased delta sleep, decreased stage 1 sleep, reduced rapid eye movement sleep, and difficulty staying asleep [4].

Comorbid Problems

GAD is frequently comorbid with other anxiety disorders and affective disorders. Children diagnosed with GAD are also at increased risk for alcohol use as a form of self-medication [2].

Developmental Course and Prognosis

The developmental course of GAD is unknown due to the high comorbidity rate associated with the disorder. The few studies in the literature are retrospective in nature with adults reporting the onset of symptomatology in childhood [3].

Relevance to Childhood Development

Considering the extensiveness of the disorder, children diagnosed with GAD are likely to have problems developing and maintaining close relationships, as well as completing everyday activities [3].

Generativity versus Stagnation (Erikson's Middle Age)

Sarah Poole, John Snarey
Emory University, Atlanta, GA, USA

Definition

Generativity is psychologist Erik H. Erikson's term for the primary developmental task of the seventh stage of the life cycle – caring for and contributing to the life of the next generation. The developmental challenge of adults in their middle years is to be procreative, productive, and creative and to overcome a pervading mood of self-absorption or personal stagnation. Generativity includes any activity that contributes to the development of others and to the life of the generations. The successful realization of generativity gives rise to the ego strength that Erikson described as the virtue of care.

Description

Erik H. Erikson viewed generativity as the principal task of middle adulthood and used the term to highlight the adult's role "in establishing and guiding the next generation" ([3], p. 267). Erikson summed up the stages in the following way: "In youth you find out what you *care to do* and who you *care to be* – even in changing roles. In young adulthood you learn whom you *care to be* with – at work and in private life, not only exchanging intimacies, but sharing intimacy. In adulthood, however, you learn to know what and whom you can *take care of*" (p. 124). Stage 7 of the life cycle marks the time a person takes their place in society and helps to take care of the next generation. Adults' societal generativity can be in the form of creating and caring for ideas, art, children, and products. Erikson notes that those who do not have children sometimes fulfill their parental responsibility by performing other altruistic and care-related activities. For example, one can help someone else's child and still exercise generativity. Therefore, this stage does not center on having children; it centers on extending one's self to make the world a better place for the next generation [7]. Due to the nature of this stage, relationships center on the workplace, the community, and the family – places where one can both creatively contribute to and care for what has been created. Regardless of the setting, the psychosocial challenge to adults is to promote the development of others, from nurturing the growth of another person to shepherding the development of a broader community.

If adults do not master this developmental task, however, they tend to become self-absorbed and stagnant. Erikson's concept of stagnation, that is, most directly applies to the failure to become socially generative. The absence of generative care threatens the entire future of the society because generativity is "the link between the life cycle and the generational cycle" ([5], p. 258). Without generativity, inactivity and meaninglessness predominate; adults embrace "pseudo intimacy" while feeling "stagnation and interpersonal impoverishment" ([2], p. 103). They focus inward, indulging their own needs instead of the needs of others. In some sense, they become their own child. An extension of self-absorption is the act of "rejectivity" or rejecting specified groups of people. Erikson elaborated on this term by noting the correlation between rejectivity and what he calls "pseudospeciation," which he defined as the distorted belief that another group not only differs from you but also poses a threat to you ([4], p. 69). For the mature, generative adult, care extends to all, not just to certain groups of people.

The virtue of care arises from the favorable resolution of generativity *versus* stagnation. Erikson notes that "care" includes "'to care to do' something, to 'care for' somebody or something, to 'take care of' that which needs protection and attention, and 'to take care not to' do something destructive" ([6], p. 53). An "ethic of care," as expanded by Snarey [13], "is an ethical position that first considers the possible effects on the next generation. Care is an inclusive concern for what love, necessity, and chance have generated. Generative care overcomes the ambivalence associated with irreversible obligations by being inclusively attentive to all that has been created" (p. 228). Giving instead of receiving generates personal contentment. Erikson [1] posits that mature humans "need to be needed, and maturity needs guidance as well as encouragement from what has been produced and must be taken care of" (pp. 266–267). In the process of caring for others, the adult also experiences further growth and personal development. In other words, just as children cannot develop into healthy adults without committed parenting, adults cannot achieve healthy maturity and generativity without the experience of nurturing future generations [7].

Research on adult development has built on or advanced Erikson's concept of generativity. Valliant and Milofsky [14] interpreted the findings of their longitudinal study of working and upper-class men as indicating that two separate developmental tasks (career consolidation *versus* self-absorption; keepers of meaning *versus* rigidity) can be understood as derive from Erikson's concept of generativity. Deemphasizing the significance of crisis, they also suggested a spiral model by which each new

stage balanced off the prior stage in a pendulum swing between "times of change and instability" and a "preoccupation with the preservation of sameness and autonomy and with following and maintaining rules" (p. 1350). A spiral model suggests the evolving, hierarchal nature of maturation and the difficulties of development without mastery of each stage. This study also illumines the role of culture in modifying the tasks of development; cultural differences influence what society deems as suitable developmental tasks for each stage ([14], pp. 1348–1351).

Erikson's concept of generativity also was elaborated in the lives of men by studying the role of fatherhood. Kotre's theorizing [8] and Snarey's [12] research centered on *generative fathering*, which describes men "who contribute to and renew the ongoing cycle of the generations through the *care* they provide as birth fathers (biological generativity), childrearing fathers (parental generativity), and cultural fathers (societal generativity)" (12, p. 1). Additionally, Snarey [12] developed the concept of "generativity chill" to describe the threats to adult generativity, and his four-decade study demonstrated that brief or long-term threats to generativity have considerable impact on a father's selfhood, bringing the father to confront his own mortality and challenging his own generativity with stagnation.

McAdams and de St. Aubin [9] introduce seven interrelated features of generativity: cultural demand, inner desire, generative concern, belief in species, commitment, generative action, and personal narration (p. 1). The creation of the Loyola Generativity Scale attempts to assess self-reported acts and autobiographical experiences to of measure the psychosocial dimensions of generativity. McAdams and de St. Aubin [10] elaborate further by pointing to "generativity scripts" or the stories people construct to answer the question of generativity. These stories outline what a person plans to do to ensure that he or she leaves a legacy for the next generation. They posit that identity deals not only with the past and present, but with future life plans of generative action manifested in the life stories or generativity scripts of individuals. Finally, Slater [11] gave new breadth to Erikson's crisis of generativity *versus* stagnation by highlighting the ways in which each of the other seven stages in Erikson's eight-stage model of the life cycle is present and expresses itself as a dimension of middle adulthood. Following Erikson's lead, he presents inclusivity *versus* exclusivity, pride *versus* embarrassment, responsibility *versus* ambivalence, career productivity *versus* inadequacy, being needed *versus* alienation, and honesty *versus* denial (pp. 59–64). Overall, the developmental concept of Generativity continues to be an effective tool for understanding how mature adults care for the next generation.

Relevance to Childhood Development

The goal of societal generativity directly involves a person in guiding and establishing the next generation. Stagnation in this period of life is counterproductive to the development of successive generations. Lack of generativity can lead to placing excessive pressure and expectations on children to redeem what adults or parents failed to do. Unrealistic burdens such as these hinder a child's development instead of promoting it. Additionally, the adult does not just fulfill the needs of children; children also fulfill the adult's need to be needed. In this sense, a mutual exchange takes place. Viewing a child in this way implies interconnectedness within the life cycle. In essence, based on whether an adult is generative or stagnant, this stage can either promote or hinder the flourishing of the next generation and future generations.

Genetic Blueprint

▶Maturation

Genetic Disorder

►Turner Syndrome

Genotype

Arthur E. Hernandez
Texas A&M University Corpus Christi College of Education, Corpus Christi, TX, USA

Definition
The genetic make up of an individual or group.

Description
The genotype determines the hereditary characteristics of an individual and is sometimes considered as the allele constitution of any particular trait. Among individuals who are the product of sexual reproduction, the genotype represents the complete set of genes transmitted by both parents. The genotype is often contrasted with the phenotype which refers to individual characteristics determined by nonhereditary experience.

Geodon®

Anisa Fornoff
Drake University, Ankeny, IA, USA

Synonyms
Ziprasidone

Definition
A prescription medication FDA approved for the treatment of schizophrenia, acute manic or mixed episodes associated with bipolar disorder, and in acute agitation in people with schizophrenia.

Description
This medication is an atypical antipsychotic available in capsule or injection.

The recommended starting dose for the oral capsules is 20 or 40 mg twice daily. Maximum recommended dose is 160 mg a day. This medication should only be taken as directed by a doctor. The intramuscular injection form of this medication is generally just used in the hospital setting.

This medication should be taken with food. Avoid drinking alcohol. Inform your doctor if you have kidney disease, a personal history or family history of heart problems, or other medical conditions.

Some side effects are listed here: twitching or muscle movements you cannot control, sleepiness, headache, dizziness, nausea, chest pain, change in heart rate, rash, anxiety, weight gain, and weakness. Tell your doctor immediately if you notice the following: fainting, slurred speech, or irregular heartbeat. The doctor may check your potassium level with a blood test. Geodon may cause an increase in blood sugar levels and possible weight gain. Elderly patients with dementia-related psychosis taking this class of medications are at increased risk of death. This medication may cause lightheadedness when going from a lying or sitting position, so it is recommended to get up slowly.

This medication should be stored out of reach of children and pets and away from light, heat, and moisture.

Relevance to Childhood Development
Geodon® is not FDA approved for use in children.

Women should let their doctor know if they are pregnant or planning to become pregnant. Talk with your doctor before breastfeeding.

Gerstmann Syndrome

Kristen Domboski, Wiley Mittenberg
Nova Southeastern University, Fort Lauderdale, FL, USA

Synonyms
Angular gyrus syndrome

Definition

Gerstmann syndrome is a condition that consists of a tetrad of neuropsychological symptoms including agraphia, acalculia, finger agnosia, and right-left disorientation. The presence of these four symptoms suggests cortical dysfunction in the left parietal lobe. The autonomous nature of the syndrome is debated, and some posit that a developmental form also exists.

Description

Gerstmann syndrome was first identified and described in a paper by Josef Gerstmann in 1924. In this paper, a case was presented of a patient who exhibited inabilities to write, to perform mathematical calculations; to recognize, name, or identify fingers; and to discriminate the right and left sides of the body. Gerstmann later reported additional cases of patients with the same tetrad of symptoms, and he hypothesized that these cardinal symptoms resulted from a lesion in the left angular gyrus [7, 14]. Gerstmann believed that a unifying disruption of body image integration, or body scheme, accounted for all four symptoms and was responsible for the shared spatial deficit root of each symptom. Due to this belief of a unifying theme, Gerstmann argued that the symptoms constitute an autonomous syndrome [8].

Researchers and clinicians have subsequently disputed the existence of Gerstmann syndrome as a discrete entity [3, 5]. Cases have been presented consisting of the tetrad of symptoms with no additional deficits [4, 15], often referred to as "pure Gerstmann syndrome." However, patients frequently exhibit a mixed presentation of symptoms, including some or all of the cardinal symptoms along with other symptoms. Some of these other symptoms include constructional apraxia [2], ideational apraxia [6, 14], alexia [3], hemianopsia [5, 15], color agnosia [5], and aphasia [5, 21]. Because of the overlap and variability of the presentation of the cardinal symptoms with these other deficits, it is argued that an autonomous syndrome does not exist [11]. The tetrad of symptoms is less likely to occur in patients without aphasia than in patients with aphasia, refuting the notion that the disorder is purely spatial [21]. The syndrome may develop in primary form, where no additional deficits have been noted within the course of the illness and the tetrad manifests as the primary presentation. The secondary form refers to cases where the clinical presentation initially includes additional symptoms (i.e., aphasia, constructional apraxia) and over time, most resolve with the exception of the Gerstmann tetrad. Generally intact functions in patients who present with pure or partial Gerstmann syndrome include intellectual functioning, memory, and personality [7].

The cardinal symptoms of this syndrome most frequently occur following damage to the left parietal lobe, and for this reason the syndrome is thought by some to carry value in regards to lesion localization. The left angular gyrus, located at the inferior parietal lobe at the temporal and occipital junctions, is more specifically implicated, and accounts for the belief that this syndrome is related to deficits with visuospatial processing [4], mental manipulation of images [15], or body scheme [7]. A unifying theme of spatial cognition is evident [26]. Case reports of pure Gerstmann syndrome entail discrete focal damage to this region, such as in a cerebrovascular accident (CVA) or glioma. Patients may present with Gerstmann symptoms secondary to diffuse damage or focal damage to regions other than the angular gyrus as well. Deficits in addition to the cardinal symptoms are more likely to occur in these cases, such as with patients with diffuse posterior cortical atrophy (PCA) who have been observed to exhibit some or all of the Gerstmann syndrome symptoms [25]. The four cardinal symptoms comorbid with other neurological deficits have also been observed in cases with lesions in the left temporo-parieto-occipital lobes, left posterior frontal lobe, and right parietal lobe in left-handed patients [15]. The additional deficits are assumed to be caused by damage to tissue adjacent to the angular gyrus [7]. Of significance, lesions to the angular gyrus may not produce a pure Gerstmann syndrome, yet the identification of a pure Gerstmann syndrome invariably denotes tissue damage to this specific region.

Finger Agnosia

Patients with finger agnosia are unable to name, identify, recognize, or differentiate their fingers, or imitate finger movements although vision and sensorimotor functioning remains intact. The deficit is not restricted to identifying right versus left [7] and the difficulty is often most pronounced for the three middle fingers [5]. While Gerstmann attributed finger agnosia to a defect with body image, finger gnosis is also mediated by language [14]. The common comorbidity of aphasia with not only finger agnosia, but also the rest of the tetrad of symptoms, supports the claim that Gerstmann syndrome is not a unique disorder but instead the result of multiple presumable etiologies [3]. However, cases of the syndrome without aphasia [16] have corroborated the finding that finger gnosis is an ability reliant upon spatial functioning and can become impaired when language functions remain intact. The left angular gyrus has specifically been

shown during repetitive transcranial magnetic stimulation to disrupt finger schema [22]. Historically, fingers have been instrumental in developing numerical and calculation abilities, which may account for the co-occurrence of finger agnosia and acalculia. When one's ability to recognize and utilize the fingers is blunted, as in a lesion in the angular gyrus, a disruption in arithmetic calculations may ensue, even for adults who do not use their fingers for solving arithmetical problems [22].

Right-Left Disorientation

Gerstmann found that a disruption in the ability to discriminate and identify the right and left sides of the body, for self and others, was also a commonly observed deficit when body scheme was impaired. The disorientation is exhibited despite preserved knowledge of right and left and is often most pronounced for hands and fingers. The disruption usually does not generalize to understanding sidedness for objects outside the space of the body [8].

Agraphia

This term refers to handwriting deficits despite intact letter recognition, reading, motor, and language abilities. Gerstmann conceptualized this writing impairment as a function of the loss of orientation to the hands and body, citing the spatial functioning required to perform the skill [8]. Copying written words may be less impaired that spontaneous writing. Radiographic studies utilizing functional magnetic resonance imaging has confirmed the presence of writing impairments secondary to damage to the inferior and superior parietal cortices [17].

Acalculia

Calculation ability is not thought to consist of one discrete function [1]. Disturbances in calculation can result from not only impaired numerical understanding, but also from other deficits, such as spatial relations, language, and memory. Calculation deficits can occur as result of various neuropathologies involving numerous areas of the brain. In cases of primary acalculia, where the ability to understand and execute basic arithmetical calculations is not based on other cognitive deficits such as attention, memory, or language impairment, the left angular gyrus is implicated in the calculation deficit. Recognition of numbers and understanding of numerical concepts remains intact in primary acalculia. It is this precise type of calculation disturbance that Gerstmann [7] postulated was associated with the other symptoms of his syndrome. When agraphia is also present, the acalculia is more pronounced for written arithmetic than oral [12].

Relevance to Childhood Development

While Gerstmann syndrome typically relates to an acquired condition secondary to cerebral damage, some cases of developmental origin have been reported. In children, however, the symptom presence must be considered relative to the child's developmental level. Rather than absolute inability, a deficient level of skill compared to the expected developmental level of the child may be observed. Developmental Gerstmann syndrome has been recognized more infrequently than the acquired form, possibly due to the difficulty in diagnosing the presence of the symptoms at earlier developmental levels. Another potential explanation for the paucity of information on the developmental form is that other, more well-recognized disorders better account for the symptoms. In the acquired form, symptom onset results from an injury, such as a CVA. The developmental form differs in that no specific injury is identified as the etiology of the symptoms, yet cases have been reported in children both with and without neurologic insults [19]. In case studies with children who exhibit developmental Gerstmann syndrome, soft neurologic signs suggesting parietal lobe involvement, such as gait disturbance, hypertonia, and tremor have also been reported [24]. The syndrome has been hypothesized to be attributable to learning disorders [13], perinatal trauma [12], and developmental delays, but no known etiology exists [18]. Related disorders that may better account for the symptoms of Gerstmann syndrome in childhood include Fragile X syndrome, Williams syndrome, nonverbal learning disabilities, and Asperger's syndrome. Abnormalities in the left parietal lobe often seen in Fragile X syndrome may account for the presence of the cardinal Gerstmann symptoms [9]. In Williams syndrome, which may also include visuospatial deficits, pronounced attention and verbal memory deficits are also seen [10]. Regardless of the presence or absence of developmental Gerstmann syndrome, nonverbal learning disabilities are characterized by impairments in social judgment and problem solving, and Asperger's syndrome includes deficits with social interaction, communication, and personal interests [18].

Finger Agnosia

Diagnosis of finger agnosia can be difficult in children, as this ability typically develops in later childhood to early adolescence [5]. The term is often used to describe distinct dysfunction in either finger identification or finger naming. In finger identification dysfunction, the child cannot point to or select a given finger on request. Finger naming dysfunction, also called finger anomia, entails the child's inability to name specific fingers on request. In the

developmental form of Gerstmann syndrome, either or both functions may be impaired [24].

Right-Left Disorientation

It is has been demonstrated that the majority of children can discriminate the right and left sides of their body by eight years of age [5]. Right-left disorientation may be seen as slowness or hesitation in responding to tasks requiring right and left differentiation rather than a complete lack of right-left orientation. Simple knowledge of right and left may be intact, yet performance of complex commands may be impaired [19].

Agraphia

Levels of writing impairment, called dysgraphia, vary in the developmental form of this condition, often regardless of the developmental level of the child [18, 24]. Letter and word formation can be seen as clumsy or illegible, and spelling errors may occur. The impairment may be for spontaneous writing, copying, or both. Letter sequencing and reversal is also common. Demonstrating a visuospatial nature of the symptomatology, the underdeveloped penmanship may qualitatively be considered poor use of space [2]. Disorientation for right and left impacts the manifestation of agraphia in some cases, evidenced by improper use of paper margins, misaligned writing, and disoriented letters [24].

Dyscalculia

The term dyscalculia refers to a developmental lack of acquisition of numerical or mathematical abilities [1]. Developmentally-appropriate understanding of numbers and mathematical concepts remains intact. Dyscalculia may present as difficulty sequencing numbers, writing numbers, or performing calculations verbally or in writing [27]. In dyscalculia, also sometimes referred to as developmental dyscalculia, mathematical abilities are never learned. This impairment contrasts with acalculia, where a previous understanding of mathematical concepts is halted by acquired organic brain dysfunction. In children, the co-occurrence of finger agnosia and dyscalculia are considered evidence of a learning disorder, as numerical concepts and arithmetic skills at early ages are reliant on discrimination of the fingers [26]. The acquisition of simple arithmetic skills can also be understood by examining Piaget's Concrete Operational stage of development [23], where children between the ages of 7 and 11 years typically develop an understanding of the concept of reversibility for logical problem solving. Without ability to utilize this concept, the child may manifest intact abilities, such as language, yet have impaired abilities with ordering and simple arithmetic.

While constructional dyspraxia may or may not occur with acquired Gerstmann syndrome, many consider it the fifth sign of the developmental form [2]. The child may not be able to copy drawings or manipulate blocks, but the impairment is not attributable to sensorimotor deficits. Contrasting with the acquired form, which frequently presents with aphasia, developmental Gerstmann syndrome typically does not occur with pronounced language deficits [13, 27]. Other associated features of the developmental form may include hyperactivity, attention deficit [28], mild language delays, and behavioral problems such as aggressiveness and temper tantrums [24]. Due to the scarcity of literature, varied causal hypotheses, and reduced reliability in diagnosing individual symptoms of developmental Gerstmann syndrome, there is doubt as to whether the syndrome is an independent developmental disorder. A higher incidence of cases with Gerstmann symptoms may be uncovered through more thorough neurological and neuropsychological assessment for children with learning disabilities, as some argue that the syndrome often goes unrecognized. When the syndrome is identified, averting the child's deficits by teaching compensation skills and utilization of strengths remain common treatment approaches [20].

Gestures

Seongwon Yun
Oklahoma State University, Stillwater, OK, USA

Synonyms

Action; Body language; Movement; Nonverbal communication; Signal

Definition

Gestures are bodily movements that are carried out for the purpose of communication. A wave of the hand and a nod of the head are examples of gestures.

Description

Parts of a body (e.g., hand shape, kinetic movement, face, eyes, and posture) and surrounding environments are used simultaneously when we gesture [1]. For example, when someone says, "Here" with a pointing gesture, the place can be understood only as the specific location the person is referring to. Gestures can express different things. Pointing gestures indicate things, persons, or locations as objects of references. Iconic characterizing gestures provide a visual representation of things to show physical and concrete items (e.g., using hands to show how big or small a physical item is). Symbolic designating gestures express abstract ideas in visible forms (e.g., pointing ahead in space to indicate time, "the future"). Emblematic gestures are patterns of gesture that have been conventionalized within a culture (e.g., thumbs up). People also gesture spontaneously during speech. A speaker's specific spontaneous gesture is distinguished from iconic representational gestures and emblems because it does not represent any shared meanings among people as iconic gestures or emblems do. Gestures also differ across different languages and cultures because different languages and cultures organize information about events differently. For example, people from southern India or Pakistan may shake their head from side to side to indicate "you're welcome" or "goodbye."

Gesture, Speech, and Thought

According to research findings, speech and gesture are not separate [2, 3]. In the process of making sense to others,

people use not only language but also gesture as a part of multiple resources, which include physical and cultural environments [1]. People may leave out some words and instead substitute them with gesture incorporating the relevant features of the environment. For example, a person holding a cup of hot coffee in a coffee shop may say to a salesperson, "Please give me" with hand shaking gestures up and down quickly indicating a cup sleeve. The relevant features of the environment in this example include physical environments such as the place (coffee shop) and a cup of hot coffee and cultural environments such as the interpersonal relationships between the customer and the salesperson and the context of holding a cup of hot coffee to take out. In meaning-making processes, speech and gesture occur almost at the same time at the very moment of expressing thought. Whereas speech is used to convey more conventional, segmental, and sequential meanings, gesture reflects instantaneous, global, and holistic thought in order to provide additional features of meaning accompanied with utterances.

Functions of Gestures

Why do we gesture? Individualized spontaneous gestures function for the speaker to compensate for or spur verbal formulation. Gestures can help people keep complex concepts in mind or retrieve certain words. Gestures can be regarded as a resource to construct discourse, which is composed of multiple resources such as speech, gesture, and relevant parts of physical and cultural environments. Gestures reflect a dynamic process of thinking for speaking [2]. They show a relationship between language and thought representation in the mind. Speech gestures are generated during the conceptual process for speaking, in which speech and gesture take place at the same time. Gestures also function as a cohesive device as people narrate discourse. There is a recurrent of one or more gesture features that spread out over a stretch of discourse to maintain reference and achieve cohesiveness in the discourse [3]. Gestures can also reveal meanings beyond speech. Gestures stimulate thought processes as people prepare gestures in advance. People enact their thoughts through gestures and express aspects of utterance content in visible forms.

Sign, Gesture, and Language

Sign language developed among the deaf shows an indirect relationship to spoken language [4]. Sign languages developed in deaf communities, for example, American Sign Language, are full-fledged languages, which are distinguished from spoken language and spontaneous individualized gestures. Sign language helps deaf children learn and develop resilient properties of language.

Relevance to Childhood Development

Gestures play a facilitating role in communication and in early language development [5, 6]. Gestures are used to communicate before children use their voices to express something. Infants can start understanding and using simple gestures around 6–8 months of age (e.g., rhythmic hand movements) [7]. Babies begin to use pointing gestures around 8–10 months of age [7]. Gestures not only precede language development but also have a close relationship to children's development of words and grammatical structures. For example, babies who are producing single-word utterances may use gestures in combination with words to produce sentence-like combinations (e.g., saying *want* and pointing to candies). These types of gestures and word combinations occur around 18–20 months of age [7]. Gesture continues to facilitate, expand, and speed children's early language repertoire over childhood development.

Gifted and Talented Children

Megan Parker
University of Tennessee- Knoxville, Knoxville, TN, USA

Life Dates

1984–

Educational Information

B. S. Psychology, Middle Tennessee State University (2005), M.S. Applied Educational Psychology, University of Tennessee- Knoxville (2008), Ph.D. School Psychology, University of Tennessee- Knoxville (2010).

Definition

Gifted and talented is a label that describes children who possess exceptionally advanced abilities in one or more performance areas.

Description

Identification

Traditionally, gifted children were identified and defined by their advanced intelligence, which was assessed by an IQ test. By this qualifier, a child was deemed gifted if he or she produced scores of approximately 130 or above or the 95th percentile. However, in many cases, there are now other ways for children to qualify and be identified as gifted [5]. Advanced scores on achievement assessments, exceptional grades in school, creativity, leadership, and observed advanced skills are just some of the additional components that may be used in combination with an IQ assessment to identify gifted children from the correction given [3].

Traits

Because gifted children can now be identified in many different ways, it is more difficult to distinguish characteristics that only belong to gifted children. If a child is a gifted pianist, than the child's abilities will surely be seen in his or her ability to play the piano. If a child is a gifted mathematician, than the child's abilities will shine while computing formulas and equations. The commonality among the different types of giftedness is the advanced nature of the ability. Gifted children are also often noted for their creativity, leadership skills, and advanced cognitive development.

Services

States vary on how they provide services to gifted children. Some states provide no services, and others provide comprehensive programs including advanced coursework and separate classes for every grade level in all subject areas for gifted students. There is currently no mandated federal funding for gifted education. However, the Javits Act provides funding to gifted education programs serving traditionally underrepresented students [1, 4]. The Javits Act funding is highly competitive. Also, in states that provide services to gifted students, there is not a uniform method for organizing such services into the educational system. Some states place gifted programs within Special Education; others place gifted services within general education programming.

Global Assessment of Functioning Scales

Lori J. Warner
Center for Human Development, Berkley, MI, USA

Synonyms

CGAS; C-GAS; Children's global functioning; GAF; GAPD; Social adjustment

Definition

Global assessment of functioning scales are intended for use by mental health professionals to rate the overall functioning of their patients, taking into account occupational/school, social, and psychological symptoms.

Description

There is consensus that clinical indices of overall functioning have utility in treatment of mental illness and impairment [3]. Functional impairment is often the impetus for clinical referral and entry into treatment [4]. Additionally, global assessment scales allow clinicians to integrate information from many areas of the patient's functioning into one clinically meaningful index [2]. This information can then be used in planning treatment and evaluating outcome of interventions.

The Global Assessment of Functioning Scale (GAF; [1]), the Children's Global Assessment Scale (CGAS; [2]), and the Global Assessment of Psychosocial Disability (GAPD; [5]) are the three most commonly used measures of global assessment of functioning. All are numeric scales intended for use by mental health professionals to assess the general functioning of their patients. The GAF is designed for use with patients of any age, whereas the GAPD is intended specifically for use with children under age 18, and the CGAS is for use with patients aged 4–16. The psychometric properties of all three scales have been recently summarized [3].

Each scale has specific instructions regarding which areas of functioning to assess and which to exclude (e.g., impairment due to physical or environmental limitations), and each differs in terms of the timeframe during which the rating is being made (see [3] for overview). The scales contain clinical descriptors of functioning/symptoms as benchmarks or anchor points, and ratings are made on the lowest level of functioning for the CGAS and the GAPD, whereas the GAF does not specify how to rate if functioning levels vary.

Relevance to Childhood Development

None of the scales has established psychometric properties for children under 4 years of age, and the reason for selecting age 16 as the upper limit for the CGAS is undocumented [3].

A developmental disabilities modification of the CGAS was published in 2007 (DD-CGAS; Wagner et al.) as the descriptors in CGAS scores are not easily applied to children with developmental disabilities. The DD-CGAS was found to be reliable, with apparent convergent validity for measuring the global functioning of children with Pervasive Developmental Disorders [4].

Globus Pallidus

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Definition

The Globus Pallidus is the medial portion of the lenticular nucleus, narrowly, and one part of the basal ganglia broadly, which plays a prominent role in motor modulation [2].

Description

The globus pallidus is one portion of the basal ganglia, which is a cluster of subcortical structures that have been tied to the modulation and regulation of motor activities and has also been linked to procedural memory. Together as a working whole, the basal ganglia demonstrate complex interconnections between sensory centers and the cerebral cortex that participate in the control of higher-order movement, particularly in starting or initiating movement [3]. While it is part of the basal ganglia, more narrowly the globus pallidus represents the medial portion of the lenticular nucleus [2]. In terms of its influence on motor activity, the globus pallidus reflects the site at which the excitatory and inhibitory motor pathways of the motor cortex converge [1]. More specifically, this convergence occurs at the internal part of the globus pallidus. The globus pallidus in turn projects to the thalamus and the thalamus in turn projects to the motor cortex [1]. It is the actions of these thalamic projections that controls the size and force of a movement that the cortex produces; however, given the globus pallidus influences the actions of the thalamus, functionally it is likely difficult to separate one from the other. As a result, the globus pallidus may be perceived as determining how weak or how strong a movement may be [1].

Go/No-Go Task

George Georgiou, Cecilia A. Essau
Roehampton University, London, UK

Synonyms

The go/no-go task is similar to the stop-signal task in that both investigate the ability to inhibit a response.

Definition

The go/no-go is a cognitive task aimed at determining the ability of an individual to inhibit a response deemed inappropriate.

Description

Experimental paradigms measuring response times (RTs) often assess how the information-processing sequence of perception, decision making, and action are organized. A tool commonly employed in this endeavor is the two choice task which typically requires participants to respond to a presented stimulus using one of two possible choice responses [6]. An alternative tool is the go/no-go task where participants are required to either respond (i.e., pressing designated key) or withhold a response (not pressing designated key) depending on whether a go stimulus or a no-go stimulus is presented (Verbruggen & Logan, 2008). It has been argued that compared to the two choice task, the data collected from go/no-go procedure provides a higher signal-to-noise ratio [7]. The stop-signal task paradigm closely resembles a choice reaction task with the exception that during the presentation of a series of trials, a random presentation of a stop signal will appear (Verbruggen & Logan, 2008). The stop signal indicates to participants that a response should be withheld. The ability to suppress a response (i.e., response inhibition) has been extensively investigated using the stop-signal procedure [10] and go/no-go task (Verbruggen & Logan, 2008). Although there is a tendency for some investigators to treat the go/no-go task and the stop-signal paradigm as one of the same, recent evidence has suggested that differentiating the two may be justified upon the grounds that response inhibition may not achieved in the same way across the two paradigms (Verbruggen & Logan, 2008).

Relevance to Childhood Development

The role of behavioral disinhibition is considered fundamental by a number of models of developmental

psychopathology [3]. In general terms, inhibition refers to the ability to ignore extraneous information or to prevent an inappropriate response [5]. One's inhibitory capabilities, whether suppressing a thought, emotion or a particular behavior, is considered to be a key feature of executive control [9]. Executive control refers to a group of interrelated abilities that promote the ability to pursue some thoughts and behaviors whilst suppressing others [1]. With regard to childhood development, inhibitory control is subject to rapid development in childhood between the ages of 3 and 5 [15]. As the capacity of inhibitory control increases with age [17] there is the risk of impairment as implicated in attention deficit/hyperactivity disorder (ADHD) [13].

ADHD is associated with deficits in sustained attention (or inattention), response inhibition, and hyperactivity amongst others [16]. This line of research was mainly prompted by clinical observations linking excessive distractibility, impulsivity, and hyperactivity with failures in inhibition [2]. The go/no-go procedure has proved to be a popular tool in showing that children diagnosed with ADHD exhibit poor inhibitory control [14]. Similar findings were also found with the stop-signal task [12]. There is some evidence, albeit tentative, that behavioral disinhibition has also been found in patients diagnosed with conduct disorder [8]. Nevertheless, there are suggestions that ADHD should be first and foremost be seen as a dysfunction of behavior inhibition [2].

Gonads

Carol D. Daniels
Emporia State University, Emporia, KS, USA

Synonyms

Balls; Testes; Testicles

Definition

From the Greek work, *gone*, meaning *seed*. It refers to a seed producing gland, such as an ovary or a testis [1].

Description

Gonads typically refer to the male sex glands. These glands usually occur in pairs. They are located in an external sac of skin in humans called the scrotum behind the penis. The gonads produce and store sperm and are the male's primary source of male hormones, such as testosterone. These hormones control the development of the reproductive organs and other male characteristics, such as body and facial hair, low voice, and wide shoulders [1].

Relevance to Childhood Development

The male sex glands, gonads, provide the male gamete, or *seed*, that joins with the female gamete to form a zygote

from which the embryo develops. The male seed helps to determine the sex of the zygote and the characteristics inherited from the father. As the male child progresses through puberty, the gonads release the male hormones that control the development of the reproductive organs and other male characteristics [1].

Gordon Diagnostic System

Nina Foster
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Computerized assessment of attention and self control; Computerized behavior assessment; Continuous performance test; GDS

Definition

The Gordon Diagnostic System (GDS) consists of 11 tests that aid in assessing Attention Deficit Hyperactivity Disorder.

Description

The GDS is a portable, microprocessor-based continuous performance test often used in assessing Attention Deficit Hyperactivity Disorder. The GDS can also be used as a monitor of stimulant medication and as a neuropsychological assessment of post concussion syndrome, closed head injury, neurotoxicity, Fragile X Syndrome, and Alzheimer's disease. The evaluative tests used in the GDS are Standard Vigilance Task, Standard Distractibility Test, Delay Task, Preschool Delay Task, Preschool Vigilance "0" Task, Preschool Vigilance "1" Task, Vigilance "3/5" Task, Adult Vigilance Task, Adult Distractibility Task, Auditory Vigilance Task, and Auditory Interference Task [1]. The outcomes of the evaluations are shown on a printout via the automatic printer output on the instrument. The printout notates the number of correct responses, incorrect responses, and failures to respond.

The GDS has been standardized on approximately 1,300 4–16 year olds. Standardization was primarily performed on a limited selection of individuals in the upstate area of New York, but additional protocols from various populations, including deaf, blind, emotionally disturbed, learning disabled, and Spanish-speaking have been gathered [2]. When the GDS is being used for its primary purpose of providing a behavior-based measure of inattention and impulsivity, three of the tests are used: Delay, Vigilance, and Distractibility. The Delay task provides a measure of the child's ability to inhibit impulsive responding. The Vigilance task assesses the child's ability to sustain attention, respond correctly, and inhibit incorrect responding. The Distractibility task assesses the child's ability to differentiate extraneous stimuli while responding correctly, and inhibiting incorrect responses. Moderate correlations with neuropsychological instruments, behavior-based measures, and teacher and parent evaluations of attention deficit hyperactivity disorders have been found although validity studies have primarily been performed by the developers [1, 3]. The developer recommends that the GDS is to be utilized as only one resource of data to be combined with other resources in evaluating and diagnosing attention difficulties.

Grade Equivalents

Marie C. McGrath
Immaculata University, Immaculata, PA, USA

Synonyms

Developmental norms; GEs; Grade scores; Norm referenced scores

Definition

A type of test score describing an individual's performance in relation to the performance of typical students at a given grade level.

Description

Grade equivalent scores are commonly used in reporting students' performance in educational settings. Most often, these scores are used to describe performance on academic achievement tests, though grade-based norms and grade equivalent scores are available for some other types of standardized assessment instruments (e.g., cognitive assessment instruments, speech and language assessment instruments).

Grade equivalent scores can be calculated for a test by finding the median (i.e., the 50th percentile) score obtained by children at each grade level on that test. Children who earn the median raw score for a given grade level are assigned a score equivalent to that grade level. Grade equivalent scores are generally expressed numerically in decimal format, with the number to the left of the decimal representing the grade, and the number to the right of the decimal indicating the number of months completed in that grade. For example, a grade equivalent score of 5.8 on a test would indicate that the student receiving that score answered the same number of items correctly as the typical student who has completed eight months of fifth grade.

Despite their frequent use, grade equivalent scores are prone to misinterpretation. Since grade equivalent scores represent a student's performance on a single test, they should not be interpreted to mean that the grade level represented by the grade equivalent score would be more appropriate for the student, or that, overall, the student is performing at the grade level indicated by the score. In other words, if a fifth-grade student obtains a grade equivalent score of 6.0 on a test of reading skill, it means that that student got the same number of items right on that test as the typical sixth-grader in that test's norming sample; however, it does not necessarily mean that the student reads or requires reading instruction at a sixth-grade level. Additionally, grade equivalent scores do not necessarily increase smoothly as the number of correctly answered items increases. For example, imagine a hypothetical academic achievement test on which the typical third-grader gets 17 items right, the typical fourth-grader gets 19 items right, and the typical seventh-grader gets 21 items right. For a student with a raw score of 17, increasing performance by two points (i.e., to 19) would increase that student's grade equivalent score from 3.0 to 4.0; however, if a student with a raw score of 19 got two additional items right, that student's grade equivalent score would increase much more dramatically (i.e., from 4.0 to 7.0). Finally, if the students who participate in the norming process for a given test are taught academic skills in a different sequence from test-takers, grade equivalent scores are likely to provide inaccurate estimates of skill levels. For these reasons, grade equivalent scores should be reported and interpreted with caution.

Grade Retention

Priscilla Jones, Angela Waguespack
Nova Southeastern University, Fort Lauderdale, FL, USA

Synonyms

Failing a grade; Non-promotion

Definition

Grade retention is the practice in which children are required to repeat a grade level in school because they failed to meet required benchmarks or grade level standards.

Description

Grade retention, which has been increasingly implemented in recent years, is considered one of the most scrutinized

and debated practices in education. Historically, students have been retained by well-meaning school-based decision-makers when it was believed that holding the child back would allow him/her the opportunity to "catch-up" socially or academically with peers. While teacher-based retention continues, since the 2001 No Child Left Behind (NCLB) Act, large-scale test-based retention polices have been enacted by several states in an effort to address student progression and to end social promotion. Students who fail to meet grade level standards, typically assessed by standardized tests, must be retained according to state law. This has resulted in greater numbers of students retained than ever before in the United States.

Recent estimates indicate that as many as 15% of children are retained each year, with boys, minority students, and poor children retained at the highest rates [9]. Grade retention can occur at any grade level, but practices vary depending on the source with teacher-based retentions occurring in the early grade-school years and test-based retentions occurring throughout the school career at grades designated by state policy.

Relevance to Childhood Development

Despite the widespread use of grade retention as an intervention, the preponderance of the research suggests there are many long-term negative consequences for children as a result of this practice. While some studies suggest short-term gains in retainees, meta-analyses involving 80 studies failed to support greater levels of academic achievement in retainees when compared to low-performing promoted peers [7]. Additionally, a strong correlation between retention and high school drop-out exists, with one recent longitudinal study finding that compared to promoted students, retained students were five to nine times more likely to drop out of high school [6]. Further, another study found that retainees were much less likely to enroll in college even if they did graduate from high school [4].

In addition to the lack of support for increased academic achievement when using retention as an intervention, negative social-emotional consequences for retained students have been investigated as well. Retention has been found to give rise to the development of low-self esteem in retained students, since these students are usually teased by other non-retained students [2]. Studies have found that children view being retained as a form of punishment and often feel stigmatized throughout their school career [10]. Further, research suggests that children perceive retention as one of the most significant stressful life events that can occur [1, 11] and that it becomes increasingly stressful as the child ages.

With regard to claims that retention enhances the behavioral and social-emotional functioning of children when compared to promoted students, the research is unsupportive as well. In one study, an existing relationship was found between peer rejection and academic outcomes, especially for retained students [8]. Other studies have indicated that retained students are at greater risk of exhibiting disruptive and aggressive behaviors [3, 6] and display poorer social adjustment and more problem behaviors when compared to matched controls [5].

Given the evidence that grade retention is generally considered harmful in many ways, evidence-based alternatives to retention are currently being investigated and implemented. These include incorporating system-wide prevention efforts such as high quality preschool and early reading programs for targeted at-risk groups, as well as providing effective instructional and/or behavioral interventions for students who are identified as experiencing difficulties [7].

Grey Matter

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Definition

Grey matter is a form of tissue found in the brain and spinal cord that contains neuronal cell bodies and capillary.

Description

Grey matter is a form of tissue found throughout the Central Nervous System. It is so termed based on its characteristic grayish-brown color. Grey matter obtains its color from the neuronal cell bodies and capillaries that make up the tissue [2, 3]. This is important because the functionality and survival of the neurons within the system are dependent upon the integrity of the cell body which controls and maintains the neuronal structure [4]. The presence of grey matter within the various areas of the Central Nervous System demonstrates that nerve cells have their origins and are making rich interconnections in these regions [1]. In terms of its' presence in the Spinal Cord, grey matter is found in the inner part. Functionally, grey matter in the Spinal Cord is composed of cell bodies which help organize movements carried out peripherally [3]. This conduction is made possible by the grey matter also representing the area from which the ventral roots of the Spinal Cord originate. It is through these circuits that transmissions of signals are sent away from the Spinal Cord to the muscles [3]. In regards to the brain, grey matter predominates in the outer layers, forming the cortex, which may be depicted as those areas where functions are housed.

Grief Work

Emily A. Bullington
Spartanburg School District 6, Spartanburg, SC, USA

Definition

Grief work is the working out of psychological issues connected with grief [4].

Description

Grief is a highly personal experience to which some people recover fairly quickly, while others never do. Grief work is often looked at in three stages. It begins with shock and disbelief, during which the bereaved person begins to accept the painful reality of the loss. Next, the person

will gradually let go of the bond with the dead person. They may become preoccupied with the memory of the dead person during this time. The last stage begins when a person readjusts to life by developing new interests and relationships. This pattern of grief work is common; however, grieving does not necessarily follow a straight line from one stage to the next [4].

Grieving

Emily A. Bullington
Spartanburg School District 6, Spartanburg, SC, USA

Synonyms

Anguished; Inconsolable; Mournful; Sorrowful

Definition

Grief is the combination of thoughts and feelings you experience surrounding loss [1]. It is not only a response caused by the death of someone loved but also a response characteristic of the loss of something or someone significant in an individual's life. Grieving is the process of separating oneself from losses for survival, for effecting necessary changes in life, and for fostering new attachments and commitments [2, p. 375].

Description

Grief is a highly personal experience to which some people recover quickly and others never do [4]. Some basic concepts of grief are that it is a natural reaction to loss, each person's grief experience is unique, there are no "right" and "wrong" ways to grieve, every death is different and will be experienced in differing ways, the grieving process is influenced by a multitude of factors, and grieving never ends [6, pp. 4–6].

The type of response a person will have to grieving is individual and unpredictable. While there are common experiences, each person must go through grief in their own way. Some common response types to grief include behavioral, emotional, social, physical, and spiritual [6].

Mauk and Sharpnack [2] describe three grief response phases, which include avoidance, confrontation, and reestablishment. Avoidance is when a person feels shock, denial, and disbelief. The confrontation phase is a highly emotional state when a person realizes that the significant other or loved one is dead. This phase is the one in which grief is often most intense. The reestablishment phase is the gradual decline of acute grief and the start of reentry into the everyday world.

Another widely studied pattern of grief that is similar to the previous one, and also includes three stages, is defined as a process of grief work. Grief work is the working out of psychological issues connected with grief. It often follows the path of shock and disbelief, preoccupation with the memory of the dead person, and resolution. Although the pattern of grief work just described is common, grieving does not necessarily follow a straight line from shock to resolution [4].

Many experts indicate that to speak of grief "stages" is misleading. Neimeyer [3] explains that all mourners do not follow the same path in their journey, but pass through phases at their own pace. He describes three phases in a typical grief process, which include avoidance, assimilation, and accommodation. Avoidance is when a person avoids the full awareness of reality because it is too painful to absorb. People will often act as if the deceased is still alive, or will imagine they see his or her face. This can be a confusing experience, but it can be said to be a normal reaction to loss. A person in this phase may physically feel numb, distant, or detached from their immediate surroundings. At the behavioral level, one may appear distracted, disorganized, and often unable to complete even routine activities of daily life. The assimilation phase begins as a person gradually starts to absorb the full impact of their loss. One will often begin to experience loneliness, sorrow, and the realization of the loved one's absence. Depressive symptoms likely appear during this phase and include loss of motivation, unpredictable crying spells, pervasive sadness, inability to concentrate, and hopelessness about the future. The last phase is accommodation and occurs as the anguish from the assimilation phase starts to blend into an

acceptance and reality of the death. Gradually, a person will reestablish a greater sense of emotional self-control and return to normal daily living habits.

Relevance to Childhood Development

Death is viewed in many diverse ways, especially at different ages in a person's life. Often a person's attitude towards death reflects their past experiences and their personality. Typical changes in the way a person feels toward death across the life span will depend on their cognitive development and on the typical or atypical timing of the event [4].

In general, there are some important things to remember when a child is grieving. These include remembering that children go in and out of grief, not all children talk about their grief, some children do not seem affected at all, play is one way children will deal with grief, it is not unusual for children to experience physical reactions or difficulty thinking, a child's developmental age will influence their reaction to the death, and it is not uncommon for children to believe that they have seen or heard the deceased person [5].

Children usually do not understand death or loss as final. However, infants and toddlers have an intuitive sense that something serious has happened, even if they do not entirely comprehend what it is. These young children are able to sense the emotions in their environment as well as read the expressions of others. Children who are grieving during this stage in their life will often present reactions which are sensory and physical. Some common behaviors expected at this age include crying, biting, separation anxiety, temper tantrums, and general anxiety [6].

As a child becomes preschool age they are naturally egocentric. They believe that they cause things to happen and that the world revolves around them. Death for them is often an experience of abandonment and may even believe that they have somehow caused the death. A preschool age child will often show intense but brief grief responses and may also regress to earlier behaviors such as thumb sucking or baby talk [6].

Children grade-school age see the world in a more literal sense and need concrete and detailed explanations of loss situations. They may begin to question how their lives will be different with the loss of someone, what may be the same, and may even wonder if a person is truly deceased [6]. They also have short attention spans and will move from one feeling to another rapidly. For these children, grief can often be misunderstood because "sad" emotions are quickly turned into happiness and playfulness. One must remember that children grieve with the same emotions that adults do, but for children these emotions come and go in a different way [8]. As children grow older they will begin to understand that death is final. With this feeling of finality, they may also being to worry about their own death and the death of others. The school age child will often show some common behaviors when grieving that include fighting, anger, withdrawal, regression to earlier behaviors, and not completing assignments [6].

It is important to know that many factors can influence how a child copes with death. Some of these include the nature of the death, past experiences with death, response of others to the death, support systems in and outside of the immediate family, as well as consistency and routines [5].

As a child grows older and enters their teen years, their ways of coping with grief continue to change. Adolescence is a time of identity formation and loss must be affirmed as it uniquely impacts the individual person. When an adolescent has a loss that occurs in their life, they are shocked because most of them fell that nothing can happen to them. Our assumptions about the order of the world collapse when loss occurs outside the normally expected timeline of life events [8].

The Dougy Center for Grieving Children (2004) indicates that there are six basic principles of teen grief. They report that grieving is the teens natural reaction to a death, each teen's grieving experience is unique, there are no "right" and "wrong" ways to grieve, every death is unique and experienced differently, the grieving process is influenced by many issues, and grief is ongoing.

When you look at adolescence broken down even further into middle and high school ages, even more differences in dealing with grief can be seen. Middle school students are experiencing a vast amount of disorder due to the physical and hormonal changes in their bodies. When the additional stress of grief is added to this they will likely experience a range of emotional reactions. This is also the time in which a teen will begin to get their principal support from friends rather than family. Some other common grief behaviors to expect in a middle school student include anger, fighting, moodiness, and risk-taking behaviors [6].

As a teen enters into high school they will often become more philosophical about life and death, and may believe that death won't happen to them. Teens at this stage will appear to use an "adult" approach to solving a problem; however, it is important to remember that high school students are not adults yet. Some common behaviors to expect include withdrawal from parents or other adults, pushing the limits of rules, lack of concentration, evidence of crying, sleepiness, angry outbursts, and increased risk-taking behaviors [6].

No matter what age a teenager actually is, their level of emotional and physical maturity, past experiences and family dynamics all influence his or her grief response. A grieving teen may feel conflicted about letting go of the deceased, attached to (yet separated) from the deceased, embarrassed about showing emotions, ambivalent about the person who died, or awkward about being different from their peers [7].

Some overall reactions to grief from a teen may include academic problems, crying, eating problems and disorders, nightmares and dreams, physical reactions, playing, regressive behaviors, suicidal talk or behaviors, sensory experiences. Some common emotions include anger, frustration, guilt, anxiety, isolation, relief, revenge and rage, sadness [7].

Even though grieving manifests itself differently from adults, the needs leading in the direction of resolution are the same [2]. Some basic needs of a grieving teen (or child) include assurances, boundaries, choices, food, listeners, models, privacy, recreation, routines, sleep, and truth [7]. One must remember that a child's grief responses are natural reactions when they are experiencing the loss and separation from someone they were close to and/or loved [2].

Group Homes

Mysti S. Frazier
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Extrafamilial home; In residence; Residential care; Residential group care; 24-hour care

Definition

Group homes are community based care facilities designed to provide resources to children and youth who experience abuse and/or neglect and must be removed from their homes. Group homes also include residential treatment centers for children with mental disorders and/or disabilities [5]. Group homes vary by community and include staffed residential homes and large institutions like residential schools, detention facilities, mental health centers, psychiatric wards, boarding schools, or orphanages (Anglin 2002). They do not include foster homes or family-based homes.

Description

Group home care is one of the most common community-based residential treatment placements for youth with the most difficult to treat combinations of psychiatric disorders, aggressive behavior, and histories of complex and extended personal and family problems [4]. Group homes employ staff members to attend to and teach children daily living and self-care skills, so that they may be able to provide for and take care of themselves. Daily living skills include cooking meals, doing laundry, cleaning, managing money, and learning to interact socially; self-care skills include bathing, dressing, eating, and taking needed medications [5].

It is important to note that many of the children in group homes are not considered orphans; a majority of

these children have families. The families, however, are unable to provide and/or appropriately care for their children for various reasons. It is important for the children to maintain a link to the biological family because there is a chance that they may be reunited if conditions in the family improve (Anglin 2002).

In group homes, the staff is able to help children address issues with relationships, socialization, economic concerns, and emotional well-being (Anglin 2002). All of these functions are characteristic of family life which group home staff members work to incorporate so that children may get the support that is needed as well as become well-rounded individuals. However, there is research to suggest that these settings fall short of providing a family-like atmosphere because they may not provide love and a sense of belonging (Anglin 2002).

The term "group home" implies that a home-like environment is offered; however, since many group home settings are institutional it is hard to create an intimate, loving experience. The staff of the group home is required to maintain control at all times [1]. Therefore, it is in the overall best interest of the children for the staff to maintain a hierarchy and contain problem situations right away; this results in an incongruence between the desired affects of group home living and the reality [1] (Anglin 2002).

Adequate attention to proper group home care involves sincere and constant engagement with the children and for each individual child as to not hinder their positive development [1]. Important factors to consider include the physical environment, opportunities for social interaction with peers and staff, access to adequate food, and positive attitudes from the staff [1]. Appropriate attention to these factors can predict the quality of children's experiences in group homes.

Group Therapy

Michael Block
Azusa Pacific University, Azusa, CA, USA

Synonyms

Group psychotherapy; Psychosocial therapy

Definition

Group therapy is a form of psychosocial treatment where a small group of patients meet regularly to talk, interact, and discuss problems with each other and the group leader (therapist).

Description

A psychologist, psychiatrist, social worker, or other healthcare professional typically arranges and conducts group therapy sessions. In some therapy groups, two individuals or co-therapists may share the responsibility of group leadership. Patients are selected on the basis of what they might gain from group therapy interaction and what they can contribute to the group as a whole.

Therapy groups may be homogeneous or heterogeneous. Homogeneous groups have members with similar diagnostic backgrounds (for example, they may all suffer from depression). Heterogeneous groups have a mix of individuals with different emotional issues. The number of group members varies widely, but is typically no

more than 12. Groups may be time limited (with a predetermined number of sessions) or indefinite (where the group determines when therapy ends). Membership may be closed or open to new members once sessions begin.

The number of sessions in group therapy depends on the makeup, goals, and setting of the group. For example, a therapy group that is part of a substance abuse program to rehabilitate inpatients would be called short-term group therapy. This term is used because, as patients, the group members will only be in the hospital for a relatively short period of time. Long-term therapy groups may meet for six months, a year, or longer. The therapeutic approach used in therapy depends on the focus of the group and the psychological training of the therapist. Some common techniques include psychodynamic, cognitive-behavioral, and Gestalt therapy.

In a group therapy session, group members are encouraged to openly and honestly discuss the issues that brought them to therapy. They try to help other group members by offering their own suggestions, insights, and empathy regarding their problems. There are no definite rules for group therapy, only that members participate to the best of their ability. However, most therapy groups do have some basic ground rules that are usually discussed during the first session. Patients are asked not to share what goes on in therapy sessions with anyone outside of the group. This protects the confidentiality of the other members. They may also be asked not to see other group members socially outside of therapy because of the harmful effect it might have on the dynamics of the group.

The therapist's main task is to guide the group in self-discovery. Depending on the goals of the group and the training and style of the therapist, he or she may lead the group interaction or allow the group to take their own direction. Typically, the group leader does some of both, providing direction when the group gets off track while letting them set their own agenda. The therapist may guide the group by simply reinforcing the positive behaviors they engage in. For example, if a group member shows empathy to another member, or offers a constructive suggestion, the therapist will point this out and explain the value of these actions to the group. In almost all group therapy situations, the therapist will attempt to emphasize the common traits among group members so that members can gain a sense of group identity. Group members realize that others share the same issues they do.

The main benefit group therapy may have over individual psychotherapy is that some patients behave and react more like themselves in a group setting than they would one-on-one with a therapist. The group therapy patient gains a certain sense of identity and social acceptance from their membership in the group. Suddenly, they are not alone. They are surrounded by others who have the same anxieties and emotional issues that they have. Seeing how others deal with these issues may give them new solutions to their problems. Feedback from group members also offers them a unique insight into their own behavior, and the group provides a safe forum in which to practice new behaviors. Lastly, by helping others in the group work through their problems, group therapy members can gain more self-esteem. Group therapy may also simulate family experiences of patients and will allow family dynamic issues to emerge.

Self-help groups like Alcoholics Anonymous and Weight Watchers fall outside of the psychotherapy realm. These self-help groups do offer many of the same benefits of social support, identity, and belonging that make group therapy effective for many. Self-help group members meet to discuss a common area of concern (such as, eating disorders, bereavement, parenting). Group sessions are not run by a therapist, but by a nonprofessional leader, group member, or the group as a whole. Self-help groups are sometimes used in addition to psychotherapy or regular group therapy.

Guilt

Temi Bidjerano
Furman University, Greenville, SC, USA

Definition

Guilt is an adaptive self-conscious emotion, typically evoked in situations of failing to achieve a goal or standard and when failure is attributed to internal transitional states, inappropriate actions, or non-stable internal characteristics such as lack of effort.

Description

Guilt is experienced when an individual fails to meet personal standards or goals even after exerting a great deal of effort to achieve a successful outcome and the end product has personal implications. Individuals experience guilt when they have committed a wrongdoing directly or haphazardly and feel personal responsibility for the consequences [1]. The emotion of guilt includes the self as a frame of reference and involves a certain degree of self-evaluation. Guilt is regarded also as a moral emotion, as it involves some degree of dilemma and conflict; it is based on relationships within a social context and results in the individual's intent to repair the unfortunate situation. The emotion of guilt has specific adaptive purposes. It could prevent transgression as well as encourage reparative behaviors in situations of wrongdoing.

Guilt is experienced in situations of failure attributed to internal factor and when the wrongdoing is perceived as controllable or avoidable [4]. Beliefs about controllability are exemplified by an implicit desire to repair the situation or avoid the wrongdoing in the future, rationalize the misdeed, or confess. In interpreting the wrongful act, the person feels remorseful and regretful. He/she focuses on the behavior that led to the transgression, rather than on making judgments about global imperfections of the self. Guilt co-occurs with other emotional states such as sadness, tension, worry, anxiety and restlessness and is believed to have some genetic underpinning [7]. Gender differences in the experience of guilt are also present. Parent-child transactions in early childhood have been acknowledged to play a substantial role in the socialization of guilt.

Relevance to Childhood Development

Guilt does not typically emerge before the age of 2½ and 3 year and it has both cognitive and social antecedents. One of the prerequisites is the sense of conscience and self-representation, which typically develop between 18 months and 2 years of age. During this age period, the child begins to react with distress when he/she violates a rule or a standard for behavior [3, 7]. The experience of anxiety and discomfort following a wrongful act is considered a precursor of guilt [3]. During the second half of the third year of life, another important cognitive milestone is achieved: the child becomes able to acquire and retain standards and rules for appropriate behavior [4]. Adaptive forms of guilt develop out of parental use of socialization techniques such as reasoning and induction, which consist of clearly defining expectations for appropriate behavior and providing explanation for the nature of consequences of the child's behavioral transgression on others. Induction and reasoning facilitate to a great extent the process of internalization [2, 5]. Evaluative feedback, frequently communicated by parents, enhances the growing child's understanding of the social meaning and significance of his/her behavior and leads subsequently to the internalization of adults' imposed standards for and expectations of acceptable behavior. The growing child acquire the ability to evaluate his behavior in conjunction with those standards, recognizes inconsistencies between the standard and behavior, and experiences discomfort,

anxiety and guilt when they are violated or a transgression is committed [3, 7].

Although young children do experience rudimentary forms of guilt, they do not possess a complete understanding of the emotion; neither can they reason about the factors that trigger it. In younger children's accounts, guilt is often associated with having done something naughty, feelings of regret, and a desire to repair the situation out of fear of being punished. A full understanding of the emotion and its elicitors is achieved later in life when the child acquires the ability to make explicit causal attributions. Before the age of six or seven, children learn to associate guilt with failure. It is not until the elementary school years, however, when they become capable of linking failure to lack of effort or other internal factors perceived in one's control. Thus, older children become more likely to report feeling guilty when failure occurs in the context of avoidable, controllable and preventable factors. In this respect, older children's and adults' understanding of guilt becomes increasingly similar [1, 2, 5].

In addition to normal developmental changes, individual variations in guilt experiences are also present. Girls tend to be more self-conscious and experience guilt more frequently. It has been suggested also that individual differences in temperament could contribute to differential socialization of guilt. That is, a child who is temperamentally predisposed to experience emotions with high intensity, is likely to experience also high levels of distress and discomfort following a misconduct; in turn, the transgression is likely to be attributed to internal to the self characteristics acting as an inhibitor for similar transgressions in the future [3, 7]. Inhibited and fearful toddlers were found to be more prone to internalized conscience at later ages, and therefore, more amenable to socialization and moral internalization [3]. In addition, some children tend to develop maladaptive forms of guilt, the so called "guilt-prone" style, as a result of a repeated exposure to guilt provoking experiences. The proneness to guilt is characterized by rumination over mishaps and misdeeds, blameworthiness, excessively taking responsibilities for negative events, and a sense of unworthiness [7]. It has been suggested that the parental use of socialization techniques such as power assertion and love withdrawal in early childhood is one of the sources of development of maladaptive guilt. Power assertion and love withdrawal are construed as fostering an external moral orientation in the child, which is manifested by lack of concerns about consequences for others and desire to avoid infringement of personal interests. Excessive guilt has been associated also with symptoms of depression [6].

Habit Reversal

Jesse M. Crosby, Michael P. Twohig
Utah State University, Logan, UT, USA

Synonyms

Behavioral intervention for repetitive behavior disorders; Complete habit reversal; Original habit reversal; Simplified habit reversal

Definition

Habit Reversal is a behavioral intervention for repetitive behavior problems. The original treatment consists of approximately 12 procedures organized in four phases: (1) awareness training, (2) competing response practice, (3) habit control motivation, and (4) generalization training [1]. Subsequent research has resulted in a simplified variation of the treatment. Simplified Habit Reversal (SHR) training consists of four procedures organized in three phases: (1) awareness training, (2) competing response training, and (3) social support training. SHR can be completed in one to two sessions, and it is reinforced through application outside of the session and additional booster sessions. SHR has been found to be effective in treating a wide variety of repetitive behavior problems found in children including motor and vocal tics and Tourette's disorder, thumb/finger sucking, nail biting, trichotillomania, skin picking, and stuttering [7].

Description

Habit Reversal

The original Habit Reversal treatment consists of several procedures organized in four phases: (1) awareness training, (2) competing response practice, (3) habit control motivation, and (4) generalization training [1]. The purpose of awareness training is to make the client aware of the habit through four procedures: (1) response description – the client is required to describe the details of the habit to the therapist while reenacting a typical instance; (2) response detection – the client is taught to detect each instance of the habit alerting them when it has occurred; (3) early warning – the client practices detecting the earliest sign of the habit; and (4) situation awareness – the client identifies situations, persons, and places associated with the occurrence of the habit.

In the competing response phase, the client is taught a specific response pattern that would be incompatible with the habit, thus preventing the habit from occurring. This incompatible response should involve the muscles opposite to those involved in the habit, be capable of being maintained for several minutes, produce heightened awareness of the muscles involved in the habit, be socially inconspicuous and compatible with normal activities, and strengthen the muscles antagonistic to the habit movement. The client is asked to perform the competitive response for 3 min after a premonitory urge to perform the habit or the actual occurrence of the habit. Examples of competitive behaviors include contraction of the neck muscles instead of head jerking and clenching the fists instead of nail biting.

The purpose of the habit control motivation phase is to increase motivation to engage in the treatment consistently. This is done by reviewing the inconveniences, embarrassment, and suffering associated with the habit and implementing a social support system that includes positive reinforcement for success and noting the occurrence of habits and reminding the client to continue practicing the treatment. For children with little or no motivation, parents/caregivers are instructed to physically guide the child through the exercises.

Generalization training is performed to ensure that the client is able to control the habit in everyday situations. The client is asked to practice the exercise through a symbolic rehearsal procedure in which they imagine common habit-eliciting situations, the detection of a habit, and practice performing the competing behavior. Additional practice can be given by engaging the client in casual conversation

Sam Goldstein & Jack A. Naglieri (eds.), *Encyclopedia of Child Behavior and Development*, DOI 10.1007/978-0-387-79061-9,

and identifying the occurrence of habits and then practicing the competing behavior.

Simplified Habit Reversal

The SHR treatment can be given in four sessions. The first 1 h session includes an interview, standardized assessments, and the establishment of a system for data collection. The SHR is implemented during the second 1 h session, and the last two sessions are 30 min booster sessions to monitor progress, review treatment implementation, and address any further problems [10].

The information gathered during the initial interview includes identifying the habit, the possible functions of the habit, and the sensory experiences surrounding the habit. The purpose of data collection is to monitor the effectiveness of the treatment and to identify any needed modifications to the treatment. Arrangements should be made to collect data at home in situations where the habit is most likely to occur using video monitoring, parent monitoring, or self-monitoring. Standardized assessments are given to detect the presence of any common comorbid conditions (e.g., depression, anxiety, ADHD). Clients are also asked to bring a person to the next session to help them with the treatment outside of the session (usually a parent/caregiver).

The implementation of SHR in the second session consists of awareness training, competing response training, and social support training. Awareness training contains two procedures: (1) response description, and (2) response detection; the purpose of which is to help the client recognize the habit and the associated warning signs. After giving the rationale for the treatment, the client is asked to describe both the habit and the warning signs in detail. The purpose of response detection is to help the client recognize and acknowledge the actual occurrences of the habit as well as the warning signs. The client is asked to identify both simulated and actual occurrences of the habit and the warning signs.

Competing response training teaches the client to engage in a behavior that is incompatible with the habit or the warning signs. This includes choosing a competing response, demonstrating the proper use of the competing response, teaching them to use the competing response, and having the client demonstrate the use of the competing response. The competing response could be anything that makes it difficult to engage in the behavior, and it should be socially acceptable as well as acceptable to the client. Some examples of competing responses include diaphragmatic breathing for vocal tics, depressed shoulders for shoulder jerking, pressing the lips together for jaw stretching, and making a fist with both hands for nail biting thumb/finger sucking, trichotillomania, and skin picking.

Social support training is provided to ensure treatment compliance. The primary responsibility for the social support is to help the client remember to use the competing response. The social support person is usually asked to praise the client when he or she is seen using the competing response correctly, and remind the client to use the competing response when seen engaging in the habit. Small rewards or tokens for larger rewards are often used to help children participate in SHR outside of the therapy sessions. The social support person is invited to participate in the session after the initial SHR training has occurred, and the process is demonstrated so that they understand the goals and procedures of the treatment. The booster sessions are used to review the data, address any difficulties with the treatment, and to review the procedures.

Research

Because the original Habit Reversal treatment is a package made up of several components, it was unclear which components were actually necessary for treatment effectiveness [4]. The original treatment package is also time consuming and labor intensive, so subsequent research has sought to identify the necessary components for treatment effectiveness and to simplify the procedure.

Awareness training and competing response training when used together have been found to be as effective as the original Habit Reversal treatment in the treatment of motor tics [3]. This has been supported in additional research with tics and nervous habits [4]. Social support was also found to be an important component when working with children [9], but the evidence on the inclusion of this component is mixed depending on the population of interest as later research with a college age population indicated that the social support component was unnecessary for the intervention to be effective [2].

Competing response training is thought to be central to treatment effectiveness [8]. In the original Habit Reversal procedure, it was believed that the competing response lead to a decrease in the habit behavior because it was physically incompatible with the habit behavior [1]. Thus, competing behaviors would have to include opposite muscle groups to those used in the habit behavior. However, subsequent research has demonstrated that both similar and dissimilar muscle groups are equally effective in reducing tics and habit behaviors [5, 9].

The necessary duration of the competing response has also been a subject of investigation [6]. In a study with

adult nail biting, it was found that both 1 and 3 min competing response durations lead to both short-term and long-term treatment effectiveness. Five second competing response durations lead to short-term improvements, but the effects were not maintained long-term.

Clinical Applications

In a child population the original Habit Reversal procedure has been shown to effectively treat motor tics including head/shoulder jerking, elbow flapping, eye blinking, grimacing, and head shaking. Simplified variations have been equally as effective in treating similar motor tics in children. The original and simplified versions have also had limited success in treating the motor and vocal tics and Tourette's disorder in children. Both the original procedure and the simplified variations have been used to effectively treat numerous nervous habits in children including finger sucking, thumb sucking, nail biting, hair pulling, and scratching. Both treatments have also proven effective in treating stuttering in children [7]. The application with adult populations is similar as both the original and simplified procedures have effectively treated repetitive behaviors.

Even though Habit Reversal has strong empirical support, there are still participants who do not respond to the treatment, and clinically, it has been found that additional procedures are often required. Current applications of the treatment typically augment SHR with cognitive restructuring procedures or the acceptance and mindfulness procedures of Acceptance and Commitment Therapy (ACT) and Dialectical Behavior Therapy (DBT).

Habituation

Brady I. Phelps
South Dakota State University, Brookings, SD, USA

Definition

An innate, unlearned reflex that is elicited in response (unconditioned response) to a biologically-significant stimulus (unconditioned stimulus) will typically show habituation if the stimulus is repeated. That is, measures of the response will show orderly decreases in magnitude as the stimulus is repeatedly applied. This change in behavior, known as habituation, can be seen in the withdrawal responses of various invertebrates, including protozoa to tactile stimulation, in freezing-defensive responses of rodents to auditory stimuli, and in the orienting responses of human infants to complex auditory and or visual stimuli, and is one of the most fundamental properties of behavior. More simply put, habituation is the process by which a stimulus loses its attention-grabbing properties, i.e., its "novelty," and decreases in responsiveness to the stimulus are seen when the stimulus is presented repeatedly or for an extended time period. An organism ceases to engage in attending or other responses to the stimulus; the stimulus comes to be ignored [3, 7]. Habituation is often termed "non-associative learning," since only one stimulus is involved and no associations are formed; Habituation is considered one of the most basic forms of behavior change from experience and learning [3, 7].

For some unlearned, innate reflexes, the repeated presentation of the eliciting stimulus results in an increase in measures of the reflex; this effect is referred to as sensitization and is the opposite effect of habituation [8, 13].

What are Some of the Properties of Habituation?

The formal study of habituation goes back nearly a century being described by writers in the early twentieth century, with the basic properties being outlined in the 1930s and again in the 1960s and 1970s. Some nine basic features of habituation were formally outlined and have come to serve as a formal definition of habituation:

1. If a specific stimulus elicits a response, repeated presentations of that stimulus result in decreased response or habituation; the decrease is typically an orderly function of the number of stimulus presentations.
2. If the stimulus is subsequently withheld, the response showing habituation will tend to return or recover with the passage of time, termed spontaneous recovery.
3. If the habituation experience and subsequent opportunity for recovery are repeated in a series, then habituation will progress more rapidly.
4. With all other variables held constant, the higher the frequency of stimulation, the more rapid and pronounced is habituation.
5. With weaker stimulation, habituation will progress more rapidly and be more pronounced.
6. The effects of habituation training may progress below baseline measures of the response.
7. If habituation occurs to a specific stimulus, then habituation to similar stimuli via stimulus generalization also occurs.
8. Presentation of an irrelevant stimulus will result in the recovery of the habituated response, termed dishabituation.
9. With repeated presentation of the dishabituating stimulus of #8, the degree of resultant dishabituation is decreased or shows habituation itself [8, 19].

A modified list of defining features has also been put forth with the following additional defining characteristics:

1. The process of habituation will be disrupted by any unpredictable changes in the eliciting stimulus.
2. Habituation will occur more slowly to stimuli that are presented in a varying manner relative to stimuli presented in a constant, unchanging manner.
3. Spontaneous recovery may occur faster after more rapid rates of stimulus presentation relative to slower rates of stimulus presentation.
4. Spontaneous recovery may be incomplete recovery in that some habituation will persist over a long-time period.
5. Habituation will be observed for most if not all animal species; habituation occurs in response to most stimuli, including events without ingestive consequences such as lights and noises. The rate at which habituation will be observed will differ as a function of the species, the stimuli employed, the responses being measured as well as the individual subject [11].

As defining features, any unlearned behavioral stimulus-response contingency is said to display habituation if the response decrement shows these properties.

How is Habituation Studied with Infants?

In general, studies of human infant habituation will employ variations of some basic protocols and habituation is a means of non-verbal assessment of learning [18]. In measuring the rate of a reflex such as the sucking reflex, researchers will measure the initial baseline rate of sucking to a pacifier equipped with transducers to measure muscle contractions applied to it. Then an auditory stimulus will be presented such as a human voice uttering a speech phoneme such as "ba." In response to a novel stimulus such as this, the rate of sucking will predictably increase but come to decline to baseline levels as "ba" is repeatedly presented, showing habituation. If the phoneme "pa" were to then be presented, the rate of sucking would again increase, demonstrating that the infant can discriminate between these two stimuli [2].

To measure more complex responses, slightly different procedures are used. When an intense or novel stimulus is presented, an orienting response is elicited and an infant (or any person) turns to look and fix their gaze at the source of a visual stimulus or turns their head towards the source of an auditory stimulus, as well as show changes in heart rate, EEG patterns and other autonomic responses. Initially, infants will show this orienting (or orientation) response to a stimulus but after repeated trials of stimulus presentations, infants will no longer respond to the stimulus, showing habituation of the orienting response [14–16]. Researchers in human development have used measures of the orienting response as assessment tools of complex human development, which will be described in the next section.

Habituation procedures have increasingly been employed to assess the covert-behavioral abilities of preverbal infants to study the development of perception, remembering, and what is termed "information processing" as part of basic developmental research [16]. In addition, the measures of habituation obtained with infants have been

shown to be a reliable predictor of long-term development. Indices of the speed or efficiency with which infants show habituation have been shown to predict outcomes in behaviors such as language acquisition as well as more general behavioral outcomes such as verbal and nonverbal intelligence. Infants who show difficulty during habituation or habituate at slower than normal rates have been found to be at increased risk for a range of significant developmental delays. Despite its widespread use, some writers have argued that the precise psychometric parameters of habituation need to be established before any definitive and significant dialog on the predictive value of habituation can be conducted [6, 9]. Some such studies have also been criticized for using highly artificial events as stimuli, such as an artificial voice box, instead of a stimulus with higher ecological validity, recordings of actual human utterances as auditory stimuli.

In spite of cross-study comparisons being obfuscated by procedural differences as well as in the response being measured and that normally-developing infants show a range of individual variations in habituation, acceptable measures of test–retest reliability have been obtained for some measures of habituation. Unfortunately, few such data exist for populations of high-risk infants, among whom the pertinent data would be of greater interest [4, 6].

Why and How Does Habituation Occur?

The observation that habituation is so catholic points to an obvious and basic adaptive significance. Constantly responding to meaningless stimuli would be taxing and wasteful to any organism; learning to not respond to biologically-irrelevant events while still responding to events that are biologically-significant has clear survival value [5, 7].

For some stimulus-response contingencies that show habituation, the physiological mechanisms have been identified and while habituation has 9 (or 14) defining features, only one established physiological process has been elucidated. In studies of simple reflexes of invertebrates, such as a defensive-withdrawal reflex to tactile stimulation, the organism ceases to respond as the repeated stimulation causes a dampening in the synaptic connections between the sensory neuron receptor to an effector motor neuron [7, 17]. The sensory neuron will continue to release its neurotransmitter in response to a different stimulus and the reflex will still occur to a different stimulus but not to the stimulus to which habituation has occurred. That is, the observed change in responsiveness will be stimulus specific but show stimulus generalization to physically similar stimuli [7, 10].

In terms of identifying the biological bases of habituation in vertebrates, less progress has been made but research so far points to similar neural events taking place in distinct lower brain areas depending upon the sensory modality of the stimulus and the nature of the response undergoing habituation. Little if any research has been conducted into the biological basis of habituation in humans but the infrahuman models of habituation are considered more or less applicable [10, 12].

Habituation is a ubiquitous behavioral phenomenon, seen with a wide variety of reflexes of a wide range of organisms in response to repeated stimulation and since it is so universal, it has been argued as having adaptive value [7, 10, 12]. Whether it merely reflects basic behavioral processes such as learning or more complex actions such as attention or memory is debated [1, 7]. Researchers in human development have studied habituation both for purposes of basic research as well as a possible diagnostic mechanism to map and possibly predict developmental delays and or disorders. Habituation will continue to be the subject of human development research for many years to come.

Halcion®

Anisa Fornoff
Drake University, Ankeny, IA, USA

Synonyms

Triazolam

Definition

A prescription medication FDA approved for the short-term treatment of insomnia (difficulty sleeping).

Description

This medication is a benzodiazepine, a central nervous system depressant, available in tablets.

The recommended starting dose for this medication is 0.125 or 0.25 mg taken once a day at bedtime. Maximum suggested dose is 0.25 mg a day. This medication should only be taken as directed by a doctor and is usually taken only for 7–10 days. This medication may become habit forming.

This medication should be taken with or without food. Avoid drinking alcohol and grapefruit juice. It is recommended to be ready for bed, as this mediation acts very quickly. Inform your doctor if you have liver or kidney disease or other medical issues. It is very important that you do not take more of this medication than your doctor prescribed.

Some side effects are listed here: drowsiness, dizziness, confusion, memory impairment, headache, amnesia, lightheadedness, upset stomach, and blurred vision. Certain side effects may go away during treatment. Tell your doctor immediately if you notice the following: slow heartbeat, swelling, or trouble breathing. Signs of an overdose of this medication are slurred speech or confusion, severe drowsiness, severe weakness, and staggering. If these should occur, seek medical attention immediately.

This medication should be stored out of reach of children and pets and away from light, heat, and moisture.

Relevance to Childhood Development

Halcion® is not FDA approved for use in children younger than 18 years old.

Women should let their doctor know if they are pregnant or planning to become pregnant. This medication has been shown to cause adverse effects to the fetus. Breastfeeding is not recommended while taking this medication.

Hallucinogenic Drugs

►Hallucinogens

Hallucinogens

Ioana Boie
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Hallucinogenic drugs; Psychedelics; Psychoactive drugs

Definition

The term defines substances that produce hallucinations. A number of diseases can also play a role in hallucination, such as some infections, acute brain injuries, delirium, or as a result of high fever. Additionally, poisoning or reactions to toxic substances may lead to psychotic symptoms, as can withdrawal from certain substances (e.g., barbiturates).

Description

The most common hallucinogenic substances can be classified as indole-type hallucinogens and the substituted phenethylamines. The first group, the indole-type, have a structure similar to serotonin, a neurotransmitter, which can disrupt or alter neurotransmission in neurons using serotonin. This group includes Lysergic Acid Diethylamide (LSD), Dimethyltryptamine (DMT), Psilocybin, and Psilocin. The second group, the substituted phenethylamines, are made of substances with similar structures as phenethylamine-type neurotransmitters, such as norepinephrine, epinephrine, and dopamine. These hallucinogens include Mescaline; 2,5-dimethoxy-4-methylamphetamine (DOM or STP); and 3,4-methylenedioxy-amphetamine (MDMA or ecstasy). Because of their structure, these substances also have stimulant properties, aside from the hallucinogenic ones.

Other drugs may have psychoactive properties and cause psychotic symptoms. Stimulants, such as amphetamine, methamphetamine or cocaine, as well as marijuana and hashish may cause hallucinations. Hallucinations in this context are part of a more complex behavioral syndrome, characterized by the alterations of the level of consciousness, and distorted perception of the body and of the environment caused by the disruption of the brain's ability to process the information received through the senses. Hallucinogens affect the autonomic activity in that they can affect the sympathetic and parasympathetic nervous systems, with symptoms such as pupil dilation, exaggerated reflexes, increase in blood pressure, increased body temperature, nausea, and increased heart rate. Other manifestations are acute mental effects such as anxiety, panic attacks, paranoid ideation, confusion and delirium. Some symptoms may persist in clusters and can be diagnosed as hallucinogen-induced mood disorder, hallucinogen persisting perception disorder, and hallucinogen-induced psychotic disorders.

Halstead, Ward C.

Anna Mazur-Mosiewicz, Raymond S. Dean
Ball State University, Muncie, IN, USA

Life Dates

1908–1968

Introduction

Halstead was an American psychologist [4] best known for his studies of brain-behavior relationships. With his student, Ralph Reitan, Halstead developed a series of psychological tests that laid foundations for the first fixed neuropsychological battery, the Halstead-Reitan Neuropsychological Test Battery (HRNB). Halstead also proposed using neuropsychological measures to describe neurobehavioral aspects of various diseases and impairments, such as chronic brucellosis and essential hypertension. Moreover, he was interested in the neuropsychological changes involved in the process of aging, biological bases of memory, and auditory and visual perception.

Educational Information

Halstead received his Ph.D. in physiological and comparative psychology from Northwestern University in 1935. After graduating, Dr. Halstead taught at the Medical School at the University of Chicago. During the 1930s and 1940s,

he established a working relationship with two neurosurgeons, Percival Bailey and Paul Bucy, and started the first full-time laboratory for the examination and evaluation of brain-behavior relationships in humans [6].

Halstead's approach to evaluating patients focused on the practical aspects of rehabilitation and adaptive abilities. His observations of patients with cerebral lesions led him to conclude that brain-damaged individuals had wide ranging deficits, of which severity could not be adequately identified or evaluated by any of the existing cognitive tests. Halstead studied brain-damaged persons in their routine and everyday living situations; he noticed that most of them had difficulties with understanding the complex situations and problems, analyzing circumstances, and reaching meaningful conclusions about situations in everyday life. Therefore, many of the assessment procedures developed by Halstead focused not only on the ability to solve a specific problem, but also on the ability to observe and analyze the components of the problem. Working with his patients, Halstead devised and tested an array of tasks that were originally intended to distinguish patients with bran impairments from healthy individuals. These tasks were re-examined by Halstead's student, Ralph Reitan, and eventually formed the nucleus of the HRNB. Ralph Reitan began working with Halstead in his laboratory in the 1940s and extended the work of Halstead by assembling a battery of tests for the comprehensive evaluation of brain-damaged individuals [6, 9].

Accomplishments

Halstead major accomplishment is his impact on the field on neuropsychology and neuropsychological assessment [7, 8]. He was the first to design and clinically study tasks that evaluated the functioning of the brain and nervous system. His work lead to the development of the HRNB, which is shown to be sensitive to not only the effects of brain damage, but also impairments associated with head trauma, tumors, cerebro-vascular accidents, infections, degenerative diseases, learning disabilities, and specific neurological disorders. As such, the HRNB assists clinicians with the identification of a broad range of neurological variables including location, type, severity, and status of brain lesions [1, 2, 5].

Halstead also authored the biological theory of intelligence, which was first described in his book, *Brain and Intelligence: A Quantitative Study of the Frontal Lobes* [3]. Halstead's theory was based on four factors: central integrative field, abstraction, power, and direction. Although the four-factor model of intelligence has not become widely accepted, the theory has been incorporated not only in the HRNB, but also in the model of brain-behavior relations that is the most commonly used in the implementation and interpretation of the Halstead-Reitan battery [6].

Contributions

Halstead's major contribution to the area of clinical neuropsychology was the development of a series of tests that evaluated the brain-behavior relationship in individual subjects. Additionally, he added to the overall body of knowledge in neuropsychology through his study of differential dependence of his tests on various areas of the cerebral cortex.

Halstead authored and researched the original set of tasks that became a core battery of the HRNB. Currently, the HRNB is one of the most researched and widely used clinical measure of the integrity and functioning of the brain in North America. Halstead's work and the HRNB laid the groundwork for a rehabilitation program for patients with brain damage.

Synonyms

Halstead-Reitan battery; HRB; HRNB; Neuropsychological assessment

Definition

The Halstead-Reitan neuropsychological test battery (HRNB) is a compilation of neuropsychological tests designed to evaluate the functioning of the brain and nervous system in individuals aged 15 years and older. Although the test was designed as a tool to detect brain damage, the HRNB has shown to be effective in identifying impairment associated with head trauma, tumors, cerebro-vascular accidents, infections, degenerative diseases, learning disabilities, and specific neurological disorders. The HRNB assists clinicians in the identification of a broad range of neurological variables including location, type, severity, and status of brain lesions [2, 3, 8, 10].

The Halstead-Reitan tests evaluates a wide range of nervous system and brain functions, including: visual, auditory, and tactual input; verbal communication; spatial and sequential perception; the ability to analyze information; form mental concepts and make judgments; motor output and attention; and concentration. The battery does not include specific tests of memory; rather, memory is evaluated within the context of other tests. Administration time for the complete HRNB takes 4–8 h. Test results are affected by the examinee's age, education level, intellectual ability, and – to some extent – gender or ethnicity, which should be taken into account. Of additional importance is the fixed nature of the Halstead-Reitan, which may lead to unnecessary information being gathered, or other information not assessed within the battery being missed [2, 8].

The core tests of the HRNB were developed by Ward Halstead in the 1940s as the part of a larger series of tests sensitive to brain injury [4]. These tests were later combined into a fixed battery by Ralph Reitan. Since its origins, the Halstead-Reitan instrument has grown by gradual addition and revision of its tests. Currently, the HRNB is one of the most researched and widely used measure of integrity and functioning of the brain [3, 9].

The HRNB laid the groundwork for a rehabilitation program for patients with brain injuries, the REHABIT [9]. The REHABIT integrates neuropsychological evaluation with cognitive retraining, using an approach that aims at restoring the individual's functional ability structure (as contrasted with approaches focusing on highly specific deficits or extremely general, non-specific notions of brain damage).

The HRNB core battery includes the following tests: (1) *Category Test*, (2) *Tactual Performance Test*, (3) *Seashore Rhythm Test*, (4) *Speech-Sounds Perception Test*, and (5) *Finger Tapping Test* (or *Finger Oscillation*). These five tests yield seven scores, three of which are derived from the *Tactual Performance Test* (*Total Time, Memory, Location*), which are used to calculate the Impairment Index. Additional Tests in the battery include the *Reitan-Indiana Aphasia Screening Test*, *Grip Strength*, *Sensory-Perceptual Examination*, *Tactile Form Recognition*, and *Trail Making Test* [5]. The HRNB is typically administered along with a Wechsler Intelligence Scale (i.e., The Wechsler Adult Intelligence Scales or Wechsler Intelligence Scales for Children) and a comprehensive measure of personality (i.e., Behavior Assessment System, or Minnesota Multiphasic Personality Inventory) [11–13].

Historical Background

Halstead laid the foundation for the HRNB when he noted that individuals with cerebral lesions displayed a multitude of deficits including motor problems, sensory perceptual problems related to right or left side of the body, and confusion about events and activities. In Halstead's opinion, none of existing intelligence tests were able to measure and assess these deficits. He addressed this problem by creating a series of 10 tests that were based on his biological theory of intelligence. Halstead's biological theory of intelligence was based on four factors: (1) central integrative field, (2) abstraction, (3) power, and (4) direction. Although Halstead's four-factor model of intelligence has not become widely accepted, the theory has been incorporated not only in the HRNB, but also into part of the model of brain-behavior relations that is most commonly used in interpretation of the Halstead-Reitan battery [9].

To create and select the tests, which later became the core of the HRNB, Halstead experimented with tasks that required his participants not only to solve problems, but also analyze and define the problems. His tests were published in 1947 in his text, Brain and Intelligence: A quantitative Study of the Frontal Lobes. Seven of the original 27 Halstead's tests have stood the test of time and now form the core of the Halstead-Reitan tests [8].

Reitan was a doctoral student of Halstead's who started to work with Halstead's tests during the 1950s.

Using seven selected tests, Reitan successfully differentiated individuals with and without brain injury. As existing intelligence test were not able to identify or assess brain injury, Reitan's results showed that neurological assessment of cerebral impairment should be based on a comprehensive clinical approach. In the following years, Reitan removed three of Halstead's tests due to their low ability to differentiate patients with brain injury form non-impaired individuals. He replaced the tests with new measures such as *Trail Making A*, *Trail Making B*, *Sensory Perceptual Examination*, and *Reitan-Indiana Aphasia Screening Test* [2, 8].

The NHNB has been adopted for use with younger populations and released in two new versions: the Halstead Neuropsychological Test Battery for Older Children (HRNB-C) released in 1974 and the Reitan-Indiana test battery for children (RITB-C) released in 1969. The HRNB-C is designed for examinees age 9–14 years, and the RITB-C is designed for examinees age five to eight. Both children versions use subtests from the HRNB, but contain different instructions and some of the subtests have been added or subtracted from the original battery.

Selected Tests from the HRNB

Category test. The Category Test requires the examinee to formulate and test a hypothesis and gives the examinee a positive or negative feedback regarding the hypothesis. Based on the feedback, the examinee can adjust or modify the hypothesis. The Category Test uses a large projection box. Although a computer and book versions of the test exist, the information about their validity and reliability are less available than the information about the original version of the Category Test. The original test requires the examinee to sit in front of a 10-by-8-inch screen on which a series of figures are projected. A total of 208 pictures consisting of geometric figures are presented. For each picture, the examinee is asked to decide whether they are reminded of the number 1, 2, 3, or 4. The examinee must press one of the four keys that corresponds to their number of choice. Each correct answer is rewarded with a pleasantly sounding bell, incorrect answers are punished with a buzzer. The pictures are presented in seven subtests. Correct answers rely on abstract thinking and are derived from color, shape, size, figure, and memory clues. The score is based on a total number of errors made by the examinee. The Category test is the most sensitive of all Halstead-Reitan tests to the effects of brain damage, but does not help determine localization. The test evaluates abstraction ability, or the ability to draw specific conclusions from general information. Related abilities are solving complex and unique problems, and learning from experience, concept formation, abstractions, memory, reasoning, hypothesis testing, and is a classic measure of executive functioning.

Tactual performance test. The Tactual Performance Test is one of the most complex tasks of the HRNB. The examinee is blindfolded before the test begins and seated in a chair. On the table in front of the examinee is a form board containing ten cut-out geometric shapes (cross, circle, square, etc.) and ten wooden blocks matching those shapes. The examinee is first instructed to place the blocks in their appropriate space on the form board using only the dominant hand. The same procedure is repeated using only the non-dominant hand. The third step is to complete the tasks using both hands. After the examinee completes the third task, the form board is placed out of sight and the blindfold is removed. The examinee is then given paper and pencil and asked to draw the form board and the shapes in their proper locations. There is a time limit of 15 min for each trial, or each performance segment. Scoring involves recording the time to complete each of the three blindfolded trials and the total time for all trials combined (time score), the number of shapes recalled (memory score), and the number of shapes drawn in their correct locations (localization score). Generally, the trial for the non-dominant hand should be between 20 to 30 percent faster than the trial for the dominant hand, due to the benefit of practice. If the non-dominant hand is slower than the dominant hand or more than 30 percent faster than the dominant hand, brain damage is possible. Injuries of the arms, shoulders, or hands can also affect performance and should be considered during the test interpretation. Scores should be adjusted depending on education level and may vary depending on age. The Tactile Performance Test allows the clinician to compare left and right hemispheres and estimate the general efficiency of the brain. This test measures sensory ability, particularly; tactual discrimination, nonvisual special awareness, and tactile awareness. It also evaluates motor skills, nonvisual figural memory, ability to learn, and commitment.

Seashore rhythm test (*rhythm test*). The Seashore Rhythm Test requires the examinee to listen to tape-recorded pairs of rhythmic sounds and determine whether the sounds are the same or different. The test contains thirty pairs of sounds. For each pair, individuals respond to the tasks by marking "S" or "D" respectively on their answer sheets. The pairs are grouped into three subtests. The Seashore Rhythm Test evaluates auditory attention, concentration and perception as well as and the ability to discriminate between non-verbal sounds. The test helps detect brain damage, but not localization of damage.

Adequate hearing and visual abilities are necessary to take this test. Scoring is based on number of correct items, with higher scores indicating less impairment.

Speech-sounds perception test. The Speech Sounds Perception Test requires the examinee to listen to tape-recorded nonsense syllables containing the "ee" sound. After listening to each syllable, the examinee is required to identify the correct spelling of the sound from several options. The test evaluates auditory attention and concentration, the ability to discriminate between verbal sounds, and auditory-visual integration. The Speech Sounds Perception Test may also indicate attention deficits or hearing loss. The research shows that individuals with left-hemispheric lesions tend to perform poorly on this test due to verbal comprehension component.

Finger tapping test (*finger oscillation*). The Finger Tapping Test is a measure of fine motor speed and coordination. The examinee is asked to place one hand palm down, fingers extended, with the index finger resting on a lever that is attached to a counting device. The examinee is instructed to tap the index finger as quickly as possible for 10 s, keeping the hand and arm stationary. The test assesses both dominant and non-dominant hands. The task is repeated up to 10 times till five appropriate samples are obtained. Scoring involves using the five accepted trials to calculate an average number of taps per trial for each hand. The test is sensitive to fine motor problems, brain impairment, and laterality of brain lesions. In general, the dominant hand should perform ten percent better than the non-dominant hand, and decreased performance in one hand generally is indicative of contralateral hemispheric weakness.

Reitan-Indiana aphasia screening test. The Reitan-Indiana Aphasia Screening Test is a modification of the Halstead-Wepman Aphasia Screening Test. The examinee is required to name objects, understand spoken language, identify different parts of the body, copy simple geometric shapes, identify numbers and letters, produce spoken language, use simple mathematical skills, and discriminate between right and left. These tasks are designed to elicit responses that are indicative of pathognomic signs of brain damage or are useful in making a diagnosis. Excessive difficulty or failure related to any tasks of the Reitan-Indiana Aphasia Screening Test are useful in identification of dyscalculia, expressive aphasia, receptive aphasia, auditory dysgnosia, visual dysgnosia, dysnomia, right/left confusion, spelling and construction dyspraxia. Scoring of the test can be executed in two different ways. Some clinicians score each item as passed or failed and calculate the total number of errors. Another approach is to look at each task independently and interpret the failures on specific tasks as indicative of a deficit in these areas.

Grip strength. The Grip Strength Test is designed to assess motor skills of the upper extremities. The examinee is asked to stand and with the arms close to his or hers sides while holding a hand dynamometer in one hand. Then, examinee is then instructed asked to squeeze the dynamometer as hard as possible. Alternate trials are repeated for dominant and non-dominant hand. The hand dynamometer can be adjusted to fit different hand sizes; thus, it can be used with children, adolescents, and adults. The Grip Strength Test is sensitive to lateralized impairment in the brain hemisphere contralateral to the weakness observed in either hand. The test also assesses sensorimotor difficulties, and it is used with patients with brain lesions and degenerative diseases that involve motor functions.

Sensory-perceptual examination. The Sensory-Perceptual Examination is composed of several different tasks that assess the integrity of the examinee's auditory, tactile, and visual sensory abilities. The test consists of a tactile finger localization task, auditory perception tasks, visual perception task, and it detects how accurately the examinee is able to perceive unilateral and bilateral sensory stimulation. The test assesses the ability to identify shapes without visual stimuli, the ability to identify the location of unilateral and bilateral sensory stimulation, and visual and auditory acuity. The Sensory-Perceptual Examination measures the auditory, kinesthetic, and visual sensory modalities independently of one another. Moreover, this test is sensitive to laterality of brain impairment. Examinees with lateralized lesions can often identify stimulation when it is limited to one side of the body, but may struggle with the recognition of stimuli that are presented simultaneously on both sides of the body.

Trail making test. The Trail Making Test is composed of two tasks, Trail Making A and Trail Making B. During the Trail Making A, the examinee is presented with a page with 25 numbered circles randomly arranged. The examinee is then asked to draw lines between the circles in increasing sequential order until they reach the final circle. The Trial Making B is a page with circles containing the letters A through L and 13 numbered circles intermixed and randomly arranged. The task requires the examinee to connect circles alternating from numbers to letters in a correct sequential fashion. If the examinee makes a mistake, the clinician quickly points out the mistake, and the examinee is asked to continue the task from the last correct circle. The score is the number of seconds to complete each part. Any errors made during the tasks increase the total time. The test evaluates global cerebral functioning due to the symbolic recognition, which is a left-hemispheric task, and the visual scanning component, which is considered a right-hemispheric function.

The Trial Making Test also assesses mental flexibility, inhibition, processing speed, integration of visual and motor functions, and visual attention and perception.

Tactile form recognition. The Tactile Form Recognition Test requires the subject to identify shapes through the sense of touch. The examinee is asked to identify various objects without visual stimuli and using only the tactile perception. Each hand is evaluated separately. The Tactile Form Recognition Test yields information about astereognosis and the integrity of the contralateral parietal area of the brain.

The HRNB Standardization

The HRNB was never standardized on a representative, [1] stratified sample of healthy individuals. Thus, universal standard scores drawn from a large normative sample are not available [2, 3, 8, 10]. As with other assessment tools that lack detailed standardization procedures, there is much variability in how the RBNB results should be obtained and interpreted. Reitan published the first administration and scoring manual for the HRNB in 1979. Yet, the HRNB manual does not include in-depth reliability and validity information, but rather focuses on the reasons why subtests were included into the battery. There has been several different variations of the manual published since then. Additionally, several variations of the test materials and procedures have emerged. For this reasons, the HRNB is often disputed as the fixed battery approach, which requires extremely well specified and detailed instructions and standardized scoring procedures. In addition, the HRNB was developed to be a single integrated test; however, many neuropsychologists today choose not to use the complete battery but incorporate the Halstead-Reitan subtests selectively into their assessments.

Normative Data

Collection of normative data and the selected sample is one of the major limitations of the HRNB. Halstead developed the original cutting scores for his tests using group of "normals" consisting of 28 (eight females) subjects. Ten of these subjects suffered minor psychiatric disturbances and one was a military prisoner. Three other subjects were awaiting lobotomies due to behavioral problems, which included homicidal and suicidal tendencies. Two of these subjects contributed each set of scores, before and after their lobotomies. Another criticism against the normative group is the relative youth of the group. The range of ages of the group ranged from 14 to 50 years of age (mean = 28.3). Considering that performance on cognitive and neurocognitive tests tends to decline with age, the performance of the elderly examinees is likely to fall in the impaired range despite age-appropriate neurocognitive abilities [8].

Currently, there are several independent editions of normative scores for the battery available for the test interpretation. In addition to Halstead original norms published in 1947, other major sources of norms and test administration have been published and include norms by Russel et al. [14], Heaton et al. [6], and Reitan and Wolfson [10]. Also, it is difficult to compare results between individual subtests of the HRNB due to the lack of standard score transformation data. Despite these limitations, the Halstead-Reitan test remains one of the most validated and researched neuropsychological assessment tools in the world.

Summary Scores

The impairment index by Halstead [4] is derived from five core subtests of the battery that yield seven scores: the Category Test Score, Total Time Score (Tactile Performance Test), Memory Score (Tactile Performance Test), Localization Score (Tactile Performance Test),Seashore Rhythm Test Score, Speech Sounds Perception Test Score, and Finger Oscillation Test Score. The Impairment Index provides an indicator of overall impairment by looking at the proportion of tests in which the examinee performed in the impaired range. The scores on the index range from 0.0 to 1.0. Scores of 0.0 to 50 indicate the lack of brain impairment, and the scores of 51 and above are indicative of cerebral impairment. Because only seven scores contribute to the Impairment Index, and the index does not reflect the degrees of cerebral impairments, other summary scales have been developed to incorporate the performances of a large number of the Halstead-Reitan subtests.

The average impairment index (AIR) by Russel et al. [14] is based on 12 scores each rated on a 6-point scale (from 0 to 5). The seven scores comprising the Impairment Index, Trail Making Part B, Digit Symbol form the original WAIS, Wepman's Aphasia Screening Test with scoring differences for language and spatial errors, and the number of Perceptual Errors on the Sensory Perceptual Examination. The AIR rates the patients' performance on a six-point scale, which contrasts the Halstead's binary diagnostic system.

The alternative impairment index and *alternative impairment index-revised* by Horto [7] are shorter alternatives to the Impairment Index. They are derived from the scores form the Category Test, Seashore Rhythm Test, Speech Sounds Perception Test, bilateral Finger Tapping, and Trail Making A and B. Normal range of performance

on the indexes is 0.0 to 0.2; the impaired range includes scores from mildly impaired (0.3 to 0.4) to severely impaired (0.8–1.0).

The general neuropsychological deficit score (GNDS) by Reitan and Wolfson [10] summarizes 42 Halstead-Reitan measures into four major areas: (1) Level of Performance, which includes 10 variables), (2) Pathognomic Signs, which includes 12 variables, (3) Patterns and Relationships among Tests Results, which includes two variables, and (4) Right-Left Differences, which includes nine variables. Except pathognomic signs, test performances are rated on a 4-point scale (0–3). Scores of 0 to 1 represent normal performance, and scores 2 and 3 represent impaired and severely impaired performances, respectively. The ratings from each item contribute to the GNDS, which determines four different levels of overall performance. As the overall GNDS score ranges from 0 to 168, scores 0–25 signify normal performance, scores 26–40 indicate mild impairment, scores 41–67 refer to moderate impairment, and scores above 68 imply severe impairment.

Levels of Interpretation

Reitan proposed a fourfold approach to inferential decision making using the HRNB. The four areas include: (1) Level of Performance, which involves the comparison of the examinee with normative groups of impaired and non-impaired persons; (2) Pattern of Performance, which refers to the examination of intra-test performance and subtest scores; (3) Specific Behavioral Deficits, which looks at the existence of pathognomonic signs of specific disorders; (4) Comparison of two sides to the body (right-left comparisons), which is looking for discrepancies in test performance which may reveal weakness or lateralized impairment.

Hawthorne Effect

Renee L. Allen, Andrew S. Davis
Ball State University, Muncie, IN, USA

Definition

A widely accepted definition of the Hawthorne Effect refers to the effects of subjects' awareness of their evaluation as participants of a research study [4]. Other definitions include the importance of changes in the work

environment (e.g., lighting, rest breaks) while some focus on the resilience of the change in performance. Common variables that can be found in the Hawthorne effect definitions include participants' interpretation of workplace changes being implemented for their benefit, reference to the response of subjects to change, and the presence of reduced worker boredom [2]. Researchers who support the phenomenon that is known as the Hawthorne Effect have been criticized for failing to differentiate this concept from subject reactivity to experimental conditions or from the issue of confounding variables in experimental research. Indeed, the original research itself has been deemed methodologically flawed and insufficient to suggest such an effect by some [5].

Description

The Hawthorne studies have been called the "single most important investigation of the human dimensions of industrial relations in the early twentieth century" ([1], p. 55). The Hawthorne studies, from which the concept of a Hawthorne effect originated, occurred between 1924 and 1933. The name "Hawthorne" was taken from the site of the original study that began in 1927: the Hawthorne plant of the Western Electric Company in Chicago, Illinois [5]. The seven studies that took place at Hawthorne were conducted by employees at the Industrial Research Division of the plant. These studies were then interpreted by a group of external experts that included Elton Mayo of the Harvard Business School as well as biology and public health professor Clair Turner from the Massachusetts Institute of Technology [1]. The participants of the Hawthorne studies were uneducated, low-income women who worked various jobs at the factory [4]. Reports of the Hawthorne studies are contained in Mayo's 1933 [3] book *The Human Problems of an Industrial Civilization* and Roethlisberger and Dickson's 1939 [6] book *Management and the Worker.*

The three illumination experiments are the most frequently cited experiments from the original research that are used to support the Hawthorne Effect. Conducted between 1924 and 1927, these three experiments involved the manipulation of illumination levels to investigate the relationship between lighting and worker productivity. These experiments were first conducted using workers from three different departments who were engaged in three different kinds of work tasks. Noting the flawed methodology of this experiment, the researchers then used two groups of participants from one department only. The first group of participants worked under the normal illumination conditions of the factory. The second group of participants worked under various intensities of natural and artificial illumination. As the researchers received results from the second study that did not support their hypotheses, a final experiment essentially recreated the second experiment with the exception of the use of artificial light only. The researchers involved in the illumination experiments expected to find that groups who received progressively more illumination would become more productive. Although this hypothesis was supported by the research, the illumination experiments yielded results that illustrated increased productivity among groups who did not receive increased levels of illumination. These experiments also revealed that increased productivity could occur among groups whose illumination was progressively decreased. Overall, the results from the illumination experiments suggested that the relationship between illumination and productivity must be affected by other variables, including the notion that participation in a research study could increase worker productivity.

Head Start

Justin A. Barterian, Andy V. Pham, John S. Carlson
Michigan State University, East Lansing, MI, USA

Synonyms

Pre-school programs; Project head start; War on poverty

Definition

Head Start is a federally funded program that provides a variety of services (i.e. educational, social, health, nutritional) and stimulating academic environments for economically disadvantaged children with a goal of enhancing school readiness.

Description

Head Start was initiated as part of the war on poverty in 1965. The program was created in an effort to address the needs of children in economically deprived settings. Head Start was initially started as an 8-week program, but now includes full-day options and services throughout the entire calendar year. Head Start promotes school readiness for children of economically disadvantaged families by providing academic and social-related services to families and children. These services are often based on the information gathered from a needs assessment. Furthermore, the goal of Head Start is to provide a stimulating learning environment in an effort to target several aspects of the child's educational development including: "language, literacy, mathematics, science, social and emotional functioning, creative arts, physical skills, and approaches to learning" (Head Start Act as Amended). Services are provided through center-based, home-based, or combined (center and home-based) programs. In addition to these services, Head Start provides assistance for children transitioning into elementary school by providing schools with records on the student as well as connecting the family to appropriate professionals and services within a school.

Since the inception of Head Start, 25 million children have received service through the program. In 2007, 908,412 students were enrolled in the Head Start program. Children participating in Head Start come from diverse backgrounds. During fiscal year 2007, 39.7% of the children in the program were white, 30.1% Black/African American, 18.8% unspecified other, 4.9% bi-racial/multi-racial, 4% American Indian/Alaska Native, 1.7% Asian, and 0.8% Hawaiian/ Pacific Islander. Furthermore, 12.2% of the children enrolled in Head Start are diagnosed with a disability, such as "mental retardation, health impairments, visual handicaps, hearing impairments emotional disturbance, speech and language impairments, orthopedic handicaps, and learning disabilities (Head Start Fact Sheet, 2008)." The government spends approximately $7,326 for each child enrolled in the program. Head Start often collaborates with several community agencies and businesses in providing additional services.

There have been several studies that have noted the benefits of participation in Head Start programs, as well as several studies questioning its effectiveness. Based on a comprehensive literature review, Love and colleagues [4] note that there was evidence to support the effectiveness of the program. Results from the Head Start Impact Study indicate significant improvements in school readiness skills of first grade children, including cognitive, social, and emotional skills as well as improvements in parenting practices. In addition, Head Start had a statistically significant effect on children's pre-reading, pre-writing, vocabulary, and parent reported literacy skills. These results were found for children who entered the program as early as 3-years of age. Head Start was also found to remediate problem behaviors and improve social-emotional functioning for children who entered at an early age.

Children who were enrolled in the program at 3- or 4- years old also displayed improvement in their physical health and access to health care. Head Start had an impact on access to health care for children who entered the program at 4 years old. Furthermore, the study found that Head Start had an impact on parenting practices. For children who entered the program at age 3, parents of these children demonstrated an increased use of educational activities within the household and a decreased amount of physical punishment. The study found that Head Start had an impact on the parents of children who entered the program at age 4 demonstrated by an increase of educational activities within the household and a decreased amount of physical punishment. Although there is evidence demonstrating benefits for children who recently completed a Head Start program, there have been fewer positive studies suggesting its long term benefits. Aughinbaugh [1] found no evidence supporting the long-term effectiveness of Head Start related to grade retention and math ability.

Head Start is a federally funded program that strives to meet the school readiness needs of children in poverty. Several research studies have examined and continue to examine the effectiveness of the program. There are Head Start centers located within all fifty states and several U.S. territories. Furthermore, Head Start makes special efforts to meet the needs of specific populations who are deemed at risk for educational and social difficulties in school.

Definition

Health Psychology is a dynamic theoretical and applied psychological discipline founded almost 30 years ago, and emerged as the science of the psychological foundations of health, illness and health care [3]. The diversity that characterizes this rapidly expanding field of psychology is reflected by the

- educational, scientific, and professional contributions of the discipline of psychology to the promotion and maintenance of health, the prevention and treatment of illness, the identification of etiologic and diagnostic correlates of health, illness, and related dysfunction, and the improvement of the health care system and health policy formation [5].

Description

Health psychology applies psychological theories and methodology to identify the psychosocial and developmental factors underlying physical illness and enactment of health-related behaviors. Health psychology has made substantial contributions to the understanding of health maintenance and illness prevention and a kaleidoscope of other health-related issues, such as coping with chronic illness, adherence to medication, effective doctor–patient communication, health education and promotion via the development and application of effective interventions [8, 9].

Relevance to Childhood Development

Child health psychology emerged as an interdisciplinary area, where health-related and developmental perspectives are jointly considered for the improvement of child health care. According to Drotar et al. [2] child health psychology focuses on the "*behavioral* aspects of children's health and illness," hence the integration of developmental issues within the spectrum of health-related research. Accident-relevant behaviors, child physical abuse, substance abuse in the family, chronic pediatric pain and illness, child stress, and children's reactions to medical procedures are only few of the key areas of interest in child health psychology [2, 4].

Childhood is considered to be a crucial developmental stage where illness prevention and health promotion may be particularly fruitful especially at the level of attitude formation [10, 11].

A developmental perspective to health promotion may increase the relevance and effectiveness of health education targeting children and their caregivers. Usually, child health promotion primarily targets the child caregiver (e.g., parents) on health-related issues concerning child wellbeing (e.g., [7]), and to a lesser extent it targets children themselves. The latter typically involves the use of effective, creative, and innovative methods (e.g., theater play; see [6]) to attract children's attention by taking into account their age, physical condition (e.g., obesity, medical condition), and the setting where promotion takes place (e.g., schools).

The child health professional can foster health promotion in children and families by using effective teaching strategies in various settings where learning occurs and is

encouraged (e.g., at schools; in health clinics etc.). The health educator's skills and techniques used for this purpose are as critical as the consideration of socio-cultural factors and their role in health communication and persuasion. Hence, "culturally effective" or "community-relevant" health promotion would be essential. The role of child health professionals is not limited to a sterile "lecture-type" health education. On the contrary, it involves interaction with children and their caregivers/family and discussion on issues that are relevant to health maintenance and prevention of illness [1]. These are important prerequisites for the development of effective health interventions inspired by working with children and families in applied and clinical settings.

Hebb, Donald O.

Audrey McKinlay
University of Canterbury, Christchurch, Canterbury, New Zealand

Life Dates

July 1904–August 1985

Introduction

Hebb is an internationally renowned neurophysiologist most who developed the concept of the Hebbian synapse and the Hebbian learning rule [1]. His contributions to the understanding of human learning and memory continue to have an impact on most areas of psychological thought and practice.

Educational Information

The eldest son of four children Donald Olding Hebb was a born in Chester, Nova Scotia in Canada [1]. Hebb initially pursued a career as a novelist and studied in the Faculty of Arts at Dalhousie University in Halifax where he majored in English. However, this ambition did not meet with success [1].

Hebb then motivated by the works of Sigmund Freud and went on to study as a graduate student in psychology at McGill University. In 1931 he wrote his M.A. thesis entitled *Conditioned and Unconditioned Reflexes and Inhibition* which argued that skeletal reflexes were due to cellular learning. This thesis later formed the basis for his work on the Hebb synapse [1].

Hebb became interested in physiological aspects of psychology and went on to study for a Ph.D. in this area with Lashley at the University of Chicago. Hebb's Ph.D. thesis topic was "*The problem of spatial orientation and place learning*". However, prior to completing the Ph.D. Lashley accepted a position at Harvard University and Hebb also transferred to Harvard University to continue his work with Lashley. However, he had to change his thesis topic to the study of vision in rats reared in darkness. He was awarded his Ph.D in 1936 [1].

In 1937 Hebb began his post doctoral work with Wilder Penfield at Montreal Neurological Institute [1]. At this

point Hebb began to assemble test batteries based on his observation that lesions in different areas of the brain led to different disabilities. Therefore, different aspects of strengths and weakness should be assessed rather than overall intellectual change [1]. During this process he developed two new tests 1) the verbal Adult Comprehension Test, 2) The non verbal Picture Anomaly Test [1].

Accomplishments

Hebb has been a leading neuroscientist his work has influenced most aspects of psychological thought [2]. He took a professorship of McGill University in 1947 and went on to become Chancellor from 1970–1974 and a Professor Emeritus in 1978 [1]. Under his guidance McGill University became a leading research center for physiological research [1]. Hebb became president of the Canadian Psychological Association (CPA) in 1952 and the American Psychological Association (APA) in 1961 [1].

During his life his contributions to psychology were recognized by numerous awards including: a distinguished scientific contributions award from the APA in 1961, an award from the Association for Research in Nervous Mental Disorders 1962. Nominated for the Nobel Prize in 1965, awarded the gold medal from the APA in 1974, awarded Distinguished Scientific Contribution Award from the Society for Research in Child Development in 1979 and the CPA Distinguished Scientific Contribution Award in 1980 [1]. Hebb was posthumously inducted into the Canadian Medical Hall of Fame in October 2003 [1].

Contributions

Hebb is most well known for his work on memory and learning [2]. The Hebbian synapse and the Hebbian learning rule form the bases of multiple memory systems and synaptic plasticity [1, 2]. Hebb was also involved with identified that intelligence is not exclusively innate and that early environmental influence during a child's development is crucial in determining adult intelligence [1]. Modern computer models of the brain are based on Hebbs ideas of synapse and cell assembly [2].

HELLP Pregnancy Syndrome

►HELLP Syndrome

HELLP Syndrome

Maria Stylianou, Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

HELLP pregnancy syndrome

Definition

HELLP syndrome is a life-threatening obstetric complication usually considered to be a variant of pre-eclampsia involving a combination of liver and blood disorders. Specifically, HELLP is an abbreviation of the main symptoms of this syndrome: H stands for Hemolytic anemia (Hemolytic anemia is the breaking down of red blood cells.), EL stands for Elevated Liver enzymes (indicating liver damage) and LP stands for Low Platelet count (leading to a bleeding tendency).

Description

Epidemiology

The incidence of HELLP syndrome is reported as 0.17–0.85% of all pregnancies and develops in 4–12% of women with pre-eclampsia or eclampsia [8, 13, 14]. When pre-eclampsia is not present, diagnosis of the syndrome is often delayed. The syndrome presents antepartum in 69% of patients and postpartum in 31% of patients [4]. With postpartum presentation, the onset is typically within the first 48 h after delivery; however, signs and symptoms may not become apparent until as long as 7 days after delivery.

HELLP syndrome usually begins on average between 32 and 34 weeks but rare cases have been reported as early as 23 weeks gestation [8]. Although up to 3% of HELLP cases result in maternal mortality and stillbirths occur in up to 20% of cases, the outcome for mothers with HELLP syndrome is generally good [6].

Etiology

The exact cause of HELLP syndrome is unknown, but general activation of the coagulation cascade

(Coagulation cascade is the sequence of biochemical activities, involving clotting factors that stop bleeding by forming a clot.) is considered the main underlying problem [7]. Fibrin (Fibrin is an insoluble protein that is essential to clotting of blood, formed from fibrinogen by action of thrombin.) forms cross linked networks in the small blood vessels. This leads to a microangiopathic hemolytic anemia (Microangiopathic hemolytic anemia is a disorder in which narrowing or obstruction of small blood vessels results in distortion and fragmentation of cells.): the mesh causes destruction of red blood cells as if they were being forced through a strainer [7]. As the liver appears to be the main site of this process, downstream liver cells suffer ischemia (Periportal necrosis is the necrosis of liver cells localized around the portal vein. It is usually associated with ingested toxins.), leading to periportal necrosis (Disseminated intravascular coagulation is a serious medical condition that develops when the normal balance between bleeding and clotting is disturbed). Other organs can be similarly affected. HELLP syndrome leads to a variant form of disseminated intravascular coagulation (Thrombotic thrombocytopenic purpura is a disease of unknown origin, characterized by abnormally low levels of platelets in the blood, the formation of blood clots in the arterioles and capillaries of many organs, and neurological damage.), leading to paradoxical bleeding, which can make emergency surgery a serious challenge. Some conditions may increase the risk of developing HELLP syndrome, including preeclampsia during pregnancy and previous pregnancy with HELLP syndrome.

Features

Symptoms of HELLP syndrome are progressive nausea and vomiting, upper abdominal pain, severe headaches, visual disturbance, easy bruising, swollen hands and feet. Tenderness in the upper right abdomen just below the ribs results from enlargement and inflammation of the liver [1, 3]. Edema may also occur but its absence does not exclude HELLP syndrome. Arterial hypertension is also a diagnostic requirement, but it may be mild. Rupture of the liver capsule and a resultant hematoma may also occur. Disseminated intravascular coagulation is also seen in about 20% of all women with HELLP syndrome [10], and in 84% when HELLP syndrome is complicated by acute renal failure [9].

Due to the fact that HELLP syndrome may resemble other medical conditions, such as thrombotic thrombocytopenic purpura (Acute exacerbation of systemic lupus erythematosus is a chronic generalized connective tissue disorder marked by skin eruptions, arthralgia, arthritis, leukopenia, anemia, visceral lesions, neurologic manifestations, lymphadenopathy, fever, and other constitutional symptoms.), acute exacerbation of systemic lupus erythematosus (Acute exacerbation of systemic lupus erythematosus is a chronic generalized connective tissue disorder marked by skin eruptions, arthralgia, arthritis, leukopenia, anemia, visceral lesions, neurologic manifestations, lymphadenopathy, fever, and other constitutional symptoms.) and pregnancy-induced hypertension, patients who present with symptoms of HELLP syndrome can be misdiagnosed in the early stages increasing the risk of liver failure and morbidity [11].

Treatment

Early diagnosis is critical because the morbidity and mortality rates associated with the syndrome have been reported to be as high as 25% [5]. The mortality rate among babies born to mothers with HELLP syndrome varies and depends mainly on gestation and birth weight.

In the past the only treatment advocated was to deliver the baby immediately [2]. This is due to the fact that as the liver deteriorates rapidly, hemorrhaging into the liver and from the site of the placenta can threaten the life of mother and baby. Permanent liver damage may result if delivery of the baby is delayed. Fortunately, the majority of babies born to HELLP syndrome mothers do very well, especially if weighing over 2 lbs at birth. Babies less than 2 lbs in weight, face serious problems and complications due to prematurity. Depending on the estimated gestational age and the condition of the mother and fetus a more conservative treatment could be administered [2]. Blood transfusions may be conducted for severe anemia and low platelets, magnesium sulfate may be administered to prevent seizures [3], antihypertensive medications may be given to reduce blood pressure, corticosteroids may be prescribed to help mature the lungs of the fetus [12] and then if HELLP syndrome worsens and endangers the well-being of the mother or fetus, then an early delivery may be necessary.

Patients with HELLP syndrome may be eligible for conservative management if hypertension is controlled at less than 160/110 mmHg, oliguria responds to fluid management and elevated liver function values are not associated with right upper quadrant or epigastric pain [5]. One study found that pregnancy was prolonged by an average of 15 days when conservative management (i.e., bed rest, fluids and close observation) was used in patients who were at less than 32 weeks of gestation. Maternal morbidity was not increased. For infants, the prolongation of pregnancy translated into less time in the neonatal intensive care unit, a decreased incidence of necrotizing enterocolitis and a decreased incidence of respiratory distress syndrome. Following HELLP syndrome, future pregnancies are at an increased risk and so most mothers will be advised to avoid pregnancy again.

Synonyms

Hemidecortication

Definition

A hemispherectomy is a surgical procedure to remove one of the two hemispheres of the cerebrum, which together make up the majority of the ►brain's tissue [1]. The surgery takes one of two forms: Anatomical hemispherectomies involve the complete removal of a cerebral hemisphere while functional hemispherectomies involve the selective removal of parts of a cerebral hemisphere and severing the corpus callosum such that the afflicted hemisphere in more or less left intact but is functionally disconnected from the rest of the brain [1]. Hemispherectomies are typically performed to treat intractable epilepsy [3].

While the majority of hemispherectomies are performed in the adolescent years, some are performed in the first year of life, before the acquisition of speech [2]. The outcome following a hemispherectomy in early infancy depends on which hemisphere is involved, supporting the conclusion that the cerebral hemispheres have considerable degree of specialization of function, even early in life [2]. The specific outcomes following a hemispherectomy, to the extent that such results can be summarized briefly, are summarized in Table 1.

To elaborate on some of the data presented above, left hemispherectomies, in contrast to right

Hemispherectomy. Table 1 Post-Hemispherectomy Outcomes

Behavioral measures	Left hemisphere removal	Right hemisphere removal
Measures of intelligence	Low but normal	Low but normal
Measures of language		
Simple	Normal	Normal
Complex	Poor	Normal
Measures of visuospatial abilities		
Simple	Normal	Normal
Complex	Normal	Poor

Adapted from [2]

hemispherectomies, result in deficits in comprehending spoken language when the meaning in the utterance is a function of complex syntax of the utterance, especially if the spoken sentence contains an error (as in "The tall guard wasn't shot by the armed robber"). Similarly, a left hemidecortication produces deficits in understanding the implied meaning of a spoken sentence, in using the information in a sentence to identify a missing pronoun, and in judging how the words in a sentence are inter-related [2]. Both hemispheres can function to enable a person to comprehend word meanings and both will allow a person to produces lists of words to name things. In tasks involving a search for words through the use of different cues, the left hemisphere provides a person with some advantages. While either hemispheres can arrive at a word to name an object based on its picture or from its description, only the left hemisphere can identify a word based on a prompt such as "It rhymes with. . ."; the right hemisphere alone does not function to allow a person to respond correctly to such a prompt. Both hemispheres enable a person to engage in higher-order reading comprehension but, the left hemisphere gives a person superior ability in spelling and reading words that are novel to the person and to engage in more fluent reading [2]. The left hemisphere also enables a person to read passages of prose with greater accuracy and fluency and with fewer violations or errors of the semantic content and syntax of the sentences; the superior ability given with an intact left hemisphere was summarized as the ability to use and understand the implicit and explicit rules of the use of language. The right hemisphere, however, enables a person to have better performance of a task involving learning an association between symbols and nonsense syllables [2].

In terms of visuospatial ability, individuals who had undergone right hemispherectomies had normal abilities on simple measures such as drawing an object, these individuals exhibited significant deficits on more complex measures such as reading a map or solving a maze task [2].

In summary, each cerebral hemisphere can take on some of the opposite hemisphere's abilities and functions if the opposite hemisphere is removed, but neither hemisphere can totally fulfill all of the absent hemisphere's roles [2]. With very few exceptions, individuals who have undergone a hemidecortication evidence below-average or in best case outcomes, average intellectual ability and the individual's competence on assessments of the missing hemisphere's typical functions is below normal [4].

Definition

The hemispheres of the brain refer to the two relatively symmetrical halves of the forebrain that lie on the right and left.

Description

The hemispheres of the brain refer to the two relatively symmetrical halves of the Forebrain that are topographically divided by the Longitudinal Fissure [1, 3]. While they appear divided on the surface, the hemispheres are connected by both the Corpus Callosum and the Anterior Commissure so to allow for proper neuronal communication between the hemispheres [2]. It is these connections that provide the foundation of the brain's mirror-image structure. Specifically, these noted interhemispheric connections join contralateral points that are similar in functionality [2]. For example, those points relating to the movement of the right arm will present with connections to those points, similar in hemispheric locality, that relate to the movement of the left arm. However, in terms of functional regulation, the hemispheres of the Forebrain demonstrate contralateral control such that motor and sensory functioning of the right side of the body is modulated by the left hemisphere and vice versa, the motor and sensory functioning of the left side of the body is modulated by the right hemisphere.

The subtle asymmetry of the hemispheres of the brain is largely related to their differences in morphology and physiology [4]. While the right hemisphere in most people presents as both larger and heavier, the left

hemisphere tends to be more dense [4]. The greater density of the left likely corresponds with a more intricate association circuitry of this hemisphere compared to the right secondary to the lateralization of various higher-order functions to this hemisphere. In terms of lateralization, this refers to a functional dominance of one hemisphere over the other, in which one is more responsible or entirely responsible for control of a function in comparison to the other. For example, the left hemisphere is generally dominant as language and various aspects of verbal processing are usually lateralized to this side, which are higher-order processes. As a result, there is likely a great reliance on more intricate neuronal networking and thus the left hemisphere presents with greater density [4]. For more information on the lateralization of the hemispheres, please see *Hemispheres of the Brain, Lateralization of*.

Definition

Lateralization of the brain hemispheres refers to a functional dominance of one hemisphere over the other, in which one is more responsible or entirely responsible for control of a function in comparison to the other.

Description

In addition to a multitude of other defining features, the brain Cerebrum is divided into two relatively symmetrical halves referred to as the hemispheres of the brain. Although they are relatively similar in appearance, each hemisphere is entrusted with the modulation of different functions. It is this functional asymmetry that is the hallmark of lateralization. Specifically, lateralization of the brain hemispheres refers to a functional dominance of one hemisphere over the other, in which one is more responsible or entirely responsible for control of a function in comparison to the other. This can be depicted in two general ways. First, in regards to sensory and motor functioning the hemispheres of the brain present with a contralateral pattern of control in which the left hemisphere is involved in the functioning of the right and the right hemisphere is involved in the functioning of the left [17]. Beyond this more basic aspect of lateralization, empirical evidence has demonstrated further lateralization of hemispheric functioning along the lines of higher-order cognitive functions. A general way of conceptualizing this is in regarding the left hemisphere as more prominently involved in language and other verbal processes and the right hemisphere as more involve in visual-spatial processing and other non-verbal abilities [18]. This breakdown represents the basis for the idea of left hemisphere dominance. In regards to this latter idea, dominance is determined by which hemisphere houses language. While, as suggested above, left hemisphere dominance holds true for the vast majority of individuals, there are some who present with cross-dominance as well as those who present with reverse-dominance.

Beyond the more simplistic differentiation of verbal versus non-verbal/ visual in regards to lateralization of the hemispheres, prior research has demonstrated greater specifics along these lines. Dean and Anderson [8] provided a summary table of the various lateralized functions as determined by empirical evidence that was revised by Davis and Dean [6] and then Noggle, Davis, and Barisa [23]. Based on these empirical summaries, functions that have been demonstrated as largely lateralized to the right hemisphere include: Simultaneous Processing [31]; Holistic Processing [9, 31]; Visual/nonverbal Processing [27, 31]; Imagery [28]; Spatial reasoning [25, 31]; Depth perception [4]; Melodic perception [29]; Tactile perception [3, 5]; Nonverbal sound recognition [21]; Motor integration [16], Visual constructive performance [24]; Pattern recognition [10]; Language Pragmatics [1]; Nonverbal memory [33]; and Face recognition [14, 22].

In comparison, functions that have been demonstrated as largely lateralized to the left hemisphere include: Sequential Processing [32]; Temporal Processing [20]; Analytic Processing [10]; Speech [2]; General language/ Verbal Skills [11, 12, 30]; Calculation/Arithmetic [10, 26]; Abstract verbal thought [12]; Writing (composition)

[15, 31]; Complex motor functions [9]; Body orientation [13]; Vigilance [9]; Verbal paired associates [9]; Short-term verbal recall [16]; Abstract and concrete words [19, 28]; Verbal mediation/rehearsal [7, 28]; and Learning complex motor function [9].

Hemoglobin

Marie C. McGrath
Immaculata University, Immaculata, PA, USA

Synonyms

Deoxyhemoglobin; Haemoglobin; Hb; Hematinoglobulin; Hemoprotein; Metalloprotein; Oxyhemoglobin

Definition

An iron-containing protein in red blood cells that transports oxygen from the lungs through the bloodstream for use by the body in energy-generating metabolic processes.

Description

Hemoglobin molecules are found in *erythrocytes*, or red blood cells. Hemoglobin molecules contain four subunits, each comprising an iron-containing *heme* group folded within protein chains known as *globin*. The reddish color of the heme gives blood its characteristic color; globin peptide chains are colorless. Since each heme group can bind one oxygen molecule for transport, each hemoglobin molecule can transport four oxygen molecules into the peripheral tissues of the body, where they are used in aerobic metabolic processes. When in oxygen-rich environments, the hemoglobin molecules change their structures, "unfolding" slightly to facilitate binding between the heme and oxygen molecules. Once the oxygen molecules have been released into tissue, the hemoglobin molecules again reconfigure, making the heme groups less accessible so that they will not rebind to the released oxygen molecules. The hemoglobin molecules then transport carbon dioxide molecules from peripheral tissue back to the lungs to be released via exhalation. Hemoglobin molecules that are actively involved in transporting oxygen in the bloodstream are known as *oxyhemoglobin* molecules; non-oxygen-carrying hemoglobin molecules are sometimes referred to as *deoxyhemoglobin*. In addition to their role in oxygen transport, hemoglobin molecules serve a buffering function within red blood cells, helping to maintain a pH level of approximately 7.4 in the bloodstream.

Disorders that affect hemoglobin production, structure, or function are known as *hemoglobinopathies*. Most hemoglobinopathies are genetic in origin; this category includes diseases such as *sickle cell anemia*, in which structural abnormalities in globin chains are present, and the *thalassemias*, in which rate of globin synthesis is affected. Other forms of hemoglobinopathy are acquired, rather than genetic. One such hemoglobinopathy is carbon monoxide (CO) poisoning. CO molecules bind over 200 times more strongly to hemoglobin than do oxygen molecules; therefore, exposure to even relatively low concentrations of CO can result in CO molecules binding to hemoglobin for transport throughout the body at much higher rates than oxygen molecules, leading to significant (and potentially fatal) oxygen deprivation.

Hemophilia

Synonyms

Blood-clotting disorder; Christmas disease; Factor IX deficiency; Factor VIII deficiency

Definition

A rare hereditary disorder of the blood-clotting system, where your blood does not clot normally.

Description

There are several types of blood-clotting diseases, and they are all lifelong medical conditions. With hemophilia small cuts bleed longer than usual; however, are not as great a concern as deeper cuts and internal bleeding that are more life threatening. Fortunately, with appropriate treatment

and good self-care many individuals with hemophilia can live active and healthy lives. Hemophilia is predominantly found in males (with rare exceptions), and severity varies depending on the amount of clot-forming proteins, in the body, called clotting factors. There are several types of clotting factors that work in conjunction with platelets (small blood fragments that form bone marrow). Clotting factors help platelets stick together to plug cuts at the site of injury to stop bleeding.

There are two main types of hemophilia, hemophilia A and hemophilia B. Individuals with hemophilia A are missing or have low levels of clotting factor VIII. This is the more common form of hemophilia, affecting 9 out of 10 people. Also, about 7 out of 10 people who have hemophilia A have a severe presentation of the disorder. On the other hand, hemophilia B individuals lack or have low levels of clotting factor IX. Although hemophilia is a predominantly hereditary disorder, in rare cases it can be acquired due to the formation of antibodies to clotting factors. The main treatment for hemophilia is injecting missing clotting factors into the bloodstream.

Heritability

Ioana Boie
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Heredity

Definition

Heritability is the proportion of phenotypic variance that can be accounted for by genetic differences among individuals [5]. There are several variations in the definitions of heritability, depending on the field it is used in and depending on the author's stance. For example, certain authors emphasize that heritability and heredity are not the same, although they have been used interchangeably in certain texts [1].

Description

The term has been used since the 19th century, with the meaning we attribute today described by Jay Lush in 1936. Lush was an Iowa State College professor of animal breeding, and focused on breeding animals with certain traits. He described *heritability* as the proportion of phenotypic variance (i.e., physical traits) that can be accounted for by genes. Initially, the concept was used to help plant and animal breeders predict their selection. Lush also described two types of heritability: *broad heritability* and *narrow heritability. Broad heritability* entails the entire genotype, including genes that interact non-additively. *Narrow heritability* includes only additive genetic effects, which are of interest to plant and animal breeders.

Lush also established that a heritability estimate would be useful, which provides a numeric index of how much of the observed variation in physical characteristics is due to genetic factors. In behavioral genetics, heritability calculations are done by doubling the reared-together identical-fraternal correlation differences, where there is an assumption that genetic makeup and environment do not interact, although it is known this isn't true. The statistical calculations of heritability estimates are thought to be biased and methodologically inaccurate.

Heritability and Psychiatric Disorders

Past research on heritability has focused largely on IQ and psychiatric disorders. For example, major twin studies revealed that heritability of schizophrenia is somewhere between 0.6 and 0.9, where the heritability can range from

no genetic factors playing a role in developing the disease (0.0) to where genes carry the sole responsibility for a disease (1.0) [3].

Other psychiatric disorders, such as autism, bipolar affective disorder, and ADHD are thought to be highly influenced by genetics, with heritabilities between 60 and 90% (Lerner, 2006), while antisocial behaviors have between 41 and 50% heritability, and Alzheimer's disease has 40–80%.

Hierarchical Linear Modeling

Scott Graves
Bowling Green State University, Bowling Green, OH, USA

Synonyms

Mixed models; Multilevel modeling; Random coefficient models

Definition

Hierarchical Linear Modeling (HLM) is a statistical technique that allows used for analyzing data in a clustered or "nested" structure, in which lower-level units of analysis are nested within higher-level units of analysis. For example, students are nested within classrooms, which are nested within schools.

Description

Hierarchical, or nested, data structures are common in many areas of child development research. Specifically, students exist within a hierarchical social structure that can include family, peer group, classroom, grade level, school, school district, state, and country. Hierarchical, or nested, data present several problems for analysis. In particular, individuals from the same classroom or school tend to share certain characteristics (i.e., socioeconomic status, demographics, background) and observations based on these individuals are not fully independent. These individuals tend to be more similar than people randomly sampled from the entire population and thus are not fully independent. However, most analytic techniques require independence of observations as a primary assumption for the analysis. When data is organized in this manner the fundamental assumption of regression analysis that implies that observations should be independent is violated. Since this assumption is violated in the presence of hierarchical data, ordinary least squares regression (OLS) produces standard errors that are too small. When some form of multilevel modeling is not used this fact is ignored and may severely inhibit the validity of a study's results. In order to accomplish the use of taking into account individual scores

adjusted for group differences as well as prediction of group scores adjusted for individual differences within groups, HLM allows intercepts (means) and slopes (independent variable-dependent variable relationship) to vary between higher level units. For example, the relationship between a student's personal competency (independent variable) and reading achievement (dependent variable) is allowed to vary between classrooms. This variability is modeled by treating group intercepts and slopes as dependent variables in the next level of analysis. By doing this it decreases the Type I error rate and facilitates a more accurate representation of outcomes.

Conducting a study that utilizes HLM techniques generally requires the use of specialized software. Commercially available software for this procedure includes: HLM, SAS Proc Mixed, MLwiN, and Mplus.

Relevance to Childhood Development

The study of child development is inherently a multilevel field. The term multilevel refers to a nested membership relation among units in a system. In the field of child development, students are nested in teacher classrooms, classrooms nested within schools, and schools grouped within neighborhoods. In as much as researchers are concerned with improving the outcomes of children, the study of these subjects cannot be done appropriately without taking into account their school, neighborhood, and family environments concurrently. Specifically, the development of appropriate interventions, home-school collaborations, and gathering appropriate assessment data must recognize and acknowledge the nested nature of the target child's circumstance. To account for the clustering of children within their environments, researchers can use HLM procedures to appropriately account for nesting hierarchies.

Hindbrain

▶Brain Stem

Hippocampus

Ioana Boie
University of Texas at San Antonio, San Antonio, TX, USA

Definition

The hippocampus is an anatomical brain structure that is part of the hippocampal formation, which also includes the dentate gyrus and subiculum. The hippocampus is located in the subcortical medial and ventral areas of the temporal lobe, and appears to play a role in socioemotional behavior, attention, and memory and learning, as well as locomotor activity.

Description

The hippocampus, along with other structures such as the primary sensory and motor cortex, tends to be one of the most active areas of the brain in newborns. The hippocampus is one of the structures containing the highest concentrations of *N*-methyl-D-aspartate (NMDA) receptors in the brain, making it more vulnerable to dysfunctions, neural damage due to anoxia and ischemia, as well as dysfunctions associated with psychiatric disorders. For example, it is believed to play a major role in neurodevelopmental disorders involving dysregulation of dopaminergic systems, such as schizophrenia.

Hippocampal lesions can induce hyperactivity and distractibility, possibly contributing to attention deficit hyperactivity disorder in children. These lesions can also create perseveration – with the result that the child repeats the same response over and over, even when the response is not instrumental in achieving a goal. Lesions to the hippocampal formation also may interfere with learning and habituation, resulting in longer time to realize that repetitive stimuli are familiar. With regard to memory, lesions lead to amnesia, and also affect stimuli from all modalities, thus resulting in a deficit in the consolidation of explicitly recalled memory. Lesions to the left hippocampal formation lead to problems with verbal memory while right side lesions are associated with spatial memory deficits. Some studies also show a significant shrinkage of the hippocampus in adults diagnosed with Post Traumatic Stress Disorder, however this has not been noted in children with the same diagnosis.

Holophrases

Gyasi Bramos Hantman
Nova Southeastern University, Davie, FL, USA

Synonyms

Single word utterance

Definition

Term used in the study of language acquisition to refer to the use of a single word to express a complex idea.

Description

Derived from a usage based theory of linguistic acquisition, holophrases are single word utterances used by children to convey an intention similar to that of the adult expression it derives. The majority of holophrases are conventional and stable and children learning to speak use their holophrases to a achieve variety of goals, regardless of the language being learned.

Examples of holophrases and their uses are outlined below:

- Request or indicate the existence of object (e.g., by naming them with a requestive or neutral intonation)
- Request or describe the reoccurrence of objects or events (e.g., *More, Again, Another*)
- Request or describe dynamic events involving objects (e.g., as described by *Up, Down, On, Off, In, Out, Open, Close*)
- Request or describe the action of people (e.g., *Eat, Kick, Ride, Draw*)
- Comment on the location of objects and people (e.g., *Here, Outside*)
- Ask some basic questions (*What's-that? or Where-go?*)
- Attribute a property to an object (e.g., *Pretty, or Wet*)
- Use performatives to mark specific social events and situations (e.g., *Hi, Bye, Thank you, and No*)

Relevance to Childhood Development

Holophrases form the foundation of a child's early vocabulary and typically develop around the age of 12 months. Children do not attempt to learn isolated words but rather singular constructs that correspond to full sentences used by adults. These individual lexical items appear to have a wide range of communicative intention when accompanied by symbolic gesturing.

Depending on the specific language children are learning and the kinds of discourse in which they participate with adults, children will choose different holophrases to learn to communicate their thoughts and desires. In English, most beginning language learners acquire a number of so called relational words such as *more, gone, up, down, on, and off*, presumably because adults use these words in salient ways to talk about salient events.

Holtzman Ink Blot Test (HIT)

Definition

A projective personality test created by Wayne Holtzman to correct many of the controversial limitations in the Rorschach Inkblot Test.

Description

The test is made up of two alternate forms of forty-five inkblots; the scoring is based on twenty-two personality-related characteristics. The administration usually takes 50-80 minutes to administer, and scoring can be time-consuming if not scored by a computer. The Holtzman Ink Blot Test is most often used to assess schizophrenia, depression, and head trauma. Note that Holtzman Ink Blot Test should only be administered and interpreted by mental health practitioners who are trained to use this assessment tool.

Homeless Families

Jessica Mackelprang
Nova Southeastern University, Davie, FL, USA

Synonyms

Destitute family; Homeless household; Indigent family

Definition

A homeless family is a family that lacks a consistent, stable residence and is comprised of at least one adult parent or guardian and one or more children under the age of 18 years.

Description

Homelessness is a serious public health problem in the United States. According to 2004 estimates, approximately 2.5–3.5 million Americans will experience homelessness in a given year; of these, approximately 1.35 million are children [8]. Currently, homeless families are among the most rapidly growing sectors of the homeless population. According to a 2007 report, homeless families accounted for approximately half of all homeless persons residing in rural and suburban areas in the United States [14]. Homeless families also tend to remain in sheltered situations for longer periods of time than do single homeless persons, and the adult member of the family is a single woman in 84% of cases [14]. Additionally, the majority of these families have two or more children, with at least one being younger than 6 years of age [14].

Risk Factors for Homelessness

Families who become homeless often do so following a series of traumatic events, including domestic violence, eviction due to inadequate finances, or loss of employment. These families are also more likely than single or unaccompanied adults to seek solace in an emergency shelter immediately following residential living, suggesting that a more abrupt transition to homelessness may occur among families than single adults. In fact, the U.S. Department of Housing and Urban Development reported that 20% of homeless families spent the night immediately preceding the onset of their homeless episode in a residence that they rented or owned [14]. The threat of becoming homeless is a reality for many low-income families, particularly during times of economic hardship. Between 2006 and 2007, requests for housing assistance increased 86% [6]. Unaffordable housing plays a key role in the prevalence of homelessness [10, 11]. Other risk factors for homelessness include being a part of an ethnic minority group, particularly being African American, having low educational attainment, and having minimal work experience [10].

Relevance to Childhood Development

Since the 1980s, the disadvantage experienced by homeless children has become progressively similar to that of low-income housed youth. Significant discrepancies are still noted, however, across multiple domains (e.g., health, cognitive and academic functioning) when these children are compared to the general population [10]. Some of the narrowing of this gap has been attributed to programs that were enacted as a result of the McKinney-Vento Act (►McKinney-Vento Homeless Assistance Act

(PL100-77)) which increased the availability of services to homeless individuals and families [7]. As a direct result of the McKinney-Vento Act, programs supporting education, healthcare, and job training, along with emergency, transitional, and permanent housing have been established. As such, homeless children are likely to exhibit difficulties that are akin to those experienced by age-matched, housed peers who experience a similar level of impoverishment [10].

Owing to the pervasive threats that homeless individuals are exposed to, and the emotionally devastating process of becoming homeless, homelessness has been considered a form of severe and chronic stress [3]. Violence is one of the most prevalent and devastating aspects of homelessness, and it is a common antecedent to homelessness. These families are at increased risk of experiencing direct (e.g., being victimized) and indirect forms of violence (e.g., witnessing violent acts) [1]. For instance, rates of domestic violence are high and aggressive modes of interacting may become customary, while nurturing behaviors are reduced [12]. Not only does violence disrupt interfamily relationships, but it also disturbs a family's social interactions which lead to increased isolation [12]. The combination of these environmental factors prompts fearfulness and anxiety among homeless children.

Homeless children have a greater risk of emotional and physical challenges than their housed peers Exposure to violence and trauma among homeless families has also been linked to an increased incidence of behavioral problems among children [1]. The greater the duration of homelessness, the greater the likelihood that additional trauma may be incurred [16]. The combination of economic hardship and violence plays a role in the level of aggression that is exhibited by homeless children and, correspondingly, the quality of peer interactions these children experience. Homeless children exhibit disruptive behavior at a rate of four times that of their housed peers [15]. Although externalizing behaviors may be adaptive in the lives of homeless youth, these children's relationships are often compromised by peer rejection and, subsequently, social avoidance in the school environment [1]. These children are twice as likely as other youth to go hungry and fall ill, and there is a greater likelihood that they will receive inconsistent healthcare [2, 5]. Furthermore, roughly half of homeless youth experience anxiety and/or depression [2].

The academic performance among homeless children is also hindered. Homeless youth are twice as likely as housed children to repeat a grade and to be diagnosed with a learning disability [2, 9]. One study revealed that approximately 50% of formerly homeless children in New York City had been retained at least one grade. Homeless students also experience more school mobility and higher rates of absenteeism than housed youth which may result in learning gaps and poorer academic performance [9]. These factors contribute to diminished ability to accrue credits and increased likelihood that attendance-related disciplinary action will be imposed [13]. Consequently, homeless youth are at greater risk of having poor school experiences and impoverished peer relationships, thus increasing their risk of dropping out of school in the future. Many homeless youth also demonstrate lower verbal ability than domiciled children [15]. Research has revealed that the functioning of homeless children seems to stratify into two main subgroups which are primarily differentiated by performance on behavioral, adaptive, and achievement measures. In the higher functioning group, emotional and behavioral health, adaptive functioning, and academic achievement, including intelligence, are retained while the lower-functioning portion significant deficits are observed [4]. Thus, the resources and interventions that are appropriate for some homeless families may have limited applicability for others.

Homelessness is also associated with increased family separation, particularly among families that experience chronic homelessness. Maintaining family intactness is further complicated by the fact that many shelters which allow children do not allow adult males (i.e., fathers). Although few studies have addressed the long-term ramifications of homelessness on formerly homeless children, the current body of research indicates that the short-term effects of homelessness are most dramatic and attenuate over time following stability in residence [10].

Homework

Lori Unruh
Western Carolina University, Cullowhee, NC, USA

Definition

Homework consists of those tasks that are assigned to students by teachers with the intention that the tasks be completed during non-school hours. The purpose of homework has generally been identified as providing practice, preparation, and elaboration in relation to what is being taught in the classroom. Homework practices vary considerably across a variety of factors including amount assigned, academic and nonacademic purposes, skill areas covered, amount of student choice, deadline for completion, degree of individualization, and social context for completion of task.

Description

Homework is an educational practice that is solidly entrenched in public and private school systems everywhere. It is often taken for granted by both teachers and parents in that it is assumed that homework is necessary in order for children to make adequate academic progress. In the popular literature discussions about homework are usually centered around issues related to how much and how often homework should be assigned, how long children at different ages should spend on homework, and what parents and children need to do to get through the homework requirements. What is often not addressed is what learning actually occurs during the homework process.

Since the beginning of the twentieth century, public opinions, policies, and practices regarding homework have wavered between support and opposition. Initially, homework was supported as an important means of disciplining children's minds with an emphasis on memorization skills. Later when student initiative and learning was valued more than the ability to memorize facts, homework became less important. As the United States became more concerned about global competitiveness, homework was once again seen as a way for increasing knowledge acquisition. However, that led to concerns regarding the mental health of school children in the United States as homework was seen as placing too much pressure on children. Finally, the recent push for more rigorous state-mandated academic standards has led to another push for the increased use of homework.

Proponents of homework focus on the potential for student improvements in academic skills as well as non-academic skills. Improvements in academic skills are usually measured through student performance on unit exams and standardized tests. Improvements in non-academic skills are more difficult to measure and include factors such as improved attitude toward school, better study habits, improved organization and time-management skills, greater self-discipline, and improved problem-solving skills.

Opponents of homework focus on several areas of concern with the assumption being that any academic and/or nonacademic benefits gained through homework are outweighed by the costs associated. These concerns

and therefore costs include the burden homework places on parents, the stress it causes children, the family conflict it creates, the time it takes away from other activities, and the decrease in interest in learning that it creates.

Those researchers who have analyzed the data available regarding the impact of homework on the learning process have consistently indicated that the studies involved have many methodological flaws and that conclusions are difficult to make [1–4]. Some studies have shown that there are positive effects of homework on achievement but the effect sizes have tended to be very small. Other studies have shown no effect or complex effects in which the positive impact is only for students at certain grade levels or under certain conditions. And, in a few cases, a negative impact has even been shown. These inconsistent results are due to a variety of limitations associated with research in this area. First, much of this research has been correlational and therefore, shows, at best, only an association between homework and achievement and not a causal relationship. Second, most of this research has been done with a small number of subjects and a true experimental design with random assignment to homework and non-homework groups has generally not been possible. Therefore, the results cannot be generalized across a variety of settings. Third, there are a large number of factors related to homework that cannot be controlled through the research process. This includes factors such as knowing how much homework children actually do complete, knowing whether different homework assignments are comparable, and knowing the importance of other home and family factors. Finally, learning in relation to homework has primarily been measured through grades and test scores and long-term effects have rarely been considered. In general, the research has not been able to answer one very important question: If more homework is associated with better grades, can we assume that better grades are a good predictor of a student's ability to retain this knowledge and use it later in life?

Relevance to Childhood Development

The conclusions drawn from reviewing the literature on homework have led researchers to a variety of different recommendations regarding the use of homework as an educational practice to assist children in the learning process. Cooper [2] concluded that doing homework can lead to improved academic achievement but the improvement may be limited especially for younger students and for older students if too much is given. Based on his review of the literature, specific recommendations for how to make homework more effective were identified including considerations regarding the length or frequency of assignments; whether homework assignments should focus on content from that day's lessons or include content from previous lessons or content to prepare for future lessons; whether homework should include both easy and hard material; whether homework should be compulsory or voluntary; whether students should be given choices regarding assignment content; whether teachers should individualize assignments; whether groups of students should be allowed to work on assignments; whether computers should be used; whether study aids should be provided; and how important comments, grading, and rewards are to homework. Marzano et al. [4] also concluded that homework is a strategy that increases student achievement and made similar recommendations for making homework effective. His suggestions included factors related to how much homework should be assigned at different grade levels; how much parents should be involved; how explicit the purpose of homework should be; and whether it should be commented on by the teacher. Both Cooper [2] and Marzano et al. [4] made recommendations regarding homework policies at the classroom and district level.

Buell [1] and Kohn [3] drew different conclusions regarding the research that has been done in the area of homework. They feel that the research does not support the conclusion that current homework practices lead to increases in academic skills. However, they do not recommend completely getting rid of homework without making other changes in educational practices first. They recommend that the practice of homework be re-thought and reform efforts implemented. Buell [1] asserted that since there is little research to support the academic benefits related to homework, the large amounts of homework being assigned are not primarily for the purpose of improving academic skills but instead of instilling character, which is also not supported by the research. He recommends that the amount of homework be reduced in order to provide children with more opportunities to manage and be responsible for their own free time. In addition, he recommends that instead of continuing to assign large amounts of homework, teachers should focus on changes needed in curriculum and instructional practices. He asserts that homework would not be necessary if well-trained teachers were efficient in the use of the school day and if older students were provided with more opportunities for independent work during the school day. Kohn [3] asserted that the problem with current homework practices is that they are often based on basic misconceptions about learning itself. These misconceptions include the ideas that more time automatically leads to better learning; that practice automatically leads

to better understanding; and that just getting a child to complete an activity is enough to ensure learning. Instead, he advocates for focusing more on the quality of the homework rather than the quantity; how well the child understands the activity rather than just if they completed it; and a consideration of the child's needs, goals and attitudes related to that activity. He recommends that teachers and parents question the basic assumption that homework is important and necessary. He would like to see a drop in the number but an increase in the quality of homework assignments. He would also like to see an increase in the amount of choice offered to students in homework assignments.

Homogeneity of Variance

►Homoscedasticity

Homonegativity

►Sexual Prejudice

Homophobia

James E. Vaughn III
Oklahoma State University, OH, USA

Synonyms

Heterosexism; Sexual prejudice

Definition

Homophobia, from the Greek words *homos* (same) and *phobos* (fear), is a term used to describe the irrational fear of homosexuals or the irrational fear of one's own homosexuality. Homophobia is also used to describe an aversion to homosexuals as well as prejudice toward homosexuals [1].

Description

The term homophobia has undergone an evolution in meaning since George Weinberg first coined the term in the late 1960s. Originally used to describe an irrational fear of homosexuals either in an external fashion by heterosexuals or in a more internalized form among homosexuals, the term is used more commonly today to describe prejudice against homosexuals.

Psychologist Gregory Herek (2000) has opted to replace the term homophobia with the term sexual prejudice as a better way of defining the negative attitudes leveled not only against homosexuals but bisexuals persons as well. Sexual prejudice can also be used to refer to negative feelings and attitudes toward any sexual orientation whether it is homosexual, bisexual, or heterosexual. Homophobia suggests that the source of the negative attitudes towards homosexuals is psychopathological in nature. What is most likely is that these attitudes are the result of multiple factors including the violations of cultural and or religious norms and beliefs. The term sexual prejudice conveys the negative attitudes toward homosexual or bisexual behavior, people with a homosexual or bisexual orientation, and communities of homosexual and bisexual persons [2, 3].

The term heterosexism has also been used to describe the negative attitudes toward homosexual persons by individuals and institutions. Heterosexism is defined as a belief that any form of sexual expression other than heterosexuality is inferior and unacceptable. Both the terms sexual prejudice and heterosexism do more to illustrate the ubiquitous nature of negative feelings toward homosexuals by emphasizing the cultural and institutionalized nature of the attitudes rather than reducing them to the level of the individual as does the term homophobia.

Relevance to Childhood Development

The relevance of homophobia to childhood development is somewhat complicated. It is early in social development that children become aware of religious beliefs and societal norms and this is when the negative attitudes toward homosexuals most likely begin. The issue is complex in that the negative feelings expressed as homophobia, sexual prejudice, and heterosexism often are a part of the religious values or

societal norms of the cultural in which the child belongs. Many if not most societies and religions hold negative attitudes toward homosexual persons and in some countries homosexual acts are punishable by imprisonment or even death. Educating children in views that are contrary to religious beliefs and societal norms about homosexuality may be difficult if not impossible in some situations [3].

Another issue relevant to development would be when the development of sexual identity begins in adolescence. Adolescents who may begin to identify with a homosexual orientation may be at risk for discrimination and harassment not only from peers but from parents and educators as well. Many homosexual adolescents have the added disadvantage of not having any support systems or positive role models during this period of development [4, 5].

Homoscedasticity

Marie-Anne Issa, Kevin L. Nadal
John Jay College of Criminal Justice, New York, NY, USA

Synonyms

Assumption of normality; Homogeneity of variance

Antonyms

►Heteroscedasticity

Definition

In statistics, homoscedasticity occurs when the variance in scores on one variable is somewhat similar at all the values of the other variable.

Description

To illustrate homoscedasticity, assume a group of researchers are collecting continuous data (i.e., correlation design), whereby they are looking at 10 year-olds' weight and their stress level (as measured on a scale of 1–10). The data is said to be homoscedastic if the variance in the stress scores is somewhat the same across the children who weigh 70, 85 and 90 pounds.

In regression analysis, the assumption of homoscedasticity occurs when at each level of the predictor variable, the residuals have similar variances [1, 2].

One way to test this assumption in regression analysis is through requesting a residuals scatterplot. The predicted scores lie on the first axis of this scatterplot, while the residuals (prediction errors) lie on the second axis. If the assumption of homoscedasticity is met, the shape of the data will be rectangular, with a high concentration of scores along the center. The further the scores lie from the center and/or the rectangular shape, the more the data becomes heteroscedastic [3].

In correlation studies, a bivariate scatterplot can be requested. If the assumption of homoscedasticity is met, the shape of the data distribution will be oval. Similarly, the more the data moves away from an oval shape, the more it is considered heteroscedastic.

Meeting the assumption of homoscedasticity, like meeting other assumptions that underlie most multivariate procedures, is important since it renders statistical inferences more robust. The more the variables are skewed, the less likely the data would be homoscedastic. In such cases, transformation of the skewed variables is generally recommended [3].

Homosexual

►Homosexuality

Homosexual Identity

►Sexual Identity

Homosexuality

Ronald R. Holder
Our Lady of the Lake University, San Antonio, TX, USA

Synonyms

Bisexual; Gay; GLBTQ; Homosexual; Lesbian; Queer; Transgender

Definition

Broadly defined, homosexuality refers to the sexual and/or romantic attraction to one's own gender. Men who are attracted to men are generally referred to as "gay men." Women who are attracted to women are commonly referred to as "lesbians." There has been some opposition and global controversy regarding the word "lesbian." Specifically, Lesbian, with a capital L, refers to an inhabitant of the Isle of Lesbos. The islanders of Lesbos once sued a gay rights organization over their use of the word "lesbian," stating that the impact of the word violates the civil rights of the islanders and their freedom of self-identification [2]. To disunite this unintentional lingual connection, it has become more common to use "gay woman" instead of lesbian.

Description

Definitions are deceptively simple modalities to describe words and create meaning. Homosexuality is a word that changes in meaning depending upon the context and the venue in which it is being discussed. The debates about homosexuality are generally twofold and center simultaneously on etiology and morality. The proposed solution to one of those questions often influences the answer to the other question. In 2001, Robert Spitzer, MD, presented a study that contained accounts of homosexuals who converted to heterosexuality, suggesting that homosexuality is a choice instead of a biological imperative. The media discovered the story and before checking facts or interviewing the researcher, posted headlines that proclaimed homosexuality had been scientifically proven to be a choice. Later, Spitzer admitted that the results of his study were not generalizable because the ex-gay participants were solicited from Laura Schlesinger's radio talk show, which had a definite notion of that subject [6].

Before Spitzer's study, the psychological community removed homosexuality from the DSM in 1973. Unfortunately, that controversial decision did not serve to modify the view of mainstream society that homosexuality is abnormal or that it is the result of stunted psychosexual development. Some psychologists maintained a blatantly antagonistic attitude towards gay men and women who came in for therapy. There are reports of some Psychologists using ECT (electro convulsive therapy) on clients who self-identified as gay. Psychologists also developed theories regarding the etiology of homosexuality, all of which implied abnormality. The theories were usually erroneously connected with quantitative studies that began with a definition of what constituted the different categories of sexuality while largely ignoring the qualitative experience of the subjects [7]. This attitude has been embraced by organizations that seek to "cure" homosexuals, which is defined as embracing a heterosexual lifestyle.

Heterosexuality is not only considered normal but also the only moral and Christian *choice* by ex-gay organizations that usually have affiliations with local churches. The names of some of these organizations are: Exodus International, Desert Stream Ministries, People Can Change, Evergreen International, and Regeneration, Inc. The 1999 movie *But I'm a Cheerleader* takes a humorous look at an ex-gay camp. In the movie, a young girl's friends and parents suspect that she is gay and they all agree to check her into a camp with other individuals who are in need of "the cure." The legal system is also involved in this style of heterocentrism in that the consensual sexual activity associated with gay men and women is deemed illegal in many states. Additionally, in the 2008 election, California, Arizona, and Florida voted to amend their state constitutions to define marriage as a union between a man and a woman. There are now 29 states that have amended their constitution to ban same-sex marriage. In stark contrast to the United States' apparent attitude regarding gay women and men, same-sex marriage is recognized as equal to heterosexual marriage throughout Canada, Belgium, Spain, the Netherlands and Norway.

Relevance to Childhood Development

Drescher [5] wrote that psychological professionals are now more commonly conceptualizing homosexuality as "a normal variant of human sexuality" (p. 443). With that in mind, the therapeutic search for an etiology to try and explain a client's sexuality is unnecessary and, in most cases, irresponsible. Although he could not prove it at the time, Freud believed that there was a biological basis for homosexuality and believed that homosexuals could be productive and well-adjusted members of society (Green, 2003). If a gay woman or a gay man comes in for psychotherapeutic treatment, it is far more likely that their struggle will be in constructing a cohesive narrative in their lives that includes homosexuality. Gay men will

frequently report to their therapist that when they were children and adolescents, their male caregivers attempted to force them into activities that are generally considered more masculine in nature (e.g., playing sports) and condemned any display of what would be considered feminine activities (e.g., playing with dolls). Isay stated that a parent who punishes their child for engaging in behaviors that do not fit with the dominant construct of their gender might prevent the child from developing a healthy attitude about their emerging sexuality [1].

There are many theories of development that are used to categorize human behavior. It is important to remember that not every client will fit within the narrow molds cast by those models. The same is true with the models that have been developed with regard to homosexual development. The client should be encouraged to define what being a gay man or a gay woman means within the framework of their dominant culture and familial interactions. Coleman [3] developed a five-stage model for the process of coming out, which is the moment when a gay individual reveals to their family, friends, and society at large that they are gay.

STAGE I: Pre coming out – the child will learn about the family and society's feelings about homosexuality. If negative attitudes are displayed about those feelings, the child may become depressed and conflicted and act out behaviorally.

STAGE II: Coming out – the individual acknowledges their sexuality. The key task after that acknowledgement is telling someone about it. The reaction of this confidant will shape the individual's self-image and their level of comfort about opening up to other people. The median age for this stage is 13–18.

STAGE III: Exploration – the task at this stage is to learn how to interact with other homosexuals and develop a sense of self as a homosexual person. This stage may also include seeking a sexual partner and trying to achieve a sense of self-esteem. One of the pitfalls of this stage would be using drugs or alcohol to self-medicate and soothe a wounded ego or battered self-image.

STAGE IV: First relationships – after a period of social and perhaps sexual exploration, an individual will develop a need for a stable, committed relationship. The task at this stage is learning how to exist as a gay couple in a predominantly heterosexual society. The attitudes of others play an important role in the longevity of first relationships.

STAGE V: Integration – this is an open-ended stage of development that will persist across the remainder of the lifespan. Long-term relationships that approximate heterosexual relationships in terms of commitment and familial obligations are not uncommon. This stage usually begins 10–13 years after Stage II.

This model is similar to other developmental models in that there are tasks that occur at each stage that must be completed before the moving on to the next stage. While no model will fit every single person that presents for therapeutic intervention, Coleman's model would be an empowering way to allow the young client an opportunity to see hope and acceptance rather than pathology and a lifetime of living a secret life.

The American Psychological Association has adopted standards for the ethical treatment of homosexuals and there is a wealth of literature about designing a gay affirmative practice for adults. Precious little has been written about the special challenges that gay youth face and developing practices that will affirm and assist them through their development. Crisp and McCave [4] wrote about this topic and offer suggestions about the attitudes psychological professionals should adopt to meet the needs of this unique and ubiquitous population. Beyond any textbook or scientific study, homosexual youth and adult populations deserve respect and support from the professionals from whom they seek services. There are steps that society is making to embrace homosexuality in a way that did not exist a short 10 years ago. For example, there are television channels that now carry gay programming, movies with gay affirmative messages, television shows with central characters who are gay, and websites that gay youth can access that will connect them with services and groups in their area of the world. Some of those resources are listed below and fortunately it is not a complete list.

Homozygous

Mysti S. Frazier
University of Texas at San Antonio, San Antonio, TX, USA

Definition
Homozygous, meaning similar, is a specific genotype which exists when a child has either two recessive or two dominant genes from the parents.

Description
When the DNA from a sperm and egg combine they form the unique characteristics of the offspring through the expression of dominant and recessive traits. If the chromosomes in a homologous pair of genes have similar alleles they are considered to by homozygous [1].

An example of this would be if a child receives the dominant gene trait of blue eyes from the mother and blue eyes from the father, then the child is homozygous to receive blue eyes and will in fact have blue eyes.

Hormones

Synonyms
Estrogen

Definition
A chemical that is released by the endocrine glands into the bloodstream to affect different body targets.

Description
The human body contains around 100 hormones that can be classified into two different types; peptide or steroid. Peptide hormones are created by cellular DNA in the same fashion other proteins are made. A peptide hormone binds with metabotropic receptors on the cells membrane to create a second messenger, this second messenger affects the target cell's physiology and influences the cell's functioning. Some common peptide hormones are growth proteins and insulin. Steroid hormones are created by synthesizing cholesterol and are lipid soluble. The steroids diffuse from their gland sites and cross through cell membranes to influence the cell's DNA to increase or decrease protein production. Steroids are found in a number of gland sites including the adrenal cortex, thyroid, and gonads.

There are three different categories of hormones that affect human behavior, also note that hormones may fall in more than one category, they are as follows:

1. Hormones that help maintain homeostasis in the body
2. Gonadal (sex) hormones that control the functioning of reproductive organs (e.g., Testosterone, estrogen, progesterone, prolactin, and oxytocin)
3. Hormones and stress hormones that help prepare human bodies for physiologically or psychologically challenging events or emergencies (e.g., Glucocorticoids including cortisol and corticosterone)

Further, hormones can be used to prevent or treat diseases, for replacement therapy if glands are removed or are malfunctioning, to counteract aging affects, and to gain physical advantages in sports.

Hospice

Hospice is a type of care focusing on the palliation of a terminally ill patient's physical or emotional symptoms. The hospice concept has been evolving since the eleventh century. Hospices have been places of hospitality for the ill, wounded or dying and in previous centuries for travelers and pilgrims. The modern concept of hospice includes palliative care for the incurably ill typically in their own homes. Hospice care emerged in the 17th century but many of the foundational principles by which modern hospice services operate were pioneered in the 1950's by Dame Cicely Saunders. Hospice care has rapidly expanded through developed countries.

Hospital Admissions for Young Children

►Hospitalization of Preschoolers

Hospitalization of Preschoolers

Margaux Barnes, Avi Madan-Swain
University of Alabama at Birmingham, Birmingham, AL, USA

Synonyms

Inpatient care for preschool children; Hospital admissions for young children

Definition

The period of hospitalization in a health care facility that begins with a child's admission and ends with discharge.

Description

In 2000, approximately 18% of the 36 million United States hospital admissions were for pediatric patients between birth and 18 years of age. Preschool-age children, (i.e., children between 3 and 5 years of age) accounted for approximately 3.6% of these pediatric hospitalizations [1]. The primary reasons for hospitalization of preschoolers include asthma, pneumonia, fluid and electrolyte disorders, epilepsy and convulsions, infections, gastroenteritis, chemotherapy, and radiotherapy. Medical procedures most likely to occur during these hospitalizations include diagnostic spinal tap, appendectomy, respiratory intubation and mechanical ventilation, respiratory therapy, vascular catheterization, blood transfusion, cancer chemotherapy, and antibiotic therapy. The average length of stay for pediatric illnesses is 3.9 days [1].

Relevance to Childhood Development

Hospitalization of a preschool-aged child can be extremely stressful and frightening for both the child and their family. The ability of a preschool-aged child to understand the process of hospitalization is limited by their level of cognitive development [4]. According to Piaget's theory of cognitive development, preschoolers are in the preoperational phase of development during which they begin using symbolic play and are able to use language to discuss objects that are not present. Speech at this stage is still egocentric. Magical thinking is common along with increased use of pretend play. In addition to cognitive development, preschoolers are also developing their social and emotional skills. According to Erickson [2], preschool aged children are faced with two tasks: (1) developing autonomy versus shame, and (2) learning initiative versus guilt. These tasks are necessary for young children to develop a sense of independence and self-control as well as to begin to form healthy interpersonal relationships.

Given preschooler's level of cognitive and emotional/behavioral development it is not surprising that hospitalization can be an extremely overwhelming and distressing experience. Some common difficulties experienced by preschool-aged children include problems understanding and adjusting to their new hospital environment, the necessity of constant monitoring (e.g., nurses and various other medical staff coming in and out of their room), and medical procedures. Some negative reactions to hospitalization noted in the literature include withdrawal or aggressive behaviors, increased separation anxiety, unrealistic fears, and behavioral regression (e.g., a child who has been toilet trained may start having accidents). Common pediatric fears include body mutilation, fear of the unknown, the supernatural, and separation from loved ones. More specific hospital-related concerns involve fears of intrusive procedures and pain. Fear of needles and shots is the most frequently reported hospital-related fear. The preschooler's behaviors in the hospital may also vary as a function of disease chronicity and severity. For example, research indicates that children with acute illnesses demonstrate more internalizing behavior in the hospital relative to children diagnosed and treated for chronic illnesses [3]. Further, children whose disease was considered life-threatening demonstrated more internalizing and externalizing behavior during hospitalization relative to those with non-life-threatening illnesses.

While research addressing the long-term impact of hospitalization on preschool-aged children and their families is limited, clinical interventions have been developed to promote adaptive coping during hospitalization [5]. Parents and medical team members should assess symptoms of distress including heightened somatic complaints, withdrawal, anxiety, and aggression. It is important that medical information, particularly procedures, be explained in simple and direct words. Using pictures is often helpful. Additionally, any questions asked by the preschooler should be answered directly and briefly; too much detail is counter-productive and will only serve to heighten their anxiety. Modeling appropriate coping and teaching preschooler's strategies (e.g., teaching deep breathing through use of party blower) is helpful. There

may be occasions when simply using distraction is necessary to help the preschooler through the procedure. During hospitalization it is helpful to let the child select familiar items from home to bring to the hospital. While in the hospital parents and medical team members should help the preschooler maintain a sense of control by giving them simple choices (e.g., you can take the medicine now or in 5 min) and whenever possible encourage them to participate in self-care. Preschoolers need structure and consistency. Keeping the hospital routine as close to the child's normal daily routine will help both with adjustment to the hospital and the transition home after discharge. If specific concerns are noted, most tertiary children's hospitals have medical team members who specialize in helping children adapt to their medical situations. Child-life specialists use medical and therapeutic play to help the child gain a sense of mastery over their medical situation. If more serious distress is noted, psychologists may help the child to cope with and adjust to the situation using empirically-validated clinical interventions.

It is important to remember that not all children will experience adjustment difficulties during hospitalization. Children are generally resilient and will easily adapt to the hospital environment. However because early medical experiences will have long-term impact on future health care issues it is important to address fears and concerns as soon as they are noticed.

Hostile Aggression

Micah S. Brosbe
Nova Southeastern University, Ft. Lauderdale, FL, USA

Synonyms

Affective aggression; Impulsive aggression; Reactive aggression

Definition

Hostile aggression is a type of aggression that is committed in response to a perceived threat or insult. It is unplanned, reactionary, impulsive, and fueled by intense emotion as opposed to desire to achieve a goal. Aggressors typically have a sense of a loss of control during outbursts, and characteristically experience physiological hyperarousal.

Description

►Aggression in children and adolescents can take many forms. It can include ►bullying, fighting, teasing, or rumor spreading. Definitions of aggression have varied; some define it by intention of causing harm while others define it by the action of causing harm itself [1]. Aggression in general has been classified on various different dimensions. Most notably, it has been classified by the type of aggressive acts committed and by the state of mind or intention of the aggressor.

Aggression is frequently classified as hostile versus proactive/►instrumental aggression [1]. Reactive/hostile aggression is also known as impulsive or affective aggression. It is unplanned, emotional, and characterized by a loss of control. Individuals exhibiting this type of aggression attribute more hostile intent to ambiguous events. They characteristically have increased physiological hyperarousal. Whereas hostile aggression is fueled by impulsive emotion, instrumental aggression is planned and purposeful, done as a means to an end. Individuals who commit acts of instrumental aggression do not feel a sense of loss of control, and they even experience physiological hypoarousal. The two types of aggression are correlated with each other, but still represent distinct classifications [1].

It has been claimed that the instrumental vs. hostile aggression dichotomy is no longer useful [2]. According to this assertion, it is too simplified and does not explain aggressive acts that are planned and calculated but motivated by hot-blooded anger (e.g., Columbine). Nevertheless, it is still a widely used and accepted conceptualization of human aggression.

Social information processing theory also seeks to explain aggressive behavior in individuals. According to this theory, one's perception of social events and decisions on how to react include a five step process [3]. The first step is that social cues are encoded by the person, with aggressive children selectively attending to hostile or threatening cues in the environment more than nonaggressive children. Next, as these cues are encoded, the individual interprets the cues often using past experiences as references for interpretation. Aggressive children are more likely to interpret ambiguous cues as hostile, which is known as hostile attribution bias. The next step is response search,

in which the person generates a list of possible reactions. Aggressive children generate more aggressive responses and fewer nonaggressive responses. In the fourth step, these different responses are evaluated and the person chooses one. The final step involves enacting the chosen response. Recent research has also shown that both bullies and victims have shown similar patterns of social information processing [4]. This theory has undergone tremendous research investigation since its original formulation, but it is still commonly applied to how people act in social situations and to hostile aggression.

Those with hostile aggression scored high on measures of anger and impulsivity [1]. As such, certain psychological disorders are associated with higher rates of aggression, such as attention-deficit/hyperactivity disorder (ADHD), oppositional defiant disorder (ODD), and ►conduct disorder (CD). In a study of hostile aggression in children with one or more of these diagnoses, children responded aggressively when in a high provocation situation [5]. Children with comorbid disruptive behavior disorders (i.e., ADHD, ODD, CD) responded more aggressively than children with only one or no diagnosis to low provocation situations as well. They also were more physiologically hyperaroused and continued to act aggressively for a longer period of time.

Relevance to Childhood Development

Much work has been done on examining various biological, social, and psychological variables that represent risk factors for the development of aggression. Certain biological predispositions (e.g., genetics, prenatal exposure to toxins, traumatic brain injury) can influence ability to regulate emotion or social cognitive functioning. These biological factors can interact with the environment to produce aggressive behavior [6]. Parental rejection and neglect have also been related to aggression in children. Harsh discipline and high family conflict have also been associated. Aggressive behavior in childhood leads to rejection by peers, which leads to delinquent peer associations and future aggressive and antisocial behavior [6], as well as increased risk for substance abuse in high school [7].

In a recent comprehensive study which considered several predictors of hostile aggression, a pathway of cumulative risk factors was identified [8]. Children born into environments which include low socio-economic status and parental depression were found to be at greater risk for later aggression and antisocial behavior. Harsh and inconsistent discipline is more likely in these adverse contexts and may lead to aggression. Due to this family environment, the child demonstrates cognitive and/or social deficits when entering school, and this leads to peer rejection and academic difficulties. As the child ages and moves into adolescence, the parents become less involved and able to influence the child's behavior, thus the adolescent develops associations with delinquent peers, which is a strong predictor of violent, aggressive, and antisocial behavior. Since this study indicates a chain of risk factors, intervention can be aimed at disrupting the development of aggressive characteristics at any (or every) point in the process [8].

Human Cell

The word cell comes from the Latin cellula meaning a small room. This term was coined by Robert Hooke in a book he published in 1665 when he compared the cork cells he saw through his microscope to the small rooms monks lived in. The cell is the functional basic unit of all known living organisms. The human cell was discovered by Robert Hooke. It is the smallest unit of life classified as a living thing. It is frequently referred to as the building block of life. Humans are multi-cellular possessing an estimated 100 trillion cells.

Human Evolution

Daniel Patanella
New York City Department of Education, New York, NY, USA

Synonyms

Paleoanthropology

Definition

The study of human evolution is a multidisciplinary effort known as paleoanthropology. The consensus among scientists is that early hominids first appeared in Africa and shared a common ancestor with archaic chimpanzees. After a period of great diversity, hominids spread from Africa to both Europe and Asia and, eventually, the sole surviving species of *Homo sapiens* emerged.

Description

Evolution can be thought of as the adaptation of living organisms, over time, to their environment. Adaptation occurs constantly, so evolution can never be thought of as being complete. It is best conceptualized as an ongoing process in which living things strive to continue the viability of their species within an ecosystem that is also changing. As human beings are living things, the general principles of evolutionary theory can be used to help understand the behavioral and biological similarities modern humans share with related life forms, as well as to suggest the biological underpinnings of human social systems and psychology. Both Charles Darwin and T. H. Huxley theorized about human evolution in *The Descent of Man* [3] and *Evidence as to Man's Place in Nature* [5], but in the nineteenth century, the human fossil evidence beyond *Homo erectus* and *Homo neanderthalensis* was too sparse to allow advanced theory development beyond conjecture. The explosion of fossil discovery throughout the twentieth century led to a much richer and fuller conceptualization of human evolution leading to our own species of *Homo sapiens*.

Scientists studying human evolution primarily rely on cladistics, the same classification tools used by scientists studying other types of evolution. A time-honored technique in which fossils are classified according to structural similarities, cladistics allows scientists to organize

Author's Note
This work represents the scholarship of the author and does not imply any official position of the New York City Department of Education.

taxonomical data into tree diagrams called cladograms according to similarity of physiological data. Wherever possible, DNA evidence is used to supplement and enhance the data obtained by physical remains and fossils. Anthropological evidence based on artifacts is also incorporated whenever the human species in question engaged in tool-making and use.

It is important to remember that the fossil record, almost by definition, is incomplete. It is unknown how many hominid species truly existed, and whether our current taxonomies underestimate or overestimate true hominid diversity. As even *Homo sapiens* was a preliterate species until fairly recently, there is a complete absence of written records prior to the cave art attributed to the Cro-Magnons and despite the presence of anatomical apparatus required for speech, it is impossible to do more than speculate as to which hominids possessed language and the complexity of such languages. Analogies made to the tribal structure of aboriginal peoples must also be viewed with caution, for even within our species evolution has occurred over the past 200 generations.

Chronology of Human Evolution

Between five and six million years ago, an ape-like genus of hominid known as *Australopithecus* first appeared in Africa. The earliest fossil evidence for these creatures exists in modern-day Chad and Kenya, although *Australopiths* most likely were widely dispersed throughout the continent. These earliest *Australopiths* had only recently diverged from a common ancestor they shared with what would eventually evolve into modern chimpanzees; this is based not only on fossil evidence indicating morphological and structural similarities between *Australopiths* and archaic chimpanzees but also by contemporary DNA evidence indicating that modern humans and modern chimpanzees differ in their nucleotide sequence by only about 1.27% suggesting the two living creatures share a fairly recent ancestor.

The *Australopiths* were shorter than modern humans (typically reaching a height of only 3 ft), and had a generally ape-like appearance. Yet they differed from archaic and modern apes in two key ways. First, they were truly bipedal, with shorter arms and an erect spinal cord. Second, they possessed larger brains than apes of a comparable size. We know little about the behavior of the *Australopiths* aside from inferences based on their preference for savannahs as their habitat. There were multiple species within the genus of *Australopithecus*, some of which survived in Africa until roughly one million years ago. Perhaps the best-known species of these hominids, *Australopithecus afarensis* (nicknamed "Lucy" by the team of scientists led by Donald C. Johnson, who discovered the fossils of the species), is believed to have been the direct ancestor of the *Homo* genus which would eventually lead to modern humans. More recent species of *Australopiths*, including *Australopithecus robustus* and *Australopithecus boisei* diverged away from the path that led to *Homo* and are not believed to be ancestral to modern humans.

Approximately two million years ago, several varieties of the *Homo* genus (such as *Homo habilis* and *Homo erectus*) could be found throughout Africa. The earliest of these, represented by *Homo habilis*, are transitional figures between *Australopiths* and later, more recognizably human examples of the *Homo* genus. Given the large gaps in the fossil record, it is unclear how many species of *Homo* there were, or even how many species coexisted simultaneously. However, it is very clear that *Homo erectus* was in many ways the most successful of its competitors. Unlike most early humans, *Homo erectus* survived as a species for over a million years, only becoming extinct once more recognizably modern humans appeared about 500,000 years ago. *Homo erectus* stood about 5 ft tall, which approximates the lower height limits of modern humans, had the appropriate anatomy and brain structure for speech, and used crude tools to hunt and build. In common with some other late-period humans such as *Homo ergaster*, *Homo erectus* lived in small tribes of up to 50 members and presumably had some form of social structure.

Homo erectus is also at the crux of a controversy between two competing theories of the dispersion of humans outside of Africa. Traditionally, it was believed that *Homo erectus* migrated out of Africa and that all its descendants evolved in parallel throughout Asia and Europe, leading independently to *Homo sapiens*. This theory, known as the Multiregional Origin, is largely based on the evidence of *Homo erectus* fossils found throughout Asia; both the so-called "Java Man" and "Peking Man" humans discovered in Asia were examples of *Homo erectus*. Thus, according to the Multiregional Origin theory, the various modern races developed in parallel, and interbred just enough to avoid evolving into distinct species. However, based on additional taxonomical classification of anatomical characteristics and skeletal structure, a competing theory claims that the true ancestor of *Homo sapiens* is actually *Homo ergaster*, which left Africa at a later time than did *Homo erectus*. This competing theory does not deny that *Homo erectus* migrated out of Africa, but instead maintains that *Homo erectus* became extinct and was displaced by later waves of *Homo sapiens* immigration out of Africa. This theory, known as the Out-of-Africa theory, receives strong support from the analysis of

mitochondrial DNA in surviving tissue samples (although proponents for the Multiregional theory also claim mitochondrial DNA evidence of their own). Regardless, early humans did leave Africa about one million years ago and migrated throughout Asia and Europe, ultimately evolving into *Homo sapiens*.

The diversity of different human species declines at around the same time that *Homo erectus* migrated into Asia. The last two species of human are *Homo sapiens* and *Homo neanderthalensis*. All humans alive today are classified as *Homo sapiens* whereas there have been no surviving examples of *Homo neanderthalensis* for the past 30,000 years. Again, there is considerable controversy in the literature regarding how similar these two species may have been, despite the plethora of available Neanderthal remains and the fact that Neanderthals are the best-understood hominids apart from *Homo sapiens*. On the one hand, the traditional view of the Neanderthal stereotypes the species as an ogre-like creature of limited intelligence, unable to stand fully erect, and incapable of mastering any but the crudest technologies. A more radical view claims that socially and intellectually, Neanderthals were virtually undistinguishable from *Homo sapiens* and that the two species were so genetically similar that they interbred. Recent discoveries of the impressive stone craftsmanship Neanderthals were capable of, as well as the burying of their dead in what appears to be a ritualistic manner, have not brought resolution to the controversy. Paleoanthropologists are divided regarding the crediting to Neanderthals as a hominid capable of symbolic thought capabilities that rival the *Homo sapiens* from the same period.

For close to a quarter of a million years, Neanderthals lived across the Near East and Europe. In comparison to *Homo sapiens*, Neanderthal skulls had pronounced bony brows and an enlarged occipital bun toward the rear of the skull. In terms of overall brain capacity, Neanderthals are usually considered to have larger brains than *Homo sapiens*, and physiologically Neanderthals were robust hominids possessing greater physical strength than contemporaneous *Homo sapiens*, usually identified as Cro-Magnons.

However, starting around 40,000 years ago, *Homo sapiens* migrated from Africa into Europe via both Eastern Europe and the Iberian peninsula. Within the space of about 10,000 years, *Homo sapiens* completely replaced the formerly dominant *Homo neanderthalensis* throughout Europe. Exactly how this happened is a mystery, given that Neanderthals had a strong advantage due to entrenchment and experience within Europe. It is likely that modern cognition emerged in *Homo sapiens* at around this time, and provided the necessary abilities to compete successfully with Neanderthals. Although mitochondrial DNA studies do not support this hypothesis, a strain of contemporary research suggests that Neanderthals were simply absorbed within *Homo sapiens* due to cross-breeding even if those genes are no longer found within modern *Homo sapiens*' DNA.

Human Immunodeficiency Virus (HIV)

Melissa R. Mignogna[1], Lisa Lay[2]
[1]Oklahoma State University, Stillwater, OK, USA
[2]Oklahoma State University Health Sciences Center, Tulsa, OK, USA

Synonyms

Acute HIV infection

Definition

Human immunodeficiency virus (HIV) is a single stranded RNA retrovirus that attaches itself to the proteins

on the surface of infection fighting white blood cells in the human immune system (T-cells (T-lymphocyte)). Over time the virus is replicated, many T-cells are destroyed, and the immune system is seriously impaired, sometimes leading to the diagnosis of Acquired immunodeficiency syndrome (AIDS).

Description

HIV is transmitted into the human body via infectious body fluids including blood, semen, vaginal secretions, and breast milk. Modes of transmission include contact with infected blood (e.g., injection drug use, blood transfusion, occupational needle sticks), sexual contact, ingesting infected breast milk, and transmission during child birth [2]. Testing of donated blood began in the US in March of 1985 and currently, transmission of HIV via transfused blood is very rare.

Upon entering the body, HIV attaches itself to the proteins (known as CD4, CCR5, and CXCR4 molecules) on the surface of infection-fighting white blood cells that comprise the human immune system. These specialized white blood cells are known as T-cells, and function to detect and attack foreign invaders in the blood. Upon fusing to the CD4 surface molecules, the HIV injects genetic material, or RNA, into the host cell. Next, the RNA is replicated within the T-cell. The T-cell is subsequently killed as the new HIV copies are released into the blood stream and the infection process continues. In turn, the immune system detects the loss of the T-cells, and protects itself by producing new cells [8]. Over time, more T-cells are destroyed, the viral load of HIV increases, and immune system functioning is compromised or impaired [1].

Once infected, the presence of HIV in the blood stream is measured by the means of the CD4+ count and the viral load count. The CD4+ count is the number of helper T-cells present in a milliliter of blood, representing an index of a person's immune system functioning. Non-infected individuals generally have a CD4+ count ranging from 500 to 1,500 cells, but after the first year of HIV-infection, this count decreases at a rate of approximately 30–90 cells yearly. The viral load count measures the number of HIV particles per milliliter of blood plasma, and is used to measure the rate at which CD4+ cells are being destroyed. Eventually, HIV kills enough cells that an individual's immune system is unable to eliminate other infections that can make the person sick. These infections are referred to as "opportunistic infections." AIDS is the later stage of HIV infection, and is diagnosed when either the CD4+ count is less than 200 (or the percentage of cells that are CD4+ in all lymphocytes is less than 14%), or there is the presence of an AIDS identifying opportunistic infection (e.g., Pneumocystis pneumonia, Kaposi's sarcoma). Once a diagnosis of AIDS is made, the patient is always considered to have AIDS, despite response to medications, elimination of opportunistic infection, or increases in the number of CD4+ cells [8].

The first cases of AIDS were reported in the US in 1981, with the first pediatric cases being reported in 1982 [1, 8]. Since then, the HIV/AIDS epidemic has continued to grow worldwide. Most recent CDC data indicate that by the end of 2006, more than one million people (approximately 1,106,400) in the US were living with HIV/AIDS, with 21% unaware of being infected with HIV. Ethnic minorities are disproportionately affected with HIV, including adults and children [6]. Outside the US, this epidemic is large in comparison, with approximately 33 million people living with HIV worldwide, including up to 2.3 million children. Without access to prevention methods and treatment, these estimates will surely increase [7].

Despite the growth of the HIV/AIDS epidemic, fewer people die from AIDS-related deaths than ever before with the development of antiretroviral therapy (ART), or highly active anti-retroviral therapy (HAART). According to the CDC, the estimated number of deaths among adults living with AIDS increased steadily through 1995 and since then, this number has significantly declined in the US due to the development of HAART [4]. Furthermore, deaths of children due to HIV are declining, with a reduction from 554 deaths in 1993 to 48 deaths in 2006 [6]. In essence, HAART has transformed HIV from a terminal disease to a manageable, chronic illness by increasing the lifespan and improving immune system functioning of people living with HIV. Usually consisting of a "cocktail" of three or more anti-HIV drugs, HAART is designed to inhibit HIV replication, slow progression of the disease, and delay immune system decline. HAART works by driving down levels of HIV in blood, semen, and vaginal secretions [2, 8]. Over 25 different HAART medications are currently approved for use by the FDA with clinical trials being conducted on several new medications at any given time. Currently, there are five different classes of HAART medications available: nucleoside/nucleotide reverse transcriptase inhibitors, non-nucleoside reverse transcriptase inhibitors, protease inhibitors, fusion inhibitors, and integrase inhibitors. Each class affects replication of the virus in a different way [3].

The goal for using ART is to achieve an "undetectable" viral load in the blood. All viral load tests have a cut-off point below which they cannot reliably detect HIV, which is called the limit of detection

and varies from one testing kit to another. Most viral load tests consider undetectable as less than 50 copies per milliliter of blood. Having an undetectable viral load signifies excellent viral suppression and means that transmission of the virus to others is less likely to occur. However, an undetectable viral load in a blood sample does not mean that other infectious body fluids will be undetectable of virus as well [8].

Relevance to Childhood Development

The HIV/AIDS epidemic has also impacted children in the US In 2006, approximately 9,522 children under the age of 13 had HIV or AIDS, with the large majority of these cases occurring through vertical transmission [6]. Fortunately, with the development of HAART, rates of pediatric infection occurring via mother-to-child vertical transmission have dramatically decreased. This approach involves both the use of antiretroviral medications to reduce viral load and use of antibiotics to prevent and treat opportunistic infection. The mother is treated throughout the pregnancy and during labor and delivery, and the newborn is also treated for a brief period of time with antiretroviral medications. At birth, many newborns show the presence of maternal HIV antibodies in the blood, but with treatment these antibodies disappear. With the use of ART to both mother and child and preventing HIV-positive mothers from breastfeeding, the chances of the infant contracting HIV is reduced to less than 2%, compared to the 25–30% chance of infection with no pre- and post-natal intervention [5].

Unlike the decreasing rates of pediatric HIV infection, an increase of HIV transmission has been documented in adolescents between the ages of 13 and 24, with approximately 56,500 adolescents living with HIV in 2006. Increasing rates of infection in this age category are largely due to heterosexual and homosexual transmission. A number of risk factors have been identified that make adolescents at persistent risk for infection, including having sexual intercourse at an earlier age, high rates of substance use, lack of awareness (especially in poverty-stricken areas and among youth who have dropped out of school), and increasing rates of sexually transmitted diseases [6].

Since the beginning of the US HIV/AIDS epidemic, much has been learned about the effects of HIV on childhood physical and psychological development. During the early phases of the epidemic (and currently in undeveloped nations), symptoms of infection in childhood included significant problems such as central nervous system (CNS) encephalopathy (characterized by either a loss of previously acquired development or a failure to progress in development), changes in the frontal cortex and basal ganglia, motor hyper or hypo-tonicity of muscles (i.e., increased or decreased muscle tone), and at times, early death. However, with the advent of HAART medications, these symptoms have been reduced significantly. Overall, early CNS disease and neurocognitive impairment is associated with a poorer prognosis, but implementation of HAART can result in improvement in these areas. If untreated, HIV infection can lead to significant neurocognitive and developmental difficulties, and even children who are asymptomatic may show some neurocognitive impairment. Many children treated with HAART regimens do not show global deficits in cognitive ability, although specific deficits have been identified in areas such as visual-spatial and perceptual organization, social emotional regulation, language development, and attention problems. These specific deficits can negatively impact school performance and can be addressed with special education services. Given the limitations of antiretroviral medications and evolving resistance to classes of drugs, the future of long-term HAART treatment is uncertain, with several experts anticipating that some vertically infected adolescents will eventually experience neurocognitive decline similar to AIDS-related dementia [1].

Research with a pediatric HIV-positive population has also focused on psychosocial issues such as coping with stigma, disclosure of status, etc. Caregivers of HIV-positive children who are also positive have reported feeling socially isolated, experiencing financial difficulties, and dealing with the burden of caring for themselves and infected children. However, research has suggested that psychological distress mainly occurs in the context of stressful life situations indirectly related to HIV, such as poverty, burden, and stigma [1].

Similar results have been found in children infected with HIV. Rates of clinically significant behavioral and emotional problems are higher in children with HIV than the general population, but when these children are compared to groups with similar backgrounds (e.g., ethnicity, socioeconomic status), rates of maladjustment are actually lower. This finding suggests that risk factors such as poverty, lack of insurance, and stressful life experiences have more of an impact on maladjustment than having the diagnosis of HIV. Most studies have found no significant differences in self-reported adjustment of children with HIV compared to children who have not been exposed [1].

Changes in behavior and emotional functioning can be related to the effects of the virus or the side effects of medications. Behavioral changes have been reported in children with CNS encephalopathy, and physical changes such as

small stature related to wasting, skin disturbances, ringworm, tube insertion for medication, and descended stomach can be experienced by some children. Physical changes in children's bodies can have related psychological problems, such as fear about being perceived as "different" from others. Side effects of medications include mood changes such as depression and anxiety, lipodystrophy, lipoatrophy, impaired concentration, appetite changes, nausea and vomiting, diarrhea, and changes in sleep patterns. However, these effects are not experienced by all children with HIV, and can be exacerbated or worsened by frequent hospitalizations, disruptions in normal routine, and medical procedures [1].

Disclosure of HIV status to children is an important issue, as nondisclosure has been associated with an increase of behavioral problems. There is no agreement as to when caregivers should tell a child about his/her HIV status, but the child's age, maternal depression, social support, stressful life circumstances, and severity of disease have been cited as factors related to caregiver's decision to disclose. The American Academy of Pediatrics Committee on Pediatric AIDS has recommended that a child's age and psychosocial maturity should be taken into account when considering disclosure of HIV. Once informed about HIV status, many children are told to keep their status a secret due to the negative social stigma associated with HIV. For some children, the burden of keeping HIV status a secret, feelings of shame, and feelings of being different from others can have negative effects on psychological functioning [1].

One of the primary challenges identified for children treated with HAART is medication adherence. HAART regimens can be complicated and time-demanding, and even partial non-adherence is associated with consequences such as increased viral load and resistance to drug combinations. Numerous barriers to adherence have been reported, including scheduling difficulties, food interactions, refusal and behavioral problems, and difficulty swallowing pills. Strategies that promote adherence include written medication schedules, visual aids and rewards, and allowing children to participate in the development and implementation of their treatment regimens. Counseling focused on tailoring specific regimens to the needs of families and cognitive-behavioral pain management strategies have also been demonstrated to be beneficial [1].

Research on HIV/AIDS is prolific and continues to evolve rapidly. The future will yield new developments in prevention and treatment of this virus, for children and adults alike. Since HAART medication has allowed people to live longer, healthier lives, research has begun to focus more on the long term effects of therapy and living with the HIV virus.

Humanism

►Humanistic Perspective

Humanistic Perspective

Chris Leeth
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Existentialism; Humanism

Definition

The humanistic perspective posits that people strive to achieve meaning, purpose, or actualization in their lives. Humanistic theorists and practitioners acknowledge the finality of life as well as the role of anxiety and suffering. Humanistic practitioners empathize with people as those people work through difficulties while trying to obtain goals.

Description

The humanistic perspective, also known as Existentialism, is a theoretical orientation related to counseling and development. It has had several contributors throughout time, most notably Victor Frankl, Abraham Maslow, and Rollo May. This school of thought does not possess any specific techniques of its own, but rather, draws on the techniques of other counseling theories, namely those of person-centered counseling.

The humanistic perspective's primary stance on human development and behavior is that anxiety and suffering is an inevitable and necessary part of the human condition. Further, this perspective maintains that people inherently want to grow and achieve meaning in their lives. However, obstacles can impede progress towards meaning and that is when people begin to suffer emotionally. Practitioners empathize with their clients and help them to determine life goals, how to achieve them, and how to handle possible obstacles.

Humanistic Psychology

►Humanistic Therapy

Humanistic Therapy

Michael Block
Azusa Pacific University, Azusa, CA, USA

Synonyms

Client centered therapy; Depth therapy; Gestalt therapy; Holistic health; Humanistic psychology; Person-centered therapy

Definition

A genuine, non-judgmental, and empathic model of therapy that uses open-ended responses, reflective listening and tentative interpretations to promote client self-understanding.

Description

Humanistic Therapy overlaps considerably with other existential approaches and emphasizes the growth and fulfillment of the self (self-actualization) through self-mastery, self-examination and creative expression. It holds a hopeful, constructive view of human beings and the individual's substantial capacity to be self-determining. By and large, this therapeutic approach works with present (rather than past) occurrences and attitudes with a goal of client growth and fulfillment. Humanistic psychology acknowledges that an individual's mind is strongly influenced by ongoing determining forces in both their unconscious and in the world around them, specifically the society in which they live.

The origin of humanistic therapy came out of the humanistic psychology movement in the 1950s in reaction to both behaviorism and psychoanalysis. It is explicitly concerned with the human dimension of psychology and the human context for the development of psychological theory. Although the influences of the unconscious and society are taken into account, freedom of choice in creating one's experience is at the core, and is often referred to as "self determination." The intent of the humanistic approach is to look beyond the medical model of psychology in order to open up a non-pathological view of the individual. This usually implies that the therapist downplays these pathological aspects in favor of healthy aspects. The focus is on the client's ability to initiate change. Much of humanistic therapy is to help the client approach a stronger and healthier sense of self, also called self-actualization. All this is part of Humanistic psychology's motivation to be a science of human experience, focusing on the actual lived experience of persons.

In the late 1950s, psychologists concerned with advancing a more holistic vision of psychology convened two meetings in Detroit, Michigan. These psychologists, including Abraham Maslow, Carl Rogers, and Clark Moustakas, were interested in founding a professional association dedicated to a psychology that focused on uniquely human issues, such as the self, self-actualization, health, hope, love, creativity, nature, being, becoming, individuality, and meaning – in short, the understanding of "the personal nature of the human experience." Several humanistic approaches to counseling and therapy emerged out of this movement. The developmental theory

of Abraham Maslow, emphasized a hierarchy of needs and motivations; the existential psychology of Rollo May acknowledging human choice and the tragic aspects of human existence; and the person-centered or client-centered therapy of Carl Rogers, which is centered around the clients' capacity for self-direction and understanding of his/her own development.

Critics of humanistic theory contend that it lacks a cumulative empirical base, and that some directions encouraged self-centeredness. While proponents have not presented it as a science, they recognize that rather than being objective, science is the least subjective understanding of the world of which the largest number of people are aware. Humanistic psychology addresses the nature of the human experience, calling into question the nature of objectivity and the role of objective knowledge in the personal experience of life.

Huntington's Chorea

►Huntington's disease

Huntington's Disease

Brady I. Phelps
South Dakota State University, Brookings, SD, USA

Synonyms

Huntington's chorea

Definition

Huntington's disease was first objectively described in 1872 by an American physician, George Huntington, whose name the condition now bears; Huntington termed the disease an inherited "heirloom" he had observed amongst his patients [6]. Although earlier descriptions had been presented, none had the detail of the observations recorded by Huntington himself along with longitudinal data provided by two prior generations of Huntington's, who were also medical professionals [8]. This degenerative brain disorder, which is also classified as a subcortical dementia, was first known as Huntington's chorea, as in "choreography," with chorea being a Greek word for dance [2, 9].

Huntington's disease, as a rare progressive subcortical dementia, afflicts about 5–10 in 10,000 people; Huntington's has a host of symptoms but is known for the prominent disordered-movement symptoms, characterized by the term chorea: Involuntary, twisting, writhing movements of the body and limbs, and grimacing of the face that become progressively more extreme and impairing [9]. The disordered movements result from the loss of neurons in a subcortical (below the cerebral cortex) structure, the caudate nucleus, which itself is a component structure of the basal ganglia. The basal ganglia is a movement-modulation structure and the neurons that are lost utilize the neurotransmitter known as GABA, or Gamma Amino Butyric Acid [1, 3, 9]. As Huntington's disease advances, more brain structures and regions show signs of the loss of neurons that release different neurotransmitters and the afflicted person shows signs of cognitive decline, psychotic symptoms and extreme emotional variability and disturbances, with depression being the most common disturbance of affect. Huntington's disease sufferers have a suicide rate that is

greater than other degenerative brain syndromes. The afflicted person typically dies in 15 or 20 years after the onset of symptoms, usually from causes of death seen in a bed-ridden dementia patient. There are no therapies for Huntington's disease [2, 4, 5, 9].

Huntington's disease is an inherited and autosomal dominant disorder, meaning only the genetic error needs to be inherited from only one parent and the children of afflicted individuals have a 50% chance of inheriting the disease; Huntington's is known to be due to a defect in the gene *ITI5* on chromosome 4 [9]. Individuals with normal versions of this gene have between 11 and 34 repeats of the codon or trinucleotide CAG. This means the DNA composing this gene has a recurring pattern of three component molecules (cytosine, adenine and guanine for CAG). Between 11 and 34 repetitions of this three molecule code are normal. Having between 35 and 40 repetitions is considered an at risk predisposition for pathology. Individuals with symptoms of Huntington's have as many as 100 repeats of the CAG trinucleotide, but the greater the number of repeats, the earlier the onset of symptoms and greater severity of symptoms [2, 9]. The onset of symptoms is typically observed between the ages of 30 and 50 but in a small number of cases a juvenile onset occurs that has an accelerated progress [7]; the typical age for onset occurs in midlife, often after marriage and children and the dominant nature of the inherited defect, means that many people at risk have seen their parents go into decline and die from Huntington's. A genetic test for Huntington's was developed in 1993 and only those with a family history would need to seek testing; the majority of individuals with a family history of Huntington's disease have not undergone the genetic test. The ambivalence and uncertainty of not knowing is no doubt difficult but may be preferable to knowing one is faced with a terrible demise [9].

Hydrocephalus

John Joshua Hall[1], Chad A. Noggle[2]
[1]The University of Arkansas for Medical Sciences, Little Rock, AR, USA
[2]SIU School of Medicine, Springfield, IL, USA

Synonyms

Communicating hydrocephalus; Non-communicating hydrocephalus; Non-obstructive hydrocephalus; Obstructive hydrocephalus

Definition

A condition that results from the ventricles in the brain becoming enlarged due disturbances and/or abnormalities in the flow, production, and/or absorption of cerebrospinal fluid [6, 10].

Description

Hydrocephalus results from an excessive accumulation of cerebrospinal fluid in the ventricles. The accumulation of CSF often increases intracranial pressure and the ventricles become enlarged which can result in the disruption of subcortical and cortical functions [10]. Males seem more prone to hydrocephalus with 62% of sufferers of the disease being male [10].

Various types of hydrocephalus have been theorized. Communicating hydrocephalus refers to difficulties with

the production or reabsorption of CSF [4]. Obstructive or noncommunicating hydrocephalus results from a blockage within the ventricular system [10]. Although relatively rare, hydrocephalus can also occur from oversecretion of CSF which is often caused by a tumor on the choroids plexus.

Most children with symptoms of hydrocephalus often receive a shunt. A shunt is a medical procedure where excess CSF is drained away from the ventricular system into the stomach [10]. A shunt procedure involves causing a lesion to the brain which typically occurs in the parietal lobe of the right hemisphere.

Relevance to Childhood Development

Hydrocephalus can occur at any developmental stage and can be particularly damaging to the developing brain. It is estimated that 27 out of every 100,000 newborns suffer from hydrocephalus and if untreated can result in mental retardation [10]. Premature infants also appear to be at risk for hydrocephalus due to the increased rate of intraventricular hemorrhage which can interfere with CSF reabsorption [4]. Traumatic brain injury can result in hydrocephalus due to interference in the reabsorption of CSF. Similarly, Periventricular leukomalacia, which results in atrophy around the tissue surrounding the ventricles, can lead to excess CSF accumulation [4]. Finally, congenital disorders such as spina bifida, myelomenignecele, an A Chiari malformation, and Dandy Walker Syndrome have all been linked to increased rates of hydrocephalus.

The functional effects of hydrocephalus have been reported throughout the literature. Deficits associated with a varying etiologies of hydrocephalus in children have be seen in gross and fine motor functioning [7]; visual-motor and spatial abilities [5]; specific language skills [5]; isolated domains of memory (Yeates et al. [9]; attention and executive functioning [5]; and, behavioral regulation and control [3]. While such deficits are noted, these have been seen inconsistently as they appear largely dependent upon etiology [6]. Regarding actual cognitive sequelae, this also appears to depend on age at the time of insult or injury, severity of the injury, and the presence of other comorbid disorders [4]. For example, children with hydrocephalus secondary to a brain tumor had poor cognitive abilities than children with brain tumors without hydrocephalus; however, children with spina bifida with hydrocephalus performed equally to children with spina bifida without hydrocephalus [2].

In terms of achievement skills, Hoppe-Hirsch et al. [8] found that 60% of children with shunted hydrocephalus were placed in regular classrooms; however, half of these children lagged 1 or 2 years behind their same-aged peers. Barnes and Dennis [1] found that reading abilities of children with hydrocephalus were often within the normal range; however, arithmetic was a relative weakness. Zillmer and Spiers [10] commented that calculation, spelling, and reading comprehension or tasks that require increased attention and focus of concentration are often most affected.

Hyperactivity

R. Matt Alderson, Kristen L. Hudec
Oklahoma State University, Stillwater, OK, USA

Synonyms

Fidgety; Hyperkinesias; Hyperkinesis; Hyperkinetic; Restlessness

Definition

Motor activity that is developmentally inappropriate and significantly excessive relative to same-aged peers.

Description

Hyperactivity is frequently first identified as a problem in children as they enter preschool or kindergarten, and demands of the classroom environment (e.g., sitting still during lessons) are incompatible with excessive motor activity. Clinical interviews of parents that present with concerns of hyperactivity in their children, however, often reveal a pattern of excessive activity that was present since a much earlier age. For example, retrospective reports from parents recount their children climbing on kitchen cabinets, jumping on furniture, and struggling to sit still while getting dressed. Notably, extant studies suggest that individual differences in activity level are first apparent at the 28th week of gestation, and continue along a curvilinear developmental trajectory [12]. That is, children that exhibit hyperactivity during the school-aged years likely exhibited elevated levels of activity as toddlers, relative to same-aged peers. Collectively, whether or not a child's behavior is *hyperactive* depends largely upon the context of environmental demands, social/cultural norms, and appropriate expectations given the child's age and development. Measurement of hyperactivity is most frequently obtained from parent, teacher, and caregiver (e.g., daycare provider, babysitter) reports on objective ratings scales; clinical interviews with parents and other caregivers; behavioral observations by clinicians; and sometimes the child's self-report. Self-reports from hyperactive children, particularly those with ADHD, provide minimal diagnostic value since they frequently exhibit limited insight about their behavioral problems. Additional objective measures may include pedometers, stabilimetric cushions, and actigraphs.

Relevance to Childhood Development

Attention-deficit/Hyperactivity Disorder (ADHD) occurs in an estimated 3–7% of school-age children and is characterized by difficulties with attention, impulsivity, and of course hyperactivity [3]. Presence of the disorder conveys increased risk for several pejorative outcomes including long-term scholastic underachievement and interpersonal peer problems [4], long-term impairments across more major life activities than most other disorders seen in outpatient mental health clinics [5], and an estimated annual societal cost that ranges between $36 billion and $52.4 billion [9].

The etiology of hyperactivity in ADHD is remarkably varied in extant models of the disorder. For example, Barkley's [3] behavioral inhibition model suggests that children with ADHD exhibit hyperactivity due to deficient inhibitory processes that limit children's ability to maintain task goals, avoid the execution of a response when presented with a prepotent stimulus, or stop a response once it has been initiated. A recent meta-analytic review [1] and subsequent experimental examination [2] of the stop-signal task – the primary measure used in clinic- and laboratory-based research to investigate behavioral inhibition in children with ADHD – both found that performance on the stop-signal task may be downstream of higher order cognitive processes such as working memory. The impact of these findings transcends stop-signal research and raises important concerns regarding the central role of behavioral inhibition in extant models of ADHD, and ultimately hyperactivity. A second model suggests that children exhibit hyperactivity in an attempt to minimize the aversive nature of waiting for external-delayed reinforcement [13]. In contrast, the functional working memory model of ADHD suggests that children with ADHD exhibit hyperactivity to increase arousal needed for task demands [11]. A recent study examined 23 boys (11 typically developing children and 12 children with ADHD) between 8 and 12 years of age who completed phonological and visuospatial tasks that placed increasing demands on the working memory system [10]. While all children exhibited significant increases in activity during working memory relative to control conditions, children with ADHD became significantly more active relative to the typically developing children. This is the first experiment to demonstrate a functional relationship between working memory and children's activity level.

Hyperactivity is not pathognomic to ADHD and is frequently observed in other childhood disorders. For example, children diagnosed with early onset bipolar disorder often exhibit excessive activity, pressured speech and impulsivity. The association between increased activity and the presence of manic episodes is reflected in current DSM-IV diagnostic criteria as psychomotor agitation (e.g., restlessness, pacing) and increased goal-directed activity [6]. Restlessness and fidgeting are commonly observed in children diagnosed with anxiety disorders, such as generalized anxiety disorder, obsessive-compulsive disorder, social phobia, panic disorder, and post-traumatic stress disorder [8]. For example, Glod and Teicher [7] found that children diagnosed with PTSD (n = 19) were 10% more active and associated with a greater likelihood of developing problems of hyperactivity, relative to healthy controls (n = 15). Interestingly, increased anxiety-related activity may result from an over-arousal of physiological systems common to those implicated in children with ADHD.

Hyperkinesia Syndromes

►Dyskinesia

Hyperkinesias

►Hyperactivity

Hyperkinesis

Synonyms

Hyperactivity

Description

Hyperkinesis is a state of over-active restlessness sometimes referred to as hyperactivity. Hyperkinetic disorders are a group of psychiatric diagnoses listed in the International Classification of Diseases, Volume 10. Hyperkinesis is a recent phenomena in medicine. The roots of the diagnosis and the treatment of this entity are found earlier, however. Hyperkinesis was known in the first half of the twentieth century as minimal brain dysfunction, hyperactive syndrome, hyperkinetic disorder of childhood and several other diagnostic descriptions. Although the symptoms and the presumed etiology vary, in general the behaviors are quite similar and overlap. Typical symptom patterns include extreme and excessive motor activity, restlessness, fidgeting and, for some, mood swings.

Hyperlexia

Robert Walrath
Rivier College, Nashua, NH, USA

Synonyms

Precocious reading language disorder [1]

Definition

The advanced ability to decode and read single words without comprehension, well beyond expectations for chronological age, sometimes accompanied by fascination or preoccupation with numbers and letters. Hyperlexic children tend to have difficulty with oral or verbal communication and social interactions and are often considered to have an autistic-like presentation. There is disagreement at the present time whether Hyperlexia should be considered a form of learning disability or "superability" [2].

Hypnogen

►Ambien (Zolpidem)

Hypnosis

Brian Vandenberg
University Missouri-St. Louis, St. Louis, MO, USA

Definition

Hypnosis is a procedure involving suggestions for imaginative experiences that may entail alterations in memory, perception, emotions, thoughts and behavior. Hypnotic suggestions can be offered by another or by oneself, in self hypnosis. The experience of hypnosis is facilitated by "letting it happen," rather than "making it happen," and involves a wakeful alertness, focused absorption, attenuated critical rational functions, and diminished peripheral awareness. These are often accompanied by the experience of nonvolition; that behaviors and experiences "happen to me," rather than "initiated by me" [4, 5].

Description

Hypnosis has befuddled investigators for over two centuries, and attempts to explain its unusual phenomena have been instrumental in the development of seminal psychological concepts and practices. Hypnosis sits on the fault line of mind and body; a brief communicative exchange can cure warts, enable major surgery without pain, and improve healing of burns and wounds. Hypnosis also can alter basic psychological experiences that beg explanation; loss of a sense of volition, forgetting compelling events that just happened (amnesia), responding in unusual ways, previously suggested in hypnosis, but without awareness (post hypnotic suggestion). The use of hypnosis by physicians in the nineteenth century to treat physical ailments gave rise to the "talking cure," or psychotherapy, in the twentieth century, pioneered by Freud. Psychosomatic medicine, originating in the first decades of the twentieth century, was given impetus by earlier medical use of hypnosis. Unconscious processes, the object of speculation in the nineteenth century, were given empirical credibility by hypnotic phenomena, becoming a cornerstone feature in the theories of Freud, Janet and Jung in the early twentieth century, and introduced into experimental psychology by Hilgard in the mid-to-late twentieth century [1].

Although the name, hypnosis, is derived from the Greek word *hypno,* meaning sleep, and common hypnotic procedures invoke drowsiness, it is not a form of sleep. Wakeful alertness is one of its hallmark characteristics. There is also a long history of suspicion that people are strategically feigning responses; that there is no such thing as hypnosis. This, too, is untrue, as the nonvolutional experience of hypnotized individuals attests. Many fear that hypnosis involves the surrender of will, loss of control, or helpless domination by the hypnotist. In fact, individuals are co-participants who cannot be induced to perform acts that conflict with their values, and can independently choose to end their hypnotic involvement. Another longstanding misconception is that hypnosis can provoke superhuman feats of physical strength, perceptual acuity and memory recall. These, however, cannot be enhanced beyond that which can be achieved through non-hypnotic means, and in the case of memory, hypnosis may facilitate false recollections and memory

distortions. Finally, individuals vary considerably in hypnotic responsivity, which is a stable trait not related to any personality factors, including gullibility, conformity, suggestibility, and intelligence, save for a modest relation to absorption in imaginative involvements [1, 2, 4].

Hypnosis is effective for ameliorating acute pain associated with surgery, dental procedures, debridement of burns and wounds, and childbirth, as well as chronic pain accompanying cancer, tension headaches, irritable bowel syndrome and other chronic pain conditions. It is also effective for reducing nausea and vomiting preceding chemotherapy and treatment of some dermatological conditions. Hypnosis is also a useful adjunct procedure to cognitive behavioral treatment of phobias, anxiety disorders and insomnia [3]. Hypnotherapy with children has been particularly helpful in coping with painful medical procedures associated with the treatment of cancer and burns, and managing symptoms associated with chronic pain [5].

Relevance to Childhood Development

Hypnotic responsivity has been found to emerge around the age of five, reach a peak in early adolescence and slowly decline in the later adult years. This developmental trajectory has been assessed using adult scales of responsivity. The lack of responsivity found in young children is challenged by some who question the viability of adult-based measured that involve sophisticated cognitive and linguistic abilities that exceed the capabilities of young children, who fail, not because they are unresponsive, but because they don't understand the requests. Practitioners argue that young children are more easily engaged in play and fantasy, and if the procedures appropriately utilize these abilities, young children are better candidates for hypnosis than adults. Hypnotic procedures developed for young children in clinical settings are less verbally complex and more overtly engaged, closer to play therapy than the sedentary, cognitively complex involvement that is presupposed in the adult-based measures and procedures. Clinical reports suggest that such procedures may effectively address a host of medically related difficulties that confront young children [7].

Hypoactivity

Jana Sander
Texas A&M University Corpus Christi College of Education, Corpus Christi, TX, USA

Synonyms

Lethargic; Underactive

Definition

Less active than usual.

Description

Information regarding hypoactivity, or children being underactive, may be difficult to obtain as an internet search frequently leads to hyperactivity rather than hypoactivity. Hypoactivity may be due to a disease, physical limitation such as blindness or obesity.

Lethargy in children may be caused by an illness such as the flu or a chronic condition such as diabetes. If a normally active child becomes hypoactive or lethargic, a physician should be contacted to determine the cause.

According to a study conducted by [1, p. 107] children with various medical conditions may perceive certain exercises to be more intense than healthy children of the same age. Children with an abnormality such as a heart murmur may be hyposactive due to the presumption of illness. The reduction of activity may be based upon the perception of the physician's diagnosis rather than a directive that the child should not be active.

Obviously, disease may cause hypoactivity in children and adolescents and this may cause the child to be less physically active. Additional causes of hypoactivity may include: pain, fear of seizure or attack such as asthma, lack of opportunities to be active, or isolation (p. 108).

While many of the above reasons for hypoactivity may be valid, it is important that all children and adolescents achieve some type of physical activity as their physical conditions permit. As always, checking with the child's physician and asking for specific physical activities in which the child may engage is imperative.

Hypothalamus

Edalmarys Santos[1], Chad A. Noggle[2]
[1]Middle Tennessee State University, Murfreesboro, TN, USA
[2]SIU School of Medicine, Springfield, IL, USA

Definition

The Hypothalamus is one portion of the Diencephalon that plays a vital role in nearly all aspects of motivated behavior, including feeding, sexual behavior, sleeping, temperature regulation, emotional behavior, endocrine function, and movement [4].

Description

The Hypothalamus, in combination with the Thalamus and Epithalamus, make up the Diencephalon. While as a functional hole, the Diencephalon energizes and sustains behavior [4], the hypothalamus is specifically entrusted with the regulation of nearly all aspects of motivated behavior, including feeding, sexual behavior, sleeping, temperature regulation, emotional behavior, endocrine function, and movement [4]. It is also essential to the general arousal of the nervous system [1]. The way in which the hypothalamus achieves these end goals is through its control of the Autonomic Nervous System, with its sympathetic and parasympathetic divisions, and its connections with the Pituitary gland that mediates the neural control of the endocrine system [2, 3].

Anatomically, the hypothalamus is a small, subcortical structure at the base of the brain, composed of subdivisions, or nuclei. Specifically, it is located in front of the midbrain, above the amygdala, and next to the pituitary gland it controls [6]. It forms the floor and part of the lateral wall of the third ventricle [5, 7].

Hypotonia

David Ritchie, Barry Nierenberg
Nova Southeastern University, Fort Lauderdale, FL, USA

Synonyms

Floppy baby syndrome; Floppy infant syndrome; Infantile hypotonia

Definition

Hypotonia is defined as a decrease in muscle tone and usually strength, due to a congenital disorder, trauma or environmental factors.

Description

Hypotonia will present differently based upon the etiology and subsequent severity of the muscle flaccidity. Hypotonia is not a specific disorder, but mostly a symptom of a number of other disorders which cause deterioration of the muscle fibers [2, 5, 6, 11]. A child afflicted with hypotonia will present visually like a "rag doll" because their limbs and head appear to "flop" to their sides [3]. The child's head will hang to the sides or slouch to the chest or back because the muscles of the neck are not strong enough to hold the head erect. Upon picking up a child with hypotonia, the child might slip through the

grasp because the arm muscles do not keep the arms flexed. An infant suffering from hypotonia will have hyperflexibility in their limbs enabling them to stretch farther than normally possible [9, 10]. While not in every case, a majority of cases of hypotonia diagnosed in childhood at least partially remits, with muscle tone and controllable movement returning over time [9, 10].

The etiology of hypotonia can be difficult to diagnose. Many disorders which affect the central nervous system can be responsible for decreasing muscle tone and causing paresis. Hypotonia is usually a manifestation of a number of other disorders, with Prader-Willi syndrome being the most common cause of hypotonia in children [11]. The most common cause of hypotonia disorders is congenital defects including genetic disorders such as: Prader-Willi syndrome, Cerebral Palsy, Down syndrome, Marfan's syndrome, Tay-Sachs disease and others [1, 4, 7, 8]. Other causes of hypotonia can occur through acquired disorders, infections, metabolic disorders and trauma. Traumatic brain injuries in children, occurring because of automobile accidents and Shaken Baby syndrome, are common occurrences in children which can lead to hypotonia.

Treatment of hypotonia typically centers on finding, diagnosing and treating the underlying disorder which would alleviate the hypotonic symptoms [7, 9]. Unfortunately, accurate diagnosis in some cases can be difficult to impossible; therefore alternative treatments are sometimes necessary. Physical therapy is most prescribed to treat the lack of movement and strengthen what muscle may be left. Occupational therapy is utilized to help the patient live independently and cope with the disorder into adulthood if the hypotonia does not dissipate [9]. In more severe cases, speech therapy is necessitated to help the patient swallow, feed themselves and speak [9].

Relevance to Childhood Development

Long-term impairment for the development of the child can be difficult to determine due to the plethora of etiologies of the disorder. The hypotonia itself usually has a good prognosis with early diagnosis and treatment through occupational and physical, only if the underlying pathology does not interfere with recovery [2, 9]. Therapy is mostly concerned with helping the patient compensate for the loss in neuromuscular strength in order to function independently.

Due to the loss of muscle control and coordination at key critical periods in development, the typical hypotonic child will experience delays in reaching developmental milestones [2, 6, 9, 10]. Because of the general paresis, sometimes paralysis of the muscles, the child will have the most difficulty reaching motor milestones such as rolling over, sitting, crawling, standing and walking [9]. The hypotonic child will also have impairments with language due to muscle incoordination; which can lead to, or exacerbate, learning and attention problems. Although hypotonia does not affect intellect, other disorders affecting cognitive abilities may surface due to the disorder. However, hypotonic children are only at a higher risk for learning and attention problems, not all of these children will develop such difficulties [3, 5, 6, 8, 9].

Id

Definition

The id is part of Sigmund Freud's three part psychic apparatus (id, ego, and superego) in his psychoanalytic theory of development. In Freud's theory, the id represents the mind's unconscious and unorganized basic drives, and primarily seeks to avoid pain by increasing pleasure.

Description

Upon birth the id is formed and infants are driven by instincts and seek to have their basic needs met. The basic drives that the id controls are food, water, and sex. The id is selfish, moral-less, infantile, illogical, primarily sexual, without sense of time, and is completely ruled by the pleasure-pain principle. As the child develops, the id comes into conflict with the ego (reality principle) and societal constraints.

Identity

Kenneth Foster
Texas Woman's University, Denton, TX, USA

Synonyms

Personal identity; Reference group orientation; Sense of self; Social identity

Sam Goldstein & Jack A. Naglieri (eds.), *Encyclopedia of Child Behavior and Development*, DOI 10.1007/978-0-387-79061-9,

The term identity is derived from the Latin *identitas*, which means "the same." This notion of sameness or similarity, however, falls short of providing comprehensive utility or explanation, given the myriad implications of identity. For example, fictional literature uses emotion-laden words or contexts such as loneliness, or alienation, to convey identity. That is, by emphasizing the emotional or affective value of one's sense of loss or absence of identity, the concept itself is conveyed. As a historian, Gleason [3] provides a "semantic history" which informs us that for a half century after psychology's debut, identity remained virtually absent from the social science literature. Today, a cursory search of a typical database generates countless references, including those focused on identity in a myriad of contexts such as academics, consumption, dance and the arts, success and failure, survival, and so on, ad infinitum.

Many would agree that Erik Erikson's conceptualization of identity has impacted the social sciences in a way this is akin to the impact that Freud has had on the discipline of psychology. Even his understanding of the term, however, was, in his own words, as "something vague and hard to grasp" [3] and he saw the concept as separate and apart from simply answering the question, "Who am I?" In articulating the complexities of defining identity, he emphasized that identity development is an integrative process. This process is viewed by theorists as premised by notions of roles and the ways in which one makes meaning of their world. As such, one's overall self-concept can be viewed as a gestalt, comprised of their unique personality attributes (personal identity) and their repertoire of orientations to various reference groups (social identity). It is this idea of group and role(s) identification that frame a nexus between general identity and social identity.

From a developmental perspective, the self-concept evolves first from infancy through pre-adolescence, where the drafting and designing of identity attributes and components begins. As these attributes and components evolve, mature and take hold, the child becomes more self-reflective, which is a powerful, fundamental quality. It is here that the integrated self [2, 7] begins. Setting aside discussion of genetic predisposition, we see that one's environment provides for and allows the genesis of their being, i.e., interests, preferences, and the like, which over time becomes particularistic.

As a person develops the capacity to self-reflect, her/his sense of individuality as well as their "group-groundedness" becomes more apparent. Each of many personal identity attributes and each of many social identities become integrated as the person's composite "identity." Issues of psychopathology aside, most people, by late adolescence, experience a phenomenological wholeness, or integrated self. That is, through reflexivity or awareness that one has certain capacities, the individual begins to connect the dots (albeit not necessarily in a linear fashion) that lead to a relatively stable interpretation of self.

The Person and the Situation

One of the most challenging issues for conceptualization and assessment of identity is that of situational context. A basic tenet of the sociopsychological approach is, after all, giving primacy to the social context of one's situation, in order to understand, predict, and potentially alter behavior. Typically the result of symbolic or environmental cues, situational context influences one's cognitive processes of meaning making which in turn impacts their behaviors and experiences.

Among the virtually infinite array of examples for how identity may be situationally contextualized are issues such as political behavior. For instance, one researcher [5] cites examples including "leadership, nationalism, consensus formation, social protest, stereotyping, and so on" (p. 825) and points to the increasingly pertinent implications for voter decision-making and identification with a political party as logical applications to be examined.

Situational context embeds other important conceptual issues, including salience and centrality. Identity salience (the extent to which an identity is a relevant aspect of one's self-concept at a particular moment in time), for example, is systematically examined in a variety of contexts. A particularly robust exemplar is ▶stereotype threat research [11, 12], wherein a person's racial, gender, or other social identity is made salient and such salience serves to negatively impact performance. Numerous publications highlight this robust approach to exploring how and why, for example, an Asian American woman might perform relatively well on a math test when her ethnic identity is made salient, and more poorly when her gender identity is highlighted [10]. Unlike salience, centrality typically implies a stability less affected by temporal or contextual factors. Using race as an identity case in point, racial identity centrality refers to the degree to which a person perceives themselves with respect to race. With respect to relevance, it is important to note that a basic premise in much of identity research – particularly research on social identity – is that identity is assumed to consist of both situationally determined (salience) and stable (centrality) properties.

Social Identity Theory

Social identity is a robust concept that helps us to predict, explain and possibly alter social behavior. It is a medium through which we can internalize the degree to which our group is similar to or different from other groups. The most cited definition of social identity is "The individual's knowledge that he belongs to certain social groups together with some emotional and value significance to him of the group membership" ([13], p. 292). Henri Tajfel's social identity theory [14] is largely about intergroup processes, such as discrimination and cooperation, and Tajfel offered that one's group or social identity serves to maintain and enhance an individual's self-esteem. A number of identity researchers also emphasize that at the core of social identity is the notion of the individual's identity management strategies and how, when, and with whom such strategies are implemented.

Reference Group Theory

Like social identity theory, reference group theory (RGT, [6]) is about intergroup relations. The RGT approach to social identity is a phenomenological perspective that makes conceptual room for the target to exercise agency with respect to how they are socially delineated. This approach allows a particular comprehension of the range of identity perspectives one finds in a large sample, a range not limited to the social categories typically assumed, assigned or ascribed by the larger society. So it is that if, for example, a person born in the United States is nominally Black, one of her/his ostensible group or social identities is that of "Black" or "African American." This is, at least initially, a socially ascribed identity and may or may not be a self-ascribed identity. Such an individual may in fact choose to identify primarily as "American," or "gay," or "Christian," or as "a psychologist," and the fact that he/she is nominally Black may be a less meaningful or central personal category.

There is a rather broad consensus that inherent relationships exist between social identity and group membership, subjective well-being, political affiliation and the like. The process by which one makes meaning of and enacts their singular and multiple social identities, however, tends to be less clear. Factors such as psychohistorical antecedents and temporal motivations, the difficulties of measurement, and the fragility and tenuous nature of identity conspire to make a consensual theoretical framework and assessment strategy elusive.

By adolescence, people can provide, through interviews or surveys, fairly reliable and valid insights into the personal identity and ▶reference group orientation or social identity attributes that make up their self-concept. Erikson's dominant psychosocial approach to identity was heavily influenced by the work of Freud. Erikson viewed identity as something a young, developing person has "more or less of," and that they advance across a continuum of identity that must be negotiated via exploration and commitment. The Eriksonian theoretical model, like most process models, represent a stage or process approach to "a general pattern of development from a diffuse stage of psychological immaturity to more advanced and well-formed stages of maturity" ([1], p. 11). James Marcia operationalized Erikson's identity development theory. Marcia's [8] *Identity Status Interview* assesses an individual's across set of distinct stages (diffusion, foreclosure, moratorium, achievement) that need to be resolved.

In terms of social identity measurement, we have known for a long time that because of its complexity and diversity, identity often cannot be assessed simply in a dichotomous fashion, as if one's political identity is as simple as political party membership, or that their racial identity is no more complicated than being Black or White. For example, although we study Jewish identity, Black identity, and female identity, there are various ways of orchestrating or having a sense of being Jewish or Black or female, as well as being Jewish *and* Black *and* female. Examples of some innovative assessments strategies include a scales developed to measure, simultaneously, personal and social identity [9]. These constructs are operationalized in general terms, i.e., focusing more on *general* centrality and stability, and less on the influence of situational context. Another promising strategy [4] uses a reference group approach as an identity assessment procedure. While not without inherent challenges, such innovative tools have yielded impressive results across multiple studies.

Identity Crisis

Ray Wooten
St. Mary's University, San Antonio, TX, USA

Synonyms

Internal conflict with one's views of the world; Struggle with self identity

Definition

Developmental status based on an adolescence struggling with them self identity and their self perception of themselves in the world (e.g., occupational, religious, political).

Description

This is a term often associated with Erik Erikson and James Marcia when describing an adolescent period of challenging views of themselves and the world they live in. The struggle is in developing a coherent definition of self and grappling with "who I am, where I am going, and how do fit into the larger worldview." The identity crisis includes cognitive development, familial relationships and relational cultural issues.

Relevance to Childhood Development: This is a time of tumult and exploration that if negotiated deftly can lead to psychological well being, high self-esteem, and flexibility in the world.

Identity Diffusion

Ray Wooten
St. Mary's University, San Antonio, TX, USA

Synonyms

Apathetic; Avoidance; Overwhelm

Definition

Phase or status of individual who has not resolved identity issues.

Description

This is a phase or status defined by James Marcia describing the avoidance, apathy and overwhelm often associated with identity development. The adolescent is avoiding or lacks the volition to explore alternatives of self in the world. Example of high school senior experiencing identity diffusion "I haven't really thought much about what I want to do when I get out high school."

Relevance to Childhood Development

This is part of the identity development process that is characterized as avoiding uncomfortable feelings and exploration in the world. The result retards identity development and psychological adjustment.

Identity Foreclosure

Ray Wooten
St. Mary's University, San Antonio, TX, USA

Synonyms

Characterized by commitment to something without personal exploration; Hold fast to another's view

Definition

State where an individual has accepted their parent's or authorities' views and has not thought of other opinions or views.

Description

This is a phase or status outlined by James Marcia characterizing an avoidance of identity crisis by adhering to parental or authorities' views or plans of the future. What is lacking is individual volition in investigating and exploring their own sense of identity and preferences in life. This lack of crisis and exploration leads the individual to commit to identities suggested to them by others. Example of a foreclosed identity: "My parents are physicians and always wanted me to be a physician also. I am enrolled in pre-med in college."

Relevance to Childhood Development

Identity foreclosure is a commitment to something without personal exploration of self. This often results in delays of optimal psychological health and self esteem.

Identity Formation

William E. Herman
The State University of New York at Potsdam, Potsdam, NY, USA

Definition

Identity formation has to do with the complex manner in which human beings establish a unique view of self and is characterized by continuity and inner unity. It is therefore highly related to terms such as the self, self-concept, values, and personality development. The goal of personal identity formation is to establish a coherent view of self through the process of normal human development. Abnormal development could be viewed as the establishment of an incoherent self and characterized by discontinuity or the lack of inner unity. Although the benchmarks of identity formation are most easily observed at the adolescent and adult levels of development, a fledgling identity for a person develops during his/her childhood experiences. At the core of identity formation is the human personality, but psychologists have also employed this term to speak of subcategories such as racial, ethnic, social class, gender role, spiritual, and sexual identity. The term identity formation implies both a process and end-product orientation. In other words, how an identity is established becomes important, as well as what characteristic form the identity takes. The process elements are described by developmental theories. Research studies have attempted to outline what identity formation can actually look like. For example, identity statuses such as identity achieved, foreclosure, moratorium, identity diffusion or confusion, and negative identity have been used by theorists and researchers to denote healthy/unhealthy personality outcomes (see [5]).

Description

Erik Erikson (1902–1994) was a psychoanalyst and the most prominent architect of the psychosocial construct of identity formation (see [1, 2]). He accepted many of the ideas proposed by Sigmund Freud, rejected or modified some of Freud's premises, and explored different areas of personality development as compared to Freud (identity rather than sexuality). For example, Erikson accepted the ideas of a dynamic interaction of the three parts of the personality proposed by Freud (id, ego, and superego) and conscious/unconscious motivation for behaviors. Erikson advanced the study of personality by drawing upon much of Freud's work and reinventing a personality theory that both draws upon Freud's model and offers new insights. Readers are cautioned regarding conceptualizing Freud's psychosexual theory and Erikson's psychosocial theory as totally distinct and unrelated perspectives, for oftentimes it is what these two great thinkers shared in common that is most crucial in helping us understand identity formation. For example, Erikson is known as an ego psychologist because of his focus upon the "ego" functions (logical/rational decision making, defense mechanisms, etc.) in Freud's personality model. Thus Erikson paid somewhat less attention to the "id" and "superego."

According to psychosocial development and the epigenetic principle, as a human being moves through the lifespan the most salient issues center around the person's relationships with others, identity formation, and how the self contextually develops in the cultural milieu. In this way, we can see that Erikson's theory contains elements of biology (genetic endowment), psychology, sociology, and anthropology. There is also a strong interactionist element in Erikson's psychosocial theory, since each issue of biological heritage, expressions of self, interactions with others, and cultural setting can influence the other issues and the personality of the developing person.

The formation of a person's identity is central during the fifth of eight stages of psychosocial development. All 8 stages extend over the entire lifespan and comprise the centerpiece of Erikson's theory. Although identity formation is the major task of adolescence, Erikson's developmental theory implies that the origins of identity lie in critical childhood experiences (earlier stages) and that the re-organization of identity will take place during later stages of psychosocial development and throughout the lifespan. As with the other psychosocial stages, Erikson juxtaposes a relatively mentally healthy ego state (identity achieved) with a less mental healthy state (identity diffusion). Tension is created at different points in the lifespan regarding such healthy versus unhealthy decision points at each stage. Identity achieved involves the experience of a psychosocial crisis (a personal reflective and reorganizational circumstance caused by a challenge in life) with exploration components that result in commitment. The outcome is a life characterized by personally chosen values, the ability to take calculated risks and make good decisions under stress, and the capability to adapt to change without sacrificing individuality, fidelity, and integrity.

Erikson saw adolescence as marking the end of childhood. This transitional benchmark implies that a person takes what he or she has learned from childhood in order to chart a course for the future as an adult in society with new obligations and responsibilities. He claimed that "identity formation. . . begins where the usefulness of identification ends" ([2], p. 159). Adolescence changes the playing field in the biological domain (physical/sexual maturity), psychological domain (cognitive/emotional maturity), social domain (interactions with others), and cultural domain (expectations for membership and taboos) and demands new survival tools for the human personality.

Children consciously and unconsciously adopt beliefs espoused by parents and significant others through the identification process. Modeling behavior is similar except for the fact that imitation or modeling is a much more conscious process. Identification offers a healthy learning tool during a period of development whereby children can reduce stress, please others, and survive in a complicated world. For example, children might incorporate behaviors, values, and rituals observed in childhood into personal ways of doing things without being able to think critically about the origins, meanings, or implications of such events. Childhood identifications cannot be somehow summed up and collectively employed by a mentally healthy adult personality. Therefore, such unexamined identifications are of limited usefulness during adolescence and later adulthood.

Erikson [1] stated that ego identity "is the accrued experience of the ego's ability to integrate these identifications with the vicissitudes of the libido, with aptitudes developed out of endowment, and with the opportunities offered in social roles" (p. 228). It is therefore suggested that a mentally healthy adult depends upon the reinvention of his/her self and this ideally starts around adolescence. Conscious ego strength allows a person to explore the legitimacy and value of childhood identifications for possible inclusion in a newly emerging adult personality. Ideally, some of these identifications might be maintained (if deemed personally valuable); others deleted (to the extent this is possible, given that they may be under the grip of unconscious processes); and still others modified (in order to provide personal relevance and ownership as society changes). The human potential for modifying beliefs about the world that were etched in childhood as identifications allows the personality to adapt to changes in society and within the person over the lifespan.

In this manner, young people grow into healthy adults who are, in certain ways, like their parents. But they can also individuate themselves in order to become unique individuals. In what appears to be a paradox, they ideally maintain a portion of their parents' views and historical legacy while at the same time establishing themselves as unique individuals separate from their parents and at odds with certain cultural stereotypes or expectations. This becomes the crux of healthy adolescent identity development. Herman [3] offered a transmission and development of values theory to understand how Erikson's theory nicely fits with other major theories as an explanation of adolescent development. The foreclosure (unhealthy) ego status where commitment occurs without crisis or exploration reminds us that healthy identity formation is not inevitable or an outcome experienced by all adults. Hoare [4] further suggested that identity achievement should include the ability to work from within a set of personal cultural values while at the same time being able to accept and include others from cultures that hold differing values.

Relevance to Childhood Development

Although identity formation is considered the hallmark of adolescence and not childhood, the childhood period of the lifespan is viewed as absolutely critical in terms of identity formation. Childhood offers the necessary, but not sufficient, foundation for a mentally healthy adolescence and adulthood. Erikson's theory suggests that a healthy adolescent and adult identity depends upon the further development of values and beliefs transmitted during childhood. Psychosocial development offers a built-in possibility that in later stages of development, the person may be able to overcome, or at least ameliorate, even the negative impact of maltreatment and trauma that may have occurred during childhood. This offers some realistic hope for all who survive childhood, while not denigrating the importance of people's experiences during childhood and their discovery of the trends and expectations of their society.

Identity Formation and Development

►Bicultural Identity

Identity Moratorium

Ray Wooten
St. Mary's University, San Antonio, TX, USA

Synonyms

Active exploration without achieving identity

Definition

A phase or status in which a person is actively exploring alternatives towards solidifying a sense of identity.

Description

This is a phase or status outlined by James Marcia characterizing exploration and progress towards identity achievement. The individual is currently experiencing an identity crisis and is looking for answers of the questions that have been raised. These questions are usually occupational, relational and cultural and the individuals place within these domains. Example of identity moratorium: "I have been spending lots of time analyzing my occupational interest inventories that I took at school. There are so many opportunities and I have so many questions. One day I want to be an attorney the next day a chef. I guess I will have to continue talking to people and doing research to figure out what I want to do."

Relevance to Childhood Development

Identity moratorium is an active identity development stage characterized by exploration or crisis without a commitment to a solid sense of self. Proper guidance can help the individual move towards the next step of identity achievement.

Identity Status

Amanda Bozack
University of New Haven, West Haven, CT, USA

Definition

A term originating from the psychosocial theory of development that describes adolescents' exploration of and commitment to values, beliefs, and roles.

Description

Erik H. Erikson's psychosocial theory proposes that ego development occurs throughout the lifespan in a series of stages (*trust vs. mistrust, autonomy vs. shame and doubt, initiative vs. guilt, industry vs. inferiority, identity vs. role*

confusion, intimacy vs. isolation, generativity vs. stagnation, and *integrity vs. despair*). It suggests that ego identity continuously changes based on our experiences and interactions with others and that specific challenges (or crises) arise at different points in life. During these times of crises old values and choices are re-examined. The outcome of each crisis leads to a commitment to a certain value, belief, or role [1].

James E. Marcia's contribution to psychosocial theory elaborates on stage resolution and, in particular, the *identity versus role confusion* (or *diffusion*) stage that occurs during adolescence. Erikson's theory proposes that adolescence is marked by a crisis between identity and confusion in life domains such as work, politics, religion, and gender roles. Successfully navigating the conflict will result in an ability to stay true to one's self, while failure will lead to confusion and low self-esteem. Marcia extended this idea by developing the Identity Status Interview [2]. He proposed four possible stages, or statuses, based on his findings, that mark adolescents' navigation through the *identity versus role confusion* stage: *identity diffusion, identity foreclosure, identity moratorium*, and *identity achievement.*

- Identity diffusion is characterized by adolescents who have not yet experienced a crisis of identity and have not committed to an identity. These adolescents may eventually plot a course toward moratorium and achievement, resign to a foreclosed identity, or maintain the diffused status over time.
- Identity Foreclosure is characterized by adolescents who are committed to specific beliefs about their identity without going through a crisis. These adolescents have not considered an identity for themselves outside of the identity of their youth or outside the identity desired by others.
- Identity moratorium is characterized by adolescents who are experiencing a crisis. They are in the process of exploring their identity. They have not yet committed to any future path, but are open to, thinking about, and exploring possible options. Adolescents in moratorium are usually on the path to identity achievement.
- Identity achievement is characterized by adolescents who have gone through a crisis and made a commitment. These adolescents have explored identity options and, based on that exploration, have committed to the specific beliefs and values they hold [3].

Marcia is most widely known for his work on identity statuses in the *identity versus role confusion* stage. However, identity status work has extended into other psychosocial stages as well. Marcia and colleagues have proposed that within each adult stage people may cycle through moratorium and achievement identity statuses. They suggest that while some parts of our identity that are formed in youth remain throughout our lives, much of our identity changes through the course of life experiences. When experiences are discordant with our beliefs we may shift from an identity achievement status to an identity moratorium status. This exploration and integration of our experiences may lead to a revision of beliefs. This *moratorium-achievement-moratorium-achievement* cycle is represented by the acronym MAMA [4, 5].

Identity Styles

Stacy A. S. Williams
State University of New York at Albany, Albany, NY, USA

Definition

Identity style is a theoretical construct used to refer to the manner in which individuals construct and manipulate their identities [3].

Description

Identity exploration often begins in adolescence. It was Erick Erickson who argued that adolescence is a period of psychosocial moratorium: an opportunity for adolescents to forestall adulthood by exploring different identities in order to select a stable construct by which the self can be defined. For adolescents enrolling in college, matriculation affords a period of exploration that may not be available to those whose next destination is not a college. Erickson's theory of identity development is based on his psychosocial model of human development. Successful resolution of the adolescent phase is based on successful ego resolutions at the earlier stages of development [4].

Marcia's Model

Though Erickson is ultimately the father of identity research, it was James Marcia who operationally defined his theoretical construct. Marcia's research focused on the outcome of the identity process [2], arguing that differences in identities could be accounted for by two processes: commitment and exploration. Marcia defined commitment as personal investment, sacrifice, sustaining interest in values, goals, and ideals [1]. Additionally, exploration was defined as involvement in a period of engagement and searching for acceptable goals, values, and ideals, with the intention of making a commitment. Marcia argued that commitment provided the motivation to adhere to one's values whereas exploration provided the process by which the construction of one's identity could be established. Marcia's concept of identity is often represented as two orthogonal dimensions to denote four identity styles which incorporate varying levels of commitment and exploration: diffused identity, foreclosed, moratorium, and identity achieved [1].

Diffused identity outcome is characterized by low exploration and low commitment. An adolescent who has a diffused identity is said to have not explored any particular social or personal goals and has made no commitment to any values. Diffused identity state is often referred to as an unhealthy identity state and is correlated with conformity to peer influences. A diffused identity is usually found very early during the identity exploration phase [4]. In addition, numerous studies have suggested a relationship between this identity state and psychological states, or mind-sets that prevent or limit a healthy adaptation to fulfilling personal and social goals [1].

Individuals with low exploration and high commitment are said to be foreclosed in their identity style. Adolescents in this state experience no identity crisis. They have yet to explore acceptable goals, values or ideas and often prematurely commit to an occupation or ideology based on the suggestions of others [4]. There are many different types of foreclosed adolescents and these individuals often live quiet and orderly lives [1].

Adolescents who experience high crisis (i.e., exploration) and no commitment are said to be in a moratorium state. These individuals are intensely exploring acceptable goals, values, and ideas but have yet to commit to any of the selected goals or values. Erickson suggests that a moratorium youth is doing exactly what typical youths tend to do: he or she is actively seeking out alternatives, with the goal of finding a compatible value system to integrate in their construction of self [1, 4].

The final identity outcome of Marcia's model is called identity achievement. An achieved identity is marked by high exploration and high commitment. After exploring different social identities, the adolescent commits deeply to a particular ideology and career path. The positive outcome of identity development and the successful resolving of the crisis at this stage of development lends itself to the positive outcome of identity achievement [1, 4].

Berzonsky's Model

While Marcia's identity development is outcome focused, current theories of identity style focus more on Berzonsky's cognitive model. Berzonsky argued that identity development should be conceptualized through a socio-cognitive perspective and accordingly developed a process-oriented model that emphasizes the process of exploration. Berzonsky argued that during the exploration phase, individuals are often coping and adapting to the crises that are invoked in creating and constructing an achieved identity. Through these social cognitions, the adolescent perceives and processes reality. In this process-oriented model, Berzonsky identified three process orientations: information, normative, and diffuse/avoidant [1].

There are strong parallels between Berzonsky's and Marcia's models of identity styles. There are similarities between informational and moratorium-achievement, normative and foreclosure, and diffuse-avoidant and diffusion identities [1]. Information-oriented individuals deal with identity issues by actively seeking out and evaluating values, goals, or opportunities before making commitments. When confronted with information that is different from their perceptions of self, information-oriented individuals often revise their self-conceptions [2, 5]. This orientation has been found to be associated with effortful self-exploration, introspection, self-awareness, problem-solving, coping styles, and cognitive complexity. In addition, this orientation is positively related to effective life management skills and mature relationships with others [3]. Adolescents with this process orientation were also found to perceive their parents as authoritative and engaging in open discussions. Additionally, this style was positively predicted by adolescents who perceived their parents as warm, involved and responsive to their needs in times of stress (i.e., parental support). However, the style was also related to adolescents who perceived their parents as controlling often using manipulative and intrusive strategies (i.e., psychological control) [5].

Normative-oriented individuals rely on the social norms and expectations of significant others when confronted with identity crises. These individuals rigidly

adhere to the existing identity structure, into which they assimilate all identity relevant information. Due to their rigid adherence to the accessible identity structure, the probability of cognitive distortions is increased. This identity style has been associated with intolerance for ambiguity and a need to maintain structure and closure [1]. Furthermore, Berzonsky noted adolescents with this copying style perceived their parents to be authoritarian and found their family lacking in expressiveness. Unexpectedly, this identity style also related positively to authoritative parents and found family relations to be trusting and cohesive [5]. Furthermore, this style was positively predicted by parental support and adolescents' perception of their parents as providing them with clear expectations for behaviors and monitoring behaviors (i.e., behavioral control) [5].

Diffuse-avoidant individuals are similar to Marcia's diffused identity state. These individuals avoid personal issues and delay decisions until environmental demands dictate their behavior, which often results in a fragmented identity structure. This fragmented state is also a function of situation specific identification by which individuals define themselves mainly in external terms (i.e., my reputation, my popularity). Diffuse avoiding adolescents have been found to engage in procrastination, embrace an external locus of control, and engage in emotional-focused coping behaviors [1, 2]. This style was found to relate to authoritarianism and permissive parenting styles. In addition, family environments were often characterized by lack of expressiveness and communication [5]. Additionally, this style is positively predicted by parents who exert psychological control and negatively influenced by maternal behavioral control [5].

Identity Styles and Minorities

A discussion of identity styles would be incomplete without paying particular attention to racial identity development, which is one aspect of identity exploration for people of color. William Cross Jr. and Janet E. Helms are often respectively cited in the exploration and examination of Black and White racial identity styles. Furthermore, Cross' model is often used as the framework in exploring other racial identities. Both Cross' and Helms' models are presented as stage-like theories. However, their models are not linear and individuals recycle through the stages at different points in the life cycle.

Cross' model is operationally defined as a five-stage model: pre-encounter, encounter, immersion/emersion, internalization, and internalization/commitment stage. The pre-encounter stage represents the identity that individuals are born with. This stage is highly influenced by parents and social upbringing. A person in this stage may not be aware of racism and may have internalized negative racial stereotypes. The encounter stage of identity is characterized by an event that forces the person to acknowledge racism. It is during this stage that the individual begins to identify with his or her race. This event also encourages the individual to seek out experiences to support his or her developing awareness of race identification. This stage is referred to as the immersion/emersion stage. During this stage, the individual avoids symbols of Whiteness and surrounds himself/herself with symbols of his or her race. At the end of the immersion stage, the individual emerges with an internalized identity. During the internalization phase, the person is secure with their racial identification. A person is this stage is more open to joining with other racial groups due to a strong sense of racial identity. The final stage of the model is the internalized-commitment stage where the individual sense of racial self is grounded and there is a general sense of commitment to the concerns of people of color and social justice issues in general [6].

Helms' concept of White racial identity consists of six stages: contact, disintegration, reintegration, pseudo-independent, immersion/emersion, and autonomy stage. In the first stage of the model, an individual lacks an awareness of racism and one's own White privilege. Additionally, the person internalizes negative stereotypes about persons of color. During the disintegration phase, the lack of awareness of racism is replaced by discomfort, shame and/or guilt as individuals begin to become aware of racism. At the end of this stage, individuals attempt to help other Whites see that racism exists. During the reintegration stage, a person's desire to be accepted by his or her group leads to a reshaping of beliefs that are more accepting of the group, which in turn may lead the individual to be more accepting of racism. Helms argues that individuals may become stuck at this stage if they can avoid contact with people of color [6].

The fourth stage (i.e., pseudo-independent) is characterized by an abandonment of the belief in White superiority but may unintentionally perpetuate the status quo. Helms argues that the person may feel alienated from Whites and rejected by people of color. It is at this stage that individuals seek out antiracist White allies. During the immersion/emersion stages, a person searches for a new and comfortable way to be White. The person works to replace myths and stereotypes with accurate information about what it means and has meant to be White in America. The final stage of the model is the autonomy stage. In this stage, a newly defined sense of Whiteness energizes one's effort to confront racism in

daily life. A person in this stage is often open to new ways of thinking about race [6].

In summary, identity style is a concept used to define individuals as they interact with the world around them in hopes of creating and maintaining an achieved identity. It's a process by which information is manipulated in seeking one's values, goals, and ideals. Although identity is often presented as a stage like theory, individuals tend to recycle through the stages at different times during their life cycle.

Identity Versus Role Confusion

Michael Block
Azusa Pacific University, Azusa, CA, USA

Definition

As articulated by Erik Erikson, Identity versus Role Confusion is the fifth of eight stages of psychosocial development that take place between the ages of 12 and 19. During this stage adolescents need to develop a sense of self and personal identity. Success leads to an ability to stay true to oneself, while failure leads to role confusion and a weak sense of self. In the latter phases of this stage, the child develops a sense of sexual identity.

Description

Erik Erikson explains eight stages through which a healthy developing human should pass from infancy to late adulthood. In each stage the person confronts, and hopefully masters, new challenges. Each stage builds on the successful completion of earlier stages. The challenges of stages not successfully completed may be expected to reappear as problems in the future.

The Identity versus Role confusion (or diffusion) stage is characterized by the adolescent question of "Who am I," during which time they are conflicted with dozens of values and ideas of who they should be and what they should think. The adolescent challenge is to establish a sexual, political, moral, religious, and vocational identity that is mature, stable, and consistent. Rapid physical and psychological changes assure that virtually nothing is stable and consistent and yet we must merge from this period of turmoil with a clear sense of who we are, what we believe in and what we want to do with our lives.

Gaining independence of identity and dealing with physical and hormonal changes is stressful. Our inner unrest may lead to rebelliousness, impulsiveness and outer turmoil. Peers provide security and role models. Interaction and communication give us the opportunity to discover ourselves as adults rather than as our parents' child. According to Erikson, we may achieve a clear identity, become confused and apathetic, find a negative identity, or foreclose early and take on an identity given by others.

The adolescent identity crisis involves developing values and beliefs about many areas of social, political, religious, sexual and career factors. It involves an inner and outer struggle to consider the many alternatives and choose a belief system, friendships, career and way of life we can be comfortable with on our path in life. The adolescent has entered into the exciting and confusing cognitive development stage of formal reasoning, where one can attempt to consider many alternative paths and compare and contrast possible futures.

Adolescents tend to become "egocentric" and self-focused in their search for truth, believing that they know so much more than their parents or any other generation previously living on the planet. Their logic fails in areas of egocentric thought such as "It cannot happen to me – whether it is getting pregnant or getting oneself in a car accident" or whether it is in egocentric thinking that everyone is noticing that one has an acne blemish. They are "always on stage" with an "audience" and needing to establish their own views, they are quick to reject the views of their parents.

Peer groups often give adolescents a temporary identity and they often form "cliques" in high school to bolster their lack of a strong personal identity. For example, peers

become critical in establishing an identity and girls spend endless time on the phone and in the bathroom trying on new selves and searching to become comfortable with who they are. They consult their peers, teen magazines and teen idols for their values and seem to often reject the values of their parents, a critical stage in establishing their own personal identity. Often college can serve as a "moratorium," a safe place to continue the adolescent identity struggle to find the self. Students often do not feel the pressure to "commit" to marriage or even to a major and do not have to settle down to a job, a family and a career that tends to establish their identity. College students in the teens and early 20s may take another 4–8 years of school to explore many options for establishing a firm identity in the world. This can be a very good thing as the human lifespan is much longer in the new millennium and the search for self is a critical stage in development.

Idiot Savant

Judah B. Axe
Simmons College, Boston, MA, USA

Synonyms

Autistic savant; Savant syndrome; Savantism

Definition

A person with a developmental disability and an area of genius or brilliance.

Description

Idiot savant is the term used to describe a person with a developmental disability (e.g., autism, mental retardation) with an advanced skill, often in mathematical and memory abilities [1, 2]. Approximately 10% of individuals with autism are idiot savants. Common abilities are remembering the days of weeks of dates from the distant past (e.g., being able to state that October 21, 1963 was a Monday), recalling long strings of numbers, and performing complex musical compositions after only one exposure.

The "idiot" portion of the term is based on use of the term in the medical community in the late nineteenth and early twentieth centuries to refer to individuals with IQs less than 20. As this term is no longer used, "autistic savant" and simply, "savant," are terms more in use today.

Although savantism can be genetic or acquired, the cause and neurological basis are unclear.

Illicit Drug Use in Adolescence

Sharon Morgillo Freeman
Center for Brief Therapy and Indiana/Purdue University, Fort Wayne, IN, USA

Synonyms

Illegal drug use/abuse; Illegal substance use/abuse; Illicit substance use/abuse

Definition

Illicit/illegal: Unlawful
Drug:

1. A substance other than food intended to affect the structure or function of the body use.
2. Often an illegal substance that causes addiction, habituation, or a marked change in consciousness.

Addiction: Compulsive need for and use of a habit-forming substance (as heroin, nicotine, or alcohol) characterized by tolerance and by well-defined physiological symptoms upon withdrawal; *broadly*: persistent compulsive use of a substance known by the user to be harmful.
Limbic system: A group of subcortical structures (as the hypothalamus, the hippocampus, and the amygdala) of the brain that are concerned especially with emotion and motivation.
Prefrontal cortex: The gray matter of the anterior part of the frontal lobe that is highly developed in humans and plays a role in the regulation of complex cognitive, emotional, and behavioral functioning.

Description

Illegal drug use refers to the use of substances that are obtained and used without a prescriber's permission by a person between the ages of 12 and 21 for purposes of altering their mood, consciousness and sensorium.

Relevance to Childhood Development

Brain development does not reach full "adult" capability, or completion, until approximately age 24 or 25. Therefore the brain is an organ that is still in the process of growing, changing and developing during adolescence. Specific areas of the brain that are immature during the adolescent years are the nucleus accumbens, the limbic centers and the prefrontal cortex. These areas of the brain are implicated in pleasure, reward and impulse control. The prefrontal cortex is involved in what scientists call "executive function."

Brain Function

Components of executive function include memory, planning and decision making. In other words the prefrontal cortex is involved in remembering consequences of actions, deciding whether or not a person wants to experience certain consequences and then making a plan of action based on consequences. The prefrontal cortex in essences weighs out risks/benefits of decisions and chooses between actions/behaviors.

The nucleus accumbens contains reward areas in the brain. This area of the brain usually "fights" with the prefrontal cortex in making decisions in the adolescent. This is due to the immature connection between the two areas. The nucleus accumbens is very strong in "GO!" function being "pleasure oriented" and therefore tends to over-ride the "STOP!" function of the prefrontal cortex. This immaturity explains why many adolescents like to engage in activities that provide rapid or immediate gratification such as computer games, roller coasters, fast cars, text messaging, and drug/alcohol experimentation.

Brain Damage

The adolescent brain may be more resilient to toxins due to its youth and continued development. However research shows that adolescents who are heavy users of alcohol have much more difficulty in school learning new skills and new material. This is due to the effect of alcohol on the specific area of the brain responsible for memory, the hippocampus. In fact, studies at the Treatment Research Institute in Philadelphia have shown that hippocampal volume can be reduced from 10 to 35% with extensive chronic alcohol consumption.

Adolescents who use drugs such as cocaine, ecstasy, amphetamine, methamphetamine, MDMA and cocaine directly alter the structure and development of neurons in the limbic system of the brain. These changes make it very difficult and sometimes impossible for the individual to experience pleasure without using the drug. Over time the changes to the brain may result in tolerance and cause the adolescent to depend on the drug resulting in drug addiction. In some cases the brain changes themselves may become permanent although science has not completely uncovered all of the data behind this question.

Some studies have shown that adolescents that have abstained from chronic marijuana use continued to show evidence of impairment in memory, abstract thinking and ability to focus attention for up to 12 weeks.

Environmental Issues

In addition to the primary effect of the chemical on the adolescent brain there are other factors at play when

one considers the idea of "illegal" involvement. Any child exposed to an environment where illegal activity is involved has been exposed to several factors immediately: lying, hiding information, sneaking around, disrespect of authority, insufficient parental supervision, insufficient or ineffective communication between parent/child, lack of respect for boundaries, potential legal consequences, potential impact on continuation in school involvement, potential for violence.

At best these factors are stressful. At most they can be life altering. Adolescents who begin the cycle of illegal involvement often begin to tell themselves that "everybody does it." This is primarily due to the fact that they start to eliminate friends/family etc., who do not participate in the same behaviors that they participate in order to continue their use of drugs. This provides them with "permission" to continue their behavior. If their parents are the ones who introduce them to the drugs it is even harder to convince an adolescent that drugs are potentially dangerous/damaging

Specific Illicit Drugs

The entry point for illegal drug use is often marijuana. Marijuana is also one of the most difficult drugs to discontinue. Research has shown that the risk of marijuana dependence increases six times for individuals who begin use prior to age 15 than for those who try marijuana after age 18.

A growing area of concern is inhalant abuse in teen years. Solvents are readily available and parents are often unaware that common household chemicals are being abused by their child. Breathing in chemical solvents is called "huffing" and rapidly cause the user to become high. Common chemicals include glues, nail polish remover, spray paints (silver and gold metallic especially), lighter fluid, felt tip markers, hair sprays, some deodorants, gasoline, butane, cleaning fluids and most commonly whipped cream canisters (whippets). Inhalants can disrupt cardiac conduction and cause death very rapidly or lower blood oxygen levels causing serious harm to the brain, liver, kidneys and heart. The National Institute of Drug Abuse sponsored a study in 2006 that uncovered startling statistics that 16.1% of eighth graders, 13.3% of tenth graders and 11.1% of 12th graders had used inhalants at least once.

Another common source of illegal drugs is the medicine cabinet. Teens are looking in their parents, grandparents, aunts/uncles and neighbors medicine cabinets for medications that they can "try" or sell. Most commonly these medications include: oxycodone, hydrocodone, phenobarbitol, lorazepam, oxazepam and a variety of other medications including antidepressants. Many medications can be ordered over the internet.

Heroin is making a huge comeback among the middle and upper-middle class. Adolescents that are Ivy-league bound are finding that heroin is a cheap substitute for the expensive Oxycontin that they may have found themselves addicted to courtesy of "friends."

Availability of Illicit Drugs

According to the 2007 National Survey on Drug Use and Health, the overall use of illicit drugs is declining by teens age 12–17 since 2002 (Fig. 1).

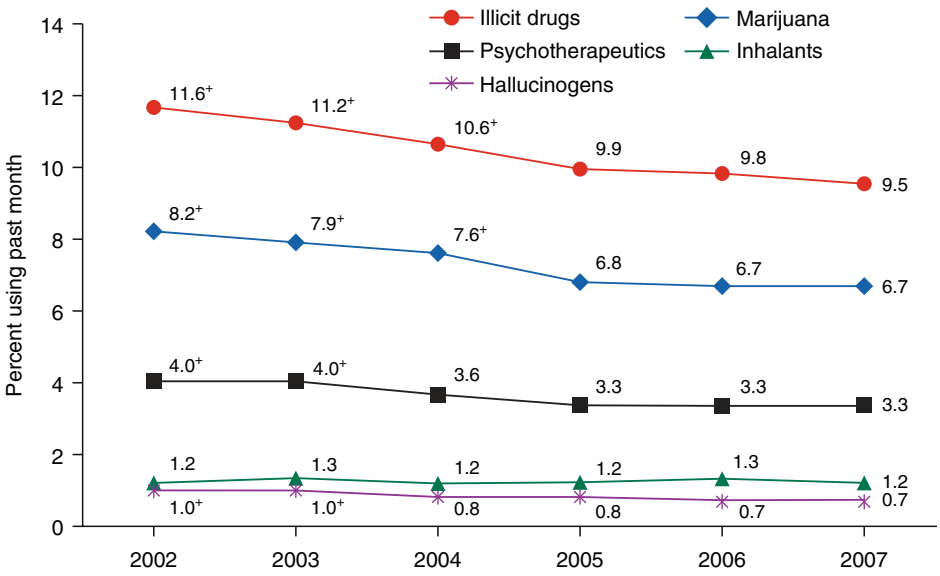
Of the youth who did use illicit drugs in both 2006 and 2007, over half aged 12 and older said they got the drugs they used most recently "from a friend or relative for free." In a follow-up question, the majority of these respondents indicated that their friend or relative had obtained the drugs from one doctor. Among persons aged 12 or older in 2007 who abused pain relievers 56.5% said they got the pain relievers from a friend or relative for free. Another 8.9% bought them from a friend or relative, and 5.2% reported stealing them from a friend or relative.

In 2007, 44.3% of past year methamphetamine users aged 12 or older reported that they obtained the methamphetamine they used most recently from a friend or relative for free. Another 30.4% bought it from a friend or relative. Around one in five users (19.8%) bought it from a drug dealer or other stranger.

Risk Factors

Illicit drug use in childhood or adolescence is usually predicted by several risk factors, or variables. A risk factor is defined as any condition that if present increases the probability that a certain unfavorable outcome will occur. Research supports that in most cases multiple risk factors must be in place for an adolescent to actually develop substance related problems however the greater the number of risk factors, the higher the likelihood of developing substance use or abuse problems. Some common risk factors include:

1. Permissive or favorable parental attitudes
2. Actual parental substance use/abuse (even if the child is not aware of actual use)
3. High family conflict
4. Inconsistent family discipline/boundaries
5. Difficult temperament
6. Low sociability
7. Rejection by peers
8. Academic failure
9. Aggressiveness



Illicit Drug Use in Adolescence. Fig. 1 Past month use of selected illicit drugs among youths aged 12–17:2002–2007 [1].

10. Peers who use drugs
11. Low self esteem
12. Negative mood
13. Impulsivity
14. High arousal needs
15. High need for social approval
16. Low assertiveness
17. Low harm avoidance
18. Disregard for authority (disrespect for authority)
19. Biological predisposition
20. Maladaptive coping responses to stress
21. Sexual victimization in childhood or adolescence
22. Lack of parental support/monitoring

Protective Factors

Protective factors for prevention of illicit substance abuse in children and adolescents include those factors likely to limit, prevent or reduce a negative outcome. These factors serve as a "buffer" between potential risk factors and substance use choices. Some common protective factors include:

1. Parents that talk to their children about drugs and alcohol and the dangers of use openly
2. Involvement in academic and extracurricular activities
3. Involvement in religious activities
4. Academic achievement
5. Strong attachment to school
6. Positive learning environment
7. Low conflict with parents and teachers
8. Peers that do not drink or use drugs
9. Prosocial bonding and behaviors
10. Strong family relationships
11. High self esteem or self-acceptance
12. Self-efficacy
13. Harm avoidance
14. Commitment to societal norms
15. Low family conflict
16. Affectionate parental relationship
17. Parental monitoring
18. Clear, consistent standards and expectations from parents
19. Long term life goals
20. Clear communication within the family
21. Structure in the family setting

Progression of the Disease

Treatment centers are noticing that individuals who are coming in for treatment have started using at a much younger age, therefore their length of time using drugs or alcohol is much longer. Studies have shown that adolescents who start drinking before the age of 15 are 4 times more likely to develop an addictive disease than adolescents who do not, regardless of genetic or environmental factors.

How to Tell if an Adolescent is Using Drugs

1. Change in overall function from previous year or two
2. Obvious presence of drugs or alcohol

3. Change in grades, motivation, skipping classes
4. Significant change in mood (especially irritability and suicidal thoughts)
5. Decreased interest in social activities and/or favorite hobby
6. Significant change in sleep habits
7. Difficulty paying attention and concentrating
8. Change in appetite (much more or less) and/or hygiene
9. Associate with different peer group that does not want to socialize with family activities
10. Legal problems, gang involvement
11. Disregard for authority, rules

One or two of the above (with the exception of #2) does not constitute cause for alarm, however any combination of three or more should point toward a formal assessment for drug abuse evaluation. Any change in mood especially suicidal ideation should include evaluation for significant mood disorder as part of the evaluation.

Imaginary Audience

Marie-Anne Issa, Kevin L. Nadal
John Jay College of Criminal Justice, New York, NY, USA

Synonyms

Adolescent egocentrism; Egocentrism; Personal fable

Definition

The concept of imaginary audience refers to the tendency of adolescents to see themselves as objects of others' attention and evaluation.

Description

The idea of imaginary audience was originally proposed by Elkind in 1967 [2], as a part of the adolescent's egocentrism, which refers to a lack of differentiation between the ego and the external world. Therefore, the adolescent

cannot distinguish between what other people are actually thinking, and what he or she is preoccupied with.

Elkind proposed that imaginary audience emerges with the start of formal operational thought, in which young adolescents can conceptualize their own thoughts, as well as other people's thoughts. However, the adolescents, now able to conceptualize other people's thoughts, may think that others are being critical or admiring of them, as the adolescents may be of themselves. As a result of worrying about others' perceptions, the adolescents may become self-conscious.

Imaginary audience has been found to be associated with many behaviors and psychological constructs, such as self-consciousness, dating behavior, peer group conformity, susceptibility to peer pressure, parent-child interactions, and problem behaviors [7]. Generally, females have been shown to score higher on imaginary audience than males, and imaginary audience should decrease by the age of 15 or 16, the age where formal operational thought becomes strongly established [1].

There are a few critiques to the concept of imaginary audience. One critique is the lack of an operational definition. Research has supported that the measures that have been developed have been unreliable and are in need of revisions [7, 9, 10]. The most widely used scale, the imaginary audience scale (IAS; [3]), is made of two subscales: the transient self (TS) and the abiding self (AS). The TS scale contains six potentially embarrassing situations, while the AS scale contains six potentially self-revealing situations. Subjects answer from three possible choices, ranging from 1 (low) to 3 (high). However, the IAS has been criticized due to the lack of strong psychometric properties, its measure of self-consciousness rather than imaginary audience, and its reliance on hypothetical situations. In addition, the audience the scale refers to is not defined and its meaning can vary with different age groups, rendering the results unreliable.

The second measure is the new imaginary audience scale (NIAS; [5]), which contains 42 items measuring how much adolescents engage in object relational ideations and personal fantasies. Adolescents rate the items on a four-point Likert scale (ranging from never to often), with higher scores depicting higher sensitivity to imaginary audience. The third measure is the adolescent egocentrism scale (AES; [4]) consisting of descriptive statements that subjects rate in terms of importance; the higher the score, the higher sensitivity to imaginary audience.

Given the lack of operational definition, research focusing on imaginary audience has been inconsistent. For example, several studies have failed to consistently show a relationship between the concept and formal operational thought, as well as an inverse relationship with age. For instance, recent research has shown that imaginary audience has been seen in late adolescents, and even in young adults going into college, which might indicate that imaginary audience might re-emerge when a person is going into a new social context or life event [6, 8].

Lapsley and his colleagues proposed an alternative theoretical framework, the "new look," whereby imaginary audience is viewed in the context of social-cognitive development. The "new look" proposed that the concept is a consequence of separation-individuation. Separation-individuation happens when the adolescent de-idealizes the parent, which creates "mourning reactions" where the adolescent is left empty and isolated. In order to fill in this void, narcissism ensues to protect the ego, until the adolescent is able to regulate from internal sources (regardless of the parent). Therefore the "new look" suggested that imaginary audience is an ideation pattern that actually helps ego development; it restores the adolescent's self-esteem when he or she faces "mourning reactions." This theoretical framework has found more empirical support among researchers.

Future research needs to focus more on operationalizing the concept, and developing measures that are more valid and reliable. Also, to better understand the developmental unfolding of the concept, longitudinal studies need to be conducted. Finally, cross-cultural research should shed more light on the importance of familial, environmental, and physiological aspects in the emergence and subsidence of imaginary audience.

Imaging Techniques

Norma S. Guerra
University of Texas, San Antonio, TX, USA

Synonyms

Images

Definition

Images are representations based on the composition and look of information [1]. Imaging techniques refer to the methods in which a person stores and recalls images.

Description

Imaging techniques are often used as a tool to facilitate learning. As images are created, we try to recall the tangible characteristics and spatial formation of information. Not all researchers agree on how memory stores images: some believe images are stored as pictures while others believe propositions are stored in long-term memory then transformed to pictures in working memory and recalled as needed. It is however generally accepted that both processes are involved: some recollection of images and some of verbal descriptions. Mentally transforming and rotating images can be used in abstract reasoning and practical decisions [2].

In terms of application, imaging techniques provide opportunity for the development of creative associations. In using imaging techniques there are maturation considerations. Younger children may likely have difficulty recalling images given their abstract properties. Thus this tool should be reserved for students who possess some skill in strategy use to which this technique may be incorporated.

Immigrant Children

Carrie L. Castañeda-Sound, Cynthia G. González
Our Lady of the Lake University, San Antonio, TX, USA

Synonyms

First-generation immigrant children; Immigrant youth; Refugee

Definition

Immigrant children were born in their native country, but migrated and reside in a foreign country.

Description

Migration

According to United States Census Bureau data, one of every five children in the U.S. is a member of an immigrant family, and the majority of those accounted for were either of Latino or Asian descent. Specifically, immigrant children from Mexico account for the largest group at 40% [10]. Most of these children reside across the six states of California, Florida, Illinois, New Jersey, New York, and Texas with more than 75% attending school in California, Florida, Illinois, New York, and Texas according to Department of Education records [4]. Legal immigrants accounted for 85% of census totals with reason and mode of migration varying greatly [4].

Immigrant children often migrate with their parents, but in some instances these children migrate with relatives, friends, or strangers to reunite with family members. Both pre-migratory and migratory conditions will affect children's well-being once they arrive to the host country. For instance, some immigrant children come from impoverished and/or war-torn and politically unstable countries and may be referred to as refugees. Sluzki conceptualized the immigration experience as including the preparatory stage and the act of migration [18]. The preparatory stage involves planning and the ability to say good-bye to family and friends. The act of migration is an experience that varies for each child and family and will be influenced by factors such as socio-economic status, the requirements for permission to leave the country of origin, and the possession of documents of legal residency within the new country. In cases where immigrant children must leave and enter countries without authorization, or as refugees, the process may be traumatizing if they have witnessed acts of violence or experienced imminent fear of being harmed. Children who have migrated under these circumstances may show symptoms of psychological disorders, social maladjustment and health issues [8].

Acculturation and Acculturative Stress

Upon arrival to the new country, the changes immigrant children experience have been conceptualized as acculturation [14]. The migration experience is thought to influence the individual's mode of acculturation [8]. Therefore, the directionality of the assimilation process as being either unidirectional or bidirectional has met with controversy [3]. Acculturation requires changes at all levels of an immigrant family including changes in language and culture [20]. Immigrant children often acculturate to the new country more quickly than the adults in their life. Researchers have attributed this to the influence of attending school. When the transition to the new country is difficult and there seems a lack of "goodness of fit", the child may experience acculturative stress. Acculturative stress has been found to be greater after the age of 14, and to negatively impact physical health and mental health outcomes [3, 11, 13].

Factors that may contribute to acculturative stress include the context of the family's arrival to the new country and the environment where they choose to reside. For example, the status of the government's policy toward that specific immigrant group may influence services received or the family's documentation status (e.g., refugee, legal permanent resident, or undocumented). Also, society's sentiment toward that particular group and the location of residence can create an atmosphere ranging from alienation to validation and support [19]. A supportive community of residence may provide cultural brokers to the newly immigrated child and family who can make the transition much easier. Cultural brokers speak the language of the immigrant family and of the host country and are able to explain the customs and laws of the new country to the family.

Impacts of Language

Early language minority immigrant groups within the U.S. experienced hostility and open discrimination [22]. The larger society tried to blend in the overwhelming numbers of immigrants by teaching them the majority language while not accepting the native language [9, 22]. Many experienced alienation from mainstream culture as a function of limited proficiency. Additionally, limited language proficiency was often precluded by low SES, limited literacy and education, and poor social support [8].

Language and Family

Adding to the complexity of issues related to family structure is language. It poses one of the greatest struggles in the immigrant parent's attempt to maintain 'control' over their children's sense of values and heritage. Because language proficiency and competence are means to accessing services and meeting needs, it often creates a dynamic which can either strengthen family bonds or alienate from the new culture [8, 12]. Because immigrant children often learn the language of the new country more quickly than their parents and relatives, they often serve as language brokers. This role involves the responsibility for

translating and interpreting for family members and often other monolingual individuals in their community. Researchers have identified that on average immigrant children begin language brokering at the age of 9 or 10 [6].

Language and School

Literacy skills and educational background are thought to contribute to the rate of language acquisition. Lower levels of literacy make it more difficult to profit from formal educational opportunity [8]. Immigrant children bring experiences, language variation and levels of literacy that greatly influence their readiness for second language acquisition and equip them for formal education and learning. Characteristics and social factors such as motivation, attitude, and native language proficiency can also lead to enhancing or deterring second language acquisition. "Pragmatic language skills" greatly contribute to adapting and accessing social interactions by serving as rules of interpersonal communication [5]. Such organizational cues as eye contact, body language, conversational etiquette serve the common purpose of engaging and sustaining acceptable social interaction [5]. The visual, verbal, and kinesthetic cues referred to as the "thematic redundance approach" are considered multimodal approaches and are as important as language itself in creating a platform for sociolinguistic development through repetitive language use and social and cultural context for interaction [5, 16].

The rate of second language acquisition can be influenced greatly by social, emotional and cultural factors. Immigrant children are likely to respond to the degree of social pressure created and alienation created for both family and community [1]. However, there is strong evidence that 'home language use' can have a positive effect on and improve academics and achievement [2]. Ada et al. also refer to the family and community as "social capital" and suggest that schools should use it to improve rather than alienate and negatively impact the second language learner's achievement [2].

Similarly, language acquisition for first and second language learners has been found to be affected by age of arrival and length of residency for immigrants. Generally, research has found that children become literate at different rates and in different ways [7, 21]. For example, oral language proficiency requires 2–3 years to establish and 5–7 for higher levels of competency [7]. Literature on English language learner immigrants also suggests that the diversity of skill levels is expanding so greatly that needs may be best served through individualized educational planning rather than through existing general language development programs. This approach may require that a more "student-centered pedagogy" be in place to meet such great needs [15, 17].

Relevance to Childhood Development

Although at risk for psychological problems and delays in language acquisition, immigrant children and their families can also be viewed as resilient with much strength related to daily survival in a foreign country. Indeed, language proficiency of immigrant children is a key factor in educational success; however, greater proficiency can increase access to learning and opportunity, increasing the likelihood of better daily functioning while fostering confidence and hope of success in their new society [8].

Synonyms

Cognitive control; Deferred gratification; Delay of gratification; Self-control; Self-regulation

Definition

The ability to resist the impulse, drive, or temptation to perform an action.

Description

Impulse control, or the ability to resist a drive to perform an action, is an ability that develops over time in an

individual. The factors contributing to the development of impulse control are complex and involve multiple domains including biological, developmental, psychological, and cultural factors [1]. The biological/anatomical aspects of the development of impulse control primarily relate to the development of specific brain structures. The cortical regions of the brain, generally the ►prefrontal cortex and more specifically the orbitofrontal cortex (OFC), are thought to be responsible for regulation of impulse control. Lower volume of the orbitofrontal cortex, located in the lower region of the frontal cortex close to the orbital region of the skull, has been associated with greater impulsivity [2]. It is notable that the brain continues to develop through age 25, which accounts for the gradual appearance of impulse control over the course of development as the brain becomes better equipped to resist certain drives.

In addition to anatomical or physiological explanations for the development of impulse control, psychological factors, including child temperament and parenting style, also have been implicated in the development and expression of impulse control. Several dimensions of temperament have been assumed to influence impulse control including irritability, unsoothability, or stimulation seeking [3]. Researchers also found that responsive and cognitively stimulating mothering tended to be associated with improved impulse control and delay of gratification in their 2-year-old children. Findings also revealed that security of mother attachment predicted better impulse control in boys [3].

A child's ability to control his/her impulses may have important later-life consequences. For example, in longitudinal studies looking at delay of gratification, 4-year-old children who were able to delay a reward in a lab setting were described as more academically and socially competent than their peers, and as having higher frustration tolerance and a better ability to resist temptation when they were described 10 years later. These children also were generally more effective communicators, had better reasoning skills, and seemed to be more skilled at tasks involving concentration and planning. Better outcomes also were seen in psychological domains, in that these children developed more effective coping skills, were better able to manage stress and were described as more self-assured [4].

Relevance to Childhood Development

Impulse control is present in varying degrees throughout a child's development. During the first year of life, an infant acts on impulses. Infants may pull hair, reach for a toy that is being used by another child, or push a bottle away when they are finished eating. These acts are performed with no regard for the consequences and are simply in response to an impulse [5].

In the second year of life, a child may have some regard for consequences or limits set by an adult, such as responding to a parent's request to stop doing something. The child will also learn about the things that he or she has been told not to touch or do and acknowledge the acquisition of this knowledge although he or she may still engage in the discouraged behavior. For example, a child may look at an object (such as a lightbulb) and say "no touch" while reaching for the object. Children also may look at their parent while reaching for the object and saying "no touch", awaiting the parent's reaction to determine whether it is safe to reach for the object. The beginnings of impulse control are starting to be expressed in this developmental stage [5].

During the third year of life, a child may begin to voluntarily control their behavioral impulses and expression of emotion. For example, a child will begin to share, even though their impulse is to keep the object for themselves. The child also may voluntarily use gentle touch with an animal, instead of having to be reminded [5].

►Cognitive control begins to develop at 18 months of age and continues to develop throughout childhood, as the child's cognitive abilities become more sophisticated, not reaching full maturity until after age 12. During this time, it is possible to see significant individual differences in a child's ability to control his/her impulses [6].

Adolescence marks a critical developmental stage for the development and application of impulse control. During this time period, there tends to be an increase in risky and impulsive behaviors. Two important brain structures, the accumbens and the prefrontal cortex, develop during adolescence and are implicated in the regulation of impulse control. The accumbens, which develops first, is responsible for reward anticipation. The prefrontal cortex is associated with increased cognitive efficiency and control and develops at a slower rate. Therefore, adolescents experience increased anticipation for rewards while not having the brain structures associated with cognitive control. This leads to the development of impulsive behavior, or, a strong drive for seeking out rewards with little regard for the consequences [7].

Impulse Control Disorders

Several psychological disorders characterized primarily by a loss of control are included in the Diagnostic and Statistic Manual-IV-TR [8]. The DSM-IV-TR details the following impulse control disorders: Intermittent Explosive Disorder; Kleptomania; Trichotillomania; Pyromania;

Pathological Gambling; and Impulse Control Disorder, Not Otherwise Specified. Impulse control disorders are experienced by approximately 5–15% of the US population. From a developmental perspective, children and adolescents are thought to be affected by intermittent explosive disorder, pyromania, and trichotillomania, while adults would be more likely to be diagnosed with kleptomania or pathological gambling.

The defining characteristics of intermittent explosive disorder (IED) include recurrent episodes of a failure to resist aggressive impulses that frequently result in serious assault against persons or in the destruction of property. Notably, these violent and aggressive outbursts occur in significant disproportion to any precipitating psychosocial stressors or events that trigger them. The aggressive outbursts tend to have a sudden onset, and are short-lived, typically lasting less than 30 minutes. Individuals diagnosed with IED often report feelings of relief and eventual remorse following their impulsive and aggressive behavior. Most of the aggressive outbursts are associated with a minor provocation from a close partner, friend, or associate; however, there are instances with no identifiable provocation [9].

IED typically first appears in adolescence or the young adult years with a mean age of onset at 15 years; however, there are some cases that begin as early as childhood. The average duration of diagnosis is approximately 20 years [10]. There is a significant gender disparity in diagnosis, with males being three to four times more likely than females to be diagnosed with IED. Genetics play a significant role in IED, as individuals with this diagnosis often have multigenerational histories of family violence.

Trichotillomania is characterized by recurrent, persistent, and excessive pulling out of one's own hair resulting in noticeable hair loss. Individuals may engage in trichotillomania during both relaxed and stressful times, but often report feeling a sense of tension before the hair pulling, and a feeling of release, pleasure, or gratification following the act. This disorder must result in clinical distress or impairment in life functioning. The primary target for hair pulling involves hair on the scalp, although hair from other parts of the body (e.g., eyelashes, eyebrows, beard, torso) also may be pulled. The recurrent nature of the hair pulling often results in bald patches to the affected area. Hair pulling may occur for short repeated episodes or for longer periods that may last several hours.

In childhood, the observance of trichotillomania among males and females is approximately equal; in adults, it is much more common in females than in males. Determining an accurate prevalence rate is challenging because of frequent denial of the disorder and the failure of many individuals with the disorder to seek professional intervention. In the most well-cited study of college students, approximately 1–2% had past or current symptoms of trichotillomania [11]. The primary ages of onset are between 5 and 8 years of age and 13 years, with an average duration of 21 years. Astute clinical evaluation is necessary for younger children because trichotillomania is often mistaken for a short-term habit of hair pulling. In fact, the behavior must last several months to be considered trichotillomania. Although the etiology of trichotillomania continues to be unknown, several lines of research suggest a neurological link to high rates of glucose metabolization, a possible serotonin deficiency, and it also is thought to have a genetic component.

Pyromania is a disorder characterized by deliberate fire setting on more than one occasion. Pyromaniacs set fires for pleasure, and often experience a sense of relief or gratification from the experience. Individuals with this disorder also have an intense fascination with fire and burning objects, as well as with watching firefighters and their efforts to put out fires. Pyromaniacs are not motivated to set fires for financial gain, to hide criminal activity, or to express anger or revenge; rather, their impulsive behavior is primarily driven by their fascination with watching things burn. The majority of pyromaniacs have a history of fire setting that began in childhood.

Pyromania is considered to be rare at any age and even rarer in childhood. Indeed, the incidence of pyromania is less than 1% in most studies. Further, in those instances when children and adolescents are arrested for pyromania, only a very small percentage qualifies as true pyromaniacs. The gender distribution is skewed heavily male, with over 90% of those diagnosed with pyromania being male. Pyromaniacs frequently have comorbid behavior, attention, and learning problems. In some cases, there is a positive history of sexual abuse and/or cruelty to animals. Common biological characteristics associated with pyromaniacs include abnormalities in the levels of the neurotransmitters norepinephrine and serotonin, as well as low blood sugar levels.

Although not a defining symptomatic feature, poor impulse control may be present in children and adolescents diagnosed with externalizing disorders such as Attention Deficit/Hyperactivity Disorder (ADHD), Oppositional Defiant Disorder (ODD), or Conduct Disorder (CD), as well as obsessive–compulsive spectrum disorders.

Impulse control disorders may be treated using a number of methods, including psychological and

pharmacological interventions. Psychological interventions include behavioral techniques taught to the child as well as the parents that address the impulsive behaviors and identify any associated triggers associated, delineate the negative consequences of acting on those impulses, and learn ways to resist the impulse [12]. Because some research suggests that low serotonergic levels are implicated in the onset of impulse control disorder, pharmacologic medications such as selective serotonin reuptake inhibitors (SSRIs) have been shown to reduce impulsive behaviors associated with many of the previously described impulse control disorders. There is some evidence that other pharmacologic agents such as lithium, buspirone, and anticonvulsants also are effective in managing impulsivity. In children with ADHD, psychostimulant agents may be utilized to reduce impulsivity [13]. Pharmacological and psychological interventions may be used separately or together in the treatment of impulse control disorders.

Impulsive Aggression

►Hostile Aggression

Impulsivity

Despina Stavrinos, David C. Schwebel
University of Alabama at Birmingham, Birmingham, AL, USA

Synonyms

Disinhibition; Temporal discounting

Definition

Impulsivity refers to a behavior pattern in which individuals demonstrate deficient control over their behavior. Multiple biological and environmental sources are believed to contribute to this temperament dimension. Extreme impulsivity that impairs one's level of functioning has been characterized as a hallmark of a number of childhood behavioral disorders. A variety of assessment techniques have been employed to measure impulsivity, including observer-rating scales, self-report, and neuropsychological tasks.

Description

Impulsivity is a dimension frequently included in theories of child temperament, behavior, and personality. While there is no widely adopted definition of impulsivity, there are a number of behaviors and behavioral tendencies universally identified as characterizing the construct, including executing action without thinking, having difficulty withholding or inhibiting action, and having the tendency to seek out immediate gratification at the expense of longer-term goals [10]. In the hierarchy of temperament factors, impulsivity is suggested by most theorists to form part of the higher order concept extraversion, together with sociability and sensation seeking [6].

Many believe the construct of impulsivity includes both cognitive and behavioral components [2, 5].

There are a number of factors that may cause one to have difficulties with impulsivity. Cognitive and behavioral factors hypothesized to be involved include attentional functioning, task comprehension, processes involved in initiating and executing responses, processes involved in delaying, inhibiting, or interrupting responses, and mechanisms of processing feedback from the environment, including the processing of reward and punishment. Environmental events may also trigger problems with impulsivity, including brain injury or other central nervous system insults, exposure to teratogenic agents, early traumatic experiences including social deprivation, child abuse and neglect, or genetic vulnerabilities that give rise to deficient executive control over behavior [3].

Although many researchers and practitioners focus on the extreme of high impulsivity, most theorists consider impulsivity to be a continuum, and therefore children fall at all levels of it. Extremely low levels of impulsivity may manifest themselves in extreme shyness, anxiety, or submissive behavior patterns. Within the normal range of functioning, impulsivity plays an important role in child development. Impulsive behavior patterns allow children to take risks, try new things, and learn and explore the world around them. Most of these outcomes are positive but at times, impulsive behavior patterns among normally developing children can lead to negative outcomes. For example, impulsive children may be at greater risk for unintentional injury [11]. Children with high levels of impulsive behavior may also experience difficulty learning or increased disciplinary action in classroom settings.

Developmental psychopathology models suggest that impulsivity during the preschool years may represent the first stage in a trajectory that can progress to early onset delinquency and other antisocial behavior patterns [8]. According to the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV; [1]), impulsivity is a feature of some personality disorders (i.e., borderline personality disorder) and certain behavior disorders including conduct disorder, disruptive behavior disorder, and the Combined and Hyperactive/Impulsive subtypes of attention-deficit/hyperactivity disorder (ADHD). In ADHD, impulsivity is manifested by the tendency to blurt out answers before questions are finished, to be impatient (i.e., difficulty in waiting one's turn), and to interrupt others – all of which have implications for successful engagement in applied settings such as developing healthy peer relationships and succeeding in school and home environments [7, 13]. It has been well documented that stimulant medications along with behavioral interventions focusing on parent training and child behavior management may reduce impulsive behaviors in children with ADHD (e.g., [4, 9, 12]).

Assessment of impulsivity in children is performed through multiple methods, including observer-rating scales (e.g., Child Behavior Questionnaire, Child Behavior Checklist, Conners Rating Scales), self-report measures (e.g., Eysenck I.6 Impulsiveness scale), and neuropsychological tests and cognitive tasks (e.g., Continuous Performance Test, Stroop word-color test, Trail Making Test). Given the multifaceted nature of impulsivity, it is advisable for clinicians and researchers to use multiple assessment methods completed by multiple reporters.

Indifferent Parenting Style

Maria-Eva Tsola, Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

Disengaged parenting style; Neglectful parenting style; Nonconformist parenting; Rejecting parenting style; Uninvolved parenting style

Definition

One of two subtypes of the general style of permissive parenting. (Definition 1: Permissive parenting is a style of parenting identified by the research of Diana Baumrind that is characterized by few demands, excessive permissiveness and lack of structure, rules and limitations.) Parents whose behavior fits in this category are uninvolved with their children and fail to provide adequate support and structure.

Description

Theoretical definitions of neglect vary, in part, depending on the purpose for which the definition is used. In general, neglect is conceptualized by most experts as parental behaviors that result in negative consequences to the child [5]. Unlike other forms of child abuse, neglect is an act of omission in care rather than commissions that endanger or harm children.

Neglectful parents demonstrate a failure to provide adequate medical care, nutrition, education, and age-appropriate supervision for their children, as well as safety, emotional contact, and sufficient environmental stimulation and structure. Definitions of neglect also involve exposure of children to spousal abuse, as well as permitted substance abuse and other maladaptive conduct by a child [1]. These elements can occur in combination with each other and with other forms of abuse.

The most pervasive feature characterizing indifferent parents appears to be a variety of parenting skills deficits. Indifferent parents are described as neither demanding nor responsive to the child. They engage in fewer positive interactions with children, less overall interaction, and more insensitive interactions. The indifferent parent is disengaged and emotionally distant from the child, is not dedicated to parenting roles and is disinterested in helping foster optimal development of the child. This type of parent tends to view parenting as a burden and may consequently limit both the quality and quantity of time dedicated to the child. Additionally, indifferent parents fail to implement guidelines and set regulations to control the child.

Even though research is not conclusive, biological, personality-emotional, socio-cultural, and experiential factors have been proposed in the etiology of the behavior termed indifferent parenting. Experts agree that there is no single cause of child neglect; rather, a variety of factors are thought to be implicated in the production of behaviors that are typical of neglect. Several studies have indicated that indifferent parents are deficient in parenting skills, have more inappropriate expectations of their children, and lack both information concerning child development, and knowledge of the complexities of the parent–child bond [5, 11, 12]. Further parental characteristics that have been found to be associated with an indifferent parenting style include impulsivity, confusion, apathy, emotional detachment, and mental illness. In terms of personal demographics, parents who neglect their children are more likely than controls to be female, single, older, younger, and undereducated [12]. The absence of the father that has been observed in a significant number of neglectful families means lower income and less tangible resources to provide for children's needs [5]. Additional factors involved in the etiology of child neglect include poverty, unemployment, social isolation, loneliness, low socio-economic status, and substance abuse [3, 5, 6, 12].

Relevance to Childhood Development

The idea that early, maladaptive parent–child relations play a fundamental role in psychopathology has long been central to developmental theorizing. A substantial body of research suggests a strong relation between family dynamics and psychological adjustment. Parenting styles have been found to have a significant impact on a child's physical well-being, psychosocial adjustment, academic achievement, and involvement in drugs or alcohol [1–3, 5, 12]. Indifferent parenting has been shown consistently to have detrimental effects on the adolescent's mental health and development, leading to a variety of emotional and behavior problems. Children from neglectful environments experience developmental, neurological, emotional, and behavioral disturbances that prevent healthy growth and development [12].

In terms of physical health, neglected children have been found to suffer more problems, including malnutrition, failure to thrive, special needs, impaired visual and motor skills, poor hygiene, and substance abuse [12]. During infancy and childhood, sustained neglect can result in maladaptive socio-emotional patterns: neglected children demonstrate greater dependency, tend to have poor social skills and insecure attachment relationships, and show little concern for their peers' distress. Neglected children also tend to express more negative emotions and to exhibit more avoidance, noncompliance, and conduct disorder. They have more difficulty monitoring and regulating their emotions [1, 6, 12]. Numerous studies indicate that indifferent or neglectful parenting tends to foster higher rates of impulsivity and involvement in delinquent behavior [4, 7–9, 11, 13]. Insufficient parental involvement, guidance and supervision have been shown to produce a disrupted and atypical attachment pattern between the child and the parent [10]. In turn, these early

disturbances in attachment relations appear to lay the foundation for disturbances in developmental processes that can lead to various forms of psychopathology.

Synonyms

IEP; Individual Education Programs

The Individual Education Plan/Program also called, IEP is a solid, legally binding commitment of resources spelled out in measureable goals and objectives that the district must provide to meet the child's needs reflective of the special education eligible disability [1]. As such, the IEP is conceptualized as both a product and a process [4], that is developed, reviewed, and revised that must include the child's present levels of academic achievement and functional performance, measurable annual goals, including academic and functional goals, specific special education and related services, extent of the student's participation in regular education programs, initial dates and duration of services; and criteria, procedures, and schedules for evaluating attainment of the short-term objectives ([5]; IDEA.Ed.gov). In simpler terms, an IEP includes a statement of the special education and related services to be provided to the student and a statement of the program modification to be implemented, in order that the student can progress appropriately toward attainment of the annual goals, be involved and matriculate through the general curriculum with opportunities to participate with other students [7].

Description

Historical Overview

During 1977, it became a matter of federal law that every child in the United States that has a disability and needs special education was entitled to a "free and appropriate education" (FAPE) under the Individual with Disabilities Education Act (IDEA) [1]. Within the IDEA framework, the IEP is likened to the centerpiece or heart and soul of the Individuals with Disabilities Education Act (IDEA) that is described as the legally prescribed mechanism for designing and monitoring students receiving special education services [5]. According to [4], the IEP should

be conceptualized as both a product and a process that includes written elements that govern the implementation of a uniquely appropriate education specific to the student's needs, as mandated by the All Handicapped Children Act of 1975 (PL 94–142) [5]. According to the U.S. Department of Education, Office of Special Education Programs, an individualized education program/plan or IEP is a written statement for each child with a disability that is developed, reviewed, and revised that must include the child's present levels of academic achievement and functional performance, measurable annual goals, including academic and functional goals, specific special education and related services, extent of the student's participation in regular education programs, initial dates and duration of services; and criteria, procedures, and schedules for evaluating attainment of the short-term objectives ([5]; IDEA.Ed.gov). Furthermore, any child that is determined eligible for special education services according to IDEA, is entitled to an IEP which is individualized to meet the child's needs that allow the child to benefit educationally, as specified by the IEP team [1]. Conclusively, there are three main components of the IEP: (1) the IEP Team, (2) The IEP Meeting and, (3) the IEP document.

IEP Meeting

The IEP meeting is conducted by the IEP Team, who has sole authority according to IDEA, of deciding what services a child will receive [1]. The IEP team should legally include people who are important to the student's education including the student's regular and special education teachers, an administrator with authority to commit educational agency's resources to implement the IEP; and one or both parents [5]. The key responsibility of the IEP team, also called the Core Team or ARD (Admission, Review and Dismissal) committee is to plan an individualized education program consisting of special education and regular education services that includes related services such as modifications and accommodations implemented in the regular education classroom. A primary component of the IEP meeting is the mandated parent participation, which should foster a tone of mutual cooperation and problem solving that parents may fully and effectively engage in the IEP meeting. Prior to the IEP meeting, parents must receive a statement of the parents' procedural protections upon each notification of an IEP meeting.

In order for the IEP team to discuss and deliberate the student's needs, the IEP meeting setting should be physically comfortable and free of distractions. Although a part of the IEP team, there is no requirement that they be present when the official version of the IEP is finalized [7]. The IEP problem-solving process involves the development, implementation, and evaluation of the IEP, in order to determine the specialized needs of students with disabilities [5]. The first step of the IEP process is identification and clarification of the presenting problem [2]. In such, all of the child's unique and multifaceted needs must be addressed across all domains affecting educational progress. According to Grzywacz et al. [7]), the IEP development is defined as a three-fold inquiry made by the IEP team: (1) What are the child's unique educational characteristics/needs,(2) What will the district do/provide in response to each of these characteristics/needs, (3) What services are effective, what goals and objectives will the child reach? After considering the above, it is important to note that the availability of services should not be considered in composition of the IEP document. Therefore, if a service is needed, it must be written on the IEP and if the district does not have it available, the service must be provided by an alternate agency, as mandated in early rulings requiring availability of services be disregarded in writing of the IEP [7].

IEP: The Document

The IEP is a written working document designed to uniquely meet the education needs of a student in special education, in efforts to guide the educational programming for students in special education. In order for a child to receive special education and related services specified, an IEP must be in effect and implemented as soon as possible following the IEP meeting Specifically, in [3], the US Supreme Court included in the criteria for appropriate education of students with disabilities the existence of an IEP that is "reasonably calculated to enable the child to receive educational benefits" [6]. Further, the IEP should build on information obtained in the comprehensive evaluation, consisting of the behaviors most central to the student's education, and not containing more than ten annual goals [9]. The annual goals of an IEP represent the amount of progress a student is expected to make in a single year. In composition of the goals, the IEP must include the amount, the location, the beginning date, and the duration of related services to be provided, with the best practices that such components be composed in measurable terms. Specifically, each goal must have two to three measurable benchmarks or objectives, that indicate "how far toward the goal, by when" the child will progress. The written IEP should also include positive behavioral interventions and discipline strategies to address behavioral concerns, while focusing on accommodations and adjustments an individual child needs for appropriate access and participation in the general curriculum [1].

As mandated by IDEA the IEP must explain the extent to which a student will not participate with nondisabled students in the general education curriculum and a statement of any individual modifications needed for the student to participate in state or local student achievement testing [7]. The IEP meeting outcome, is that that the IEP team reach an agreement regarding the provisions of the IEP, with the district being the party responsible for ensuring the decided upon services are provided. In the instance that the team fails to reach a consensus, the district is required to give the parents prior written notice of its proposal and/or refusal s relative to the child's programming and placement [1].

Relevance to Childhood Development

The IEP is relevant to childhood development due to Public Law 99–457, "Child Find" which focuses on children from birth to age 5, requiring a mandate to identify children with disabilities and those at-risk for school failure. The essence of the IEP serving as a compilation of resources to address the educational needs of children who may be experiencing atypical development further informs its relevance to childhood development. Specifically, weaknesses in a child's attainment of age-specific developmental milestones often identified prior to kindergarten, may impact learning, thus leading to the IEP process. It is further important to note that early identification of such weaknesses is invaluable is its role in helping to develop an individualized education program.

Individuals with Disabilities Education Act (IDEA)

Sharon Judge
Old Dominion University, Norfolk, VA, USA

Synonyms

2004 Education for All Handicapped Children Act; 2008 Education for All Handicapped Children Act; Special education

Definition

The Individuals with Disabilities Education Act (IDEA) is the federal law that ensures that children with disabilities receive a free, appropriate public education in the least restrictive environment (LRE).

Description

For over 30 years now, a law that Congress enacted in 1975 has governed the education of children with disabilities. That law is called the Individuals with Disabilities Education Act and is known as IDEA. In the years that followed,

IDEA was amended a number of times with the most recent revisions occurring in 2004 through P.L. 108-446, the Individuals with Disabilities Education Improvement Act [2]. Over the course of the years since it first enacted IDEA in 1975, Congress has expanded the group of students who have a right to special education. At first, the group consisted of students ages 6–18, but now it includes infant and toddlers from birth though age two, young children ages 3 through 5, and older students ages 6 through 21.

This law started into motion a movement that even today continues to impact the lives of children with disabilities and their families. This legislation was designed to ensure that all children with disabilities receive an appropriate education through special education and related services. This law established six major components that have a direct effect on children with disabilities: (1) a free appropriate public education, (2) nondiscriminatory evaluation, (3) procedural due process, (4) individualized education program, (5) LRE, and (6) parental participation.

All children, regardless of the severity of their disability, must be provided an education appropriate to their unique needs at no cost to the parent(s)/guardian(s). Educators sometimes use the term "zero reject" to describe this mandate of enrolling all students. With this law, children with disabilities have a right to attend a local school as well as receive services that support their education in general education classes or most natural settings. To accomplish this, each state has in place what is called a child find system, a set of procedures for alerting the public that services are available for children with disabilities and for distributing print materials, conducting screening, and completing other activities to ensure that children are identified. The child find procedures include children with disabilities attending private and religious schools and highly mobile children with disabilities (such as migrant and homeless children).

Nondiscriminatory evaluation attempts to eliminate discrimination in the classification and placement of children suspected to have disabilities. Prior to placement, a child must be evaluated by a multidisciplinary team in all areas of suspected disability by tests that are not to be discriminatory on a racial or cultural basis. The law requires that children be evaluated by trained professionals who must administer validated tests and administer tests in the child's first language or other mode of communication (Braille, sign language). The evaluation must not consist of only a single general intelligence test but must be tailored to assess specific areas (language, cognitive, motor, etc.) of education. Professionals cannot use a single procedure as the sole criterion for determining a special educational program for a child.

Procedural due process affords parent(s)/guardian(s) several safeguards as it pertains to their child's education. IDEA ensures that any decisions made concerning children with disabilities are done so with parent input and in compliance with clear procedures. Parents must give written consent for their children to be assessed to determine if they have a disability. Similarly, parents must be invited to attend any meetings regarding their child, and they must give written permission for the child to receive special education. Further, written notice must be made prior to any change in placement. All records are confidential, and if parents do not agree with any evaluation or special education placement, they have the legal right to go to court. If disagreements occur between parents and school professionals related to placement or any other part of special education, mediation is an informal strategy that must be offered to parents to try to resolve the disagreement. If mediation is not successful, a due process hearing occurs.

IDEA requires that an individual education program (IEP) or an individualized family service plan (IFSP) be developed for each child with special educational needs. The plan for students ages 3 through 21 is called an IEP. The IEP is based on the student's evaluation and is outcome-oriented. The IEP must include the child's present level of educational performance, measurable annual goals, special education and supplementary aids and services, participation in general education and state- and district-wide assessment programs, dates and frequency of services, placement, transition services, and a statement about how the child's progress in meeting annual goals will be measured and how the child's parents will be informed. The IEP must be reviewed and updated annually. Of course, it may be revised more often if necessary.

IFSPs are created for infants and toddlers and their families when eligibility for early intervention is established [1]. This requirement underscores the significant role of the families. This legal document is the early intervention analog to an IEP, but is more holistically conceived than the latter. Each IFSP must include present levels of child's developmental status, the family's resources, priorities, and concerns related to enhancing the child's development, expected major outcomes, specific services provided, projected dates of initiation and duration of services, name of the service coordinator, and steps taken to support the transition to the preschool program. Under Part C, family members other than the child with a disability may be receiving services. Reflecting the rate

of change in infants and toddlers, IFSPs are reviewed at least every 6 months or more often if needed.

The principle of the least LRE is based on the requirement that schools must offer a variety of settings that provide the most appropriate placement options for students with disabilities and from which these students can benefit. The LRE is the setting most like that of nondisabled children that also meets each child's educational needs. It is now presumed that the general education setting is the LRE for the majority of children with disabilities, and educators must justify any instance in which a child with a disability is not educated there. Young children with disabilities receive special education and related services in a variety of school and community sites. The team developing the child's IEP or the IFSP determines the appropriate placement based upon the child's needs. However, a full continuum of educational services must be available for children with disabilities. These include general education classes, resource rooms, special classes, special schools, and homebound or hospital placements.

Parents and students bring added knowledge about the student's problem and expertise in helping to create solutions. This legislation requires that parents participate fully in the decision-making process that affects their child's education. IDEA explicitly calls for the active involvement of parents in all aspects of educational programming for their children with disabilities. When the provisions of IDEA are fully implemented, both letter of the law and the spirit of the law are protected. When this is the case, there is a supportive and mutually respectful relationship between families and professionals from the start.

Relevance to Childhood Development

The field of special education service delivery is entering a new era of accountability. The recent alignment of the IDEA Amendments of 2004 (P.L. 108-446) with the No Child Left Behind Act of 2001 (NCLB; P.L. 107-110) places more emphasis on the achievement outcomes of special education students than ever before. Language in IDEA 2004 recognizes the previous lack of expectations and low achievement levels of students with disabilities. Both pieces of legislation include the expectation that students with special needs will achieve the same academic standards as children without disabilities. IDEA requires that students with disabilities have access to the general education curriculum (the same curriculum that students without disabilities have) to the maximum extent possible. Further, IDEA strengthens the role of parents and ensures that they have meaningful opportunities to participate in the education of their child.

IDEA defines special education as specially designed instruction, at no cost to the child's parent(s)/guardian(s), to meet the unique needs of a student with a disability. Special education is individualized to the student to meet a student's needs. To be eligible for special education services, (a) a student must have a disability and (b) that disability must adversely affect the student's education performance. IDEA describes 14 categories of disability. Some states follow these federal categories, whereas others use slightly different terms and definitions for describing disabilities.

Since the needs of and services provided to infants and toddlers are so different from the needs and services for older students, IDEA is divided into two parts. Part B of IDEA contains the requirements for providing special education and related services to children with disabilities from 3 through 21 years of age whereas Part C authorizes grants to states to develop and maintain early intervention programs for infants and toddlers with disabilities, birth to age 3 years and their families. Part C, the infants and toddlers program, has parallels with the provisions and requirements of Part B; however, these provisions and requirements differ in important respects from those of Part B. For example, while Part B eligibility is based on categories of disabilities, eligibility for Part C programs are often based on a diagnosis of "development delay" that requires early intervention services. Instead of an IEP, Part C programs have IFSP in recognition that services must be provided to the family as well as to the infant or toddler. Since very young children are served in a variety of locations (including the home), Part C services are to be provided in "natural environments" which are the types of settings in which infants and toddlers without disabilities would participate.

►Autonomy

Inductive Parenting

Robert Sean Bannon
Emporia State University, Emporia, KS, USA

Synonyms

Authoritative parenting; Child-centered parenting; Reasoning-oriented parenting

Definitions

A supportive style of parenting that involves the use of reason during the establishment and enforcement of child behavior limits.

Description

Popularly considered the most balanced parenting style, inductive parenting involves the utilization of clear limits, rules and consequences with a certain level of flexibility in order to maintain responsiveness to a child's fluctuating emotional status. Inductive parenting encourages *autonomy* and open communication in the child, while maintaining a high level of parental demand regarding conduct and behavior. Child security is provided through adherence to consistent routines and schedules while the value of a child's input encourages independence. The decision-making process is a collaborative effort between parents and children that involves negotiation and understanding, although the final decision remains with the parent.

According to studies, the effects of inductive parenting style extend through childhood indo adolescence. Due to the encouragement of open communication and independence, children raised in this parenting style develop less problem behaviors, higher self-confidence, higher control over aggression, exhibit higher degrees of academic success, function well in social environments and display a high measure of social responsibility.

Inductive Reasoning

Inductive reasoning is the type of reasoning involving moving from a set of specific facts to a general conclusion. Inductive reasoning involves drawing conclusions from objects or entities that have been examined to establish a conclusion about an object or entity that has not been examined. Inductive reasoning is also used to build theories in which specific facts are used to create the theory, explain the relationships between facts and thereby allow prediction of future knowledge. Inductive reasoning is the primary philosophical method used to examine phenomena such as morality, faith and existence.

Infancy

Jana Sander
Texas A&M University Corpus Christi College of Education, Corpus Christi, TX, USA

Synonyms

Baby; Babyhood; Early childhood; Formative year; Newborn; Tot

Definition

Infancy is generally considered to be the year of life.

Description

Physical Development

Motor development during infancy advances in an ordered manner from head down (cephalocaudal) and trunk of the body outwards (proximodistal). In other words, the infant will first gain control of their head and lift it. As the child ages, they are able to control the neck, trunk, legs and feet. Likewise, they acquire control of their shoulders, then arms, hands, and finally fingers ([2], p. 236).

Reflexive actions are the primary types of motor skills the newborn exhibits. Most of the reflexes are considered

to be related to survival. For example, sucking, rooting for the breast or bottle, grasping, and eye blink ([2], p. 236).

From ages 1 to 4 months the infant's average length is 20–27 inches and the average weight is about 8–16 lb. The infant can grasp objects with their entire hand, raise their upper body and head when the arms are in the prone position, and can turn their head from side-to-side when lying down ([2], p. 236).

From ages 4–8 months the infant can use the pincer grasp, reaches with one arm rather than both, can transfer objects from one hand to the other, shakes and pounds objects, and puts most things into their mouth. In addition, the child can hold their own bottle, sit alone, pull into a crawling position, and at the end of this period begins to crawl ([2], p. 239). Children of this age gain approximately 1 lb each month and 1/2 in. in length. Teeth being to appear thus increasing drooling, chewing, and biting ([2], p. 236).

From 8 to 12 months children gain about 1 lb and 1/2 in. each month (p. 237). At this age children reach with one hand when offered an object, pokes with one finger to explore objects, puts objects into containers, and releases objects by dropping or throwing them. Also, children begin to pull up to a standing position, cruising by holding onto furniture, crawls up and down stairs, and walks while holding an adult's hand. Some children may walk alone at this age [2, p. 239].

Cognitive and Language Development

During the first month of life, the infant begins to study their own hand, may put body movements in rhythm to adult speech patterns, and prefers the primary caregiver's voice to that of a stranger. Additionally, the infant communicates through crying and may prefer certain voices, sounds or music [2, p. 254].

During months 1 through 4 the infant begins to recognize familiar objects, does not search for objects that fall or otherwise disappear, and imitates gestures such as bye-bye. The child also reacts to familiar voices, babbles or coos when spoken to, and laughs out loud (p. 254).

From 4 months through 8 months the infant begins to focus on smaller objects and reaches for them. The child also imitates actions such pat-a-cake and peek-a-boo. If an object is hidden the child will search for it and drops one toy when handed another. The infant will bang objects together, play with small toys, and coordinates eyes, hand and mouth to explore an object. Responding to name and simple commands such as "Wave bye-bye," occurs during these months. The infant can now respond to the voice of others, produce vowel sounds and some consonants, and babble by repeating syllables (p. 254).

From 8 to 12 months the child points to objects, follows simple directions, drops toys intentionally, as well as puts blocks into a cup when asked. In addition, the infant can put a spoon in their mouth and turn pages of a book. Further, the child babbles to initiate socialization, shakes head "no," enjoys simple songs, and hand a toy to an adult when asked (p. 255).

Social/Emotional Development

During the infant stage bonding and attachment are critical. Bonding refers to the process where the adults in the infant's life become emotionally attached to the child. While attachment is the emotional bond the infant forms with the primary care givers in her life (Morrison, p. 253). These two concepts are critical for the infant to develop secure emotional relationships for the rest of their lives.

Emotional self-regulation is another aspect of the infant's social/emotional development. This refers to the ways humans are able to adjust to their emotional states. During the first few months of life, infants do not have much ability to regulate their emotions. They become overwhelmed by stimuli and may turn away or begin to suck or cry when their emotions become too intense. By 2–4 months of age the infant gains in the ability to tolerate more stimulation. Caregivers can build upon this growth by adjusting the pace of their interactions with the baby to help the child not become overwhelmed with stimulation. At the end of the first year of life the baby can begin to self-regulate by crawling or walking away from unpleasant stimuli ([1], p. 403).

Infant Death

►Infant Mortality

Infant Mortality

Angelina Stavrou, Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

Infant death

Definition

The term infant mortality is used to describe the number of deaths of new-born children aged 1 year and younger.

Description

Infant mortality refers to deaths of infants under the age of 1 year and measured by the infant mortality rate, expressed in number of deaths of children under the age of 1 year for each 1,000 live births. The infant mortality is used to compare the health and well-being of populations within one country and between countries of different socio-economic development. Infant mortality numbers also provide important information about level of medical services, child-rearing behavior, and sanitation and help estimate communities at risk.

In relation to timing of death the infant mortality is divided into four categories [3].

1. Perinatal mortality only includes deaths between the fetal viability (22 weeks gestation) and the end of the 7th day after delivery, and has obstetric origins, similar to those leading to stillbirths. World Health Organization reports over 6.3 million perinatal deaths a year, almost all of which occur in developing countries, and 27% of them in the least developed countries alone. Stillbirths account for over half of all perinatal deaths. One third of stillbirths takes place during delivery, and is mostly avoidable.
2. Intrapartum deaths (i.e., those occurring during delivery) are closely linked to place of, and care at, delivery. According to WHO reports, in developing countries, just over 40% of deliveries occur in health facilities and little more than one in two takes place with the assistance of a doctor, midwife, or qualified nurse.
3. Neonatal involves death through the end of the 27th day of life and usually reflects physiological problems during pregnancy that cause pregnancy complications and premature delivery. Various reports state, that in developing countries the risk of death in the neonatal period is six times greater than in developed countries; in the least developed countries it is over eight times higher.
4. Post-neonatal is death of infant from day 28 of life up to 1 year. Post-neonatal mortality is usually associated with social and environmental factors early in the infant's life, even though deaths from birth defects also occur in this period.

Causes

The most common cause of infant mortality worldwide include premature birth, low birth weight, birth defects, sudden infant death syndrome (SIDS), pneumonia and dehydration from diarrhea. Infanticide, abuse, abandonment, and neglect are other factors behind why some infants die before their first birthdays [1].

Methods of Estimation

Empirical data is used to estimate infant mortality in a given region. When no survey or registration data point is available, the neonatal mortality rate is estimated from the under-5 mortality using a regression adjusted for AIDS [10]. The reliability of infant mortality estimates depends on accuracy and completeness of reporting and recording of births and deaths. Underreporting and misclassification are common, especially for deaths occurring early on in life.

Disaggregation

A full report presents infant mortality data by race, origin of the mother, birthweight, period of gestation, sex of infant, plurality, trimester of pregnancy prenatal care began, maternal age, maternal educational attainment, live-birth order, mother's marital status, mother's place of birth, maternal smoking during pregnancy, age at death, and underlying cause of death [2].

Relevance to Childhood Development

The survival of infants in their first year of life is very important factor that is widely accepted as an indicator of the general health and wellbeing of a given population.

According to the latest UNICEF report almost 10 million children under five died worldwide in 2006, of which 4 million die within the first month of life, half of these within the first 24 h. Many of these deaths are related to the lack of adequate medical and nursing intervention at the time of birth [9].

The five countries with the highest rates of infant mortality were Sierra Leone, with 270 deaths per 1,000 live births; Angola with 260; Afghanistan with 257;

Niger with 253; and Liberia with 235. In contrast, Sweden and Iceland were among the countries with the lowest mortality rates – 3 deaths per 1,000 live births [3].

The report notes, that in developing counties: "Pneumonia kills more children than any other disease – more than AIDS, malaria and measles combined. It is a main cause of deaths in every developing region." The report goes on to note how other factors such as malnutrition and environmental conditions play a crucial role in heightening the vulnerability of children to pneumonia [6].

While considering the efforts on reduction in infant mortality in a given country, it is essential to know the top leading causes and underlying causes of mortality in children in the country, the policies and strategies to address them, and progress of work in those areas [7].

Income levels and education, both at the societal and individual levels, are closely associated with infant mortality.

Prevention

In developing countries simple movement against infant mortality, especially post neonatal mortality can reduce infant deaths due to diarrhea and infectious disease and other causes. This can be achieved through basic public health actions like promoting health care, providing nutrition, and non-formal education to preschool children and to pregnant and lactating women, offering sex education, adolescent clinic services, and community support and involvement [4]. Finally, early and continuous prenatal care helps recognize conditions and behavior that may result in low birth weight babies, such as smoking, drug and alcohol abuse, inadequate weight gain during pregnancy and repeat pregnancy in 6 months or less [5, 8].

Infantile Amnesia

Maria Perdikogianni[1], Xenia Anastassiou-Hadjicharalambous[2]
[1]Center for Therapy, Training and Research (KESY), Nicosia, Cyprus
[2]University of Nicosia, Nicosia, Cyprus

Synonyms

Childhood amnesia

Definition

The inability to recall events from early childhood.

Description

Infantile amnesia is characterized by a relative absence of memory before the ages of 3 or 4 [1, 5]. This term does not refer to a complete absence of memories but rather a scarcity of memories during infancy, memories that can later be influenced by individual experiences and cultural factors as well as how these early events are remembered and relayed to the children by parents [2, 9]. A few people can apparently recall momentous experiences that occurred when they were as young as 2 years old, such as the birth of a sibling but not earlier. Of course we all retain procedural memories from our toddler years, when we first learned to use the spoon, drink from a cup and take our first steps, just as we can retain semantic memories acquired in early life (the rules of counting, names of people and things, etc.). However, as

adults we can no longer remember being fed as an infant by our parents, taking the first steps or saying our first words. That's the result of infantile amnesia [5].

Explanations for Infantile Amnesia

Infantile amnesia was first formally studied in 1893 by the psychologist Caroline Miles [1] but it was Sigmund Freud who offered one of the most famous and controversial explanations of infantile amnesia when he tied the phenomenon in with his other psychological theories [1, 5, 8, 9]. Freud theorized that infantile amnesia is the result of the mind's attempt to repress memories of traumatic events that occur in the psychosexual development of every child. These memories, according to Freud, have disturbing sexual and aggressive content and that's why they are suppressed. This would lead to the repression (Definition 1: Repression according to Freud is the classical defense mechanism that protects you from impulses or ideas that would cause anxiety by preventing them from becoming conscious.) of the majority of the first years of life [1, 4, 5, 8, 9].

Cognitive developmentalists claim that adults have trouble recalling the events of childhood because they no longer think as children do. As adults we use very different cognitive schemas (Definition 2: A schema is an outline or image universally applicable to a general conception, under which it is likely to be presented to the mind (five dots in a line are a schema of the number five; a preceding and succeeding event are a schema of cause and effect.)) from those we use in early childhood, and these adult schemas are not useful in restructuring early events from the memories stored at that time. As preschoolers we may encode our experiences far less elaborately since our information processing abilities are still limited and thus have very few cues for retrieving early memories later on in life. Only after we begin school do we learn to think as adults do, use language to organize memories and store not only events but thoughts about those events [9].

Researchers who argue that the development of the cognitive self is crucial in the establishment of autobiographical memory do not disagree that developments in language, socioemotional and memory factors are also play an important role in autobiographical memory. Research has shown that what's lacking in early infant memory is not simply a memory capacity or a language system but rather the development of self as a cognitive entity, a personal frame of reference that constitutes memory autobiographical in a unique way [5]. According to this theory, children develop self-awareness by about 2 years of age and memories are inherently associated with one's sense of self. When memories are encoded before self-awareness develops they are not comprehensible to the individual even though some information is stored in the brain.

Biological researchers believe that the brain and the nervous system are not entirely formed in young children and thus do not allow for the development of adequate memory stores and effective retrieval strategy. Evidence for this comes from three different sources. First, that the hippocampal region of the forebrain is immature in young children. Second, that the prefrontal cortex is immature at birth and undergoes a period of rapid synaptogenesis (Definition 3: Synaptogenesis is a process involving the formation of a neurotransmitter release site in the presynaptic neuron and a receptive field at the postsynaptic partners, and the precise alignment of pre- and postsynaptic specializations.) toward the end of the first postnatal year along with the improvement of other cognitive tasks. Finally, the third source states that these changes in synaptic efficiency or hormonal modulation that follow certain types of stimulation may only become functional beyond infancy [5, 9].

Another explanation attributes the cause of infantile amnesia to the incomplete development of language in young children. This theory states that infants do not have the language capacity to encode autobiographical memories in such a way that their adult selves can interpret correctly. Research by Gabrielle Simcock and Harlene Hayne showed children's inability to translate early, preverbal experiences into language because they lacked the language skills to do so. As a result these experiences could not become part of autobiographical memory since they could not be encoded [4, 8]. This theory seems to be supported by the typical process of language development. The language of 1-year olds is limited to one-word utterances and childhood amnesia predicts that adults have very few, if any, memories of this time. By the age of three children utter two or three word sentences and by their fifth year their speech resembles that of an adult. This language development seems to correspond to infantile amnesia because most adults' earliest recallable memories go back to the age of 3 or 4.

Recent research has found patterns in the extent of infantile amnesia and the most prominent ones are gender and race. Research has shown that in general the earliest recollections of females are earlier and more vivid than those of males, and this pattern is due to differences in how males and females interact as children, especially the types of conversations they have [3, 6].

Race has also been shown to play a role in the effect of infantile amnesia as in certain studies Asian adults reported significantly later memories than European

adults, while Maori (Definition 4: Maori are one of the aboriginal inhabitants of New Zealand; Maori was also the original language of New Zealand.) adults, whose traditional culture puts an emphasis on the past, reported significantly earlier memories than adults in the other two cultural groups. In all three cultures the memories reported by females contained a lot more information than those reported by men [6].

Relevance to Childhood Development

Infantile amnesia provides an explanation to the adults' inability to recall events and experiences from their early years. People often find infantile amnesia difficult to accept and often claim to remember events from the first or second year of life. Researchers who explore childhood cognitive development, and continue to research infantile amnesia aim to identify new characteristics and possible explanations for this phenomenon. Whatever the explanation for infantile amnesia, scientists agree that our first memories may provide some useful insight into our personalities and they prove to be an important social tool.

Infant–Mother Attachment Studies, of Ainsworth

Douglas K. Symons
Acadia University, Wolfville, ON, Canada

Synonyms

Attachment theory

Definition

Mary Ainsworth's seminal research on infant–mother attachment built upon John Bowlby's Attachment Theory to describe different patterns of infant-caregiver attachments. It led to the development of a classification system of these relationships, the Ainsworth Strange Situation, which serves as a "gold standard" for attachment classification in infancy [6]. Basing her work on extensive home-based observations and cross-cultural data paid testimony to the universality of the development of early social relationships in humans.

Description

Thousands of studies in child development have been published on infant–mother attachment formation, and all are based on the seminal research of Mary Ainsworth and her academic descendents whom conducted research under her supervision and training workshops [7]. Attachment Theory was based on principles from psychiatry, ethology, evolution, and personality development, but Ainsworth is credited with emphasizing the developmental elements of the theory and building on the observational methodology required to assess relationships. Her research in the 1960s [1, 3, 5] was a foundation for John Bowlby's trilogy on Attachment, Separation, and Loss, which delineated Attachment Theory.

Ainsworth initially conducted hundreds of hours of observations of infant–mother pairs in Uganda [2] and Baltimore [6] to investigate how relationships develop in two distinct cultures. Parent–child pairs ultimately balance the competing demands of proximity-seeking, which a relatively helpless infant requires for survival, and exploration, which an infant needs to interact with

the environment and maximize her or his own development. She observed that infants exhibited different kinds of behavior during naturalistic separations and reunions with their mothers [5], and consequently developed the Strange Situation as a laboratory procedure to systematically observe this behavior, classify the relationship, and thus examine individual differences.

The Strange Situation consists of eight sequential episodes in which an infant plays with its mother, a stranger enters the room and joins the interaction, the mother leaves, the mother returns for a first reunion, the mother then leaves the baby alone in the room, the stranger returns, and then the mother returns for the second reunion while the stranger leaves. This sequence is recorded and detailed behavioral coding takes place later that focuses on proximity- and contact-seeking behavior, contact-maintaining behavior, resistance behavior through poor distress resolution, avoidance of the mother during reunion, search behavior during separation, and positive social signaling from a distance. These ratings are used to classify babies into three groups that are well-known in child development: insecure-avoidant, secure, and insecure-resistant. What was essential to this research was that this lab-based behavior was related to other home-based observations, as well as observations of how sensitive mothers were to infant cues and needs. But she carefully distinguished infant–mother attachment from other developmental processes such as cognitive abilities of the infant.

Building on its ethological roots, Ainsworth's research emphasized the importance of detailed and extensive observations of social behavior both in the home and in laboratory behavior. The scripted social interaction of the Strange Situation stressed the importance of standardized methodology and objective scoring criteria. The classification system emphasized the developmental aspects of Bowlby's attachment theory, gave researchers a way of examining individual differences in early relationships, and served as a model to examine different kinds of intimate relationships later in childhood and even into adulthood [4]. Participants in the initial wave of attachment research of the 1970s are now entering mid adulthood, and thus long term predictive validity studies have been published in the past 10 years, and more are on the way.

What constitutes a threat to a person and thus activates the attachment system changes radically across age, as do the means by which proximity-seeking and avoidance are displayed, and the internalization of relationship processes into the cognitive domain necessitates other means of assessment. But Attachment Theory is relevant from "cradle to grave," and Ainsworth's research dominates how we conceptualize the cradle end of things.

Inhalants

Preciosa Calderon
San Bernardino, CA, USA

Synonyms

Dusting; Huffing; Poppers; Whippets

Definition

Breathing in vapors or gas through the nose or mouth for a soothing effect.

Description

Inhalants are breathable chemicals that are commonly found within the home (ex. cleaning fluids, air fresheners, and gasoline). Chemicals are inhaled in the nose or mouth (known as, huffing) with the purpose of having a mind-altering experience. Intoxication last only a few minutes which causes the user to continue use over long sessions to remain intoxicated. Common effects of intoxication are: lack of coordination, dizziness, slurred speech, and possible aggression. Some users may also experience hallucinations and delusions. Physical side effects caused by inhalants are vomiting, nausea, and confusion. Long-term abuse of inhalants may cause permanent damage to the lungs, brain and central nervous system. When inhalants are consumed in high dosages heart failure may also occur. This is known as "sudden sniffing death". Inhalants are easily available and legal to have for any environment. Most at risk uses are young children and adolescents.

Inhibition

Despina Stavrinos, Katherine W. Byington
University of Alabama at Birmingham, Birmingham, AL, USA

Synonyms

Repression; Self-control; Self-restraint; Suppression

Definition

Inhibition refers to an active suppression process that functions to help people refrain from giving in to an urge when doing so could result in undesired consequences [14]. Having extreme difficulty with inhibiting behavior in a way that impairs daily functioning is a hallmark of the common childhood behavioral disorder, Attention-Deficit/Hyperactivity Disorder (ADHD). A variety of assessment techniques are employed to measure inhibition, including observer-rating scales, neuropsychological tasks, and cognitive tasks.

Description

Effective daily functioning often requires behavioral inhibition and the role of inhibition is particularly important in childhood. For example, a very young child might struggle to resist the urge to eat a cookie before dinner and a school-aged child might struggle to resist the urge to cheat off of a classmate's paper. The processes involved in resisting such urges are commonly referred to as self-regulatory or inhibitory control processes [12]. Inhibition is a construct that is frequently included in models of executive functioning - a higher order concept that describes the control of thought and behavior. While there is no widely adopted definition of inhibition, there are a number of behaviors and behavioral tendencies that most scholars use to describe the construct. Such behaviors might include suppressing an active or prepotent process, having the tendency to withdraw in a new situation, or reacting to something unfamiliar with initial avoidance, distress, or subdued affect [2, 3, 9].

Inhibition is measured on a continuum; that is, some people are generally more inhibited than others [4]. At the lower extreme are those who are described as *inhibited*, or

who tend to exhibit more restraint and self-control when faced with the urge to engage in an undesirable behavior in range of different situations. At the upper extreme are those who are described as *uninhibited,* or who have a tendency to react spontaneously or almost as if without thinking in nearly all situations [8]. Although a person may be consistently described as generally inhibited or uninhibited from childhood through adulthood, for most individuals, the ability to inhibit oneself tends to sharpen to some extent across development [15].

Within the normal range of functioning, inhibition plays an important role in child development. Behaviorally, uninhibited children are more likely to try new things, act independently, and learn and explore more aspects of the world around them than their inhibited, shy, and less risk-taking counterparts. Although this type of exploration and independence is often positive and can foster a child's development, being uninhibited can, at times, lead to unwanted outcomes. Specifically, uninhibited children may be at greater risk for unintentional injury [13]. For example, an uninhibited child who sees a ball roll into the street may be less likely to consider the outcomes of running into the street and may dart out in traffic to get the ball.

A child with an uninhibited behavioral profile may also encounter difficulties in the school and home environments. Children who are less inhibited may have a harder time attending to and learning new material and may require increased discipline and redirection. A child who has a harder time resisting the urge to talk to his friend in class is also likely to miss his teacher's instructions for a task or miss the explanation of an academic concept while he is talking. These types of behaviors can not only decrease a child's ability to progress academically, but can, at times, result in social disapproval by classmates due to the frequent negative attention the child receives. However those who fall on the inhibited end of the spectrum tend to be more shy, which is particularly evident not only in social situations with peers but also in unfamiliar situations. These children may also be less likely to speak up to ask questions in class or when something is making them uncomfortable.

Clinical levels of inhibition or disinhibition can contribute to child psychological disorders. Specifically, extreme disinhibition is a prominent characteristic of children with ADHD. It has been proposed that the principal cause of ADHD is a deficit in behavioral inhibition or in the ability to suppress a prepotent or ongoing response [1]. On the other end of the spectrum, extreme inhibition is a common characteristic of children with anxiety disorders. Psychotherapeutic treatments of such disorders are widely accepted, and longer-term cognitive and behavioral treatments have proven quite useful in the remediation of such conditions (e.g., [10]). However, research indicates that because the development and manifestation of inhibition is so complex, it is not easily improved or "cured" with simple "quick-fixes" (e.g., [5, 12]).

Given the multifaceted nature of inhibition, it is advisable for clinicians and researchers to use multiple assessment methods completed by multiple reporters to adequately assess inhibition. Assessment of inhibition in children is typically performed through observer-rating scales completed independently by parents and teachers (e.g., Child Behavior Questionnaire, Behavior Rating Inventory of Executive Function), neuropsychological tests, and cognitive tasks. Researchers have also utilized a number of pencil-and-paper cognitive tasks measuring behavioral inhibition for many years. Measures such as the "Draw-A-Line" and "Draw-A-Circle" task require participants to draw a line or circle as slowly as possible without stopping or lifting their pencil. These tasks present a restraint challenge in that participants are expected to experience the urge to quickly complete the circle. Those with lower levels of inhibitory control are expected to have a more difficult time resisting the impulse to complete the circle quickly [6, 11, 13].

Although paper-and-pencil methods such as the ones described above are still used, computerized neuropsychological tasks have become increasingly popular measures of inhibition due to their ease of use. One common instrument is a stop-signal paradigm which has been used frequently in pediatric inhibitory control research (e.g., [7, 15]). Two prominent examples of this type of task include the Go-Stop task and the Go/NoGo task. In both of these tasks, participants are asked to respond to visual stimuli (e.g., letters) in a controlled manner. That is, they are asked to respond (i.e., "go") almost immediately only after seeing specified stimuli and not to respond (i.e., "stop"/"no-go") to other stimuli. The more dominant "go" stimuli are presented more frequently than the "no-go" stimuli and thus create a more powerful tendency to respond. As participants become more engaged in the task, it becomes increasingly difficult to inhibit incorrect responses.

Initiative Versus Guilt

Matthew C. Lambert, Heather M. Kelley
Texas Tech University, Lubbock, TX, USA

Synonyms

Erikson's preschool stage of social-emotional development

Definition

In Erickson's theory of social emotional development, the psychosocial conflict encountered during the preschool years, which is resolved by engaging in playful, creative, and or novel expressions and experiences. The degree to which children develop a sense of *initiative* is closely associated with the degree to which caregivers allow children to express themselves without being overly critical or punitive toward novel expressions.

Description

Initiative versus guilt is the third stage in Erikson's 8-stage theory of social-emotional development. This stage, also referred to as the preschool stage, can include many children in the age range of 3–6. During this period, Erikson postulated that children are faced with psychosocial conflicts about expressing themselves in unique, creative, and purposeful manners. He suggested that the extent to which parents or caregivers allow and encourage these types of expression contributes to the child's sense of *initiative*. Conversely, the extent to which parents or caregivers restrict or punish novel expressions contributes to the child's sense of guilt.

Erikson (1998), as well as numerous subsequent researchers, define *initiative* as "an emotional state, often acquired during the preschool years, in which children assert themselves, make creative attempts, take risks, and reach out to peers [2, 3]." The construct of guilt can be conceptualized as an emotional state in which children feel as though their actions are wrong or that they themselves are bad and lack worth [2, 5].

Remember that Erikson's work was influenced by the psychoanalytic work of Sigmund Freud [4]. It is during this stage that Erikson hypothesized that the *superego*, or conscience, is beginning to develop. He believed that the *superego* is shaped by experiences that young children have during this stage of his theory. He believed that a child's sense of *initiative* and a child's *superego* were closely related. Creative activities such as instances of pretend play influence the development of a healthy *superego* [1]. However, caregivers who are overly strict or overly punitive can lead to a guilt-ridden *superego* and a child who is overly critical of themselves and less inclined to make novel efforts in the future limiting a child's repertoire. Although an overly guilt-ridden *superego* is a detriment to future development, a sense of guilt is necessary for children to develop a healthy conscience.

Relevance to Early Childhood Education

Learning is discovering and to discover, one may fail before succeeding. A healthy sense of exploration or *initiative* is an advantageous characteristic to possess for success in any learning context. For example, active learning pedagogies such as inquiry learning or project-based learning require children to be motivated to engage in novel, but purposeful behaviors and accept failure and error as part of the learning process. Children who posses

more *initiative* are also more likely to approach peers in attempts to engage in collective activities such as socio-dramatic play.

Inner City Destitution

►Inner City Poverty

Inner City Poverty

Tony Wu
Walden University, Diamond Bar, CA, USA

Synonyms

Inner city destitution; Low socio-economic status; Urban poverty

Definition

Poverty occurring in inner cities and urban areas that affects millions of people and has been associated with physical and psychological distress, economic hardship, and high crime rates.

Description

Poverty has detrimental consequences for quality of life, especially for inner city or urban residents. Children and families living in poverty have more stressful life events, higher unemployment rate, crime incidents, medical and mental illnesses, economic hardship, less access to education and health care, as well as less satisfaction with employment [8]. Given these chronic distress, strains, inadequate social support, coupled with distraught family relationships, incidents of psychological illnesses are widespread for the poor. For instance, Haring et al. [4] found that low socio-economic status is associated with depression and other mental illnesses, and lowered psychological well-being. Study has documented that urban poverty is more harmful than rural poverty due to the nature of urban environment [6].

Wilson and Aponte [9] found that 81% of African–American female-headed families lived in urban areas in which 57% of these families were below the poverty line. It was also estimated that close to one-half of the poor in the United States are single mothers with children [2]. It appears that urban poverty is especially harmful for single mothers, given they are required to raise children in bad neighborhoods, with limited resources and support. Similar trend continues to be observed more than 2 decades later. In a review of national data, Brooks-Gunn and Duncan [1] found dismal outcomes for inner city children. For example, poor children have higher incidences of medical problems, developmental delays, low birth weight, growth delay, lead poisoning, lower IQ and grades, higher dropout rates, severe emotional and behavioral problems, and higher number of teenage out of wedlock childbearing.

One of the major concerns for inner city poverty is the educational equity and quality for urban children. One challenge facing urban school district is recruitment and retention of highly qualified teachers. Studies have found that inner city teachers have tended to graduate from less prestigious training institutions, are less likely to have specialized subject areas, and have lower grades in universities. They are also less likely to have advanced degrees than teachers of more affluent school districts [3, 5]. For teachers, determining whether to teach at urban schools is a difficult one due to the implications for teachers, school districts, the poor, and the larger community. However, the unfortunate trend is that highly qualified teachers tend to avoid poor schools, while experienced teachers are leaving inner city schools at a record rate [7].

Inner Speech

Jana Sander
Texas A&M University Corpus Christi College of Education, Corpus Christi, TX, USA

Synonyms

Self-talk

Definition

Talking to oneself but not uttering words aloud.

Description

Inner speech may include all of the ideas of verbal speech but in abbreviated form. In other words inner speech is a type of self-talk that assists children in organizing their cognitive processes. As children grow and mature this type of self-talk helps them to monitor their behavior or accomplish challenging tasks.

Metacognition can be facilitated by the use of inner speech, a kind of self-talk that enables students to direct and monitor their cognitive processing, and derive a deeper understanding and appreciation of their own thinking processes [1].

Insecure-Resistant Attachment

Douglas K. Symons, Alicia L. Szielasko
Acadia University, Wolfville, ON, Canada

Synonyms

Ambivalent attachment; Insecure-ambivalent attachment; Insecurity; Preoccupied attachment

Definition

Insecure-resistant (aka anxious-ambivalent) attachment is an attachment classification developed within attachment theory and initially described in the work of Mary Ainsworth and John Bowlby. Infants of this attachment category have excessive distress upon separations from an attachment figure such as a caregiver, and when the caregiver returns, tend to continue their distress and do not use their caregivers as a secure base [2]. Distress can take the form of crying, tantrums, and angry behavior toward the caregiver. In other words, the infant resists parent attempts to sooth the distressed child, is distrustful and uncertain that he or she serves as a secure-base. This creates insecurity, anxiety, and dependency that can continue within intimate relationships throughout the lifespan.

Description

The attachment system balances child needs to proximity-seek for protection and explore the environment. It is activated in times of distress and attachment figures are needed to serve as a secure-base. It is felt that insecure-resistant attachment is related to insensitive parenting that is inconsistent. This can be because parents are intrusive, not aware of what the specific needs are of a child at a given moment, or insensitively ignore or misread infant cues [4, 6]. Sometimes parents are available to serve as a secure-base, sometimes they are not. Over time, the infant learns that they cannot be sure if their needs will be met by the caregiver, and thus they are distrustful and over-solicitious of care. Preoccupation with care means exploration is restricted, and the emotional tone of the relationship is indicated by anxiety and insecurity. Because they are not sure if they have a secure-base, more events are seen as threatening, and the attachment system becomes hyperactivated. While a secure child can be soothed by a parent when distressed, a resistant child is difficult to sooth, although at the same time they are more dependent on or clingy with the parent [7]. Attachment style appears to arise from a parenting environment and is not a simple function of either temperament nor genetic influence [8].

In infancy, anxious-resistant attachment is assessed using behavioral observations of the strange situation and some of its variants. Normative samples show that 7–15% of infants are classified in this group in the United States with similar percentages in other countries. By the preschool age, attachment begins to be reflected in behavior which is more representational, and doll-play tasks, sentence completion tasks, and story-telling tasks have been developed. Figure 1, for example, shows a parent dropping off a child on her or his first day of school from the Separation Anxiety Test, and children are asked a series of questions about this scenario that probe for attachment-relevant information. Within each kind of task, the absence of secure-base themes can be examined, and the presence of excessive distress, worry and distrust about a parent's support, dependency and clinginess, and anxiety are present. In fact Bowlby's original formulation of this form of attachment was used to account for anxiety disorders and interpersonal problems later in life, and anxious-resistant attachment is predictive of these kinds of clinical problems. The percentage of children classified as insecure-ambivalent is similar to that in infancy, but there may be a shift in gender toward girls being more and boys being less likely to be in this category (insecure boys shift toward avoidance) [5].

In adolescence and adulthood, common methodology to assess attachment uses discourse methods to address the present state of mind with respect to attachment events [1]. Feeling unloved and inability to move beyond relationship events with parents is indicative of preoccupied attachment, which has conceptual and empirical continuity with anxious-resistant attachment. The other common approach is to use self-report methodology about either recollections of the caring and overprotection received from their own parents during childhood, or

Insecure-Resistant Attachment. Fig. 1

anxiety and avoidance reflected in their current romantic relationship. Bowlby initially proposed that attachment is really about yea/nea answers to two questions fundamental to interpersonal processes: Am I loved? Am I lovable? In romantic relationship research, answers to these two question lead to a two-dimensional model of attachment style, and individuals with an anxious-resistant background are not sure whether they are loved or not [3]. In other words, the uncertainty they have about using others as a secure base continues into adulthood, and leads to dependency within relationships. Constant affirmation that they are indeed loved is sought, but does not seem to have a lasting impact.

Institutional Review Boards

Marie C. McGrath
Immaculata University, Immaculata, PA, USA

Synonyms

Committees for the Protection of Human Subjects; Human Subjects Review Boards; IRBs; Research Ethics Review Boards

Definition

Institutional committees that review research proposals to determine whether those proposals meet legal and ethical standards for protection of human subjects.

Description

The U.S. Department of Health and Human Services (HHS) [2] defines research involving human subjects as any research that involves one or more of the following activities: communication or interaction between a researcher and a participant; manipulation of a participant's environment by a researcher; observation and/or recording of a participant's behavior in a manner that leaves the participant identifiable to others; and/or gathering identifying information from records or other data sources. While innumerable advances in a variety of scientific and technological disciplines can be credited to research involving human subjects, such practices often involve risk to the individuals who participate. In addition to the risks inherent in the use of experimental treatments, a review of the history of human subjects research reveals many examples of studies involving either ethically ambiguous or clearly unethical practices on the part of researchers. These practices range from intentionally creating stressful situations for subjects (e.g., Stanley Milgram's research examining subjects' willingness to inflict pain at the direction of an authority figure), to knowingly withholding treatment likely to benefit participants, even when doing so is likely to lead to sickness and/or death (e.g., the Tuskegee Syphilis Study), to actively causing physical harm or death to subjects (e.g., Nazi experimentation).

Since World War II, many government agencies and international organizations have developed policies and regulations designed to protect individuals who participate in research studies. In 1979, the U.S. National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research [3] published "Ethical Principles and Guidelines for the Protection of Human Subjects of Research" (also known as the Belmont Report), which identified three basic principles of ethical research: *respect for persons*; *beneficence*, or maximizing benefit and minimizing harm to subjects; and *justice*, or using equitable and fair practices to select individuals to participate in and benefit from research. HHS subsequently developed enforceable regulations designed to implement the findings and recommendations of the Commission. One of these regulations mandates the review of any proposed study at institutions where research is conducted (such as universities or hospitals) by trained committees that are specifically charged with the task of protecting subjects. These committees are known as *Institutional Review Boards* (IRBs).

To determine whether a research project is consistent with HHS guidelines, an IRB committee reviews both the actual materials to be used in the study (e.g., surveys, assessment instruments, consent forms) and a description, provided by the researcher(s), of the rationale for the study, the experimental procedure to be used, and the precautions taken to protect participants. Specifically, the researcher(s) must demonstrate that the proposed study involves or includes: either minimal risk to, or a positive risk-to-benefit ratio for, participants; fair and non-coercive procedures for subject selection; procedures for obtaining informed consent from participants (or their guardians, if applicable); and concern for the safety and confidentiality of participants.

HHS regulations state that IRBs must comprise at least five members from varied professional backgrounds. At least one member of the IRB should be a community member with no other affiliation with the institution. Diversity in IRB committee membership, both in areas of professional expertise and in demographic characteristics, is encouraged in order to incorporate a variety of perspectives into the review process.

HHS requires that IRB approval be sought for federally-funded research projects, but does not mandate IRB approval for privately-funded or non-funded research projects. Additionally, HHS exempts several specific types of federally-funded research projects from its IRB review requirement. Exempted projects include: studies conducted in schools or other educational settings examining educational practices that would be implemented whether or not the research was being conducted; research examining existing (i.e., archival) data, documents, records, or specimens; and studies conducted by agencies or organizations examining the benefit of programs that they administer. In each of these cases, data on human subjects must be recorded in a way that leaves human subjects unidentifiable; if subjects can be identified by

the data collected in a study, that study is no longer exempt, and must undergo the IRB review process.

Despite HHS's limited IRB review requirements, the vast majority of institutions require that all proposed studies using human subjects, whether or not they are federally-funded or appear to meet exemption criteria, be submitted for IRB review. In a recent study of researchers' experiences with their institutions' IRBs conducted by Ashcraft and Krause [1], 99% of respondents reported that all research using human subjects conducted by researchers affiliated with their institutions must be approved by their IRBs. Protocols that meet the federal exemption criteria referred to above may be reviewed using a streamlined process (sometimes referred to as an *exempt review*). Similarly, protocols that appear to pose minimal risk (i.e., no more risk than would generally be experienced by an individual during the completion of routine activities) to human subjects may be reviewed using an *expedited review* process.

Research involving non-human animal subjects is reviewed by Institutional Animal Care and Use Committees (IACUCs), in accordance with the provisions of the Animal Welfare Act (Public Law 89-544), rather than by IRBs. IACUCs review and monitor research protocols involving animals to ensure that such research is conducted under appropriate conditions by qualified staff, and that pain and/or distress to animal subjects is minimized, and that veterinary care is provided. In addition to their research-related responsibilities, IACUCs are charged with monitoring the facilities and conditions in which animal subjects are kept to ensure that the animals are cared for appropriately and humanely.

Instructional Hierarchy

Derek D. Reed[1], James K. Luiselli[2]
[1]University of Kansas, Lawrence, KS, USA
[2]The May Institute, Inc., Randolph, MA, USA

Definition

A theoretical model of skill acquisition used as a basis for instructional placement and decision-making.

Description

The instructional hierarchy is a model of skill acquisition premised on the theory that children will best acquire skills through progressive instructional techniques beginning with content accuracy (see [1, 4]). Upon demonstrating adequate competency of the content (i.e., accuracy), instruction should then focus on training the learner to become fluent in the skill (i.e., high rates of accurate responding during timed probes). As fluency is achieved, the instructional hierarchy progresses to the promotion of the generalization of the skill to meaningful educational contexts. The final goal of the instructional hierarchy is to foster adaptation of the target skill to novel contexts and demands.

Relevance to Childhood Development

Under the Individuals with Disabilities Education Improvement Act of 2004, the United States federal government set in "response to intervention" model of determining special education placement in public schools. As such, students identified "at risk" are to be provided with empirically-supported treatments with their progress continually monitored to determine the degree to which their academic skills improve under more intensive teaching strategies. Failing to respond dictates that more intensive empirically-supported treatments be provided. Ultimately, if students fail to respond to highly intensive, individualized, and empirically-supported treatment, the student may then be referred to special education services. The instructional hierarchy aids in this process by providing educators and clinicians with a framework to identify

the instructional level of the at-risk student. Teaching at-risk students at their instructional level – utilizing the instructional hierarchy model – has proven successful in areas such reading (e.g., [3]) and mathematics (e.g., [2]) difficulties. Thus, the implications of this approach are that when students' instructional levels are identified, teaching them at their individual levels may keep them in general education and prevent unnecessary expenditure of special education resources.

Instrumental Aggression

Tamara Del Vecchio
St. John's University, Queens, NY, USA

Synonyms

Proactive aggression

Definition

Instrumental aggression is harmful behavior engaged in without provocation to obtain an outcome or coerce others.

Description

One of the most robust distinctions within the field of aggression is between hostile and instrumental aggression [4]. In contrast to hostile aggression, in which the perpetrator is impulsive, emotion driven and reactive, instrumental aggression is conceived as proactive, premeditated and cold-blooded [1, 3]. The goal of instrumental aggressive behavior is to obtain a preferred outcome or to coerce others. Instrumental aggression is founded in the social learning model of aggressive behavior in which aggression is learned through vicarious reinforcement and maintained by the expectation that this behavior will result in a reward [3]. Instrumental aggression is also associated with callous-unemotional traits such as lack of guilt and empathy and it can be either physical or relational.

Instrumental aggression predicts later delinquent behavior, Oppositional Defiant Disorder and Conduct Disorder [6]. Early hostile aggression predicts later instrumental aggression; however, the opposite direction of association between the subtypes has not been supported. This finding that hostile aggression precedes instrumental aggression is considered to be due to the difficulty young children have in modulating their emotional and impulsive behaviors. As these abilities develop, children can better moderate their behavior and engage in more controlled pro-social and anti-social behaviors [5].

The dichotomous view of aggression has been debated with some questioning whether there are two distinct subtypes of aggression. The argument against the subtypes contends that hostile aggression can also have instrumental goals such as retaliation or restoration of status [2]. In addition, instrumental aggression can be both hot-blooded and premeditated; the two concepts are independent [2]. Moreover, it is unclear how much planning should occur before a behavior is considered premeditated.

Relevance to Childhood Development

Aggression is often considered age-normative for very young children due to its frequency. Moreover, the frequency at which children engage in aggressive behaviors decreases with age as children develop better pro-social behavior skills. However, a small subset of children will persist in their engagement of instrumentally aggressive behavior eventually resulting in negative outcomes such as conduct disorder and delinquency. Instrumental aggression is also associated with callous-unemotional traits which are considered important for development of an anti-social pattern of behaving. The relative stability of aggressive behavior and associated negative outcomes emphasize the significance of this behavior.

Intelligence Norms

Marie C. McGrath
Immaculata University, Immaculata, PA, USA

Synonyms

Norm-referenced intelligence testing

Definition

Intelligence test performance data collected from a sample of individuals that is thought to be representative of the general population for which the test is intended.

Description

Most modern tests of intelligence or cognitive ability are norm-referenced testing instruments. The norm samples for such tests are generally *stratified*, rather than random; in other words, they are selected to match the characteristics of the larger population with which the test will be used on variables of interest. For example, the developers of an intelligence test designed for nationwide use will likely attempt to recruit a norm sample in which the proportions of various demographic variables (e.g., age, sex, ethnicity, socioeconomic status, disability status, and educational attainment, among others) resemble those found in the general population, as indicated by census data. The test data gathered from the norm sample are subsequently used as a basis for assessing the performance of other test-takers.

Intelligence Quotient

Marie C. McGrath
Immaculata University, Immaculata, PA, USA

Synonyms

Deviation IQ; Full scale IQ; IQ; Ratio IQ

Definition

A score representing overall level of performance on psychological tests of intelligence or cognitive ability.

Description

Intelligence quotients (more commonly referred to as *IQ scores*) provide quantitative information on an individual's overall performance on measures of cognitive ability. Early intelligence tests quantified cognitive ability in the form of "mental quotient" scores, which were calculated by dividing an individual's "mental age" (MA), or the age group in which the typical individual demonstrated the same level of ability as the test-taker, by that individual's chronological age (CA). In 1916, test developer and intelligence researcher Lewis Terman adapted this calculation method by multiplying the MA/CA ratio by 100 to yield an integer rather than a decimal; he referred to the resulting scores as an "intelligence quotient." In Terman's schema, typical performance for one's age was represented by equivalence between mental and chronological ages (i.e., by a *ratio IQ* of 100).

Most modern tests of cognitive ability permit calculation of an overall score, though not all tests explicitly refer to this score as an intelligence quotient or IQ score (e.g., the *Woodcock-Johnson Tests of Cognitive Abilities* – Third Edition yields a general intellectual ability, or GIA, score rather than an IQ score). Modern tests of cognitive ability generally yield ▶deviation IQ rather than ratio IQ scores; while these scores are derived using different calculation methods than those involved in ratio scoring, they are similar to Terman's scores in that typical performance is represented by a score of 100.

IQ scores have been found to predict achievement in a variety of domains (e.g., academic achievement, occupational success) and remain relatively stable over time. However, they do not represent exact measurements of cognitive ability. A variety of factors (including the specific test administered, the individual's mood or motivation level, or chance responding) may cause variability in scores. For this reason, IQ scores are often reported in the context of a *confidence interval*, which provides a range of values around a given score and indicates the percentage of times that the reported range should contain an individual's true score. For example, a 95% confidence interval of 95–105 reported for an IQ score of 100 would indicate that, 95% of the time, the test-taker's score on that test would likely fall between 95 and 105. Reporting scores in this manner emphasizes that IQ scores are not absolute measures of cognitive ability, and provides a more accurate representation of performance.

Intelligence Testing

R. Steve McCallum
University of Tennessee, Knoxville, TN, USA

Synonyms

Cognitive testing; General cognitive aptitude testing; Intellectual testing/assessment; IQ testing; Mental ability testing

Definition

Intelligence testing refers to the process of identifying, quantifying, and characterizing cognitive abilities by administration and scoring items designed for that purpose. Typically, methods and tasks used to assess intelligence are first investigated in the experimental laboratory and later adapted for administration according to a prescribed and standardized protocol. Standardized assessment allows individual-difference comparisons to peers. Some of the more common abilities assessed by intelligence tests include working and long-term memory, processing speed, vocabulary knowledge, numerical facility, and auditory and visual processing.

Description

Meaningful assessment of intelligence requires that the construct be carefully defined. Random House Webster's College Dictionary [12] describes intelligence as the capacity for learning, reasoning, and understanding; aptitude in grasping truths, relationships, facts, meanings, etc.; and mental alertness or quickness of understanding. Modern efforts to define intelligence began in earnest in the late 1800s. In 1921 a classic symposium was convened by the editors of the *Journal of Educational Psychology* entitled "Intelligence and Its Measurement," and attended by many of the prominent theorists of the day. It was not until 1985 that a similar event occurred, when Sternberg and Detterman recreated the earlier symposium by asking current expert the same questions (as those put to the expert in 1921) regarding the nature of intelligence. A book chapter written by Sternberg [17] provided over 20 definitions shared by these experts (in 1985). Many of the characteristics mentioned by the experts in 1921 and again in 1985 are similar to those listed in the dictionary definition provided above (e.g., ability to learn, knowledge, speed of mental processing, higher order components including abstract reasoning); however, there are salient differences (e.g., the experts also listed physiological mechanisms, executive processes, adaptation to the environment). Currently, there is not a consensus on the definition of intelligence, i.e., not all experts agree on its characteristics. Differences across definitions depends on the extent to which theorists focus on within-individual characteristics (e.g., working memory capacity, speed of processing, neural latency time) versus environmental variables (e.g., cultural expectations, rules), and the interaction between the two influences.

Obviously, intelligence is a multi-faceted and complex construct, and it is inferred from behaviors. Consequently, the measurement of intelligence is also complex. Just as there is no one controversy-free definition of intelligence, there is no single widely accepted measure of intelligence. And, to make the situation even more complicated, behaviors that might be considered intelligent in one culture may seem less so in another, depending on the extent to which the two cultures have developed different expectations for success. To understand the controversies and the contributions associated with use of intelligence tests, an awareness of testing history may be helpful.

History of Intelligence Testing

Although practically useful intelligence tests were not developed until late in the nineteenth century, the concept of intelligence is much older [8]. The Chinese recognized that varying levels of intelligence could be predictive of career success as early as 2000 BC, and Hindu scholars discussed intelligence in the Bhagavadgita around 500 BC, as did Aristotle (400 BC). But, the first really useful intelligence tests were developed based on the efforts of a number of educators and mental health workers from western Europe (4). For example, in France Esquirol, Itard, Sequin, and Binet focused on the study, treatment, and evaluation of the insane and mentally deficient, established the use of sensory-based evaluation and treatment strategies, defined the need for a classification system to diagnose mental retardation, and then used it to aid in making admission decisions to special schools and to

select civil servants. In England, Sir Frances Galton constructed simple tests of memory, motor, and sensory functions in an attempt to differentiate highly successful from less successful individuals, and was one of the first to use quantitative mathematical data analysis procedures. As a result, some refer to him as the father of mental testing [4]. In Germany, Ebbinghaus, Wundt, Wernicke, Kraepelin, and Cattell emphasized individual differences in a variety of sensory-motor tasks, as well as tasks of attention, memory, and higher order cognitive functions (e.g., ability to recognize similarities and differences among objects). In addition, these pioneers recognized the need for rigorous control in the testing situation and began to emphasize the use of standardized administration procedures. Many of these early innovations culminated in the development of the first useful intelligence test by Binet and colleagues (e.g., Simon, Henri) in 1895. The 1905 version, known as the Binet-Simon Scale was the first to acknowledge age-based cognitive development, contained items arranged by difficulty, was capable of diagnosing degrees of mental retardation, and became the prototype for subsequent scales [16]. The Binet-Simon Scale was used in Paris to identify children who had mental retardation, and particularly those who were less likely to profit from the typical educational curricula. Importantly, Binet was among the first to challenge the view that intelligence was genetically fixed at birth; he argued in favor of the view that intelligence is fluid, and is influenced significantly by environmental and cultural factors [7].

The testing movement flourished in the United States after the introduction of the Binet-Simon Scales. There were several revisions of the Binet-Simon Scale [1], the first of which occurred in 1908 by Henry Goddard and the second by Lewis Terman of Stanford University in 1916. This second version, called the Stanford Extension and Revision of the Binet-Simon Scale (shortened to the Stanford-Binet), included Louis Stern's concept of mental quotient, which is obtained by dividing the mental age by the chronological age. Terman and his associates renamed this ratio the intelligence quotient (IQ). This ratio IQ was used until 1972 when the deviation quotient replaced it in a newly normed version of the Stanford-Binet. The deviation quotient is obtained from direct comparison of an examinee's performance with same-age peers and specifically by comparing the examinee's score with the mean and variance of the population (of same-age peers).

The Stanford-Binet is now in its fifth edition [18]. The newest version of the Stanford-Binet has incorporated a number of innovations, some of which were introduced in scales of intelligence first developed by Wechsler in 1939 (e.g., pooling like items into subtests, pooling subtests together to form global scores subordinate to the most global score). Wechsler also integrated into the first Wechsler scale, called the Wechsler-Bellvue Intelligence Scale, Form I, ideas for items taken from existing tests (e.g., Information and Comprehension subtests from the Army Alpha; Arithmetic, Digit Span, Similarities, and Vocabulary subtests from the 1916 Stanford-Binet; Block Design subtest from the Kohns Block Design Test; and Coding and Digit Symbol from the Army Beta test). This test was the prototype for other similar tests (e.g., Wechsler Intelligence Scale for Children), and modern versions of these tests are still available. Tests like the Stanford-Binet, the Wechsler scales, and other commonly used scales (e.g., Woodcock-Johnson Tests of Cognitive Abilities-III; Diagnostic Ability Scales-Revised) are used when an examinee needs to be assessed using a psychometrically sound measure of intelligence. Most of these tests yield a general score, a cognitive ability composite, based on differential weighting of subtests, each of which measures a somewhat narrow component of intelligence.

Many experts use a statistical procedure called factor analysis to help them determine the nature of the psychological constructs assessed by the tests they use. Factor analysis relies on correlation coefficients as a starting point. These coefficients express the strength of the relationship between two variables, and will be described in more detail below. When scores from several subtests are entered into a factor analysis correlation coefficients are created first, then the procedure aligns scores to maximize similarities within the data set such that subtests assessing the same or similar subconstructs combine, forming factors. For example, a test containing 12 subtests may assess primarily six factors, with two subtests defining or *loading* on a particular factor (e.g., working memory), two more on another factor (e.g., processing speed), and so on. This strategy is used to identify the number of factors within a battery, and a more sophisticated version of the process, called confirmatory factor analysis, is used to test the extent to which the factor structure of an intelligence test conforms to a theoretical model presumed by test authors to underlie the particular test. Factor analytic procedures are commonly used to determine the subconstructs assessed and the relationship between various subconstructs. For example, the Wechsler Intelligence Scale for Children-IV assesses primarily four basic factors or subconstructs of intelligence: verbal comprehension, perceptual organization, processing speed, and working memory. Another commonly used test of intelligence, the Woodcock-Johnson Tests of Cognitive Abilities, is based

on the theoretical and experimental work of Raymond Cattell, John Carroll, and John Horn (CHC Model), and assesses comprehension-knowledge, long-term retrieval, visual-spatial thinking, auditory processing, fluid reasoning, processing speed, and short-term memory. Confirmatory factor analysis provides considerable evidence in support of the WJ-III's ability to assess these abilities [20].

Most current individually administered intelligence tests are model-based, meaning that they were developed to assess the subconstructs of intelligence considered important by the test authors. For example, as mentioned above, the WJ III was designed to assess the CHC model of intelligence. Similarly, the Cognitive Assessment System, or CAS, was developed by Naglieri and Das [11] to assess the following subconstructs of intelligence: planning, attention, simultaneous processing, and successive processing (i.e., PASS model). Other commonly used individually administered tests include the various Wechsler scales designed for either preschoolers, children, or adults, the Differential Ability Scales [3], the Kaufman Assessment Battery for Children-II [6] and the Kaufman Adolescent and Adult Intelligence Scale.

Relevance to Childhood Development

Originally, tests of intelligence were developed primarily to predict academic functioning. And, they perform that role well [16], in part because authors of the most widely used tests are careful to incorporate into the test development process procedures that ensure strong psychometric properties (e.g., reliability, validity). In addition, intelligence tests predict relatively well other important outcomes (e.g., job success). Evidence in support of these conclusions comes from studies reporting correlation coefficients. As mentioned above, these coefficients are statistical indicators that define the magnitude of the relationship between any two variables. Correlation coefficients reflect the power of one variable to predict another, and range from −1.0 to +1.0. A value of 0 indicates a complete lack of relationship between two variables and consequently, no predictive relationship. On the other hand, 1.0 defines the maximum overlap between two variables, and consequently, perfect prediction. The literature contains hundreds of studies showing relationships between various measures of intelligence and academic and job performance. Most of these studies show moderate to moderately strong correlations coefficients, typically ranging from 0.50–0.70 for academic measures and 0.30–0.60 for job-related measures. Because of the large data base, educators know that children with high scores on intelligence tests will likely earn concomitantly high scores on measures of academic success and grades. Likewise, those who earn low scores on intelligence test are also likely to earn low academic achievement test scores and grades. One traditional interpretation of these data is that academic performance is influenced by intelligence. Of course, the relationship is somewhat reciprocal. Those who excel academically gain knowledge that can then be displayed on cognitive subtests designed to assess retention of vocabulary, relationships among objects, and so on.

For years, test of intelligence have been prized for their predictive power. However, many of those who use intelligence tests currently expect more from these tests. In particular, the goal of many examiners is to use the pattern of cognitive strengths and weaknesses obtained from the testing process to partly explain current academic failures/successes and to use this knowledge to help inform intervention strategies. The basic assumption that underlies this expectation rests on the aptitude x treatment model. This model assumes that educators can use cognitive strengths to plan academic interventions. For example, using result from administration of the CAS (which assesses planning, attention, and simultaneous and successive processing) an examiner might find that simultaneous processing is a relative and normative strength. Because simultaneous processing relies on the ability to understand relationships among elements of to-be-learned content in a holistic pattern, as opposed to processing these elements in serial order, it is assumed to rely significantly on visual-spatial patterning. Consequently, an examinee with a simultaneous processing strength might profit more from use of visual aids, such as flowcharts, maps, diagrams, and so on, than on a presentation relying on a auditory, sequential presentation (e.g., auditory lecture). Of course, recommendations built on such theoretical assumptions should be tested for each child assessed rather than assumed. This aptitude x treatment paradigm is intuitively appealing and logical, and although there is some research support for this approach [8], much of the literature is equivocal; more research is needed.

Another use of intelligence tests relies on the ability of short group-administered tests to screen students who function at the extremes of the intellectual distribution. Because intelligence is roughly normally distributed [5] those that function two or more *standard deviations* below the mean are often identified as mentally retarded assuming they have concomitant deficits in adaptive behavior; similarly, those who function two or more standard deviations above the mean are sometimes identified as gifted/talented. These individual are among the most extreme, approximately within the bottom and top 3% of the population, respectively, and consequently may profit from

specialized intervention (e.g., special education services). Individuals who are identified as significantly low or high by a group testing process may go on to be tested using individually administered intelligence tests. Results from the individually administered tests may then be used at the identification stage for identifying those who have mental retardation and those who are gifted/talented.

Because intelligence tests have been used to help identify children for special education services and because there has been overrepresentation of minority children in these classes in many states intelligence tests came under intense scrutiny, particularly since the 1970s. Tests were accused of being biased against minority children by many educators and policy makers. In the main, these accusations have not been supported by careful statistical analyses [14], though many of the most widely used intelligence tests produce lower mean scores for members of minority groups. As analyses have shown, differential mean scores across groups do not necessarily indicate bias against the lower scoring group, though a lower mean score is often taken as a red flag, and invites more scrutiny of the tests producing such scores. One of the beneficial outcomes of the increased attention devoted to producing fair(er) tests has been the development recently of a spate of really good nonverbal intelligence tests. These tests are based on the assumption that language may *not* provide a good window on the intellect for all individuals, although it does for many. Language may be a barrier for examinees who are deaf or have limited hearing, those who have other language-based deficits, those who are from non-mainstream cultures, and those who may be emotionally impaired (e.g., pathologically shy). Some individually administered multi-dimensional nonverbal tests include the Leiter International Performance Scale-Revised [15], the Universal Nonverbal Intelligence Test (UNIT) [2], and the Wechsler Nonverbal Intelligence Scale [19]. Some group administered tests include the General Ability Measure of Adults (GAMA) [10], the Naglieri Nonverbal Ability Test (NNAT) [9], and the various versions of the Raven Progressive Matrices [13].

In summary, although humans have made informal judgments about the intellectual ability of those in their environment for thousands of year, practically useful formal tests of intelligence tests have been around only since the late 1800s. In some ways modern tests are very different from their early predecessors. For example, they are more sophisticated psychometrically, assess more functions associated with intelligence, are more likely to be based on theoretically conceptualizations of intelligence, are amenable to computer-based interpretation, and can provide more explanations for the cognitive abilities that underlie real-world performance (e.g., academic strengths/weaknesses). However, in other ways they are very similar to the early versions in content, administration format, and usefulness, i.e., they are still better at predicting performance than they are at providing remediation suggestions, though there is significant progress along this dimension. Innovations have not been linear, That is, most innovations have occurred within the past 25 years (since the early 1980s). In the future, authors of intelligence tests likely will continue to focus on relating intelligence to theories of intelligence, implications for treatment of academic and work-related deficits, and on discovering brain-behavior relationships related to intellectual performance.

Intelligence Testing Without Verbal Communication

►Universal Nonverbal Intelligence Test

Intentionality

Tamara Del Vecchio
St. John's University, Queens, NY, USA

Synonyms

Deliberate; Purposeful

Definition

A state of being or action that is deliberate or purposeful.

Description

Intentionality is purposeful and conscious action or state, and differs from desire which can be impossible to fulfill or fulfilled accidentally. Determining whether an action is right or wrong requires a more complex cognitive process than simply evaluating whether the outcome of the action is positive or negative. Therefore, differentiating the outcome from the intention is an integral part of child development. Children develop an understanding on intentions during the preschool years, and can distinguish intentions from desires by an average of 4 years of age [3].

Understanding intention is an important component for the development of theory of mind, moral thinking, and pro-social behavior. Theory of mind development is dependent on children's ability to infer intentions, desires, and emotions of others based, at least partly, on their understanding of their own. In addition, understanding intentionality enables children to develop more complex conceptions of moral responsibility in which the determination of blame is based not only on the severity or wrongness of the outcome but also the actor's intentions [4]. Moreover, a mismatch between a positive intention and negative outcome could result in feelings of sadness or guilt [1]. Furthermore, intention plays a role in planning and deliberate pro-social and anti-social action.

Assessments of intentionality are considered necessary mechanisms within cognitive models of aggressive thinking and behavior. Negative intentionality bias refers to the tendency to attribute hostile intent to a perpetrator in an ambiguous situation that lacks clearly hostile or benign cues. Aggressive children endorse more negative purposeful behavior to ambiguous situations than their non-aggressive counterparts suggesting a deficit in cognitive processing or cue identification in aggressive children [2]. These cognitive biases are thought to predict the aggressive behavioral response. For example, if a child believes that they have been acted upon negatively on purpose, they would be more likely to believe a retaliatory response was justified and act accordingly.

Interaction Theory of Language Development

Loretta C. Rudd, Matthew C. Lambert
Texas Tech University, Lubbock, TX, USA

Definition

The theory that language is acquired from an interaction of a human's innate biological capabilities to acquire language with exposure to language in the environment in which the child is developing.

Description

The interaction theory of language development is a compromise between the nativist theory and the behaviorist theory of language development. The interaction theory recognizes that both environmental and biological factors are important in language development [2]. Within this theory of compromise are theorists who are closer to one end of the extreme than the other. However, all interactionists believe that language acquisition occurs as a result of the natural interaction between children and their environment, more specifically, their parents or caregivers.

For example, interactionists believe that language is a byproduct of children's social interactions with the important people in their lives. Vygotsky [4] believed

that children developed thought and language by actively interacting with adults. He stated, "The child's concepts have been formed in the process of instruction, in collaboration with an adult" (p. 191). Like Vygotsky, interactionists believe that language develops as a natural consequence of these interactions and that it progresses to more complex levels as the interactions mature [1]. The more mature interactions provoke more complex language structures from parents and caregivers, and this cycle continues until children's language and social skills reach adult levels.

Relevance to Childhood Development

While interactionists agree with behaviorists that parents and caregivers play a significant role in language acquisition they also agree with nativists that children come to the language acquisition process with innate cognitive and linguistic abilities. They do not believe that either of these ideas is the most important aspect in language acquisition. Instead, interactionists believe that the single most important influence on language acquisition is children's interactions with the important people in their environment. Indeed, it has been determined empirically that children reared in language-rich environments with adult caregivers whose language styles match their focus of attention, have enhanced vocabulary skills at and early age [3]. These enhanced vocabularies in turn prove to enhance reading abilities in elementary grades.

Internal Motivation

Lindsay Lennertz
Nova Southeastern University, Fort Lauderdale, FL, USA

Synonyms

Autonomous motivation; Intrinsic motivation

Definition

Internal motivation describes the engagement in or attraction to an activity for the sake of enacting the activity, such that there is no known external incentive for said activity.

Description

Two types of internal motivation have been discussed in the literature: that which arises out of direct enjoyment for engaging in a given task, and that which comes from a sense of internalized obligation or responsibility to engage in a task [6].

In order to fully understand internal, or intrinsic, motivation it is necessary to gain a working knowledge of its conceptual opposite: external motivation. External motivation is the result of external reward or incentive. Also referred to as extrinsic motivation, this occurs when a person acts in order to obtain something, such as praise or tangible rewards [6].

Several theories have sought to clarify the determinants of internal motivation. Self-determination theory (SDT) describes internal motivation as a form of

autonomous motivation. This line of research has shown that people have an inherent need to feel competent, autonomous, and connected to others, and are best off when allowed opportunities to engage in goal-directed activities that serve these ends [1]. A behavioral explanation for internal motivation is also provided by operant theory, which asserts that one always performs an activity due to some type of incentive or reward [2]. This reward may be a tangible reinforcer or even a feeling that one has as a result of engagement in a task. The developmental progression or elicitation of motivational states has been studied extensively. Some examples of researchers and their respective theories include: Bernard Wiener's Attribution Theory; self-efficacy studies by Albert Bandura; locus of control and goal orientation discussed by Julian Rotter and others; and scaffolding for the Zone of Proximal Development (ZPD) as demonstrated by Lev Vygotsky [2].

Substantial research conducted by Deci and Ryan on SDT has demonstrated that human well-being is based upon the provision for the essential needs of competence, autonomy, and self-determination [5, 7]. Their research has proposed that intrinsically motivated behaviors are engaged in to meet these emotional needs and fulfill our sense of well-being. In summary, essential needs are linked to intrinsic goals, such that intrinsic goal pursuit is inherently associated with providing for one's needs which enable a sense of well-being [4]. Healthy personality development and integration is likewise positively correlated with one's fulfillment of intrinsic needs or goals, and personal value found in daily activities can therefore be said to enhance one's sense of well-being [5, 7].

Internal motivation has been said to be responsible for the drive toward mastery of a task, and is associated with greater interest, excitement, and confidence for the given task [7]. Greater achievement of goal progress, and increased quality of life, in terms of self-fulfillment and satisfaction in general, have similarly been found to be a product of internalized motivation [4]. Altruistic or selfless behavior is also associated with internal motivation, as such behaviors are pursued in the absence of tangible rewards [2].

Relevance to Childhood Development

> Intrinsic motivation has emerged as an important phenomena for educators – a natural wellspring of learning and achievement that can be systematically catalyzed or undermined by parent and teacher practices
>
> (Ryan & Stiller, as cited in [6]).

For an educator, knowing how to foster the internalization of goals valued by teachers and schools is a key aspect of student success. Motivation and its internal and external subtypes have been studied thoroughly by educational psychologists since the 1970s [2]. Internal motivation has been correlated with enhanced academic achievement and student satisfaction [8]. Furthermore, it has been shown that individuals with increased internal motivation believe that their behavior is responsible for their success [2]. As a result, they view their abilities as non-fixed structures that are changeable. It follows that those with sufficient internal motivation will likely hold the perception that they play a valuable role in whether or not they can or will reach their goals. This internal locus of control (LOC) is hypothesized as an aspect of one's sense of self-competence [2].

Many have debated whether extrinsic rewards weaken internal forms of motivation. Self-determination theorists argue that providing rewards will undermine the natural interests a child has in her or his own goals or activities. Other theorists have opposed this argument, and provided evidence that certain forms of reward work to stimulate one's internal motivation [3].

Teachers who utilize methods that encourage student autonomy, choice, and self-direction, instill more intrinsically-based motives for achieving one's potential [6, 7, 10]. These results can be generalized to settings outside of the classroom. For example, parents who have supported autonomy in their children find related increases to their children's grades and tests of achievement. Greater autonomy in the parent–child relationship has likewise been linked to healthier lifestyle choices, and strengthened social and career goals for children [6, 7].

Both internal and external motivation for school performance has been shown to be greater in children who are also enjoying school [9]. It has been furthermore deduced that school children who lack positive social interactions are not as likely to enjoy school, which in turn leads to lowered motivation for school-related activity [10]. Likewise, children who are raised in home environments that provide support and education in a non-controlling manner, motivate a child, internally, to fall in suit with household rules and expectations [10].

Theories of motivation have proposed to understand how this concept it is engendered and maintained. A largely researched area, the effect of reward and incentive, has been studied to determine the most effective intervention strategies for influencing children's behavior and supporting the development of motivation.

Intimacy Versus Isolation (Erikson's Young Adult Stage)

Gregory C. Ellison II
Emory University, Atlanta, GA, USA

Definition

"When childhood and youth come to an end, life, so the saying goes, begins" ([4], p. 100). According to Erik

Erikson, the young adult's life begins with the development of *intimacy*, the capacity to commit oneself "to concrete affiliations and partnerships and to develop the ethical strength to abide by such commitments, even though they may call for significant sacrifices and compromises" ([1], p. 263). Intimacy requires a firmness of ego strength or identity formation, as a central feature of Erikson's sixth stage is the ability to find oneself by losing oneself in another. Erikson is careful to not limit intimacy to affiliations of a sexual nature, but also includes friendship, combat, and inspiration as potential sites for intimate encounters.

Description

In the third chapter of *Identity, Youth and Crisis*, Erikson individually introduces and explains each of the first five stages of the life cycle (from infancy to adolescence). However, the three succeeding adulthood stages are addressed collectively under the subtitle "Beyond Identity." While one might consider the aggregate treatment of adulthood as evidence of Erikson's preferential treatment of the early stages of life, one need only examine the significance of the subtitle – "Beyond Identity" – to understand the grouping of the life cycle's latter stages. The intimacy of young adulthood tests the firmness of identity established in adolescence. The psychosocial transition to adulthood begins in adolescence, as the youth is challenged to achieve a sense of ego identity. Adolescents emerging from the fifth stage and in search of identity are often eager to fuse with the identity of others, but an appropriate ego strength is vital to withstand and endure the intimate encounters of young adulthood. The deep involvement required for intimacy with another demands ego strength to put one's own individual identity at risk ([5], p. 51). Hence, the earliest stage of adulthood is marked by movement beyond an adolescent fragile identity, threatened by role confusion, to a more secure identity in young adulthood that is capable of taking chances with itself to explore and develop intimate relationships.

Erikson posits that the young adult who has evolved beyond the identity crises of adolescence is capable of experiencing intimacy in working or studying for a specified career, socializing with the other sex, engaging in erotic encounters, entering into marriage, or starting a family. Consistent with the psychoanalytic tradition of emphasizing genitality as a condition for maturity, Erikson views erotic encounters with the opposite sex as a particular developmental milestone of intimacy. He highlights that though sexual intimacy may precede true and mutual psychosocial intimacy, sexual maturity requires a sense of mutual devotion. He explains:

> Before such genital maturity is reached, much of sexual life is of the self-seeking, identity hungry kind; each partner is really trying only to reach himself. Or it remains a kind of genital combat in which each tries to defeat the other. All this remains as part of adult sexuality, but it is gradually absorbed as the differences between the sexes become a full polarization within a joint lifestyle ([3], p.137).

The tenets of mutual devotion and shared identity, vital elements of both sexual maturity and intimacy, provide a framework for Erikson to introduce the virtue of love as the human strength assigned the sixth stage of the life cycle.

Erikson defines love as a "mutuality of devotion forever subduing the antagonisms inherent in divided function" ([2], p. 129). In *Insight and Responsibility,* he identifies love as the greatest and most dominant of the human virtues, and explains why love is assigned to a particular stage. Indeed, love could be seen as the virtue binding other stages together; love can be observed in instances ranging from the infant's attachment to the mother to the "adolescent's passionate and desperate infatuation" ([2], p. 127). However, Erikson believes that love evolves and transforms from receiving love throughout preadolescence to intentionally caring for others in adult life. Adult love is marked by mutuality as mates and partners develop a shared identity and engage in a process of "mutual verification through an experience of finding oneself, as one loses oneself, in another" ([2], p. 129). In this sense, love, like intimacy, is strongest when identity can be risked to enter into relationship with another.

As intimacy with others is the result and test of firm identity formation, true engagement is challenged when ego strength is weak. Since intimacy, in its best sense, requires selfless devotion to another, persons with weak egos who attempt intimate relationships are in jeopardy of "interpersonal fusion amounting to a loss of identity" ([4], p. 134). Lacking such true engagement causes the ego to lose its flexible capacity to risk itself in the affections of others. Over time, repeated unsuccessful attempts at intimacy may lead to *isolation*, the inability to make sacrifices and compromises in order to intimately affiliate with others.

A form of such isolation and a counterpoint of intimacy in Erikson's sixth stage is distantiation: "the readiness to repudiate, isolate, and if necessary, destroy those forces and people whose essence seems dangerous to one's own" ([3], p. 136). In its worst sense, distantiation results when individuals struggling to maintain identity

differentiate sharply and cruelly between the familiar and the foreign. This framework moves beyond competitive and combative attempts at creating intimacy to extreme polarization and blind prejudice. Though a distantiated person may develop relationships with persons familiar to them, the quality of these relationships is still marked by isolation and is antithetical to intimacy. Erikson further explains, Intimacy with one set of people and ideas would not be really intimate without an efficient repudiation of another set. Thus, weakness or excess in repudiation is an intrinsic aspect of the inability to gain intimacy because of an incomplete identity ([3], p. 135).

Though distantiation and isolation pose significant obstacles to the young adult, even these negative outcomes can have desirable attributes that are necessary for continued development throughout the life cycle. For instance, even persons with strong egos must exhibit boundaries when intimately committing themselves to ideas and to others. Furthermore, in foreshadowing the seventh stage of generativity and its virtue of care, the ability to subsume oneself in the intimate act of caring for others poses great danger to the caregiver who lacks self-awareness and is unable to isolate or distance herself enough to establish healthy boundaries.

Relevance to Childhood Development

The goal of intimacy is to develop relationships marked by true engagement, shared identity, and mutual devotion. These characteristics, undergirded by the virtue of love, provide the groundwork for generative persons who are committed to guiding and establishing the next generation. Isolation, however, thwarts the process of connecting intimately to others, notwithstanding succeeding generations. The inability to develop intimate and loving relationships during young adulthood threatens the livelihood of developing children because young adults are those most often engaged in procreation and the raising of young children. Additionally, distantiated young adults are likely to become distantiated older adults, and will have the power to influence succeeding generations to also be blinded by prejudice and consumed with polarized notions of community.

Intimate Friend

Julie Newman Kingery, Tyson R. Reuter
Hobart and William Smith Colleges Developmental and Clinical Psychology, Geneva, NY, USA

Synonyms

Best friends; Chums; Close friend; Mutual friend

Definition

A reciprocal positive relationship between two individuals who typically view themselves as equals. This relationship is characterized by self-disclosure and trust.

Description

Friends share a mutual, dyadic relationship involving positive features such as cooperation, positive affect, guidance and support, effective conflict resolution, and companionship [10]. Researchers who study children's peer relationships evaluate friendship quality, or the extent to which particular friendships possess these characteristics. One key qualitative aspect of mutual friendships is intimacy, which involves disclosure of personal information, sharing feelings, and emotional support [11]. Friendships characterized by high levels of intimacy serve as a context in which youth can engage in self-exploration and solve personal problems. With intimate friends, youth experience loyalty, mutual understanding, and trust.

Developmental Changes in Friendship

From childhood through adolescence, the level of intimacy in close friendships increases significantly. In early childhood, children's views of friendship tend to be concrete, with friendships focusing on shared activities and parents facilitating and supervising social interactions. The role of intimacy in friendship becomes increasingly important during adolescence when youth emphasize the importance of loyalty and share intimate thoughts and feelings with their friends. Throughout adolescence, individuals acquire more intimate knowledge about their friends' lives, increase in levels of sharing and cooperation with friends, and are more sensitive to their friends' feelings [4]. In addition to increased levels of intimacy with age, friends become more similar to each other with respect to attitudes and values, personality characteristics, and academic performance.

Gender Differences in Friendship

The friendship feature of intimacy plays an important role in distinguishing girls' same-sex friendships from those of

boys. During late childhood and adolescence, girls report higher levels of emotional closeness and intimate self-disclosure in their friendships in comparison to boys [5]. The friendships of adolescent girls tend to focus on mutual goals and concerns, and exchange of feelings. In contrast, the friendships of adolescent boys center on activities such as sports and video games and involve higher levels of competition and conflict. One disadvantage of the higher levels of intimacy in girls' friendships is that girls tend to engage in corumination, which involves repeated discussions of problems and negative feelings with friends. Although these conversations contribute to greater feelings of closeness between friends, corumination is also associated with increased levels of anxiety and depression [12]. Because girls are more likely to exchange intimate information with their friends, at times they may use this information to engage in relational aggression, which involves harming another's reputation or sense of belonging. Ironically, the intimacy of girls' friendships may contribute to these friendships being more fragile [3].

Relevance to Childhood Development

Theoretical Background

Harry Stack Sullivan [13] was one of the first developmental theorists to emphasize that involvement in friendship makes vital contributions to children's and adolescents' psychological development. Sullivan outlined a progression of specific interpersonal needs that emerge across various stages of development. During the preadolescent stage (9–12 years), there is an emergent need for intimacy and consensual validation, which is fulfilled primarily through involvement in same-sex friendships or "chumships." With friends or "chums," youth learn to divulge and receive private information and to build a friendship that is based on loyalty and trust. Through interactions with intimate friends, the preadolescent builds a foundation of skills (e.g., cooperation, compromise, competition, empathy, mutual self-disclosure, perspective taking) to implement in same- and opposite-sex relationships during adolescence and adulthood.

Whereas Sullivan believed that the development of intimacy occurs before an adolescent's sense of identity is fully established, Erik Erikson [7] asserted that intimate relationships cannot occur until after an adolescent has developed a coherent sense of identity. According to Erikson's theory of psychosocial development, it is not until early adulthood that individuals who have established their identity during adolescence can participate in a truly intimate relationship. There is empirical support for both Sullivan's and Erikson's theories, with some individuals developing an identity before becoming involved in intimate relationships with friends or romantic partners, and other individuals establishing a sense of self by participating in intimate relationships.

Contemporary Research

Involvement in intimate friendships serves several key functions throughout development, including self-validation and ego support, emotional support, guidance and assistance, and reliable alliance [1]. In terms of self-validation and ego support, intimate friends enhance one another's self-esteem by providing compliments, expressing feelings of concern, listening, and seeking advice. Friends also serve as a source of emotional support, providing reassurance and a sense of security in new situations such as school transitions. Children and adolescents also turn to their friends for guidance and assistance, as friends devote a considerable amount of energy to helping accomplish each other's goals by providing advice and information. Friendship also promotes feelings of reliable alliance, which includes loyalty, faithfulness, and being available to provide assistance when help is needed.

Friendships characterized by positive features such as intimacy and support are associated with higher levels of self-esteem and lower levels of anxiety among youth [6]. Children and adolescents involved in friendships characterized by lower levels of intimacy and emotional support are at risk for internalizing difficulties such as loneliness and depression [9]. Friendship has also been linked to aspects of school adjustment, including academic performance, achievement motivation, attitudes toward school, and more positive emotional and academic adjustment across school transitions [8].

The influence of close friendships during childhood is also associated with relationship quality, feelings of self-worth, and mental health extending into adulthood [2]. Overall, intimate friendships during childhood and adolescence serve many important functions that impact both concurrent and long-term adjustment. Based on this research, interventions aimed at increasing the level of intimacy in friendships would likely lead to more positive emotional, social, and academic adjustment.

Intrauterine Growth Restriction

Synonyms

Intrauterine growth retardation; IUGR

Definition

Intrauterine growth restriction refers to the poor growth of a baby while in the womb. Specifically, it refers to a fetus whose weight is below the 10th percentile for its gestational age.

Description

Many different things can lead to intrauterine growth restriction. An unborn baby may not get enough nutrition due to heart disease in the mother, high altitudes, multiple pregnancies (twins, triplets, etc.), placenta problems, pre-eclampsia or eclampsia. Congenital or chromosomal abnormalities are often associated with below-normal weight. Infections during pregnancy that affect the fetus, such as rubella, cytomegalovirus, toxoplasmosis, and syphilis my also affect the weight of the developing baby. Risk factors in the mother that may contribute to IUGR include alcohol abuse, drug addiction, high blood pressure or heart disease, poor nutrition and smoking. Depending on the cause of IUGR, the fetus may be symmetrically small, or have a head that is normal size for gestational age, while the remainder of the fetus is growth restricted. If the mother is small, is may be normal for her to have a small fetus, but this is not due to IUGR.

Intrauterine growth restriction may be suspected if the uterine fundal height, or the measurement of the size of the uterus, is less than expected for gestational age. This condition is usually confirmed by ultrasound. Further tests may be needed to screen for infection or genetic problems if intrauterine growth restriction is suspected. Intrauterine growth restriction increases the risk for intrauterine death. If this condition is suspected, the pregnant woman will be closely monitored with several pregnancy ultrasounds to measure the baby's growth, movements, blood flow, and fluid around the baby. Non-stress testing will also be done. Depending on the results of these tests, delivery may be necessary.

The prognosis for normal newborn growth and development varies by the degree and cause of intrauterine growth restriction. Depending on specific cause, intrauterine growth restriction increases the risk for a variety of pregnancy and newborn complications. Infants may have a non-reassuring fetal heart rate during labor, requiring delivery by c-section. Avoiding alcohol, smoking and drug use, along with receiving regular prenatal care can help control the risk factors associated with intrauterine growth restriction during pregnancy.

Intrinsic Motivation

Pei-Hsuan Hsieh
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Internal motivation

Definition

Intrinsic motivation is when children engage in activities because they find the activities enjoyable.

Description

When individuals engage in activities that are personally enjoyable to them without the incentive of an external reward, they exhibit intrinsic motivation. For example, when a child has intrinsic motivation for a task, he will commit to the activity with enjoyment (such as a hobby), regardless of whether there are rewards or not. When a child practices piano simply because he enjoys it, he exhibits intrinsic motivation. Intrinsically motivated learners seem to have the most positive learning outcomes. They tend to engage in tasks willingly and are more eager to spend time to learn the material, and are more likely to process information and achieve at a higher level.

Children may develop intrinsic motivation due to the following reasons: curious about their world, interest in the activity, and value for the task. Children who are more competent in the task also have more intrinsic motivation.

Relevance to Childhood Development

Young children are often excited about going to school to learn new things and tend to have more intrinsic motivation to learn. As children get older, they become less intrinsically motivated. They become less confident as they encounter failures and become increasingly aware of how they perform as compared to their peers. In elementary school, children are given more opportunity to choose activities that they perceive to be enjoyable. During the transition from elementary to secondary school, children often experience anxiety and lose their intrinsic motivation. This is especially true when secondary educators focus on competition and the importance of good grades.

James, William

John Snarey, Ashley E. Coleman
Emory University, Atlanta, GA, USA

Life Dates

1842–1910

Introduction

William James is known as the "father of American psychology" and the "most American philosopher." His early, pioneering work on consciousness, emotions, habit, memory, the will, and the self, changed the way the American psychological community perceived and studied the human mind. James's biographers provide an unusually detailed portrait of his life because of the many letters he wrote to family and friends, and his journal entries, in which he expressed lucidly his innermost thoughts and ideas in their developing stages. Born on January 11, 1842, in New York City, James was an ardent believer in the importance of experiential learning in the construction of knowledge. Robert Richardson, the author of a major biography of James, has written about James's "love of spontaneity and activity and his positive fondness for chaos and chance" ([10], p. xiv). William James lived between multiple worlds (New England, various countries in Europe) and between multiple fields of study (art, medicine, psychology, philosophy); his academic and geographic transience fit well with his openness to ascertaining life's enduring lessons. James's diverse academic pursuits and innovative thinking made him a cultural pioneer. He was able to fuse his multifarious interests into a dynamic philosophical system and made lasting contributions to the study of religion and psychology.

Biography

William James was the oldest of five children born to wealthy, liberal New England parents Henry James, Sr., and Mary Walsh. His siblings were novelist Henry James, Jr., diarist Alice James, and Civil War officers Garth and Robert James. Henry, Sr., had a complex and difficult relationship with his own father, William of Albany, New York, an Irish immigrant. This pattern of a conflicted father–son relationship continued on a more subdued level in William's generation. William James's variety of vocational aspirations (art, medicine, science, philosophy) was the source of many interpersonal struggles with his father. His father's geographic unsettledness, which kept his family traveling between Western Europe and the United States, may have further added to William's educational and vocational identity confusion.

Educational Information

According to biographer Richardson [10], James attended nine schools before he enrolled in the Geneva Academy in Switzerland at age 17 in 1859. Even though his formal studies at the academy focused on anatomy and mathematics, James's interests extended well beyond the then conventional realms of education. The next year in 1860, the James family returned to New England so that William could study art with the renowned William Morris Hunt; despite his son's passion and talent, Henry Sr. considered art a hobby and not an appropriate or acceptable career for William. In 1861, at the age of 19, William decided against a career as an artist (perhaps acquiescing to his father's wishes) and entered Lawrence Scientific School at Harvard University to study chemistry. Although he later decided to switch his course of study to anatomy and physiology, he found life at Harvard quite agreeable.

James was in many ways self-taught. Following the end of this third term he took a respite from the Scientific School, during which he studied the classic works of some of history's greatest thinkers (e.g., Darwin, Comte, Quetelet, Spinoza, and Pythagoras). James systematically composed and compiled abstracts of what he read, beginning with Max Müller's "Lectures on the Science of Language" and continuing with Henry T. Buckle's essay on John Stuart Mill, and Jonathan Edwards' "Great Christian

Sam Goldstein & Jack A. Naglieri (eds.), *Encyclopedia of Child Behavior and Development*, DOI 10.1007/978-0-387-79061-9,

Doctrine of Original Sin Defended." The beginning of James' self-education took place against the backdrop of the Civil War, in which his brother, Garth (Wilky) James, was gravely wounded in duty as a soldier for the Union Army.

In 1864, he enrolled in Harvard medical school, but the opportunity for new life experiences and travel remained alluring. In 1865, James embarked on an 8-month expedition to Brazil, where he helped Harvard professor Louis Agassiz conduct field research along the Amazon River. The study focused on species of fish, as well as insects, reptiles, and larger animals. James traveled 2,000 miles up the river before he returned to medical school in the United States. Not long after his return, he traveled to Europe to attend physiology lectures in Berlin. His studies were interrupted as he experienced intervals of unhappiness, depression, and the residual effects of the smallpox that he had contracted in Brazil. In November of 1868, after a few more years of restless travel, William returned to Cambridge, Massachusetts, and passed his Harvard medical exams in June of 1869. Yet, for William James, M.D., this academic milestone did not fully resolve his occupational confusion. As James biographer Howard Feinstein [1] notes, "William still lingered indecisively amid the lost Atlantis of art, the necessity of science, and the allure of philosophy" well into the 1870s (p. 250).

Family and Professional Life

While he continued to independently study physiology, psychology, and philosophy, James was offered a 1-year position to teach physiology at Harvard College in 1872. Teaching was clearly therapeutic for James, defeating his demons of depression; he was popular with the students and his appointment was renewed. A half-dozen years after he began his career as a professor, he also began his life as a family man. He married Alice Howe Gibbens in 1878, and their first child, Henry, was born in 1879. He and his wife had four more children: William (b. 1882); Herman (b. 1884), who died 5 months after his birth; Peggy (b. 1887); and Aleck (b. 1890).

In addition to James's lifelong cross-disciplinary interests, his "partiality for biography and memoir – for narrative and of personal experience – stayed with him, feeding what, over time, became a central structural principle in some of his best writing" (Richardson, [10], p. 126). James's uncommonly poetic style of expressing his ingenious theories contributed to his distinguished career. This approach earned him enduring respect and admiration in the fields of both psychology and philosophy.

James died of heart failure on August 30, 1910, at his summer home in Chocorua, New Hampshire, at the age of 68. His ashes were buried in his family's plot in Cambridge Cemetery.

Accomplishments

Work in Psychology

There are many streams of thought in James's work. Each succeeding book possesses a more profound exploration of previously broached topics, magnifying ideas that were previously quick sparks of intellectual imagination.

His major publication was the 1890 two-volume work entitled *The Principles of Psychology* [2], which revolutionized the study of the mind and states of consciousness. This book project took James more than 10 years to complete and is comprised of 28 chapters on such topics as "brain activity," "habit," "the methods and snares of psychology," "the stream of thought," "the consciousness of self," "the emotions," and the "will." In *Principles,* James creatively combined natural science with the wisdom of a philosopher. In the chapter on emotions, he wrote that "the varieties of emotion are innumerable. Anger, fear, love, hate, joy, grief, shame, pride, and their varieties, may be called the coarser emotions, being coupled as they are with strong bodily reverberations" ([3], p. 241). Such insights demonstrate James's understanding of the intricate relationship between the mind and the body. James is recognized by psychologists as being the first to champion the revolutionary idea of a coherent connection between the immaterial and material spheres of the human being. For this reason, *Principles* earned him the title "father of American psychology." William James's theories continue to inspire the field of psychology today, especially through the shorter and more widely read version of the book, *Psychology: The Briefer Course.*

The issues that he presented in *The Principles of Psychology* assuredly inspired his next major publication, *The Will to Believe* [4], a compilation of ten works, including articles and lectures, in which James discussed the importance of belief to the human mind. He argued that humans make a particular choice to believe in a universe where good and truth exist, and he defends the right to believe. Linda Simon [11] noted that the essays "contain some of his most eloquent statements on the intellectual and emotional risks of religious belief; the philosopher's contribution to a society's moral life; the genesis and importance of genius; and the accomplishment of psychical research" ([11], p. 274). James's writing on the right or will to believe was a hinge between his psychological and religious studies.

Study of Religion

James experienced a series of unfortunate events in the last 2 decades of the nineteenth century, including the death of two of his younger siblings (Wilky, d. 1883, and Alice, d. 1892) and several dear friends, as well as his own health complications – both physical ailments and bouts of depression. These experiences likely prompted his reflective turn toward religious matters and, in particular, his search for the functions or fruits of religious experiences. In addition, James's complex relationship with his father, who, in defiance of his own strict Calvinist upbringing, had adopted a personal and detached spirituality, influenced William's search for a distinct perspective on religion.

Around the turn of the twentieth century, James began to make more frequent use of theological ideas in the lectures he gave in the United States and abroad. In 1901 and 1902 James delivered a famous series of lectures in Edinburgh, Scotland, as a part of the Gifford Lectures; the two-part series focused on natural religion or the idea that there is an organic, unprompted religious feeling common to all people. He argued that philosophers cannot fully capture human experience in their rhetorical thoughts and stories. Instead, he asserted that full human nature is demonstrated through religious experience, namely, engagement with whatever one considers the divine.

James's career constantly straddled the fence between the rigor of hard science and the importance of recognizing the variability of experience through philosophy and art. Throughout his Gifford lectures, James applied reason to the inexplicable parts of human existence and applied the scientific method to the study of religious experience, which he considered separate from institutionalized religion. His lectures were published as *The Varieties of Religious Experiences: A Study in Human Nature* (1902) [6]. The collection demonstrated the commonalities of religious experience across cultures throughout time and space, and became one of James's most important and influential works. It remains a foundational work in the study of religion.

Philosophical Pragmatism

In addition to his groundbreaking work in psychology and religion, William James was also a founder of the influential philosophy called Pragmatism, which arose from the post-Civil War struggle to redefine American culture in the absence of slave society and in the midst of what took its place, namely, ideological warfare, demagoguery, and the vivid appearance of class, racial, and gender conflicts. Pragmatists faced the challenge of relating ideas to practical material outcomes [13]. Americans needed a new way of thinking – a scheme – to help them make sense of modernity. William James, along with Charles Pierce, Oliver Wendell Holmes, and John Dewey, developed such a way of thinking and with their ideas, transformed the way Americans saw the world [9]. Pragmatism began as a method for mediating the contrasting philosophical approaches of these four men and their colleagues: the "tender minded" theorists who employ rationalism ("the habit of explaining the parts by wholes") and the "tough minded" theorists who use empiricism ("the habit of explaining wholes by parts") ([8], p. 7). It is also a philosophical approach to delineating truth. Philosophy must have an empirical *modus operandi*, and "make some positive connection with this actual world of finite human lives" ([7], p. 14). Pragmatism held that truth, in order for it to be so, must be verifiable through tested hypotheses and must remain so in a variety of circumstances. Theories, therefore, are instruments for abstracting the truth through a practical mode of understanding; truth is able to be repeatedly proven. James writes, "true ideas are those that we can assimilate, validate, corroborate and verify" ([7], p. 88).

James's move away from a narrowly defined scientific perspective toward more religiously and philosophically informed work in his last decade of life could also mark a means of redeeming the numerous family misfortunes he encountered in mid-life and later. "James not only survived numerous crises, but also achieved the kind of wisdom that only comes from suffering" ([12], p. 338). James wrestled with the mysteries of life through his writings, with each one showing his growth toward who *he* was and what *his* interests were, and away from the identity path constructed for him by his father.

Contribution to Child Development

In 1892, James addressed a group of teachers in Cambridge, Massachusetts, in a series of psychology lectures that were later published as *Talks to Teachers* [5]. This was arguably his most significant work in the field of child development and learning. In these lectures, he drew from the theoretical basis he had already established in *The Principles of Psychology*. Using general human psychological principles and applying them to students in classrooms, James discussed the child as a "behaving organism," practically oriented and acting out his or her thoughts within a stream of consciousness. He described "native reactions," or innate, automatic responses to outside stimuli. James encouraged those who work with children to use these responses as tools for teaching and learning in the elementary classroom. For example, fear, love, imitation, curiosity, and emulation are natural

components of the human developmental process. Beyond "fear of punishment" James urged that "love" (the instinctive desire to please those whom we love), "curiosity" (the impulse towards better cognition), and "imitation" (learning by observing role models) also be used in the classroom, making the most of the instinctual tendencies of even the youngest of children. James discussed habit formation, memory, attention, and association of ideas as important tools for the classroom, each one harnessing what is natural in child development.

James-Lange Theory of Emotion

Ashley E. Coleman, John Snarey
Emory University, Atlanta, GA, USA

Definition

First proposed by American psychologist James [5] and independently developed by Danish psychologist Lange [8], the James-Lange theory of emotion states that the immediate, primary cause of an emotion is physical. Bodily changes and physiological processes, which occur as a result of environmental stimuli, evoke certain feelings in the conscious mind. In this sense, emotions are bodily sensations or processes variously combined.

Description

The James-Lange theory can be illustrated by the following anecdotes. A child sees her father walk into the room carrying her toys. She begins to grin, her heart beats a little faster, her pupils dilate, and she runs toward him. These bodily changes represent the emotion of excitement. In a different instance, a man walking down a deserted street at midnight hears footsteps behind him. He looks back and sees a large figure approaching. The man converts his walk into a run, he breathes more rapidly, his nostrils flare, his eyes widen, and adrenaline flows through his veins. These bodily changes represent the emotion of fear. The emotions that these two individuals experience are different, of course, but the way each one responds physiologically plays an important part in both situations. The girl felt excitement because she smiled and charged ahead, the man felt afraid because he ran away, and not conversely [5].

History of the Theory

William James was the first psychologist to delineate the imperative role of physiological changes in emotional experience. For James, "The bodily changes follow directly the perception of the exiting fact and that of feeling of the same changes as they occur is the emotion" [5, p. 189]. Before his revolutionary 1884 publication, "What Is an Emotion?" [5], the scientific community widely believed that the reaction to a stimulus was cognitive, and that the bodily changes that resulted were primarily reactions to a thought. Only a year after James's work on this topic was published, Carl Lange independently published an article stating similar views on the importance of the physiological mechanisms of emotions [8]. Thus, the hypothesis of emotion became known as the James-Lange theory. Before this theory gained credence, an emotion was assumed to begin when a person interpreted an emotion-inciting stimulus, which was then followed by a bodily reaction. As an alternative, the James-Lange theory proposed that after the stimulus is interpreted, a bodily reaction occurs, which is followed by an emotional response [3]. In James's words, "quick as a flash, the reflex currents pass down through their pre-ordained channels, alter the condition of muscle, skin and viscus; and the alterations, apperceived like the original object, in many specific portions of the cortex, combine with it in consciousness and transform it from an object simply-apprehended into an

object-emotionally felt" [5, p. 203]. Though only a small modification in the order of events, this proposition changed the face of the field of psychology. Many research studies have demonstrated how emotions are induced after the body makes corresponding muscle changes. Today it is not uncommon for the instructor of an introductory course in psychology to conduct a demonstration in which half of the class members are asked to hold a pencil in their mouth sideways, like a dog with a bone, and half are asked to hold a pencil in their mouth longways, like a straw; while all class members rate how funny they find a set of cartoons. Students who engaged the muscles used to smile invariably find the cartoons funnier than students who engaged the muscles used to frown.

Critiques of the Theory

German psychologist Wilhelm Wundt, often cited as the founder of modern psychology, was one of the first critics of the theory of emotion proposed by the founder of American psychology. Wundt believed that feelings were primary and, thus, similar to other hard-wired primal sensations. Other critics, however, often overlooked a qualification made by the James-Lange theory, which is that a stark distinction can be made between the "coarser" emotions and the "subtler" emotions. James writes, "the varieties of emotion are innumerable. Anger, fear, love, hate, joy, grief, shame, pride, and their varieties, may be called the coarser emotions, being coupled as they are with strong bodily reverberations" [6, p. 241].What is important to note is that in the James-Lange theory, not all emotions are said to initiate strong physiological reactions. James clarifies that "softer" emotions such as "moral, intellectual and aesthetic feelings" do not have the same type of bodily response. For the latter type of emotion, there is a "thinness and paleness of these feelings, (and) when unmixed with bodily effects, is in very striking contrast to the coarser emotions" [5, p. 251]. But, as was James's pattern, his qualification followed his strongly expressed generalization. For James, nevertheless, incitation of the nervous system and the instantaneous physiological changes in the body are imperative for strong (or coarse) emotions and best represent the theory.

A common misconception of the James-Lange theory has incited considerable denunciation and refutation [3]. Many scholars have wrongly assumed that James meant that emotion is *only* the physiological changes, which is quite different from the arguments he presents in his publications on emotion [5], (James, 1884). Although the bodily changes are necessary for emotion, they are not the only component of an emotion [3]. (Unlike James, Lange stated without qualification that the actual physical changes, such as the constriction of blood vessels, *are* emotions.) Nevertheless, for both James and Lange, emotions do not just magically emerge in the mind and simply stay there, occasionally inciting physical manifestations of their existence. Strong (coarse) emotions without the physiological transformations incited by the perception and interpretation of a stimulus have little to no meaning. James writes that "a purely disembodied human emotion is a nonentity. . .emotion dissociated from all bodily feelings is inconceivable" [5, p. 194]. Moreover, "if we fancy some strong emotion and then try to abstract from our consciousness of it all the feelings of its bodily symptoms, we find that we have nothing left behind" [6, p. 246]. Emotion is physical in its truest sense, causing bodily changes that are autonomic and instantaneous. Through the lens of the theory, emotion must be felt – in a physiological sense – in order to truly have a significant impact on the human psyche.

Perhaps the James-Lange theory of emotion is best understood in the context of James's interests in philosophy, psychology, and physiology. As shown in many of his writings, James revolutionized the conceptual framework for the mind-body connection as the basis from which to derive other psychological claims. For almost a century, many theorists either completely or partially rejected the James-Lange theory due to its radical stance on the physiological bases of emotion. For James, however, it was a testable hypothesis. If emotion is, in fact, the bodily responses to an outside stimulus, then it should be true that voluntarily executing actions that are normally associated with an emotion will cause that emotion. James, that is, realized that reactions to particular events as stimuli are, at least in part, taught by association and, as he expected, empirical research has supported the expected correlation for facial expressions, autonomic arousal, and instrumental behaviors. Not until the 1980s, however, did "neuroscience research on the role of peptides and receptor cells establish that (both) James-Lange and their critics were right in that emotions originate in both the body changes and mental perceptions" [1, p. 28]; cf. [2]. As Laird and Bresler [7] summarize, "through a self perception process, individuals "construct" their emotional experience from a variety of sources, including physiological responses, expressive behavior, instrumental behavior, and contextual elements" [7, p. 636]. Though the realm of emotion is still somewhat mysterious, the James-Lange theory first established that the body and the brain are coupled in emotional reactions; this discovery has sparked successive generations of scholars to contribute to understanding emotion in normal adults.

Relevance to Childhood Development

As a corollary of his theory, James writes, "it ought to be that any voluntary arousal of the so-called manifestations of a special emotion ought to give us the emotion itself" [5, p. 197]. If this is true, then children's lack of ability to control physical manifestations of emotion causes them to have less control over their emotions. Younger children, in particular, demonstrate this precise claim. James explains, "each fit of sobbing makes the sorrow more acute, and calls forth another fit stronger still, until that last repose only ensues with lassitude and with the apparent exhaustion of the machinery" [5, p. 197]. Inevitably, during the years of healthy development from childhood to adulthood, the brain and its behavior mechanisms mature, and a greater equilibrium is achieved in emotional regulation. Among the early critics of this hypothesis with regard to children and adult differences was psychoanalyst Ferenczi [4]. He argued that the James-Lange theory of emotion is not relevant for adults, but has only relevance to the construction of emotion in children. Ferenczi agreed that early childhood emotions do largely originate from bodily sensations, but he believed that, as older children and adults develop new capacities to control their emotions, everything changes. If, in fact, a direct connection exists between physiological events and the production of emotion, a way to synthesize emotion should exist as well. In a reciprocal cause-and-effect process, emotions and bodily reactions have an interdependent relationship. It should thus be possible to intentionally synthesize emotion from conscious physical changes, or to act out an emotion in order to produce the emotion.

Jaundice

Ioana Boie
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Icterus

Definition

Jaundice is a condition characterized by the yellow discoloration of a person's skin and the sclerae of the eyes. This condition is a result of an increased level of bilirubin, the bile pigments in the blood resulting from various pathological conditions described below.

Description

Jaundice can present in a light lemon-yellow hue, indicative of haemolysis, or a green hue, indicative of severe hepatic disease or biliary tract obstruction. Jaundice can occur at any age, and the presentation and causes vary somewhat across age.

Jaundice in Adults

There are three types of jaundice in adults: (1) Haemolytic jaundice, in which the amount of bilirubin exceeds the liver's capacity to process it, and where the bilirubin is caused by an abnormal level of hemoglobin from the destruction of red blood cells; (2) hepatocellular jaundice, in which the bilirubin levels increase in the blood because the liver cells are either damaged or died as a result of viral infection or liver failure; (3) obstructive jaundice, or cholestatic, in which the bile cannot be discharged from the liver because the bile ducts are blocked by gallstones, an abnormal growth, or the ducts may be absent.

There are many causes of jaundice, including starvation, circulating infections, medications, and liver and pancreatic diseases. In adults, the causes of jaundice can be determined through a systematic historic evaluation and examination; jaundice can be associated with carcinoma of the pancreas, liver, and billiary tract in younger patients, and gallstones, hepatoma and hepatic metastases in middle-aged and older individuals. The deterioration of these organs can be a result of Hepatitis A, B, C, hematological disorders. Jaundice may be associated with ethanol and drug use.

Relevance to Childhood Development

Physiological jaundice is present in 60% of healthy newborn infants, and in 80% of pre-term infants, and it occurs

after the age of 24 h, with a peak on the third or fourth day of life, and it tends to disappear by the seventh to tenth day of life. Although physiological jaundice will not last past a couple of weeks, its persistence may indicate the need for further investigation of the origin of pathology. Some of these causes may be haemolysis, in the case of rhesus disease, or ABO incompatibility, red cell defects, extravascular blood, sepsis, increased enterohepatic circulation, galactosemia, hypothyrodism, decreased conjugation, bile duct obstruction, biliary hypoplasia, or neonatal hepatitis.

Breast milk jaundice is associated with breast-fed babies due to the existence of β-glucoronidase in the maternal milk, which contributes to deconjugating the bilirubin in the bowel, and increases its circulation in the blood.

Crigler–Najjar syndrome is a moderate to severe form of hereditary jaundice due to decreased conjugation.

Joint Attention

Lydia Aydlett
Western Carolina University, Cullowhee, NC, USA

Synonyms

Directing attention; Gaze following; Interpersonal engagement; Joint focus of attention; Shared attention; Shared focus; Social referencing

Definition

Joint attention appears in infancy, is a form of social cognition, and is characterized by the capacity of infants to coordinate their attention with that of a social partner [13].

Description

Joint attention occurs when two people are focused on the same attribute of their environment at the same time and both are aware of the other's focus on and interest in that attribute ([16]). Evidence for joint attention is demonstrated when the infant is able to share attention with, follow the attention of and direct the attention of another [4]. Infants engage in joint attention when they understand that other people have goals and that people are able to direct their personal attention in the pursuit of those goals. Each of the expressions of joint attention (sharing attention, following attention, directing attention) requires that the infant understand that other people are intentional. Shared attention is basic to all forms of joint attention and involves the infant and adult attending to an object of interest for a period of time. In addition, it requires that the infant look from the object to the person and back to the object. The alternation of gaze indicates intentionality on the part of the infant in incorporating another's attention into their own interests.

When infants begin to follow the attention of another, one can make a stronger case for the infant's ability to understand the other as an intentional agent. For example, when an infant looks where an adult points or looks where the adult looks, the infant indicates an understanding that the adult is intentionally focusing his attention on an object of interest.

When infants direct the attention of others, their own communication is judged to be intentional when it is goal oriented. Goal orientation is demonstrated when the infant persists until the goal is reached and alternates gaze between the other person and the goal [4]. Burner [3] suggests that the most sophisticated form of joint attention is the "meeting of the minds," the act of sharing full understanding with another person of an object, event, or action. The meeting of the minds requires understanding of the object or event within its context which comes from the joint participation of both individuals in a common culture.

Relevance to Childhood Development

Joint attention is fundamental to the development of social cognition and language. How infants come to understand that others have minds, intentions, and goals

and that language is the vehicle for communicating intentions and goals is intricately entwined in the development of joint attention.

Although discussion continues in the field regarding the timing of the emergence of joint attention in infants, enough evidence has accumulated to specify when components of joint attention emerge [1]. The development of joint attention begins at birth; when infants are alert and oriented to another person they are available for shared attentiveness with an adult. From 6 to 8 weeks of age, interpersonal engagement emerges as infants engage in affective reciprocity with others during face-to-face interactions. At 5 to 6 months of age, the next step in the development of joint attention takes the form of object engagement. In object engagement, infants show interest in objects and the manual skills to manipulate them and adults support their object exploration. The early stage of true joint attention emerges at 9–10 months of age when infants point, social reference, and request and refer to objects. Joint attention skills are consolidated at 13 months with the appearance of the infant's first words and with sustained episodes of joint engagement. By 18 months, symbols emerge in infants' interactions and infants are able to share with others a focus on objects that are absent and events other than present ones.

This developmental sequence demonstrates the overlap of joint attention skills with other developmental domains and the dependence of the adaptive development infants on the presence of joint attention skills. When children have deficits in joint attention, the consequences are profound.

For example, children with autism do not share attention with others unless it is to obtain something that they want. They do not seek affective reciprocity, do not share their interest in objects, and do not engage in social referencing. Children who do not engage in joint attention are typically severely impaired in language development [15]. Further, faulty joint attention predicts later difficulty understanding what others might be thinking when they say something or otherwise interact [14].

In summary, joint attention is developmental skill that emerges over infancy and forms the basis of social cognition and language development. The consequences of the disruption of joint attention skills are profound.

Joint Focus of Attention

Loretta C. Rudd, Leah E. Johnson
Texas Tech University, Lubbock, TX, USA

Synonyms
Joint attention

Definition
Joint focus of attention is a triadic episode of interaction involving a caregiver, an infant/toddler and an object.

Description
During joint attention caregiver and infant share attention to an object thus providing a didactic experience for the infant (e.g., the caregiver names the object – "ball" while the infant is visually attending to the ball) [1]. At around the 1-year birthday infants begin to look to where the important adult is looking. In addition, infants begin to direct adult attention to external objects using gestures; thus, a triangle is formed in which the infant and parent or caregiver focuses her attention on an external object or event [3, 4]. The ability to focus attention on external objects and events provides the infant with the initial means by which to share experiences with others [8]. By allowing for the sharing of experiences, joint attention has a central role in the child's development of both social and communicative skills [2].

Relevance to Childhood Development
Research indicates that language acquisition is fostered by joint attention [9, 10, 11]. Specifically, when adults engage in attention-following behaviors for longer periods of time, language acquisition is enhanced [7]. The optimum time to engage in these specific types of joint attention is when the child is between the ages of 18 and 24 months [5]. Those children whose mothers engage in more frequent and longer bouts of joint attention during the period between 18 and 24 months score higher on vocabulary measures [7]. A strong correlation exists between vocabulary and reading ability, thus indicating that joint attention is a necessary developmental milestone in the future academic success of children [12].

Joint Legal Custody

Douglas K. Symons
Acadia University, Wolfville, ON, Canada

Synonyms
Guardianship

Definition
Joint legal custody is a situation in which separated or divorced parents of a child share joint decision-making power over significant decisions in a child's life with respect to education, religion, medical care, and major activities requiring parental permission.

Description
Custody of children is either held by both parents, one parent as in sole custody, or a legal guardian such as an extended family member or children service agency. If parents are divorcing, there must be final dispensation of all outstanding assets of the marriage and a determination of the custody arrangement for the children. Prior to divorce, disputing parents may petition the court to determine custody matters in a separation agreement. Joint legal custody ends when children reach the age of consent, which in some jurisdictions is at 18 years.

Joint legal custody requires that parents be able to communicate with one another with respect to children's needs. This can be problematic if there is residual anger and conflict associated with the marital breakdown. A common source of confusion for parents is the difference between custody, which is legal decision-making, and access, which is where the child resides and the nature of contact with each parent. Joint legal custody does not mean that children reside with each parent an equal amount of time, for example, spending alternate weeks with one parent and then the other. In fact, joint legal custody is independent of access arrangements, although in sole custody decisions, the children would almost certainly reside with the custodial parent. There have been trends for joint legal custody to be more common and sole custody less common than decades ago.

Sometimes psychologists are asked by the court to conduct a custody and access assessment. The guiding principles of these assessments are to assess children's developmental needs and make recommendations on what arrangements would best meet these needs [4, 8]. These are required when parents and their respective legal counsel cannot come to an agreement suitable to both parties, so they can be contentious for parents. Accordingly, various psychology professional associations have written formal guidelines for their members to follow when conducting these assessments so that ethical, professional, and empirically-based standards are followed. The American Psychological Association has such standards [1], as do several provinces in Canada [7]. Around 40% of first marriages end in divorce in a variety of Western Countries, and children from the marriage are often involved, so it is not surprising that there are considerable self-help resources on the internet and in the popular press. Custody battles over children of public figures such as Hollywood stars garner considerable attention, but are atypical.

A custody and access assessment is not always needed when parents can avoid conflict and come up with their own arrangements. Professional assistance in the form of mediation may help with this for some couples [9]. Divorce is not easy on children, but it is harder when parents have their own psychological issues, there is ongoing conflict between parents, and financial support issues have not been worked out [2]. There is a positive impact on children of minimising conflict between divorcing parents and promoting positive mental health of each parent [6]. An understanding of child development, divorce, custody arrangements, and access scheduling is therefore very helpful [3, 5]. Joint custody can be advantageous in some situations, and children's adjustment in joint custody situations is generally more positive than in sole custody situations.

The process by which parents can make joint decisions about important aspects of a child's life and share access is called co-parenting. Conflict within the co-parenting relationship is stressful for parents and children, and can serve to disrupt effective decision-making and access transitions. It is important that parents separate their potentially negative feelings towards the other parent and their respect for the relationship between the other parent and the children. While marriages sometimes come to an end, a child will have the same biological parents for their whole lives.

Participation in illegal behavior by a minor who falls under a statutory age limit." (Siegel & Welsh, p. 6)

Approximately 1.5 million youths under the age of eighteen are arrested each year for crimes ranging from drunk driving and drug use to gang violence and murder (Siegel & Welsh). The increase in violence and delinquency among youth has been a focus of study in the 20th century in addition to the creation and study of the juvenile justice system including all correctional agencies developed to address juvenile delinquency. (Siegel & Welsh) Many delinquent behaviors are attributed to breakdowns in family structure, reports of abuse and neglect, impoverished living conditions, and inadequate health care. (Siegel & Welsh) Programs addressing rehabilitation and treatment of juvenile delinquency as well as prevention have been developed but their efficacy is still under scrutiny. (Siegel & Welsh)

Synonyms

Childhood-onset diabetes; Diabetes mellitus; IDM; Insulin dependent diabetes; Type 1 diabetes

Definition

Juvenile diabetes is a disorder of the autoimmune system that causes the body to cease the production of insulin. Pancreatic islet cells within the pancreas are destroyed, resulting in deregulation of blood glucose levels.

Description

The American Diabetes Association (ADA) states that the exact causes of diabetes are still uncertain, however, both environmental and genetic causes have been implicated [1]. Juvenile diabetes, or type I diabetes, is an autoimmune disorder that occurs as a result of the immune system attacking the insulin producing beta cells within the pancreas. These pancreatic islet cells are destroyed resulting in a lack of insulin within the body. Insulin is a hormone that converts sugar or glucose and starches into energy and is essential for survival.

Symptoms

A lack of insulin due to juvenile diabetes can lead to hyperglycemia, or high blood sugar that is typically marked by excessive thirst and urination, blurry vision, and increased sugar levels in urine. Furthermore, hyperglycemia can lead to a loss of consciousness and diabetic ketoacidosis (DKA) if untreated [2]. Alternatively, hypoglycemia, or low blood sugar is evidenced by increased perspiration, dizziness, confusion, nausea, and shaking. Hypoglycemia is usually the result of not eating, physical overexertion, or excessive insulin treatments [6].

Prevalence

In regards to prevalence, the ADA estimates juvenile diabetes to be one of the most common disorders in childhood with 1 case in every 400-600 children [1]. Additionally, the International Diabetes Federation (IDF) estimates that worldwide, 65,000 new cases of juvenile diabetes are expected annually in children under the age of 14 [3]. It has also been estimated that the national cost of diabetes (type 1 and 2 diabetes collectively) in the United States was $174 billion in 2007 when considering medical expenses and estimated loss of productivity [1].

Treatment

The treatment for juvenile diabetes is multifaceted [6]. Individuals are asked to closely monitor their dietary intake, monitor and test their blood glucose levels, receive varying amounts of insulin injections, limit physical overexertion, and reduce stress. Since carbohydrates greatly affect blood sugar levels, counting and accurately monitoring the amount of carbohydrates an individual consumes during meals and snacks is paramount. To inform the individual if any changes in dietary intake and/or insulin administration need to be implemented, testing of blood glucose levels is conducted. Blood glucose is usually tested via multiple finger pricks at set times throughout the day, such as before meals and bedtime. Insulin can also be administered through an insulin pump.

Complications

Adhering to this regimen limits short term complications through ensuring that individuals avoid low or high blood glucose levels. Potential long term complications of juvenile diabetes include damage to nerves and possible amputation of appendages, retinopathy and possible blindness, renal failure, and even cardiac damage. There is also some evidence that individuals with juvenile diabetes may experience some resulting cognitive difficulty. Specifically, individuals with diabetes may experience learning disabilities, difficulties with long term memory, processing speed, and executive functioning (e.g., [4, 5]).

KABC-II

Definition

The KABC-II is a reliable and valid measure of cognitive abilities of children ranging from ages 3-years, 0-months to 18-years, 11-months. It is a revision of the original KABC [1].

Description

The KABC-II was constructed using dual theoretical models: the Cattell-Horn-Carroll (CHC) model (see [7]) and [4–6] neuropsychological model. Administration time for the core battery varies based upon age from 30 to 70 min using the CHC model and 25 to 55 min using the Luria model. When interpreted using the Luria model, the KABC-II yields a Mental Processing Index (MPI) that excludes acquired knowledge [2]. Therefore, the Luria model of the KABC-II measures *sequential processing*, *simultaneous processing*, *learning ability*, and *planning ability* [3]. The CHC model of the KABC-II measures five broad abilities: *short-term memory* (Gsm), *planning ability* (Gf), *long-term storage and retrieval* (Glr), *visual processing* (Gv), and *crystalized ability* (Gc). However, planning ability is only included in ages 7–18 because a factor corresponding to planning was not discovered in children younger than 7 [3]. The FCI and MPI indices have a mean standard score of 100 and a standard deviation of 15.

The CHC model is the default model except in cases where the examiner believes that crystallized ability will compromise validity [2]. This could occur if a child has limited English language proficiency, has a language disorder, or has been diagnosed with Autism [2]. The KABC-II also provides a Nonverbal index (NVI) that is intended for use with children who are not fluent in English. The NVI can be administered in pantomime and responded to by pointing or other motor responses [3]. Kaufman and Kaufman [3] recommend that the NVI only be used when assessing children who are deaf or hard-of-hearing, children with moderate to severe speech impairments or language disorders, and children who are non-English-speaking. The NVI should never be used as a replacement for the FCI or MPI if a child does not have any of the aforementioned conditions.

The KABC-II demonstrated internal consistency in that the manual reports mean split-half reliability coefficients of 0.95 for ages 3–6 and 7–18 for MPI, 0.96 for ages 3–6 and 0.97 for ages 7–18 for FCI, and 0.90 for ages 3–6 and 0.92 for ages 7–12 for NVI. Results of confirmatory factor analysis provided construct validity for the KABC-II in that a four-factor model emerged for ages 4 and 5–6, and five factors emerged for ages 7–12 and 13–18. Correlations between the KABC-II FCI and WISC-IV full scale IQ was 0.89. KABC-II FCI and Woodcock–Johnson Tests of Cognitive Abilities General Intellectual Ability correlated at 0.78.

Relevance to Childhood Development

Kaufman et al. [2] outline many significant benefits of using the KABC-II to evaluate children. The authors note that the dual theoretical perspective offered by the KABC II is the first benefit to the assessment of children. The CHC model allows an examiner to examine cognitive strengths and weaknesses which can assist in developing specific intervention strategies which has proved useful in the assessment of specific presentations (e.g., learning disabilities). For example, Baddeley (1986) found that

Sam Goldstein & Jack A. Naglieri (eds.), *Encyclopedia of Child Behavior and Development*, DOI 10.1007/978-0-387-79061-9,

working memory, and accepted aspect of short-term memory (Gsm), is correlated with many areas of academic performance. In fact, both verbal and visual-spatial working memory tasks appear to correlate with math ability [9]. Therefore, if an individual appears to have a significant discrepancy between his or her short-term memory than other skills, it may provide evidence of the need for further assessment of math achievement. The KABC-II has also been shown to provide fairer assessment to minorities using the MCI index that excludes measures of acquired knowledge [2]. Finally, as noted previously, the KABC-II provides a nonverbal index that can be utilized with children who are deaf or hard of hearing, have language disorders or other speech difficulties, or are not fluent in the English language. Providing three separate scales not only provides the examiner increased flexibility but also alleviates the cost of purchasing a nonverbal cognitive assessment.

Critics have argued that the KABC-II does not properly represent fluid reasoning and suggest that supplementing the Gf measures from the KABC-II with measures of Gf from other intelligence tests batteries may be beneficial [8]. The authors themselves argued that some of the supplemental subtests may not clearly assess what they purport to measure. For example, Kaufman and Kaufman [3] themselves state that story completion measures visual-spatial and crystallized abilities as well as fluid reasoning abilities. Aside from noted complaints, the KABC-II remains a reliable and valid measure of cognitive abilities and provides many benefits to clinicians and others.

Klonopin (Clonazepam)

Lauren Connell Pavelka
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Clonazepam (generic)

Definition

Klonopin is an anticonvulsant that belongs to a class of medications called benzodiazepines, which act on the central nervous system (CNS) to produce a calming effect by producing gamma aminobutyric acid (GABA), a naturally occurring chemical in the body. The generic form of Klonopin is Clonazepam.

Description

Klonopin is used to treat seizure disorders or panic disorder. It can be used alone or as an adjunct in the treatment of the Lennox-Gastaut syndrome (petit mal variant), akinetic and myoclonic seizures. It may also be useful in patients with absence seizures (petit mal), who have failed to respond to succinimides. Klonopin is also indicated for the treatment of panic disorder, with or without agoraphobia, as defined in DSM-IV. Unlabeled uses of Klonopin include treatment of insomnia, nystagmus, and restless leg syndrome.

Some side effects of Klonopin may include: drowsiness, dizziness, memory problems, fatigue, muscle weakness, loss of balance/coordination, slurred speech, drooling or dry mouth, sore gums, runny or stuffy nose, changes in appetite, nausea, diarrhea, constipation, blurred vision, headache, nervousness, insomnia, skin rash, or weight changes. More serious side effects, which require immediate medical care include: confusion, hallucinations, unusual thoughts or behavior, hyperactivity, agitation, hostility, involuntary eye movements, weak or shallow breathing, depressed mood, suicidal ideation, chest tightness, irregular heartbeat, painful urination, bruising/bleeding, or new or worsening of seizures.

This drug and other benzodiazepines may produce psychological and/or physical dependence. Due to these concerns, in addition to the potentially serious side effects and interactions with other medications, Klonopin should be used only under supervision of a medical professional.

This review of Klonopin contains general information. For complete information about Klonopin and individual use, a health care professional should be consulted.

Relevance to Childhood Development

The safety and effectiveness of using Klonopin to treat children and adolescents suffering from panic disorders or other psychiatric conditions are not well established. Though some reports claim overall efficacy in treating pediatric patients, these studies are not long-term. Most concerning is the risk of physical or psychological dependence. For children being treated for seizure disorder, benefit-risk considerations should be made.

Kohlberg, Lawrence

John Snarey, Andrea Green
Emory University, Atlanta, GA, USA

Life Dates

1927–1987

Introduction

American developmental psychologist Lawrence Kohlberg spent his life in pursuit of universal justice. "Kohlberg

opened the eyes of psychologists and educators to the fact that people's moral thinking changes as they grow up, and that these changes continue to follow predictable stages of development as they grow older" [12]. He is best known among psychologists for his six-stage model of moral cognition and development. Kohlberg also developed three methods of moral education: adult role models as moral exemplars, peer interaction through moral dilemma discussions, and democratic participation in a morally grounded democratic school community, which he referred to as Just Community programs.

Laurence (original spelling) Kohlberg was born in Bronxville, NY, an affluent suburb of New York City, on October 25, 1927. His father, Alfred Kohlberg, was a wealthy textile importer with production facilities in China during World War II (Sino-Japanese War) and the Cold War. Alfred later became known as the head of the "China Lobby" due to his support of Chiang Kai-shek and right-wing politics (e.g., he was a fierce supporter of Joseph McCarthy and a founding director of the John Birch Society). Laurence's mother and Alfred's second wife, Charlotte Kohlberg (nee Albrecht), was a chemist who would later become a noted inventor in the field of plastics.

Early Life and Education

"Laurie," as his family called him, was the youngest of four children born to his nominally Jewish father and Christian mother. He attended Public School No. 8 in Yonkers and Mark Twain Middle School in Bronxville. In terms of his home life, his early years were marked by the privileges of wealth and an unusual degree of upheaval and dispersion. Just before Laurie was 4 years old, his parents separated; his father (who held temporary legal custody) and mother maintained a rotating 6-month custody arrangement from 1933 to 1938. In 1938 Charlotte sued to break the shared custody arrangement with Alfred. In 1941, however, a judge dissolved the custody order and allowed each Kohlberg child to choose the parent with whom he or she wanted to live. Fourteen-year-old Laurence and his older sister Roberta chose their father as their custodial parent.

Alfred Kohlberg hired a tutor to coach Laurence in Greek and Latin in order to prepare him to enter Phillips Academy, an elite preparatory high school in Andover, MA. His classmates there remembered him as a genuine intellectual who rebelled against arbitrary social conventions, such as rules that prohibited visiting girls on nearby campuses, and who often was placed on probation. As a high school student during World War II, he witnessed incidents of anti-Semitism, closely followed current events involving the Nazis' treatment of European Jews, and began to identify with his Jewish heritage. Alfred too had become involved in aiding European Jews through the United Jewish Appeal, but he also founded the American Jewish League against Communism (AJLAC). He loathed socialistic Zionism and was ashamed of Jews who had become communists.

After Laurie finished high school in 1945, he joined the US Merchant Marine. For the next 2 years he sailed on the U.S.S. George Washington and traveled to Europe, where he witnessed the aftermath of World War II and met Holocaust survivors. By the time his tour of duty ended, he had become a Zionist sympathizer and a nonviolent activist on behalf of victims of the war. As documented by Kohlberg's biographer, Robert E. Herzstein, the relationship between Alfred and Laurence was quite complex [2]. Laurence joined the *Haganah*, the Jewish defense organization in Palestine, and returned to Europe on the ship *Paducah*. Renamed the *S.S. Redemption* for its role for the *Haganah*, the vessel was outfitted to smuggle European Jewish refugees through the British blockade and relocate them in Palestine, then a British-controlled territory. Kohlberg served as its second engineer. He willingly broke British laws, which he saw as unjust, to assist desperate refugees. While en route to Palestine in October 1947, he and his fellow crew members, along with many refugees, were captured by the British and taken to an internment camp on Cyprus. Three months later, the *Haganah* provided the British with forged papers with false names and obtained the release of Kohlberg and others. Kohlberg made his way to Palestine but refused to participate in the fighting; he lived on a kibbutz until he was able to return to the US in 1948. Kohlberg's first published article appeared in the *Menorah Journal* in 1948. In this article he relayed his experiences on the *S.S. Redemption*. The account was entitled "Beds for Bananas," which alluded to the crew's cover-story to explain the dozens of wooden shelves lining the cargo area of the ship. The ship's cargo hold, outfitted for smuggling Jewish refugees, was said to be for hauling bananas.

In the fall of 1948, Kohlberg enrolled in the Hutchins College of the University of Chicago. He studied the philosophies of Socrates, Plato, John Locke, and Immanuel Kant, and the pragmatism of John Dewey. "Larry," as he now identified himself, concentrated his studies in philosophy, psychology, and sociology and acquired his A.B. degree in just 1 year by successfully completing a series of examinations. In 1950, at age 23, Kohlberg began his graduate work in academic psychology at the University of Chicago. His choice resulted in part from the continued influence of the great philosophical questions he pondered aboard the *S.S. Redemption,* in Palestine, and at the

University of Chicago: "What is virtue?" and "What is justice?" Kohlberg was dissatisfied with the answers provided by the dominant schools in psychology: Freudianism and Behaviorism. Kohlberg proposed that the foundational virtue is justice, which he defined as equity or equal respect for all people.

Research and Theory Development

As early as 1950, Kohlberg began refining his quest to elaborate a universal, non-relative theory of justice and eventually integrated into his theory the views of developmental psychologist Jean Piaget (1896–1980), who found that cognitive development was implicated in moral development. The amalgamation led Kohlberg to search for the cognitive-developmental foundations of universal moral principles. He began the empirical work for his dissertation in 1955, using a sample of 84 Chicago boys aged 10–16 years. With an interest in the structural-developmental model Piaget had employed to delineate his theory of cognitive development in children [10], Kohlberg conducted interviews in which he used moral dilemmas to test whether children possessed an underlying developmental framework for reasoning about morality.

The most famous dilemma concerned a man named Heinz, whose wife was dying. Kohlberg asked the boys, "Should Heinz steal a life-saving drug or let his wife die for lack of the drug? Why or why not?" As Kohlberg examined the boys' reasons, he discovered distinct age-related differences in the complexity of the moral reasoning they used to arrive at and justify their answers. His 1958 dissertation proposed six stages of moral development – in contrast to Piaget's two – and took a bold stand for the validity of universal justice-oriented moral principles.

Kohlberg's six stages of moral development were organized into three levels – *preconventional, conventional, postconventional* – with two stages each; each stage reflects a moral philosophy or moral worldview that is independent of the specific contents and questions of moral decision making. In short, Kohlberg posited that the six stages were universal and not culturally specific.

Kohlberg called Stages 1 and 2 the *preconventional stages* because children, ages 4–10 years, pass through them before they become aware of socially customary or conventional forms of moral reasoning. In Stage 1, which Kohlberg, like Piaget, called *heteronymous morality*, a younger child unquestioningly obeys authority figures. Children at Stage 1 avoid breaking rules set by external authorities because they are afraid of punishment or external physical consequences. In Stage 2, termed *individualism, instrumental purpose, and exchange*, school-aged children follow rules only when it is in their immediate interest to do so. What is moral is a reciprocal type of concrete exchange ("You scratch my back, I'll scratch yours.").

Stages 3 and 4 are the *conventional stages*. They are the stages in which the majority of people spend most of their lives – conforming, in several ways, to societal or group expectations. People usually enter Stage 3, *mutual interpersonal expectations and conformity*, during pre-adolescence and adolescence. People at Stage 3 equate what is morally right with what is perceived to be "good" and "nice" by others; they conform to the rules and expectations of others so that others will like or approve of them. Kohlberg referred to Stage 4 as *social system and conscience maintenance* because at Stage 4 people believe that the "moral right" stems from their allegiance to a particular social system. Thus they equate morality with what a legal system says is right or wrong, or with the moral rules of a social institution (see Chapter Kohlberg's Theory of Moral Development).

Kohlberg termed Stages 5 and 6 *postconventional* because moral reasoning at these stages goes beyond the moral reasoning used by most social groups or institutions. Stage 5 is characterized by a focus on *prior rights, human rights, and the social contract*. Moral reasoning at Stage 5 is motivated by the kind of thinking John Locke used to describe his social contract theory of government [9]. Locke held that people have certain basic rights, such as rights to life and to property ownership, which exist *prior* to society. Like Locke, people reasoning at Stage 5 believe the purpose of society is to protect individuals' rights and to promote communal welfare. The moral reasoning that characterizes Stage 6 employs *universal ethical principles* to resolve moral dilemmas. Stage 6 thinkers function from a universal ethical principle that views all human beings as free and autonomous. People are ends in themselves and not simply the means to an end. Persons at Stage 6 take the perspective of the oppressed, to ensure that they receive fair, just, and principled treatment (see Chapter Postconventional Morality).

On the basis of his dissertation, Kohlberg received his Ph.D. from the University of Chicago in 1958. The theories and findings on which he elaborated in his dissertation formed the foundation of his distinguished career, which was marked by pioneering ideas and landmark publications. Kohlberg died on January 17, 1987, in Boston, MA. His cremated remains were subsequently scattered into the ocean at Wellfleet, a harbor community on Cape Cod, MA.

Accomplishments

Lawrence Kohlberg's stage model of moral development is his greatest contribution to developmental psychology. Furthermore, his pedagogical models for moral education and the practice of democratic-community schools created a lasting framework for the formation of justice-oriented future citizens [8, 11]. Kohlberg's developmental conception of the aims and nature of moral education challenged the then-current indoctrination approaches to character education in the classroom from kindergarten through grade 12. His three-pronged approach to moral education – moral dilemma discussion, moral exemplars, and Just Community schools – taught that effective pedagogy must attend to both the moral judgment development of the individual and the moral atmosphere and democratic development of the community.

Kohlberg's dissertation [3], early professional articles [4], and popular publications [5] on his six-stage theory eventually initiated a new field of study, the psychology of moral development and education. He went to Yale University as an assistant professor in 1958 and returned to the faculty at the University of Chicago in 1962. During this time, he advocated for his developmental stage model, for moral development as a discrete field of psychological inquiry, and for the validity of universal moral principles.

He joined the faculty of Harvard University as a full professor in the Graduate School of Education in 1968. Subsequently, in 1974, he founded the Center for Moral Education and Development, which became a hub of research, training, and educational activities in the new field. In 1981, he published the first volume of his collected essays on moral development, *The Philosophy of Moral Development* [6]. The empirical findings from his 20-year longitudinal study were published in 1983 as a *Society for Research on Child Development Monograph*. The next year, the second volume of his collected essays, *The Psychology of Moral Development*, was published [7]. Also in 1984, with Anne Colby and several other colleagues, he published the long-awaited two-volume moral stage scoring manual, *The Measurement of Moral Judgment*. With Clark Power and Ann Higgins, he completed the work for their volume on moral education, which was published in 1989 as *Lawrence Kohlberg's Approach to Moral Education* [11].

Contribution to Understanding Childhood Development

Lawrence Kohlberg saw children and adolescents as moral philosophers, capable of forming their own moral judgments. His six stages of moral development, which encompassed childhood through adulthood, followed the characteristics of the Piagetian structural stage model [10]. He based these stages of sociomoral reasoning on a theory of evolving mental structures or cognitive schemata within the developing brain. Each stage represents a qualitatively different way people resolve moral dilemmas. The six stages form an invariant sequence: people do not skip stages or reverse their order. Similarly, Kohlberg theorized that the six stages were hierarchically integrated – higher stages are better in the sense that a person reasoning at a higher stage can understand the moral reasoning used by those at lower stages, but the converse would not be true. Kohlberg also hypothesized that these six stages were universal: that they apply to all human beings at all times, even though many persons do not progress through all of the stages.

Kohlberg began an intense reflection on moral education in the late 1960s, when he became convinced that achieving a just society would require proactive intervention to enable children to become more likely to reach postconventional moral development. Kohlberg developed methods of moral education that would promote moral development and mature character through exposure to information about moral exemplars, classroom moral dilemma discussion, and Just Community programs in which democratic education was a normative feature. Like pragmatist educator John Dewey, Kohlberg taught that school communities were uniquely capable of providing a democratic context in which to facilitate moral development [1]. His three approaches to moral education, which integrated socialization and developmental methods, strengthened a community's moral climate as well as the moral reasoning of the individuals within the community. He advocated focusing on the lives of moral exemplars who would embody, through their words and deeds, the ideal of universal ethical principles. He and his colleagues implemented a method of integrating moral dilemma discussions (like those he piloted during his dissertation research) into humanities and social studies programs. Children are best equipped to help one another achieve moral maturity since they often reason within one stage of one another, and their interaction provides optimal dilemmas for discussion and resolution, articulated in a language they understand. A central feature of the Just Community approach was the weekly community meeting, which would help students and participants acquire the democratic habits of thinking and acting according to a standard of fairness for all.

Kohlberg's attention to moral, educational, and political philosophies began with taking seriously the moral dilemmas in his own history and background. His innovative responses to these moral dilemmas led to the

development of what is now considered the field of moral psychology and education, and changed the shape of conversation about the development of moral maturity in psychology and philosophy. He created lasting frameworks for approaching the study of the development of moral cognition and education and inspired programs to prepare citizens for living in a participatory democracy.

Kohlberg's Theory of Moral Development

Robert Walrath
Rivier College, Nashua, NH, USA

Definition

Lawrence Kohlberg's theory of moral development conceptualizes the sequential cognitive and developmental process of moral reasoning in children.

Description

Kohlberg's theory was developed by presenting ethical and moral dilemmas to children in a short story format, followed by questions to elicit their feelings and decisions about the character's actions. After studying the responses, he concluded there are three levels of moral development, each with two stages, as described below.

Level I: Preconventional Morality

In this initial level, children make decisions based on external consequences to their behavior, without consideration of the feelings of others. This level is typical of elementary school aged children.

Stage 1: Punishment and Obedience Orientation

Decisions are rule based to avoid punishment. The physical consequences of an action determine if it is right or wrong.

Stage 2: Individualism, Instrumental Purpose, and Exchange

Decisions are based on meeting one's own needs, with the beginning understanding that you should do things that lead to a reward and avoid behaviors leading to punishment. Others are helped only if it benefits the child himself.

Level II: Conventional Morality

At this level, children shift to decision making based on rules or norms of the group to which they belong. Conformity to the expectations of others and general social norms is most important. External rules begin to be internalized. This level begins to emerge in adolescence.

Stage 3: Interpersonal Conformity

Sometimes referred to as the "Good-Boy/Nice Girl" phase, children begin to think that being "good" is what pleases others and living up to expectations is important. There is the beginning thinking about intention as well as outward behavior.

Stage 4: Social System and Conscience

Also called the "Law and Order" orientation, rules are not questioned and the shift is toward respecting authority and maintaining the social order, and away from pleasing others.

Level III: Postconventional Morality

At this level, moral values have been individualized and internalized, independent of social or norm group membership. Kohlberg considered this level (especially at Stage 6) to be rare, with most adults' moral reasoning typical of Stages 3 and 4.

Stage 5: Social Contract

Rules are perceived as necessary and promoting fairness, but individual rights are emphasized, leading to perceptions that rules and laws can be ignored or changed in some circumstances.

Stage 6: Universal Ethical Principles

Behavior is based on more abstract and personalized principles that are considered "acts of conscience" for the individual, but that are related to universal concepts such as freedom, justice and respect.

►Postconventional Morality

Kolb, Bryan

Tracey McLellan
University of Canterbury, Christchurch, New Zealand

Introduction

Dr. Kolb is considered one of the world's most influential neuroscientists and distinguished researchers of behavioral neuroscience. He is regarded as a "founding father of behavioral neuroscience" in which the focus is on the interaction of neuronal changes and behavior [1].

Educational Information

Dr. Kolb was awarded a B.Sc. and M.Sc. in Psychology from the University of Calgary. In 1973, he received his doctorate of philosophy from Pennsylvania State University. Dr. Kolb completed postdoctoral fellowships at the University of Western Ontario and at the Montreal Neurological Institute.

Accomplishments

Dr. Kolb developed the first course in human neuropsychology in Canada. He was a post-doctoral fellow at the Montreal Neurological Institute at the time. Dr. Kolb's later research on the plasticity of the brain, or how new brain cells grow, has informed many new treatments for individuals with Alzheimer's disease, brain injury and drug abuse problems. Dr. Kolb has received numerous international honors and is a long-standing member of the Group of One Hundred [1]. This International Neuropsychology Symposium assembles together the most eminent behavioral neuroscientists in the world.

Contributions

Dr. Kolb's outstanding contribution was the discovery that we can grow new brain cells. He and his team demonstrated how the growth of new brain cells can restore cerebral and, therefore, behavioral functions [2]. An important focus of Dr. Kolb's research was the identification of factors that effect the cerebral cortex in an embryo and during early childhood development. Strategies for improving the recovery from early brain injury, as well as precautions for pregnant mothers were consequently identified by Dr. Kolb and his research team.

Current Involvement

Currently, Dr. Bryan Kolb is a Professor in the Department of Neuroscience at the University of Lethbridge, Alberta, Canada. He also holds adjunct appointments at the University of Calgary and the University of British Columbia. In addition, Dr. Kolb is an Associate Director of the Canadian Institute for Advanced Research, Experience-based Brain and Biological Development program. Dr. Kolb is a Killam Fellow, a Fellow of the Canadian Psychological Association, the American Psychological Association, the American Psychological Society, and the Royal Society of Canada. Dr. Kolb has authored several books, including *An Introduction to Brain and Behaviour* and *Fundamentals of Human Neuropsychology* [3]. The latter is employed internationally as a standard text [4].

Ladd-Franklin, Christine

Kelli Vaughn-Blount
York University, Toronto, Canada

Life Dates

(1847–1930)

Introduction

Christine Ladd-Franklin, American psychologist and logician, was best known in psychology for her theory of color vision and as a strong proponent for women's equality within psychological science and academia.

Educational Information

Christine Ladd-Franklin, like many of her psychological female cohort, found the road to higher education to be a rocky one. Ladd-Franklin began her collegiate career at Vassar College. However, unlike many at the time, she did not come with extensive financial resources. She entered Vassar in the fall of 1866 but was only able to complete one year before financial problems forced her to withdraw. After a year of teaching, and with some assistance from an aunt, Ladd-Franklin returned to Vassar in 1868 and completed her A.B. in 1869. It would be some years, though not unproductive ones, before Christine Ladd-Franklin would continue her formal education. Between 1869 and 1876 she unofficially continued her education by attending courses as a non-admitted student at Washington College, Jefferson College, and Harvard [10]. Her studies at Washington and Jefferson focused primarily on mathematics. Her Harvard studies are still controversial; although, it is agreed that she spent at least one summer there pursuing botany studies. It was also during this period that she was teaching science and mathematics in girls' high schools [8, 9].

In 1876, aware of the potential detriment of her sex, Ladd-Franklin wrote to the world-renowned mathematician James J. Sylvester at the newly formed Johns Hopkins University to inquire if her sex might in fact be a detriment to her admission [7]. Receiving Sylvester's support, and that of the newly developed fellowship program, she submitted her application for graduate studies to the university. The application was submitted under the name C. Ladd (her maiden name) with impeccable credentials. She was officially accepted. That was until the trustees' of the university discovered that C stood for Christine at which point Sylvester had to intervene on her behalf. Ladd-Franklin was finally admitted as a full time student, with special provisions, and three years of support from the fellowship but would not be formally recognized as equal to her peers for many years. While attending Hopkins, Christine Ladd-Franklin studied mathematics under Sylvester and symbolic logic under physicist Charles S. Pierce. She was the first American woman to formally receive graduate instruction in both [4, 8]. Like Mary Whiton Calkins at Harvard and Lillien Jane Martin, fellow Vassar alum, at Göttingen, Christine Ladd-Franklin completed all of the requirements for the Ph.D. at Johns Hopkins in 1882. She was however denied the degree, based solely on her sex, until 1926. Ladd-Franklin was seventy eight years old when she finally received her doctorate but she was still the one of the three pioneers mentioned above to do so. To date neither Harvard nor Göttingen has officially recognized Calkins or Martins degrees. Lillien Martin was awarded an honorary doctorate from the University of Bonn in 1910 allowing her to be officially referred to as doctor in her life-time. Mary Whiton Calkins, however, was offered only an alternative degree from Radcliffe in 1903 (Harvard's women's college during that period), which she refused on the grounds that she had attended Harvard and not Radcliffe.

Sam Goldstein & Jack A. Naglieri (eds.), *Encyclopedia of Child Behavior and Development*, DOI 10.1007/978-0-387-79061-9,

Christine Ladd-Franklin and Lillien Martin also shared one other similarity in their pursuit of higher education, G. E. Müller. Ladd-Franklin was the first female student and first American student of Georg Elias Müller at Göttingen in 1891 [3]. However, she spent only one year at the university. Lillien Martin followed in 1894 and would become the first woman and only American student to pursue a full five years of study under Müller at Göttingen. In later years, Ladd-Franklin would further her studies in color vision at the University of Berlin under Herman Von Helmholtz while Martin would go on to study mental imagery under Oswald Külpe at the University of Bonn.

Accomplishments

Christine Ladd to her detriment married fellow student and mathematician Fabian Franklin upon completion of her studies. Her marriage is important in that it not only exemplifies her feminist leanings, with the use of a hyphenated name, but also because the choice to marry would forever hinder her career. Christine Ladd-Franklin taught logic, mathematics, and psychological science throughout her career. In the early 1900s she primarily taught courses in logic and mathematics at Johns Hopkins. The bulk of her career, from 1915 until her death, would however be focused on psychology and philosophy at Columbia University. Due to her marital status, Columbia never provided her with a full professorship contract. A professional slight that was common to married women of the early twentieth century [7–10].

Christine Ladd-Franklin began publishing early. Her first recorded works on mathematics were published during her undergraduate years at Vassar. Between 1873 and 1871 she published mathematical formulas in the London *Educational Times*, *The Analyst: A journal of Pure and Applied Mathematics*, and the *American Journal of Mathematics*. It has been noted by historians that Ladd-Franklin's 1877 publication in *The Analyst* is the first by a woman to appear in a mathematics journal [4, 8].

She is also considered a pioneer in the study of symbolic logic with her dissertation, *The Algebra of Logic*, appearing in the now seminal 1883 work edited by Pierce titled *Studies in Logic by Members of the Johns Hopkins University*. Philosophy historians have noted that Christine Ladd-Franklin reduced syllogism to a single formula and developed the primary principle for a recognized validation of forms of syllogisms [7]. Ladd-Franklins earliest foray into psychology through symbolic logic be seen in the 1889 edition of the *American Journal of Psychology*. Her influence on study of logic continues and has been widely recorded (See [12]).

Contributions to Psychology

It was in Germany that Ladd-Franklins earlier studies in botany, biology, and logic began to come together under a psychological umbrella of color vision. Her exposure to the two prominent color theories of the time: Helmholtz (later Young-Helmholtz) and Ewald Hering would alter the course of her already promising career. Christine Ladd-Franklin developed her own cumulative theory of color vision proposing that rather than the now classic, three or four, static color perception framework (e.g., Helmholtz or Hering) that a process existed whereby the ability to perceive color combinations evolved over time. The earliest version of her theory on color sensation was presented at the Second International Congress of Psychology in 1892 and published in the German Journal *Zeitschrift fur Psychologie* that same year. The American introduction to Ladd-Franklin's theory, in a formal publication, appeared in *Science* in 1893.

The bulk of the theory can be reviewed in Christine Ladd-Franklin's book *Colour and Colour Theories*, which included many of her publishing's on the topics [6]. This original text offers several colored images providing accessible visual summations of the theory. Ladd-Franklin's theory included the only evolutionary postulate for the recognition of color sense perception with increased differentiation of photochemical receptors during that time [13]. Many considered her theory to be superior to both Helmholtz and Hering (See [2, 11]). Yet, the former continue to be cited in psychologies introductory texts while Ladd-Franklins is omitted.

Ladd-Franklin published approximately 400 articles and books in mathematics, logic, and psychology in her life-time but is often remembered for the strength of her feminist ideologies rather than the insightfulness of her research. She was not known to let a sexist slight pass her by. She was one of the first two women, the other being Calkins, to be elected to the American Psychological Association, in 1893, but her tendency to buck the patriarchy within the discipline omitted her inclusion on prominent committees. She also often published on issues of equality for women within the academy. In 1903, Christine Ladd-Franklin had been listed in Catell's Men of Science volume and was one of only three women psychologists starred that year, indicating eminence in the field. The most prominent of her publishing's on women appeared the following year with her 1904 paper on *Endowed Professorships for Women* [5].

Ladd-Franklin's battle of wills with Edward Titchner regarding the Society of Experimentalists is an often-cited example of her refusal to recognize female psychological scientists as anything other than equals. Titchner's refusal

to admit women to the Experimentalists meeting is well recorded – as is Ladd-Franklin's constant letters to him debating the decision. Margaret Floy Washburn and June Etta Downey were the first women officially admitted to the society, after Titchners death, but Christine Ladd-Franklin was the first to attend the meetings. Ludy Benjamin [1] has noted that at the 1914 meeting in New York, where Ladd-Franklin resided, she attended one session of the meeting. Titchner noted in a letter to Robert Yerkes that Ladd-Franklin had threatened some manner of a scene at the event and possible public protests in print. She had warned Titchner prior to the meeting that action was forthcoming and kept her word.

Christine Ladd-Franklin's contributions to the history of women in psychology finally began to be recognized in the 1980s. The height of which culminated in the Association of Women in Psychology's (AWP) Christine Ladd Franklin Award in 1992. The award is given to the member with the most significant contribution to the AWP. The organization provides this description for the award "in honor of Christine Ladd-Franklin... an early scientist whose career provided a painful example of the way institutional sexism operated to exclude women from careers in psychology and the sciences." It could also be added that she also showed what the women in nineteenth and early twentieth century managed to accomplish in spite of it.

Language Acquisition

Amy Burger, Ivy Chong
Florida Institute of Technology, Melbourne, FL, USA

Synonyms

First language acquisition; Language learning; Native language acquisition

Definition

Language acquisition refers to the processes by which humans learn their native language(s) as children.

Description

For typical children, the foundations for language acquisition are laid before birth when the developing fetus is exposed to adult speech sounds. After birth, infants show signs of attending to speech and show a preference for their caretakers' speech sounds [1]. As an infant matures, he or she will begin experimenting with vocalizations and various forms of babbling (Babbling consists of strings of random sounds composed of vowel-consonant or consonant-vowel combinations. Babbling is likely essential for speech development [1].) will begin around the age of 4 months. Between 7 and 12 months, an infant will begin to look at an object when its name is spoken and show other signs of word recognition [1]. Between the ages of 8 and 12 months, the infant begins to imitate the speech and communicative gestures of adults and older children: the emergence of echolalia (Echolalia is defined as the immediate imitation of another speaker's speech [1].) is considered an important part of speech development. The child's use of his or her first adult word will begin around

12 months of age. The use of two-word sentences will begin around 18 months, and by the age of 24 months, a typical child will have a vocabulary of 200–300 words and will be able to form short sentences. Parents and caretakers often respond to their child's developing language with a speech style known as motherese or parentese (Motherese, also known as parentese or baby-talk, is the style of speaking to young children and infants which typically involves slower speech, sentences that are shorter and simplified, and exaggerated pitch changes and stress patterns [1].). The shorter length of utterances typical of motherese may help to improve some types of language skills in young children [1].

After age 2, the child's language acquisition increases rapidly. The vast majority of children will achieve basic competency in their language by age 5 [2]. Around age 6, typical children will begin to use all parts of speech, and sentences will become more complex. Between the ages of 8 and 12, children gain the ability to verbalize problems and ideas, including abstract concepts. The breadth of vocabulary and use of subtle, complex, and creative language will increase during adolescence and continue to develop throughout the lifespan [1].

Theories of Language Acquisition

There are numerous theories of language acquisition. Three major theories of language acquisition are the behavioral theory, sociolinguistic theory, and the psycholinguistic or nativist model.

The behavioral theory of language acquisition, developed by the behavioral psychologist B. F. Skinner, proposes that language is learned when other persons in the child's environment respond to the child's use of language [1]. According to Skinner, reinforcement is defined as an event that follows a behavior and increases the future probability of that behavior. When children make speech sounds, others respond in a positive way to these sounds, which reinforces these behaviors and causes the child to engage in them more often [1]. According to this theory, adults gradually shape (Shaping refers to the training of a behavior through the reinforcement of behaviors that are increasingly close approximations of the desired behavior. After a closer approximation is acquired, the other approximations are no longer reinforced. This process continues until the organism acquires the desired behavior [1].) children's language use by initially reinforcing the production of any sounds, then reinforcing only specific sounds that can be used to form words in the child's native language, and later only reinforcing adult words used correctly. As the child matures, other people gradually stop reinforcing language use acceptable in young children and begin to reinforce only the acceptable adult uses of language. This process continues until the person has achieved the language competency accepted in his or her environment. This theory has been criticized because studies of parent–child interaction have not found evidence that this type of reinforcement of language use actually occurs consistently [2]. However, most scientists recognize that environmental input is essential for language acquisition and can influence and improve language use [1].

The psycholinguistic or nativist model, first developed by Noam Chomsky, proposes that all human beings have an innate ability to learn language. Chomksy referred to the mechanism that facilitates language acquisition as the language acquisition device (LAD). According to this theory, all typical humans are hard-wired to use basic, universal rules of language which exist in all languages [1]. However, transformational rules, which govern grammar, word order, and other differences that are specific to each language, must be learned by the child as he or she matures. According to this theory, children gradually learn the transformational rules of their own language by hearing the speech of other adults and testing out the patterns of speech when they create their own utterances. This explains why children make mistakes by overusing common rules of their language: for example, children may say "mans" instead of the correct term "men" because they have learned to add a final "s" to pluralize a word. However, this theory has been criticized because it fails to recognize the effects that social interactions and the environment can have on language acquisition and use [1].

The sociolinguistic theory proposes that language is learned through social interactions which cause the child to associate meanings with words used in social contexts. According to this theory, language acquisition begins when a child begins to learn language as caregivers imbue a child's actions with meaning when they respond to early communication attempts [1]. After social communication is established, caregivers model speech and, when the child imitates their speech, provide feedback that confirms, corrects, or expands the meaning and function that various utterances have when used in a social context. Thus, the communication of intentions and desires first begins in nonverbal forms; after this is established, the child learns to use verbal language to communicate. This theory accepts the view that an innate LAD may exist, but proposes that a social support system is necessary for language acquisition to occur successfully [1].

Relevance to Childhood Development

Clearly, language use is one of the most important skills learned in childhood. Knowledge of theories and

developmental milestones related to language acquisition can be helpful to parents, caretakers, and educators who wish to design educational and play activities that are suited to specific age groups. Appropriate use of milestone information also can be helpful for identifying problems with speech, language, or hearing. However, parents should also consider the fact that developmental milestone charts provide only approximate information and that individual variation is expected [1]. Understanding the different theories of language acquisition also can aid parents and guardians in selecting interventions for children with language delays or disorders and evaluating the different interventions offered by professionals.

Language Development

Loretta C. Rudd, Heather M. Kelley
Texas Tech University, Lubbock, TX, USA

Definition

Language development is a higher level cognitive skill involving audition and oral abilities in humans to communicate verbally individuals' wants and needs.

Description

Language is a complex system involving several components. The components of language include phonology, semantics, syntax, and pragmatics. Language development occurs in a fairly predictable fashion. Most typically developing children acquire the skills in each of the four areas by the end of their ninth year of life. While some children may develop more quickly than this, others may develop a bit slower. The important issue is that language develops in a typical sequence across all four areas.

The area of phonology includes the sounds of speech. Most typically developing children have acquired all speech sounds of their first language by the end of their ninth year. The typical order of phonological development begins with the sounds produced at the front of the month and progresses to complex blends of sounds.

The second component of language development is semantics, or the meaning of words. It is remarkable that infants begin with no words at birth and typically produce upwards of 250 words by the end of the second year of life. By the time children are 6 years old, they typically have a working vocabulary of 10,000 words! Children who are growing in language-rich environments may have even larger vocabularies.

Syntax, or sentence structure, is the third component of language development. As children develop language they begin to use more complex sentence structures. They progress from using one-word utterances (~12–18 months), to two-word utterances (~18–24 months), to three-word utterances (~24–30 months), and finally they are capable of using complex sentences that join more than one thought or event. Most typically developing children have mastered the rules of adult syntax by age 5.

The final component of language development is pragmatics. Pragmatics is an understanding of how we use language to communicate with others. Pragmatics includes the social conventions of a culture, such as, politeness, turn-taking routines, non-verbal cues that indicate the listener understands, and cultural variations of these.

Relevance to Childhood Development

Language development does not begin when children utter their first words around the end of the first year of life. Indeed, language development begins even before birth! There is evidence to indicate that newborns prefer human voice to other sounds and can even recognize their own mother's voice over voices of other humans. The amount of talk directed at the young child is strongly linked with children's vocabulary growth and in turn their future reading and writing skills. Children who are reared in language-rich environments do significantly better in reading and writing than children reared in impoverished environments. The critical element of language development to child development is that language development is at the root of most cognitive, social and emotional tasks associated with later success in school.

Laterality

Anna Mazur-Mosiewicz, Raymond S. Dean
Ball State University, Muncie, IN, USA

Synonyms

Cerebral lateralization; Handedness; Lateral dominance; Split brain; Unilateral hand preference

Definition

Laterality, which is often referred to as unilateral hand preference or handedness, is the preference for one side of the body over the other. Examples include right-handedness and left-footedness. Laterality is related to cerebral *lateralization*. Laterality is crucial to understanding language functions because of their association with the dominant hemisphere of the brain.

In most cases, handedness is genetically determined; however, early trauma or prenatal events are known to affect the adult and preference. Left hand preference that is due to an early hemisphere lesion is referred to as *pathological left-handedness* [1].

Description

The reason for hand preference is not completely understood; however, there are small but significant anatomic differences between the dominant and non-dominant hemispheres. For example, the *planum temporale* tends to be larger in the dominant hemisphere. Also the *sylvian fissure* and *occipital horn* tends to be longer in the dominant cerebral hemisphere. Even though there is no clear explanation as to why left-handedness occurs, traditional hypothesis suggest that the left-hand preference is a result of the left-hemispheric disease in early life, which also explains why there is more left-handed individuals among the learning-disabled or cognitively impaired populations than among right-handed individuals [1, 3].

Laterality reflects the functional supremacy of one of the cerebral hemispheres. The majority of humans displays the left cerebellar dominance. Generally, each cerebral hemisphere controls the contralateral side of the body (i.e., left cerebral hemisphere is controls the right side of the body) including muscular control, sensory input, and

other lateralized functions that are associated with a particular hemisphere. This pattern is not clearly established in all individuals. In fact, many individuals are mixed-dominant and not completely right-handed or left-handed, but they tend to favor one hand for complex tasks [1].

Studies estimate that about 90–95% of all adults display general right-handed preference. In early childhood, only 70% of children present right-handedness; yet, in middle and late adulthood, the percentage of right-handed individuals increases to 99%. This change is explained partially by the practice of forcible repression of left-handedness and the accommodation of left-handers to tools and norms of the right-handed environment. About 95–99% of right-handers have left-hemispheric language representation.

The majority of non-right-handed (*nondexteral*) individuals present left cerebral language dominance; however, they are more likely to have atypical language representation (right or bilateral) with the familial history of left-handedness. The incidence of the right cerebral dominance is harder to estimate due to bilateral hemispheric distribution in these individuals. Yet, the incidence of right-hemispheric language dominance in left-handedness increases linearly with the degree of left-handedness, form 4% in strong right-handers to 15% in ambidextrous individuals and 27% in strong left-handers. General estimations indicate that in nondexterals, 78% is left-hemispheric dominant, 15% have bilateral language distribution, and about 8% present right-hemispheric dominance [1].

In right-handed individuals, aphasia is usually related to left-cerebral lesion. In these individuals, aphasia due to pure right-hemispheric lesion happens only in 1% of cases. Cerebral dominance in ambidextrous and left-handed individuals is rarely so uniform. In fact, in 60% of left-handed individuals, aphasia is due to lesions in the left hemisphere, and a majority of right-hemispheric aphasias is reported in left-handers. Moreover, language disorders in left-handed patients with right hemispheric lesions are usually less severe and enduring than in right-handed individuals. Thus, it is often proposed that non-right-handed individuals have bilateral representation of language functions [4].

There are several ways that help to determine which hemisphere of the brain is the dominant one: (1) behavioral outcomes of the brain lesion (the loss or impairment of language functions is usually associated with lesions in the dominant hemisphere); (2) the preference for greater facility in the use of the right or left hand; (3) the preference for greater facility in the use of the right or left foot; (4) the arrest of speech in association with a focal seizure or after electrical stimulation of the anterior language area during a surgical procedure; (5) injection of sodium amytal into the left internal carotid artery, which produces a one or 2-min-long period of mutism that is followed by misnaming, and paraphasic speech if the left hemisphere is the dominant one; (5) dichotic listening test in which different words are presented simultaneously to two ears, yields ear-hemisphere advantage for the dominant cerebral hemisphere; (6) observing the increase in cerebral blood flow during language processing tasks; (7) and lateralization of speech and language functions following the commissurotomic procedure [1].

Laterality and Cognitive Development

Left-handers tend to perform better than right-handers on visuo-spatial tasks. These group differences are likely related to the fact that left-handers have visuospatial functions mediated in a more diffuse manner by both hemispheres and not localized in the right hemisphere, while right-handers have the visuospatial functions more localized in the right hemisphere. Laterality also is related to cognitive abilities and gender. Left-handed males tend to perform similarly to right-handed females in their superiority on tests of verbal skills and sequential processing, and left-handed females and right-handed males appear to have advantageous visuo-spatial skills and nonverbal auditory processing abilities [4].

Higher proportion of nondexterals than right-handers present extreme cognitive functions. At the lower end of the distribution are individuals whose left-handedness was caused to early brain injury. At the other end are individuals with superior intellectual abilities. These individuals tend to become skilled mathematicians, professional athletes, architects, lawyers, and chess players. Additionally, more left-handers enjoy artistic (manual and graphic) and musical talents [1, 4].

Laughter

Tawnie Caballero, Brett R. Nelson, Laura Parres
California State University, San Bernardino, CA, USA

Synonyms

Cackle; Chuckle; Chortle; Giggle; Guffaw; Snicker

Definition

An explosive sound that is the sign of amusement. Origin: From the Old English *hliehhan*, is of onomatopoeic (sound-imitating) origin.

Description

Laughter is the communication of emotion in a social situation and part of the universal human vocabulary. Laughter may express various emotions such as joy, amusement, nervousness, fear, shame, and even aggression. Laughter is one of the few vocalizations that is shared by humans and non-human primates. Tickling is one of the most common and reliable triggers to human and primate laughter. Researchers have found that laughter is not consciously controlled. It is defined by a specific repeated vowel sound such as "ha ha ha" or "he he he." Different laugh types differ with respect to emotional dimensions. An associated term "schadenfreude" is defined as laughing at another's misfortune.

Relevance to Childhood Development

As early as the first few weeks of life, infants begin experiencing the world through auditory and visual channels. During the first months of development, babies may smile and produce "laughter-like" vocalizations at the sight of a familiar face. The close interaction between mother or caregiver and child fosters healthy attachment. Laughter vocalizations are a naturally occurring part of child development. "Cooing," cuddling, and tickling will elicit the laughter response in very young infants.

As children reach toddler age, they continue to develop socialization by using laughter in communication. Children will often play and laugh to express amusement and silliness with family members and friends. Children usually find humor in silly sounds of cartoons and physical humor. During the schooling years, children may quickly learn the social "norms" among their peers in regards to laughter. Laughter can be used either to include or exclude children from a social group.

Humor is often used in a therapeutic way to elicit laughter. Laughter is associated with the reduction of stress and provides a brief escape from stressful events. The phrase "Laughter is the best medicine" is based on current research of the many health benefits. Laughing can reduce vasoconstriction (the narrowing of blood vessels) and may decrease levels of the "stress" chemicals Cortisol and epinephrine. Doctors, such as Patch Adams, M.D., have used humor therapy and clowning in their medical practice for treatment of terminally ill patients to provide coping techniques.

In regard to parenting, functions of laughter can vary according to an individual's perception of their child (ren) and specific kinds of interaction. Skilled therapists can observe interactions between parent and child to identify how laughter is used in relationships. Laughter may be used as a means to negotiate tensions or while discussing delicate issues (nervous laughter). A parent may also use laughter to calm concerns they have about his/her child(ren).

Conclusion

Laughter is a commonly overlooked, yet universal function of human social communication. The meanings of different types of laughter are relative to human development. In humans as young as toddlers, laughter can be used to include or exclude peers from a specific social group. Health benefits of laughter include stress reduction and the reduction of vasoconstriction and stress chemicals.

Law of Effect

Elizabeth G. E. Kyonka
West Virginia University, Morgantown, WV, USA

Synonyms

Principle of reinforcement

Definition

The Law of Effect is E. L. Thorndike's description of the principle of connectionism: an individual is more likely to repeat behaviors that are accompanied or closely followed by satisfaction and less likely to repeat behaviors that are accompanied or closely followed by discomfort in a particular situation, when that situation recurs.

Description

Thorndike's Law of Effect

At the end of the nineteenth century, Edward L. Thorndike pioneered a means of measuring learning. He constructed several chambers, each equipped with an escape hatch that could be opened by a particular mechanism such as depressing a lever or pulling a string. He would place a cat (dog, or chick) in the same "puzzle box" several times and recorded escape latency – the amount of time it took the cat to execute the required mechanism and exit the chamber. Upon succeeding, cats were rewarded with access to food for a brief period. Thorndike deemed a decrease in escape latency over successive trials evidence of "animal intelligence," or learning.

The first time a cat experienced a puzzle box it would explore the box, guided by impulse or instinct, and usually took a long time to escape. Once they had escaped successfully from a puzzle box several times, most cats executed the required escape response quickly. Thorndike [5] attributed the decrease in escape latency to a strengthening of the association between stimulus (puzzle box) and response (whatever action was required to escape). Thorndike [6] described the improvement of performance upon repeated trials as the Law of Effect:

> Of several responses made to the same situation, those which are accompanied or closely followed by satisfaction to the animal will, other things being equal, be more firmly connected with the situation, so that, when it recurs, they will be more likely to recur; those which are accompanied or closely followed by discomfort to the animal will, other things being equal, have their connections with that situation weakened, so that, when it recurs, they will be less likely to occur. The greater the satisfaction or discomfort, the greater the strengthening or weakening of the bond (p. 244)

According to Thorndike, the effect of reinforcement is a strengthening of the association between stimulus and response. The corollary effect of punishment is a weakening of the association between stimulus and response. Thorndike's Law of Effect does not provide any insight into how the association comes about in the first place. As such, the law of effect can be considered a definition of positive reinforcement (and positive punishment), a key concept for theories of learning in respondent and operant behavior: a reinforcer is anything that strengthens a preceding behavior.

Theories of Matching: The Quantitative Law of Effect

Herrnstein [4] conducted an ▶operant conditioning experiment in which pigeons pecked at two concurrently-presented options that were reinforced at different rates. For several different reinforcement ratios, the percent of pecks to a particular alternative equaled the percent of reinforcers obtained on that alternative: the relationship between rates of responding and rates of reinforcement was proportional. This observation is a restatement of the law of effect as a description of choice between different alternatives that made it possible for Herrnstein to express the relationship as a mathematical equation:

$$\frac{B_1}{B_1 + B_2} = \frac{kR_1}{k(R_1 + R_2)} \quad (1)$$

In Eq. 1, *B*s denote rates of responses, *R*s denote rates of reinforcement, k is a constant multiplier that drops out and subscripts 1 and 2 refer to different types of responses (alternatively, a target behavior and all other possible behaviors).

The relationship between rates of responses and reinforcement is known as the "matching law" and often appears in its most general form [2]:

$$\log\left(\frac{B_1}{B_2}\right) = s * \log\left(\frac{R_1}{R_2}\right) + \log b \quad (2)$$

In Eq. 2, Variables *B*, *R* and their subscripts are as in Eq. 1. The parameter s refers to the sensitivity of responding to reinforcer ratio, and the parameter $\log b$ to bias, a constant preference for one alternative that is independent of reinforcer ratio. The original matching law described by Herrnstein is a special case of the generalized matching law. The generalized matching law provides a good description of behavior in a variety of experimental choice procedures [3].

Relevance to Childhood Development

The law of effect and the generalized matching law are best understood in experimental conditions where both response and reinforcer are concrete, discrete and easily measurable. However, the principle applies to all circumstances in which learning occurs, in humans of all ages as well as in cats and pigeons.

The matching law has been used as a means of describing behavior in applied settings notably including classroom environments. It enables psychologists and educators to quantify and assess on-task or appropriate behavior relative to off-task or inappropriate classroom behavior. Results of empirical studies [1] have produced strategies for reinforcing, both individually and classroom-wide, appropriate behaviors such as homework completion that "may allow educators to increase the probability of students choosing to engage in assigned tasks."

A practiced understanding of the law of effect can be particularly useful when teaching preverbal or nonverbal children. Consistent positive reinforcement of a behavior encourages that behavior, whether it is desirable or no. Many parents will identify with those in this case study of a toddler [7]: While the toddler had been sick for an extended period as an infant, one of his parents or a caregiver would monitor him at bedtime until he fell asleep. If the toddler cried or fussed after he was left alone in his bedroom, an adult would return to tend to him. At bedtime, the toddler's crying response was strengthened by the satisfaction he received from his parents' attention. It is no wonder his crying continued after his health returned! When his parents stopped reinforcing the toddler's unnecessary crying, his tantrums ceased with no apparent ill effects.

Lead Poisoning

Amber R. Whited, Andrew S. Davis
Ball State University, Muncie, IN, USA

Synonyms

Plumbism; Saturnism

Definition

Lead poisoning is a medical condition in which the body contains toxic levels of lead.

Description

Lead has been put to many uses throughout history. It was mixed into cosmetics and medicines, as well as added to pottery enamel and glass used to make food containers. In more recent times, lead was used for soldering the edges of tin sheets together in order to make cans for preserving food. Lead has been used in pipes for household plumbing, as well as in household paints. It was also added to gasoline. As a result, children and adults were often exposed to toxic levels of lead. In modern times, the primary source of exposure for children is lead in paint. Contaminated dust and soil is the second most common source. Young children are at higher risk of exposure, as they engage in hand-to-mouth activities more frequently than older children and adults [3, 8].

Lead levels are typically measured in micrograms per deciliter (μg/dL) in the blood. The Centers for Disease Control and Prevention [6] recommends individual intervention for children with a blood level of 15 μg/dL or higher and community interventions in areas where many children have blood levels of 10 μg/dL or higher. The average blood lead level in the United States is 2 μg/dL.

Symptoms of early or mild lead poisoning (about 25–60 μg/dL) often include digestive problems, such as nausea, loss of appetite, or constipation. Fatigue and difficulty sleeping may be noted. Individuals may develop

anemia. More severe levels of lead poisoning (above 80 µg/dL) can include kidney disease, encephalopathy, paralysis (lead palsy), or partial or total blindness. Some individuals may have a blue line along the gum line, faintly at mild levels and more pronounced with severe exposure, which is unique to lead poisoning; however, many individuals do not develop this symptom. If left untreated, severe lead poisoning may result in convulsions, coma, or death [1–3, 5, 7, 8].

The primary method of treating lead poisoning is chelation therapy. The most common chelating agents used are penicillamine, mese-2,3-dimercaptosuccinicacid (DMSA), ethylenediaminetriacetate (EDTA), and 2,3-dimercaptopropanol (BAL). Penicillamine and DMSA are taken orally and are more commonly prescribed for mild or chronic cases and when treating children. EDTA and BAL are administered by injection and are used for acute lead poisoning. When used with children, injections are typically intramuscular. Proper nutrition is very important during chelation therapy, as the agents used can bind to essential minerals, such as zinc and iron [2, 9].

Relevance for Childhood Development

Prenatal exposure to lead has been associated with spontaneous abortions and premature births [10]. Although 80 µg/dL is typically identified as severe exposure, encephalopathy has been found as low as 65 µg/dL. Signs of encephalopathy in children may include restlessness, drowsiness, difficulty concentrating, headache, and vomiting. Seizures may also be noted [4].

Lead poisoning has been found to have a negative impact on the performance on intelligence tests, even at mild levels. Deficits in visual-motor coordination are common. Behavior disorders may develop, with signs of aggressiveness or destructiveness. Children with lead poisoning have been found to be absent from school more frequently, as well as to have higher rates of school failure. Academically, children often perform more poorly on school work, especially verbal activities, such as reading and vocabulary. Auditory processing skills may be weakened. Reaction times tend to be slower for children with lead poisoning [4, 8].

Research has been inconsistent in determining the permanence of deficits for children following treatment for lead poisoning. Some studies have found children can improve with reduction of lead levels, while other studies have found continued deficits. Reduction of environmental exposure is critical to treatment of lead exposure, as reexposure is more likely to cause permanent damage to the central nervous system, even when the second exposure is at a low level [4, 9].

Learned Helplessness

Leah E. Johnson, Matthew C. Lambert
Texas Tech University, Lubbock, TX, USA

Definition

The pattern of attributions and behaviors that leads an individual to see no connection between the behavior and the outcomes resulting in feelings of hopelessness, depression, and passivity [5].

Description

Learned helplessness is the perception of little or no relation between one's behaviors and outcomes. Learned helplessness theory assumes individuals seek explanations for events, particularly negative events such as school failure,

interpersonal problems, poor health, or loss in sports. These explanations and the attributions that underlie them affect expectations for future events. These future expectations then determine behavioral responses, including passivity, anxiety, and depression. Children who develop learned helplessness tend to attribute their failures to a lack of ability. However, when these children succeed they attribute it to external factors, such as luck, rather than ability [5].

The theory of learned helplessness was first proposed in 1967 by Steven Maier and Martin Seligman when they were graduate students at the University of Pennsylvania. The students were involved in a series of experiments concerning negative reinforcement using dogs. In these experiments, a group of dogs received uncontrollable shocks. These dogs were then placed in a situation when they could control the shocks received. The dogs did not display any learning in the new situation- lying passively in the box while receiving shocks that could be controlled, unlike the control group and the dogs that received controllable shocks through the duration of the experiment. Similar results were found in later experiments with rats, monkeys, cats, and humans. From these first experiments, Seligman and others developed their theory of learned helplessness.

Seligman's theory of learned helplessness is composed of three components: contingency, cognition, and behavior. Contingency is the outcome of a person's actions; that is the result experienced due to a person's behavior. Cognition is the person's perception and explanation of the outcome or contingency. Thirdly, behavior is the action a person takes in response the contingency and cognition. Learned helplessness is similar to Weiner's attributional model, particularly the cognition piece of the theory. Under the theory of learned helplessness, Seligman proposed that people differ in their explanatory, or attributional, style. Research shows that there are consistent individual differences in explanatory style. Some people tend to attribute events to internal, stable, and global causes. Such a student may explain a failure on an exam by saying that he or she is stupid and just cannot learn that subject. Explanatory style appears to generalize to new situations.

The generalizability of explanatory style or cognition is more like a trait. The generalizability of learned helplessness along with uncontrollability of events can help explain depression in some people. Seligman proposed that the uncontrollability of an aversive event enhances the fear-arousing characteristics of the event and leads to depression if the experience is prolonged, intense, or becomes frequent. Seligman also contended that the helplessness he observed in his experiments with the dogs was parallel with severe depression in humans. Some similarities include the failure to solve problems that are solvable and a lack of initiation of action. He also noted that like chronic depression, helplessness can be difficult to break up once it established. Learned helplessness cannot explain all facets of every case of depression, but it may identify a set of cognitions that are involved in at least some cases.

Relevance to Childhood Development

When children with learned helplessness encounter a difficult task, they experience an anxious loss of control and do not persist. Over time, the ability of children with learned helplessness does not predict their performance [1]. These children do not develop the metacognitive and self-regulatory skills necessary for high achievement because they do not recognize the relationship between behaviors and outcomes. Children who have developed learned helplessness become involved in an ongoing cycle of a lack of effective learning strategies, reduced persistence, and a sense of loss of control [1].

Learning

Daniel Patanella
New York City Department of Education, New York, NY, USA

Synonyms

Behaviorism; Cognitive-behaviorism; Conditioning; Latent learning; Literacy; Neo-behaviorism; Social learning

Definition

Learning refers to changes in behavior and cognition as the result of experience. Traditional learning theory is

closely associated with behaviorism, cognitive-behavioral research, and an empiricist-associationist philosophy.

Description

As a psychological discipline, learning refers to changes in behavior and changes in cognition as the result of experience. Traditional learning theory is closely associated with behaviorism, cognitive-behavioral research, and an empiricist-associationist philosophy. A broad distinction may be drawn between conditioning, as represented by Watson [10] and Skinner [7] and the eclectic cognitive-behavioral learning perspectives of such psychologists as Tolman [9] and Bandura [1]. Regardless of their theoretical diversity, all learning theorists subscribe to the behaviorist maxim that the proper dependent variables in psychological research should be observable, verifiable behaviors.

Conditioning

Conditioning refers to any process by which an organism acquires new behaviors through repeated experience. There are two main types of conditioning. The first is known as classical conditioning, represented by such researchers as Pavlov [5] and the Watson [10], who popularized the term "behaviorism." The second, known as operant or instrumental conditioning, derives from the works of Skinner [7] and his followers. Classical conditioning is a form of learning in which an organism comes to associate one stimulus with another, usually prompting a behavior previously associated only with the first stimulus. It is concerned with the re-association of a reflexive behavior to a formerly neutral stimulus. Operant conditioning is a form of learning primarily concerned with the effects of reinforcement and punishment upon behaviors. The behaviors addressed by operant conditioning are much broader in scope than the reflexes of classical conditioning.

Within classical conditioning, several components of the conditioned response may be measured and serve as the dependent variable of interest. The amount of time it takes for an organism to respond to a conditioned stimulus is referred to as "latency," the strength of the response is referred to as "magnitude," and the likelihood that the conditioned response will occur at all is called "probability." Examination of these three aspects of learned behaviors has partially led to two important and influential elaborations of our understanding of classical conditioning, namely opponent-process theory, and the Rescorla-Wagner theory. The opponent-process theory, largely developed by Solomon [8], provides an associationist context for explaining certain instances (such as habituation to drugs) in which the conditioned response becomes the opposite of the unconditioned response. The Rescorla-Wagner theory, created by Rescorla and Wagner [6] allows for mathematical prediction of responses based upon the given trajectory of a learning curve, offers a possible learning-based explanation on habituation to repetitive stimuli and also helps explain how organisms distinguish among multiple conditioned stimuli at any given time.

Operant conditioning, in contrast, is not as dependent upon reflexive behavior and is primarily concerned with the effects of reinforcement and punishment upon behaviors. Operant conditioning focuses on the consequences of behaviors, and what makes learned behaviors stronger or weaker. Behaviors that are reinforced are likely to persist whereas lack of reinforcement will likely result in a decrease in the behavior. Ferster and Skinner [2] distinguished among four different schedules of reinforcement in *Schedules of Reinforcement* (1957), and their definitions have become part of standard operant conditioning lexicon. These schedules of reinforcement have been observed in both the laboratory and the real world, and behaviors reinforced using unpredictable schedules are not only highly resistant to extinction but will also continue long after reinforcement has ceased. Series of discrete behaviors can be combined in lengthy chains, resulting in very complex learning and the actual reinforcements used can be far removed from the typical biologically-based primary reinforcements that one normally associates with laboratory research. The Skinnerian concept of "radical behaviorism" conceptualizes even thought processes as subject to the rules and laws of conditioning.

Neo-Behaviorism and Social Learning

In contrast to the orthodoxy of classical and operant conditioning, neo-behaviorism is a set of diverse theories that allows for the inference of nonobservable constructs such as motivation and internal states. (As is evident from both the Rescorla-Wagner and opponent-process theories, however, classical and operant conditioning do include complex and abstract theorizing.) Social learning bridges the gap between behaviorism and social psychology.

The work of both Guthrie [3] and Hull [4] is primarily of historical interest, yet both neobehaviorists introduced important concepts to learning theory. Guthrie stressed the role of contiguity in learning, elaborating upon the necessity of properly linking the unconditioned and conditioned stimuli during classical conditioning and reconceptualizing forgetting as the establishment of new contiguities that successfully competed against the old ones. Hull attempted not only to incorporate the mathematical rigor of proofs and postulates into learning, but also stressed the importance of intervening variables, such as drive, habit

strength, and incentive value of the reinforcement. The work of both researchers helps point the way toward contemporary neural network cognitive psychology.

Tolman [9] is considered the father of cognitive behaviorism. Set apart from both classical and operant conditioning, Tolman's system examined learning aside from the confines of strict minimalist environments, preferring to use mazes rather than puzzles or Skinner boxes in the laboratory. Tolman reported that his lab rats were able to learn the routes of their mazes even prior to reinforcement, as evidenced by their shorter than expected latencies when reinforcement was finally introduced; he referred to this non-reinforced learning as "latent learning," a concept that is still current. Tolman also introduced the study of insight into behavioral learning. While insight had been a topic explored by Gestalt psychologists, Tolman studied insight learning within the context of rats in a maze. Both latent learning and insight learning are similar in that neither seems to be strict stimulus-response learning, and both make use of what Tolman called a "cognitive map," a broad purely mental schematic of the immediate environment to be utilized in order to behave efficiently and solve problems.

Social learning theory, as introduced by Bandura and elaborated upon by subsequent researchers, is even more removed from traditional behaviorist tradition. According to social learning theory, it is not necessary to be a participant in an activity in order to learn. Rather, by observing the actions of others, one can learn vicariously through modeling. This is largely learning through imitation, an aspect of learning previously overlooked by other theorists. Initially, the theory focused on the acquisition of antisocial behavior in children but the utility of social learning theory has broadened considerably, and social learning theory is not only an integral part of contemporary learning theory but also an essential component of many behavior modification programs.

Developmental dyslexia; Learning difficulty; Learning disorder; Spelling disabilities

Definition

The most influential definition of learning disabilities is found in the United States federal law Individuals with Disabilities Education Improvement Act (IDEA) 2004:

The term "specific learning disability" means a disorder in one or more of the basic psychological processes involved in understanding or in using language, spoken or written, which disorder may manifest itself in imperfect ability to listen, think, speak, read, write, spell, or to do mathematical calculations. Such term includes such conditions as perceptual disabilities, brain injury, minimal brain dysfunction, dyslexia, and developmental aphasia. Such term does not include a learning problem that is primarily the result of visual, hearing, or motor disabilities; of mental retardation; of emotional disturbance; or of environmental, cultural, or economic disadvantage [5].
